Intermediates of α-Eliminations [*]

BY PROF. DR. W. KIRMSE
CHEMISCHES INSTITUT DER UNIVERSITÄT MARBURG (GERMANY)

α-Elimination denotes the removal of two substituents from the same carbon atom. Present-day knowledge of these reactions, their intermediates, and end-products is reviewed, with particular emphasis on the question of the occurrence of carbenes and the role of organometallic (carbanion) intermediates.

1. Introduction

Elimination reactions cover a wide field in preparative and theoretical organic chemistry. However, α- or 1,1-elimination has long been overshadowed by the more familiar β- or 1,2-elimination [1] which has been more extensively investigated. This is the reason for the cursory treatment of α-elimination even in modern textbooks. Nevertheless, interest in these reactions can be traced back a long way. Attempts were made to prepare methylene from methanol [2], methyl chloride [3], and methylene iodide [4] before the tetravalency of carbon had yet been established. Influenced by his work on isonitriles and fulminic acid derivatives, *Nef* [5] published his "general methylene theory" in 1897, in which he tried to explain all substitutions as resulting from α-elimination and addition. This concept fell into disfavor because of its excessive generalization, and only recently has it been reinstated in certain special cases. Isolated references to α-elimination may be found in the works of *Löb* [6], *Staudinger* [7], and *Ingold* [8].

The development of carbene chemistry [9] has given a new impetus to the work, since α-elimination was of interest as a possible route to "energy-deficient" carbenes. The results obtained were first interpreted simply as carbene reactions. It was soon shown, however, that organometallic (carbanion) intermediates could also play an important part, and in certain cases the appearance of carbenes was denied [10]. It is hoped that a critical survey of the field, including own results, some of which have not been published, will contribute to the elucidation of these problems.

2. Solvolysis of Haloforms

As a result of the excellent work of *Hine* and his school, the reaction of haloforms (trihalogenomethanes) with bases is one of the most thoroughly investigated cases of α-elimination. The most important results will now be summarized, since they present several problems of α-elimination in a particularly clear light.

In fluorine-free haloforms the base-catalysed H–D interchange is 10^3 to 10^5 times faster than any other reaction [11–15]. Solvolysis is therefore introduced by

the rapid and reversible formation of a trihalogenocarbanion [Equation (a)].

$$HCX_3 + B^{\ominus} \rightleftharpoons X_3C^{\ominus} + BH \qquad (a)$$

The rate-determining step of the solvolysis is to be found among the subsequent reactions of the trihalogenocarbanion. There are two possible interpretations which fit the kinetic data (the reaction is first order with respect to the haloform and the base [16,17]):

α) A slow S_N1 reaction of the trihalogenocarbanion to give a dihalogenocarbene, followed by rapid conversion of the carbene into carbon monoxide and formate (the course of which does not concern us here) [see Equation (b)].

$$X_3C^{\ominus} \xrightarrow{\text{slow}} X_2C: + X^{\ominus}$$
$$X_2C: \xrightarrow[H_2O,\ HO^{\ominus}]{\text{fast}} CO,\ HCO_2^{\ominus} \qquad (b)$$

β) A slow S_N2 reaction of the trihalogenocarbanion, according to Equation (c).

$$X_3C^{\ominus} + H_2O \xrightarrow{\text{slow}} X_2C^{\ominus}\text{-}\overset{\oplus}{O}H_2 + X^{\ominus}$$
$$X_2C^{\ominus}\text{-}\overset{\oplus}{O}H_2 \xrightarrow[H_2O,\ HO^{\ominus}]{\text{fast}} CO,\ HCO_2^{\ominus} \qquad (c)$$

In the carbene mechanism (b), the nucleophilic attack takes place after the rate-determining step, whereas in mechanism (c) the nucleophilic attack is identical with the rate-determining step. It follows that the effect of added anions $X^{\ominus}$ on the kinetics provides a means of distinguishing between the two mechanisms (b) and (c). In (c), the starting materials and the end-products of the substitution are identical:

$$X^{\ominus} + X_3C:^{\ominus} \rightarrow X^{\ominus} + X_3C:^{\ominus}$$

Such a reaction cannot affect the kinetics. In (b), on the other hand, the step

$$X^{\ominus} + :CX_2 \rightarrow X_3C:^{\ominus}$$

constitutes a reversal of the rate-determining step, and hence leads to a decrease in the overall rate of the reaction. Such an effect has in fact been observed on addition of halide ions [17]. The action of nucleophilic anions in the reaction of haloforms with bases therefore consists, at least partly, in addition to the intermediate carbene. The addition of olefins, preferably in aprotic media, yields 1,1-dihalogenocyclopropanes [see Reaction (d)] [9,18,19]. Competitive experiments have shown that the olefin behaves as a nucleophile in this reaction (the rate of the reaction increases with increasing electron density of the C=C bond). By analogy with the behavior of nucleophilic anions, it could be assumed that olefins react with the dihalogenocarbene and not with the trihalogeno carbanion. However, this view has been shaken by the latest observations according to which trichloromethyllithium, which is stable at low temperatures, attacks olefins as an electrophile [20].

$$B^{\ominus} + HCX_3 + \rangle C{=}C\langle \rightarrow \text{(cyclopropane, X X)} + BH + X^{\ominus} \qquad (d)$$

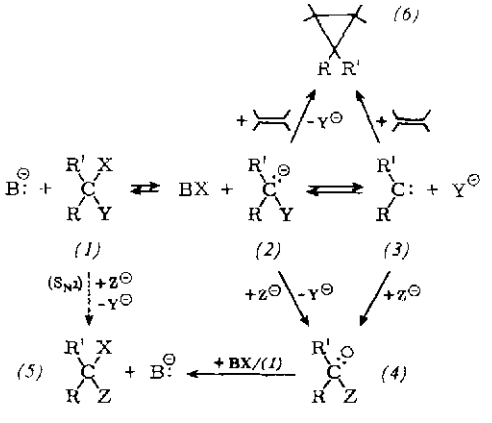
Haloforms with two fluorine substituents occupy a special position. The solvolysis of these compounds is unexpectedly fast, and takes place without H–D exchange [14,21,22]. The behavior of haloforms containing one fluorine atom [13,23] shows that fluorine makes carbanion formation more difficult, and stabilizes the carbene. *Hine* has therefore suggested a concerted α-elimination mechanism for haloforms containing two fluorine atoms. The energetically unfavorable trihalogenocarbanion stage is by-passed, and the relatively stable difluorocarbene is formed directly [Equation (e)].

$$B:^{\ominus} + HCF_2X \rightarrow B^{\delta\ominus}\cdots H\cdots CF_2\cdots X^{\delta\ominus} \rightarrow BH + :CF_2 + X^{\ominus} \qquad (e)$$

On the other hand, difluoromethyl phenyl sulfone, $C_6H_5{-}SO_2{-}CHF_2$, follows the two-step mechanism (stabilization of the carbanion) [24].

3. Scheme of the α-Elimination

On the basis of the special case of the solvolysis of haloforms, a scheme for the α-elimination will now be formulated and its general applicability tested [see Scheme 1].



Scheme 1. The general principle of α-elimination.

Two substituents (R, R') on the reacting carbon atom do not participate directly in the α-elimination. One group (X) can be removed as a cation by means of a base ($B:^{\ominus}$), while a second group (Y) may be lost as an anion. If these steps occur in suc-

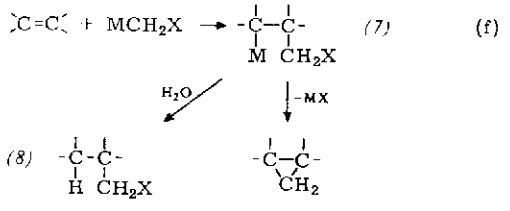
cession, an organometallic (or carbanion) intermediate *(2)* is formed. Direct formation of carbene *(3)* from *(1)* is also possible, as seen in the case of haloforms with two fluorine atoms. These reactions finally lead to substitution products *(5)* and/or olefin addition products *(6)*. In certain cases, "dimers" of the type RR'C=CRR' are formed. All the end-products can be derived from the intermediates *(2)* or *(3)*.

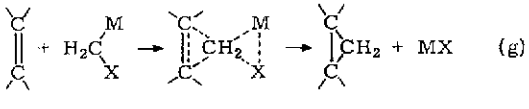
A nucleophile $Z^{\ominus}$ can yield a new organometallic (carbanion) intermediate *(4)*, either by addition to the carbene *(3)*, or by substitution in *(2)*. This intermediate then adds on X to form the substitution product *(5)*. Direct substitution in the starting material *(1)* can also lead to *(5)*. It is generally comparatively easy to rule out this alternative. It is much more difficult to decide whether the reaction proceeds *via (2)* or *via (3)*. The solvolysis of haloforms provides an example of the addition of nucleophiles to carbenes. On the other hand, halogen in the halogenomethyl derivatives of zinc [25,26], aluminum [10,26], and mercury [27] very readily undergoes nucleophilic substitution. An analogous reaction must therefore be expected in the case of unstable intermediates of type *(2)*. The origin of the olefin addition products *(6)* is also ambiguous. Photolysis and thermolysis of diazo compounds show beyond doubt that carbenes can add onto olefins. However, the halogenomethyl derivatives of zinc [ICH_2ZnI, $(ClCH_2)_2Zn$] [28,29], aluminum [10] (R_2AlCH_2X), and other metals [29] also convert olefins into cyclopropane derivatives. A preliminary decompositon into metal halide and carbene can be ruled out with reasonable certainty.

The course of these organometallic syntheses of cyclopropanes is subject to some controversy. *Hoberg* [10] has suggested a two-stage mechanism (f) which he has supported by isolating hydrolysis products *(8)* of the intermediate *(7)*. The strict stereospecificity of the cyclopropane formation requires that the *Hoberg* mechanism

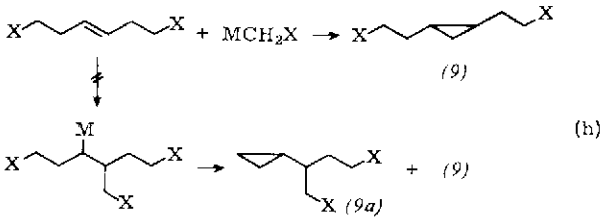


should involve not only stereospecific addition and elimination, but also configurational stability of the intermediate *(7)*. (The addition products *(7)* obtained from geometrically isomeric olefins are diastereoisomers.)

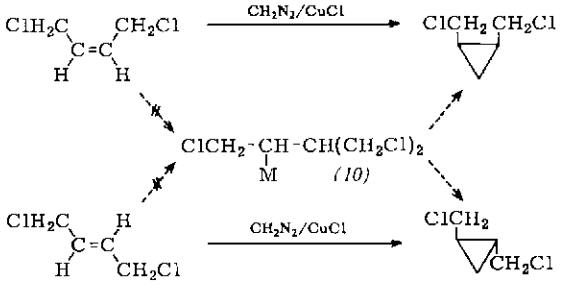
Wittig [29], *Simmons* [28], and *Closs* [30] have postulated a single-step mechanism (g), in which the organometallic reagent is assigned the role of a "carbene-complex".



This mechanism readily explains the stereospecificity and the electrophilic behavior of MCH_2X. A convincing argument in favor of mechanism (g) is provided by the reaction of 1,6-dihalogeno-3-hexenes with halogenomethyl derivatives of zinc [31], which yields only the cyclopropane derivative *(9)* expected from mechanism (g), without any of the isomer *(9a)* required by mechanism (f) [see Equations (h)].



Furthermore, the cupric chloride-catalysed reaction of diazomethane with olefins [32] does not proceed *via* intermediates of type *(7)*. *Cis*- and *trans*-1,4-dichlorobut-2-enes are converted stereospecifically into *cis*- and *trans* - 1,2 - bis(chloromethyl)cyclopropanes [33] in accordance with mechanism (g), whereas mechanism (f) should lead *via* a common intermediate *(10)* to an identical mixture of the isomers [see Scheme 2].



Scheme 2. The cupric chloride-catalysed reaction of diazomethane with olefins.

4. Methyl and Methylene Derivatives

Attempts to prepare methylene by α-elimination from methyl alkyl ethers and butyl-lithium [34], as well as from methyl chloride and phenylsodium [35], or pentylsodium [36] led to homologous hydrocarbons. These are substitution products in accordance with Scheme 1. The organometallic compound functions as a base ($B:^{\ominus}$) and, at the same time, as a nucleophile ($Z^{\ominus}$) [see Scheme 3].

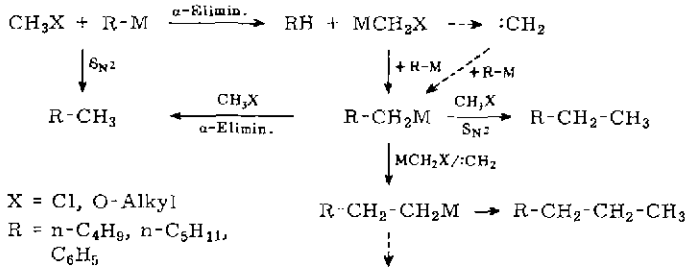
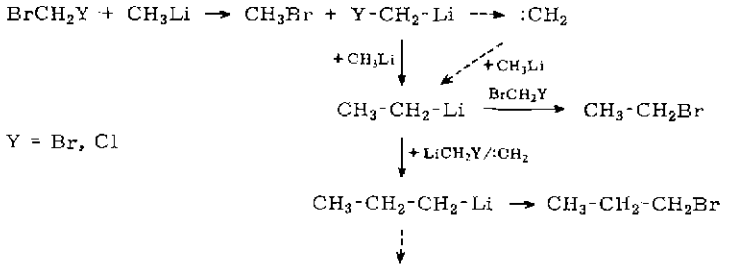


Scheme 3. The preparation of homologous hydrocarbons from organometallic compounds and methyl ethers or methyl halides.

Only the higher homologs ($R-CH_2-CH_3$, etc.) in Scheme 3 can definitely be regarded as products of α-elimination, since the $R-CH_3$ hydrocarbons probably result mainly from Wurtz reactions (S_N2). It has been possible to show that the analogous reaction of methylene bromide or chlorobromomethane with methyl-lithium [37] probably involves pure α-elimination, induced by halogen-metal interchange (see Scheme 4). (Earlier experiments with phenyl-lithium [38] did not lead to any definite conclusion regarding the mechanism.)



Scheme 4. The preparation of homologous alkyl halides from methylene halides and organometallic compounds.

Olefins can be converted into cyclopropane derivatives in moderate yields by any of the α-elimination reactions discussed above [10,35,39]. This fact can be no longer regarded as evidence of the existence of free methylene (cf. Section 3). The characteristic insertion into C–H bonds, such as is observed with methylene from diazomethane or ketene, does not occur in α-eliminations. The existence of free methylene is very improbable in these reactions.

Similar problems arise in the chemistry of chlorocarbene. As expected, the abstraction of a proton from methylene chloride is easier than from methyl chloride [see Equation (i)]. Alkyl-lithium compounds are suitable bases [40], poor yields being obtained with potassium t-butoxide [41].

$$CH_2Cl_2 + R-Li \rightarrow R-H + LiCHCl_2 \dashrightarrow :CHCl + LiCl \qquad (i)$$

Closs has successfully carried out stereospecific additions to olefins, using a methylene chloride/base system. Whenever isomerism is possible, the formation of the sterically more hindered product is favored in these reactions [40,42]. The olefin again behaves as a nucleophile [43]. Consequently, benzene is attacked with difficulty [41,44], while phenoxides [45], pyrrole, and indole [46] react much more readily. Methylene chloride and triphenylphosphine form an ylide [47,48]. The reaction of methylene chloride with excess alkyl-lithium leads to alkylcarbenes and their secondary products [49].

Closs has recently succeeded in preparing chlorodiazomethane in solution and decomposing it [50]. Chlorocarbene prepared in this way was substantially more reactive than that obtained by α-elimination. This observation lead *Closs* to believe, "... that in the α-elimination a truly free carbene might be bypassed" [50]. The situation cannot be more accurately described at present, since the different energy contents of intermediates produced in different ways must also be considered. The recent successful preparation of dichloromethyllithium in solution at low temperature [51] (detection by reaction with carbonyl compounds) promises further elucidation of this problem.

The α-elimination of hydrogen chloride from α-chloroethers in accordance with Equation (k) requires the use of alkyl-lithium compounds (t-butyl-lithium on occasions, to suppress S_N2 reactions) [52,53], while potassium t-butoxide is sufficient in the case of the corresponding sulfur [54] and selenium compounds [55]. The

$$R-A-CH_2Cl + B^{\ominus} \rightarrow BH + R-A-\overset{\ominus}{\underset{\cdot\cdot}{C}}HCl \dashrightarrow R-A-CH: \qquad A = O, S, Se \qquad (k)$$

smooth addition of the intermediates to olefins was interpreted as a carbene reaction. The objections to this view have been discussed already.

In the reaction of trithio-orthoformates *(11)* with potassium amide in liquid ammonia, the presence of the carbanion intermediate *(12)* is indicated by a green color. The intermediate can be trapped by alkylation with methyl iodide [56]. The main product, tetraethylthio-

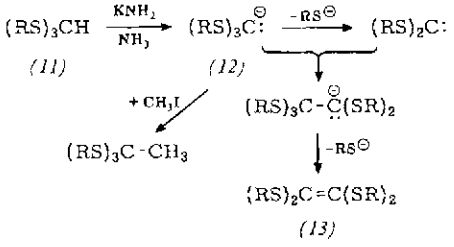
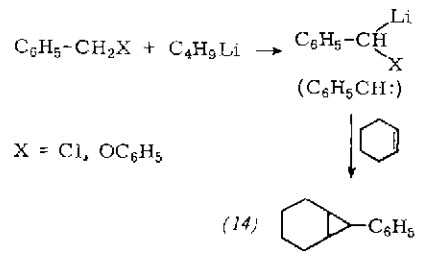
ethylene *(13)* is thought to result from the combination of diethylthiocarbene with *(12)*. However, there is no independent evidence for the occurrence of the carbene.



5. Benzyl and Vinyl Derivatives

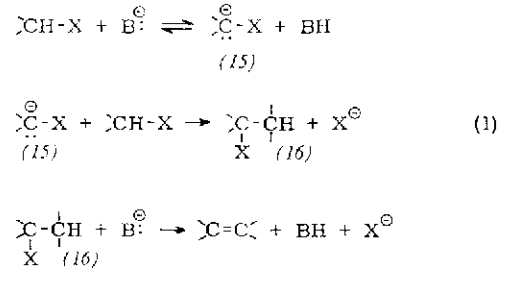
The reaction of benzyl halides or benzyl ethers with bases has only occasionally led to intermediates which can add onto olefins.

Diphenylmethyl bromide reacts with potassium amide in the presence of 1-octene to give 1,1-diphenyl-2-hexylcyclopropane in 7% yield [57]. A 14% yield of 7-phenylnorcarane



(14) has been obtained from benzyl chloride, n-butyl-lithium, and cyclohexane [58], while the corresponding reaction with benzyl phenyl ether gave only 2% of 7-phenylnorcarane [59].

The action of bases on benzyl halides generally yields stilbene derivatives [*]. Good preparative results are obtained with alkali metal amides in liquid ammonia [63]. The first plausible mechanism was suggested by *Hahn* [64] and *Kleucker* [65]. According to this the



carbanion intermediate *(15)* is thought to be alkylated by more benzyl halide, followed by elimination of hydrogen halide from the "dimeric halide" *(16)* [see Equation (1)].

Halides of type *(16)* have been isolated in good yields [63], and recently even from the reaction of benzyl chloride with butyl-lithium [65a]. The substitution *(15)* → *(16)* in the case of α-phenylethyl chloride proceeds with inversion of configuration [66]. H–D exchange in the case of 9-bromofluorene is fast compared to the elimination of hydrogen bromide; the rate of formation of difluorenylidene is proportional to the square of the 9-bromofluorene concentration [67]. These results confirm the postulated course of Reaction (1), and largely rule out the possibility of a carbene intermediate.

However, there are also observations which are less compatible with Scheme 1. Benzyl chloride, 4-nitrobenzyl chloride [68], and 4-nitrobenzyldimethylsulfonium salts [69] obey a first-order rate-law with respect to the concentration of >CHX and of base. Only in the last case has preliminary H–D exchange definitely been observed [70]. No satisfactory interpretation has yet been found for these reactions, especially with regard to the isotope effect [68,69], and the substituent effect [69,70].

1-Halogeno-2,2-diarylethylenes are converted into diarylacetylenes by alkali metal alkoxides [71–73], hydroxides [74], or amides [75], as well as by organolithium compounds [76]. The corresponding reaction of 1,1-dihalogeno-2,2-diarylethylenes proceeds with lithium [77], alkyl-lithium compounds [76], phenyl-lithium or triphenylmethylpotassium [78].

On the basis of careful investigations on the H–D exchange [79], the stereospecificity of the rearrangement [80,81], and the effect of substituents [82], it seems

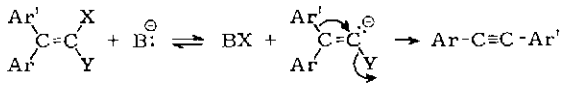
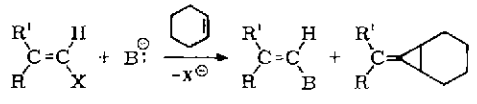
probable that the rearrangement takes place at a vinyl anion stage *(17)*, and that alkylidenecarbenes do not take part in it [83].



X = H, Halogen
Y = Halogen

(17)

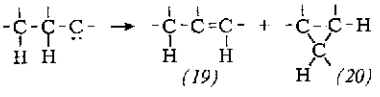
1-Halogeno-2,2-dialkylethylenes *(18)* do not rearrange to give acetylenes. On treatment with potassium t-butoxide [84], or with phenyl-lithium [85], substitution and olefin addition have been observed. 1,1-Dibromo-2-methylprop-1-ene behaves similarly in the halogen-metal exchange with methyl-lithium [85a]. These reactions do not permit any distinction between carbene and carbanion intermediates.



(18)

6. Halogeno- and Dihalogeno-alkanes

The reactions discussed in Sections 4 and 5 were ambiguous in the sense indicated in Scheme 1. On the other hand, α-eliminations on halogeno- and dihalogeno-alkanes permit a clear differentiation between the intermediates. Alkyl- and dialkylcarbenes are stabilized by intramolecular insertion to form olefins *(19)* and cyclopropanes *(20)* [9]. Since such reactions are unknown with carbanions, they provide a good indication of the appearance of carbenes, particularly in the quantitative comparison of elimination reactions with the decomposition of diazo compounds.

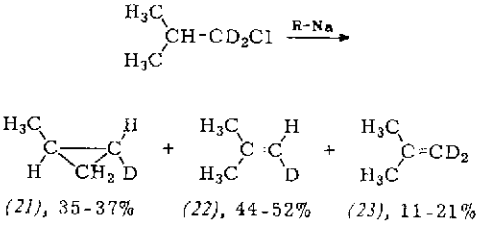


(19) *(20)*

a) α-Elimination of Hydrogen Halide

Whitmore has obtained cyclopropane derivatives by reaction of neopentyl chloride [86,87] or neophyl chloride [*] [88] with sodium or alkylsodium compounds.

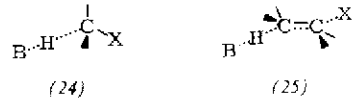
More recent work has shown [89,90] that cyclopropanes are also formed from alkyl chlorides with hydrogen in the β-position. Whereas *Whitmore* had postulated a γ-elimination, experiments with D-labelled compounds have shown that α-elimination occurs [89–92]. Cyclopropane derivatives obtained from alkyl chlorides doubly deuterated in the α-position contained only one deuterium atom, *e.g. (21)* [89,90].



(21), 35-37% *(22)*, 44-52% *(23)*, 11-21%

The olefins *(22)* and *(23)* produced in the same reaction, on the other hand, consisted of a mixture of singly and doubly deuterated compounds, *i.e.* β-elimination competes with α-elimination to a varying extent. This competition depends on the strength of the base. Hardly any α-elimination is observed with alkyl-lithium compounds [89] or with sodamide [90] provided that β-hydrogen is present. In the case of neopentyl chloride, however, α-elimination occurs even with sodamide [91].

The activation energy of the α-elimination must therefore decrease much more rapidly with increasing base-strength than does that of β-elimination. This seems plausible from a consideration of the transition states. In the case of α-elimination, the energy required to remove hydrogen is compensated only by the energy of the new bond to the attacking base. This bond will be relatively strong, even in the transition state *(24)*. This is further substantiated by the small isotope effect in the α-elimination [89]. In the transition state of the β-elimination *(25)*, on the other hand, not only is a new B–H bond formed, but also a new C–C bond. The B–H bond is therefore weaker (the reaction shows a greater isotope effect [93]) and makes a smaller contribution to the energy balance.



(24) *(25)*

Easier cleavage of the C–X bond also favors β-elimination. The incidence of α-elimination decreases on passing from alkyl chlorides to alkyl bromides, and thence to alkyl iodides (using the same base) [90]. Only β-elimination occurs in the case of secondary alkyl chlorides, even with the strongest bases [89,90].

Experiments with deuterium-labelled compounds have shown that the cyclopropane derivatives prepared from primary alkyl halides result from an intramolecular

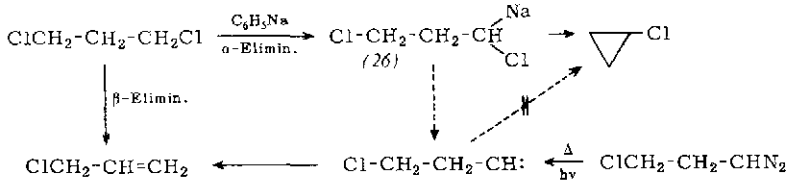
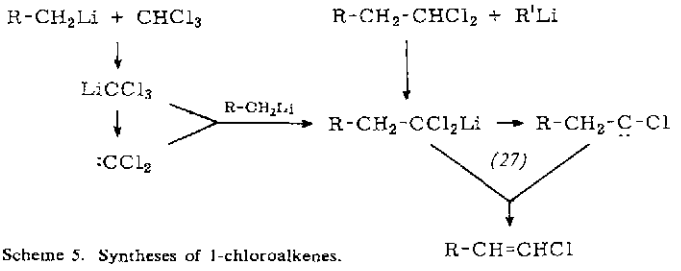
carbene reaction (cf. [94,95]). In agreement with this, the nature of the halogen atom has no effect on the composition of the α-elimination products [90,91]. The formation of the carbene stage is further corroborated by good agreement with the results of the decomposition of the diazo compounds.

Whether the carbenes are formed *via* an organometallic (carbanion) intermediate or in a concerted mechanism is less certain. The reaction of 1,3 dichloropropane with phenylsodium [96] points to a two-step mechanism. A mixture of 40 % cyclopropyl chloride and 60 % allyl chloride is obtained in moderate yield. The photochemical or catalytic decomposition of 3-chlorodiazopropane, on the other hand, yields more than 95 % of allyl chloride (cyclopropyl chloride occurs at most in traces) [96]. It seems likely that the high yield of cyclopropyl chloride is due to a 1,3-elimination from the organometallic intermediate *(26)* (cf. Section 6b). The question as to whether allyl chloride results from α- or from β-elimination must remain unanswered.



The α-hydrogen atom in 1,1-dichloroalkanes is more readily removed than in alkyl chlorides, even with alkyl-lithium compounds [97]. Whereas the reaction of the intermediate with more alkyl-lithium predominates in the case of 1,1-dichloroethane [98], higher 1,1-chloroalkanes yield considerable quantities of 1-chloroalkenes. These 1-chloroalkenes may be regarded as α-elimination products for the following reasons: 1-chloroalkenes are obtained in the same *cis/trans* ratio (approximately 9:1) from alkyl-lithium compounds and chloroform as from 1,1-dichloroalkanes. A common intermediate *(27)*, in accordance with Scheme 5, is the best explanation of this fact. β-Elimination from 1,1-dichloroalkanes takes place with alkoxides and gives an entirely different *cis/trans* ratio (approximately 1:1).

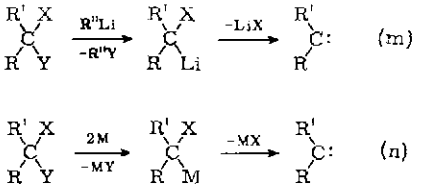


Scheme 5. Syntheses of 1-chloroalkenes.

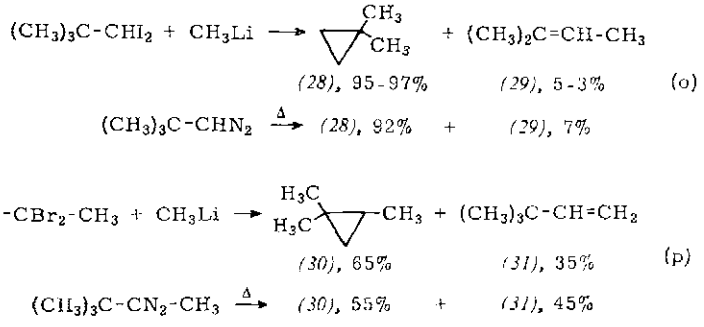
As long as corresponding rearrangements are unknown in the case of carbanions, hydrogen shift to form the 1-chloroalkene must be regarded as an alkylchlorocarbene reaction [97].

b) α-Elimination of Halogen

Competition between α- and β-elimination must be ruled out in the case of the removal of halogen from *gem*-dihalides, since halogen-free products can be formed only by α-elimination. The α-elimination of halogen can be effected with alkyl-lithium compounds [see Equation (m)] or, less smoothly, with metals [see Equation (n)] [99]. In Reaction (m), at least one of the halogen atoms must be bromine or iodine; the first step is halogen-metal exchange. In Reaction (n), both halogen atoms are removed as anions, the necessary electrons being supplied by the metal



Carbene formation can again be detected by typical intramolecular insertion reactions [see Equations (o) and (p)]. The ratios of the product yields largely correspond to those obtained in the decomposition of diazo compounds [99].



2,2-Dibromobutane and 2-bromo-2-chlorobutane gave identical butene mixtures with different alkyl-lithium compounds. The eliminating agent and the departing halogen atom cannot therefore participate in the product-determining step. These results can hardly be explained otherwise than by a carbene intermediate.

Organometallic intermediates were also detected in Reaction (m) by intramolecular capture [100]. When 1,1,3-trihalogenoalkanes are reacted with methyl-lithium, bromine, or iodine in the 1-position is exchanged for lithium whereas unactivated halogen in the 3-position fails to react. The organometallic intermediate *(32)* can undergo 1,3-elimination of lithium halide to yield a cyclopropyl halide. If the reaction proceeds to the carbene stage (or if the carbene is formed in a concerted mechanism), allyl halide (by β-hydrogen shift) and cyclopropyl halide (by insertion into the γ-C–H or into the Cl–C bond), are to be expected as end-products. The source of the

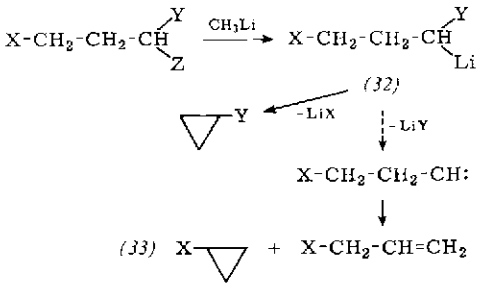
[99] *W. Kirmse* and *B. v. Wedel*, Liebigs Ann. Chem. *666*, 1 (1963).

cyclopropyl halides can be ascertained by using different halogen atoms. On ring closure of *(32)*, halogen (Y) in the 1-position is retained, while cyclopropyl halide *(33)* formed from the carbene contains halogen (X) in the 3-position.



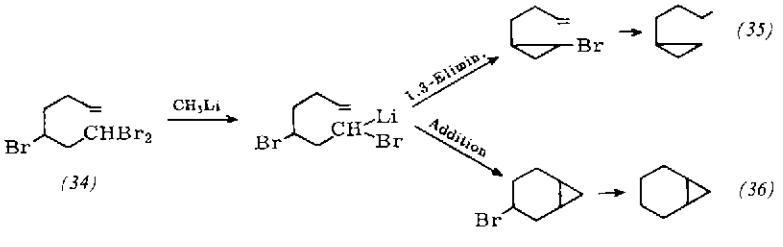
The first of these alternatives is unambiguously supported by experiment. Allyl halides (or their secondary products) have not been found in any case, whereas cyclopropyl halides have been obtained in good yields. 1,1-Dibromo-3-chloropropane gave only cyclopropyl bromide, and 1,3-dibromo-1-chloropropane gave only cyclopropyl chloride. It is thus shown that ring closure proceeds from the intermediate *(32)* with retention of the halogen atom in the 1-position.

Substitution of iodine for Y in *(32)* is observed in the presence of lithium iodide (the starting material and the end-product do not react with lithium iodide) [100]. Thus the high reactivity of halogen in the α-halogenoalkyl derivatives of zinc, aluminum and mercury (Section 3) is also found in the corresponding lithium compounds.

c) Addition of Intermediate Products of the Elimination to Olefins

As has been seen in the foregoing sections, both carbenes and organometallic (carbanion) intermediates can be detected in the α-elimination reactions of halogeno- and dihalogeno-alkanes. The question now arises: which one of these intermediates is responsible for the addition to olefins? This problem is best examined once more by means of competitive intramolecular reactions.

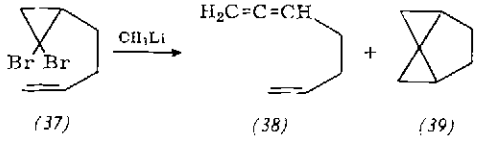
The 1,3-elimination of lithium halide involves organometallic intermediates of type *(32)*. Addition to olefins, which competes with this 1,3-elimination, would have to be a direct addition of the organometallic intermediate. However, no such competition is observed



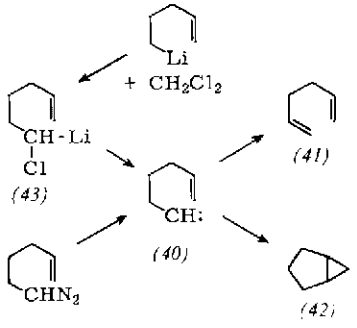
in the reaction of 5,7,7-tribromohept-1-ene *(34)* with methyl-lithium [100]. Reductive dehalogenation of the products yields n-butylcyclopropane *(35)*, but no norcarane *(36)*.

[100] *W. Kirmse* and *B. v. Wedel*, Angew. Chem. *75*, 672 (1963); Liebigs Ann. Chem., in the press.

Skatteböl has reacted 1,1-dibromo-2-(buten-3-yl)-cyclopropane *(37)* with methyl-lithium, and isolated the spirane *(39)* in addition to the allene *(38)* [101]. The ratio of the quantities of the compounds *(38)* and *(39)* was found to depend on temperature. Unfortunately, the mechanism of the conversion of 1,1-dihalogenocyclopropanes into allenes is not yet clear [102–105]. It cannot therefore be stated which intermediate of this interesting reaction is intercepted by the olefin addition.



The competition between hydrogen shift and olefin addition has been investigated with 4-pentenylcarbene *(40)* [106]. The reaction products are 1,5-hexadiene *(41)* and bicyclo[1.3.0]hexane *(42)*. The decomposition of 6-diazohex-1-ene proceeded only when catalysed by copper, and gave compounds *(41)* and *(42)* in yields of 55 % and 45 %, respectively. The reaction of 4-pentenyllithium with methylene chloride leads, *via* the organometallic intermediate *(43)*, to the same products *(41)* and *(42)* in yields of 87 % and 13 %, respectively.



The experiments described above, although as yet incomplete, give no indication of a direct reaction between α-halogenoalkyl-lithium and olefins. The experiments relate only to compounds of type R–CHX–Li and give no information concerning organometallic intermediates with two or three α-halogen atoms.

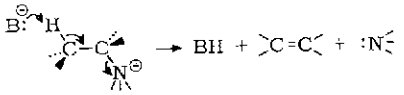
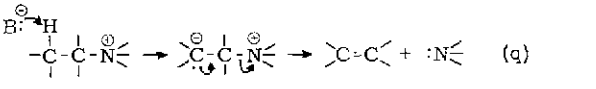
7. Quaternary Ammonium Salts and Tertiary Sulfonium Salts

The Hofmann degradation of quaternary ammonium hydroxides can generally be described as an E2 elimination with simultaneous removal of β-hydrogen and tertiary amine [107]. This requires that the participating groups should have a planar *trans*-configuration, as shown in *(44)*. The possibility of α-elimination



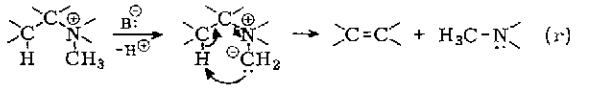
(44)

would be expected to arise whenever this *trans*-configuration cannot be achieved. Nevertheless, careful investigations on *trans*-(2-phenylcyclohexyl)trimethylammonium hydroxide [108–111] have shown only pure β-elimination. The reaction probably proceeds by an E1cB mechanism [see Equation (q)] promoted by the phenyl group.



(q)

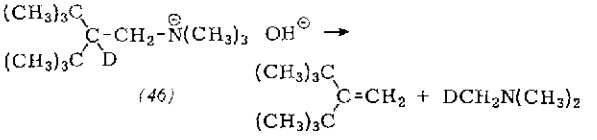
An ylide (α',β)-mechanism has been found only with quaternary ammonium hydroxides in which the β-hydrogen atom is not activated, but is strongly sterically hindered [112,113]. In such cases, an α-hydrogen atom is first removed, and the resulting ylide *(45)* gives rise to the Hofmann degradation [see Equation (r)] by a cyclic proton shift.



(45)

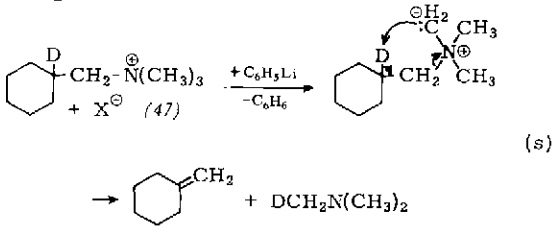
(r)

Trimethyl-(2-t-butyl-3,3-dimethyl-[2-D]-butyl)ammonium hydroxide *(46)* decomposes to the extent of 75 % in accordance with Equation (r) [113].



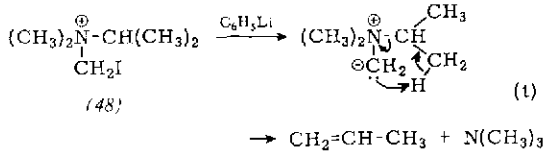
(46)

Whereas the ylide mechanism (r) is the exception with ammonium hydroxides, the reaction of quaternary ammonium salts, *e.g.* [2-D]-cyclohexylmethyltrimethylammonium salts *(47)* with organolithium compounds generally follows this route [see Equation (s)] [111,114 to 116]. Remarks made in Section 6 naturally apply to the transition from the β- to the "α,β"-elimination with increasing base-strength.



(s)

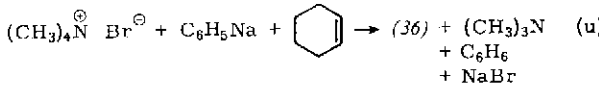
α',β-Elimination can also be induced by halogen-metal exchange on α-halogenated quaternary ammonium salts, *e.g. (48)* [Equation (t)] [114].



(48)

(t)

Owing to the smooth intramolecular elimination according to Equation (r), no β-hydrogen atom need be present in order to obtain carbenes from quaternary ammonium salts. Treatment of tetramethylammonium bromide with phenylsodium/phenyl-lithium in the presence of cyclohexene gives norcarane in 10 % yield, in accordance with Reaction (u) [117]. As in the experiments discussed in Section 4, the formation of methylene in this reaction is questionable [*].



(u)

The situation is clearer in the case of the tertiary sulfonium salts; β- and α',β-eliminations can again be detected according to the strength of the base [120,121]. However, alkyldiphenylsulfonium salts, *e.g. (49)*, open up a route to alkylcarbenes, which can undergo intramolecular insertion, *e.g.* according to Equation (v) [122].

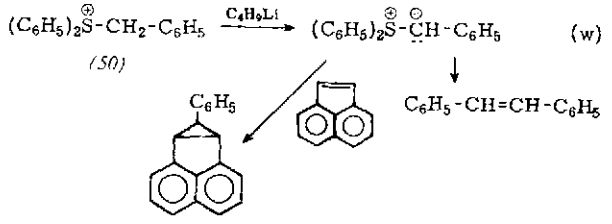
On the other hand, the addition of methylene to polar double bonds [123, 124], which can formally be achieved with trimethylsulfonium salts, as well as the formation of ethylene from these compounds [124], must be regarded as a sulfonium ylide reaction. This is probably also true of the similar reactions (w) of diphenylbenzylsulfonium salts *(50)* [125].



8. Future Prospects

The results which have been referred to illustrate the importance of α-elimination in numerous substitution and addition reactions. Investigation of these reactions is made interesting, yet at the same time difficult, by the various intermediates with similar chemical properties. According to present-day knowledge, both of substituted alkylmetal compounds (or carbanions) and carbenes behave as electrophiles. The conversion α-olefins into cyclopropane derivatives, which originally did much for the development of the carbene concept, is becoming increasingly recognized as a reaction of organometallic (carbanion) intermediates. Olefin addition has become completely useless as a means of detecting carbenes. At present the only reliable criterion for the occurrence of carbenes is the (intramolecular) insertion into C–H bonds, which has permitted detection of alkyl- and dialkylcarbenes. It is not surprising that these are the very compounds in which α-elimination proceeds to the formation of carbene intermediates.

With the transition from primary to secondary and tertiary carbon, the tendency towards S_N1 reactions steadily increases, while the S_N2 mechanism is suppressed. Alkyl groups should therefore also favor the transition into the carbene, which is analogous to the S_N1 mechanism, in the case of α-substituted alkylmetal compounds (carbanions).

Cyclopropenylium Compounds and Cyclopropenones

BY DR. A. W. KREBS

ORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT HEIDELBERG (GERMANY)

The predictions of Hückel's rule gave the incentive to numerous investigations which led ultimately to a new definition of aromatic character, and which have added greatly to our knowledge of the properties and reactivity of aromatic compounds. Increasing use was made of physical measurements as criteria for the aromaticity of a compound. The first member (n = 0) in the series of Hückel's (4n + 2) π systems is the cyclopropenylium cation. The predictions regarding the stability of this system have been confirmed at least qualitatively by the synthesis of cyclopropenylium salts. Properties and reactions of cyclopropenylium compounds and cyclopropenones were investigated.

I. Introduction

Ever since the discovery of benzene by *Faraday* in 1825, the theory of the cyclic unsaturated systems has been of interest to organic chemists [1, 2]. The formulation of the (4n + 2)π-rule by *Hückel* [3] in 1931 was a milestone in this development. The (4n + 2)π-rule can be expressed as follows:

Planar monocyclic systems with trigonally hybridized atoms containing (4n + 2) π-electrons possess a characteristic electronic stability.

Not only did this rule provide an explanation on the basis of quantum theory of the special position of benzene, which was already known, but it also allowed predictions to be made regarding the stability of systems which had not yet been synthesized.

The validity of Hückel's rule for n = 1 was verified by the preparation of the tropylium cation [2, 4–5b] and by the agreement between the observed properties and

[1] Concerning the historical development of the theory of aromatic compounds, which is not discussed in detail in the present paper, see *e.g. C. K. Ingold*: Structure and Mechanism in Organic Chemistry. Cornell University Press, Ithaca 1953, pp. 156–196 and [2].

those predicted by theory [6]. *Roberts, Streitwieser*, and *Regan* [7] were the first to point out the theoretically expected stability of the simplest aromatic system, *i.e.* the cyclopropenylium cation *(1)*, with n = 0. These predictions can be represented diagrammatically as shown in Fig. 1 [2,8].

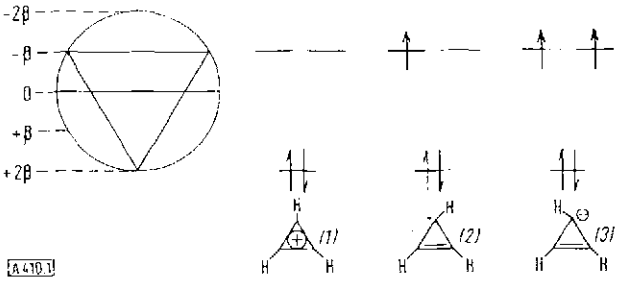

Fig. 1. Graphical representation of the energy levels for cyclopropenyl systems.

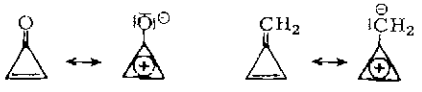
The delocalization energy, DE, of the cyclopropenylium cation *(1)* is found to be the difference in the π-electron energies of *(1)* and of ethylene; that is, DE = 4β − 2β = 2β. Similarly, the delocalization energies of the cyclopropenyl radical *(2)* and the cyclopropenyl anion *(3)* are found to be 1β and zero, respectively. Large delocalization energies were obtained in a similar manner for cyclopropenone *(4)* and for methylenecyclopropene *(5)*, and for their derivatives [7, 9, 10].



(4) *(5)*

Table 1. Delocalization energies DE for cyclopropenyl derivatives as calculated from the Hückel theory, and the increase ΔDE on phenyl substitution.

	Cation		Radical		Anion

1,2-Diphenylcyclopropenyl	6.70	0.70	6.20	1.20	5.69	1.69
1,2,3-Triphenylcyclopropenyl	9.19	1.19	8.68	1.68	8.18	2.18
Cycloheptatrienyl	2.99		2.54		2.10 [*]	

[*] Triplet.

Table 2. Delocalization energies DE of some cyclopropenone derivatives as calculated from the Hückel theory, and the increase ΔDE on phenyl substitution [9].

	DE [β]	ΔDE [β]
Cyclopropenone	1.36	
Phenylcyclopropenone	3.75	0.39
Diphenylcyclopropenone	6.15	0.79
Methylenecyclopropene	0.96	
1-Phenylmethylenecyclopropene	3.37	0.41
1,2-Diphenylmethylenecyclopropene	5.79	0.83

The predicted stability of the three-membered ring cation *(1)* leads naturally to a comparison of it with the tropylium cation, $C_7H_7^{\oplus}$. In fact, the development of the chemistry of the cyclopropenylium compounds was completely analogous to that of the tropylium compounds. In comparing *(1)* to $C_7H_7^{\oplus}$, however, it should be noted that the calculated delocalization energy DE of an aromatic compound is not identical with the so-called empirical resonance energy RE which is experimentally determined from the heat of combustion or of hydrogenation. The reason for this is that the M.O. calculations take into account only the contribution of the delocalization of the π-electrons towards the stability of the molecules; no allowance is made for other factors such as ring strain, change in state of hybridization or in bond lengths, or, in certain cases, the electrostatic work of charge separation.

The ring-strain energy of the cyclopropenylium cation *(1)*, which can be estimated from the ring strain of cyclopropene [11,12] and the additional strain arising from the change in the hybridization in *(1)* [13], is about 74 kcal/mole, as compared with about 7 kcal/mole for the tropylium ion.

If we assume β=32 kcal/mole [14], the calculated delocalization energy 2β of the cyclopropenylium cation is overcompensated by the ring-strain energy. It is, therefore, impossible to foretell whether the high delocalization energy makes the cyclopropenylium system sufficiently stable to permit its isolation.

[6] In recent years, the validity of the Hückel rule has also been confirmed for n = 2 by synthesis of the cyclooctatetraene dianion and the cyclononatetraenyl anion: *A. R. Ubbelohde*, Chem. and Ind. *1956*, 153; *T. J. Katz*, J. Amer. chem. Soc. *82*, 3784, 3785 (1960); *H. P. Fritz* and *H. Keller*, Z. Naturforsch. *16b*, 231 (1961); *T. J. Katz* and *P. J. Garratt*, J. Amer. chem. Soc. *85*, 2852 (1963); *E. A. La Lancette* and *R. E. Benson*, ibid. *85*, 2853 (1963). Cyclodeca-1,3,5,7,9-pentaene appears to be unstable in comparison with 9,10-dihydronaphthalene for steric reasons: *E. E. van Tamelen* and *B. Pappas*, J. Amer. chem. Soc. *85*, 3296 (1963); *E. Vogel* and *H. D. Roth*, Angew. Chem. *76*, 145 (1964); Angew. Chem. internat. Edit. *3*, 228 (1964).

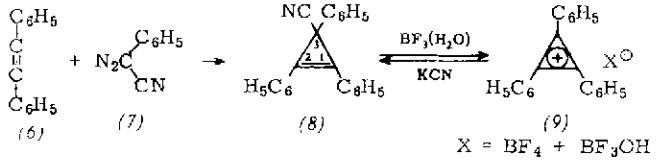
II. Cyclopropenylium Compounds

A. Preparation of Cyclopropenylium Compounds

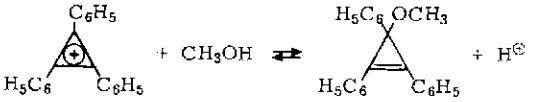
The starting materials for all syntheses were cyclopropenes which are generally obtained by addition of carbenes to substituted acetylenes.

Thus, by reacting phenyldiazoacetonitrile *(7)* with diphenylacetylene *(6)*, *Breslow* [15,16] obtained 1,2,3-triphenylcyclopropenyl cyanide *(8)* which yielded the mixed fluoroborate/hydroxofluoroborate of the 1,2,3-triphenylcyclopropenylium cation *(9)* on treatment with moist boron trifluoride etherate.



(6) *(7)* *(8)* *(9)*

X = BF_4 + BF_3OH

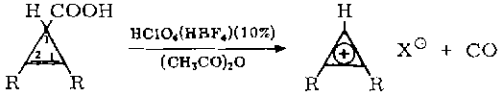


(10)

1,2,3-Triphenylcyclopropenyl methyl ether *(10)* was found to he a suitable starting material for the preparation of cyclopropenylium salts, giving 1,2,3-triphenylcyclopropenylium bromide on reaction with hydrogen bromide [16].

A number of other triaryl-substituted cyclopropenylium salts [13,17] and the diphenylcyclopropenylium cation [18] were synthesized directly by addition of arylchlorocarbenes to diarylacetylenes or to phenylacetylene.

Another method of preparing disubstituted cyclopropenylium salts, *e.g. (11)* and *(12)*, consists in the decarbonylation of 1,2-disubstituted cyclopropenecarboxylic acids with strong acids in acetic anhydride [19 to 21].

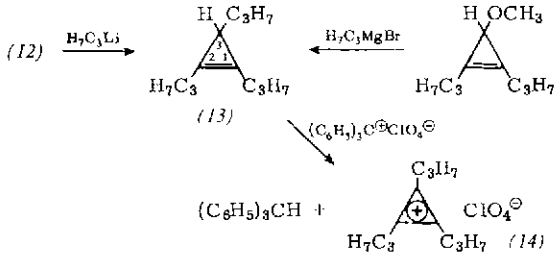


(11): R = C_6H_5

(12): R = C_3H_7

$X^{\ominus}$ = $ClO_4^{\ominus}$, $BF_4^{\ominus}$

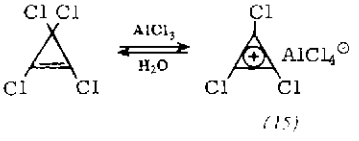
The reaction of *(12)* with propyl-lithium gave 1,2,3-tripropylcyclopropene *(13)* which was then converted to tripropylcyclopropenylium perchlorate *(14)* by hydride abstraction with the triphenylmethyl cation [21].



(13) *(14)*

A method based on hydride abstraction with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in the presence of acids had previously been used for the preparation of a number of triphenylcyclopropenylium salts from 1,2,3-triphenylcyclopropene [22].

Attempts to prepare the unsubstituted cyclopropenylium cation *(1)* by hydride abstraction from cyclopropene with the triphenylmethyl cation were unsuccessful [12]. Attempts to detect *(1)* in the gas phase and to determine its heat of formation by mass spectrometry also failed to yield any definite result, since it could not be decided whether the observed $C_3H_3^{\oplus}$ ion had the structure *(1)* or that of a propargyl cation [12,23]. On the other hand, the trichlorocyclopropenylium *(15)* [24] and tribromocyclopropenylium cations [25] were obtained as the tetrahalogenoaluminates by reaction of the corresponding tetrahalogenocyclopropenes with aluminum trihalides. Tetrachlorocyclopropene was reobtained on careful hydrolysis of *(15)*.



(15)

B. Proof of Structure and Physical Properties of Cyclopropenylium Compounds

Although many methods of preparation, such as the decarbonylation of the cyclopropenecarboxylic acids and hydride abstraction with triphenylmethyl perchlorate clearly pointed to the stability of the cyclopropenylium cation, final evidence for the symmetry of the cation was only provided by physical investigations.

1. Solubility

All cyclopropenylium compounds, both aromatic and aliphatic, are soluble only in highly polar solvents such as alcohols, acetonitrile, dimethylformamide, or aqueous acids, but insoluble in ether, chloroform, or benzene. On the other hand, covalent cyclopropene derivatives, such as *(8)*, are soluble in benzene. In contrast to the cyclopropenylium chlorides and bromides, *(8)* does not give a precipitate with ethanolic silver nitrate [15,16].

2. X-Ray Structural Analysis

An X-ray structural analysis carried out on triphenylcyclopropenylium perchlorate showed conclusively that the compound consists of triphenylcyclopropenylium

cations and perchlorate anions [26]. The three-membered ring and the three phenyl carbon atoms attached to it lie in the same plane. All the C–C distances in the three-membered ring are 1.40 Å, *i.e.* roughly the same as those in benzene (1.39 Å). The semicyclic C–C single bonds are 1.45 Å in length, and are thus shorter than the "normal" C–C single bond (1.54 Å), as is the central C–C bond in butadiene (1.48 Å) [27] or biphenyl (1.48 Å) [28].

Contrary to earlier belief [10, 13], the triphenylcyclopropenylium cation is not planar in structure, the phenyl groups being twisted out of the plane of the three-membered ring at an average angle of 21° owing to steric hindrance of the hydrogen atoms in the *ortho* position. Therefore the shortening of the semicyclic bonds can be attributed primarily to the change in hybridization, multiple-bond character resulting from mesomerism being only a secondary factor [29].

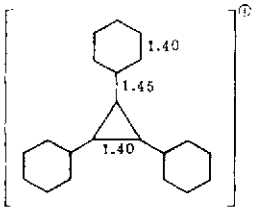

Fig. 2. Bond lengths in the triphenylcyclopropenylium cation (Å) [26].

3. Spectra

In contrast to cyclopropene [30], the cylcopropenylium compounds with only alkyl substituents do not absorb in the ultraviolet region above 185 mμ [21]. This agrees with the simple Hückel theory which predicts an excitation energy of 3β for the $\pi \rightarrow \pi^*$-transition (see Fig. 1). Since this excitation energy is much greater than that calculated for ethylene (2β), the $\pi \rightarrow \pi^*$-transition in the cyclopropenylium cation should occur at very short wavelengths (< 180 mμ).

With the exception of the triphenyl compound, the aryl-substituted cyclopropenylium compounds [13, 16–19] also give ultraviolet spectra which are quite different from those of the covalent cyclopropenes.

The similarity and simplicity of the infrared spectra of trichlorocyclopropenylium tetrachloroaluminate *(15)* and the hexachloroantimonate were accepted as evidence of the high symmetry of the $C_3Cl_3^{\oplus}$ cation [24]. Only one band in the IR spectrum, which occurs between 1400 and 1430 cm^{-1}, depending on the substitutents, has so far been assigned to the cyclopropenylium system itself [21, 31].

The nuclear magnetic resonance spectra give more information on the bonding in the cyclopropenylium cations [17, 20, 21] than the UV and IR spectra, since a linear relationship exists between the chemical shift of aromatic protons and the π-electron density per C-atom of the aromatic system in question [32]. This rule, which was established for the "classical" aromatic systems ($C_7H_7^{\oplus}$, C_6H_6, and $C_5H_5^{\ominus}$), has frequently been used as a test for aromatic character in a newly synthesized compound [6]. Fig. 3 shows that the value of −3.0 ppm (in relation to benzene) found for the ring proton of the dipropylcyclopropenylium cation [21] is in close agreement with the value expected from this rule.

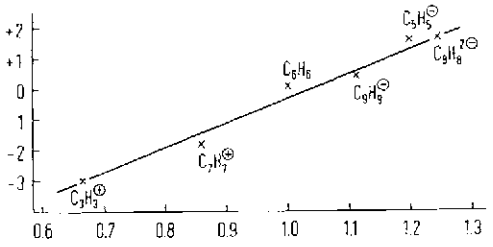

Fig. 3. Chemical shift of aromatic protons δ (in ppm in relation to benzene as a function of the π-electron density ρ_π per C-atom) [33].
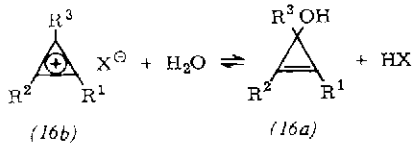
Ordinate: δ [ppm]
Abscissa: ρ_π

The apparent reason for this agreement is that the effects of the ring current, which is smaller than in benzene, and of the changed hybridization in the three-membered ring on the position of the ^1H-resonance absorption just balance each other, so that only the influence of the π-electron density per C-atom is of any importance.

However, interesting conclusions can also be drawn from the NMR spectra of the substituents on the cyclopropenylium system. These show that all the propyl groups in the tri- and dipropylcyclopropenylium cations are equivalent, that all cyclopropenylium salts, irrespective of the nature of the substituents, have a similar charge distribution, and that, even in the phenyl-substituted cations, not much of the positive charge is distributed over the phenyl groups [21].

4. Cyclopropenylium-Cyclopropenol Equilibria

The influence of substituents on the stability of cyclopropenylium ions has been studied mainly by measurement of the pK-values [34] for the equilibrium *(16a)* ⇌ *(16b)*.



(16b) *(16a)*

The pK-value of the cations is determined by two factors: 1. The cations are better stabilized by propyl groups than by phenyl groups. 2. The covalent carbinols, on the other hand, are better stabilized by phenyl groups

[*] $K = \frac{[ROH]\,[H^{\oplus}]}{[R^{\oplus}]\,[H_2O]}$

than by propyl groups. Since the pK-value depends on the difference in the free energies of the cation and the carbinol, both factors are involved.

The propyl groups stabilize the cation by an inductive effect, just as a methyl group raises the pK value of the tropylium cation [35]; however, the stabilization is much more pronounced in the case of the cyclopropenylium cation, owing to the higher charge density. Phenyl groups also stabilize the cyclopropenylium cation, as shown by a comparison of the pK-values of the di- and triphenylcyclopropenylium cations, but by a mesomeric effect; an inductive effect, such as prevails *e.g.* in the phenyl [36] and heptaphenyltropylium cations [37], would lower the pK value in this case. However, a comparison with the corresponding free radicals [38, 39] and anions [40, 41] [*] shows that this resonance stabilization is not the only factor determining the stability of the phenyl-substituted cations.

The pK-values of some cyclopropenylium compounds were used as a test of the accuracy of the M.O. calculations. Good agreement was found between the calculated and experimentally determined pK-values within a series of very similar compounds, using suitable parameters [13].

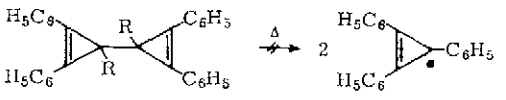
The pK-value of the triphenylcyclopropenylium cation was related to that of other cations by hydride abstraction. Competitive experiments gave the following order of stability:

tropylium > triphenylcyclopropenylium > perinaphthenylium > trianisylmethylium > triphenylmethylium [42].

C. The Cyclopropenyl Radical and Anion

The enhanced resonance stabilization of the cyclopropenylium cation compared to the free radical and, in particular, compared to the anion was the most important of the M.O. predictions regarding the unsaturated three-membered ring systems (see Introduction) [7, 9, 10, 41, 43, 44]. Since ring strain is comparable in these three systems, it should be possible to check the M.O. calculations on this point.

The properties of bis(triphenylcyclopropenyl) *(17a)* were as expected: even at high temperatures *(17a)* shows no tendency to dissociate into the radicals *(18)*



(17a): R = C_6H_5 *(18)*

(17b): R = H

[38]. This qualitative finding was also supported by a quantitative investigation, in which the difference in the free energies of triarylcyclopropenylium cations and the corresponding free radicals was determined polarographically from the reversible reduction potentials [39].

Table 4. Reversible one-electron reduction potentials of cyclopropenylium cations and of the triphenylmethyl cation.

Salt	Reversible reduction potential [V]
Triphenylcyclopropenylium-$ClO_4^{\ominus}$	−1.132
Diphenyl-*p*-anisylcyclopropenylium-$ClO_4^{\ominus}$	−1.24
Trianisylcyclopropenylium-$ClO_4^{\ominus}$	−1.49
Triphenylmethylium-$ClO_4^{\ominus}$	−0.090

The difference of 1.04 eV (≈ 24 kcal/mole) between the triphenylcyclopropenyl and triphenylmethyl compounds roughly agrees with the result required by the simple Hückel theory, and evidently reflects the loss of resonance in the cyclopropenyl radical.

According to the predictions of the simple Hückel theory, the cyclopropenyl anion *(3)*, like cyclobutadiene, should possess no delocalization energy, and should exist as a triplet in the ground state; even the anion with three phenyl substituents has a delocalization energy which is lower by 1 β than that of the cation (see Introduction).

Attempts to prepare the 1,2,3-triphenylcyclopropenyl anion from 1,2,3-triphenylcyclopropene with alkali metal amides [41] or from 1,2,3-triphenyl-3-ethoxycyclopropene with potassium [45] were unsuccessful; undesired reactions occurred in every case.

When [3-^{3}H]-1,2,3-triphenylcyclopropene was treated with potassium t-butoxide in boiling t-butanol, there was no exchange of tritium for hydrogen, whereas [α-^{3}H]-triphenylmethane had lost 80 % of its activity after 8 hours under the same conditions [41]. All these results demonstrate the instability of the triphenylcyclopropenyl anion. It is possible, however, that cyclopropenyl anions can be stabilized by substituents in certain cases. For example, 1,2-diphenyl-3-t-butoxycarbonylcyclopropene *(19)* exchanges 5 % of the

hydrogen in the three-membered ring for deuterium on treatment with potassium t-butoxide in boiling deuterio-t-butanol; nevertheless, this exchange proceeds much more slowly than in the case of an ester of a cyclopropanecarboxylic acid, a fact which indicates that the double bond has a destabilizing influence [40].

D. Homocyclopropenylium Cations

According to the concept of homoaromaticity [46,47], the non-classical carbonium ions *(20)*, *(21)*, and *(22)* [and their derivatives, *e.g. (23)*], which have been postulated as intermediates in solvolytic reactions, were regarded as mono- [48], bis- [49–52], and trishomocyclopropenylium ions [47,53,54], and their relative stabilities were explained by their relationship to the cyclopropenylium system.

(20) *(21)* *(22)* *(23)*

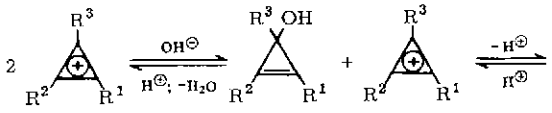
However, the evidence for the existence of these cations is the subject of the more general controversy regarding classical [55,56] and non-classical [52] carbonium ions.

E. Chemical Reactions of the Cyclopropenylium Salts

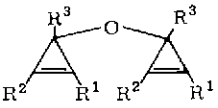
Owing to their integral positive charge, the cyclopropenylium compounds readily react with nucleophilic reagents. These reactions often constitute the first stage of a rearrangement, leading either to ethylene derivatives or to less strained five- or six-membered ring compounds.

1. Reactions with Bases

An equilibrium is set up between the cyclopropenylium cations *(16b)* and the covalent carbinols *(16a)* in aqueous or aqueous-alcoholic solution; the position of the equilibrium depends on the substitutents on the cation and on the pH of the solution (cf. Section II.B.4). However, the carbinols *(16a)* can also act as bases and react with a further cation to form the ethers *(24)*. Consequently, the carbinols, unlike the ethers, cannot be isolated [13,15,16,19,21].

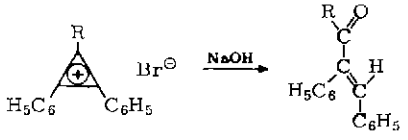


(16a)



(24)

In strongly alkaline solution (10 % NaOH), on the other hand, the ring is irreversibly opened; triphenylcyclopropenylium bromide *(25a)* gives 1,2,3-triphenylpropenone *(26a)* [16] *via* the ether as an intermediate, while the diphenyl derivative *(25b)* gives 2,3-diphenylpropen-1-al *(26b)* [18,19].



(25a): R = C_6H_5 *(26a)*: R = C_6H_5
(25b): R = H *(26b)*: R = H

The cyclopropenylium cation is also attacked by the anion of organometallic reagents (cf. Section II.A); thus, for example, the reaction of *(25a)* with methylmagnesium bromide yields 3-methyl-1,2,3-triphenylcyclopropene [41].

2. Reduction of the Cations

The reduction of *(25a)* with lithium aluminum hydride gave triphenylcyclopropene *(27)* in high yield [41]. This reaction is, therefore, formally the reverse of the preparation of cyclopropenylium salts by hydride abstraction [21,22,42].

(25a) *(27)*

The reaction of triphenyl- or dipbenylcyclopropenylium salts with zinc dust, like polarographic reduction (see Section II.C), gave the dimers *(17a)* and *(17b)* of the corresponding free radicals. These dimers rearrange at 130 °C to form benzene derivatives; 1,2,4,5- and 1,2,3,4-tetraphenylbenzenes have been isolated as products of the thermal rearrangement of bis-3,3'-(diphenylcyclopropenyl) *(17b)*, which may proceed *via* a prismane intermediate [*] [38,57,58].

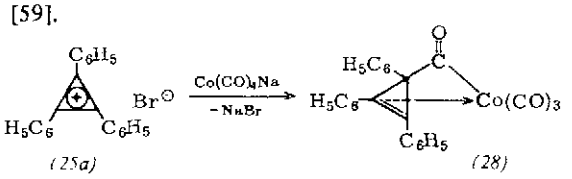
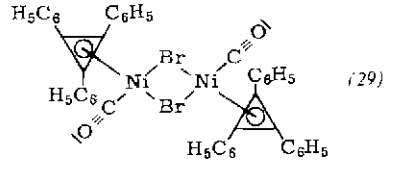
3. Reactions with Transition-Metal Complexes

Cobalt tetracarbonylate reacts with *(25a)*, with carbonylation of the cation, to form a π-complex which has been formulated as *(28)*; the desired symmetrical π-complex of the triphenylcyclopropenylium cation is not obtained [59].



(25a) *(28)*

Attempts to obtain this complex by reaction of *(25a)* with potassium trichloro(ethylene)platinate(II), followed by thermal elimination of ethylene from the resulting product, were also unsuccessful [31]. On the other hand, *(25a)* reacted with tetracarbonylnickel with evolution of CO to form a complex which was stable in the solid state, and which was assigned the structure *(29)* [60].

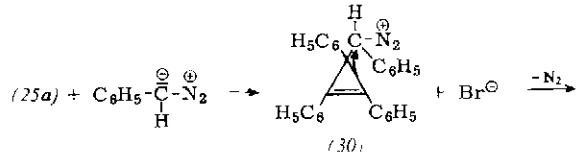


(29)

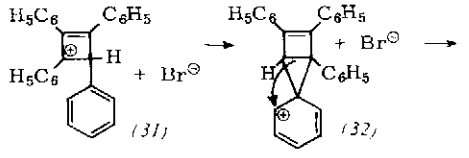
Compound *(29)* is regarded as a complex of formally zerovalent nickel with the triphenylcyclopropenylium cation. Each atom is tetrahedrallynickel surrounded by four pairs of electrons, two of which are supplied by the bromide anions, one by the carbon monoxide group, and one by the cyclopropenylium group. Recently a dipbenylcyclopropenone-nickel carbonyl complex has also been prepared [65].

4. Reactions with Diazo Compounds and Azides

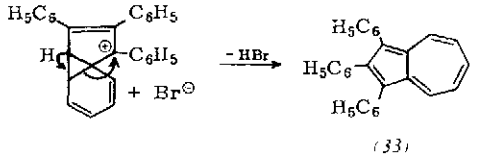
Compound *(25a)* reacts with phenyldiazomethane to form 1,2,3-triphenylazulene *(33)*. It is assumed that the diazonium compound *(30)* is first formed, and that this



(30)



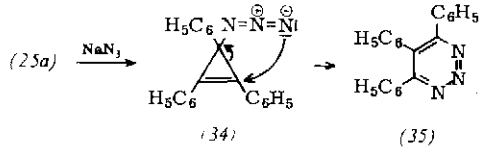
(31) *(32)*



(33)

loses nitrogen, with ring expansion, to form the cyclobutenyl cation *(31)*. The latter undergoes rearrangement, *via* the phenonium ion *(32)*, to form *(33)*. In the presence of excess phenyldiazomethane, the principal product is pentaphenylcyclopentadiene, formed by ring expansion of *(31)* [60a].

Sodium azide reacts with *(25a)* to form 1,2,3-triphenylcyclopropenyl azide *(34)*, which slowly rearranges, even at room temperature, to 4,5,6-triphenyltriazine *(35)* [60b, 60c]; this stabilization with ring expansion is typical of many similar cyclopropene derivatives [60d].

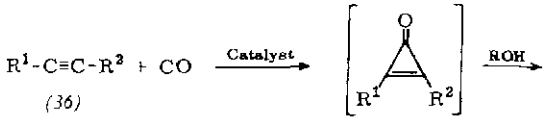


(34) *(35)*

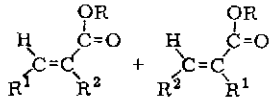
III. Cyclopropenones

Whereas in the case of the seven-membered ring compounds tropone was synthesized before the tropylium cation [2], the first cyclopropenone, namely diphenylcyclopropenone *(37)* [61, 62] was only described after the first cyclopropenylium salt.

However, cyclopropenones had previously been postulated (although with no conclusive evidence) as intermediates [63], particularly in the catalytic carbonylation of acetylenes *(36)*, which, in the presence of water or alcohols, leads to acrylic acids or acrylates [64].



(36)



This assumption has been tested in recent years in the case of diphenylcyclopropenone *(37)*. The results indicate that no cyclopropenone intermediate occurs in the carbonylation of acetylenes [65].

Interest in the cyclopropenones was rekindled by the predictions of the M.O. calculations (see Introduction) and the preparation of cyclopropenylium salts. The validity of the M.O. calculations was clearly shown by the isolation of the stable cyclopropenones. According to classical concepts, the more highly strained cyclopropenones should be much less stable

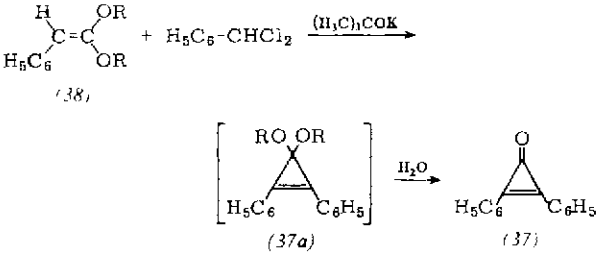
than the cyclopropanones, as is the case with the corresponding four-membered ring compounds [66]. However, cyclopropanones have so far only been detected as intermediates in a few reactions, but have not been isolated [67–71].

A. Preparation of Cyclopropenones

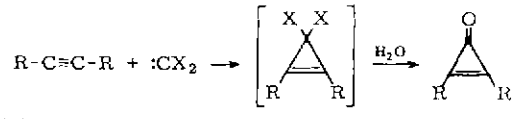
Of the four known syntheses of cyclopropenones, three proceed *via* substituted cyclopropenes which can be converted to cyclopropenones by hydrolysis; the fourth method is similar to the Favorskii reaction, the three-membered ring being formed only in the last step.

Diphenylcyclopropenone *(37)* was first prepared by the addition of phenylchlorocarbene to phenylketene acetal *(38)*, followed by elimination of HCl to form cyclopropenone ketal *(37a)* which is readily hydrolysed to *(37)* [61].



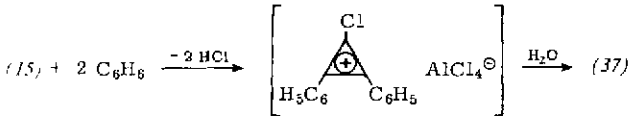
(38) *(37a)* *(37)*

A simpler synthesis of cyclopropenones is based on the addition of dichloro- or dibromo-carbenes to disubstituted acetylenes *(36a)* or *(36b)* and hydrolysis of the resulting product [62, 72, 73].

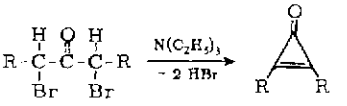


(36a): R = C_6H_5; X = Cl, Br
(36b): R = n-C_3H_7

Compound *(37)* is also formed from benzene and the trichlorocyclopropenylium cation *(15)* *via* a Friedel-Crafts reaction followed by hydrolysis [25].



A fundamentally different method uses α,α′-dibromoketones *(39)* as the starting materials; these lose 2 moles of hydrogen bromide to form cyclopropenones on treatment with triethylamine or other bases [74–77].



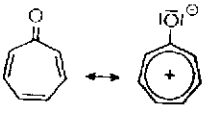
(39)

R = C_6H_5, n-C_4H_9
R + R = $(CH_2)_5$, $(CH_2)_9$

The unsubstituted cyclopropenone *(4)* has not yet been synthesized; however, this is due to its instability rather than to failure of the methods of preparation [62, 74].

B. Physical and Chemical Properties of the Cyclopropenones

The high stability of the cyclopropenylium cation suggests that, as in the case of tropone *(40)*, the zwitterionic form of *(4)* makes a considerable contribution to the ground state of the cyclopropenones; this should also be reflected in their properties.

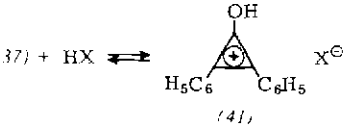


(40)

1. Basicity

Cyclopropenones are much more basic than other α,β-unsaturated ketones, with the exception of tropone [78–80]. Hammett's H_0-values (at which half of the ketone is protonated in aqueous solution) are -2.5 ± 0.3 (ca. 5.5 N $HClO_4$) for *(37)* and -0.4 ± 0.2 (ca. 1.3 N $HClO_4$) for *(40)* [80]. Dipropylcyclopropenone is more basic than diphenylcyclopropenone *(37)* [72, 73]; the substitutent effect in this case is therefore the same as in the case of the cyclopropenylium cations.

The high basicity of the cyclopropenones is often used in their separation and purification [62, 72–74]. The salts *(41)* of *(37)* can be obtained in crystalline form, and can be decomposed by heat or by weak bases to give cyclopropenone again [62].



(41)

The structure of the salts *(41)* is shown by the disappearance of the two typical cyclopropenone bands (see below) and the appearance of an OH band and of the cyclopropenylium band

(see Section II.B.3) in the IR spectrum. This change in the IR spectrum has been used for quantitative determination of the temperature dependence of the equilibrium *(37)* ⇌ *(41)*, and in this way the thermodynamic data were determined [78,79].

2. Spectra

The IR spectra of all cyclopropenones are characterized by two very intense bands at 1845–1865 and 1620 to 1645 cm^{-1} [61,62,72–79]. The authors are not in agreement as to the assignment of these bands; however, according to the solvent dependence of the positions of the bands, the band at 1850 cm^{-1} arises from the cyclopropene system with two substituents on the double bond, while that at 1640 cm^{-1} is due to the C=O stretching vibration [81]. The occurrence of the carbonyl band at this wave number, which is low for small-ring ketones [82], points to the high single-bond character of the C=O bond, and hence to the considerable contribution of the zwitterionic form of *(4)* to the ground state of the cyclopropenones. This is further supported by the high intensity of the carbonyl band and by the large dipole moments of 5.08 D and 5.3 D for dipbenyl- *(37)* and cycloheptenocyclopropenone *(42)*, respectively (cf. benzophenone 3.0 D; tropone 4.3 D; trimethylamine oxide 5.03 D) [62,81,83–85].

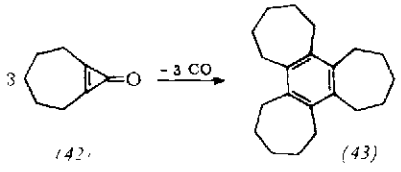
The nuclear magnetic resonance spectra of the cyclopropenones also agree with this structure. Thus the signals of the α-methylene protons occur at lower fields than those of the corresponding covalent cyclopropenes, but are not so strongly shifted as those of the cyclopropenylium salts [73,81]. In the case of the cyclopropenones, the differences Δ in the chemical shifts of the signals of the α- and β-CH_2 groups (which are proportional, in many cases, to the electronegativity of the substituents [21,86]) also lie between the values found for cyclopropenes and for cyclopropenylium salts [73,81].

C. Chemical Reactions of the Cyclopropenones

The reactions of the cyclopropenones can be subdivided into decarbonylations and additions. In the addition reactions, the reactant adds on either to the C=O or to the C=C double bond; this is often accompanied by rearrangements with opening of the three-membered ring [87].

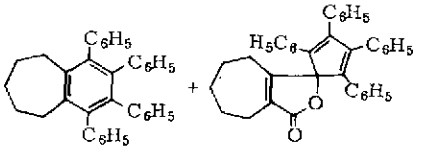
1. Decarbonylation

The thermal decomposition of the cyclopropenones at 130 – 250 °C leads to the formation of the corresponding acetylenes, with loss of carbon monoxide; the decarbonylation of dialkylcyclopropenones requires higher temperatures than that of diphenylcyclopropenones *(37)* [61,72–74,77]. Photolysis of *(37)* also yields diphenylacetylene and carbon monoxide [65,88]. Triscycloheptenobenzene *(43)* is formed on heating cycloheptenocyclopropenone *(42)* [74]. If *(42)* is decomposed in the



(42) *(43)*

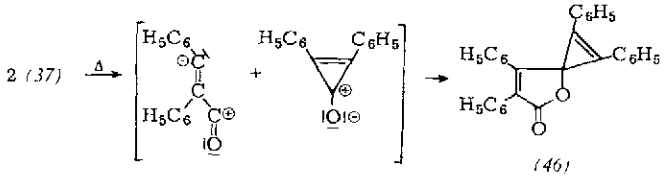
presence of tetraphenylcyclopentadienone, a small quantity of *(43)* (about 3 %) is formed, together with 1,2-cycloheptene-3,4,5,6-tetraphenylbenzene *(44)* (23 %) and *(45)* (21 %) as the principal products [77].



(44) *(45)*

Compounds *(43)* and *(44)* are probably formed *via* cycloheptyne as an intermediate [89]; however, addition of the strained C=C double bond of *(42)* to the tetraphenylcyclopentadienone, followed by elimination of 2 moles of carbon monoxide, cannot be excluded.

It is not yet certain whether the two C–C bonds are broken successively or simultaneously in the decarbonylation of cyclopropenones (which can be regarded as the reversal of a carbene addition). The dimer, which probably has the structure *(46)*, may be formed from *(37)* *via* an intermediate, since diphenylacetylene is the principal product of thermal decomposition of *(37)* only at high temperatures (> 160 °C). Between 145 and 150 °C, particularly in the presence of catalytic amounts of base, the main product is *(46)*, which cannot be thermally decomposed to give diphenylacetylene [77].



(46)

2. Addition Reactions

Additions to the carbonyl group can occur by electrophilic attack on the electron-rich oxygen atom, or by the attack of nucleophiles on the carbon atom which carries

[81] *A. Krebs*, unpublished work.

[82] Cyclopropanone has a band at 1825 cm^{-1} [70].

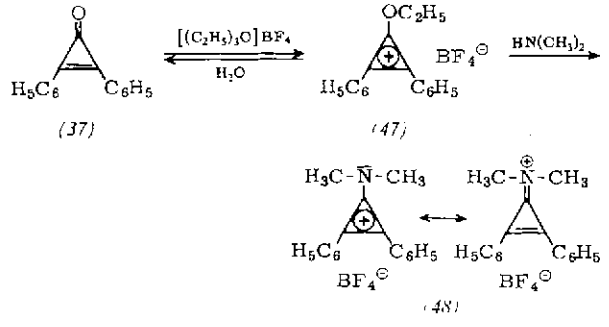
a partial positive charge. However, nucleophilic addition to the carbonyl carbon atom is more difficult than in other α,β-unsaturated ketones, owing to the charge delocalization in the zwitterionic form of *(4)*.

α) Electrophilic Additions to the Carbonyl Group

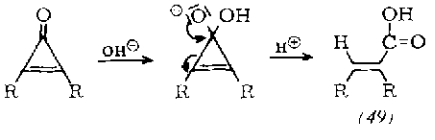
This group of reactions includes protonation of the cyclopropenones with strong acids (see Section III.B.1) and alkylation with triethyloxonium fluoroborate, which in the case of *(37)* leads [76, 89a] to ethoxydiphenylcyclopropenylium fluoroborate *(47)*. The enhanced reactivity of *(47)* as compared with *(37)* is shown in the reaction with dimethylamine; the product is dimethylaminodiphenylcyclopropenylium fluoroborate *(48)* whose stability towards boiling water can be explained by resonance [76].



(37) *(47)* *(48)*

β) Nucleophilic Additions to the Carbonyl Group

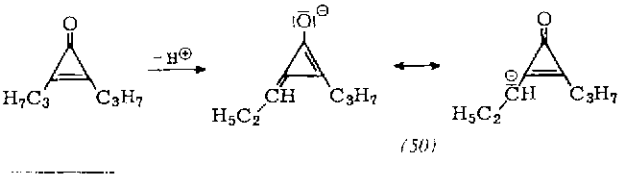
The hydrolysis of cyclopropenones with sodium hydroxide to yield α,β-unsaturated acids *(49)* [62, 72–74] probably begins with an addition of the $OH^{\ominus}$ ion to the C-atom of the carbonyl group; thus it proceeds in a manner similar to the ring-opening of the cyclopropanone intermediate in the Favorskii rearrangement [90].



(49)

The same gradation of reactivity is observed in this reaction as in the decarbonylation: the alkyl-substituted cyclopropenones are more stable than diphenylcyclopropenone [72–74]. This may be due either to the greater stabilizing action of the alkyl groups on the ketone (as suggested by basicity measurements) or to an increase in the stabilization of the transition state by the phenyl groups during ring-opening.

On the other hand, dipropylcyclopropenone reacts with other bases, such as sodium methoxide in methanol, to give the 2-propyl-3-propylidenecyclopropenolate anion *(50)*, as has been demonstrated by deuterium-exchange [80, 94].



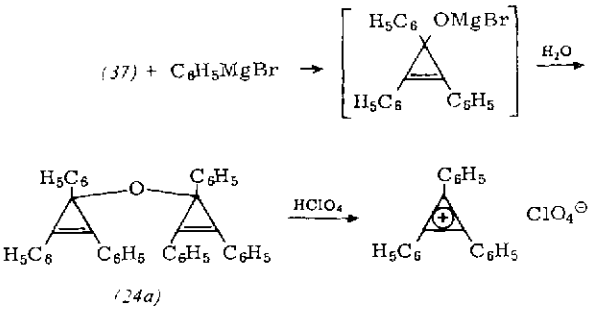
(50)

[89a] *B. Föhlisch*, personal communication.

[90] *A. Kende*, Organic Reactions *11*, 261 (1960).

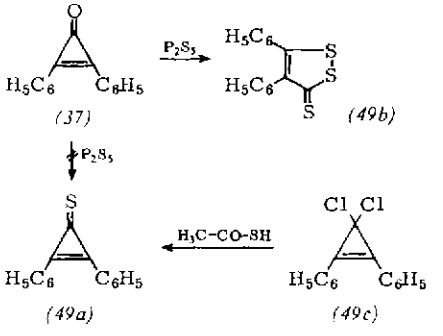
[90a] For a discussion of the mechanism of the reaction of *(37)* with hydroxylamine, see [73], pp. 42–44.

Grignard compounds also add in some cases to the carbonyl group of the cyclopropenones, whereas in the case of the tropones, this reaction occurs only to a very small extent, the principal reaction being 1,3-addition [91]. The different course taken by the reaction of *(37)* with phenylmagnesium bromide [73] is due either to steric factors or to the fact that the formation of a cyclopropanone is so difficult that the 1,3-addition is suppressed in favor of the formation of the ether *(24a)*.



(24a)

When it was attempted to convert *(37)* into the thioketone *(49a)* by reaction with phosphorus pentasulfide, only 4,5-diphenyltrithione *(49b)* was obtained [89a]. However, *(49a)* could be prepared from 3,3-dichloro-1,2-diphenylcyclopropene *(49c)* and thioacetic acid [91a].



(37) *(49b)* *(49a)* *(49c)*

Lithium aluminum hydride attacks the C=O and C=C double bonds of *(37)* to form 2,3-diphenylcyclopropan-1-ol [62], the structure of which, however, does not appear to be quite certain.

Even in the polarographic reduction of *(37)*, it could not be decided which of the two double bonds was first reduced [92].

Compound *(37)* forms a hydrazone with 2,4-dinitrophenylhydrazine [62]; the *p*-toluenesulfonylhydrazone, on the other hand, could only be obtained by the reaction of 3,3-dichloro-1,2-diphenylcyclopropene with *p*-toluenesulfonylhydrazine [93]. Hydrazine [93], semicarbazide, and hydroxylamine [62] did not yield the normal carbonyl derivatives with *(37)*. This inertia is evidently a result of the delocalization of the positive charge in the zwitterionic form of *(4)*.

[91] *G. L. Closs* and *L. E. Closs*, J. Amer. chem. Soc. *83*, 599 (1961); *T. Nozoe*, *T. Mukai*, and *T. Tezuka*, Bull. chem. Soc. Japan *34*, 619 (1961).

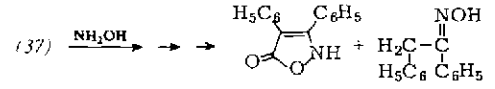
[93] *W. M. Jones*, personal communication.

γ) Additions to the C=C Double Bond

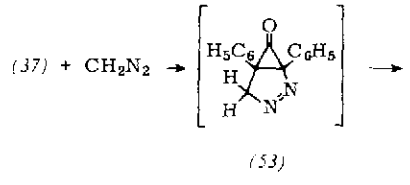
The reaction of *(37)* with hydroxylamine yields 3,4-diphenylisoxazolone *(51)* and desoxybenzoin oxime *(52)* [73].



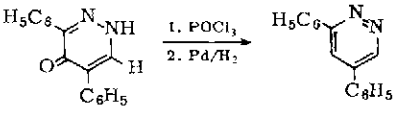
(51), 70% *(52)*, 11%

The first step is assumed to be a 1,4- or 1,2-addition (to the C=C double bond) of the hydroxylamine. The intermediates then undergo oxidation, or oxidation and decarboxylation, to form *(51)* or *(52)* [90a].

Diazomethane does not attack the carbonyl group, as it does in the case of saturated cyclic ketones, but adds as a 1,3-dipole (as in the case of normal α,β-unsaturated ketones) to the strained cyclopropene double bond of *(37)* [76,94] or dipropylcyclopropenone [94]. The cyclopropanone intermediate *(53)* isomerizes to 3,5-diphenyl-4-pyridazone *(54)*, the structure of which has been proved by reduction to *(55)* [76,94].



(53)



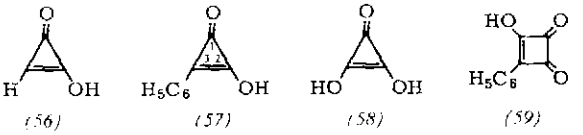
(54) *(55)*

The catalytic hydrogenation (Pt/H_2) of *(37)* gave dibenzyl ketone in one case [73]; other authors isolated 2,3-diphenylcyclopropan-1-ol as the sole product [62].

D. Cyclopropenone Derivatives

1. Hydroxycyclopropenones

The hydroxycyclopropenones are of interest on account of the analogy to the tropolone series and the high calculated delocalization energies of the anions of hydroxycyclopropenone *(56)* [95] and of 2-hydroxy-3-phenylcyclopropenone *(57)*, and of the dianion of dihydroxycyclopropenone *(58)* [96]. Thus *(56)*, *(57)*, and *(58)* should be very strong acids ($pK_a \approx 0$), as is 4-hydroxy-3-phenylcyclobutene-1,2-dione *(59)* [95].



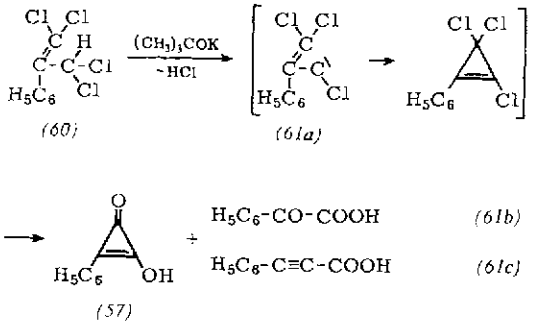
(56) *(57)* *(58)* *(59)*

[94] *P. T. Izzo* and *A. S. Kende*, Chem. and Ind. *1964*, 839.

[95] *E. J. Smutny*, *M. C. Caserio*, and *J. D. Roberts*, J. Amer. chem. Soc. *82*, 1793 (1960).

[96] *R. West* and *D. L. Powell*, J. Amer. chem. Soc. *85*, 2577 (1963).

However, of these compounds only *(57)* has been synthesized; the reaction of 1,1,3,3-tetrachloro-2-phenylpropene *(60)* with potassium t-butoxide, which probably proceeds *via* the vinylcarbene *(61a)*, led to *(57)*, phenylpyruvic acid *(61b)*, and phenylpropiolic acid *(61c)*. In accord with the predictions, *(57)* has $pK_a \approx 1$ [97].

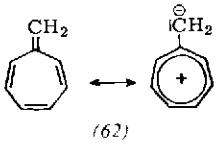


(60) *(61a)* *(61b)* *(61c)* *(57)*

Whereas the "aromatic" oxo-anions $C_4O_4^{2\ominus}$, $C_5O_5^{2\ominus}$, and $C_6O_6^{2\ominus}$ are known, the first member of this series, namely the dianion of *(58)* $C_3O_3^{2\ominus}$, has not yet been described [96]. Attempts to obtain *(58)* by hydrolysis of tetrachlorocyclopropene always led to ring-opening [98].

2. Methylenecyclopropenes (Triafulvenes)

Methylenecyclopropene *(5)* is the simplest cross-conjugated cyclic system. For this reason, and owing to its relationship with cyclopropenone on the one hand and 1-methylenecycloheptatriene (heptafulvene) *(62)* on the other hand, methylenecyclopropene *(5)* and its derivatives became the objects of theoretical studies at an early stage [7, 9, 99]. Despite the large calculated delocalization energy (see Table 2), the M. O. theory requires that *(5)* owing to the high free-valence index at the exocyclic methylene group should be readily polymerizable and should be highly reactive towards free radicals [*] [7]. In agreement with this, no derivatives of *(5)* without substituents on the exocyclic C-atom have as yet been isolated. On the other hand, substituents which can stabilize a negative charge on the exocyclic C-atom by inductive or mesomeric effects should increase the contribution of the zwitterionic form of *(5)* to the ground state, and so cause an increase in the chemical stability of the methylenecyclopropene.



(62)

The first synthesis of a stable methylenecyclopropene, namely 1,2-diphenyl-3,4'-(2',6'-dibromoquino)cyclopropene *(64)*, was achieved by thermal cleavage of the ether linkage in the cyclopropenylium salt *(63)*, bromination of the resulting diphenyl-(*p*-hydroxyphenyl)-

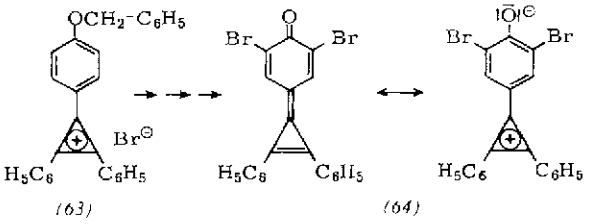
[*] For a definition of the free-valence index, see *e.g. A. Streitwieser jr.*: Molecular Orbital Theory. Wiley, New York-London 1961, p. 56.

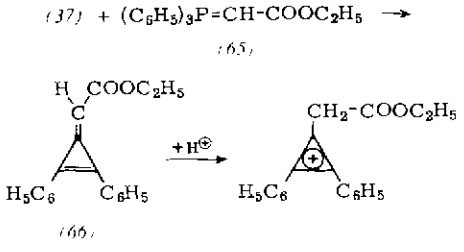
cyclopropenylium bromide with *N*-bromosuccinimide, and finally reversible elimination of HBr with a tertiary amine to yield *(64)* [17]. Compound *(64)* is much more



(63) *(64)*

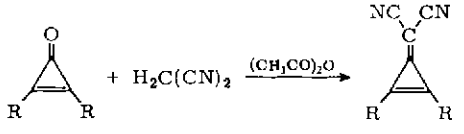
basic than diphenylcyclopropenone *(37)*. 10-(Diphenylcyclopropylidene)anthrone resembles compound *(64)* and was obtained [99a] by reacting diphenylcyclopropenylium perchlorate *(11)* with anthrone.

However, the simplest route to the methylenecyclopropenes is the Wittig olefination of cyclopropenones. Thus, 1,2-diphenyl-4-ethoxycarbonylmethylenecyclopropene *(66)* is obtained by the reaction of *(37)* with triphenylphosphine-ethoxycarbonylmethylene *(65)* [100].



(66)

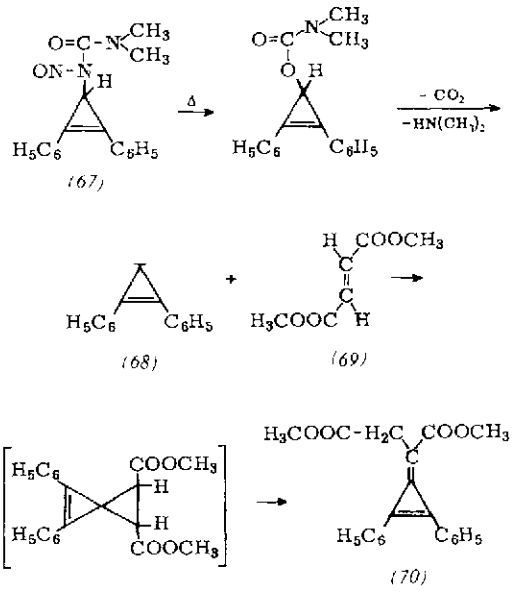
Condensation of *(37)* [100a] and dipropylcyclopropenone [100b] with malonodinitrile yields the correcponding 1,1-dicyanomethylenecyclopropenes *(66a)* and *(66b)*.



(66a) R = C_6H_5
(66b) R = C_3H_7

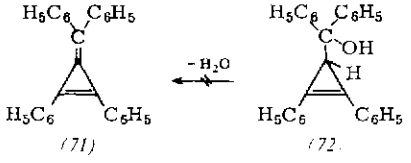
Another methylenecyclopropene, namely *(70)*, has been obtained during attempts to trap 1,2-diphenylcyclopropenylidene *(68)* with dimethyl fumarate *(69)*; *(68)* was formed on decomposition of the urea derivate *(67)* [93, 101].

Attempts to prepare tetraphenylmethylenecyclopropene *(71)* by elimination of water from *(72)* led to rearrangement with formation of 1,2,4-triphenylnaphtbalene and 1,2,3-triphenylazulene *(33)* [102].



(67) *(68)* *(69)* *(70)*

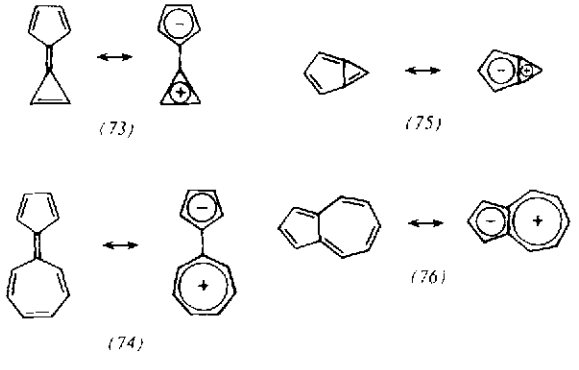
The NMR spectra of *(66)* [100] and of *(66b)* [100b], the high dipole moment of 7.9 D for *(66a)* [100a], the position of the carbonyl band in *(64a)* [99a], and also the strong solvent dependence of the ultraviolet spectra of



(71) *(72)*

(66) [100] and of *(66a)* [100a] prove how considerable the contribution is of the zwitterion form to the ground state of the methylenecyclopropene compounds: it was estimated to be almost 50 % in the case of *(66b)*. This also agrees with the fact that protons add preferentially to the exo-methylene carbon atom of *(66)* and *(70)* to form the cyclopropenylium system.

The formal combination of the cyclopropenylium cation with the cyclopentadienyl anion gives two interesting derivatives of methylenecyclopropene, namely calicene *(73)* and bicyclo[3,1,0]hexatriene *(75)*; these are the three-membered ring analogs of sesquifulvalene *(74)* and of azulene *(76)*.



(73) *(75)* *(74)* *(76)*

Although the considerably large values of 2.94 and 2.39 β have been obtained for the calculated delocalization energies of *(73)* and *(75)* [7], attempted syn-

[101] *W. M. Jones* and *J. M. Denham*, J. Amer. chem. Soc. *86*, 944 (1964).

[102] *R. Breslow* and *M. Battiste*, J. Amer. chem. Soc. *82*, 3626 (1960).

theses of these systems have so far been unsuccessful [103, 104].

Compound *(73)*, like *(74)*, may lack the postulated resonance stabilization, since the properties of *(74)* and its derivatives can be satisfactorily explained by the structure with substantially localized double bonds [105, 106]. In the case of *(75)*, the resonance energy is probably consumed by the enormous ring-strain energy; this is shown by the fact that *(75)* can also be described as a valence isomer of a *m*-dehydrobenzene.

IV. Conclusion

The chemistry of the cyclopropenylium compounds is only eight years old. In this short period, however, the important questions have already been answered, so that only a few problems of synthesis remain unsolved, *viz.* the unsubstituted cyclopropenylium cation *(1)*, the benzocyclopropenylium cation, and bicyclo[3,1,0]hexatriene *(75)*.

The preparation of the substituted cyclopropenylium salts, cyclopropenones, and methylenecyclopropenes has extended the number of the "Hückel aromatic" systems. The study of their properties and reactivities has impressively demonstrated the expected relationship with the "Hückel homologous" seven-membered ring compounds. If equality of the bond lengths and the existence of a ring current are accepted as criteria of aromatic character, the cyclopropenylium salts deserve to be called aromatic compounds.

I am indebted to Prof. R. Breslow for discussions and suggestions and also to Dr. Th. Eicher, Dr B. Föhlisch, Prof. W. M. Jones, Dr. A. S. Kende, Dr. H. Prinzbach, and Prof. R. West for making available unpublished results. Thanks are also due to Prof. H. A. Staab for suggestions made on perusal of the manuscript.

Syntheses of Oxide Halides

BY DR. K. DEHNICKE

LABORATORIUM FÜR ANORGANISCHE CHEMIE DER TECHNISCHEN HOCHSCHULE, STUTTGART (GERMANY)

Knowledge of the oxide halides has made significant advances in recent years as a result of new methods of preparation. Moreover, the systematic study of older methods has led to versatile syntheses which permit the preparation of many new oxide halides. A brief outline of the scope, limitations, and difficulties of the various processes is given together with a number of examples.

I. Partial Hydrolysis of Halides

Although the method of partial hydrolysis of halides has been known for a very long time it can only be used in special cases to prepare definite anhydrous oxide halides. The reaction proceeds according to the General Equation (a).

$$MX_5 + H_2O = MOX_3 + 2\,HX \qquad (a)$$

However, the course of such hydrolyses is greatly complicated by the fact that other reactions, such as the formation of stable hydrates, oxyacids of the halides, hydroxo compounds, oxides, etc. are also formed in many cases. The method can, therefore, be succesful only if the reaction product is somehow stabilized or removed, *e.g.* by making use of its volatility. Examples are found in the preparations of $POCl_3$ [1] from PCl_5, of $P_2O_3Cl_4$ [2] from $POCl_3$, or of the silicon oxide halides of general formula $Si_nO_{n-1}Cl_{2n+2}$ which can be obtained by partial hydrolysis of $SiCl_4$, and of which the representatives up to n=10 have been isolated [3–7].

Oxide halides can also be stabilized in the crystal lattice. In such cases partial hydrolysis of the halide can even be carried out with excess water. This group includes certain oxide halides of mercury, *e.g.* $2HgCl_2 \cdot HgO$ [8]. In addition to the homopolar character of the Hg–X

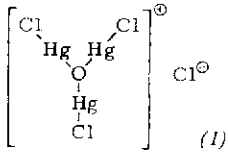
bond, the high symmetry of complex structural groups is also found to be a stabilizing factor in these compounds [cf. Formula *(1)*].



(1)

The method of partial hydrolysis of halides is particularly successful in the preparation of the oxide halides of the trivalent elements antimony, bismuth, indium, the rare earths, and some actinides. All these oxide halides are structurally related, and presumably the lattice is a stabilizing factor here, in that it prevents complete hydrolysis by steric effects.

The oxide fluorides of the rare earths, MOF, have been found to possess an unusually high thermal stability; they are prepared by partial hydrolysis of the trifluorides at 800 °C in a current of moist nitrogen [9–11]. The formation of higher oxides of cerium and praseodymium as by-products can be suppressed by admixture of a little hydrogen or ammonia with the carrier gas [10].

The oxide fluorides NbO_2F and TaO_2F can be prepared by simply drying solutions of niobium and tantalum pentoxides in hydrofluoric acid [12]. However, it should be pointed out that it is very difficult to obtain products which are completely free of OH^- ions by this method. For example, when a solution of Ti^{4+} in hydrofluoric acid is dried, the product is a "$TiOF_2$" [13] which can have an OH content of up to 50 % of the fluorine content, and which must, consequently, be formulated as TiO(OH)F [14]. This compound still retains the ReO_3-type lattice of $TiOF_2$ [15], owing to the practically equal ionic radii of OH^- and F^-.

Finally, the partial hydrolysis method still enjoys a certain importance in the preparation of a number of oxide chlorides, oxide bromides, and oxide iodides of the rare earths and actinides. Whereas ammonical hydrolysis is used in the preparation of the oxide chlorides and oxide bromides of these elements [16–19], the oxide iodides MOI (M = La, Sm, Tm, Y, Ac, Pu) can be prepared by simply heating the triiodides in moist air [20–22].

The extent to which halides can be subjected to partial hydrolysis has been explored in many directions. Mention is made only of the unsuccessful attempts to prepare $ZrOCl_2$ [23–25], or the surprising course of the hydrolysis of $TaCl_5$ [26,27], which – in contrast to $NbCl_5$, which yields $NbOCl_3$ – leads not to an oxide chloride, but exclusively to Ta_2O_5; this reaction can be used for the separation of niobium and tantalum [28].

II. Special Cases of the Partial Hydrolysis of Halides

A number of oxide halides can be obtained by controlled thermal decomposition of definite hydrates; it should be noted, in this connection, that hydration may be assumed to be a primary step in hydrolysis. For example, the thermal decomposition of $FeCl_3 \cdot 6H_2O$, after mixing with 5 moles of $FeCl_3$, leads to the elimination of HCl to yield FeOCl [29], as shown in Equation (b).

$$\frac{1}{6}\,(FeCl_3 \cdot 6\,H_2O + 5\,FeCl_3) = FeCl_3 \cdot H_2O + FeOCl + 2\,HCl \quad (b)$$

In special cases a partial hydrolysis can be combined with an oxidation or a reduction. In this way the oxide halides EuOI [30] and PuOF [31] are obtained by oxidizing hydrolysis of EuI_2 in an oxygen atmosphere, or reducing hydrolysis of PuF_4 with atomic hydrogen.

Instead of the controlled thermal decomposition of halide hydrates, it is possible in many cases to use the thermal decomposition of definite etherates. Thus the thermal decomposition of the monoetherates of $NbCl_5$, $NbBr_5$, and $TaCl_5$ starts at 90 °C with the elimination of ethyl halide to yield the solvate-free oxide halides $NbOCl_3$ [see Equation (c)], $NbOBr_3$, and $TaOCl_3$ [32].

$$NbCl_5 \cdot O(C_2H_5)_2 = NbOCl_3 + 2\,C_2H_5Cl \quad (c)$$

III. Commutation [*] of Oxides and Halides

By far the most important method for the preparation of oxide halides is the thermal combination of a halide with the corresponding oxide [see Equation (d)].

$$MO_2 + MCl_4 = 2\,MOCl_2 \quad (d)$$

[*] It seems reasonable to use the term "commutation" to describe the reverse of a "dismutation" in which no redox reaction occurs.

$$MO_2 + MCl_4 \underset{\text{dismutation}}{\overset{\text{commutation}}{\rightleftharpoons}} 2\,MOCl_2$$

The term "comproportionation" will always be used to describe the reverse of a "disproportionation", in which a redox reaction is involved.

$$MO_2 + MCl_6 \underset{\text{disproportionation}}{\overset{\text{comproportionation}}{\rightleftharpoons}} 2\,MOCl_3$$

This method has recently gained considerably in importance and versatility, both practically and theoretically, as a result of the extensive studies by *Schäfer* [33] on chemical transport reactions. The limitation of this method is that the reaction of the halide with the oxide must proceed at a lower temperature than the decomposition of the expected oxide halide. Whereas the problems encountered in the preparation of oxide halides by partial hydrolysis are predominantly kinetic, thermodynamic effects come to the fore in this case. Most of the compounds involved have a high thermal stability.

The commutation method is very useful for the preparation of the oxide fluorides of the rare earths, MOF [11,34–38], the high thermal stability of which has already been seen from their preparation by partial hydrolysis at 800 °C.

The importance of the detailed study of the thermodynamic relationships in such oxide/halide systems can be clearly seen from thermal equilibrium measurements on the system $Ta_2O_5/TaCl_5$ which exists in equilibrium with gaseous $TaOCl_3$ at temperatures above 500 °C [39]. On cooling, the reverse reaction occurs and $TaOCl_3$ decomposes; however, the composition of $TaOCl_3$ can be confirmed by other methods [32,40]. In the case of niobium, $NbOCl_3$ [41] and Nb_3O_7Cl [42] can be obtained by simple commutation of the oxide and the halide, with preparatively useful results.

The commutation method can sometimes also be modified to give oxide halides of intermediate valence states. Thus TiOCl [43] is prepared by "comproportionation", either from TiO_2 and $TiCl_3$ according to Equation (e),

$$TiO_2 + 2\,TiCl_3 = 2\,TiOCl + TiCl_4 \qquad (e)$$

or by the addition of metallic titanium to a $TiO_2/TiCl_4$ mixture [Equation (f)].

$$2\,TiO_2 + TiCl_4 + Ti = 4\,TiOCl \qquad (f)$$

A completely analogous method can be used for the preparation of VOCl [44] and CrOCl [45], both of which crystallize in the same lattice as FeOCl which is rather less stable thermally, and consequently cannot be prepared by this method [44–46]. The comproportionation method can be used for the preparation of $NbOCl_2$ [42] and $TaOCl_2$ [42] by adding metallic niobium or tantalum in stoichiometric amounts to the oxide/halide mixture. It is possible to obtain $ReOCl_4$ [47] from Re_2O_7 and $ReCl_5$ at 70 °C by a particularly careful comproportionation, although excess Re_2O_7 leads to the formation of ReO_3Cl [47].

In the case of the elements of the main groups whose oxide halides can be prepared by the commutation method, the temperatures used are generally rather low, and furthermore, thermally unstable compounds are often encountered. However, low temperatures necessitate the use of reactive oxides, such as are found in the case of the elements boron, phosphorus, arsenic, sulfur, and selenium. Thus B_2O_3 dissolves in BCl_3 to form the cyclic trichloroboroxole $(BOCl)_3$ [48,49], and As_2O_3 dissolves in $AsCl_3$ to form the open-chain polymer $(AsOCl)_m$ [50]. BF_3 and BBr_3 can also be reacted with B_2O_3 above 250 °C and under pressure to form trimers, namely the trihalogenoboroxoles, the products decomposing again into the starting materials on slow cooling [48,49]. By rapid cooling, however, it is possible to obtain $(BOF)_3$ which is stable below −125 °C [51]. Owing to the low reactivity of Al_2O_3, a temperature of 440 °C is required for the preparation of AlOBr [52], while the corresponding gallium oxide halides, GaOX, with the exception of GaOF, can all be prepared from GaX_3 and Ga_2O_3 between 300 and 400 °C [53].

IV. Reactions of Halides with Oxides of Other Elements

In many cases where the temperatures required for reaction of the halide MX_{2n} with the oxide MO_n are too high to yield the oxide halide, a foreign oxide $M'O_m$ can be successfully used. This method has the disadvantage that it is often difficult to separate the foreign halide $M'X_{2m}$ which is also formed [54,55]. Suitable sources of oxygen are oxides yielding halides $M'X_{2m}$ which volatilize readily or which dissolve readily in inert solvents. On the other hand, the reaction can also be used in cases where a readily volatile or readily soluble oxide halide $MO_{n-x}X_{2x}$ is formed. Finally, when this method is used for the preparation of oxide halides of intermediate valence states, redox reactions can sometimes be carried out simultaneously. The wide variety of possible sources of oxygen make this reaction appear extremely susceptible to development; the example of VOCl [56,57] was described as early as 1911 [Equation (g)], but has only very recently become prominent again.

$$VCl_3 + CO_2 = VOCl + COCl_2 \qquad (g)$$

[57] *F. Wedekind* and *C. Horst*, Ber. dtsch. chem. Ges. *45*, 262 (1912).

This method has recently been used to prepare new oxide halides, and has also been used as a simplified method of preparing oxide halides which are already known.

As_2O_3, Sb_2O_5, Bi_2O_3, and SiO_2 are found to be particularly suitable as sources of oxygen, as are TiO_2, CrO_3, NO_2, and SO_3. Thus pure $TiOCl_2$ is obtained very readily by the dissolution of As_2O_3 in $TiCl_4$ [54, 55], while CrOCl can be prepared from Bi_2O_3 or TiO_2 and $CrCl_3$ at a somewhat higher temperature [45]. The preparation of $TaOCl_2$, described above [42], can be modified in such a way that the oxygen is supplied by the quartz wall of the reaction vessel in the reaction of $TaCl_5$ with Ta. Oxide halides of elements of the main groups have also been prepared: *e.g.* AlOCl [58] from $AlCl_3$ and Sb_2O_5, and AlOI [59] from AlI_3, preferably with As_2O_3. SOF_4 [61], which is of interest on account of its versatility as a reactant [60], can be obtained from SF_4 by the use of vigorous oxidizing agents such as CeO_2 or CrO_3. The oxidation can also be carried out with NO_2 at 200 °C, or with catalytic quantities of NO_2 using atmospheric oxygen as the oxidizing agent.

V. Preparation of Oxide Halides by Thermal Degradation

The preparation of oxide halides by thermal degradation is subject to two conditions. On the one hand, decomposition must proceed at temperatures at which the resulting oxide halide is stable. On the other hand, the products must be easily separated and should therefore exhibit, for example, wide differences in their volatilities or solubilities.

Some oxide halides are obtainable by thermal degradation of other oxide halides. Thus, the I_2 vapor pressure over $NbOI_3$ reaches 1 atm at 270 °C, and $NbOI_2$ [62] is formed, while $TiOI_2$ loses iodine at 120 °C in vacuo, with formation of TiOI [63]. When $NbOCl_3$ is heated in a sealed tube, Nb_3O_7Cl is formed together with NbO_2Cl [64]. Thermal treatment of the bismuth oxide halides also yields compounds of complicated composition. For example, when heated to 700 °C BiOCl gives $Bi_{24}O_{31}Cl_{10}$ [65, 66]; the unusual ratios of the atoms in the latter can be explained from the sequence of the layers in the lattice [66], and this also accounts for its high thermal stability.

Other starting materials for the preparation of oxide halides by thermal degradation are strontium and barium fluorosulfonates which give good yields of sulfuryl fluoride at 500 °C, in accordance with Equation (h) [67].

$$Sr(SO_3F)_2 = SrSO_4 + SO_2F_2 \quad (h)$$

VI. Preparation of Oxide Halides by Partial Halogenation of Oxides

Just as it is possible to replace part of the halogen in halides by oxygen, using an oxygen donor, oxides can be reacted with halogen donors. The particular problems of this method are very similar to those described in Sections III and IV. It has been found that halides which react to give readily volatile by-products are particularly suitable, *e.g.* BF_3, $COCl_2$, CCl_4, HF, HCl, HBr, F_2, Cl_2, certain interhalogen compounds, and, very recently, SeF_4.

On the other hand, it is also possible to use halides which do not give volatile reaction products if the resulting oxide halide itself is volatile or dissolves without decomposition. Of this group, particular mention should be made of $HOSO_2F$, SbF_3, AgF, KF, and CaF_2.

1. Chlorination with $SOCl_2$

Thionyl chloride has for some time been found to be a particularly easily manipulated reagent for the preparation of oxide chlorides. Thus $VOCl_3$ [68] can be prepared by simply heating V_2O_5 under reflux with the stoichiometric quantity of thionyl chloride. For the preparation of $NbOCl_3$ [69, 70] and $WOCl_4$ [69], on the other hand, the reaction must be carried out under pressure. However, the oxide chlorides are formed in a very pure state and in practically quantitative yield when the sulfur dioxide formed according to Equation (i) is removed.

$$WO_3 + 2\,SOCl_2 = WOCl_4 + 2\,SO_2 \quad (i)$$

2. Halogenation with CCl_4 and CBr_4

Some oxides can be partially halogenated with halides of carbon, generally at about 200 °C and therefore under pressure, with good results. To prevent complete halogenation of the oxide, stoichiometric quantities of the reactants are used. The carbon-halogen compounds must be free from carbon-hydrogen compounds, since reduction can otherwise occur. The reaction proceeds with formation of the readily volatile phosgene, *e.g.* according to Equation (j), and is particularly suitable

$$Nb_2O_5 + 3\,CCl_4 = 2\,NbOCl_3 + 3\,COCl_2 \quad (j)$$

for the preparation of $NbOCl_3$ [71], $NbOBr_3$ [72], and $WOCl_4$ [73]. The tungsten oxide bromides $WOBr_4$ and WO_2Br_2 [74] can be prepared by varying the quantity of CBr_4 used.

3. Halogenation with Halogens and Interhalogen Compounds

Among the halogens, only fluorine and interhalogen compounds containing fluorine can replace oxygen in oxides, owing to the electronegativity relationships. The replacement of bromine and iodine in oxide bromides and oxide iodides by chlorine and bromine, respectively, is of little interest, since it is easier in most cases to prepare the oxide chlorides directly. On the other hand, the replacement of chlorine in oxide chlorides by elementary fluorine is desirable in certain cases. The following may be used as fluorinating agents: F_2, ClF_3, BrF_3, IF_3, and IF_5.

The reaction proceeds more readily with the polar interhalogen compounds than with fluorine, and consequently lower temperatures can be used in the former case. Thus a temperature of 475 °C is required for the preparation of VOF_3 [75] from V_2O_5 and F_2, and even higher temperatures for the fluorination of MoO_3 with F_2. On the other hand, reactions with interhalogen compounds always proceed at lower temperatures; OsO_3F_2 [76] can be very easily obtained from OsO_4 and BrF_3. IF_3 and IF_5 are also occasionally used for the partial fluorination of oxides. CrO_3 and IF_3 react smoothly to give CrO_2F_2 [77], while IF_5 can be used to prepare MnO_3F from $KMnO_4$; similarly, $KReO_3$ reacts with IF_5 to yield ReO_3F [78]. VOF_3 [79] is very easily obtained by fluorination of $VOCl_3$ with ClF_3; this reaction proceeds even at room temperature

4. Fluorination with SF_4 and SeF_4

It has been found very recently that SF_4 and SeF_4 are particularly effective fluorinating agents in some cases. Their reaction products SOF_2 and $SeOF_2$ are highly volatile, and can, therefore, be easily removed.

The excellent fluorinating properties of SF_4 and SeF_4 are essentially due to their structure: they form trigonal bipyramids in which two fluorine atoms and the lone pair of electrons are arranged equatorially, and the remaining two fluorine atoms occupy the apices [80, 81]. The compounds are thus structurally similar to the interhalogen compounds which are known to be good fluorinating agents, and to certain fluoride chlorides of group V elements, *e.g.* SbF_3Cl_2 which also forms a trigonal bipyramid [82]. Such structural similarities are reflected in the chemistry of these compounds. Thus CrO_3 can be fluorinated to CrO_2F_2 [83] at 5 °C using SF_4. Also SeF_4 reacts very satisfactorily with CrO_3 or, more simply, with $K_2Cr_2O_7$, to form CrO_2F_2 [84, 85].

5. Halogenation with Hydrogen Halides and Halogenosulfonic Acids

In the reaction of hydrogen halides with oxides, the former are used in large excess; the reaction is carried out in the flowing gas to remove the water which is formed in accordance with Equation (k). For example,

$$MO_2 + 2\,HX = MOX_2 + H_2O \quad (k)$$

the oxide chlorides of the rare earths, MOCl, can be prepared by passing a current of moist HCl over the sesquioxides M_2O_3 at high temperatures [86]; this reaction can also be used for the preparation of AmOCl [87]. When halogenosulfonic acids are used as the halogenating agents, pyrosulfuric acid or alkali metal hydrogen sulfate is formed as a by-product [see Equations (l) and (m)].

$$CrO_3 + 2\,HOSO_2F = H_2S_2O_7 + CrO_2F_2\ [88] \quad (l)$$

$$KMnO_4 + HOSO_2F = KHSO_4 + MnO_3F\ [89] \quad (m)$$

It is necessary, for the separation of the products, that halogenation should yield a readily volatile oxide halide. In this way NO_2Cl [90, 91] can be prepared under very mild conditions at −60 °C from chlorosulfonic acid and HNO_3.

6. Special Halogenating Agents

In this section we shall mention a few less important halogenating agents which have, nevertheless, made possible the synthesis of certain oxide halides. This group includes acetyl bromide which reacts with CrO_3, as shown in Equation (n), and S_2Cl_2 which is the active

$$CrO_3 + 2\,CH_3COBr = CrO_2Br_2 + (CH_3CO)_2O \quad (n)$$

reagent for the chlorination of MoO_3/sulfur mixtures to give $MoOCl_4$ [93] [Equation (o)].

$$MoO_3 + S + 2\,Cl_2 = MoOCl_4 + SO_2 \quad (o)$$

Finally, BF_3 [94, 95], VF_5 [96] and CoF_3 [97] are also occasionally suggested as fluorinating agents for oxides.

VII. Transhalogenation of Oxide Halides

The most important transhalogenating agents are HBr and HF which are reacted with oxide chlorides [Equation (p)]. The reactions generally proceed to completion,

$$MOCl_2 + 2\ HX = MOX_2 + 2\ HCl \qquad (p)$$

since the HCl formed is more volatile then HF and HBr. In this way, it is possible to prepare VOF_2 [97] from $VOBr_2$, ReO_3F [89] from ReO_3Cl, or $SeOBr_2$ [98] from $SeOCl_2$.

Use is also made of the insolubility or the volatility of one of the reactants in the transhalogenation of oxide halides using other halogenating agents. Thus, $SOCl_2$ reacts very readily in liquid SO_2, with KBr dissolved in the latter, to yield $SOBr_2$ [99] which is deposited as a white precipitate. The volatility of $SeOF_2$ is utilized in the fluorination of $SeOCl_2$ by heating with KF [100]. In some cases, SbF_3 has also been found to be a good fluorinating agent for oxide chlorides, if a little $SbCl_5$ is added as a catalyst. Fluoride chlorides of Sb^{5+}, the particular fluorinating properties of which have already been mentioned, presumably occur as intermediates. In this way, high yields of COF_2 [101] can be prepared from $COCl_2$ in an autoclave.

VIII. Oxide Halides with Two Halogen Components

A number of oxide fluorochlorides can be prepared by reacting oxide chlorides with the theoretical amount of a fluorinating agent. Thus, SbF_3 is also suitable for partial fluorination of $COCl_2$ to give COFCl [101], or of $SOCl_2$ to give SOFCl [101]. To prepare CrO_2FCl [102], the oxide fluoride is combined with the oxide chloride in the molar ratio of 1:1.

An original preparation of sulfuryl fluoride chloride, SO_2FCl, involves controlled chlorination of an organically substituted oxide fluoride, namely benzenesulfonyl fluoride [see Equation (q)].

$$H_5C_6 \cdot SO_2F + Cl_2 = H_5C_6\text{-}Cl + SO_2FCl\ [101] \qquad (q)$$

IX. Oxide Halides from Halides and Oxygen

Just as fluorine can be used to replace part of the oxygen in oxides, part of the chlorine and bromine in chlorides and bromides can be replaced by oxygen, as shown in Equation (r).

$$MCl_4 + {}^1/_2\ O_2 = MOCl_2 + Cl_2 \qquad (r)$$

The lower reactivity of oxygen as compared to fluorine is compensated to some extent by the greater reactivity of chlorides and bromides as compared to the oxides. Thus VOCl [46] can be obtained by heating VCl_3 in a stream of oxygen, and UO_2Cl_2 [103] is formed from UCl_4 and oxygen at 300 °C. In other cases this method suffers from disadvantages, the most obvious of which are the heterogeneity (solid/gaseous) and the difficulty of metering the oxygen supply.

X. Oxide Halides by Oxidation of Lower Oxides or Oxide Halides with Halogens

This reaction, which has been known in principle for some time in the cases of NO and SO_2, was applied a few years ago to the preparation of ReO_3Cl [104] (from ReO_3 and chlorine at 160 °C) and ReO_2Br_2 [105] (from ReO_2 and Br_2).

The disadvantage of the low reactivity of many oxides can be avoided by reacting them, so the speak, in the nascent state with halides, *i.e.* by burning the element in gaseous halogen containing oxygen. In this way, for example, OsO_3F_2 [76] can be prepared from osmium in a current of O_2/F_2, or rhenium can be converted to $ReOF_5$ [106]. The required oxygen can also be formed in some cases by fluorination of the glass, as in the fluorination of ruthenium in a current of BrF_3/Br_2 to obtain $RuOF_4$ [107], or in the preparation of $CrOF_4$ [108] by direct fluorination of chromium. The method is still at a relatively early stage of its development and interesting variations are possible.

XI. Oxide Halides from Halides and Dichlorine Monoxide

The electropositive character of chlorine in dichlorine monoxide can be utilized for the preparation of oxide halides. Cl_2O reacts with many chlorides and bromides with partial replacement of chlorine or bromine by oxygen; hypochlorites occur as intermediates which cannot be isolated, and these spontaneously lose further halogen to form oxide chlorides [see Equation (s)].

$$MCl_4 + Cl_2O = [Cl_3MOCl] + Cl_2 = MOCl_2 + 2\ Cl_2 \qquad (s)$$

This reaction was discovered as early as 1875, during a study of the properties of Cl_2O which reacted with PCl_5 to yield $POCl_3$ [109]; however, the reaction was not studied further until recently.

[108] *A. J. Edwards*, Proc. chem. Soc. (London) *1963*, 205.

[109] *P. Spring*, Bull. Acad. Sci. Belgique 2, *39*, 895 (1875).

Oxide bromides can also be prepared by this method; however, when attempts are made to achieve higher yields, the chlorine liberated begins to form the oxide chloride. The reaction proceeds according to Equation (t).

$$MBr_4 + Cl_2O = MOBr_2 + Br_2 + Cl_2 \quad (t)$$

Owing to the oxidizing action of Cl_2O and Cl_2, only oxide chlorides in the highest valence states can be prepared by this method. The reactions proceed under very mild conditions at room temperature (and below), and, with the exception of the oxide bromides, are entirely free from side reactions. The only by-product formed is chlorine which can be easily removed. Cl_2O is very readily obtained by passing chlorine over mercuric oxide. It is not necessary to remove entrained chlorine, since this is formed as a by-product in any case; in the case of the oxide bromides, however, separation is recommended. The mildness of the conditions which can be achieved is shown particularly clearly in the case of $PbOCl_2$ [40, 109a] which is very sensitive to heat, and which is prepared from $PbCl_4$ and Cl_2O at $-10\,^{\circ}C$.

Thus it is possible, using the dichlorine monoxide method, to obtain thermally unstable oxide halides which cannot be prepared by commutation, and also oxide halides, the preparation of which (*e.g.* by partial hydrolysis of a halide) is subject to interference by by-products. Thus, it is also possible to prepare $SbOCl_3$ [110] and SbO_2Cl [111] from $SbCl_5$ and Cl_2O at room temperature, as well as VO_2Cl [112] from $VOCl_3$, $SnOCl_2$ [113] from $SnCl_4$, $TiOCl_2$ from $TiCl_4$ [113a], and AsO_2Cl [114] from $AsCl_3$.

The preparation of oxide chlorides is rather more difficult when it is necessary to use a solid chloride, *e.g.* $MoCl_5$, $TaCl_5$, or $ZrCl_4$, as the starting material. In this case, it may be helpful to add the theoretical amount of Cl_2O to a slurry of the chloride in CCl_4 cooled to $-30\,^{\circ}C$, and to warm slowly to room temperature with stirring. Good yields of $TaOCl_3$, $Ta_2O_3Cl_4$ [40], $ZrOCl_2$ [115], and $MoOCl_4$ [116] can be obtained in this way from the corresponding chlorides. The efficiency of the dichlorine monoxide method is shown especially clearly by the example of $ZrOCl_2$; all attempts to prepare this oxide chloride by other methods have failed.

The preparation of oxide bromides from metal bromides and Cl_2O can be achieved in the melt, using CCl_4, however, in the case of $TiBr_4$ to yield $TiOBr_2$ [117]; similarly, $SnOBr_2$ [117] is obtained from $SnBr_4$.

Oxide fluorides can also be prepared, in some cases, with the aid of Cl_2O. The starting materials must be definite fluoride chlorides, the chlorine of which is quantitatively replaced by the oxygen of Cl_2O, as shown in Equation (u). Thus $TiOF_2$ [118] is obtained by a

$$MF_2Cl_2 + Cl_2O = MOF_2 + 2\,Cl_2 \quad (u)$$

smooth reaction from TiF_2Cl_2, while $SbOF_3$ [119] is formed from SbF_3Cl_2, and SbO_2F [111] from $SbFCl_4$.

XII. Oxide Halides from Halides and Ozone

The reaction between certain halides and ozone is analogous to the reaction of oxide halides with chlorine monoxide. There is also some similarity between the structures of Cl_2O and O_3: the bond angle is $116\,^{\circ}$ in ozone, and is $109\,^{\circ}$ in Cl_2O. Ozone is rather less reactive than dichlorine monoxide [*]. Thus $TiCl_4$, $SnCl_4$, and $VOCl_3$ react only at their boiling points, but yield extremely pure oxide chlorides $TiOCl_2$, $SnOCl_2$, and VO_2Cl [120]. The reactions proceed in accordance with Equation (v).

$$TiCl_4 + O_3 = TiOCl_2 + O_2 + Cl_2 \quad (v)$$

Apart from the exceptional purity of all products, the main advantage of this method over that using Cl_2O is the reaction of ozone with bromides at low temperatures to yield oxide bromides. Thus, $TiOBr_2$ can be obtained easily and very cheaply by passing a current of ozone, diluted with oxygen, into titanium bromide; $SnOBr_2$ is obtained from $SnBr_4$, and $VOBr_3$ reacts with ozone to yield the thermally unstable $V_4O_9Br_2$ [120].

Finally, it has very recently become possible to prepare oxide iodides by the ozone method. Since the metal iodides have relatively high melting points, so that reactions in the melt cannot be considered, it is necessary to use solvents for the reactions, which must be carried out as far as possible in the homogeneous phase; cyclohexane has proved to be a particularly useful solvent. Less soluble iodides are stirred up; as the dissolved iodide reacts with ozone, the supply is replenished from the solid. In this way it has been possible to prepare the oxide iodides $TiOI_2$, $SnOI_2$ [63], and $Ge_2O_3I_2$ [14]. A remarkable point about this reaction

$$TiI_4 + O_3 = TiOI_2 + O_2 + I_2 \quad (w)$$

[117] *K. Dehnicke*, Angew. Chem. *73*, 763 (1961).

[118] *K. Dehnicke*, Angew. Chem. *74*, 495 (1962).

[119] *J. Weidlein*, Diploma Thesis, Technische Hochschule Stuttgart, 1962.

[*] The reasons for the lower reactivity of O_3 towards MX_n as compared with that of Cl_2O may be the following: The greater bond angle of O_3 causes a decrease of donor properties of the central O-atom compared with that of Cl_2O. This renders more difficult the rate-determining primary step of adduct formation with the metal halides which act as Lewis acids. In addition, the polarity of the O–O bond of O_3 is less than that of the O–Cl-bond in Cl_2O (cf. *K. Dehnicke*, Chem. Ber., in the press).

[120] *K. Dehnicke*, Angew. Chem. *75*, 419 (1963); Angew. Chem. internat. Edit. *2*, 325 (1963).

(w) is that the iodine liberated does not react with the ozone to form iodine oxides until all the metal iodide has been consumed.

XIII. Preparation of Oxide Fluorides with the Aid of Chlorine Nitrate

A number of oxide fluorides cannot be prepared by the method using Cl_2O, owing to the low polarity of the M–Cl bonds in the fluoride chlorides which would be used, *e.g.* SnF_2Cl_2. However, using the more strongly polar chlorine nitrate, $ClONO_2$ [121, 122], definite oxide fluorides can be obtained by an indirect route.

The products of the primary reaction [Equation (x)] are the fluoride nitrates [127] which can generally be isolated [*].

$$MF_2Cl_2 + 2\ ClNO_3 \rightarrow MF_2(NO_3)_2 + 2\ Cl_2 \qquad (x)$$

Chlorine nitrate is easily obtainable from N_2O_5 and Cl_2O [125] which are condensed in succession onto the fluoride chloride. In a second reaction step (y) the fluoride nitrate

$$MF_2(NO_3)_2 \rightarrow MOF_2 + 2\ NO_2 + {}^1/_2\ O_2 \qquad (y)$$

is thermally decomposed to form the corresponding oxide fluoride. This method is used for the preparation of $AsOF_3$ [126] from AsF_3Cl_2, $SbOF_3$ [119] from SbF_3Cl_2, SbO_2F [127] from $SbCl_4F$, $SnOF_2$ [118] from SnF_2Cl_2, and Sn_2OF_6 [127] from SnFCl.

However, the fluoride chlorides required are only available in limited number and purity. It is, therefore, worth noting that lower fluorides also react with chlorine nitrate to yield the desired fluoride nitrates [see Equation (z)], the thermal decomposition of which

$$MF_2 + 2\ ClNO_3 = MF_2(NO_3)_2 + Cl_2 \qquad (z)$$

yields oxide fluorides, in accordance with Equation (y). Thus, the oxide fluorides $SbOF_3$, SbO_2F, and TlOF [127] can be prepared in this way from SbF_3, SbOF, and TlF, respectively.

I am very grateful to Prof. J. Goubeau for his valuable advice and constant encouragement, and to the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft for financial support.

Empirical Parameters of the Polarity of Solvents

BY DR. C. REICHARDT

CHEMISCHES INSTITUT DER UNIVERSITÄT MARBURG/LAHN (GERMANY)

The empirical parameters of the polarity of solvents which have been determined recently are reviewed: Y-values (Winstein, Grunwald), X-values (Gielen, Nasielski), Ω-values (Berson, Hamlet, Mueller), Z-values (Kosower), E_T-values (Dimroth, Reichardt, Siepmann, Bohlmann), R- and S-values (Brownstein). Their field of application and interrelationships are discussed. The theoretical principles of the solvent effect on the reaction rate and light absorption of organic compounds are briefly described, and mention is made of attempts to correlate the physical characteristics of the solvent with the empirical parameters.

I. Introduction

The influence of solvents on the course of chemical reactions has long been known, but has only recently received sufficient attention as a result of the more detailed study of reaction mechanisms. As early as 1890, *Menschutkin* wrote that a reaction cannot be separated from the medium in which it takes place [1]. This raised the problem of how the solvent affected the dissolved molecules, and the physical quantities by which this influence could be described in greater detail. *Menschutkin* postulated a relationship between the rate of reaction and the structure of the solvent. Most investigations were directed towards correlating the

[1] *N. Menschutkin*, Z. physik. Chem. *1*, 611 (1887); *5*, 589 (1890); *6*, 41 (1890).

equilibrium constants, the rate constants of the reactions, or the positions of ultraviolet and infrared absorption bands with the so-called "polarity" of the solvent. Attempts were made to express the polarity in terms of the dielectric constant, the dipole moment, the refractive index, or other properties of the solvent. Efforts to derive valid quantitative relationships were not very successful, owing to the simplifications used.

The "polarity" of a solvent [1a] is determined by its solvation behavior which in turn depends on the action of intermolecular forces (Coulomb, directional, inductive, dispersion, and charge-transfer forces, as well as hydrogen-bonding forces) between the solvent and the solute [2]. As has often been found (and as was to be expected owing to the complexity of the interactions), the macroscopic dielectric constant does not provide a direct measure of the interactions on the molecular scale, *i.e.* the solvating power of a solvent cannot be described by a single parameter.

Since the "polarity" of a solvent can, therefore, only be incompletely specified by individual physical characteristics of the solvent, attempts have recently been made to obtain such characteristics by experiment. It was sought to draw conclusions about the polarity of a solvent by working backwards from the effect of the solvent on a solvent-dependent standard process (the rate of a chemical reaction; the absorption of light by a solvatochromic dye [2a]), and to derive empirical parameters of the polarity of the solvent from the rate constants or absorption maxima determined in many solvents.

II. Basic Principles of the Solvent Effect

A. Influence of the Solvent on the Reaction Rate [3]

The qualitative influence of the solvent on aliphatic substitutions and eliminations has been investigated in detail by *Hughes* and *Ingold* [4], using a simple solvation model. According to these authors, the rates of reactions in which ionic charges arise or are compressed into a smaller space during passage through the transition state increase with the polarity of the medium surrounding the reactants and the activated complex. The reaction is retarded if ionic charges disappear or become distributed throughout a larger space. Reactions in which ionic charges are formed or disappear during passage through the transition state are much more strongly influenced by the solvent than those in which the activation process simply involves "charge diffusion". Thus, on replacing water by alcohol, the specific rate of substitution reactions is altered by a factor of 10^3 to 10^6 in the former case, but by a factor of between 3 and 10 in the latter case. A fundamental factor in assessing the effect of the solvent is therefore the charge type to which the reactants belong.

The reason for acceleration or retardation of the reaction is the difference in the stabilization of the starting materials and of the activated complex by solvation; this is more clearly illustrated by Fig. 1 (cf. [3c]). The two curves I represent the free enthalpy profile for a given reaction in a solvent in which neither the starting

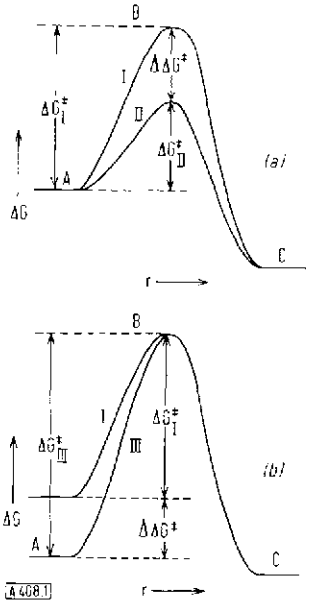

Fig. 1. The free enthalpy profile of a reaction with (a) an unsolvated (I) and a solvated (II) transition state, and (b) unsolvated (I) and solvated (III) starting materials.
$\Delta G_I^{\ddagger}$, $\Delta G_{II}^{\ddagger}$, $\Delta G_{III}^{\ddagger}$ = free enthalpies of activation,
A = starting materials;
B = transition state;

r = reaction coordinate.

[1a] The term "solvent polarity" is used throughout the paper to include the sum of all intermolecular interactions of which the solvent is capable. However, it excludes interactions which lead to definite chemical changes in the substrate as a result of protonation, oxidation, complex formation, etc.

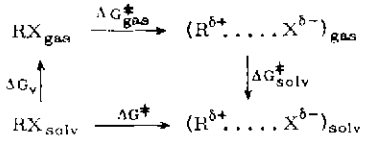
materials nor the activated complex are solvated. If only the activated complex is solvated in another solvent, then profile II in Fig. 1a is obtained. The free enthalpy of activation is reduced by an amount $\Delta_A G^{\ddagger}$, so that the reaction is accelerated. If, on the other hand, only the starting materials are solvated, curve III in Fig. 1b is obtained. The free enthalpy of activation is increased by the amount $\Delta_A G^{\ddagger}$, with the result that the reaction proceeds more slowly. The solvation of the end products does not affect the reaction rate directly. Since in reality both the reactants and the activated complex are solvated, the rate of the reaction will be determined by the difference between the two free enthalpies of solvation.

The situation is complicated by the fact that increased solvation leads to an increase in the order, and hence to a decrease in the entropy; this results in restriction of the freedom of movement, not only of the reactants, but also of the solvent molecules [4a]. Molecules of polar solvents exhibit a high degree of orientation, even in the absence of dissolved polar substances, owing to the strong interaction between the molecules, while those of non-polar solvents are only ordered to a smaller extent. If a polar transition state is formed from non-polar reactants, the greatest increase in the orientation associated with solvation, *i.e.* the greatest decrease in entropy, occurs in non-polar solvents. Thus the entropy of activation for the reaction of aniline with ω-bromoacetophenone is −56 cal/degree/mole in benzene, −39 in acetone, and −28 in ethanol [5]. A strongly negative entropy of activation slows down a reaction just as much as a high activation energy.

The effects of solvation can be illustrated for an ionization process by the cycle shown in Scheme 1 [6].



Scheme 1. The free enthalpy cycle in the solvation of RX.

The free enthalpy of activation $\Delta G^{\ddagger}$ in solution is thus the sum of the molar free enthalpy of vaporization ΔG_v of RX, the free enthalpy of activation of the reaction in the gas phase $\Delta G^{\ddagger}_{gas}$, and the free enthalpy of solvation of the activated complex $\Delta G^{\ddagger}_{solv}$:

$$\Delta G^{\ddagger} = \Delta G_v + \Delta G^{\ddagger}_{gas} + \Delta G^{\ddagger}_{solv} \qquad (1)$$

The change in the free enthalpy of activation $\Delta_A G^{\ddagger}$ on changing solvents is then

$$\Delta_A G^{\ddagger} = \Delta_A G^{\ddagger}_{solv} + \Delta_A G_v \qquad (2)$$

Thus the problem of the influence of the solvent on the rate of reaction can be essentially reduced to the determination of the free enthalpies of solvation of the starting materials and of the activated complex.

An accurate quantitative determination is difficult, owing to the complexity of the interactions between the solvent and the substrate [3g, 7]. Nevertheless, many authors have attempted, either empirically or on the basis of definite theories, to correlate rate constants or enthalpies of activation with a characteristic parameter of the solvent, in a form such as

$$k = f(\varepsilon, \mu, \ldots) \quad \text{or} \quad \Delta G^{\ddagger} = f(\varepsilon, \mu, \ldots) \qquad (3)$$

An early attempt in this direction was *Dimroth*'s relationship between the rate constant k and the solubilities of the reactants [8a]. During investigation of the intramolecular rearrangement of an ester of 5-hydroxy-1-phenyl-1,2,3-triazole-4-carboxylic acid in various solvents, this author found, in agreement with a rule formulated earlier by *van't Hoff* [8b], that the rate constant of the rearrangement reaction is inversely proportional to the solubility L of the isomer which is being transformed:

$$k = \text{const} \cdot \frac{1}{L} \qquad (4)$$

This and similar relationships have, however, only limited application [3d, 3e, 9].

For reactions between neutral non-polar molecules in dilute solutions, *Scatchard* [10] and *Hildebrand* [11] derived a relationship between the activity coefficient γ_2 of the solute in various solvents and the quantity $\delta = \sqrt{\Delta E/V}$ which is known as the internal pressure (or cohesive energy density):

$$RT \cdot \ln \gamma_2 = V_2(\delta_2 - \delta_1)^2 \qquad (5)$$

V_1 and V_2 are the molar volumes, ΔE_1 and ΔE_2 are the molar energies of vaporization of the pure solvent and the pure solute, γ_2 is the activity coefficient of the solute, referred to a standard state of the pure liquid solute, and δ is a measure of the cohesion forces acting on the molecular scale.

The use of this equation for the determination of the rate constant of a reaction

$$A + B \rightarrow C^{\ddagger} \rightarrow \text{products} \qquad (6)$$

leads to the following expression

$$\ln k = \ln k_0 + \frac{V_A}{RT}(\delta_1 - \delta_A)^2 + \frac{V_B}{RT}(\delta_1 - \delta_B)^2 - \frac{V_C}{RT}(\delta_1 - \delta_{C^{\ddagger}})^2 \qquad (7)$$

where k_0 is the rate constant in an ideal solution. The rate of reaction in a given solvent depends only on the difference between the internal pressures of the solvent and the reactants on the one hand and the activated complex on the other hand. Assuming that the activated complex is similar to the reaction products, the following rule, empirically derived by *Richardson* and *Soper* [12], applies: If the products of a reaction possess a

[4a] The change in the free entropy of activation $\Delta S^{\ddagger}$ on solvation is included in the free enthalpy of activation $\Delta G^{\ddagger}$ of Fig. 1, according to $\Delta G^{\ddagger} = \Delta H^{\ddagger} - T\Delta S^{\ddagger}$.

higher internal pressure than the starting materials, the reaction is accelerated by solvents with high internal pressures. The concept of internal pressure is applicable only to reactions between non-polar molecules, since other properties of the solvent, such as its ability to form hydrogen bonds and its dielectric properties, are disregarded.

In a reaction between neutral, but polar molecules [12a], the electrostatic forces of attraction predominate, leading to an orientation polarization. Equation (8) was derived by *Kirkwood* [13] for the change in free enthalpy when a molecule with dipole moment μ and radius r passes from a medium of dielectric constant 1 into a medium of dielectric constant D.

$$\Delta G = -\frac{\mu^2}{r^3} \cdot \frac{D-1}{2D+1} \tag{8}$$

Taking into account the relationship arising from the theory of the transition state [3], application of Equation

$$k = \frac{RT}{N_L h} K^{\neq} = \frac{RT}{N_L h} \cdot e^{-\Delta G^{\neq}/RT} \tag{9}$$

(8) to Reaction (6) (where A, B, and $C^{\neq}$ represent polar compounds) leads to Equation (10).

$$\ln k = \ln k_0 - \frac{N_L}{RT} \frac{D-1}{2D+1} \left[\frac{\mu_A^2}{r_A^3} + \frac{\mu_B^2}{r_B^3} - \frac{\mu_{C^{\neq}}^2}{r_{C^{\neq}}^3} \right] \tag{10}$$

(k and k_0 are the rate constants in media with dielectric constants D and 1, respectively). This can be still further generalized to

$$\ln k = \ln k_0 - U \cdot \frac{D-1}{2D+1}, \tag{11}$$

where U is a constant which is independent of the solvent. The qualitative conclusion to be drawn from this equation is that a reaction which passes through a polar transition state is accelerated by a solvent of higher dielectric constant; quantitatively, a linear relationship is found between ln k and (D−1)/(2 D + 1).

Reasoning from different points of view, *Amis* [14] as well as *Laidler* and *Landskroener* [15] deduced a relationship between ln k and 1/D [15a]. In many reactions in binary solvent mixtures, the dielectric constants of which vary with the ratio of the components, a straight line is obtained on plotting ln k against (D−1)/(2 D + 1) [16, 17]. However, this relationship usually breaks down when reaction rates in different solvents of different dielectric constants are compared.

The deviations in solvent mixtures are essentially due to selective solvation as a result of the greater interaction between the molecules of the solute and those of the more highly polar components of the solvent mixture. Each solute molecule is thus surrounded by a medium having a dielectric constant which differs from the macroscopic value. Anions are preferentially solvated by solvents which form hydrogen bonds, and cations by solvents whose molecules possess free electron pairs, and hence have electron-donating properties [18].

In reactions between ions alone, or between ions and neutral molecules, electrostatic interactions clearly predominate. The equations derived for both types of reactions show a relationship between ln k and 1/D.

For a reaction between ions, the following relationship can be derived from *Coulomb*'s law [10]:

$$\ln k = \ln k_0 - \frac{N_L Z_A Z_B (e^2)}{DRT \cdot r^{\neq}} \tag{12}$$

$Z_A e$, $Z_B e$ = charges on the ions A and B; $r^{\neq}$ = equilibrium distance between the ions in the activated complex; k_0 = rate constant in a medium of infinite dielectric constant.

It follows from Equation (12) that, in reactions between two oppositely charged ions, ln k increases linearly with 1/D, while in the case of similarly charged ions ln k decreases with 1/D.

The influence of the solvent on a reaction between ions and neutral molecules can be described by Equation (13) [3c, 3g, 16] which is derived from *Born*'s equation [19] giving the free enthalpy for the transfer of an ion into a continuous dielectric.

$$\ln k = \ln k_0 + \frac{N_L (Ze)^2}{2 \cdot DRT} \cdot \left(\frac{1}{r} - \frac{1}{r^{\neq}} \right) \tag{13}$$

Ze = charge on the ion; $r, r^{\neq}$ = radii of the ion and of the activated complex, respectively; k_0 = rate constant in a medium of infinite dielectric constant.

Since $r^{\neq}$ is greater than r, the reaction rate should decrease with increasing dielectric constant.

All these relationships between the rate of reaction and the "polarity" of the solvent, which are derived from the classical electrostatic model with the dielectric constant of the continuum, take into account only some interactions, and disregard all specific effects, such as hydrogen-bonding. Consequently, they give only a rough picture of the effect of a solvent on a given reaction. Owing to the complexity of the situation, it seems very difficult to obtain a relationship similar to Equation (3) between the rate constants and one or more of the physical parameters of the solvent, in which all the relationships named above would be included. Indeed, according to *Popovici* and *Pop* [20], a general relationship of this type is impossible.

[12a] The term "polar molecules" includes molecules with a permanent dipole moment.

B. Influence of the Solvent on the Absorption of Light [21]

It was observed long ago, during comparison of the absorption spectra of a substance in the gas phase and in solution, that the solvent causes a change in the position, intensity, and shape of the bands [22a–22d]. *Hantzsch* termed this phenomenon "solvatochromism" [22c]. Even then a relationship between the influence of the solvent and its properties was being sought (*e.g. Kundt*'s rule [22a]). The reason for the solvent-dependence of the wave number of the absorption and emission of light is the difference in the stabilization of the ground state and excited states by intermolecular forces, which can lead to an increase or decrease in the excitation energies [23].

This does not take into account spectral shifts due to fundamental alteration of the chromophore system by the solvent as a result of protonation, oxidation, complex formation, or equilibrium displacements.

The solvent effect depends primarily on the nature of the electron transition in question. The influence of a given solvent varies according to whether we are dealing with an $n\rightarrow\sigma^*$ [24], $n\rightarrow\pi^*$ [25], $\pi\rightarrow\pi^*$ [21], or a charge-transfer transition [26]. The ground state of the first two types is far more strongly influenced by solvents which form hydrogen bonds, and which therefore cause a particularly strong depression of the n-electron level, than are the other states [27a–27g]. The resulting hypsochromic shift is used as a criterion to distinguish between $n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ transitions [28]. The following considerations are confined to $\pi\rightarrow\pi^*$ absorptions.

When a dipole-free compound (*e.g.* benzene) is dissolved in a non-polar solvent (*e.g.* n-hexane, CCl_4, CS_2), a shift of the absorption bands with respect to the positions in the gas spectrum is observed, this shift being always bathochromic. This is due to dispersion forces which depend on the polarizability and hence on the refractive index n of the solute and of the solvent. This relationship between the absorption shift and a function of the refractive index (using n_D at the frequency of the sodium D-line instead of $n_{\lambda\rightarrow\infty}$ at frequency 0) was also observed by *Lauer* and *Oda* [29] for benzene, by *LeRosen* and *Reid* [30] for lycopin, and by *Sheppard* [31] for cyanine dyes, all of which possess very readily polarizable π-electron systems.

Theoretical calculations, which take into account only the dispersion interactions, were carried out by *Bayliss* [32a], *Longuet-Higgins* and *Pople* [32b], *Weigang* [32c], and recently also by *Liptay* [21e]. It was found that dispersion interactions must always lead to a bathochromic shift of the absorption in solution in relation to that in the gas phase.

The equation derived by *Bayliss* [32a] is as follows:

$$\Delta\tilde{\nu}\ [\mathrm{cm}^{-1}] = \frac{3\,c^2}{8\pi^2 c^2 m}\cdot\frac{f}{\tilde{\nu}a^3}\cdot\frac{n^2-1}{2n^2+1} \qquad (14)$$

($\Delta\tilde{\nu}$ = band shift in relation to gas phase; f = oscillator strength; a = radius of the absorbing molecule, which is assumed to be spherical; $\tilde{\nu}$ = wave number of the transition; n = refractive index; the other symbols have the conventional meanings).

Experimental tests of Equation (14) and other relationships gave the required connection between $\Delta\tilde{\nu}$ and the refractive index only for a few solvents (hydrocarbons, aryl halides) [29–32c].

Yet other forces of interaction also occur between molecules with a permanent dipole in the ground state (μ_G) and non-polar or polar solvent molecules; the most important of these, apart from hydrogen bonding forces [33a, 33b], are polarization forces (electrostatic directional and inductive forces between dipoles and induced dipoles). The extent of the interaction, and hence of the spectral shift, depends both on the polarity of the dye

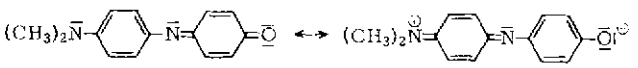
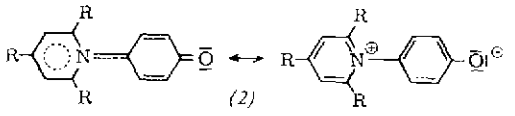
and on that of the solvent, and is especially large in the case of intramolecularly ionic dyes, such as merocyanines [34a–34e] (*e.g.* phenol blue *(1)* [30–35]) or the pyridinium-*N*-phenol betaines (*e.g. (2)* [36]). In dyes of this type, an electron-donating group is joined to an



(1)



(2)

electron-accepting group *via* a conjugated system. The excitation is associated with a charge transfer between the two groups, resulting in an appreciable change in the magnitude and direction of the dipole moment in the excited state (μ_A) [37]. A qualitative differentiation is made between dyes with predominantly non-polar ground states [*(1)*; $\mu_G < \mu_A$], the long-wave absorption band of which undergoes a bathochromic shift as the polarity of the solvent increases (positive solvatochromism), and dyes with polar ground states [*(2)*; $\mu_G > \mu_A$], which exhibit the opposite absorption behavior (negative solvatochromism).

There are basically two theories regarding the mechanism of this interaction. Most theoretical calculations of the change in energy levels of dissolved molecules caused by the solvent are based on the fact that the effective electric field at the position of the dissolved molecule is replaced by the Onsager reaction field [13] for a polarizable point dipole in a spherical cavity. Calculations of this kind were carried out by *Ooshika* [38a], *Bayliss* and *McRae* [38b], *McRae* [38c], *Lippert* [38d], *Bakshiev* [38e], *Bilot* and *Kawski* [38f], and recently also by *Liptay* [21e]. These led to complicated relationships between the absorption shift and functions of the dielectric constant and refractive index of the solvent.

The model can be simplified by regarding the solute and solvent molecules as point dipoles surrounded by a homogeneous isotropic dielectric continuum and by disregarding all specific interactions such as hydrogen bonding and formation of electron donor-acceptor complexes; in such a case, however, the equations derived cannot agree exactly with the experimental findings.

A second line of reasoning is based on the fact that intramolecularly ionic dyes such as the merocyanines can be represented by a polar and a non-polar resonance structure, to which can be assigned the wave functions Ψ_1 and Ψ_2, according to the valence bond method. The linear combination of these ware functions

$$\Psi_G = a \cdot \Psi_1 + b \cdot \Psi_2 \qquad (15)$$

describes the electron distribution in the ground state. It was postulated by *Brooker* [34a], *Kiprianov* [21b], and *Dimroth* [21a], who independently carried out detailed investigations on the pronounced solvatochromism of the merocyanines, that a change of the solvent resulted in a displacement of the resonance position of the dye. The coefficients a and b should therefore depend on the solvent. According to the term diagram developed by *Förster* [39], the excitation energy is a minimum in the case of resonance structures of equal energy (a = b). In the case of polar dyes (a > b), the effect of increasing the polarity of the solvent is to increase the contribution of the polar resonance structure to the ground state; the symmetry of the π-electron system decreases further, and the result is a hypsochromic shift. Non-polar dyes (b > a) should exhibit the opposite absorption behavior for a similar change of solvent, since in this case the symmetry of the π-electron system increases with increasing participation of the polar resonance structure.

Quantitative calculations for the Brooker dyes have been carried out by *Simpson* [40a] and *Platt* [40b].

Recent investigations [41a], particularly by *Schweig* [41b] and *Liptay* [21e], indicate that the effect of dispersion and polarization interactions (which are essentially determined by the dipole moment in the ground state and its change on excitation) on the ground state and excited states probably makes a greater contribution to the total solvatochromism than the displacement of the resonance position of the dye. *Liptay* emphasized [21e] the fact that the concept of resonance change is equivalent to the concept of polarization (measured by the polarizability); consequently, the model developed to explain the solvatochromism by the effect of resonance implicitly corresponds to the model which considers the interaction between the solvent and the dye as the interaction between polarizable point dipoles in a homogeneous dielectric continuum.

Owing to the many possible interactions which can occur between the dye and the solvent, and owing to the simplified molecular model on which the calculations were based, attempts to discover generally valid quantitative relationships between macroscopic properties of the solvent and its effect on the spectra have met with only partial success [*].

III. Empirical Relationships for the Polarity of the Solvent

A. The Winstein-Grunwald Equation

Grunwald and *Winstein* [42] investigated solvolyses of aliphatic compounds proceeding by an S_N1 mechanism; from these investigations, they derived the "Y-values" as a quantitative measure of the ionizing power of a solvent. The relationship between Y and the rate of solvolysis is given by Equation (16).

$$\log \frac{k_A}{k_B} = m\,(Y_A - Y_B) \qquad (16)$$

k_A and k_B are the rate constants of an S_N1 solvolysis in solvents A and B, m is a constant at a given temperature, and is characteristic of the compound being solvolysed.

Since Equation (16) contains only differences between Y-values, the absolute values of Y can be arbitrarily fixed. The solvolysis of t-butyl chloride at 25 °C was chosen as the standard reaction, and Y was defined as

$$Y = \log k^{BuCl} - \log k_0^{BuCl} \qquad (17)$$

k^{BuCl} and k_0^{BuCl} being the rate constants of the solvolysis of t-butyl chloride at 25 °C in a given solvent and in a standard solvent (aqueous ethanol, 80 % by volume), respectively. By definition, the Y-value for 80 % ethanol is zero, and m for t-butyl chloride is 1.000. The general equation therefore reduces to the form (18)

$$\log \frac{k}{k_0} = m \cdot Y. \qquad (18)\ [*]$$

where k is the rate constant for the compound in question in a given solvent, k_0 is the rate constant in 80 % ethanol under the same conditions, and m is the sensitivity of this compound towards a change in the ionizing power of the solvent in relation to that of t-butyl chloride. Since according to the transition state theory, the logarithm of the rate constant is proportional to the free enthalpy of activation ΔG^+, Y bears a linear relationship to the free enthalpy [43].

A number of Y-values are listed in Table 1. These lie between +3.493 (water) and − 3.26 (t-butanol); the larger the value of Y, the greater is the ionizing power of the solvent. Y-values are also known for a series of solvent mixtures (mixtures of ethanol, methanol, acetone, dioxane, acetic acid, formic acid, and formamide with water, as well as acetic acid/formic acid and dioxane/formic acid mixtures). Experimental difficulties have prevented extension of the Y-scale to include other solvents.

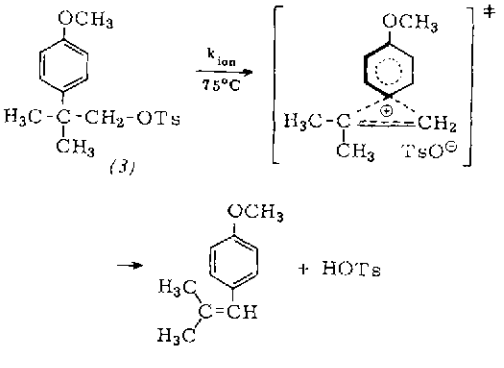
The Y-values are an empirical measure of the ability of a solvent to solvate ions, and in many cases give better correlations with the logarithms of the rate constants of solvent-dependent reactions than do the dielectric constants [42, 17]. Equation (18) is satisfactorily obeyed by the rates of solvolysis of certain tertiary halides and secondary sulfonates, but it can be successfully applied to primary derivatives (which react by an S_N2 mechanism) and secondary derivatives (which exhibit borderline behavior) only if the solvents to be compared differ in polarity and nucleophilic character to an equal extent.

If, for example, Y is plotted against log k for the solvolysis of benzhydryl chloride or neophyl chloride (1-chloro-2-methyl-2-phenylpropane) in various binary mixtures, each mixture (dioxane, acetic acid, or ethanol with water) gives a different straight line, although, if Equation (18) were strictly valid, all the points should lie on the same straight line. Thus parameter m, which is supposed to be independent of the solvent, must contain another factor which is a measure of the nucleophilic character of the solvent. Compounds which react by an S_N mechanism undergo nucleophilic attack by the solvent during the formation of ions in the transition state; the reactivity of the compounds therefore also depends on the nucleophilic character of the solvent, and cannot be measured by Y.

The range of application of Equation (18) can be extended if each compound is given a series of m-values, each of which is valid for one pair of solvents [44]. As an example, the following m-values have been found for t-butyl bromide: 0.941 for ethanol/water, 1.067 for glacial acetic acid/water, and 0.921 for dioxane/water mixtures.

In this connection, mention must be made of *Swain*'s relationship [45], which accounts for these deviations of the m-values in terms of nucleophilicity and electrophilicity parameters of the solvent.

In a recent paper, *Smith*, *Fainberg*, and *Winstein* [46] introduced another standard reaction for characterizing the polarity of solvents, namely the ionization of *p*-methoxyneophyl *p*-toluenesulfonate *(3)*. The ($\log k_{ion}$)-values (for a selection see Table 1) of *(3)* were determined in sixteen solvents (particularly those containing



[42] *E. Grunwald* and *S. Winstein*, J. Amer. chem. Soc. *70*, 846 (1948); *S. Winstein*, *E. Grunwald*, and *H. W. Jones*, ibid. *73*, 2700 (1951); *A. H. Fainberg* and *S. Winstein*, ibid. *78*, 2770 (1956).

[*] Note the formal analogy between this equation in the form $\log k = \log k_0 + mY$ and Equation (11).

no OH-groups), and in some solvent mixtures. These values provide a measure of the solvating power of a solvent as good as that provided by the Y-values for solvents containing OH-groups. The (log k_{ion})-values show good correlation with the Y-values (although each pair of solvents gives a different straight line), with the Z- and E_T-values described below, and with the (log k)-values for a number of rearrangements [46]. They are only roughly related to the dielectric constants, disagreement being particularly marked in the case of solvents containing protons and forming hydrogen bonds.

B. The X-Values

Equation (16) makes it possible to measure the ionizing action of a solvent for electrophilic aliphatic substitutions on a saturated carbon atom [47]. This was recently

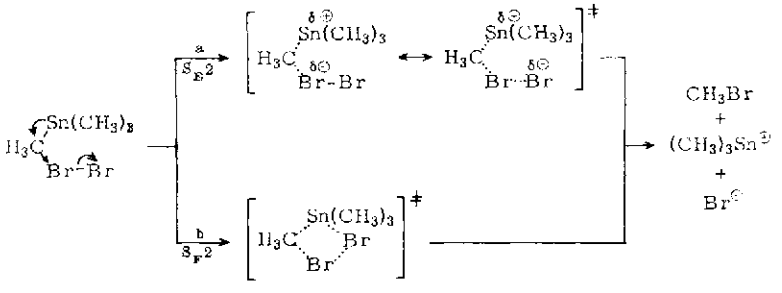
[47] Review by *G. Köbrich*, Angew. Chem. *74*, 453 (1962); Angew. Chem. internat. Edit. *1*, 382 (1962).

shown by *Gielen* and *Nasielski* [48] in the case of the reaction of halogen with tetraalkyltin compounds,which proceeds by an S_E2 mechanism. The relationship given by these authors is as follows

$$\log \frac{k}{k_0} = p \cdot X \qquad (19)$$

k and k_0 are the rate constants of an electrophilic aliphatic substitution on an organometallic compound in a given solvent or in glacial acetic acid which is used as the standard solvent (X = 0), p is a constant which depends on the electrophile and on the organometallic compound, and X is proportional to the polarity of the solvent.

As a standard reaction (for which p is assumed to be equal to unity), the authors chose the reaction of bromine with tetramethyltin (see Scheme 2) which in polar solvents probably passes through a non-cyclic polar transition state (Route a). On stepwise reduction of the polarity of the solvent, a cyclic transition state (Route b) gains importance.



Scheme 2. Transition states of the reaction of tetramethyltin with bromine.

X-Values are at present known for only four solvents (CH_3OH 0.91; DMF: 0.8; C_6H_5Cl: −1.9; CCl_4: −4.8), and no correlation is observed on comparison with the dielectric constants. The solvent series obtained from the X- and Y-values do not quite agree, since the reaction rate is again influenced not only by the stabilization of the polar transition complex as a result of solvation, but also by the electrophilic and nucleophilic character of the solvent. The electrophilic substitution is probably supported by a nucleophilic "pull" of the solvent on the leaving group (−SnR_3). The coupling constants $J(^{117}Sn-^1H)$ obtained from the NMR spectrum of $(CH_3)_3SnBr$ in various solvents, which can be taken as a measure of the nucleophilic character of the solvent with respect to tin, show a correlation with the X-values, in agreement with this assumption [48].

C. The Ω-Values

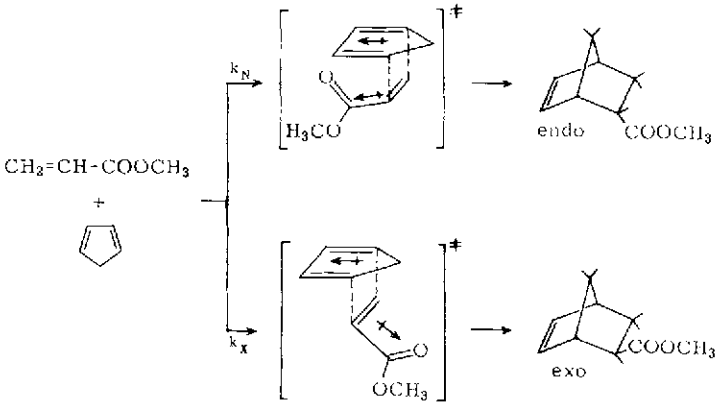
The fact that the rate of Diels-Alder reactions is affected, although only slightly, by the solvent [49] was used by *Berson*, *Hamlet*, and *Mueller* [50] in setting up a polarity scale. These authors found that, in the Diels-Alder addition of cyclopentadiene to methyl acrylate, the ratio of the endo-product (N) to the exo-product (X) depends on the solvent. Since the reaction is kinetically controlled, the product ratio N/X equals the ratio of the specific rate constants. The authors define

$$\log \frac{k_N}{k_X} = \log \frac{N}{X} \equiv \Omega \qquad (20)$$

where Ω is proposed as a new empirical parameter of the polarity of the solvents

The values of Ω at 30 °C lie between 0.445 (triethylamine) and 0.845 (methanol), and are known for twelve solvents (for a selection see Table 1). Owing to the low solubility of the reactants in polar media, the extension of this scale is subject to narrow limits.

The increase in Ω with increasing polarity of the solvent corresponds to an increase in the difference of the free enthalpies of activation, $\Delta G_X^{\ddagger} - \Delta G_N^{\ddagger}$, and is readily understandable, if it is assumed that the total dipole moment of the endo-transition state is greater than that of the exo-transition state. The resulting better solvation of the endo-transition state lowers the enthalpy of activation to a greater extent, in accordance with Fig. 1a, and so leads to preferential endo-addition (see Scheme 3).



Scheme 3. Endo- and exo-products in the Diels-Alder reaction between cyclopentadiene and methyl acrylate. (The arrows indicate the directions of the dipole moments).

The Ω-values show a good correlation with log(N/X)-values of other dienophiles, the (log k_{ion})-values, and the Z- and E_T-values; a satisfactory relationship with the dielectric constants, on the other hand, exists only for aprotic solvents.

D. The Z-Values

The first suggestion that solvatochromic dyes should be used as indicators for the polarity of solvents was made by *Brooker* et al. [51], but *Kosower* was the first to set

[48] *M. Gielen* and *J. Nasielski*, Recueil Trav. chim. Pays-Bas *82*, 228 (1963); J. organomet. Chemistry *1*, 173 (1964).

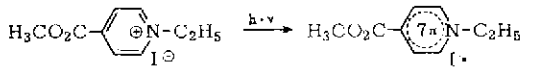
[49] *A. Wassermann*, J. chem. Soc. (London) *1942*, 623; Mh. Chem. *83*, 543 (1952); *W. Rubin*, *H. Steiner*, and *A. Wassermann*, ibid. *1949*, 3046.

[50] *A. Berson*, *Z. Hamlet*, and *W. A. Mueller*, J. Amer. chem. Soc. *84*, 297 (1962).

[51] *L. G. S. Brooker*, *G. H. Keyes*, and *D. W. Heseltine*, J. Amer. chem. Soc. *73*, 5350 (1951).

up a comprehensive solvent scale in this way [52]. The latter author found that the charge-transfer absorption of 1-alkylpyridinium iodides exhibited a pronounced negative solvatochromism, and chose 1-ethyl-4-methoxycarbonylpyridinium iodide *(4)* as a test dye. *Kosower* termed the molar transition energies E_T [see Eq. (21)] calculated from the position of the absorption maximum [$\tilde{\nu}$ in cm^{-1}] "Z values".

$$E_T\,[\text{kcal/mole}] = h \cdot c \cdot \tilde{\nu} \cdot N_L = 2.859 \cdot 10^{-3} \cdot \tilde{\nu} \equiv Z \qquad (21)$$



(4)

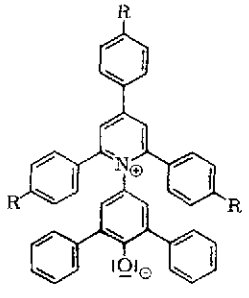
High Z-values correspond to a high transition energy. The stronger the stabilizing effect of the solvent on the ion-pair in the ground state as compared with that on the less polar excited state, the lower the wavelength of the intermolecular charge-transfer band [52, 53]. The experimental Z-values therefore provide a direct empirical measure of the solvation behavior of a solvent towards *(4)*.

The Z-values lie between 94.6 (water) and 60.1 (iso-octane), and have been determined for 23 pure solvents and for a number of aqueous solvent mixtures (for a selection see Table 1) [*]. The Z-value could be obtained by direct measurement only over the range from chloroform ($Z = 63.2$; $\lambda = 452$ mμ) to 70 % ethanol ($Z = 86.4$; $\lambda = 331$ mμ), corresponding to a ΔE_T range of 23.2 kcal/mol ($\Delta\lambda = 121$ mμ). Higher Z-values could not be determined directly, since the specific absorption of the pyridinium cation masks the low-intensity short-wave charge-transfer band. However, the excellent linear correlation with the Y-values of suitable binary solvent mixtures (*e.g.* $Y = 0.41632\,Z - 35.877$ for methanol/water) permits determination of Z for polar solvents by extrapolation.

Owing to the insolubility of *(4)* in non-polar solvents, pyridine 1-oxide was used as a second standard dye; in this case, however, the maximum shift of the solvatochromic band, namely 28 mμ ($\lambda = 254$ mμ in water; $\lambda = 282$ mμ in iso-octane), is very small and the correlation between Z and the E_T-values of pyridine 1-oxide is only moderately good. No relationship exists between Z and the dielectric constants. However, *Kosower* has shown [54a–54l] that Z exhibits an excellent correlation with other solvent-sensitive absorptions, such as the $n \rightarrow \sigma^*$ absorption of alkyl halides [54h], the $n \rightarrow \pi^*$ and $\pi - \pi^*$ absorption of mesityl oxide [54a], the $\pi \rightarrow \pi^*$ absorption of phenol blue [54a], and the charge-transfer absorption of tropylium iodide [54l], as well as with kinetic data (Menschutkin reaction, Finkelstein reaction, etc. [54a]).

E. The E_T-Values of Pyridinium N-Phenolbetaines

Probably the most comprehensive solvent scale to date is that determined by *Dimroth, Reichardt, Siepmann* and *Bohlmann* [55a–55c]. The E_T-values calculated from Equation (21) for the pyridinium *N*-phenolbetaine *(5)* used as the test substance provide an excellent characterization of the polarity of solvents, owing to the extraordinarily large displacement of the solvatochromic band. This displacement of a solvatochromic band observed in the case of *(5)* is the largest so far known: the long-wave band is situated at 810 mμ ($E_T = 35.3$ kcal/mole) in diphenyl ether and at 453 mμ ($E_T = 63.1$ kcal/mole) in water corresponding to a hypsochromic



(5): R = H
(6): R = CH_3

shift of 357 mμ ($\Delta E_T = 27.8$ kcal/mole). Since the solvatochromic band lies in the visible region of the spectrum, it is even possible to make a visual estimation of the polarity of a solvent (CH_3OH: red; $CH_3-CHOH-CH_3$: blue; $CH_3-CO-CH_3$: green). Compound *(5)* is protonated at the oxygen atom by acids and the long-wave band disappears, so that no E_T-value can be found for solvents such as glacial acetic acid. Compound *(5)* is insoluble in aliphatic and aromatic hydrocarbons. However, the solvent scale could be extended to these solvents with the aid of alkylated, more soluble betaines, *e.g. (6)*. Owing to the excellent correlation of the E_T-values of *(5)* with those of *(6)*, E_T-values of *(5)* in solvents in which its solubility is too low can be obtained by extrapolation [55c].

Thus E_T-values are known for 62 pure solvents and five solvent mixtures (for a selection see Table 1). The

E_T-values change on addition of an electrolyte and decrease with increasing temperature, owing to the pronounced thermochromism of the pyridinium *N*-phenolbetaines [56].

It should be noted that solvents such as formamide (D = 109.5), methylformamide (D = 182.4), and dimethylsulfoxide (D = 48.9), which are described as "highly polar" on account of their dielectric constants and their good solvent power towards salts, are by no means so polar in their behavior towards *(5)*. Methylformamide, the solvent with the highest dielectric constant, is in fact no more polar than methanol, while dimethylsulfoxide has an E_T-value similar to that of t-butanol. Protonic solvents always exhibit more highly polar behavior than aprotic solvents of the same dielectric constant (cf. *e.g.* n-butanol and acetophenone). When the OH-groups are shielded by bulky substituents, alcohols become more like aprotic solvents (cf. benzyl alcohol → t-butanol → pyridine). Increasing steric hindrance is also always associated with decreasing E_T-values in aprotic solvents (cf. pyridine → picoline → 2,6-lutidine).

There is a good linear correlation between the E_T-values and the other empirical parameters for the solvent polarity; this correlation can be expressed by Equation (22):

$$y = a \cdot E_T + b \qquad (22)$$

where a and b were determined by the method of least squares and have the values given in Table 2.

Table 2. Correlation of the E_T-values [pyridinium *N*-phenolbetaine *(5)*] with Z, log k_{ion}, Ω, and S according to Equation (22).

y	a	b
Z	1.259	13.76
log k_{ion}	0.179	−12.35
Ω	0.0154	−0.0389
S	0.0134	−0.704

The E_T-values also exhibit a good, generally linear correlation with a large number of solvent-sensitive absorption bands and with a number of kinetic data [57].

F. Brownstein's Linear Free Enthalpy Relationship

By formal analogy with *Hammett*'s linear free enthalpy relationship [58] for the reactions of substituted benzene derivatives, *Brownstein* formulated the following equation [59]:

$$\frac{\log k_S}{\log k_E} = S \cdot R \qquad (23)$$

k_S is the rate constant, equilibrium constant, or the function of a spectral shift in various solvents at 25 °C, and k_E is the corresponding parameter in absolute ethanol. S is a constant which depends on the solvent (S = 0.00 for absolute ethanol), while R is a measure of the sensitivity of the system in question towards a change of solvent.

As a reference system, *Brownstein* chose the standard dye *(4)* used by *Kosower*, and assigned to it an R-value of 1.00. This choice is just as arbitrary as the choice of the dissociation of benzoic acid in water at 25 °C as the reference reaction for the *Hammett* equation (ρ = 1).

Having chosen a standard solvent and a standard reaction, it is now possible to calculate R- and S-values for every reaction and every solvent. From *Kosower*'s work 58 S-values were used to determine R-values for 9 reactions. In continuation of this process, 158 S-values and 78 R-values were deduced, including R-values for solvent-dependent ultraviolet, infrared, and nuclear resonance absorptions, rates of reactions, and positions of equilibria. The *Brownstein* relationship brings together a large number of experimental data, and the S-values represent an empirical generalization of the special solvent parameters.

IV. Conclusion

All these empirical parameters constitute a more comprehensive measure of the polarity of a solvent than the dielectric constant or any other single physical characteristic, since they reflect more faithfully the complete picture of all the intermolecular forces acting in solutions. The solvent-dependent standard processes may be regarded as probes which permit a purely empirical investigation of the solvent effect. In applying these parameters, however, it is tacitly assumed that the contribution of intermolecular forces in the interaction between the solvent and the standard substance is the same as in the interaction between the solvent and a substrate. This is probably true only in very few cases, so that the use of these parameters for characterizing the solvating action of any solvent and conclusions as to the solvation of any organic molecules appear to be very restricted. However, until the theory of solutions leads to the development of generally applicable laws for the influence of the solvent on rates of reaction and absorption of light, these parameters are of practical value.

With the aid of the *Hammett* equation [58], it is possible, knowing the empirical σ-values for any given substituted aromatic compound, to calculate the approximate effect of the substituents on the equilibrium or on the rate of a reaction (the reaction constant ρ of which has been found from the reactions of other members of the same series of compounds). In the same way, the polarity parameters make possible the semi-quantitative estimation of the effect of solvents on the rate of substitution reactions or the position of absorption bands of solvatochromic dyes, and so lead to conclusions regarding the reaction mechanism or the nature of the light absorption.

In view of the wide variation in the energies of the standard processes, the good agreement found for all the

parameters is surprising. One always obtains substantially similar orders for the solvents: Z changes by about 24 kcal/mole in the solvent range from iso-octane to methanol, E_T of *(5)* by about 25 kcal/mole between n-hexane and methanol, $-2.3\ RT \log k_{ion}$ by 7 kcal/mole between ether and methanol, while $-2.3\ RT\,\Omega$ changes by only 0.5 kcal/mole between decalin and methanol.

I am very grateful to Prof. Dr. K. Dimroth for his encouragement of this work, for helpful discussions, and for his critical perusal of the manuscript. Thanks are also due to Dr. W. Liptay, Würzburg, for helpful criticism.

Protonic States and the Mechanism of Acid-Catalysed Esterification

BY PROF. DR. H. ZIMMERMANN AND DR. J. RUDOLPH [*]

INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT MÜNCHEN (GERMANY)

Protons can be very mobile in condensed phases; the length of time they are present in any one place is minute. The significance of proton mobility in the course of chemical reactions is considered in the case of acid-catalysed esterification by the normal carbonyl addition mechanism. – The properties of the protons in the carboxylic acid/alcohol system can be discussed on the basis of a semiconductor term diagram. The high mobility of the catalysing protons in the semiconductor system suggests that formation of the esterification intermediates occurs in two reaction steps which proceed at different rates. In the first rapid step the transition state is reached by proton transfers via hydrogen bridges. The proton rearrangement involved proceeds so rapidly that the heavy molecular skeletons retain their mutual spatial positions (Franck-Condon principle for proton-catalysed reactions). In the second slower step, the intermediate is formed by rearrangement of the groups of atoms. – Decomposition of the intermediate, with formation of either the starting materials or the end products, proceeds via a mechanism similar to that for the formation.

I. Introduction

The proton is of fundamental importance in being an elementary particle. Its radius is some five orders of magnitude smaller than those of the atoms and ions of other elements. The proton can therefore possess appreciable mobility in condensed phases, in contrast to heavier atoms, ions, and molecules, and so it remains in any given place for only a very short time; this is one main source of difficulty encountered in the discussion of proton-catalysed reactions.

In general, during an acid-catalysed reaction, a proton becomes attached to a molecule A, with formation of a cation $AH^{\oplus}$. The cation then interacts with a co-reactant B, and the reaction product $ABH^{\oplus}$ is converted into the final product AB with loss of a proton:

$$A \xrightarrow{+H^{\oplus}} AH^{\oplus} \xrightarrow{+B} ABH^{\oplus} \xrightarrow{-H^{\oplus}} AB$$

The life-time of $AH^{\oplus}$ is generally very short because of the high mobility of the proton; contrasted with this the time required for reaction between $AH^{\oplus}$ and B is much longer, since the heavy molecules must approach each other until they are separated only by the bond distance in $ABH^{\oplus}$. Since the mobility of the heavy particles is much less than that of the proton [**], the formation of the reaction product $ABH^{\oplus}$ is not completed in the time during which the proton remains in the vicinity of the reaction center. The catalysing proton initiates the reaction, but does not complete it. Using proton-catalysed esterification as an example, it will be shown below that, in spite of the short time during which the proton remains in the reaction complex, catalysis is possible, provided certain conditions affecting the course of the reaction are fulfilled.

The mechanism of esterification has been investigated in detail by many workers [1]. According to these investigations, proton-catalysed esterification usually proceeds by carbonyl addition, via an intermediate which can be regarded as the monoester of the ortho-carboxylic acid. This mechanism may be symbolized as in Scheme 1. Evidence for this mechanism will not be discussed in detail here, since it is generally known [1], but instead an attempt will be made to explain the reaction from the point of view of protonic states.

Protonic states are discussed here by analogy with electronic states [2]. Protons and electrons are ele-

mentary particles which are subject to wave-particle dualism and can be described by wave mechanics; they differ quantitatively but not qualitatively; thus it seemed worthwhile to apply the results obtained for electronic states qualitatively to the behavior of protons in chemical reactions.

II. Protonic Semiconductors

The reaction medium of esterification contains mobile protons derived from the carboxyl group of the acid, the hydroxyl group of the alcohol, and the catalyst. The protons occupy states of definite energy. To characterize these, it is convenient to draw up a term diagram. An energy diagram has already been used by *Gurney* [3] in his discussion of prototropic reactions. We shall extend *Gurney*'s considerations and apply them in a modified form to the protonic states of esterification. An auto-dissociating substance AH may be considered first.

$$2\,AH \rightleftharpoons A^{\ominus} + AH_2^{\oplus} \qquad (1)$$

The proton of a molecule AH occupies a state with an energy characterized by term I (Fig. 1a). The energy of the free proton p was chosen as the zero point on the energy scale (Term III, Fig. 1a). If the molecule AH is supplied with the dissociation energy D_1, the proton is

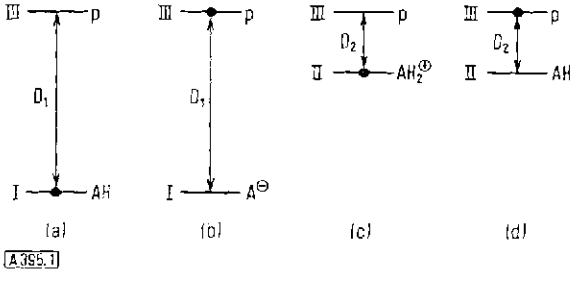

Fig. 1. Proton transitions between states in the term diagram of a molecule AH.

[2] *H. Zimmermann*, Angew. Chem. *76*, 1 (1964); Angew. Chem. internat. Edit. *3*, 157 (1964).

[3] *R. W. Gurney*: Ionic Processes in Solution. McGraw Hill, New York 1953, p. 132ff.

transferred from I to III (Fig. 1b). Chemically, this excitation of the proton corresponds to dissociation of the molecule:

$$AH \rightarrow A^{\ominus} + H^{\oplus} \qquad (2)$$

After the excitation there remains an empty term I; this should evidently be allocated to a molecule formed by removal of a proton from AH, *i.e.* the anion $A^{\ominus}$. Term I has thus two meanings: when occupied, it corresponds to the molecule AH, when empty it corresponds to the ion $A^{\ominus}$. It may be assigned therefore to a conjugate acid-base pair.

Free protons cannot exist in condensed phases. Consequently, the proton in term III formed by dissociation is either recaptured by the anion $A^{\ominus}$ or transferred to a second molecule AH.

$$AH + H^{\oplus} \rightleftharpoons AH_2^{\oplus} \qquad (3)$$

In the latter process it moves into a state II which can be assigned to the molecule $AH_2^{\oplus}$ (Fig. 1c). If we supply this molecule with energy D_2, a proton passes from II to III, with dissociation of $AH_2^{\oplus}$. The empty term II corresponds to AH, the conjugate base of $AH_2^{\oplus}$ (Fig. 1d). A proton can be more readily separated from the cation $AH_2^{\oplus}$ than from the neutral molecule AH. D_2 is therefore smaller than D_1, and term II lies above term I.

The molecule AH can react in two ways. As a proton donor, it can be assigned to the occupied term I (Fig. 1a), and as a proton acceptor, it corresponds to the empty term II (Fig. 1d). Since each molecule simultaneously possesses both acidic and basic properties, it should have both terms I and II assigned to it. The complete term diagram of a molecule is reproduced in Figure 2. The terms are characterized by the conjugate acid-base pair.

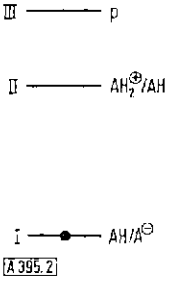

Fig. 2. Term diagram of the protonic states of a molecule AH in the ground state.

Intermolecular proton transfers between acid-base pairs can therefore be described as proton transitions between an occupied term of the donor and an unoccupied term of the acceptor. Let us consider two adjacent molecules AH with position coordinates R_1 and R_2. The term diagram of the molecule pair in the ground state is shown in Figure 3a. If the system is supplied with excitation energy, intermolecular proton transfer from I to II can occur, according to Equation (1). The result of the excitation is an ion-pair $A^{\ominus}/AH_2^{\oplus}$ with the position coordinates R_1 and R_2 (Fig. 3b). The anion $A^{\ominus}$ contains no mobile protons, and accordingly, terms I and II are empty. The cation $AH_2^{\oplus}$ possesses two mobile protons. Dissociation of the first proton (for-

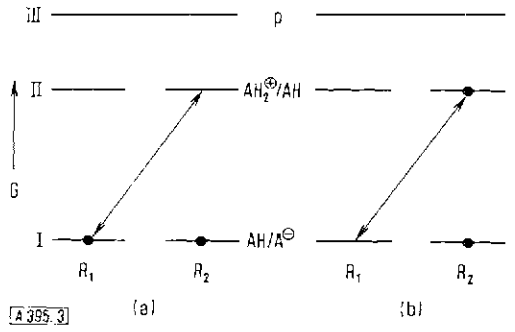

Fig. 3. Term diagram of two adjacent molecules AH. (a) Ground state; (b) ion-pair (G = free enthalpy).

mation of AH) occurs more readily than subsequent removal of the second proton (formation of $A^{\ominus}$).

In prototropic reactions it is convenient to use the free enthalpy $\Delta G = -RT\ln K$ as a measure of the energy in the term diagram in question. The energy difference between the donor term and the acceptor term is then a direct measure of the position of the reaction equilibrium.

Let us now consider a system of several AH molecules; it can be shown that such a system behaves as a protonic semiconductor. In order to understand this approach more fully the properties of electronic semiconductors will first be reviewed briefly for purposes of analogy [4].

A semiconductor is generally a solid which behaves as an insulator at low temperatures, but whose conductivity increases with rising temperature. Semiconductor properties can be understood with the aid of a band model. The semiconductor may consist of atoms, ions, or molecules. The highest doubly occupied and the lowest unoccupied electron term of a constituent unit are represented in Figure 4a. In a semiconductor, the states of different units are in mutual interaction. The terms are split into energy bands (Fig. 4b). In the

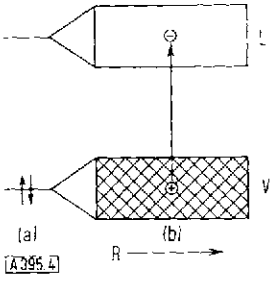

Fig. 4. Band model of an electronic semiconductor (R = position coordinate).

ground state, the band of lower energy (valence band V) is fully occupied; the band of higher energy (conductivity band L) is empty. The system behaves as an insulator, since the prerequisite for conductivity is that electrons can be accelerated in the applied external electric field, and here in the fully occupied valence band there is no room for electrons with increased energy.

If thermal energy is supplied, electrons can be raised from the valence band into the conductivity band. Both energy bands are then only partly occupied and conductivity occurs. From a purely formal standpoint, the electron transition from V to L results in the formation of a "charge pair", *i.e.* an electron in the conductivity band and a positive hole, *i.e.* a defect electron, in the valence band (Fig. 4b). Both the electron in L and the defect electron in V can migrate in an electric field, giving rise to charge transport. Since the electron transition from the valence band to the conductivity band is favored by an increase in temperature, the conductivity increases with rising temperature.

Since the individual AH molecules of a protonic semiconductor can act as both proton donors and proton acceptors, they are mutually linked by hydrogen bridges. This results in coupling of the protonic states of many molecules, although this is extremely weak compared to the interaction of electronic states. In principle, however, energy bands are also formed here, although the band width is only very small and the individual molecules largely retain their individuality. In place of the broad energy bands of electronic semiconductors, protonic semiconductors contain quasi-degenerate energy bands.

In the ground state of a protonic semiconductor, the band of lower energy (valence band V) is completely filled. Each protonic state of V is occupied by a proton. The band of higher energy (conductivity band L) is empty. The system contains only AH molecules. Like an electronic semiconductor, the protonic semiconductor is also non-conducting in the ground state, since no charge carriers exist (Fig. 5a).

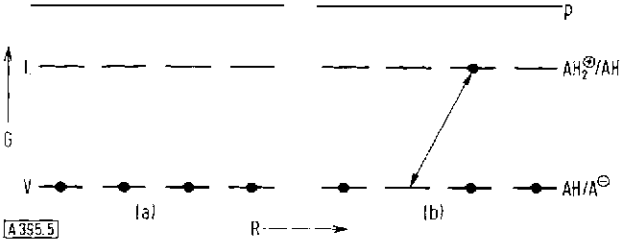

Fig. 5. Term diagram of a protonic semiconductor. (a) Ground state; (b) excited state (G = free enthalpy; R = position coordinate).

When thermal energy is supplied, intermolecular proton transfers can occur with promotion of a proton from the valence band to the conductivity band (Figure 5b). Just as for an electronic semiconductor, conductivity now occurs, since a proton in L and a negative hole, a defect proton in V, are produced (Fig. 5b). The "charge pair" formed, $AH_2^{\oplus}$ and $A^{\ominus}$, assumes the function of current transport. Since the proton transition from V to L is facilitated by heating, with the result that more charge pairs are produced, the conductivity of protonic semiconductors increases with rising temperature.

Electronic and protonic semiconductors differ in the mechanism of charge transport. In the energy bands of an electronic semiconductor, there are states which extend over the whole solid. A given electron can move throughout the entire semiconductor and so give rise to conductivity. On the other hand, the protons in a protonic semiconductor can move primarily only within hydrogen bonds between adjacent molecules. Charge

Conductivity band:

$$\cdots H\text{-}A^{\oplus}\text{-}H\cdots A\text{-}H\cdots A\text{-}H\cdots A\text{-}H\cdots \longrightarrow \cdots H\text{-}A\cdots H\text{-}A\cdots H\text{-}A\cdots H\text{-}A^{\oplus}\text{-}H\cdots$$

Valence band:

$$\cdots A^{\ominus}\cdots H\text{-}A\cdots H\text{-}A\cdots H\text{-}A\cdots \longrightarrow \cdots A\text{-}H\cdots A\text{-}H\cdots A\text{-}H\cdots A^{\ominus}\cdots$$

[4] *W. Finkelnburg:* Einführung in die Atomphysik. Springer, Berlin-Göttingen-Heidelberg 1962.

transport over long distances is not effected by one single proton, but by mutual cooperation of many protons. The mechanism of charge transport in the conductivity and valence bands is represented below for the sake of completeness.

The charge can be rapidly transported in the energy bands (with the enthalpy of reaction $\Delta G = 0$); it is delocalized over the entire semiconductor.

The proton transitions in the hydrogen bridges take place between conjugate acid-base pairs:

$$\cdots H-A^{\oplus}-H\cdots A-H\cdots \overset{p}{\leftrightarrow} \cdots H-A\cdots H-A^{\oplus}-H\cdots$$

$$\cdots A^{\ominus}\cdots H-A\cdots \overset{p}{\leftrightarrow} \cdots A-H\cdots A^{\ominus}$$

During this transition, the protons move in potential fields with symmetrical double minima. Their presence is equally possible in both potential troughs, and consequently they oscillate across the hydrogen bridges. Rapid transposition of the protons in bridge bonds with double minima has been detected experimentally in favorable cases [5–7].

The transposition of protons in a hydrogen bond with a symmetrical double minimum can take place in two ways: *via* proton jumps or *via* a tunnel effect. The tunnel effect depends on the height and width of the potential wall between the two troughs. The potential field in which the proton moves within the bridge bond can be estimated. It can be shown that, unless the hydrogen bridges present are very weak, the tunnel effect should occur very often. Protonic states are then formed which extend over the region of both potential troughs and in which the protons are delocalized. In the wave mechanical picture, the two protonic states ψ can be described by protomerism between the limiting states of the bridge bond [2].

$$\psi = (1/\sqrt{2})[\psi(H-A^{\oplus}-H\cdots A-H)] \pm [\psi(H-A\cdots H-A^{\oplus}-H)]$$

$$\psi = (1/\sqrt{2})[\psi(A^{\ominus}\cdots H-A)] \pm [\psi(A-H\cdots A^{\ominus})]$$

The interaction of protomeric limiting states is slight. The energy difference ΔE between symmetrical and asymmetrical linear combinations is therefore small, and the band width in protonic semiconductors can be neglected.

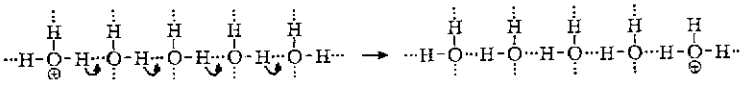
From the corpuscular approach protomerism corresponds to the oscillation of a proton between the two potential troughs of the bridge bond. The average life-time τ of the proton in one of the potential minima [8] and hence the life-time of the ions $AH_2^{\oplus}$ and $A^{\ominus}$ is very short:

$$\tau = 1/2c\Delta E$$

where c = velocity of light; ΔE = term splitting [cm^{-1}].

For very strong hydrogen bridges of the type $H-A^{\oplus}-H\cdots A-H$, term-splitting may be assumed to be at least 1 cm^{-1}. This corresponds to an average life-time of less than 10^{-11} sec. It therefore follows, for example, that an acid-catalysed reaction between co-reactants AH and B must be initiated during the very short time while the catalysing protons are in the vicinity of AH, *i.e.* during the life of the species $AH_2^{\oplus}$.

However, the mechanism of proton transport is not fully described by the foregoing discussion. Let us examine briefly the conditions in ice. *Eigen* and *DeMaeyer* [9] have shown that ice is a protonic semiconductor. The crystal consists of a three-dimensional network of water molecules linked together by hydrogen bridges. Ice exhibits conductivity towards direct current. The charge carriers may be assumed to be $OH_3^{\oplus}$ and $OH^{\ominus}$ ions formed by dissociation of the water. Charge can be transported through the crystal in the normal manner by proton jumps in hydrogen bridges in an electrical field [*(4)* → *(5)*].



(4) *(5)*

Conductivity for direct current requires that charge transport should always be possible in the same direction. However, after a single passage of charge, the chain of water molecules is in a condition *(5)* unsuitable for further transport of charge. To explain conductivity for direct current, therefore, it must be assumed that a state which makes the chain suitable for renewed proton-passage will be brought about by rotation of water molecules in the crystal.

By combination of proton jumps in hydrogen bridges and reorientations of water molecules, a proton can migrate as an individual through the entire ice crystal. This mechanism for proton transport may be generally valid for protonic semiconductors.

According to investigations by *Eigen*, *DeMaeyer*, and *Spatz* [9–11], the rate-determining step of the conductivity in ice is the proton transition in hydrogen bonds. Here proton transfer follows a "non-classical" mechanism, probably involving a tunnel effect. The mobility of the proton is only one or two orders of magnitude less than that of electrons in metals [9–11].

Semiconductors are generally solids. However, it is not absolutely essential to restrict the concept in this sense. We shall therefore apply the term semiconductor generally to any system which, independently of the state of aggregation and nature of the charge carrier, possesses a conductivity which is zero at very low temperatures and increases with rising temperature. It is thus possible to include liquid systems.

III. Protonic States in Carboxylic Acid/Alcohol Systems

Nuclear magnetic resonance measurements on carboxylic acid/alcohol systems have shown that the protons of the carboxyl and hydroxyl groups are mobile. Instead of two separate signals for the carboxyl and hydroxyl groups, one common signal is always observed. Thus the protons cannot be distinguished in nuclear magnetic resonance experiments, a fact which indicates rapid proton exchange.

The chemical shift of the signal is generally a monotonic function of the mole-fraction. By way of example, the findings for the acetic acid/ethanol system are reproduced in Figure 6; an approximately linear function is obtained. This shows that the proton exchange must extend over a range so large that it encompasses the

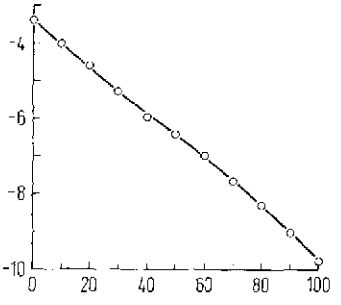

Fig. 6. Concentration dependence of the chemical shift of the OH signal in the NMR spectrum of the acetic acid/ethanol system.
Standard: CH_3 signal of acetic acid
Ordinate: Chemical shift δ[ppm].
Abscissa: Concentration of acetic acid [mole-%].

carboxylic acid and the alcohol in a ratio which corresponds to the "macromolecular" mole-fraction of the overall system. The protons can thus migrate over large distances and enter randomly into interaction with various molecules. A single signal with an average chemical shift is then observed in the NMR spectrum.

The kinetics of proton exchange in alcohols and alcohol/carboxylic acid mixtures have been investigated by other authors [12, 13]. In agreement with our views, the protons are exchanged *via* the ions present in the system.

As explained above, proton migration is possible over large distances in protonic semiconductors. It can be shown that carboxylic acid/alcohol systems also possess semiconductor properties. This explains the proton mobility shown by the NMR experiments.

The conductivity of the acetic acid/ethanol system was measured by *Drutman* [14] (Fig. 7); it depends on the mole-fraction and on the temperature. At a given mole-fraction, it always increases with rising temperature. Extrapolation to absolute zero gives extremely low values for the conductivity. The system thus behaves as a semiconductor.

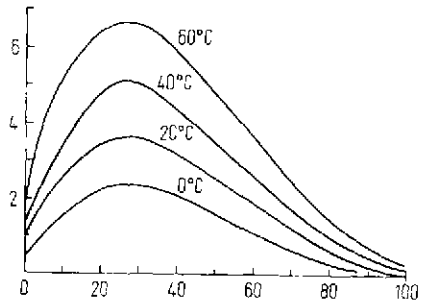

Fig. 7. Concentration dependence of conductivity in the acetic acid/ethanol system at various temperatures [14].
Ordinate: Conductivity $\varkappa \cdot 10^6$ [ohm^{-1} cm^{-1}].
Abscissa: Concentration of acetic acid [mole-%].

The semiconductor term diagram of the acetic acid/ethanol system is shown in Figure 8. It was derived from the normal affinities of the prototropic reactions:

$$2\,C_2H_5OH \rightleftharpoons C_2H_5O^{\ominus} + C_2H_5OH_2^{\oplus} \qquad \Delta G_{25\,°C} = 29.6\ \text{kcal/mole}$$

$$2\,CH_3COOH \rightleftharpoons CH_3COO^{\ominus} + CH_3C(OH)_2^{\oplus} \qquad \Delta G_{25\,°C} = 20.5\ \text{kcal/mole}$$

$$CH_3COOH + C_2H_5OH \rightleftharpoons CH_3COO^{\ominus} + C_2H_5OH_2^{\oplus} \qquad \Delta G_{25\,°C} = 15.8\ \text{kcal/mole}$$

The free enthalpies ΔG were calculated from the known equilibrium constants for dissociation and autoprotolysis, taking the molarity into account [15–17]. The energy of the conductivity band of water (system

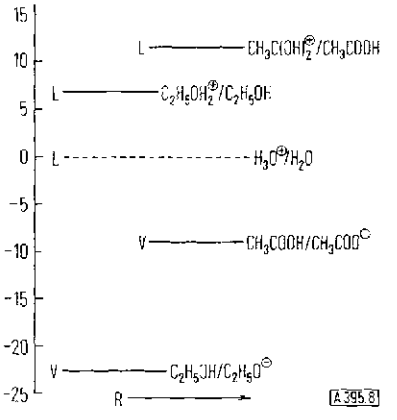

Fig. 8. Term diagram of the protonic semiconductor acetic acid/ethanol.
Ordinate: Free enthalpy G [kcal/mole].

$OH_3^{\oplus}/OH_2$) was arbitrarily chosen as the zero point of the term diagram. The position of the term can be established [17] by the reaction:

$$CH_3COOH + H_2O \rightleftharpoons CH_3COO^{\ominus} + OH_3^{\oplus} \qquad \Delta G_{25\,°C} = 8.9\ \text{kcal/mole}$$

In acetic acid/ethanol mixtures, the above free enthalpies of the prototropic reactions are only approximately valid, owing to solvation. However, solvation occurs in all systems predominantly *via* hydrogen bridges. Since the bond energies of bridge bonds differ only slightly from one another, the molecules and ions should possess similar solvation energies in different media. The position of the terms then depends only

[15] *S. Kilpi* and *M. Puranen,* Ann. Acad. Sci. fennicae, Ser. A *57,* Nr. 10, 3 (1941).

[16] *G. Brière* and *N. Félici,* C. R. hebd. Séances Acad. Sci. *251,* 1004 (1960).

[17] *E. Grunwald* and *B. J. Berkowitz,* J. Amer. chem. Soc. *73,* 4939 (1951).

slightly on the ratio of acid to alcohol in the mixture. It is therefore sufficient in a qualitative discussion to consider terms of constant energy.

At very low temperatures the valence bands of the acetic acid and of the ethanol are fully occupied. The system then exhibits no conductivity. At higher temperatures, protons pass from V to L to form charge pairs, and conductivity occurs. Dissociation of either acetic acid or ethanol alone requires more energy than dissociation of the acid in alcoholic solution (see ΔG values). In acetic acid/ethanol mixtures, therefore, more charge pairs are formed than in the pure components, and it is plausible that the conductivity – as a function of the mole-fraction – passes through a maximum (Fig. 7). However, detailed discussion of the position of the maximum is possible only if the mobilities of the protons in the energy bands are known. Knowledge of the temperature dependence of the mobility would also be necessary to explain completely the temperature dependence, and hence the activation energy, of the conductivity.

In the esterification of carboxylic acids with alcohols, mineral acids are added as catalysts. Since strong acids are practically completely dissociated in water, the valence band of the acid lies above the conductivity band of water, and hence certainly in the vicinity of the conductivity band of alcohol. It is therefore easy for this conductivity band to become occupied. In the absence of a catalyst, appreciable occupation of the term is not possible owing to the high excitation energy of this state. The conductivity bands of acetic acid and ethanol lie energetically close together (see Fig. 8). Proton transfer between the two bands is therefore readily possible. In chemical notation it corresponds to the reaction:

$$C_2H_5OH_2^{\oplus} + CH_3COOH \rightleftharpoons C_2H_5OH + CH_3C(OH)_2^{\oplus}$$
$$\Delta G_{25\,^{\circ}C} \approx 5 \text{ kcal/mole}$$

If the conductivity band of the alcohol becomes appreciably occupied owing to the presence of the catalysing mineral acid, $CH_3C(OH)_2^{\oplus}$ ions can be formed in large numbers. It is generally assumed that these ions are of vital importance to the course of esterification. However, it must be realized that the $CH_3C(OH)_2^{\oplus}$ ion corresponds to a proton in the conductivity band of the acetic acid. The proton can pass through the system very rapidly, and the ion is consequently very short-lived. The charge is delocalized, and the ion simply represents one of the possible protomeric limiting forms.

In concluding this section, further discussion of the reaction medium in which the esterification takes place seems appropriate: in the solution, the heavy molecules form a three-dimensional lattice held together by hydrogen bridges. The protons oscillate rapidly in the bridge bonds. Moreover, the bridge bonds are continuously being reoriented. It is therefore possible for the protons to move between the molecular skeletons throughout the entire lattice. Whereas the heavy molecules change their positions only relatively slowly, a swarm of rapidly moving protons streams between the molecules. The protons thus behave like electrons in metals, and one is tempted to formulate a "proton gas" in analogy to the electron gas.

IV. Short-Range Structure and Franck-Condon Principle in Proton-Catalysed Reactions

According to the conventional views on the mechanism of proton-catalysed esterification [1], the intermediate *(2)* is formed by addition of an alcohol molecule onto the protonated carboxylic acid *(1)*.

As shown in Section III, the cation $RC(OH)_2^{\oplus}$ is only very short-lived, owing to the mobility of the protons in the conductivity band of the carboxylic acid. For a reaction to occur, therefore, the alcohol and acid molecules must be present in the reaction medium in such a steric arrangement that the reaction can be initiated immediately after addition of the catalysing proton onto the carboxyl group. The short-range structure of the molecules is therefore particularly important for the occurrence of the reaction.

During the very short time within which the catalysing proton is in the reaction complex the reaction must overcome the activation barrier. It is now generally assumed that the protonated form of the carboxylic acid *(1)* is sufficiently long-lived to permit reaction with the alcohol molecule to give the intermediate *(2)*. The monoester of the orthoacid *(3)* is finally formed by elimination of a proton from *(2)*.

However, it is difficult to imagine how the reaction proceeds in the manner described. During the very short life-time of $RC(OH)_2^{\oplus}$ it would be necessary not only for the heavy, inert carboxylic acid and alcohol molecules to approach to within bonding distance of each other, but also for the bonds to be formed with a change in the hybridization of the carboxyl carbon atom, *i.e.* again with rearrangement of heavy groups of atoms [*]. These difficulties can be avoided if it is assumed that, simultaneously with the separation of the catalysing proton from the reaction complex, the activation barrier of the reaction is overcome. The reaction has then progressed so far, even with extremely short residence times of the catalysing proton, that it proceeds of its own accord to form the end product after separation of the proton. The mechanism of esterification will be discussed below in more detail. In this context, the problem of short-range structure shall be considered first.

The short-range order in liquids is due to secondary valence forces acting between the molecules. In the esterification medium, the secondary valence forces to

[*] These considerations can be taken even further. It is known from infrared spectroscopic investigations that the life of an $OH_3^{\oplus}$ ion in aqueous solutions is about 10^{-13} sec [18, 19]; it may be assumed that the life of $R'OH_2^{\oplus}$ or $RC(OH)_2^{\oplus}$ is not appreciably longer, since the ions correspond to protons in the conductivity bands of water, the alcohol, or the carboxylic acid ($\tau < 10^{-11}$ sec). From photochemical reactions it follows that higher excited singlet states with a life of 10^{-11} to 10^{-12} sec are generally incapable of reacting with heavy molecules. Such reactions are possible only for the lowest excited singlet or triplet state with lives of about 10^{-3} or 10^{-8} sec, respectively. It is likely, therefore, that the life of $RC(OH)_2^{\oplus}$ is too short to undergo a reaction with R'OH with formation of *(2)* under these conditions.

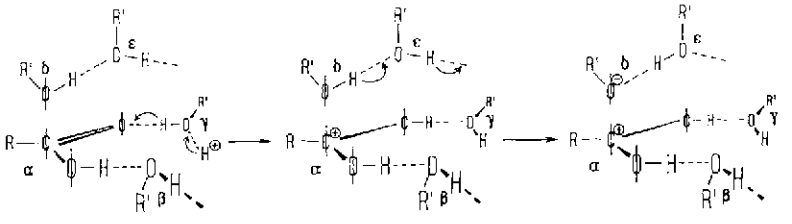
be considered are hydrogen bridges and electrostatic interactions between molecules.

For the sake of simplicity, let us examine a carboxylic acid molecule in a dilute alcoholic acid solution. The carboxyl group can act both as a proton donor and as a proton acceptor. Accordingly, the acid molecule is linked to two alcohol molecules by hydrogen bridges. The charge distribution of the carboxyl group of an acid molecule was calculated by the simple Hückel LCAO-MO procedure (see Fig. 13). The parameters on which the calculation is based are presented in SectionV. The partial charges on the oxygen atoms of the carboxyl group are involved in hydrogen bonding. The remaining partial charge on the carbon must be compensated by the lone-pair of electrons from another alcohol molecule. For steric reasons it can be assumed that the oxygen atom of this third alcohol molecule is situated above the positive carbon atom of the carboxyl group. The arrangement of molecules within the immediate vicinity of a carboxylic acid molecule in the reaction medium is shown schematically in Figure 9a [**].



(a) (b) (c)

Fig. 9. Short-range structure about an acetic acid molecule in dilute alcoholic acid solution (a). Formation of the ion $RC(OH)_2^{\oplus}$ (b) and of the ion pair $RC(OH)_2^{\oplus}/R'O^{\ominus}$ (c) by proton transfers in hydrogen bridges.

The conductivity band L of the alcohol is partially occupied by the catalysing mineral acid. As already mentioned, a proton can be transferred easily from L to an acid molecule. This results in the formation of the ion $RC(OH)_2^{\oplus}$ which is solvated by alcohol molecules (Fig. 9b). This complex will rapidly release a proton again into the conductivity band of the alcohol, owing to charge delocalization. Three routes are possible:

1. A proton is transferred from molecule α to molecule γ by reversal of the formation of $RC(OH)_2^{\oplus}$, the initial state in the reaction medium being restored.

2. A proton is transferred from molecule α to molecule β. The resulting atomic arrangement is the mirror image of the original state. Carbonyl and hydroxyl groups are interchanged. However, the original and final states are physically equivalent.

3. A proton is transferred from molecule δ to ε with formation of the ion pair $RC(OH)_2^{\oplus}/R'O^{\ominus}$ (Fig. 9c).

It is immediately noticeable that proton transfers according to Routes (1) and (2) make no contribution to esterification. On the other hand, the ion-pair formation by Route (3) is of interest. Let us first examine the energy relationships in the reaction medium with the aid of a term diagram. Figure 10 shows the protonic

[**] The various molecules are designated by Greek letters. The axes of the p-functions are also shown in the diagram.

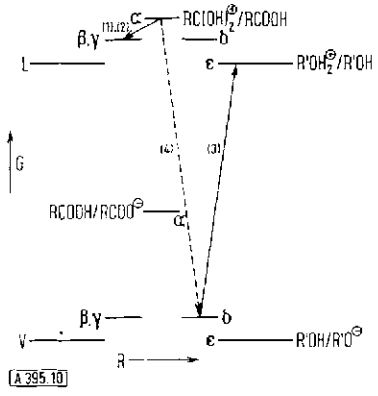


Fig. 10. Term diagram of protonic states in the reaction complex during formation of the intermediate (3) from carboxylic acid and alcohol (G = free enthalpy; R = position coordinate).

states of the ion $RC(OH)_2^{\oplus}$ and of the alcohol molecules surrounding it. Owing to the polarizing action of the cation, it must be expected that the alcohol molecules β, γ, and δ of the first solvation shell are better proton donors and poorer proton acceptors than molecules which remain at a greater distance from the cation, such as molecule ε. Consequently, the donor and acceptor terms of the molecules of the first solvation shell will be raised, as illustrated diagrammatically in Figure 10. As can be seen from Figure 10, proton transfers by Routes (1) and (2) are energetically easy, but ion-pair formation by Route (3) can occur only when energy is supplied.

The donor term of the alcohol molecule δ is raised with respect to that of molecule ε. Proton transfer by Route (3) is then facilitated compared to dissociation of the pure alcohol. Since alcohol is already appreciably dissociated under normal conditions, elimination of a proton from molecule δ by Route (3) at a higher temperature, *i.e.* under esterification conditions, will certainly be possible. Ion pairs $RC(OH)_2^{\oplus}/R'O^{\ominus}$ can thus be formed occasionally in the reaction medium. This only requires proton transfer in hydrogen bridges.

The ion pairs are stabilized on account of the electrostatic interaction. They are of high energy and are therefore metastable in the reaction medium. Deactivation by direct proton transfer from $RC(OH)_2^{\oplus}$ to $R'O^{\ominus}$ is not possible [Fig. 10, Route (4)], since there is no hydrogen bridge between the molecules α and δ (see Fig. 9). However, a lower energy state can be reached by electronic interaction, *i.e.* if the ions become linked by a covalent bond. The ion pair can then undergo deactivation by direct transformation into the esterification intermediate (Fig. 11). As will be shown in the following section, electronic interaction is possible. The bond is

formed without necessitating any great activation energy. The ion pair becomes stabilized spontaneously with formation of the esterification intermediate *(3)*.

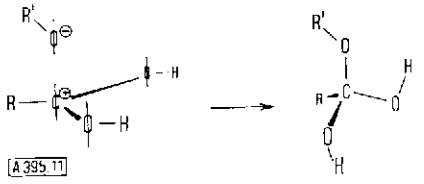

Fig. 11. Formation of the esterification intermediate *(3)* from the ion pair

The reaction course following from the above conclusions corresponds to the one described in Scheme 1. Initial addition of a proton onto the carboxyl group of the acid is immediately followed by elimination of a proton from the alcohol molecule δ of the solvation shell with formation of an ion pair. This reaction step involves participation of a catalysing proton in the reaction complex and is extremely fast. Energy must be supplied for the separation of the proton by Route (3) (see Figs. 9 and 10). The activation energy barrier of the reaction is reached and the transition state can be approximately described by the ion pair $RC(OH)_2^{\oplus}/R'O^{\ominus}$. Deactivation now takes place in a slower reaction step, and the esterification intermediate is formed in the absence of the catalysing proton. The heavy molecules thus have sufficient time to move into their new equilibrium positions.

The ion pair is therefore formed only by rapid proton transfers in hydrogen bridges. The transition state is thereby reached without appreciable change in the position coordinates of the molecules. Thus, the arrangement of the atoms in the transition state of a proton-catalysed reaction is given approximately by the short-range structure in the reaction medium.

A similar situation is encountered in the excitation of electronic states in molecules. The electron distribution in a molecule can be very rapidly changed by absorption of light. According to the Franck-Condon principle, the atoms, which are comparatively heavy, do not have sufficient time at the instant of excitation by light to change their positions. The equilibrium position of the atoms corresponding to the new electronic state is therefore only reached by a subsequent slower reaction step.

The Franck-Condon principle can be applied directly to proton-catalysed reactions. Proton transfers across hydrogen bridges can result in such a rapid change in proton distribution in the reaction complex that the heavy molecules do not have time to take up their new equilibrium positions. An atomic arrangement compatible with the new proton distribution is only reached in a subsequent slower step with formation of the reaction product. Thus, even in chemical reactions, we observe an analogy in the behavior of electrons and protons.

V. Interactions between Electronic States of the Coreactants

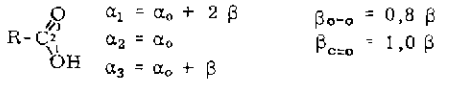
We concluded from the protonic states in the carboxylic acid/alcohol system that the esterification intermediate is formed by interaction of the ion pair $RC(OH)_2^{\oplus}/R'O^{\ominus}$. We shall now show, by consideration of the pertinent electronic states, that the interaction in this ion pair is much greater than that in the molecule pairs RCOOH/R'OH or $RC(OH_2)^{\oplus}/R'OH$, so that the reaction proceeds practically exclusively *via* the ion pair.

The vital step leading to the esterification intermediate is the formation of a σ-bond between the oxygen atom of the alcohol and the carbon atom of the carboxyl group of the acid. The carbon atom changes from trigonal to tetrahedral hybridization. The carboxyl group offers resistance to the change in hybridization, since the resonance energy of its π-electron system must be overcome. However, the energy balance is compensated by the newly formed σ-bond.

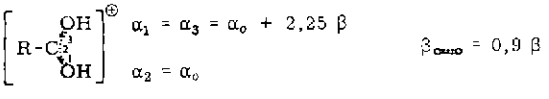
Formation of the σ-bond is initiated by mutual approach of the co-reactants. The π-electron system of the carboxyl group of the acid and the lone pair of electrons on the oxygen atom of the alcohol then mutually overlap. Interaction of the electronic states produces the energy ΔE, which can be used to break down the π-electron system, and so make it possible for change of hybridization and formation of a σ-bond to occur. It is likely that the reaction proceeds more readily as the energy gain ΔE resulting from the mutual approach of the co-reactants increases. ΔE has been evaluated for a few simple cases by the Hückel LCAO-MO method [*].

[*] The eigenfunctions were formed in the usual manner by linear combination of orthogonally normalized atomic eigenfunctions. The Coulomb and resonance integrals, α and β, were based on the following values [20]:

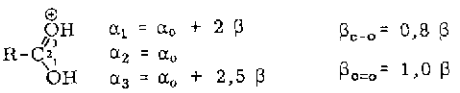
For



For



α_1, α_3, and $\beta_{C\ O}$ were assumed in the calculation to be mean values of the corresponding Coulomb and resonance integrals of a limiting structure of the protonated carboxyl group. For



The lone pair of electrons on the oxygen atom of the alcohol molecule (cf. Fig. 9) was approximated by a p-function. The Coulomb integrals of the oxygen atom are

for R'OH $\alpha = \alpha_0 + 2\beta$

for $R'O^{\ominus}$ $\alpha' = \alpha_0 + 0{,}5\beta$

The Coulomb integral α' was estimated by the ω-rule [21]:

$$\alpha' = \alpha + \xi\,\omega\,\beta$$

α corresponds to the Coulomb integrals of the oxygen atom in the absence of an excess charge ($\alpha = \alpha_0 + 2\beta$); ξ represents the excess charge at the oxygen atom, ($\xi = -1$); ω is a constant factor with a value of 1.5; thus, α' is found to be $\alpha' = \alpha_0 + 2\beta - 1.5\beta = \alpha_0 + 0.5\beta$.

The resonance integral γ between the oxygen atom of the alcohol molecule δ and the carbon atom of the carboxyl group of the acid was varied between $\gamma = 0$ and $\gamma = \beta$ in order to account for the increase in interaction as the co-reactants approach each other.

[20] *A. Streitwieser jr.*: Molecular Orbital Theory. Wiley, New York-London 1961, p. 135.

[21] *A. Streitwieser jr.*, [20], p. 115.

The gain in energy ΔE when the co-reactants approach each other is represented in Figure 12 as a function of the intermolecular interaction integral γ.

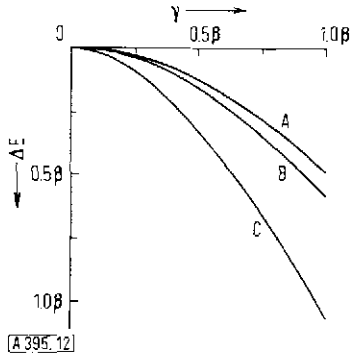


Fig. 12. Increase in the energy of interaction ΔE on mutual approach of co-reactants RCOOH/R'OH (A), $RC(OH)_2^{\oplus}/R'OH$ (B), and $RC(OH)_2^{\oplus}/R'O^{\ominus}$ (C).
Abscissa: resonance integral γ between co-reactants.

The interactions between

A. RCOOH and R'OH
B. $RC(OH)_2^{\oplus}$ and R'OH
C. $RC(OH)_2^{\oplus}$ and $R'O^{\ominus}$

were investigated.

The interaction energy in the ion pair $RC(OH)_2^{\oplus}/R'O^{\ominus}$ is about twice as great for all values of γ as that in the molecule pairs RCOOH/R'OH and $RC(OH)_2^{\oplus}/R'OH$. On the other hand, the interaction energies of RCOOH/R'OH and $RC(OH)_2^{\oplus}/R'OH$ differ only slightly. Since experience has shown that no reaction occurs between RCOOH and R'OH, it does not appear plausible that the slight increase in the energy of interaction between $RC(OH)_2^{\oplus}$ and R'OH should be responsible for bringing about the reaction. It is more likely that the increased interaction in the ion pair $RC(OH)_2^{\oplus}/R'O^{\ominus}$ makes the reaction possible.

The interaction energy also serves in part to compensate for the electrostatic repulsion between the reactants. Charge distributions and π-bond orders of the molecules RCOOH and $RC(OH)_2^{\oplus}$ are shown in Figure 13. The electrostatic interaction is determined primarily by the charges on the carbon

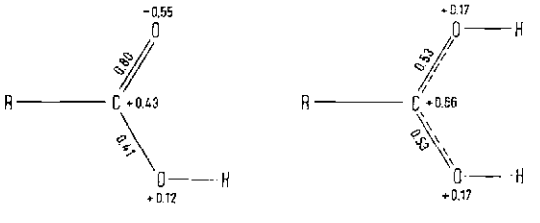

Fig. 13. Charge distribution and π-bond orders in the RCOOH molecule and in the $RC(OH)_2^{\oplus}$ ion.

atom of the carboxyl group and on the oxygen atom of the alcohol molecule δ. The charge on the carbon atom of the $RC(OH)_2^{\oplus}$ ion is rather higher than that in RCOOH; consequently, the electrostatic repulsion of the alcohol molecule is reduced. However, an appreciable greater reduction of the repulsive forces is to be expected in the ion pair $RC(OH)_2^{\oplus}/R'O^{\ominus}$, since in this case the oxygen atom of the alcohol molecule carries an excess negative charge. Thus, in the ion pair, the reactants can come together more closely, and the interaction energy ΔE increases correspondingly.

According to our conclusions, therefore, the reaction conditions in the ion pair $RC(OH)_2^{\oplus}/R'O^{\ominus}$ are much more favorable than those in other molecule pairs. Consequently, it appeared reasonable to assume that, during esterification, the intermediate *(3)* is in fact formed *via* the ion pair. The ions can only be formed if energy is supplied. On the other hand, reaction of the ion pair to form the intermediate has a comparatively low activation energy. The transition state in the formation of the intermediate *(3)* from $RC(OH)_2^{\oplus}$ and R'OH is then – as mentioned above – approximately described by the ion pair.

For the ion pair $RC(OH)_2^{\oplus}/R'O^{\ominus}$ to be formed, a proton must be given up by the alcohol molecule δ of the solvation shell around the cation $RC(OH)_2^{\oplus}$ to the conductivity band L of the alcohol. The ability of the ion pair to exist depends essentially on the fact that this proton in the conductivity band of the semiconductor can be removed very rapidly. If this were not possible, the ion pair could be immediately deactivated by proton capture, and the formation of the intermediate would be inhibited. Moreover, the intermediate itself would also be sensitive to acid and would decompose on addition of a proton. This could lead to either the original acid and alcohol or to the end products, namely ester and water.

Decomposition of the solvated intermediate *(3)* into ester and water is represented in Figure 14. According to the Franck-Condon principle for proton-catalysed reactions, the energy-rich transition state *(6)* is reached

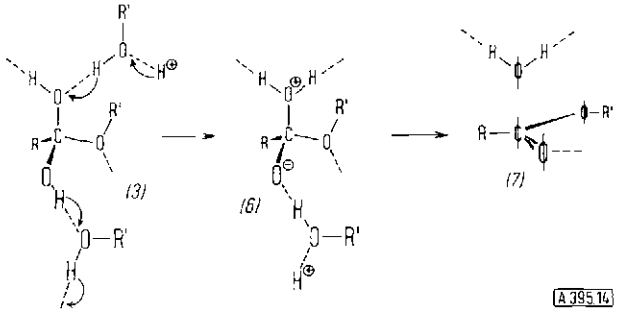

Fig. 14. Proton-catalysed decomposition of the intermediate *(3)* during esterification.

by a rapid change in proton distribution in the reaction medium. The final product *(7)* is formed in a subsequent slower reaction step, with rearrangement of the heavy groups of atoms. The formation of the π-electron system favors this step.

On formation of the intermediate *(3)*, the energy-rich ion pair $RC(OH)_2^{\oplus}/R'O^{\ominus}$ is converted into a neutral molecule with equalization of charge. On decomposition of the intermediate, the zwitterion *(6)* is converted into the neutral molecule pair, again with equalization of charge. In both reaction steps the polar transition state is reached by rapid proton jumps in hydrogen bridges. The subsequent deactivation of the transition state is reserved for a slower later step involving rearrangement of heavy groups of atoms.

According to our considerations, the reaction proceeds *via* a polar transition state; this also readily explains the

increase in the rate of reaction with increasing dielectric constant of the solvent found in the acid-catalysed hydrolysis of esters [1,22].

VI. Concluding Remarks

Discussion of the importance of the mobility of protons in the course of chemical reactions has been attempted in this paper, using acid-catalysed esterification as an example. Conditions are considered which are significant, not only in esterification, but in proton-catalysed reactions generally. Our observations are necessarily incomplete and have the character of an approximation. However, we believe that the great importance of protons in chemistry justifies our attempted interpretation.

We wish to thank Prof. G. Scheibe for his helpful interest in this work. We are also indebted to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Badische Anilin- und Sodafabrik for financially and materially supporting our investigations on "Protonic States in Chemistry".

Eliminations from Olefins

BY DOZ. DR. G. KÖBRICH

INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT HEIDELBERG (GERMANY)

Eliminations from olefins are very often initiated by bases, and usually lead to formation of acetylene derivatives. In view of the numerous side-reactions and subsequent additions or rearrangements observed, the nature of the base used is of considerable significance. Organometallic bases are very versatile. In addition to dehydrohalogenation, dehalogenation by metals, and also thermolytic and photolytic eliminations (e.g. the retrodiene reaction with exchange of substituents) are discussed. Elimination from low-membered cyclic olefins yields cycloalkynes having strained ring-systems, and the existence of these can be demonstrated by trapping them. The mechanisms known for β-elimination (E2, E1 and E1cB) occur also in the case of olefins; however – due to the sp^2-hybridization of the carbon atoms taking part – they are realized with different rates of reaction relative to saturated compounds. α-Eliminations from olefines having aryl residues in the β-position lead to formation of arylacetylenes by rearrangement of the carbon skeleton. The mechanism of this reaction, which is known as the Fritsch-Buttenberg-Wiechell rearrangement, is discussed in considerable detail, and several variations of the reaction are considered. According to present-day knowledge carbenes are involved in α-eliminations only when both β-positions of the olefin are occupied by aliphatic substituents, or when they are occupied by aromatic residues where rearrangement to acetylenes is impossible for steric reasons (as for example with 9-chloromethylenefluorene). With organolithium compounds a number of dehydrohalogenations, which are formally β-eliminations, actually proceed via deprotonation on the halogen-bearing carbon atom (α-metallation). α-Metallations are the rate-determining steps when ether is used as solvent, but proceed quickly in tetrahydrofuran even at low temperatures. Compounds of the type >C=C(Li)Cl may be prepared by this method and are recognized as intermediates in α-eliminations.

I. Introduction

Eliminations from olefins generally yield acetylenes, and constitute the most important method of synthesizing this class of substances. Reactions of this type have been known for over a hundred years and have since been the subject of many investigations. A number of reviews have been published fairly recently, in which some of the results from this field are collected, particularly from the viewpoint of the preparation and properties of acetylenes [1–4]. The aim of the present article is to survey the methods of carrying out elimination reactions of olefinic derivatives, for these have been greatly extended within recent years, and to describe present-day knowledge of the reaction mechanisms concerned with emphasis on base-initiated reactions.

[4] *J. F. Arens* in: Advances in Organic Chemistry. Interscience Publishers, New York 1960, Vol. II, p. 121.

II. Classification of Elimination Reactions

The methods for eliminating substituents from olefinic hydrocarbons may be divided into two major groups: the first involves elimination using bases or metals, and includes dehydrobalogenation as its most important type. The second includes endothermic eliminations, *e.g.* retrodiene reactions. In this paper which naturally cannot review the entire literature, β-eliminations will be discussed first. In these reactions, residues X and Y are eliminated from different carbon atoms, in accordance with Equation (a). α-Eliminations are initi-

$$X-\overset{|}{C}=\underset{|}{C}-Y \rightarrow -C\equiv C- + X + Y \qquad (a)$$

ated by the same methods, X and Y being situated on the same carbon atom; such eliminations are dealt with in Section IIIc.

In the whole of this review, the prefixes "α" and "β" are used to designate olefinic carbon atoms in accordance with normal usage in the literature. This usage is different when applied to designate reaction mechanisms than when applied to characterize compounds. Thus, the α-carbon atom in styrenes is the one bearing the phenyl group, while in acrylic acids (including cinnamic acids!) it is the one adjacent to the carboxyl group. From the point of view of reaction mechanisms, the α-carbon atom is the one from which a cation (especially a proton) is liberated; the anion which is simultaneously released can then be removed from the adjacent (*i.e.* "β"-) carbon atom ("β-elimination") or from the same (*i.e.* "α"-) carbon atom ("α-elimination").

A. Elimination of Hydrogen and a Group Containing a Hetero-Atom

Many reactions involve removal of a proton [Equation (a), Y = H] and either a hetero-atom (*e.g.* halogen) or a group containing a hetero-atom from an olefin by the action of a base. Since the nature of the base is of vital importance, this section will be divided according to the bases used.

1. Elimination by Oxygen Bases

The reaction of halogenated olefins with oxygen bases such as alkali metal hydroxides or alkoxides provides a general method of preparing acetylenes. The first substituted acetylene, *viz.* methylacetylene, was prepared by this method from bromopropene [5]. Dihalogenoalkanes are more readily available and hence are more frequently used in preparative work, but here halogenoethylenes occur as intermediates. Following further investigations [6,7], *Glaser* applied the method to halogenostyrenes and cinnamic acids [8]. Ethanolic KOH was found to be particularly suitable for the elimination of hydrogen halide [see Equation (b)] and led *inter alia*, to the smooth conversion of β-chlorostyrene or β-bromostyrene into phenylacetylene [8,9] and of *cis*- or *trans*-chlorostilbenes [10,11] and bromostilbenes [12] into diphenylacetylene (tolane). Vinyl bromide [13] and its alkyl homologues [14] react with sodium ethoxide on a boiling water bath to give the

$$H_5C_6-CH=C(R)X \xrightarrow[120-140\,^\circ C]{KOH/C_2H_5OH} H_5C_6-C\equiv C-R \qquad (b)$$
$$R = H,\ C_6H_5$$

corresponding alkynes; the yields decrease with increasing chain length. Monohalogenoacetylenes can also be prepared in this way, *e.g.* bromo- or chlorophenylacetylenes from α,β- or β,β-dibromo- or dichlorostyrene [9] and chloroacetylene from 1,2-dichloroethylene; in the latter reaction, the *cis*-isomer reacts about 20 times faster than the *trans*-form [15].

The interesting dihalogenoacetylenes cannot be prepared with alkalis in this manner. When heated with alcoholic potassium hydroxide trichloroethylene does not yield the expected dichloroacetylene; apart from dichlorovinyl ethyl ether, the only product obtained is monochloroacetylene [16]. Tribromoethylene reacts similarly.

The "wet" process is further limited by the fact that monosubstituted acetylenes isomerize in the presence of base, with migration of the triple bond along the chain to yield disubstituted acetylenes, which are thermodynamically more stable [1,17]. One example of this is the complete rearrangement of the labile compound mycomycin *(1)* to its stable isomer *(2)* with a terminal methyl group on treatment of *(1)* with 0.1 N potassium hydroxide at room temperature [18].

$$HC\equiv C-C\equiv C-CH=C=CH-(CH=CH)_2-CH_2-COOH \rightarrow$$
(1)

$$H_3C-C\equiv C-C\equiv C-C\equiv C-(CH=CH)_2-CH_2-COOH$$
(2)

Competing substitutions and secondary reactions can also occur; they arise from the ease with which the initially formed acetylenes undergo nucleophilic additions. Thus, β-chlorostyrene reacts to give not only phenylacetylene according to Equation (b), but also β-styryl ethyl ether [9] and even, under more vigorous conditions, phenylacetaldehyde [19]. The principal products of the reaction of vinyl chloride with alkali metal alkoxides and the corresponding alcohols in an autoclave at 80–100 °C are vinyl ethers. The observation that acetylene was formed, but that the amount of it

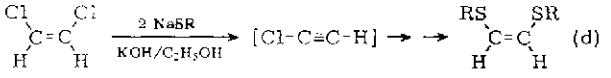
decreased with time, while no products other than the vinyl ethers were formed, suggested that acetylene was an intermediate, and led to the discovery of base-catalysed vinylation of alcohols [20]; see Equation (c).

$$CH_2{=}CHCl \xrightarrow[-ROH,\ -NaCl]{NaOR} HC{\equiv}CH \xrightarrow[ROH]{NaOR} CH_2{=}CH{-}OR \qquad (c)$$

Substitution of many halogeno-olefins with aryl or alkyl sulfides also proceeds only in the presence of catalytic quantities of alkali metal hydroxide or alkoxide. A formal double substitution of *cis*-dichloroethylene leads, in accordance with Equation (d), to excellent yields of *cis*-1,2-di(arylthio)ethylenes [21–23].



(d)

Since the presence of alkali is essential, since chloroacetylene reacts with thiolates to give the same product, and since the reaction rate depends on the concentration of alkali, but not on that of the thiolate [24], this reaction is a multistage elimination-addition process, whose rate-determining first step is dehydrohalogenation of the substrate to form chloroacetylene. It is significant that *trans*-dichloroethylene does not satisfy the steric conditions for the energetically favored *trans*-elimination of HCl and is inert under these conditions.

The elimination of hydrogen halide is thus of both practical and theoretical interest as first step in the elimination-addition mechanism – one of at least three mechanisms known at present for nucleophilic substitutions of olefins.

Addition of nucleophiles onto the acetylenes initially formed can often be avoided if the gaseous halogeno-olefin is allowed to pass over heated solid potassium hydroxide. Use of this method with chlorostyrene yields only phenylacetylene [9]; similarly, *(3)* gives 3,3,3-trifluoropropyne [25].

$$CF_3{-}CH{=}CHX \rightarrow CF_3{-}C{\equiv}C{-}H$$
(3)

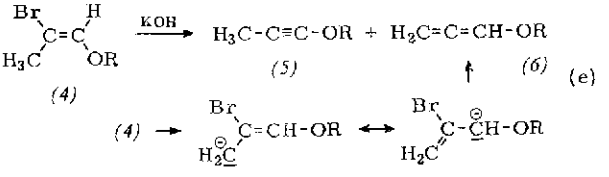
Dichloroacetylene was first prepared from trichloroethylene by this method [26].

$$Cl_2C{=}CHCl \xrightarrow[130°C]{KOH} Cl{-}C{\equiv}C{-}Cl$$

The "dry" process was found to be the first practicable method for the preparation of alkynyl ethers (which react extremely readily with nucleophilic reagents) from β-halogenovinyl ethers [4,27], although the yields are moderate [28].

$$R{-}CCl{=}CH{-}OR' \xrightarrow{KOH} R{-}C{\equiv}C{-}OR'$$

Preparative variants include distillation of the halogenoethylene with KOH under reduced pressure, or dropping the halide onto molten alkali at 200 °C [29]. A fundamental disadvantage of all oxygen bases still remains: the eliminations generally proceed smoothly only when the hydrogen and halogen can be removed from mutual *trans*-positions. Thus, *(4)* reacts with potassium hydroxide much less smoothly than the geometrical isomer, and its reaction yields a mixture of the allene *(6)* and the alkynyl ether *(5)* [30]. It is possible that this reaction, which is formally represented as a β-elimination from the olefin, actually proceeds by deprotonation in the allyl position to the ether oxygen atom [see Equation (e)].



(e)

On the other hand, *cis*-elimination of hydrogen chloride from *trans*-chlorostilbene at high temperatures on oxide surfaces proceeds more readily than *trans*-elimination from the *cis*-isomer, evidently for steric reasons [31]. It is not yet known whether these are free-radical or ionic reactions.

2. Elimination by Alkali Metal Amides

The use of the more reactive alkali metal amides in place of alkoxides has been known for a long time, at least in principle. Thus, various arylated or alkylated chloro- and bromo-olefins are converted into the corresponding acetylenes by sodamide in purified mineral oil between 110 and 180 °C [32]. Although it is theoretically possible for sodamide to add onto the alkyne initially formed [33] – a property which is exploited in the vinylation of amines [20] – the use of this reagent

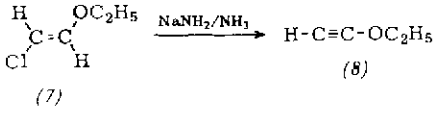
in liquid ammonia has enjoyed increasing preparative importance, mainly because it eliminates hydrogen halide readily even from *cis*-positions of ethylene derivatives. Thus, not only *cis*-β-chlorovinyl ethyl ether, but also its *trans*-isomer *(7)* is converted into ethynyl ethyl ether *(8)* [33]. The same compound is also formed



(7) *(8)*

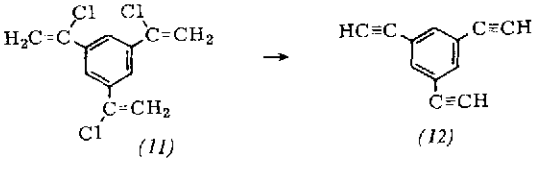
$ClCH_2-CH(OC_2H_5)_2$ *(9)*

from *(9)*, the chlorovinyl ether *(7)* occurring as an intermediate; *(8)* is therefore readily obtainable [34]. Liquid ammonia is a much better solvent for *cis*-elimination than aprotic solvents. Thus HBr is eliminated from the *trans*-form of *(10)* by treatment with sodamide in liquid ammonia, but not in dioxane at 77 °C. The *cis*-isomer reacts in both solvents [35].

$$Br-CH=CH-CH_2NH-C_4H_9 \rightarrow H-C\equiv C-CH_2NH-C_4H_9$$

(10)

Both halogen atoms of *trans*-dichloroethylene can be exchanged for mercapto groups in liquid ammonia [36], since the preceding elimination of HCl to form chloroacetylene occurs readily [37]. The method can be used for the preparation of various ethynylthiophenes under mild conditions [38]. Similarly, phenylacetylene is produced from α-chlorostyrene [39], and 1,3,5-triethynylbenzene *(12)* can be obtained in 60 % yield from *(11)*, which does not react with boiling methanolic potassium hydroxide [40].



(11) *(12)*

3. Elimination by Organo-Alkali Metal Compounds

Organometallic compounds, especially those of alkali metals, are most versatile in elimination reactions of the type under consideration. These are very strong bases and permit the elimination of HX from substrates which react only unsatisfactorily or not at all with weaker bases. At the same time, their nucleophilic character is comparatively weak; consequently, although subsequent addition onto the alkyne formed can be forced to occur in certain cases [41], it is generally possible only with halogenoacetylenes. Finally, besides debydrohalogenation, organolithium compounds can also effect dehalogenation according to Equation (f) under very mild conditions, owing to their ability to undergo halogen-metal exchange reactions [42].

$$Br-\underset{|}{\overset{|}{C}}=\underset{|}{\overset{|}{C}}-X \xrightarrow[-RBr]{R-Li} Li-\underset{|}{\overset{|}{C}}=\underset{|}{\overset{|}{C}}-X \xrightarrow{-LiX} -C\equiv C- \qquad (f)$$

β-Chlorostyrene reacts with two moles of either phenyllithium [43] or n-butyl-lithium [44] in ether at room temperature; the reaction is strongly exothermic. Hydrolysis of the resulting lithium salt *(13)* leads to an almost quantitative yield of phenylacetylene [43].

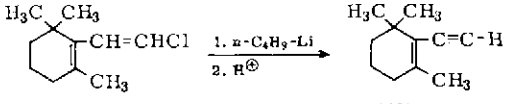
$$H_5C_6-CH=CHCl + 2\ H_5C_6-Li \xrightarrow[-C_6H_6]{-LiCl} H_5C_6-C\equiv C-Li \quad (13)$$

$$\xrightarrow{H^{\oplus}} H_5C_6-C\equiv C-H$$

Acetylene is obtained from vinyl bromide or vinyl chloride in a similar manner. Vinyl chloride is formed as an intermediate in the reaction of 1,2-dichloroethane with phenyl-lithium [45]; see Equation (g).

$$ClCH_2-CH_2Cl \xrightarrow[-HCl]{H_5C_6-Li} CH_2=CHCl \xrightarrow[2.\ H^{\oplus}]{1.\ H_5C_6-Li} HC\equiv CH \qquad (g)$$

On the other hand, in order to achieve smooth dehydrochlorination of 1,3,3-trimethyl-2-(β-chlorovinyl)cyclohexene *(14)*, n-butyl-lithium, which is more reactive, must be used; the resulting product is 2-ethynyl-1,3,3-trimethylcyclohexene *(15)* which polymerizes readily [46].



(14) *(15)*

With regard to the mechanism of the reaction it is significant that, in contrast to β-chlorostyrene, β-chloro-β-methylstyrene does not react completely with phenyl-lithium, even when the reaction is continued for some days, and resinous by-products are formed [47] (cf. Section III.B).

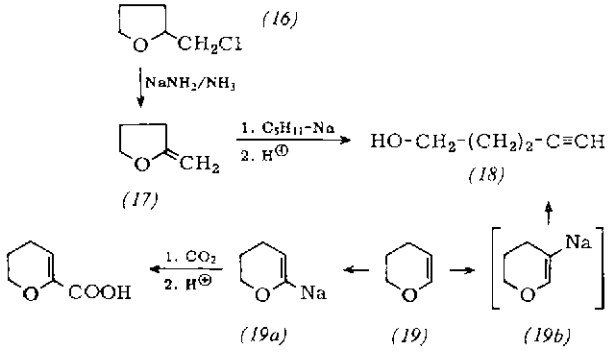
Vinyl ethers can also be cleaved at room temperature with phenyl-lithium [45]. These eliminations yield acetylenes and lithium alkoxide but proceed more slowly than dehydrohalogenation. Vinyl phenyl ether reacts completely in accordance with Equation (h) within a few hours, but with more basic vinyl isobutyl ether, the reaction is complete only after several days.

$$CH_2{=}CH{-}OR \xrightarrow[2.\ H^{\oplus}]{1.\ H_5C_6{-}Li} H{-}C{\equiv}C{-}H + H{-}OR \qquad (h)$$

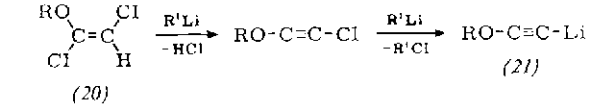
R = C_6H_5, i-C_4H_9

In the same way, the ring of α-methylenetetrahydrofuran is opened by amylsodium to yield 1-pentyn-5-ol *(18)* [48]. Amylsodium can also be used to metallate either of the olefinic hydrogens in dihydropyran *(19)*. The α-sodio compound *(19a)* is stable under the reaction conditions and can be detected, for example, by the formation of a carboxylation product with CO_2, whereas the β-sodio compound *(19b)* forms the open-chain compound *(18)*; *(18)* is also obtained from 3-bromodihydropyran by halogen-metal exchange with n-butyl-lithium [48].



2-Methylenetetrahydrofuran *(17)* results from treatment of *(16)* with sodamide in liquid ammonia, and is also converted into *(18)* under these conditions [49].

Where competition occurs between halogen and ether functions, as expected, halogen is eliminated preferentially even when the elimination of the alkoxide can occur via the energetically favorable *trans*-β-elimination. Thus, 1,2-dichlorovinyl ethers *(20)* are converted by organolithium compounds into chloroethynyl ethers, which then undergo halogen-metal exchange to form lithium acetylides *(21)* [50].



R = C_6H_5, C_2H_5

1-Ethoxy-2-thioethoxyethylene *(22)* is broken down by two moles of n-butyl-lithium into lithium ethoxide and the thioether *(23)* [51].

$$H_5C_2O{-}CH{=}CH{-}SC_2H_5 \xrightarrow{2\ n\text{-}C_4H_9\text{-}Li} C_2H_5OLi + Li{-}C{\equiv}C{-}SC_2H_5$$

(22) *(23)*

Elimination of lithium ethyl sulfide could conceivably compete with the above reaction but is not in fact observed; diethoxyethylene does not react under these conditions. The mobility of the hydrogen atom on the carbon atom bearing the thioether group is greater than that of the other hydrogen atom, since the carbanion *(23a)* is stabilized by resonance with the d-orbital of the sulfur atom. Since the

$$[H_5C_2O{-}CH{=}\bar{C}{-}SC_2H_5 \longleftrightarrow H_5C_2O{-}CH{=}C{=}\bar{S}C_2H_5]^{\ominus}$$

(23a)

deprotonation is the slowest step in the reaction in ether (cf. Section III.B), elimination of the ethoxyl group can be satisfactorily interpreted as a β-elimination. α-Elimination, which is also feasible, would lead to elimination of thiolate and consequently does not occur [51].

Nevertheless, vinyl thioethers can also be cleaved with organolithium compounds. Thus, thiophenol is eliminated as its lithium salt from *(24)* on reaction with n-butyl-lithium in ether, even at 0 °C [51, 52]. Since the fragments are obtained as lithium salts, the reverse

$$H_5C_6S{-}CH{=}CH{-}SC_6H_5 \xrightarrow[0°C;\ in\ H_5C_2{-}O{-}C_2H_5]{n\text{-}C_4H_9\text{-}Li} H_5C_6S{-}C{\equiv}C{-}Li + H_5C_6S{-}Li$$

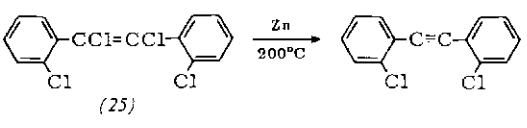
(24)

reaction is suppressed; lithium phenyl sulfide is insoluble, and so the acetylide, carrying a strong negative charge owing to anion formation, undergoes nucleophilic attack only with difficulty. To prevent recombination during work-up, the insoluble material must be filtered off or alkylated [52].

B. Elimination by Metals

1. Elimination of Halogen

The elimination of two halogen atoms attached to olefinic carbon atoms by metals in the absence of solvent is a classical route to acetylenes, but one which is seldom of practical value. However, α,β-dibromostyrene gives phenylacetylene in approximately 50 % yield on heating with zinc dust [9]; similarly, *(25)* is converted at 200 °C into bis-*o*-chlorophenylacetylene [53], whereas



diphenyldichlorostilbene is reported to be unaffected by sodium in the absence of solvent, even at 190 °C [54]. Dehalogenations, especially those effected by electropositive metals, occur readily in suitable solvents.

[48] *R. Paul* and *S. Tschelitchev*, Bull. Soc. chim. France *1952*, 808; cf. the review by *M. Schlosser*, Angew. Chem. *76*, 124 (1964); Angew. Chem. internat. Edit. *3*, 287 (1964).

[49] *G. Eglinton*, *E. R. H. Jones*, and *M. C. Whiting*, J. chem. Soc. (London) *1952*, 2873.

[50] *J. Normant*, Bull. Soc. chim. France *1963*, 1876.

[51] *W. E. Parham*, *R. F. Motter*, and *G. L. O. Mayo*, J. Amer. chem. Soc. *81*, 3386 (1959).

[52] *W. E. Parham* and *P. L. Stright*, J. Amer. chem. Soc. *78*, 4783 (1956).

[53] *F. Fox*, Ber. dtsch. chem. Ges. *26*, 653 (1893).

[54] *A. H. Gill*, Ber. dtsch. chem. Ges. *26*, 649 (1893).

Tolane dibromide *(26)* and the vinyl compound *(27)* are smoothly debrominated by zinc dust in acetone [55].

$C_6H_5-CBr=CBr-C_6H_5$ *(26)* $C_6H_5-CBr=CBr-CBr=CBr-C_6H_5$ *(27)*

Acetylenedicarboxylic esters are formed in good yield from dibromofumarates, as well as from the more slowly reacting dibromomaleates, by heating them with zinc in moist ether at 60–70 °C [56]. Zinc dust is particularly effective in alcohol; for example, *(28)* is converted into perfluoro-2-butyne in 90 % yield [57, 58].

$CF_3-CBr=CBr-CF_3 \rightarrow CF_3-C\equiv C-CF_3$ *(28)*

The use of zinc dust in ethanol always leads to reductive dehalogenation when the expected product is a halogenated acetylene. Tetrabromoethylene gives a mixture of acetylene and bromoacetylene instead of the expected dibromoacetylene [9]. Thus diacetylene and

$$Cl_2C[=CCl-CCl]_n=CCl_2 \xrightarrow{Zn/C_2H_5OH} H-C[\equiv C-C]_n\equiv C-H \quad (i)$$
$$n = 1;\ 2$$

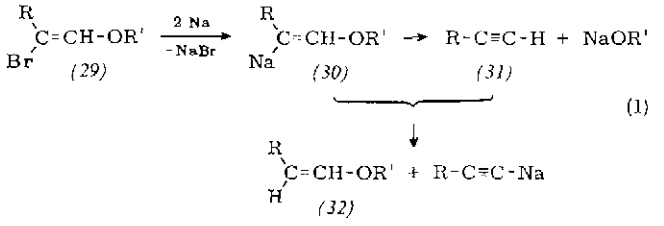
triacetylene can be obtained from perchlorobutadiene [59] and perchlorohexatriene [60], respectively, provided that the products are distilled off continuously to prevent reduction to an olefin [see Reaction (i)].

Dehalogenations with sodium in ether proceed very smoothly: for example, various α,β-dichlorostyrenes containing nuclear substituents are converted into the corresponding arylacetylenes [61]. Formation of the Grignard compound prior to the elimination step using the less reactive magnesium can be conveniently carried out in tetrahydrofuran [62]. In this way, 1-fluoro-1,2-dibromoethylene gives an 80 % yield of monofluoroacetylene [63], as shown in Equation (k).

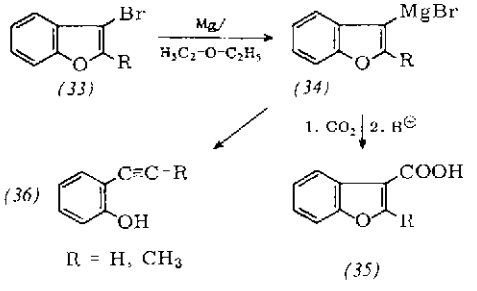
$$FCBr=CHBr \xrightarrow[65°C]{Mg/THF} F-C\equiv C-H \quad (k)$$

2. Cleavage of Ethers

β-Halogenated vinyl ethers follow the same reaction scheme as that shown in Equation (k). Thus, reaction of β-substituted β-bromovinyl ethers *(29)* with sodium powder in aprotic solvents, followed by hydrolysis, yields the expected acetylene *(31)* as shown in Equation (l); however, production of *(31)* is accompanied by formation of the dehalogenated ether *(32)*, since the intermediate *(30)* is evidently capable of converting part of the acetylene *(31)* formed into the sodium acetylide [64].

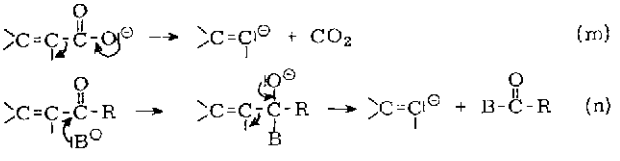


3-Bromobenzofuran [65] and its 2-methyl derivative [66] react even with magnesium in ether; after carboxylation, only traces of the carboxylic acid *(35)* to be expected from the Grignard compound *(34)* are present, the principal products being *o*-alkynylphenols *(36)*.



C. Fragmentation Reactions

Carbanions are known to occur not only in deprotonation and halogen-metal exchange reactions, but also as intermediates during decarboxylations in alkaline media [Equation (m)] and in the base-catalysed cleavage of esters and ketones [67] [Equation (n)].



Elimination occurs if the adjacent carbon atom carries a leaving group; the reaction is then referred to as a fragmentation.

1. Fragmentation Reactions of Acrylic Acid Derivatives

Examples of the fragmentation of olefinic carboxylic acids are mentioned in the earlier literature. Thus, when the potassium salt of β-chloro-*cis*-cinnamic acid *(37)* is heated at 120 °C for 5 h in concentrated aqueous solu-

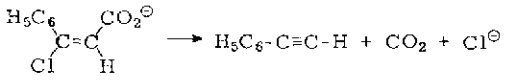
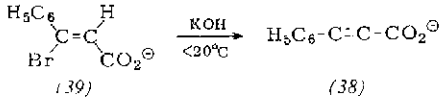
tion, it is completely converted into phenylacetylene [68]; the latter is also formed when the free acid is steam-distilled from weakly alkaline solution [69].



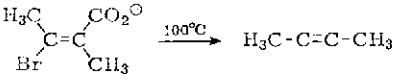
(37)

This reaction of β-chloro-*trans*-cinnamic acid in alkaline media cannot be *a priori* assumed to be a fragmentation. An alternative mechanism could involve elimination of hydrogen halide to yield phenylpropiolic acid *(38)*, which decarboxylates extremely readily [9]. Dehydrobromination of β-bromo-*trans*-cinnamic acid *(39)* by aqueous alkali does in fact occur even below 20 °C [70].

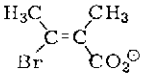


(39) (38)

Thus, there is no ambiguity only in the absence of hydrogen atoms on the α-carbon atom, or when the reaction occurs in neutral media. These prerequisites are met by the two geometric isomers of 2-bromo-3-carboxy-2-butene. Of these, the salt of angelic acid *(40)* reacts on merely heating at 100 °C in water; that of tiglic acid *(41)* does not react under these conditions[71].

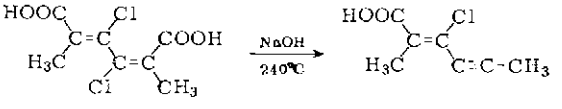


(40)



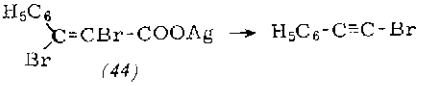
(41)

The preference for *trans*-elimination is obvious here, as well as in the reaction of the isomeric β-bromocinnamic acids. β-Bromo-*cis*-cinnamic acid undergoes fragmentation about 100 times more rapidly than its stereoisomer *(39)*, and hence presumably by a different mechanism (cf. Section III.A.1) [72]. The configuration of *(42)* was assigned on the grounds that, on heating at 240 °C with sodium hydroxide, it is converted into the acetylene derivative *(43)* [73].



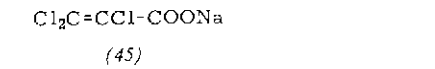
(42) (43)

Silver α,β-dibromocinnamate *(44)* yields 1-bromo-2-phenylacetylene on heating at 120–140 °C [9].

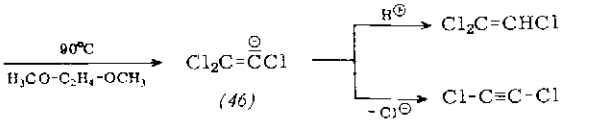


(44)

Similarly, sodium perchloroacrylate *(45)* is decarboxylated on prolonged heating at 90 °C in glycol dimethyl ether; reaction products are dichloroacetylene and trichloroethylene, since the intermediate carbanion *(46)* can be stabilized either by capture of a proton or by elimination of chloride [74].



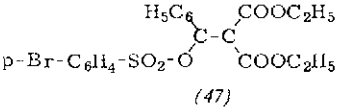
(45)



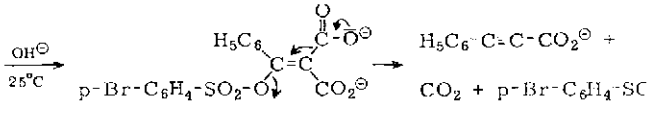
(46)

The carbanion *(46)* can be chlorinated with perchloropropene or isolated as its acetyl derivative by treatment with acetic anhydride [74].

Good leaving groups are particularly effective in promoting fragmentation. Thus, compound *(47)*, which can be prepared from diethyl benzoylmalonate and *p*-bromobenzenesulfonyl chloride, is broken down to propiolic acid, *p*-bromobenzenesulfonic acid, and carbon dioxide on standing for 12 h at room temperature with 0.2 N NaOH in aqueous dioxane [75]. This fragmentation is of



(47)



interest as a model reaction for the postulated mechanism of the biosynthesis of acetylene derivatives [76], a process which has not yet been clarified. The cleavage proceeds *in vitro* only when the enolic double bond is conjugated with another unsaturated group, but acetylene syntheses *in vivo* are subject to no such limitation.

2. Other Fragmentation Reactions

Only a few examples of fragmentations of olefins initiated by base in accordance with Equation (n) are so far known. 3-Chloro-3,4-dimethoxycinnamaldehyde *(48)* reacts with alkali to give 3,4-dimethoxyphenylacetylene *(49)* in approximately 80 % yield. The 4-mono-

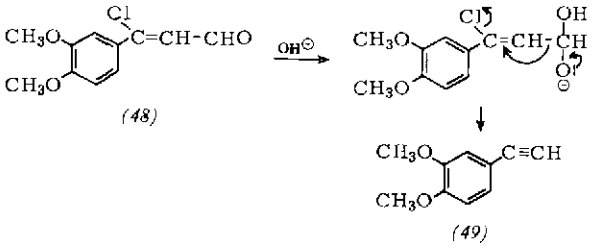
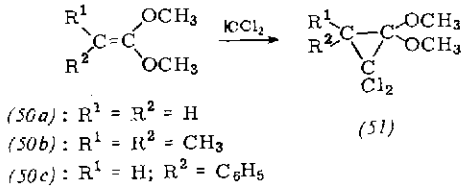
methoxy derivative and the compound with no nuclear substituent react in a similar manner [77].



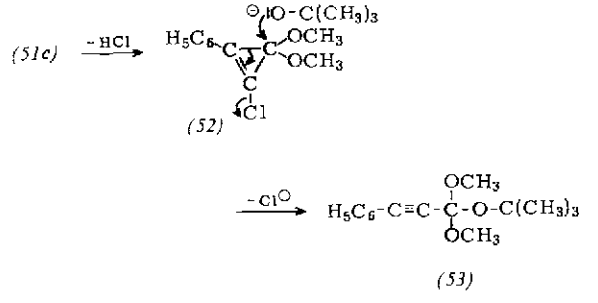
(48) (49)

Another interesting reaction belonging to this group is the "cyclopropanization" of ketene acetals with dichlorocarbene produced *in situ* from chloroform and potassium t-butoxide [78]. Whereas *(50a)* and *(50b)* give the expected cyclopropanone acetals *(51a)* and *(51b)* in good yield, the reaction of *(50c)* under the same conditions gives about 20% of the mixed orthoester *(53)*, among other products. The initially formed three-membered ring compound *(51c)* contains an acidic hydrogen atom on the carbon atom bearing the phenyl group, and reacts with excess butoxide with elimination of HCl to yield the cyclopropene derivative *(52)*. This highly strained system reacts further with base by elimination of chloride to form the product *(53)*.



(50a): $R^1 = R^2 = H$
(50b): $R^1 = R^2 = CH_3$
(50c): $R^1 = H$; $R^2 = C_6H_5$

(51)



(52) *(53)*

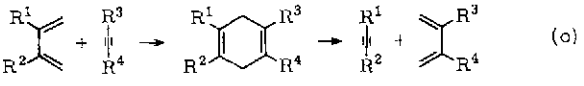
Evidence for the validity of this mechanism comes from the fact that an acetylene derivative analogous to *(53)* is also formed from *(51a)*, but not from *(51b)*, which cannot form a cyclopropene derivative without undergoing rearrangement [78].

D. Thermolytic and Photolytic Reactions

Endothermic cleavages are observed mainly with cyclic olefins, and have frequently been found to be of practical value. The driving force behind these eliminations is generally ring strain (*e.g.* in bicyclic compounds), the possibility of formation of an aromatic system, or the formation of gases of low free energy (*e.g.* nitrogen or carbon dioxide).

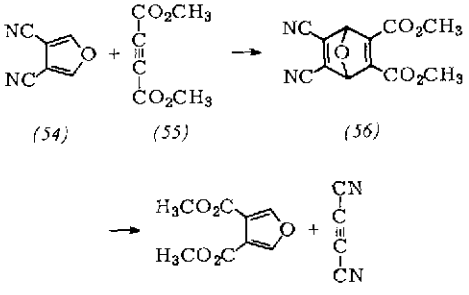
1. Retrodiene Reactions

Apart from the trivial case involving reformation of the starting materials, reversal of the diene synthesis can lead to decomposition involving cleavage of C–C bonds within the moiety that was originally the diene component of the adduct [79]. If the dienophile is an acetylene derivative, its substituents are exchanged in the final product for those in the 2- and 3-positions of the diene [Equation (o)].



(o)

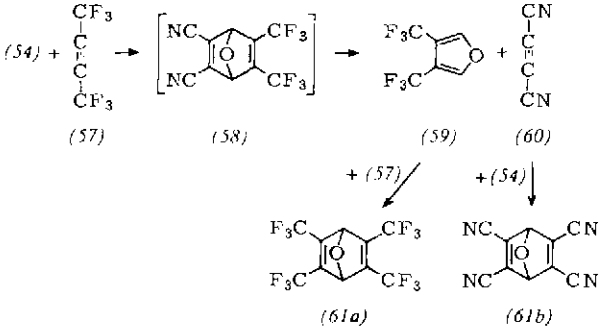
Thus, when compound *(56)*, which can be obtained from 3,4-dicyanofuran *(54)* and dimethyl acetylenedicarboxylate *(55)*, is heated at 175–180 °C, it gives exclusively dimethyl furan-3,4-dicarboxylate and dicyanoethyne. The reaction proceeds even more readily



(54) *(55)* *(56)*

without isolation of the intermediate adduct *(56)* [80] if *(54)* and *(55)* are boiled in xylene or mesitylene.

The Diels-Alder reaction of *(54)* and perfluoro-2-butyne *(57)* follows a more complex course [81]. The reaction proceeds only at 160 °C and yields only the symmetrical products *(61a)* and *(61b)* in yields of 30 and 35%, respectively. The primary adduct *(58)* is apparently unstable under the conditions of its formation, and undergoes a retrodiene reaction to form the compounds *(59)* and *(60)* with "transposed" substituents; these in turn react selectively with the starting materials to yield the energetically favored symmetrical products.



(57) *(58)* *(59)* *(60)* *(61a)* *(61b)*

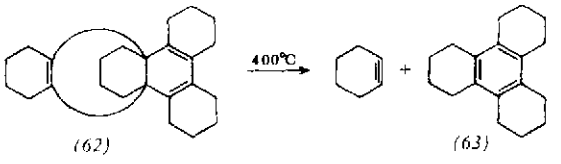
[80] *C. D. Weis*, J. org. Chemistry *27*, 3520 (1962).

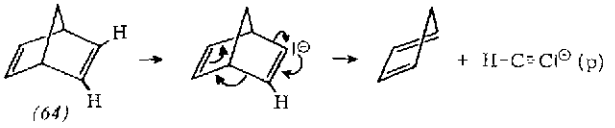
[81] *C. D. Weis*, J. org. Chemistry *27*, 3693 (1962).

If an aromatic compound can be formed, even a highly strained and hence energy-rich cycloalkyne can be eliminated under vigorous conditions. Thus, according to *Wittig*, the cyclobutene ring of the polycyclic compound *(62)* is opened at 400 °C to form cyclohexyne and dodecahydrotriphenylene *(63)* in 29 % yield [82].



(62) *(63)*

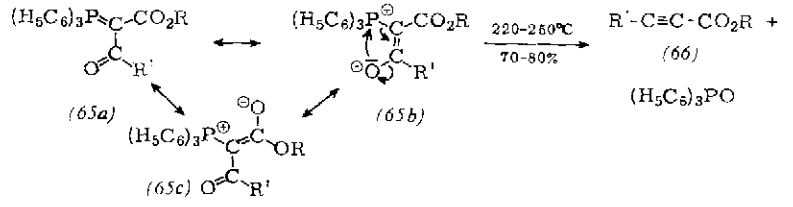
The reaction of amylsodium and bicyclo[2,2,1]heptadiene *(64)* [83] followed by carboxylation yields acetylene and (dimeric) cyclopentadienoic acid; these can also be formally regarded as resulting from a retrodiene reaction. Since metallation with n-butyl-lithium results in substitution of only vinyl hydrogen [84], it may be assumed that the reaction with amylsodium also leads first to introduction of metal on a vinyl carbon atom, followed by the cleavage, as indicated in Equation (p).



(64) (p)

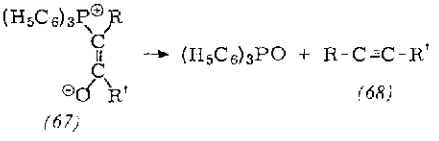
2. Cleavage of Acylated Methylenephosphoranes

The acylalkoxycarbonylmethylenetriphenylphosphoranes *(65a)–(65c)*, which can be obtained by acylation of alkoxycarbonylmethylenephosphoranes are stabilized by resonance but decompose at 220–250 °C to give good yields of triphenylphosphine oxide and the corresponding propiolic esters *(66)* [85].



(65a) *(65b)* *(65c)* *(66)*

On the basis of resonance formulae *(65a)* and *(65b)*, the reaction can be regarded as an intramolecular *Wittig* synthesis. Like the latter, it is generally applicable, since all betaines *(67)* in which neither R nor R′ is hydrogen but in which one or both are phenyl or some other electron-attracting group evidently give good to very good yields of disubstituted acetylenes *(68)* [86].

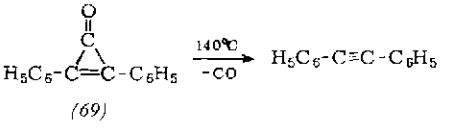


(67) *(68)*

Diacetylenes can also be obtained by this method when R = $-C\equiv C-R''$ [87].

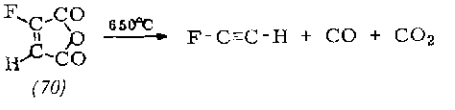
3. Elimination of CO, CO_2, and N_2 from Unsaturated Cyclic Compounds

It is known that CO is readily eliminated from bicyclic compounds with a carbonyl bridge; analogously carbon monoxide can be eliminated from the highly strained diphenylcyclopropenone *(69)* at 140 °C to give moderate yields of diphenylacetylene [88].



(69)

Pyrolysis *in vacuo* (5–7 mm) of fluoromaleic anhydride *(70)* gives excellent yields of fluoroacetylene which readily undergoes trimerization; the compound was in fact first prepared by this method [89].



(70)

Alkali metal salts of *N*-(*p*-toluenesulfonamido)triazoles *(71)* undergo photolytic elimination of sulfinate and nitrogen to yield acetylenes (when R = R′ = C_6H_5, yield = 85 %) [90].

This method is especially interesting for the preparation of cycloalkynes with small rings under mild conditions.

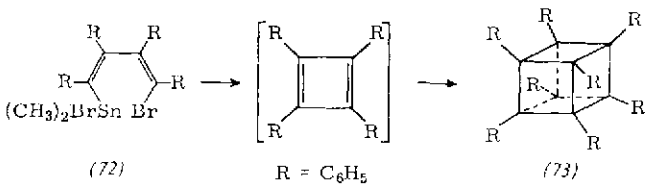
4. Ring Closure *via* 1,4-Elimination

An interesting 1,4-elimination is observed with the *cis*-diene *(72)*. On thermolysis, this compound loses dimethyltin dibromide to form octaphenylcubane *(73)* [91] (presumably *via* tetraphenylcyclobutadiene). The



(72) R = C_6H_5 *(73)*

formation of tricyclo-octadiene derivatives, which is observed in dimerization reactions of cyclobutadienes [82,92], is believed to be suppressed in this reaction in favor of the formation of *(73)*, owing to the size of the phenyl groups. – Meanwhile it has been shown [91a], that octaphenylcyclooctatetraene instead of *(73)* is formed from *(72)*.

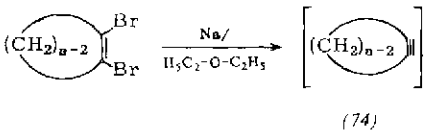
5. Cleavage of Cyclooctatetraene

Cyclooctatetraene can be cleaved to acetylene and benzene by normal or mercury-sensitized photolysis [92a]. The 1,2,4,6-tetraphenyl derivative is converted under the same conditions into diphenylacetylene and *p*-terphenyl, using heptane as solvent; an intermediate of unknown constitution is involved [92b].

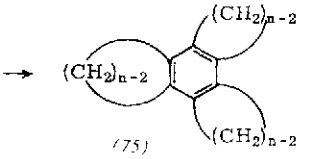
E. Reactions of Strained Cycloalkynes

Owing to substituent effects, the acetylenes obtained by β-eliminations from olefins often possess enhanced reactivity leading to subsequent addition reactions (cf. Section II.A). This is particularly true when the alkyne is part of a small-ring system. Examination of atomic models shows that the smallest ring system in which the four carbon atoms involved in sp hybridized bonds are free of strain is cyclononyne; the smaller rings have a higher energy content due to bond deformation. and are consequently more reactive [93].

Apart from the oxidation of dihydrazones of cycloalkanediones, the principal methods of preparing cycloalkynes are the elimination reactions discussed in Sections II.A and II.B applied to the corresponding cycloalkenes. Efforts in this direction started as early as the turn of this century but were at first unsuccessful [94]. *Favorsky* et al. [95] concluded from the cyclic trimers *(75)*, obtained by treatment of dihalogenocycloalkenes with sodium in ether, that the monomeric compounds *(74)* (n = 5, 6, or 7) were formed as intermediates; however, these could not be isolated.



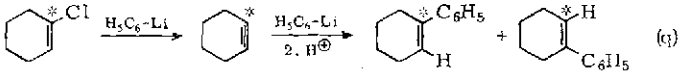
(74)



(75)

Thus it was not until 1933 that the first cycloalkynes – with 15 and 17 carbon atoms in the ring – were synthesized by dehydrobromination of the corresponding bromo-olefins with alcoholic potassium hydroxide at 180 °C; their chemical behavior was found to be similar to that of the open-chain acetylenes [96]. Cyclononyne can be obtained either by heating 1-chlorocyclononene with KOH [97] or by oxidizing cyclononadione dihydrazone [98]; cyclooctyne can also be prepared by the latter method [99] or by the action of alkali metal amides on 1-chlorocyclooctene in liquid ammonia [100].

1-Phenylcyclohexene, which is obtained by the reaction of 1-chlorocyclohexene with phenyl-lithium in ether [45], and 1-phenylcyclopentene, which is prepared in the same way from 1-chlorocyclopentene [101], are both formed *via* symmetrical intermediates – presumably cyclohexyne and cyclopentyne, respectively – since, when one of the two olefinic carbon atoms in the starting material is labelled with ^{14}C, the phenyl substituent is found on both olefinic carbons to almost equal extents in the product [102]; see Equation (q).



(q)

Other methods of preparing cyclohexyne are the reaction of 1-fluorocyclohexene with n-butyl-lithium and the formation of a Grignard compound from

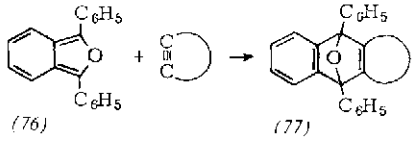
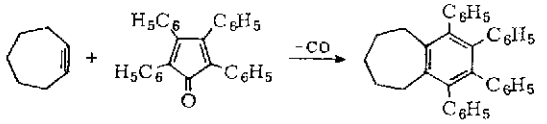
1,2-dibromocyclohexene [103]; these reactions can also be used to prepare seven- and five-membered rings [100, 103].

In an elegant method of detecting cycloalkyne intermediates these are trapped with 1,3-diphenylbenzo-[c]furan *(76)* to form *(77)* or with other dienes [82, 93, 100, 103]; at the same time, this reaction yields qualitative information regarding the life-time of



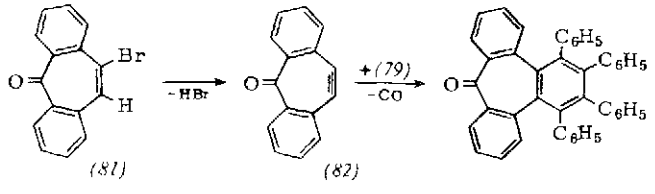
(76) *(77)*

such intermediates, which decreases with decreasing ring size, as is reflected in decreasing yields of adduct. It has recently been shown by capture with dienes that cycloheptyne *(78)* is stable for several minutes at room temperature. The compound was prepared from the triazole derivative *(71)*, R + R′ = – $(CH_2)_5$ – (see Section II.D.3), and converted into 2,3,4,5-tetraphenylbenzocycloheptene *(80)* in moderate yield by treatment with tetraphenylcyclopentadienone *(79)* even after completion of the photolysis [90].



(78) *(79)* *(80)*

Elimination of HBr from bromodibenzotropone by treatment with potassium t-butoxide in ether gives the cycloheptyne derivative *(82)* which can be trapped by furans or tetracyclone [104].



(81) *(82)*

The rate of elimination of hydrogen bromide is influenced strongly by cationic activation of the olefinic hydrogen atom by the carbonyl group. When *(81)* is compared to the corresponding dimethylacetal and the analogous sulfone [*(81)*, $C(OCH_3)_2$ or SO_2 instead of C-O], the rate constants are reduced by a factor of 150 in the case of the acetal, but increased by a factor of at least 1000 in the case of the sulfone.

Here, as in similar eliminations from furan and thiophene derivatives, similarities can be observed with the chemistry of benzyne [105].

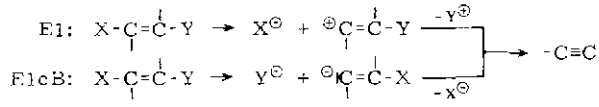
A. β-Eliminations

According to *Ingold* [106], β-eliminations can occur either in one step (E2) or in two (E1). The E2 mechanism is a synchronous process in which the elimination of substituents X and Y from two adjacent carbon atoms and the formation of the π-bond between the carbon atoms occur simultaneously; the four atoms involved lie in a single plane and, for reasons which have not yet been satisfactorily explained [106a], X and Y are always in *trans*-relationship to each other.

Two-stage eliminations are characterized by primary loss of the anion $X^{\ominus}$ to form a carbonium ion (E1 mechanism) or by primary removal of a cation $Y^{\oplus}$ to form a carbanion (E1cB mechanism).



The three mechanisms E2, E1, and E1cB represent extremes of a continuous range of possible courses; the factors determining which course is adopted have recently been discussed in detail [107] for saturated compounds, for here plentiful experimental data are available.

Mechanistic studies of β-eliminations from olefins are relatively rare. Owing to the greater electronegativity of sp^2-hybridized carbon compared to sp^3-hybridized carbon [108], it may be expected, in principle, that olefinic carbon atoms can accept a negative charge more readily than saturated carbon atoms, but can much less readily accept a positive charge. Hence, although E1 reactions, as well as S_N1 reactions, involving carbonium ion intermediates frequently occur with saturated compounds, they are less likely to occur with olefins. Conversely, base-initiated eliminations, which for saturated compounds proceed by an E2 mechanism, and only in exceptional cases by an E1cB-type mechanism [109], evidently proceed more readily *via* carbanions in the case of olefins, even when the steric conditions for the E2 mechanism are satisfied.

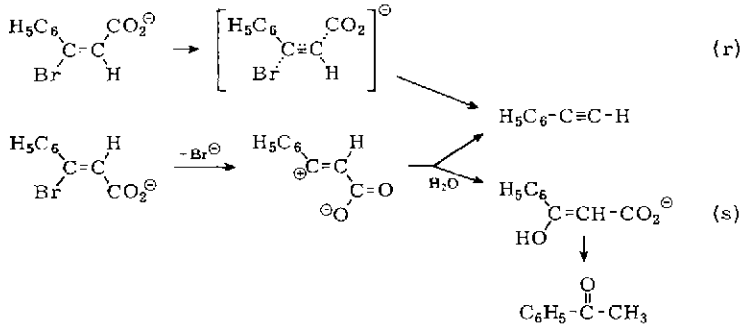
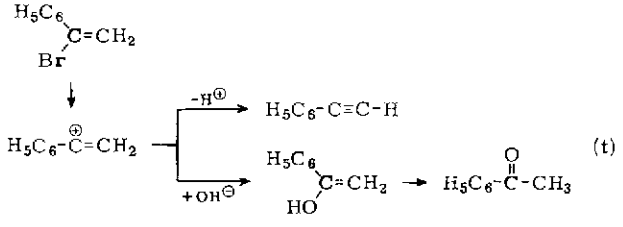
The ease of fragmentation of halogenated acrylates in which the halogen is *trans* to the carboxylate group (Section II.C.1) suggests that the cleavage follows an E2 mechanism, as indicated in Equation (r). β-Bromo-*trans*-cinnamic acid is more difficult to decarboxylate, and in this reaction acetophenone is found as a by-product [72]. This is compatible with the assumption of an initial unimolecular reaction involving formation of a carbonium ion which undergoes a rapid secondary reaction to form the products isolated [72], see Equation (s).



(r)

(s)

This mechanism is probably followed owing to the good solvating power of the medium, as well as to the negative charge of the carboxylate group which helps to stabilize the carbonium ion. The latter effect is not decisive, however, as can be seen from the fact that α-bromostyrene also undergoes solvolysis in ethanol/water at 100 °C [110]. Besides acetophenone, the products include about 20 % phenylacetylene; a base-catalysed dehydrobromination can be excluded for formation of the latter. Here, too, the branching of the reaction course is therefore likely to occur starting from the initially formed carbonium ion, as shown in Equation (t). As expected, formation of the carbonium ion is facilitated by



(t)

electron-donating groups in *para*-position to the phenyl group (stabilization of the positive charge); a *p*-amino group causes acceleration of the reaction by a factor of 10^8 compared to the rate for the parent compound. Conversely, the solvolysis is suppressed by the electron-attracting nitro group [110].

[110] *C. A. Grob* and *G. Cseh*, Helv. chim. Acta *47*, 194 (1964).

In order to become acquainted with the controlling factors in these eliminations, dehydrohalogenation of olefins by base, being the simplest and most important type of reaction, may be considered. Both mechanisms involve bimolecular reactions of first order with respect to both substrate and base. The following statements can be made:

1. When an oxygen base is used, *trans*-eliminations always proceed much more rapidly than *cis*-eliminations. In addition to the examples given earlier (Section II.A.1), it should be mentioned that dehydrochlorination of *trans*-chlorostilbene with NaOH in ethanol is about 400 times faster than that of the *cis*-isomer [111].

The preference for *trans*-elimination agrees with the fact that additions onto acetylenes, especially those catalysed by bases, are always *trans*-additions [112], as *Michael* [113] pointed out.

2. If cleavage of the carbon-halogen bond is involved in the rate-determining step, the rate of elimination under a given set of conditions is expected to decrease in the order I > Br > Cl > F corresponding to increasing bond energy. Thus, *trans*-elimination of hydrogen halide from *cis*-1,2-diiodoethylene with sodium methoxide at 60 °C is 10^2 and 10^5 times faster than that from the dibromo and dichloro compounds, respectively (cf. Table 1) [114].

Table 1. Rate constants k_2 and activation parameters (activation energy E_a and entropy $\Delta S^{\neq}$) for the dehydrohalogenation of dihalogenoethylenes with sodium methoxide in methanol [114].

	cis-Isomer			*trans*-Isomer		
	k_2 [l/mole/sec]	E_a [kcal/mole]	$\Delta S^{\neq}$ [e. u.]	k_2 [l/mole/sec]	E_a [kcal/mole]	$\Delta S^{\neq}$ [e. u.]
$C_2H_2Cl_2$	1.4×10^{-5}	35.1	+ 22	4.2×10^{-9}	29.0	− 12

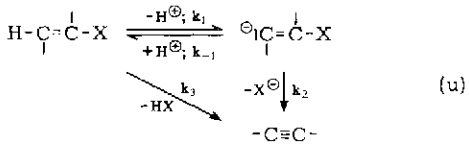
3. The more strongly a proton is acidified by electron-attracting substituents on the olefin, the more readily will it be detached by base; this substituent effect is greatest for a substituent on the same carbon atom as the leaving hydrogen atom. Thus, dehydrobromination of *cis*-β-bromostyrene with NaOH/isopropanol at 43 °C proceeds more slowly than that of the corresponding *p*-nitro-*cis*-β-bromostyrene [115] by a factor of 1200 [116].

4. If the carbon atom bearing the leaving group X also carries an electron-attracting substituent, the elimination is retarded, since this substituent renders the carbon atom, to which it is attached, more positive and so opposes release of the bonding doublet.

The question is, therefore, when is the E2 reaction realized, and when does an E1cB mechanism prevail? In view of the apparently favored position of the synchronous process in general, there is a tendency to classify all bimolecular eliminations *a priori* as E2 reactions, whenever a carbanion cannot be detected as an intermediate. Strictly speaking, a carbanion can be detected only if the corresponding organometallic compound can be isolated and its rate of decomposition measured.

In principle, as the parameters 1. to 4. are varied, an E1cB mechanism should be favored when halogen is firmly bonded to the carbon atom and the α- and β-carbon atoms carry electron-attracting substituents. These conditions are ideally satisfied in trifluoroethylene whose lithium derivative (as a potential carbanion) can be prepared in solution [117] and is reasonably stable in ether at −70 °C [118] (for further examples, see Section III.B). If the intermediate carbanion cannot be isolated, it must be detected indirectly by introduction of reagents which can compete with the elimination step for the carhanion. The simplest case, the reversibility of the deprotonation, is tested by carrying out the reaction in the presence of a deuterium donor; elimination is then interrupted prematurely and the substrate is examined for incorporation of deuterium. An equivalent method is the use of a deuterated substrate in the presence of a proton donor.

Detection of a carbanion intermediate makes an E1cB mechanism likely, but does not prove it conclusively; it is conceivable that the elimination still occurs as a synchronous process, and that the acid-base equilibrium ($k_1 \rightleftarrows k_{-1}$) indicated by Equation (u) represents a reversible side-reaction.



(u)

[116] *S. J. Cristol* and *W. P. Norris,* J. Amer. chem. Soc. *76*, 3005 (1954).

[117] *D. Seyferth, D. E. Welch,* and *G. Raab,* J. Amer. chem. Soc. *84*, 4266 (1962).

[118] *P. Tarrant, P. Johncock,* and *J. Savory,* J. org. Chemistry *28*, 839 (1963).

The possibility has recently been discussed that the energy of the transition state of the E2 elimination may be less in such cases than that of the elimination step from the carbanion ($k_3 > k_2$) [119].

An additional criterion for the two-stage process is provided by kinetic measurements: the deuterated, compound should undergo elimination in deuterium-active media at approximately the same rate as the non-deuterated substrate in the corresponding protonic solvent, since an isotope effect can manifest itself in only a slight displacement of the initial equilibrium $k_1 \rightleftarrows k_{-1}$, with a resultant slight change in the steady-state concentration of the carbanion, but it cannot affect the rate-determining elimination step to any great extent.

Competition experiments also yield information on the configurative stability of the intermediate carbanion, since, if inversion of configuration occurs, the starting material which is recovered is a mixture of *cis*- and *trans*-isomers if one of the two olefinic carbon atoms carries different substituents [120] [*].

Apparently all olefins with hydrogen and halogen substituents on the same unsaturated carbon atom can undergo base-catalysed H–D exchange, as indicated by experiments on bromostyrene, 1,2-dihalogenoethylenes [121], and 1,1-diphenyl-2-chloroethylene [122]. The rates at which *cis*-dichloroethylene and *cis*-dibromoethylene undergo exchange with sodium methoxide in D_2O are roughly equal, but the rates of deuteration of the *trans*-compounds decrease in the order of decreasing acidity of their hydrogen atoms, *i.e.*

CHCl=CHCl > CHBr=CHBr > CHI=CHI.

Isomerization of the bromo-olefins, but not of the chloro-olefins, occurs in the course of this reaction. The isotope effect k_h/k_d found for the *cis*-dibromo compound at 35.4 °C is 1.03, a very low value indeed [121]. Thus it seems that this *trans*-elimination proceeds by an E1cB mechanism. This mechanism can also be assumed to apply to the elimination of HCl from trichloroethylene; this compound is deuterated in alkaline media [123]. The intermediate trichlorovinyl anion can be isolated as its Hg salt by alkaline mercuric cyanide [16]. The same method can be applied to *trans*-dichloroethylene, but not to the *cis*-isomer [124]. The trichlorovinyl anion is also obtained as an intermediate on decarboxylation of salts of perchloroacrylic acid [74] (see Section II.C.1).

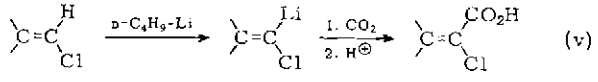
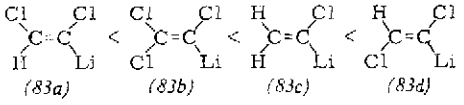
B. Metallated Halogeno-Olefins as Intermediates

Some of the chloroethylene carbanions which have so far been formulated only as intermediates can be prepared in solution as their lithium derivatives by metallation of the chloroethylenes with n-butyl-lithium in tetrahydrofuran at sufficiently low temperatures. Subsequent carboxylation and acidification [see Equation (v)] yield the chloroacrylic acids expected from *(83b)* to *(83d)*, in yields of 80–100 % [125].



(v)

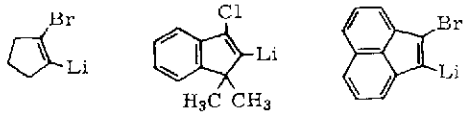
The stabilities of the carbanions increase as follows:



(83a) *(83b)* *(83c)* *(83d)*

It can be seen that the more unstable compounds have the metal atom in the *trans*-position with respect to a halogen atom. *trans*-β-Elimination evidently takes place with greater ease than the equally feasible *cis*-β- or α-eliminations [125].

A few five-membered cyclic olefins, *e.g. (84)*, *(85)*, and *(86)*, with adjacent lithium and halogen substituents are



(84) *(85)* *(86)*

stable for some time even at room temperature, since elimination of lithium halide is opposed by the extremely high ring strain in the cyclopentyne derivative expected as elimination product (cf. Section II.E) [125a]. Proof that vinyl chloride, for example, is deprotonated on the halogen-substituted carbon atom by means of n-butyl-lithium in tetrahydrofuran, raises the possibility that this reaction, as well as other dehydrohalogenations caused by strong bases in ethereal solvents and formally appearing as β-eliminations proceed *via* α-metallation. On the basis of his work on β-bromostyrene *Cristol* put forward this suggestion together with the observation that several dehydrohalogenations by organolithium compounds or alkali metal amides described in the literature proceed very readily when the halogen-substituted carbon atom is also bonded to a hydrogen atom [126]. This phenomenon is illustrated [47] by the fact that β-methyl-β-chlorostyrene reacts only incompletely with phenyl-lithium in ether, even after several days, whereas β-chlorostyrene reacts instantaneously under these conditions (cf. Section II.A.3).

1,1-Diphenylchloroethylene also reacts more rapidly with phenyl-lithium than either of the two isomeric chlorostilbenes [111], obviously because the hydrogen atom is more acidic. The α-metal compounds cannot be detected in ether which is only slightly polar, because here the deprotonation is the slow step, and therefore the rate-determining one, being followed by the elimination which proceeds rapidly. On the other hand, in the more strongly polar tetrahydrofuran, the rate of irreversible removal of protons can be increased by means of the organometallic base, so that it occurs more quickly than the elimination (see below).

A number of examples have been reported in which *trans*-elimination of hydrogen halide by strong bases was not more favored than *cis*-elimination, and sometimes proceeded even more slowly than the latter. These examples are listed in Table 2 (cf. Section II.A.3). Isomerization prior to elimination might make it appear as if the rates were approximately equal, but

Table 2. Relative rates of dehydrohalogenation of stereoisomeric olefins with strong bases.

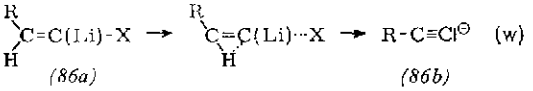
this is not the case [120]. Owing to the stability within the series *(83a)* to *(83d)* there is no reason to suppose that in these cases the validity of the rule is broken, according to which removal from the *trans*-arrangement of the two substituents at neighboring carbon atoms is preferred. Thus the reaction rates must depend on differences in the acidity of the olefinic hydrogen atoms and on steric factors and solvent effects.



(86a) *(86b)*

(w)

It is an interesting question, though not yet fully solved, how α-metalled substrates *(86a)*, bearing a hydrogen atom on the β-carbon atom, are converted into the end product of the elimination, *viz.* an anionized acetylene

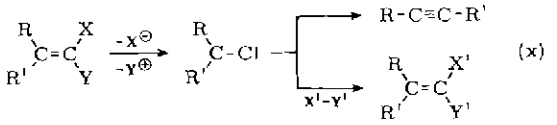
derivative *(86b)*. A carbene is not formed as a product of α-elimination [Equation (x)] in the case of vinyl chloride [125] and β-chlorostyrene [127]. A competitive experiment [127] shows that phenylacetylene is excluded as an intermediate arising from dehydrochlorination of β-chlorostyrene using phenyllithium in ether. Accordingly, the β-hydrogen atom is abstracted by the base [either *(86a)* or excess reagent] while it is yet bound to the β-carbon atom. This process may occur on an intermediate where – by analogy with the Fritsch-Buttenberg-Wiechell rearrangement (see following section) – the hydrogen atom is situated between both olefinic carbon atoms [Equation (w)] thus assisting removal of halogen [125]; or the base can attack the metallated substrate *(86a)* directly [127]. In *(86a)* the metal atom promotes negative polarization of the olefin. This makes deprotonation of the β-carbon atom more difficult, but facilitates removal of halogen from the α-carbon atom. Is it probable that protons become sufficiently mobile only when partial removel of the halogen atom, involving (relative) positive polarization of the rest of the molecule, occurs. The mechanism of dehydrohalogenation of substrates of type R–CH–CHX with organolithium compounds is then a limiting case of α-elimination and "E1-type" β-elimination.

C. α-Eliminations

α-Eliminations are characterized by the fact that both leaving groups X and Y are situated on the same carbon atom. The methods of cleavage are the same as those discussed for β-eliminations. In contrast with the latter, however, α-eliminations do not lead directly to stable products, but instead an organic residue with an



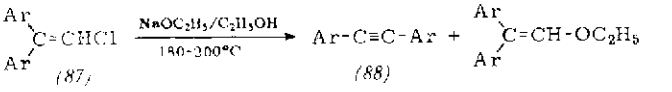
(x)

electron sextet can be considered to be formed, as indicated in Equation (x), which is then stabilized by secondary reactions, such as addition of suitable reagents or rearrangement to acetylenes.

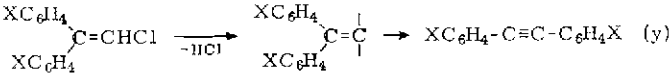
1. Fritsch-Buttenberg-Wiechell Rearrangement

a) *Scope and Limitation*

In 1894, while investigating 1,1-diaryl-2-chloroethylenes *(87)* [131, 132], *Fritsch*, *Buttenberg*, and *Wiechell* found that the parent compound and its various *p*-substituted derivatives were converted into diphenylacetylenes on reaction with sodium ethoxide/ethanol at 180–200 °C. Vinyl ethers were also formed in this reaction by substitution, in amounts depending upon the aromatic residues involved. Thus, only 9 % of the acetylene *(88)* is obtained from *(87)* with Ar = C_6H_5, but the yield of *(88)* is 85 % when Ar = *p*-CH_3–C_6H_4. The positions of the substituents in the aromatic residue remain unchanged during the rearrangement, *i.e.* the bonds which are broken and the new bonds which are formed are on the same aromatic carbon atom.



The rearrangement was formulated as a sextet rearrangement, according to Equation (y) [131]. The reaction between molten KOH and 1,1-diphenyl-2-bromoethylene also gives high yields of diphenylacetylene



(y)

[133]; α-methyl-β-bromostyrene is converted in a similar manner into phenylmethylacetylene, 1-phenylcyclopropene being postulated as an intermediate [134]. Diphenylacetylenes can be obtained from the appropriate chloro- [135] or bromo-olefins [136] under very much milder conditions with alkali metal amides in liquid ammonia, often in 90–95 % yields.

1,1-Diphenyl-2,2-dichloroethylene also gives diphenylacetylene on reaction with sodium powder/benzene [137] or phenyl-lithium/ether [138]; its reaction with sodamide or benzhydrylpotassium in liquid ammonia, on the other hand, leads predominantly to substitution products [138].

α-Eliminations from diarylhalogenoethylenes initiated by organolithium compounds were first investigated by *Curtin*. 1,1-Diphenyl-2-bromoethylene *(89)* is rapidly attacked by n-butyl-lithium in ether at –35 °C; sub-

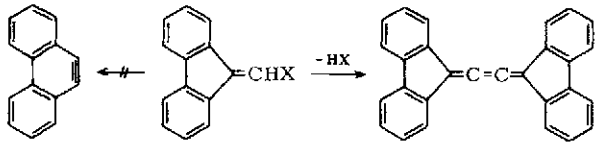
sequent carboxylation yields roughly equal amounts of diphenylacetylene and β-phenylcinnamic acid *(90)*, owing to competition between deprotonation and halogen-metal exchange [Equation (z)]. The halogen-free lithium compound is stable, and can therefore be converted into a derivative, while the metal compound *(91)* postulated as a primary product of metallation, rearranges instantaneously to diphenylacetylene, with elimination of LiBr [139].

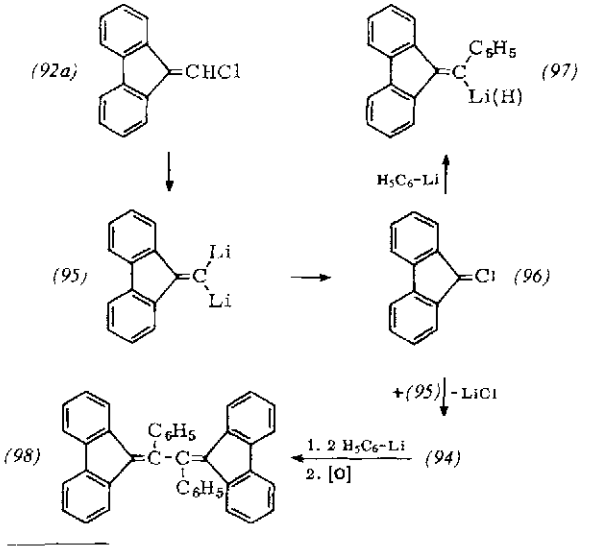
In accordance with the rule formulated by *Wittig*, replacement of bromine by chlorine in *(89)* leads predominantly to metallation (Route 2); with iodine instead of bromine in *(89)*, halogen-metal exchange (Route 1) predominates. The extent to which the reaction follows each of the two paths also depends on the organolithium compound, salt effects, and effects of the substituents on the aryl residue [139, 140]. The reaction of 1,1-diphenyl-2,2-dibromoethylene with phenyl-lithium can only proceed by Route 2, *via* halogen-metal exchange [140].

The interesting question of the extent to which linkage of the two aryl residues suppresses the Fritsch-Buttenberg-Wiechell rearrangement has been examined independently by two groups of workers [140, 141]. Rearrangement of 9-halogenomethylenefluorene *(92)* should lead to the highly strained compound 9,10-dehydrophenanthrene *(93)*; however, the reaction of *(92)*, X = Br, with potassamide in liquid ammonia leads to a 95 % yield of the cumulene compound *(94)*,



(93) *(92)* *(94)*

which was already known [142] and which is also the principal product of the reaction of *(92)* with phenyl-lithium in ether at −35 °C [140]. The reaction of 9-chloromethylenefluorene *(92a)* with phenyl-lithium



[139] *D. Y. Curtin* and *E. W. Flynn*, J. Amer. chem. Soc. *81*, 4714 (1959).

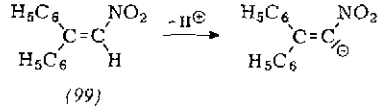
[140] *D. Y. Curtin* and *W. H. Richardson*, J. Amer. chem. Soc. *81*, 4719 (1959).

[141] *C. R. Hauser* and *D. Lednicer*, J. org. Chemistry *22*, 1248 (1957).

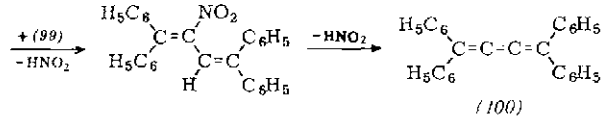
[142] *R. Kuhn* and *G. Platzer*, Ber. dtsch. chem. Ges. *73*, 1410 (1940).

yields only 18 % of 1,4-bis-*o,o'*-biphenylylbutatriene *(94)*, together with an approximately equal amount of 9-benzylidenefluorene *(97)* and a hydrocarbon of the supposed structure *(98)*; *(98)* may result from additon of two moles of phenyl-lithium onto *(94)*, followed by oxidation. The formation of the cumulene derivative *(94)* and of benzylidenefluorene *(97)*, is thought to be due to the carbene compound *(96)* [140, 141], which can add on phenyl-lithium or the metal compound *(95)* postulated as an intermediate.

1,4-Bis-*o,o'*-biphenylylbutatriene *(94)* could also be formed by an alternate route, such as that discussed for the formation of tetraphenylbutatriene *(100)* from 1,1-diphenyl-2-nitroethylene *(99)* with potassium t-butoxide. This route is easily understood from Equation (α) without further comment [143].

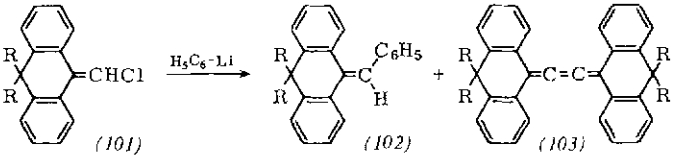


(99) (α)



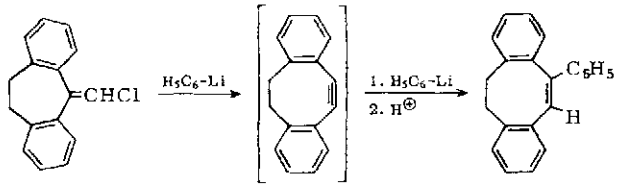
(100)

Phenyl-lithium reacts with 10,10-dialkyl-9-chloromethylene-9,10-dihydroanthracene *(101)* to form the hydrocarbons *(102)* and *(103)* which seem to have been formed in the same way as *(94)* and *(97)* from *(92a)* [140].



(101) *(102)* *(103)*

On the other hand, the seven-membered ring compound *(104)* does not give a cumulene derivative, but gives instead 3-phenyldibenzo[*a,e*]cycloocta-1,3,5-triene *(106)* the only product identified, in 23 % yield.



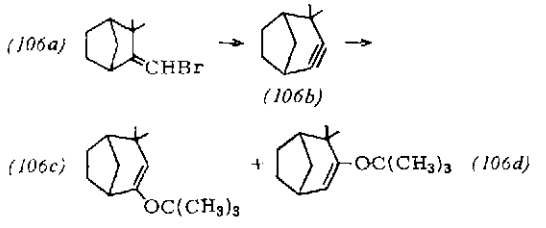
(104) *(105)* *(106)*

It appears that this system is already flexible enough to permit a Fritsch-Buttenberg-Wiechell rearrangement to occur. Dibenzo[*a,e*]cycloocta-1,5-dien-3-yne *(105)* formed in the first step is so reactive, because of ring strain (Section II.E) that it adds on phenyl-lithium across the triple bond [140].

β-Dialkylated halogeno-olefins are not known to undergo the Fritsch-Buttenberg-Wiechell rearrange-

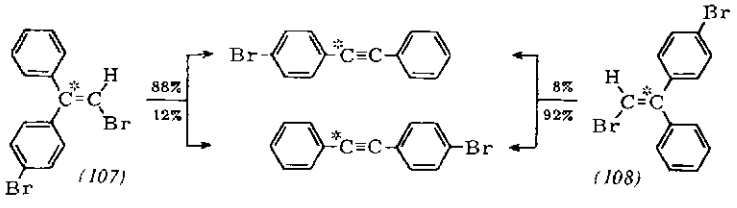
[143] *W. M. Jones* and *C. D. Broaddus*, J. org. Chemistry *26*, 2316 (1961).

ment. An exception is the bicyclic ω-bromocamphene *(106a)* which, using potassium t-butoxide in toluene, gives in high yield a mixture of the isomeric ethers *(106c)* and *(106d)*; the reaction involves ring enlargement, the strained compound *(106b)* probably being formed as an intermediate [143a].



b) *Mechanism*

In view of the experimental findings discussed above, it might appear that α-elimination proceeds *via* a carbene, which either undergoes the Fritsch-Buttenberg-Wiechell rearrangement as shown in Equation (x) or is stabilized by addition reactions. However, it appears from a number of observations that formation of carbenes does not occur during reactions where the rearrangement takes place. Thus, typical carbene reactions, such as their addition onto multiple bonds (*e.g.* in diphenylacetylene already formed by the reaction or in added olefins) or insertion reactions, are unknown [144]. It has also been shown that the rearrangement is stereospecific. Thus, the principal product obtained when *trans*-[2-^{14}C]-2-(*p* bromophenyl)-2-phenylvinyl bromide *(107)* is heated for 36 h with potassium t-butoxide in t-butanol is *p*-bromodiphenylacetylene in which the labelled carbon atom carries the bromophenyl residue, whereas the *cis*-isomer *(108)*, gives the same product with the phenyl residue attached to the radioactive carbon atom [145].

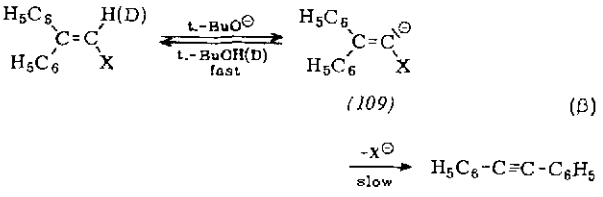


Essentially similar behavior is shown by the analogous chloro compounds on rearrangement with n-butyllithium in ether [128]. Thus, since the reaction is stereospecific, it cannot be due to a carbene which is symmetrical with respect to the olefinic axis.

The same isotope technique was used to show that, during α-elimination from 1-phenyl-1-(*p*-anisyl)-2-bromoethylene with sodium glycoxide, the anisyl group always migrates preferentially [146]. The greater tendency of the anisyl group to migrate has been confirmed by other experiments.

However, this experiment is not conclusive, since it has evidently not yet been checked whether partial isomerization of the substrate (which is quite possible at high temperatures) prior to elimination might not simply be simulating a uniform migration.

Eliminations in alkoxide/alcohol systems differ characteristically in their mechanism from those with lithium alkyls in ether. Kinetic measurements with potassium t-butoxide in t-butanol revealed an isotope exchange between the olefinic hydrogen of diphenylhalogenoethylenes and *O*-deuterated solvents, which is rapid in comparison with the rearrangement [122]. It can therefore be assumed (with the limitation discussed above, cf. Section III.A.2) that the rearrangement is preceded by rapid establishment of an acid-base equilibrium as indicated in Equation (β), and that the rearrangement is in fact that of the carbanion *(109)* [122].



The effect of the halogen atom on the rate of rearrangement at 95 °C decreases in the order Br > I ⋙ Cl; the opposing effects of bond strength and acidification of the vinyl hydrogen cause optimum reaction to occur with the bromo compound [122].

In the reaction of diarylhalogenoethylenes with butyllithium in ether, on the other hand, the rate-determining step is deprotonation [139], as evidenced by the lower rate of reaction of the deuterated ethylenes and by the fact that vinyl-lithium intermediates cannot be isolated. Consequently, it cannot be said with certainty whether the anion *(109)* postulated in Equation (β) (or the corresponding lithium compound) is in fact formed in this solvent, or whether the reaction is a multicenter concerted process with simultaneous deprotonation, elimination of halogen, and migration of the aryl residue [111].

As with the halogenoethylenes discussed above, the metallation is greatly accelerated by using n-butyllithium in the more strongly polar solvent, tetrahydrofuran and becomes the faster reaction step. The halogenovinyl-lithium compounds *(110)* can therefore be prepared and characterized as the carboxylation products *(111)* [147].

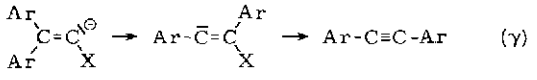
Lithium chloride is eliminated on heating, yielding the corresponding diarylacetylenes; this supplies conclusive proof that the rearrangement occurs in the (potential) carbanion [147].

To summarize: the Fritsch-Buttenberg-Wiechel rearrangement takes place in the vinyl anion; it does not proceed *via* a carbene intermediate, but is largely stereospecific, the group in the *trans*-position relative to the halogen migrating to the neighboring carbon atom; the rearrangement is intramolecular, since no symmetrical acetylenes are isolated when the starting materials contain dissimilar aryl substituents; the nature of the halogen atom has a decisive influence on the rate of the rearrangement.

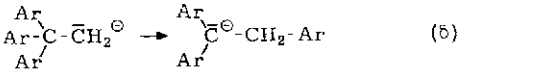
On the basis of these facts, two mechanisms are possible:

1. The migrating aryl group is transferred to the anionic vinyl carbon atom carrying the halogen atom by an intramolecular nucleophilic aromatic substitution; this results in displacement of the negative charge to the adjacent carbon atom. Halide is then eliminated in a secondary reaction [cf. Equation (γ)].



(γ)

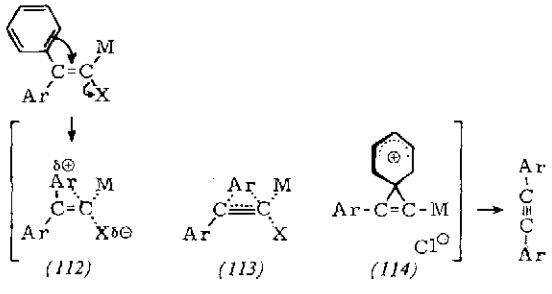
A parallel to this is the rearrangement of 1,1,1-triarylethyl anions [Grovenstein-Zimmerman rearrangement, see Equation (δ)] [148], although the driving force for



(δ)

this isomerization – namely greater stabilization of the resulting carbanion – can scarcely be effective in Reaction (γ) [*]. Moreover, on the basis of the observed effect of the halogeno substituent, it is necessary to make the improbable assumption that the elimination of halogen from the rearranged anion is rate-determining.

2. The halogen is eliminated from the anion with simultaneous migration of the aryl residue, possibly *via* transition or intermediate states such as *(112)–(114)*



(112) *(113)* *(114)*

[148] *H. E. Zimmerman* and *A. Zweig*, J. Amer. chem. Soc. *83*, 1196 (1961); *E. Grovenstein* and *L. P. Williams*, ibid. *83*, 412, 3537 (1961). The rearrangement does not always proceed intramolecularly, cf. *E. Grovenstein* and *G. Wentworth*, J. Amer. chem. Soc. *85*, 3305 (1963).

[*] It can be shown by deuterium exchange that a phenyl substituent does not appreciably acidify the hydrogen atom on an olefinic carbon atom to which it is attached. This can be explained by the fact that benzenoid and olefinic carbon atoms have the same hybridization [121].

[M = metal] which differ only in the extent to which the breaking and formation of bonds and the build-up of the electron doublet has advanced.

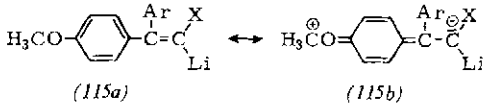
A mechanism of this type was postulated by *Bothner-By* in 1955 [145]. It requires that the aryl residue assumes a partial positive charge in the transition state, whereas it is negatively charged in Mechanism 1.

The question as to which mechanism is correct can be settled conclusively by introduction of substituents into the aryl residue: rearrangement by Mechanism 2 should be accelerated by electron-releasing substituents in the *o*- and/or *p*-positions, whereas that by Mechanism 1 should be retarded. It is found in confirmation of Mechanism 2, for instance, that the lithium compound *(110)*, Ar = C_6H_5, is still at least 83 % undecomposed after 1 h at −72 °C, whereas at least 91 % of its *p*-methoxy derivative *(110)*, Ar = *p*-CH_3O-C_6H_4, is rearranged. Furthermore, 88 % of *(110)* with Ar = *p*-Cl-C_6H_4 remains intact at −45 °C under conditions under which the unsubstituted derivative (Ar = C_6H_5) is completely decomposed [147, 149].

Mechanism 2 is also supported by kinetic measurements on various nuclear-substituted diarylhalogenoethylenes in the system t-butoxide/t-butanol [150] and ethoxide/ethanol [151] at elevated temperatures. However, here allowance must be made for the possible occurrence of side reactions and for the fact that nuclear substituents have a strong effect on the acidity of the vinyl protons [139, 147, 149] and hence, *via* the initial acid-base equilibrium [Equation (β)], on the steady-state concentration of vinyl anions.

All the experimental results obtained so far indicate that the aryl residue migrates with its bonding electron pair to the adjacent carbanion. The negative charge on the olefinic carbon atom evidently satisfies the condition for easy elimination of halogen.

The extent to which the migrating aryl residue favors the elimination in the sense of anchimeric assistance is not yet known. The great retendency of the *p*-methoxyphenyl compound *(110)* to undergo rearrangement compared to the unsubstituted compound can be explained, not only by a stronger neighboring-group effect of this substituent relative to phenyl, which is really quite plausible, but also because it imparts additional negative charge to the α-carbon atom as a result of resonance *(115a)* ↔ *(115b)* which is demonstrated



(115a) *(115b)*

by the greater difficulty of metallation of this compound compared to the simple phenyl derivative [147, 149]. The fact that the lithium derivative of *(116)* rearranges more slowly [149] and that in the ethoxide/ethanol system *(117)* rearranges more rapidly [152] than their respective stereoisomers may

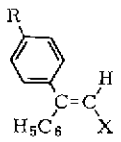
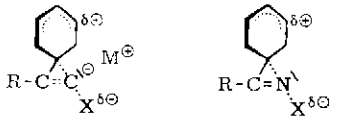
be due to active participation of the migrating aryl residue in the expulsion of halogen.



(116): R = X = Cl
(117): R = OCH_3; X = Br

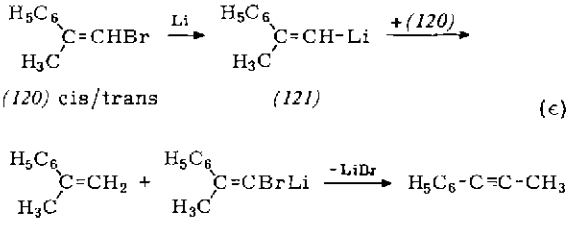
If an electromeric effect such as the mesomerism *(115a)* ↔ *(115b)* were the decisive factor, the opposite result would be expected. The neighboring-group effect should be weaker than in the formally comparable [145] first step of the Beckmann or Chapman rearrangement where a phenonium ion occurs as an intermediate [153], since the group $X^{\ominus}$ is probably more easily expelled from the carbanion *(118)* than from the uncharged nitrogen atom in *(119)*.



(118) *(119)*

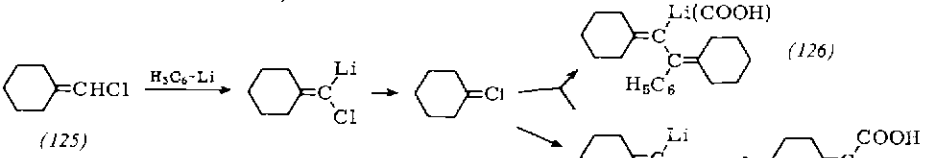
c) *Variants*

The production of disubstituted acetylenes *via* a rearrangement is also observed occasionally in the reaction of halogenated ethylenes with alkali metals, when an α-hydrogen atom is present. For example, *(120)* reacts with lithium in ether to yield equimolar quantities of methylphenylacetylene and α-methylstyrene [154]. It may be assumed that, owing to the difference in acidity between the halogenated and the non-halogenated olefin, the lithium compound *(121)* initially formed undergoes metal transfer with unreacted substrate *(120)* which then undergoes the Fritsch-Buttenberg-Wiechell rearrangement [Scheme (ε)].



(120) cis/trans *(121)* (ε)

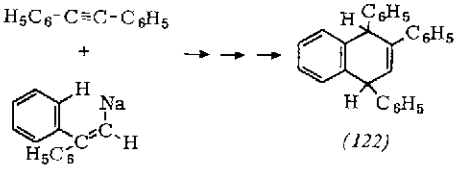
The olefins and acetylenes occurring as by-products in the reaction of β-halogenostyrenes [134] or 1-halogenopropenes with metals are probably formed in a similar manner,



(125)

although no definite conclusion can be reached at present owing to the presence of the β-hydrogen atom, and another mechanism has been proposed for the decomposition of the Grignard compound [155].

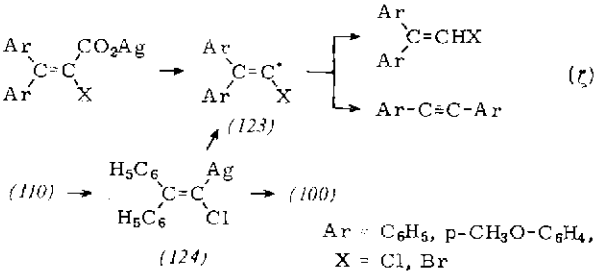
1,2,4-Triphenyl-1,4-dihydronaphthalene *(122)* is obtained on treatment of 1,1-diphenyl-2-bromoethylene with sodium in ether [156]. It is assumed that here the ring closure is due to addition of the metal compound onto diphenylacetylene formed analogously to the methylphenylacetylene in Equation (ε).



(122)

Attention is called in this connection to the formation of 1,2,3-triphenylnaphthalene by the action of lithium on diphenylacetylene; this reaction is related to the above with regard to the cyclization [157].

Rearrangement of the carbon skeleton is also observed on thermolysis of the potassium and silver salts of α-halogeno-β-arylcinnamic acids [158]. The thermolysis of the potassium salts proceeds *via* carbanions [cf. *(109)*], that of the silver salts possibly *via* free radicals *(123)* [Equation (ζ)] which are partly converted into ethylene by uptake of hydrogen, but which mainly undergo elimination of halogen to yield acetylenes.



(ζ)

(123)

(110) → *(124)* → *(100)*

Ar = C_6H_5, p-CH_3O-C_6H_4,
X = Cl, Br

The same products are obtained by decomposition of the silver compound *(124)*, which in turn is formed by metathesis of the lithium alkenyl *(110)* with AgCl at low temperatures; furthermore, up to 40% tetraphenylbutatriene *(100)* can also be isolated [159].

2. α-Elimination *via* Carbenes

With the exception mentioned in Section III.C.1.a, no rearrangement of β,β-dialkylhalogenoethylenes to dialkylacetylenes has so far been observed. As in the case of substrates with interlinked aryl residues, reactions

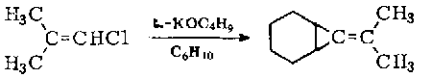
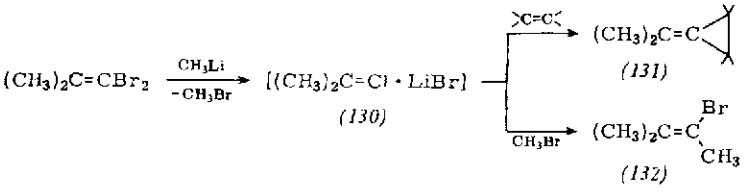
occur here which are compatible with the intermediate formation of carbenes. Treatment of chloromethylenecyclohexane *(125)* with phenyl-lithium in ether, followed by carboxylation, yields the acids *(126)* and *(127)* [160].

Compound *(129)* can be obtained in 8 % yield from 1-chloroisobutylene *(128)* and potassium t-butoxide in refluxing tetrahydrofuran in the presence of cyclohexane [161].



(128) *(129)*

One variant of the reaction *(128)* → *(129)* makes use of halogen-metal exchange between 1,1-dimethyl-2,2-dibromoethylene and methyl-lithium; with olefins, particularly vinyl ethers, the cyclopropane derivatives *(131)* are obtained, sometimes in good yield; these are always accompanied by bromotrimethylethylene *(132)* in a quantity inverse to the yield of cyclopropane.

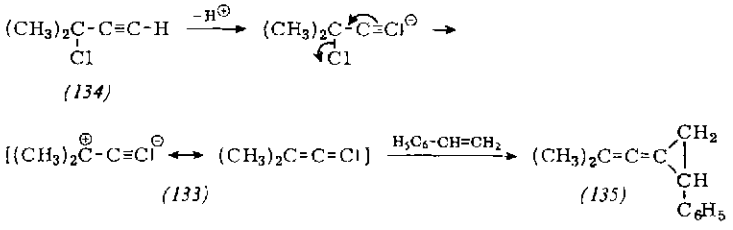


(130) *(131)* *(132)*

Whether, as has been suggested [162], both products are formed from the same intermediate *(130)*, which must then possess both electrophilic and nucleophilic properties, has not yet been settled, since other mechanisms are conceivable for the formation of *(132)*.

Apart from the fundamental objections which can be brought against the occurrence of carbenes in organometallic reactions [163], carbene reactions such as additions onto double bonds occur during α-elimina-

tions from olefins, as far as is known at present, only when isomerization by migration of a β-substituent (H or an aryl group) is not possible. 1,2-Shifts also predominate for aliphatic [164] and, in particular, for cyclopropyl compounds [165] and can be often more readily explained as reactions of the organometallic intermediate. The formation of carbene is facilitated here, as with haloforms, by hetero-substituents which permit resonance stabilization of the electron sextet ($X-\dot{\underset{|}{C}} \leftrightarrow {}^{\oplus}X = \dot{\underset{|}{C}}^{\ominus}$) [166]. Among the olefins, a similar stabilization is possible with the allenecarbenes. This is probably the reason for the ease of formation of *(133)* by γ-elimination on treatment of 3-chloro-3-methylbut-1-yne *(134)* with bases [166a]; *(133)* can be isolated in 48 % yield by trapping it with styrene as the cyclopropane derivative *(135)*.



(134) *(133)* *(135)*

The same product was obtained from 1,1-dimethyl-3-chloroallene — which is isomeric with *(134)* — by reaction of potassium t-butoxide in the presence of styrene [168].

Similarly, the adduct *(137)* is obtained on treating *(136)* with acetic anhydride and potassium hydroxide in absolute ether in the presence of styrene [167]; in the absence of styrene a dimer, tetraphenylhexapentaene *(138)*, is formed [169].

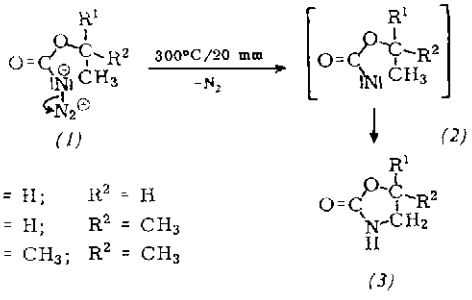
Pyrolysis of Alkyl Azidoformates in the Gas Phase [1]

By Dr. R. Kreher and Dipl.-Ing. D. Kühling

Institut für Organische Chemie der Technischen Hochschule Darmstadt (Germany)

Photolysis or thermolysis of alkyl azidoformates *(1)* causes elimination of nitrogen leading to alkoxycarbonylazenes *(2)*, which insert themselves into C–H bonds or dehydrogenate the solvent to form the corresponding alkylurethanes [2]. In order to avoid these secondary reactions, we investigated the pyrolysis of alkyl azidoformates in the gas phase in the presence of nitrogen as inert diluent. At 300 °C/20 mm, the ethyl, isopropyl, and t-butyl esters *(1a)*–*(1c)* release nitrogen to form oxazolidones *(3)* in yields of 45–75 %.



(1) *(2)* *(3)*

(a), R^1 = H; R^2 = H
(b), R^1 = H; R^2 = CH_3
(c), R^1 = CH_3; R^2 = CH_3

When ethyl azidoformate was thermolysed in carbon tetrachloride or 1,1,2-trichlorotrifluoroethane, it is not the oxazolidone *(3a)* that is formed [2a]; instead, two molecules of the azido ester interact with loss of nitrogen to form diethyl azodicarboxylate [2a, 3]. This compound could not so far be detected during pyrolysis in the gas phase. We assume that the concentration of *(1)* and *(2)* in the gas phase is so small as a result of the dilution with nitrogen that the dimerization observed in solution cannot occur [4].

In contrast, t-butyl azidoformate *(1c)* reacts exclusively intramolecularly to form the oxazolidone *(3c)* in solution as well. It seems that the t-butyl group shields the azene nitrogen and that the close proximity of the methyl group promotes the cyclization [2a, 2b].

According to *Smolinsky* and *Feuer* [5], thermal decomposition of (*S*)-2-methylbutyl azidoformate in the gas phase yields 4-ethyl-4-methyl-2-oxazolidone. The configuration of the asymmetric carbon atom remains unchanged during this reaction.

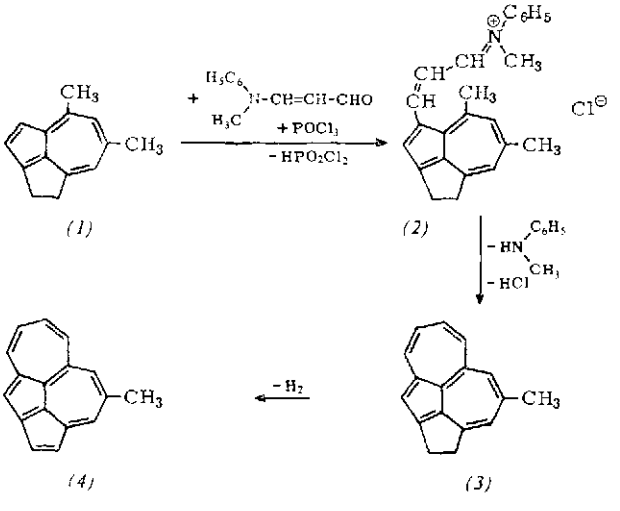
Pentaleno[2,1,6-def]heptalene – a Non-benzenoid Isomer of Pyrene

By Prof. Dr. K. Hafner, Dipl.-Chem. R. Fleischer, and K. Fritz

Institut für Organische Chemie der Universität München (Germany)

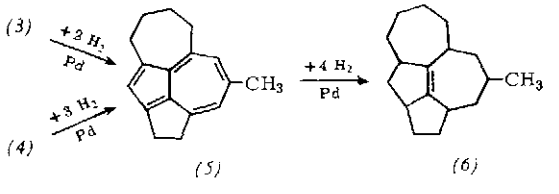
Polycyclic conjugated non-benzenoid hydrocarbons are of great theoretical interest in connection with the question of the relationships between structure and aromaticity [1].

Starting from 4,6-dimethyl-1,8-cyclopentenoazulene *(1)* [2], we have prepared a non-benzenoid isomer of methylpyrene, *viz.* the tetracyclic hydrocarbon *(4)*, which can formally be viewed as consisting either of a pentalene and a heptalene system or of two azulene systems. Moreover the structural elements of sesquifulvalene and heptafulvene are recognizable. Hydrocarbon *(1)* reacts with *N*-methylanilinoacrolein in the presence of phosphorus oxide chloride at 20 °C to form the immonium salt *(2)* in 90 % yield; the perchlorate of *(2)* forms dark violet crystals which decompose above 260 °C. When *(2)* is heated with sodium methoxide in boiling methanol, it loses a molecule of *N*-methylaniline and undergoes intramolecular condensation to give *(3)*, m.p. 62–63 °C, in 35 % yield; the trinitrobenzene π-complex of *(3)* melts at 196 °C. Dehydrogenation of *(3)* with chloranil in benzene at 20 °C produces a 65 % yield of *(4)* as thermostable black needles, m.p. 109 °C, which



(1) *(2)* *(3)* *(4)*

dissolve in organic solvents to give wine-red solutions which exhibit a green fluorescence. The electronic spectrum of *(4)* in n-hexane has maxima at 255 (log ε = 4.55), 262 (4.57), 284 (4.75), 291 (4.83), 317 (4.24), 367 (3.55), 382 (3.61), 396 (3.38), 405 (3.35), 421 (3.58), 449 (3.76), 504 (2.74), 539 (3.00), 582 (3.11), 710 (2.08), and 813 mμ (1.70). Its NMR spectrum contains a multiplet for the 9 ring protons at 1.5–3.3 τ in addition to a singlet for the methyl protons at 7.25 τ. Compound *(4)* forms a π-complex with trinitrobenzene of m.p. 209 °C. When hydrogenated at normal pressure it absorbs 3 moles of hydrogen to form the azulene derivative *(5)* as



(3) *(4)* *(5)* *(6)*

blue-green needles, m.p. 64 °C; the trinitrobenzene derivative of *(5)* melts at 139 °C. Reduction of *(3)* also gives rise to *(5)*. Further catalytic hydrogenation of *(5)* at normal pressure leads to an uptake of 4 moles of hydrogen, presumably to yield the hydrocarbon *(6)*, whose double bond can be detected with bromine or tetranitromethane. Although *(4)* is a cyclic conjugated system with $4n$ π-electrons ($n = 4$), it is surprisingly inert toward electrophilic reagents. It dissolves in 70 % perchloric acid and can be recovered unchanged from the solution by dilution at 0 °C.

Synthesis of Olefins from Sulfenes and Diazoalkanes via Episulfones

By Priv.-Doz. Dr. G. Opitz and Dipl.-Chem. Klaus Fischer

Chemisches Institut der Universität Tübingen (Germany)

Diazomethane and sulfur dioxide react to form ethylene sulfone [1], which yields ethylene by elimination of SO_2. The reaction of higher diazoalkanes and sulfur dioxide leads via the corresponding episulfones to symmetrically substituted olefins [2].

We have now found that sulfenes $R^1-CH=SO_2$ [3], which are produced by dehydrochlorination of primary alkanesulfonyl chlorides with triethylamine, react readily *in situ* with diazoalkanes at 0 °C to form isolable episulfones *(1)*. Thermal elimination of SO_2 from the latter produces unsymmetrically substituted olefins *(2)* in good yields.

	R^1	R^2	R^3	Yield [%]	M.p. [°C] (B.p. [°C/mm])
(1a)	H	H	H	64	19
(1b)	C_2H_5	H	H	95	(80/0.2; decomp.)
(1c)	C_6H_5	H	H	35	39 (decomp.)
(2c)	C_6H_5	H	H	67	
(1d)	$C_6H_5CH_2$	H	H	99	49—51
(2d)	$C_6H_5CH_2$	H	H	97	(44/10)
(2e)	$C_6H_5CH_2$	H	CH_3	91	(62/10)
(1f)	$C_6H_5CH_2$	CH_3	C_2H_5	76	77—78
(1g)	7,7-Dimethyl-2-oxobicyclo-[2,2,1]hept-1-yl	H	H	94	83—85
(2g)		H	H	74	63 - 64
(1h)		H	CH_3	36	77—79
(2h)		H	CH_3	64	(62/0.02)
(2i)		CH_3	C_2H_5	71	(67/0.02)

When phenylethanesulfonyl chloride is added slowly to a solution of diazomethane and triethylamine cooled in ice, triethylamine hydrochloride is precipitated with simultaneous evolution of nitrogen, and allylbenzene episulfone *(1d)* is formed. The solution is filtered at room temperature and the ether evaporated from the filtrate leaving 99 % *(1d)* as colorless crystals, m.p. 49—51 from petroleum ether, which release SO_2 slowly at room temperature and rapidly on heating to 80 °C to afford a 97 % yield (based on the original sulfonyl chloride) of allylbenzene *(2d)*. The episulfones *(1a)*, *(1b)*, *(1c)*, *(1d)*, *(1f)*, *(1g)*, and *(1h)* have bands in the infrared at 3080 cm^{-1} due to the C—H vibration from the three-membered ring and intense sulfone bands at 1160 and 1305 cm^{-1}.

The olefin forms without isomerization, even when — as in the examples *(2d)—(2f)* — isomerization would lead to an increase in conjugation and hence in resonance energy. The synthesis of olefins by this method may be of preparative use. This is shown by the reaction of the readily available D-camphor-10-sulfonyl chloride to give the 10-alkylidene derivatives *(2g)—(2i)* of camphor whose synthesis by other methods is probably extremely difficult.

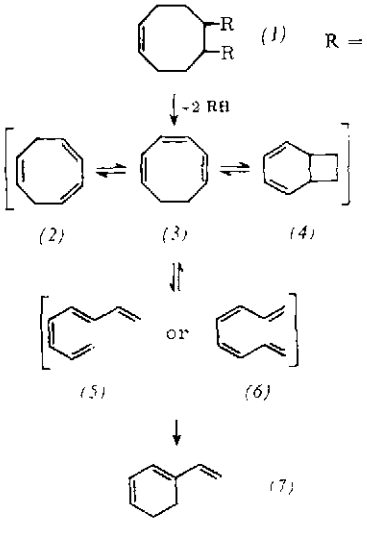
Preparation of 1-Vinylcyclohexa-1,3-diene from 5,6-Diacetoxycyclooctene

By Dr. W. Ziegenbein [*]

Wissenschaftliche Abteilung der Chemischen Werke Hüls AG., Marl/Westfalen (Germany)

Following pyrolysis of 5,6-diacetoxycyclooctene *(1)*, b.p. 103—105 °C/1.5 mm, $n_D^{20} = 1.4731$, at 500 °C/20 mm under nitrogen, refinement of the products by distillation affords a hydrocarbon fraction, b.p. 47 °C/20 mm, $n_D^{20} = 1.5400$, in about 50 % yield which consists mainly of an olefin of the composition C_8H_{10} and a little styrene. The olefin can be isolated in about 40 % yield based on *(1)* by chromatography with n-pentane on a cloumn (2 m long) of Al_2O_3. This hydrocarbon ($n_D^{20} = 1.5377$) is colorless, is polyunsaturated, and polymerizes readily when pure; it is not 1,3,6-cyclooctatriene *(2)*, 1,3,5-cyclooctatriene *(3)*, bicyclo[4,2,0]-octa-2,4-diene *(4)* [1], *trans,trans*-1,3,5,7-octatetraene [2], nor *cis,trans*-1,3,5,7-octatetraene *(5)* [3]. Its elemental composition, its ultraviolet, infrared, NMR, and mass spectra, its oxidative degradation, and its hydrogenation to ethylcyclohexane identify the compound as the hitherto unknown 1-vinylcyclohexa-1,3-diene *(7)*, $\lambda_{max} = 288$ ($\varepsilon = 8340$), 298 (8420), and 310 mμ (4980) in isooctane.

The results of the pyrolysis of the diacetate *(1)* can be explained by intermediate formation of the valence-bond isomers *(2)* or *(3)* or of *(4)*, which is in equilibrium with these two, and of *cis,trans*- *(5)* or *cis,cis*-1,3,5,7-octatetraene *(6)* [4].



The formation of styrene can be explained by dehydrogenation of *(7)*, probably *via* ethylbenzene as isomerization product.

Compound *(7)* is also produced in 15% yield alongside a 1,2-trimethylenecyclopentadiene on pyrolysis of 2,3-diacetoxybicyclo[3,3,0]octane, b.p. 96–96.5 °C/1 mm, $n_D^{20} = 1.4647$.

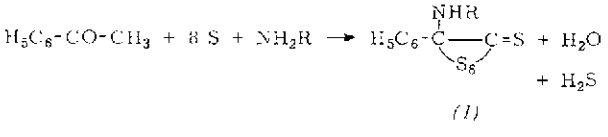
Synthesis and Elucidation of the Structures of 7-Alkylamino-7-phenyl-8-thioxo-1,2,3,4,5,6-hexathiocanes

By Prof. Dr.-Ing. F. Asinger, Dr. W. Schäfer, and Dipl.-Chem. H.-W. Becker

Institut für Technische Chemie
der Technischen Hochschule Aachen (Germany)

Elemental sulfur and primary amines react with acetophenone in methanol [1] at room temperature to yield 7-alkylamino-7-phenyl-8-thioxo-1,2,3,4,5,6-hexathiocanes *(1)* [see Table 1]. All the hexathiocanes are stable, intensely



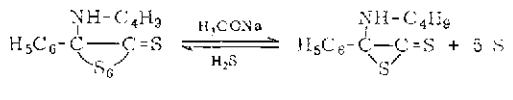
(1)

Table 1. 7-Alkylamino-7-phenyl-8-thioxo-1,2,3,4,5,6-hexathiocanes *(1)*.

Compound	R	M.p. [°C]	Yield [%]
(1a)	CH_3	145–146	22
(1b)	C_2H_5	139	18
(1c)	n-C_3H_7	139	11
(1d)	i-C_3H_7	140	10
(1e)	n-C_4H_9	109–110	20

yellow, crystalline compounds; they are also formed from acetophenone imines, sulfur and amines.

The constitution of the hexathiocanes has been proved unequivocally by degradation experiments with *(1e)* and by nuclear magnetic resonance studies of *(1a)* [2]. The NMR spectrum of *(1a)* [3] contains three proton signals: the signal from the monosubstituted benzene ring at $\delta = -0.1$ ppm, the peak for the secondary amino group at $\delta = 1.1$ ppm, and the signal for the methyl protons at $\delta = 4.5$ ppm, which is split into a doublet, indicating that the methyl group is directly adjacent to the hydrogen atom of the secondary amino group. Since desulfurizing hydrogenation of *(1e)* with Raney nickel



(1e) *(2)*

at room temperature affords n-butyl-1-phenylethylamine [4], the position of the nitrogen atom in the molecule is assured. Reduction of *(1e)* with hydrogen sulfide in the presence of amines [5] yields bis-(2-phenylethyl) polysulfide, and treatment of *(1e)* with sodium methoxide in methanol causes elimination of elemental sulfur produce 2-n-butylamino-2-phenyl-3-thioxothiirane *(2)*, which can be "resulfurized" with hydrogen sulfide and sulfur to reform *(1e)*.

Gas-Chromatographic Separation and Estimation of Aliphatic Monocarboxylic Acids with 1—5 Carbon Atoms

By Dr. H. J. Langner [1]

Institut für Lebensmittelhygiene
der Freien Universität Berlin (Germany)

Quantitative separation and estimation of formic acid and acetic acid mixed with aliphatic monocarboxylic acids containing 3–5 carbon atoms involve considerable difficulties.

We have now succeeded in separating and estimating these acids by gas chromatography in the form of their amyl esters. About 100 mg of the free acids are weighed into a 10 ml measuring flask with a standard ground-glass joint, and 3 ml of diethyl ether, 0.1 ml of boron trifluoride, and an equimolar (based on the free acids) amount of 1-pentanol are added; the flask is attached to a Dimroth condenser 50 cm long and heated in an air-bath until the first white vapors of BF_3 appear. The solution, which contains a quantitative yield of the amyl esters [2] is cooled to room temperature and filled up to the mark with ether. The solution is dried over anhydrous sodium sulfate plus sodium hydrogen carbonate and is then ready for chromatographic analysis.

The analysis was conducted with a 50 m capillary band column filled with Apiezon L grease in a Perkin-Elmer F 6/4 HF Fraktometer. The working temperature was 100 °C and the rate of gas flow was 1 ml of helium per minute. One microliter samples were injected at a separating factor of 1:100.

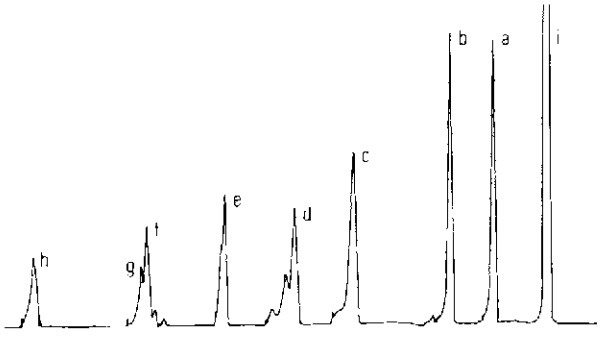

Fig. 1. Gas chromatogram of the amyl esters of: a = formic acid, b = acetic acid, c = propionic acid, d = isobutyric acid, e = n-butyric acid, f = isovaleric acid, g = 2,2,2-trimethylacetic acid, and h = n-valeric acid; i = diethyl ether (solvent).

A flame ionization detector was used on account of the extremely minute amounts of material to be expected from biological materials; the detector sensitivity was X:4 and R:1. The temperature of the injection block, the detector leads, and the standard gas outlet was 300 °C.

The recorder was a Siemens Elektronenkompensograph with a speed of 1 cm/min. By utilizing the complete sensitivity of the apparatus, quantities of acid down to 0.1 ng (10^{-10} g) can be detected; by concentrating the ether solutions (the esters boil at 110 °C and higher) and by decreasing the separating factor to 1:5–1:10 amounts down to 10^{-12} g can be measured. Figure 1 shows a typical gas chromatogram.

A mean error of ± 2.5 % was observed in six acetic acid analyses with samples weighing 100.5–207.9 mg; for ten injections of 207.0 mg of acetic acid, 207.16 ± 0.1 mg was recovered.

Received, November 9th, 1964 [Z 861/687 IE]
German version: Angew. Chem. 77, 95 (1965)

[1] We are indebted to *E. Malek*, Berlin, for carrying out the analyses.

[2] Excess amyl alcohol is used for the esterification of biological material. Amyl alcohol recurs as an unsymmetrical band between acetic acid and propionic acid and does not interfere.

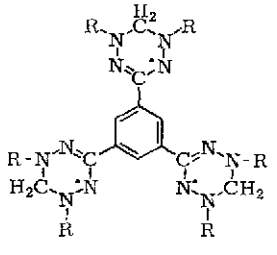
A Stable Triradical [*]

By Prof. Dr. Richard Kuhn, Dr. F. A. Neugebauer, and H. Trischmann

Institut für Chemie, Max-Planck-Institut
für Medizinische Forschung, Heidelberg (Germany)

The ease of formation and stability of the verdazyls [1] has made it possible to secure a compound with three unpaired electrons per molecule. 1,3,5-Triformylbenzene was converted *via* its trisphenylhydrazone with crystalline benzenediazonium chloride in pyridine into its extremely insoluble red trisformazan, which decomposes explosively at 272 to 273 °C.

A suspension of this derivative in dimethylformamide (DMF) reacted with BaO plus $Ba(OH)_2$ and methyl iodide [1] to form the deep green triradical 1,3,5-tris-(1,5-diphenylverdazyl-3-yl)benzene *(1)*, which contains ten six-membered rings (7 benzene rings and 3 heterocycles) in conjugation, and which crystallizes from DMF/methanol as almost black prisms which decompose at 242–243 °C.



(1), R = C_6H_5

On catalytic hydrogenation over $Pd/BaSO_4$ in DMF, *(1)* rapidly absorbs 1.48–1.50 moles of hydrogen (calc. 1.50 moles). Its molar extinction in DMF (ε = 12500 at λ_{max} = 721 mμ) is almost three times as large as that of 1,3,5-triphenylverdazyl (ε = 4400 at λ_{max} = 720 mμ).

The paramagnetic susceptibility μ_{eff}/μ_B of *(1)* – calculated for three non-coupled unpaired electrons it should be $\sqrt{9} = 3$ – was measured with the magnetic balance and was found to be 2.96 ± 0.06 at 298 °K, 2.97 at 195 °K, and 3.02 at 77 °K. Its ESR spectrum – like that of 1,3,5-triphenylverdazyl – extends over 50 gauss [2]. The fact that the hyperfine structure of *(1)* is not resolved – in contrast to that of 1,3,5-triphenylverdazyl with 9 lines at 6-gauss intervals in intensity ratios of 1:4:10:16:19:16:10:4:1 – is considered to be due to interaction between the spins of the free electrons.

The measurements revealed that the three unpaired electrons in the π-electron system of the triradical are practically free from coupling (↑ ↑ ↑) in the magnetic field of over 3000 gauss used.

In contrast to the biradicals porphyrindin [3] and nitrosoindigo [4] whose paramagnetism decreases with decreasing temperature, the electrons in the triradical *(1)* remain unpaired down to 77 °K, although mesomeric forms of a zwitterionic monoradical can be written in which the spin concentration of the substance would be reduced to one-third (↑ ↓ ↑).

The Crystal Structure of Nitrogen Selenide

By Dr. H. Bärnighausen, Dipl.-Chem. T. von Volkmann, and Prof. Dr. J. Jander [1]

Chemisches Laboratorium der Universität Freiburg/Brsg.
and Anorganisch-Chemisches Laboratorium
der Technischen Hochschule München (Germany)

In continuation of our studies on the crystal structure of nitrogen selenide [2], we have now succeeded in interpreting its three-dimensional Patterson synthesis. The resultant structural model – which is presently being refined – gave a reliability index of 13 % for the 536 X-ray diffraction lines observed and therefore seems sufficiently well established.

Nitrogen selenide consists of discrete N_4Se_4 molecules. Although nitrogen sulfide N_4S_4 [3] and N_4Se_4 are not isotypic, there is great similarity between the molecular geometries of the two compounds. Thus, for example, as in N_4S_4, the nitrogen and selenium atoms in N_4Se_4 are in an alternating sequence and assume the boat form of a strongly puckered eight-membered ring, whose symmetry can be described in good approximation by the symbol $\bar{4}2m$. The four nitrogen atoms in the eight-membered ring almost form a square with N–N distances of 2.82 Å, and the four selenium atoms are situated at the corners of a slightly deformed tetrahedron. The distances between selenium atoms separated by a nitrogen atom are 2.97 Å on the average, while those situated diagonally opposed in the eight-membered ring are only 2.76 Å apart. This distance is very much shorter than the effective diameter of selenium atoms held together by van der Waals forces. It follows that the molecule must be subject to a strong geometric strain, which may afford an explanation for the tendency of nitrogen selenide to explode. The average value for the length of the Se–N bonds is 1.80 Å and thus corresponds roughly to the sum of the respective covalent radii [r(Se) + r(N) = 1.14 + 0.7 = 1.84 Å]. The N–Se–N bond angle is 103 ° and the Se–N–Se bond angle is 111 °.

The arrangement of the N_4Se_4 molecules in the crystal lattice is approximately that of a hexagonal closest packing. The hexagonal pseudo-cell has the lattice constants a ≈ 10 Å and c ≈ 5.9 Å and is oriented in such a way relative to the monoclinic unit cell that the c axis coincides with the direction [$\bar{1}$12], and the hexagonal basis lies approximately in the ($\bar{1}$11) plane, which is the main limiting surface of the platelet single crystals. The c/a ratio of 1.7 agrees well with the theoretical value of 1.633 for hexagonal closest packing. However, the base of the pseudo-cell has a considerable deformation, which is most probably due to relatively strong intermolecular

interactions, since the distances between the Se and N atoms in neighboring molecules is shorter by 0.2 Å on the average than the sum of the corresponding van der Waals radii.

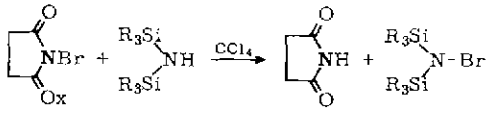
N-Bromohexamethyldisilazane [1]

By Dr. N. Wiberg and Dipl.-Chem. F. Raschig

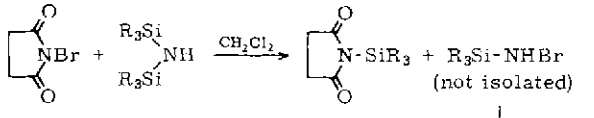
Institut für Anorganische Chemie
der Universität München (Germany)

N-Bromohexamethyldisilazane *(1)* is formed in about 60 % yield from *N*-bromosuccinimide at temperatures between 0 and 25 °C. Surprisingly, no *(1)* is formed in acetone or



R = CH_3 *(1)*

methylene chloride; instead, cleavage of the Si–N bonds occurs, and *N*-trimethylsilylsuccinimide *(2)* is produced in 50–70 % yield.



R = CH_3 *(2)*

N-Chlorosuccinimide and *N*-iodosuccinimide react with hexamethyldisilazane even in carbon tetrachloride to yield *(2)*. The *N*-chlorohexamethyldisilazane [2] to be expected is not formed; however, a little *N*-iodohexamethyldisilazane [3,4] could be detected in the reaction mixture together with nitrogen triiodide.

These results lead to the conclusion that *(2)* is probably formed by cationic exchange of the bromine for the trimethylsilyl group, whereas the formation of *(1)* – by analogy to allyl bromination by *N*-bromosuccinimide [5] – proceeds via a radical mechanism.

Compound *(1)* is a yellow-brown liquid, b.p. (extrapolated) 176 °C/760 mm, which smells rather like bromine; it has log p [mm] = −2326/T + 8.060, a Trouton constant of 23.7 cal/mole/°C, a heat of evaporation of 10.6 kcal/mole, $d^{21} = 1.13$, and $n_D^{21} = 1.4580$. It is thermally more stable than *N*-chlorohexamethyldisilazane [2], but both compounds have similar chemical properties.

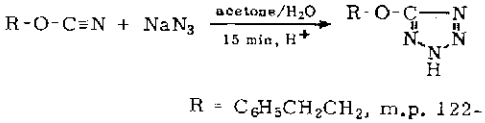
Addition Reactions of Cyanic Esters

By Dr. D. Martin, Dipl.-Chem. H.-J. Herrmann, cand. chem. S. Rackow, and K. Nadolski

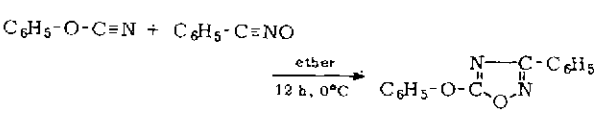
Institut für Organische Chemie der Deutschen Akademie der Wissenschaften zu Berlin, Berlin-Adlershof (Germany)

The cyanic esters recently described [1,2] are characterized by the high reactivity of their C≡N group. Reactions which occur with nitriles only under drastic conditions and on prolonged heating proceed very readily, sometimes even in the cold, with these esters, as can be seen from the following survey. On account of their strong dehydrating action, cyanic esters ought to be of interest as agents for eliminating water in acylation and phosphorylation reactions.

1. *Cycloadditions*



R = $C_6H_5CH_2CH_2$, m.p. 122–124 °C, 36%
R = C_6H_5, m.p. 37–138 °C, 93%



m.p. 52–54 °C, 30%

2. *Addition of amines*

R	R^1	R^2	M.p. [°C]	Yield [%]
C_6H_5	C_6H_5	H	104–105	47
C_6H_5	$-(CH_2)_2-O-(CH_2)_2$	–	66–67	95

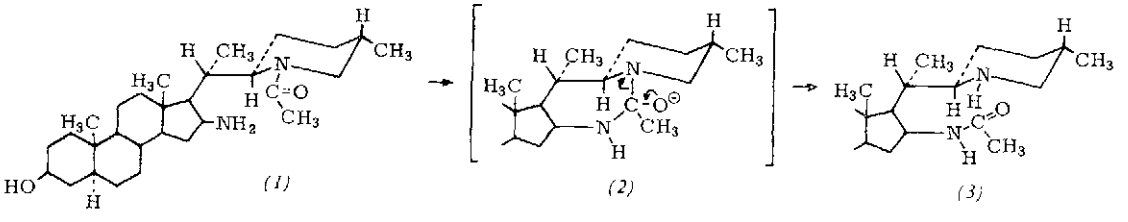
1,4-N → N′-Acyl Migration in a Diamino Steroid [1]

By Dr. G. Adam and Dr. habil. K. Schreiber

Institut für Kulturpflanzenforschung Gatersleben der Deutschen Akademie der Wissenschaften zu Berlin (Germany)

Up to the present, intramolecular $N \rightarrow N'$-acyl migrations have been observed only in simple ethylene diamine derivatives [2] and in 3,8-diazabicyclo[3,2,1]octanes [3]. These examples are all 1,2-diamino compounds.

We have now found that (22*R*,25*S*)-16β-amino-22,26-acetimino-5α-cholestan-3β-ol *(1)* [4] gives rise to a new amino steroid with $R_F = 0.11$ [4] when heated for 30 h at 110 °C with 6.7 N HCl in absolute ethanol in a sealed tube; the new product was separated from unchanged *(1)* by fractional crystallization of the hydrochlorides from methanol/acetone.



The new hydrochloride, m.p. 320–323 °C (decomp.), is less soluble and is obtained in 56 % yield; it has the same elemental composition $C_{29}H_{50}N_2O_2 \cdot HCl$ as the hydrochloride of *(1)*, m.p. 278–281 °C (decomp.). The free base has a double melting point (164–167 and 230–232 °C) and $[\alpha]_D^{19} = +26.8°$; its infrared spectrum contains bands at 1550 and 1651 (secondary amide), 3265 (secondary amine), 3305 (secondary amide), 3395 and 3450 cm^{-1} (hydroxyl). From this it follows that *(1)* is not hydrolysed to the diamine by the ethanolic hydrogen chloride; instead, the acetyl residue migrates from the secondary to the primary amino group to form *(3)*. This is confirmed by the molecular mass spectrum of the free amine *(3)*.

The reaction probably proceeds via a seven-membered cyclic transition state *(2)*. It appears that the peculiar steric arrangement in the region of the two nitrogen atoms brings the reaction centers involved into close proximity. At present it cannot be decided whether and to what extent differences in the basicity or nucleophilicity of the two nitrogen atoms are of importance. Measurements of the apparent acidity constants [5] of *(1)* and *(3)* gave $pK^*_{MCS} = 9.22$ and 9.06, respectively, *i.e.* there is a relatively small difference in basicity. Attempts to effect the reverse acyl migration *(3)* → *(1)* by means of alkali or thermal treatment were without success.

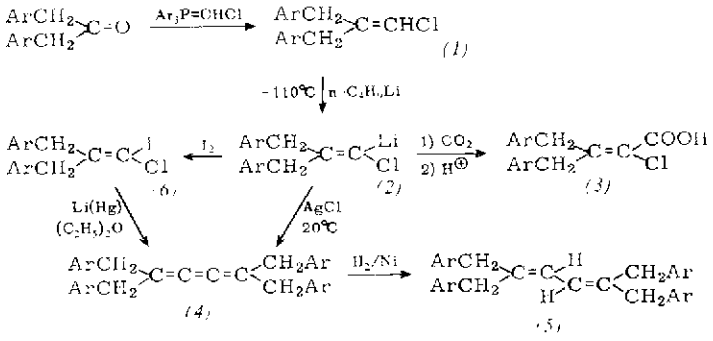
Tetrabenzylbutatriene (1,6-Diphenyl-2,5-dibenzylhexa-2,3,4-triene) [1]

By Doz. Dr. G. Köbrich and W. Drischel [1a]

Organisch-Chemisches Institut
der Universität Heidelberg (Germany)

On account of their tendency to polymerize and of their sensitivity towards alkalies and acids, benzylcumulenes could not be obtained to date by any of the known cumulene syntheses [2]. We have now obtained tetrabenzylbutatriene *(4)* in the following way. Chloromethylenation [3] of dibenzyl ketone gives a 55 % yield of pure 1,1-dibenzyl-2-chloroethylene *(1)*, b.p. 135–137 °C/0.2 mm, $n_D^{20} = 1.5722$. Metallation of *(1)* with n-butyl-lithium at −110 °C [4] leads almost exclusively to 2,2-dibenzyl-1-chlorovinyl-lithium *(2)*, despite the presence of acidic benzyl/allyl hydrogens in the molecule, for carboxylation of the metallation product led to the acid *(3)*, m.p. 111 °C, which was isolated in 92 % yield; the structure of the acid *(3)* was proved by its NMR spectrum and other properties. When *(2)* was allowed to warm up to room temperature in the presence of an equimolar amount of silver chloride, a 69 % yield [based on *(1)*] of pure *(4)* was obtained. This compound is stable in the solid state and is

relatively insensitive to heat; it melts at 121–122 °C. However, it polymerizes rapidly in solution, *e.g.* on attempts to crystallize it from cyclohexane without exclusion of oxygen.



Ar = C_6H_5

The proof of the structure *(4)* is based on its molecular weight, ultraviolet spectrum (λ_{max} = 274.5 mμ, log ε = 4.40 in cyclohexane), and NMR spectrum which contains no signals for olefinic protons but only peaks for aromatic protons and for a single species of aliphatic protons at −3.2 ppm (tetramethylsilane as standard). The ratio of aromatic to aliphatic protons is 5:2.

Catalytic hydrogenation of *(4)* over Raney nickel afforded an oil plus tetrabenzylbutadiene *(5)* [m.p. 154–154.5 °C, main peak in the ultraviolet λ_{max} = 253 mμ, log ε = 4.51], whose NMR spectrum indicates olefinic protons by a sharp signal at −6.35 ppm; the ratio of aromatic:aliphatic:olefinic protons is 10:4:1.

Another synthesis of tetrabenzylbutatriene *(4)* proceeds by way of 1,1-dibenzyl-2-chloro-2-iodoethylene *(6)*, m.p. 54 °C, which is obtained in 97 % yield from *(2)* with iodine. When shaken with lithium amalgam in diethyl ether at room temperature, *(6)* dimerizes by α-elimination to form *(4)*.

CONFERENCE REPORTS

VIth International Congress of Biochemistry

The Congress was held from July 26th to August 1st, 1964 in New York. The results presented in over 600 plenary and symposium lectures and research reports combined to form an impressive mosaic representing the current status of biochemistry. In particular, the advances made in the chemistry and biochemistry of nucleic acids and proteins and, in this connection, in genetics and in evolutionary research became most evident. In the following report, an attempt is made to summarize some of the most remarkable results.

Nucleic Acids

P. Berg (U.S.A.) reported on the concentration of specific species of t-RNA [1] from *Escherichia coli*. Gradient partition chromatography on columns (1–4 m long) of dextran gel using solvent systems containing aqueous potassium phosphate, ethoxyethanol, butoxyethanol, and triethylamine led to three- to sevenfold enrichment. At the same time, t-RNA species of the same specificity were separated. A second approach involved enzymatic loading of the desired t-RNA with an amino acid, oxidation of unloaded t-RNA chains with periodate, and separation of the products on a column of aminoethyldextran. Depending on the purity of the starting material, five- to sevenfold concentration of valine-specific t-RNA was achieved. Since the losses of t-RNA incurred are only small, both processes can be applied in series.

M. Staehelin (Switzerland) chromatographed the products of hydrolysis of crude yeast t-RNA with pancreas RNase and obtained di- and trinucleotides containing the following unusual nucleosides: 1-methylguanosine, 2-methylguanosine, 2,2-dimethylguanosine, inosine, 6-methyladenosine, 5-ribosyluridine, 5-methylcytidine, and thymine riboside. In order to identify these components, use was made, *inter alia*, of ribonuclease T_1, which has the following specificity: phosphodiester bonds on 2-methylguanosine are split with formation of a 3′-terminal phosphate group; phosphodiester bonds on 2,2-dimethylguanosine are also cleaved, but here cyclic phosphates are formed; phosphodiester bonds on 1-methylguanosine remain unaltered. Serine-specific t-RNA does not contain any thymine ribotide, but does contain the unusual doublet guanyl-5-hydroxymethylcytidine.

R. W. Holley et al. (U.S.A.) degraded purified alanine-, tyrosine-, and valine-specific t-RNA with takadiastase-RNase T_1 and found an unusual tetranucleotide with the sequence TpΨpCpGp, where Tp represents ribothymidylic acid and Ψp is pseudouridylic acid. Since this tetranucleotide was isolated from all three types of t-RNA, it is thought that it occurs quite generally in t-RNA and is in some way involved in the transferring activity. Ψp also occurs in alanine-specific t-RNA as a dinucleotide with 1-methylinosinic acid.

A t-RNA containing 8-azaguanine instead of guanine was examined by *D. H. Levin* and *M. Litt* (U.S.A.). They obtained this product by incubating *Bacillus cereus* with 8-azaguanine.

[1] The following abbreviations have been used in this report:
RNA = ribonucleic acid
t-RNA = transfer RNA
m-RNA = messenger RNA
RNase = ribonuclease
DNA = deoxyribonucleic acid
DPN = diphosphopyridine nucleotide (nicotine adenine dinucleotide)
DPNH = reduced DPN
CoA = coenzyme A
ATP = adenosine triphosphate
ADP = adenosine diphosphate
P = phosphate

Chromatography of the RNA on hydroxyapatite gave fractions with 8-azaguanine contents of between 26 and 62 %. Differences in the secondary structure of these fractions were detected from the course of their ultraviolet absorption on warming from 20 to 90 °C. As the content of 8-azaguanine rose, the melting temperature T_m and hyperchromicity decreased. Hence it follows that the hydrogen bonds in the pair 8-azaguanine-cytosine are weaker than those in the pair guanine-cytosine, with the result that the RNA containing the guanine analogue is more thermolabile.

U. Z. Littauer (Israel) investigated the significance of the methylated purine and pyrimidine bases which always occur in t-RNA in small amounts. t-RNA of low methyl content obtained from *E. coli* cells grown on a methionine-deficient medium takes up amino acids to about the same extent as normal t-RNA. However, the transfer activity of normal t-RNA in the synthesis of poly-Phe and poly-Leu is about 25 % higher than that of low-methyl t-RNA. In addition, low-methyl t-RNA is degraded by diesterase from *E. coli* about twice as fast as normal t-RNA. Methylation apparently therefore confers greater stability on the t-RNA in metabolic processes.

Eleven enzymes which transfer methyl groups from *S*-adenosylmethionine to nucleic acids were discovered in *E. coli* by *M. Gold* and *J. Hurwitz* (U.S.A). Six of these enzymes react only with t-RNA, and four others with t-RNA or ribosomal RNA. A further enzyme fraction is specific for DNA. The enzymes were separated and purified. They also differ in their specificities for the bases to which the methyl groups are transferred.

F. C. Wettstein (U.S.A.) described the structure of the active complex involved in the biosynthesis of proteins: there are always three molecules of t-RNA attached to the ribosome. One of these bears the activated amino acid, the second holds the growing polypeptide chain, and the third contains neither protein nor amino acid. This third molecule of RNA is released from the ribosome in a buffer containing a low concentration of Mg^{2+} ions; the two other RNA molecules are more securely attached.

In order to examine the site of attachment of ribosomes onto microsomal membranes, *D. Sabatini* (U.S.A.) dissociated microsomes from guinea-pig liver by adding increasing amounts of EDTA. No dissociation occurs at EDTA concentrations below 10 μmoles per amount of microsomes obtained from 0.5 g of liver. Small subunits (32 S) are split off between 10 and 20 μmoles of EDTA; larger subunits (47 S) and unattacked ribosomes remain attached to the microsomes. Above 20 μmoles of EDTA (up to 200 μmoles), further ribosomes are dissociated, and the 47 S, subunits are also released from the microsomes. The necessity for such high EDTA concentrations suggests that Mg^{2+} ions participate in the bonding between the ribosomes and the microsomes. Electron micrographs of negatively stained microsomes revealed that the groove between the 32 S and 47 S subunits in ribosomes runs parallel to the microsomal membrane surface. From this and the dissociation data it follows that ribosomes are attached to the microsomes only *via* their 47 S subunits.

Actinomycin forms a complex with DNA and thus inhibits RNA synthesis. Nucleohistones bind much less actinomycin than pure DNA does. The portions of the DNA occupied by histones are apparently unable to form complexes with actinomycin. These findings were used by *E. Harbers* and *H. Bujard* (Germany) to demonstrate that transplanted tumors of rats and mice have a higher histone:DNA ratio than normal tissue in these rodents. This observation may help to explain the tumor specificity of actinomycin.

H. Bielka (Germany) found a difference between ribosomal RNA from normal and from malignant cells. He isolated ribosomal RNA from normal rat liver and from hepatoma which had been induced by butter yellow or diethylnitrosamine. Both types of RNA had the same base composition, but the number of free amino groups in the RNA from healthy liver (about 45 % of the total amino groups) was higher than that in hepatoma RNA (about 25 %). The denaturation temperature (helix-coil transformation) is higher for hepatoma RNA (57.6 °C) than for healthy liver RNA (52.8 °C). In addition, hepatoma RNA is split more slowly by RNase than normal liver RNA.

According to *U. Bachrach* (Israel), oxidized spermine, *i.e.* the dialdehyde

$$OHC-(CH_2)_2-NH-(CH_2)_2-NH-(CH_2)_2-CHO,$$

forms a complex with the DNA from coliphages of the series T-uneven. The aldehyde is formed from spermine by the action of the enzyme serum amine oxidase. Phages incubated with the dialdehyde at 37 °C are still absorbed by *E. coli* cells and inject their DNA into the cells, but the DNA is no longer infectious and does not prevent subsequent infection with virulent T5 phages.

The mode of action of levophanol, a growth inhibitor for *E. coli* with a morpholine-like structure, was investigated by *E. J. Simon* (U.S.A.). This substance inhibits the incorporation of [^{14}C]uracil into ribosome RNA by up to 90 or 95 %, but influences the synthesis of other types of RNA to a much lesser extent. For example, the induction of β-galactosidase proceeds still at half of the original rate within two hours after addition of levophanol; this suggests a continuous synthesis of m-RNA. t-RNA isolated from cells containing levophanol by density gradient centrifugation contains 60–70 % less [^{14}C]uracil than t-RNA from a normal control culture. Levophanol inhibits the synthesis of RNA in 16-S and 23-S ribosome components to roughly equal extents.

Phosvitin, the most important phosphoprotein from hen's egg yolk, is biosynthesized by the laying hen only in the liver. *P. J. Heald* and *P. M. McLachlan* (England) found that neither other tissues of the mature hen nor the liver of chicks form phosvitin. If cockerels are injected with diethylstilbestrol, the same phosvitin concentration is present in their plasma proteins 48 h after administration of the hormone as in laying hens. *O. Greengard* and *G. Acs* (U.S.A.) found that the effect of diethylstilbestrol demands an intact RNA-synthesizing system in its initial stages, for if actinomycin is administered to the cockerels within 5 h after the application of the hormone in order to inhibit RNA synthesis, no phosvitin is formed.

Fractionation of hexa- and heptaribonucleotide fractions was accomplished by *B. P. Doctor* and *G. J. McCormick* (U.S.A.) using countercurrent distribution. They treated yeast t-RNA with RNase from pancreas and separated the hydrolysis products according to their chain lengths by chromatography on DEAE-cellulose using 7 M urea and an NaCl gradient. The hexa- and heptanucleotide fractions were then subjected to 600 transfers in a countercurrent distribution using a system prepared as follows: 30 g of ammonium sulfate plus 1 ml of acetic acid were made up to 100 ml with distilled water, and 4 ml of formamide and 40 ml of 2-ethoxyethanol were added to this solution. The separation gave five fractions containing hexanucleotides and four containing heptanucleotides. The guanylic acid content of these fractions decreased with rising partition coefficients, their content of adenylic acid increased in the same direction.

The interaction between nucleic acid bases was used by *H. Tuppy* and *E. Küchler* (Austria) to separate nucleosides by chromatography; guanosine was linked *via* its sugar residue onto a fine-grain resin. A chromatographic column filled with this exchanger retained deoxycytidine from an aqueous mixture of deoxycytidine and thymidine more strongly than the thymidine. On the other hand, a column of resin loaded with adenosine instead of guanosine retained the thymidine more strongly. These findings suggest some specificity in the interactions between the bases. It must be primarily hydrogen bonds which are responsible for the effect, for methylation at positions at which hydrogen bonds are normally formed reduces the separatory action of the resin; no separation at all is obtained with a 7 M solution of urea as a solvent.

D. Lipkin et al. (U.S.A.) reported on methods for iodinating nucleosides and nucleotides. The best reagents were iodine monochloride and *N*-iodosuccinimide in *N*-ethylacetamide or dimethylsulfoxide. Iodination of pyrimidine bases leads to 5-iodo derivatives, guanine and xanthine derivatives yield the 8-iodo compounds. Alkaline hydrolysis of 5-iodocytidine and 5-iododeoxycytidine leads *via* a rearrangement to 6-hydroxy derivatives, whereas 5-iodouridine after the same treatment gives rise to a new type of cyclonucleotide, *viz.* 6-hydroxy-*O*(6),5'-cyclouridine.

Proteins, Peptides, and Amino Acids

Three symposium lectures were devoted to the relations between the biological activities of peptides and their amino-acid compositions. *V. du Vigneaud* (U.S.A.) and *J. Rudinger* (Czechoslovakia) reported on their investigations of oxytocin. *Rudinger* expressed the opinion that every phase in the biological activity of a substance (transport, binding, action, excretion, inactivation) is probably dependent in different ways upon the nature of the molecule and that the effects produced by different structural changes are not directly comparable. *DuVigneaud* et al. found that the phenolic hydroxyl group in the tyrosyl residue in oxytocin makes a significant contribution to the avian-depressor and oxytocic effects produced by the protein, although both of these properties are still manifested in the absence of this hydroxyl group. It is remarkable that the reduction in the blood pressure brought about by the hormone is less when the hydroxyl group is methylated than when it is missing. If the free amino group in the cysteinyl residue 1 is removed, then a substance is obtained which in some respects is more active than the unchanged hormone. On the other hand, here too blockage of the amino group by acetylation or methylation leads to almost complete loss of activity or even to anti-hormonal activity. *Rudinger* et al. substituted the same amino group with amino-acid residues or short peptide chains which could be removed enzymatically and found that the products possessed protracted antidiuretic, uterotonic, and natriuretic activity, depending on the nature of the group attached.

K. Hofmann (U.S.A.) reported on functional relationships in ACTH, a straight-chain polypeptide containing 39 amino acids. In corticotropins from the pituitaries of pigs, sheep, beef, and humans, amino acids 1–24 are the same in all species, differences occuring only in the positions 25–32. The smallest synthetic polypeptide exhibiting ACTH-like activity, *i.e.* producing a decrease in the ascorbic acid content of the adrenals and stimulating steroid synthesis, contains the amino acids 1–13. If the peptide chain is extended corresponding to its natural structure, the full activity of the natural hormone (about 100 units/mg) is attained when the chain contains a total of 20 amino acids. It therefore appears that the "active site" of the hormone lies in the *N*-terminal tridecapeptide, and that the amino acids 14–20 (particularly 15–18) are responsible for attachment of the hormone onto the receptor. *N*-Acetylation or oxidative deamination of the *N*-terminal serine residue causes significant reduction in the activity of the hormone, but replacement of the serine by glycine has practically no effect. The hydroxymethyl side-chain therefore appears to have no significance for the biological activity. Glutamic acid in position 5 seems to be equivalent to glutamine as concerns biological activity, but the C-amino groups in lysine residues 11, 15, and 16 must not be blocked by formylation.

In the research reports, *K. Harada* and *S. W. Fox* (U.S.A.) described the formation of aspartic acid, threonine, serine, glutamic acid, proline, glycine, alanine, valine, alloisoleucine, isoleucine, leucine, tyrosine, phenylalanine, *etc.* from methane ammonia, and water vapor at 900–1100 °C on SiO_2 or Al_2O_3. Since all the components of this reaction are postulated to have occurred in a primitive terrestial atmosphere, it can be considered that a thermochemical synthesis of amino acids may have taken place under these conditions.

A general method for preparing *C*-substituted amino acids was described by *J. Kollonitsch* et al. (U.S.A.). When the amino acids are dissolved in strong acids (H_2SO_4, $ClSO_3H$, conc. HCl, or CF_3COOH), the functional amino and carboxylic groups are protonated and thus protected, but the carbon chain is still accessible to free-radical chlorination. This surprisingly selective reaction leads to chloro amino acids without racemization; the latter are suitable starting materials for further substitutions. For example, depending on the conditions, L-glutamic acid gives rise to γ- or β-chloroglutamic acid in yields of 70–80 %. Hydrolysis of the γ-chloroglutamic acid gives the γ-hydroxy derivative, and ammonolysis of the β-chloroglutamic acid yields β-amino-L-glutamic acid, a new diamino dicarboxylic acid. γ-Chloro-L-lysine is obtained similarly in 80 % yield, and its hydrolysis produces γ-hydroxy-L-lysine. Catalytic deuterolysis of many of the chloro amino acids gives rise to specifically labelled amino acids.

D. W. Nooner and *J. Oró* (U.S.A.) described non-enzymatic synthesis of polypeptides using polyphosphate esters according to the method of *Schramm* [2]. They heated amino acids with polyphosphate esters in a 1:3 ratio at 60 °C and obtained polymers of DL-leucine, DL-valine, DL-serine, and DL-phenylalanine in yields of up to 60 %. The degree of polymerization for the polyleucine was about 12, but shorter peptides were also detected, which are probably intermediates.

J. H. Pazur and *K. Kleppe* (U.S.A.) were able to show that the glucose oxidase from *Aspergillus niger* is a glycoprotein. The enzyme was purified by fractionation with ammonium sulfate and chromatography on DEAE-cellulose and contains about 15 % D-mannose, D-glucose, and D-glucosamine. The protein and carbohydrate remained inseparable on curtain electrophoresis and density gradient centrifugation. Hydrolysis of the enzyme with protease and separation of the products on Sephadex yielded a glycopeptide, which on hydrolysis with acid yielded D-mannose, D-glucosamine, glutamic acid, aspartic acid, serine, threonine, and ammonia.

A procedure for cleaving acyl-proline bonds specifically with $LiAlH_4$ was reported by *M. A. Ruttenberg* and *L. C. Craig* (U.S.A.). The peptide is dissolved or suspended in anhydrous tetrahydrofuran and treated with a ten- or one-hundredfold molar excess of $LiAlH_4$ for 1 h at room temperature or at 0 °C. Excess hydride is decomposed with 6 N HCl, the solution is evaporated to dryness *in vacuo*, and the residue is desalted by chromatography on a column of Sephadex G-25 equilibrated with 50 % acetic acid. The reaction affords an aldehyde and an *N*-terminal proline. The aldehyde group is reduced to a hydroxyl group with $NaBH_4$ or H_2/PtO_2. Peptides split in this way (yields in brackets) include: Gly-L-Pro (20 % at 25 °C), L-Leu-L-Pro-Gly (23 % at 0 °C, 98 % at 25 °C), *S*-benzyl-L-Cys-L-Pro-L-Leu-Gly (100 % at 25 °C), gramicidin S (42 % at 25 °C), and tyrocidin B (30 % at 0 °C). Side reactions encountered include reduction of the carboxamido groups of glutamine and asparagine, and reductive cleavage of other peptide bonds, where the reactivity decreases in the series tertiary amides ⩾ primary amides > secondary amides. The process has proved its value in helping to elucidate the structure of the cyclic decapeptide tyrocidin B. This peptide contains a proline residue and was cleaved there to give an open-chain peptide, whose amino-acid sequence was then determined using conventional methods.

Biochemical Genetics

The changes that have occured in the structure of cytochrome c in the course of evolution were investigated by *E. Margoliash* and *E. L. Smith* (U.S.A.). Depending on its source, this protein contains 104–108 amino acids plus a hem group,

[2] *G. Schramm, H. Grötsch,* and *W. Pollmann,* Angew. Chem. *74,* 53 (1962); Angew. Chem. internat. Edit. *1,* 1 (1962).

which is attached covalently to the peptide chain. Cytochrome c molecules from 13 species (yeasts, insects, vertrebates) showed over 50 % identity in the amino-acid sequence of their peptide chains. This suggests that all the cytochrome c types existing today have been derived from a common ancestral form. Moreover, the number of differences decreases the closer the species are related phylogenetically. Thus, for example, the cytochrome c molecules from the species of mammals investigated differ from those of birds in only 10–15 amino acids. The difference between the cytochrome c of mammals and birds on the one hand and that of fish on the other amounts to 18–21 amino acids; that of mammals, birds, and fish differs from that of baker's yeast by 43–49 amino acids. The cytochromes of humans and rhesus monkeys differ by only one amino acid, but those of humans and tuna by up to 21. Some of the constant amino-acid sequences are related to the function of the protein, but for others no such relationship is known and possibly does not exist. The greatest differences occur at positions 89 and 92 of the peptide chain: six different amino acids have been found in position 89 and five in position 92.

Similar conclusions were drawn by *V. Rudloff* (Germany) from his investigations of hemoglobins from various species of animals. There are significant differences in the amino-acid sequences in the hemoglobins of higher and lower vertebrates. The hemoglobin from lampreys (*Lampetra fluviatilis*) has a molecular weight of only 17000 – that of other vertebrates has a molecular weight of 64000 – and consists of only a single peptide chain, which resembles neither the α- nor the β-chain of human hemoglobin but which appears to be intermediate between these and myoglobin. It is therefore possibly an evolutionarily primitive form.

V. G. Allfrey (U.S.A.) investigated the differences between genetically active and inactive components of chromosomes. He found that only about 20 % of the genetic material in a mammalian cell is active. The remaining 80 % is balled together and is easier to remove from the cell than the active portion. The histone content of both fractions is the same, but the histones of the active portion are more strongly acetylated. It therefore appears that the minute structural changes induced by acetylation suffice to render a gene active without losing the protective and stabilizing action of the histones.

Mechanisms of Enzyme Action

The formation and stabilization of the three-dimensional structure of ribonuclease were the topics of the lecture by *C. B. Anfinson* (U.S.A.). Reduced ribonuclease contains 8 mercapto groups. The reduced enzyme is rapidly reconverted quantitatively into the native enzyme in dilute solution at a slightly alkaline pH in the presence of oxygen. The primary structure therefore appears to determine the tertiary structure of the protein. When the regeneration of the native enzyme is prevented by carrying out the oxidation at a low pH or in 8 M urea, an inactive protein is formed containing "incorrect" disulfide bridges. However, when this is incubated with traces of a mercapto compound, it undergoes disulfide exchange, and the active enzyme can be recovered. These reactions were used to test the extent to which the amino-acid side-chains influence the formation of the active tertiary structure. Attachment of polyalanyl residues onto the ε-amino groups of nine out of the ten lysine residues in the protein has no effect on the reoxidation, even when 60 molecules of alanine are incorporated into one molecule of RNase. It can therefore be concluded that the side-chains of these lysine residues are oriented outwards from the molecule. The ε-amino group of lysine-41 cannot be alanylated in the presence of polyanions (orthophosphate, cytidylate, or RNA). Polyanions also prevent alkylation of the histidine residues 12 and 119. It is therefore possible that there is a cluster of basic residues (induced or stabilized by polyanions) in the active center of the enzyme.

B. S. Hartley (England) reported the primary structure of beef chymotrypsinogen A. The molecule contains 245 amino acids and 5 disulfide bridges (Cys-1 to Cys-122, Cys-42 to Cys-58, Cys-135 to Cys-200, Cys-167 to Cys-181, and Cys-190 to Cys-219). The molecule is activated by tryptic cleavage of the bond between Arg-15 and Ileu-16. Subsequent chymotryptic cleavage of the bonds at residues Leu-13, Tyr-145, and Asp-NH_2-147 has only a slight effect on the activity of the enzyme and does not suffice alone to activate the enzyme. All 14 lysine residues, Cys-1, the *N*-terminal Ala-148, and the *C*-terminal Tyr-145 can be modified without loss of activity, hence these residues appear to be on the exterior of the molecule and to contribute only little to its catalytic effect or to maintenance of its tertiary structure. In contrast, the *N*-terminal Ileu-16 cannot be phenylated with fluorodinitrobenzene in the enzyme in the native state, and modification of this amino-acid residue can lead to alteration of the pH-dependence of the enzymatic activity. The *C*-terminal asparagine-245 also appears to reside within the molecule. There is much evidence that His-57 is involved in the active center. In this connection, it appears remarkable that the two histidine residues in positions 40 and 57 of the molecule are brought into close proximity by the disulfide bridge from Cys-42 to Cys-58, and that similar sequences are observed in trypsin and in chymotrypsinogen B.

The stereochemistry of enzymatic hydrogen transfer to pyridine nucleotides was discussed by *C. Donninger* (England). During the oxidation of substrates by pyridine coenzymes, the hydrogen from the substrate is transferred to C-4 of the pyridine ring. The reaction is stereospecific, the hydrogen transferred entering above [Formula *(1)*] or below [Formula*(2)*] the plane of the ring.The absolute configuration of the hydrogen introduced at C-4 was elucidated by means of deuterium labelling using a new ring degradation developed by *J. W. Cornforth*, which involves addition of methanol onto the 5,6-double bond, ozonization of the 2,3-double bond, and oxidation of the product with peroxyacetic acid. This treatment results in deuteriosuccinic acid *(3)* which is compared with synthetic deuteriosuccinic acid of known absolute configuration at C-2. It was thus shown that enzymes such as yeast alcohol oxidoreductase, which transfer a hydrogen to the "A" side of the pyridine ring produce *(4R)*-[4-D]DPHN *(1)*, *i.e.* the hydrogen is added onto that side of the nicotinamide ring from which the ring atoms 1–6 are viewed in an anticlockwise order.

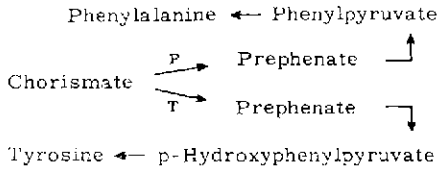
(3)

Hybrid isozymes of lactate dehydrogenase were obtained by *C. L. Markert* (U.S.A.). Lactate dehydrogenase (LDH) from vertebrates is generally a mixture of five isozymes formed by combination of two differing subunits into groups of four. These isozymes dissociate when they are dissolved and then frozen in the presence of certain salts. On thawing, statistical recombination of the subunits occurs. Mixtures of LDHs from different sources (fish, amphibia, reptiles, birds, mammals) gave hybrid isozymes after such treatment. Thirty-five isozymes were detected in mixtures containing four different subunits; three different subunits gave rise to 15 isozymes. All the hybrid isozymes exhibited enzymatic activity, but this was progressively less the greater the evolutionary distance between the species was whose LDHs were hybridized.

Special Topics in Biochemistry

F. Gibson and *R. Cotton* (Australia) detected two enzymes (prephenate synthetases) which convert chorismic acid into prephenic acid; these were obtained by chromatography of

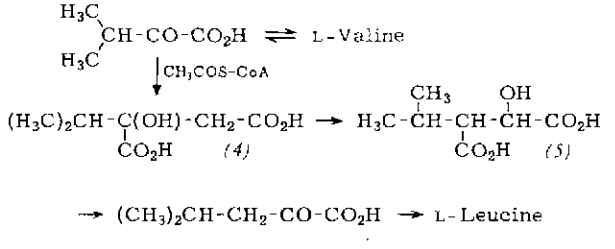
cell extracts from a wild type *Aerobacter aerogens* on DEAE-cellulose. End-product inhibition and repression tests with these enzymes demonstrated that one is responsible for phenylalanine synthesis (P), the other for tyrosine synthesis (T).



Mutants were obtained containing either one or neither of the prephenate synthetases. Strains which are auxotrophic for tyrosine have no enzyme T. Prephenate dehydrogenase, which catalyses the reaction prephenic acid → 4-hydroxyphenylpyruvate, passes through the column together with the prephenate synthetase T activity, and both activities may be lost and regained by single mutations. Similarly, prephenic aromatase (prephenic acid → phenylpyruvate) passes through with the prephenate synthetase P.

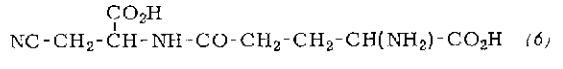
Washed cell suspensions of the anaerobic microorganism *Clostridium tetanomorphum* decompose tyrosine with formation of CO_2, H_2, and NH_3. Experiments to clarify the route of this anaerobic degradation were carried out by *N. Brot* and *H. Weissbach* (U.S.A.), who found that incubation of [u-^{14}C]tyrosine with growing or dormant cells of *Cl. tetanomorphum* yielded phenol containing 60 % of the radiocarbon. The degradation of L-tyrosine to phenol also occurs in cell-free systems, where the reaction is stimulated by pyridoxal phosphate. Another degradation product identified was pyruvic acid. Decomposition of the latter by phosphoroclastic cleavage could lead to the formation of CO_2 and H_2.

2-Isopropylmalic acid *(4)* and 3-isopropylmalic acid *(5)* are intermediates in the biosynthesis of leucine. *C. M. Stevens, J. M. Calvo,* and *M. G. Kalyanpur* (U.S.A.) investigated the mechanism of the rearrangement of *(4)* to *(5)*, which is comparable with the rearrangement of citric acid to isocitric acid. Following administration of [1-^{14}C]valine and [2-^{3}H]acetate to leucine-requiring mutants of *Neurospora crassa*, doubly labelled *(4)* and *(5)* are obtained, the radiocarbon:tritium ratio being the same in both compounds. α-Oxoisocaproic acid obtained from *(5)* by enzymatic or chemical oxidation contained no tritium.



Pyrolysis of *(5)* yielded 2-isopropylmaleic anhydride with an unchanged ^{14}C:T ratio. Enzymatic dehydration of *(5)* afforded the *cis*-acid. Measurement of the optical rotatory dispersion of the ethyl xanthate derivative of *(5)* proved that its carbinol carbon atom has the D_S-configuration. Furthermore, it can be concluded from the NMR spectrum of the *O*-acetyl anhydride of *(5)* that the natural compound is *erythro*-D_S-3-isopropylmalic acid. This implies that the enzymatic conversion of *(4)* to *(5)* proceeds *via* stereospecific *trans*-elimination and addition of water.

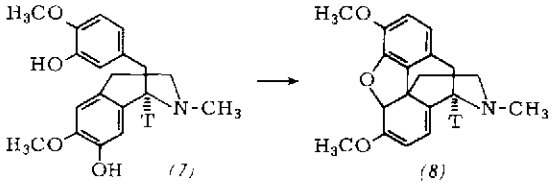
In various species of *Lathyrus* (sweet pea) and vetch, cyanide is a very efficient precursor for the cyano group in γ-glutamyl-β-cyanoalanine *(6)* which occurs in these plants. The formation of β-cyanoalanine was studied by *S. N. Nigam* and *C. Ressler* (U.S.A.). When [3-^{14}C]-L-serine was fed to seedlings of *Vicia sativa* (common vetch) through the roots, only 0.5 % of the radioactivity recurred in the dipeptide, but the degree of incorporation rose to 46 % when unlabelled KCN was administered simultaneously. The labelled dipeptide was hydrolysed with acid, and the aspartic acid formed converted into alanine with *Clostridium welchii*. The alanine still contained 90 % of the radioactivity. Hence serine in the presence of cyanide is an excellent precursor for carbon atoms 1–3 of β-cyanoalanine.



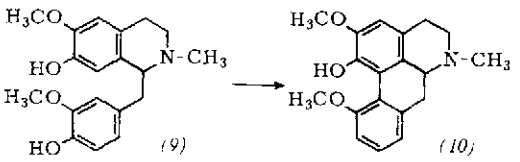
The formation of urea in tissues of ureide plants and in fruit bodies of higher basidiomycetes was examined by *H. Reinbothe* (Germany). Urea and glyoxylic acid are formed together in the course of aerobic degradation of purines. The glyoxylate can either form a ureide with the urea, as in ureide plants such as *Pelargonium zonale*, or participate to a large extent in the resynthesis of purines. There is thus a reaction cycle in operation in which the aerobic degradation of purines is connected *via* glyoxylate to the *de novo* synthesis of purines. There are at least three modes of urea formation in the fruit bodies of higher fungi (*Lycoperdon, Agaricus*) which accumulate urea: 1. the ornithine cycle, 2. aerobic degradation of purines, and 3. a hitherto unknown mode of pyrimidine catabolism. Two enzymes involved in arginine metabolism were found in the fruit bodies of *Lycoperdon*: arginase and an L-amino-acid oxidase. During oxidative degradation of arginine, γ-guanidobutyric acid is formed and can be partially degraded further to γ-aminobutyric acid and urea.

Earlier studies on the biosynthesis of the antibiotic cyclic decapeptide tyrocidin in intact cells of *Bacterium brevis* revealed that the synthesis of this peptide proceeds differently from the biosynthesis of proteins, since tyrocidin synthesis is unaffected by chloramphenicol and puromycin, whereas protein synthesis is completely inhibited. Actinomycin also causes total inhibition of RNA and protein synthesis but has no effect on the biosynthesis of tyrocidin, as *B. Mach* and *E. L. Tatum* (U.S.A.) were able to show. The synthesis of the decapeptide probably therefore requires no short-lived m-RNA. It was also found that in the biosynthesis of the tyrocidins A, B, C, and D the substitution of three single amino acids by others was dependent upon the concentration of these amino acids in the medium. This was attributed to a low specificity of the enzymes concerned and is also in contrast to the absolute specificity of such reactions during the biosynthesis of proteins.

A. R. Battersby (England) described some recent results on the biosynthesis of morphine alkaloids and of colchicine. [1-^{3}H]Reticuline was separated into its antipodes, and the incorporation of both forms into the thebaine in poppies was compared. It was found that only (−)-reticuline *(7)*, which has the tritium on C-1 in the same steric arrangement as the corresponding hydrogen atom in natural thebaine *(8)*, recurs in the thebaine isolated with about 60 % of its tritium activity. When (±)-reticuline is administered, the whole of the tritium is lost, since transformation to the (−)-antipode occurs before incorporation.

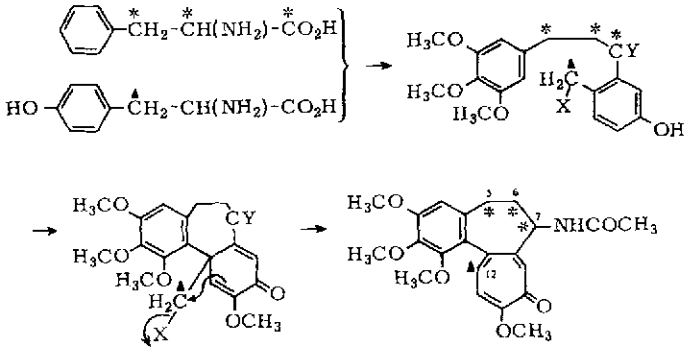


The ability to act as a precursor of thebaine also depends on the methylation pattern of the labelled compound. For example, the base *(9)* in which the hydroxyl and methoxyl groups in the benzyl residue are interchanged does not give rise to thebaine; instead, it is a precursor of isothebaine *(10)*.



(9) (10)

Although it was known from previous work that it is phenylalanine which gives rise to the phenyl residue and carbon atoms 5, 6, and 7 of colchicine, the mode of formation of the tropolone ring remained obscure. Experiments with [3-^{14}C]-tyrosine have now shown that when this compound was fed to *Colchicum autumnale*, 81 % of its radioactivity recurred in C-12 of the colchicine. It can therefore be concluded that colchicine is built up from phenylalanine and tyrosine, the 3-carbon atom of the tyrosine becoming C-12 of the tropolone ring *via* a ring expansion. Tyrosine and phenylalanine are therefore not equivalent precursors in this plant.



The biosynthesis of dideoxyhexoses in bacteria was investigated by *J. L. Strominger* et al. (U.S.A.). Ascarylose (3,6-dideoxy-L-mannose) is produced by extracts of *Pasteurella pseudotuberculosis*, Type V, by the following route: CTP + D-glucose-1-phosphate → CDP-D-glucose → CDP-4-keto-6-deoxy-D-glucose → CDP-ascarylose. TPNH is the reducing agent for the last step. CDP-3,6-dideoxy-D-glucose (CDP-paratose) is formed in a similar manner in extracts of *P. pseudotuberculosis*, Type III.

Lipids and Steroids

P. R. Vagelos et al. (U.S.A.) and *F. Lynen* et al. (Germany) gave reports on the course of the biosynthesis of fatty acids. Whereas the fatty-acid synthetase derived from yeast is a multienzyme complex, the synthetase from *E. coli* can be separated into its components. Three of these (E_I–E_{III}) are essential for the condensation of acetyl-CoA with malonyl-CoA:

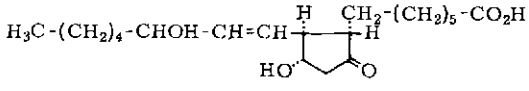
$$CH_3\text{-}CO\text{-}SCoA + HS\text{-}E_{II} \xrightarrow{HS\text{-}E_I} CH_3\text{-}CO\text{-}SE_{II} + CoA\text{-}SH$$

$$CH_3\text{-}CO\text{-}SE_{II} + HO_2C\text{-}CH_2\text{-}CO\text{-}SCoA \xrightleftharpoons{HS\text{-}E_{III}}$$

$$CO_2 + CoA\text{-}SH + CH_3\text{-}CO\text{-}CH_2\text{-}CO\text{-}SE_{II}$$

Fatty-acid transacylase (E_I) is extremely sensitive to SH inhibitors. E_{III} is the thermostable acyl transferase in the fatty-acid synthetase cycle; it has a molecular weight of 9500 and has been purified until chromatographically and electrophoretically uniform. It is also homogeneous in the analytical ultracentrifuge. E_{II} contains a cysteine residue. The enzyme E_{III} can also function as a transacylase, conveying the malonyl residue from malonyl-CoA to E_{II}. The main metabolic product of the fatty-acid synthetase in *E. coli* is *cis*-vaccenic acid, whose methyl-terminal carbon atoms are derived from acetyl-CoA, the remainder of the carbons in the chain being supplied in C_2 units by malonyl-CoA. *Lynen* and his collaborators concentrated fatty-acid synthetase from baker's yeast over one-hundredfold and obtained a preparation which was homogeneous when examined by electrophoresis or by electron microscopy. It had a molecular weight of 2.3×10^6, contained seven enzyme activities, and synthesized stearyl-CoA from acetyl-CoA and 8 moles of malonyl-CoA. Quantitative analysis of the terminal amino acids indicated the presence of seven polypeptide units in the complex. All the intermediates of fatty acid biosynthesis are attached covalently to the complex *via* mercapto groups which can be divided into peripheral groups (react readily with *N*-iodoacetamide or *N*-ethylmaleimide) and central groups (relatively resistant to these reagents). After saturated fatty acids containing 16–18 carbon atoms have been synthesized by the complex, they are transferred from a central to a peripheral SH group and are transferred from there to CoA, *i.e.* they are released from the complex.

Prostaglandines are complicated carboxylic acids of structure *(11)* which were investigated by *S. Bergström* (Sweden). They occur in mixtures in the seminal plasma of man and sheep, for example, and stimulate smooth muscle and depress the blood pressure. They also influence lipid metabolism. Prostaglandin E_1 in a concentration of 2.8×10^{-7} M counteracts the fat-mobilizing activity of adrenalin, noradrenalin, glucagon, and ACTH in rats. It also appears to inhibit the activity of a lipase in adipose tissue induced by adrenalin. However, injections of prostaglandin E_1 into humans increase the content of free fatty acids in arterial blood, and the fat-mobilizing effect of infused noradrenalin is not counteracted.



(11), Prostaglandine E_1

W. L. Byrne and *M. C. Ganoza* (U.S.A.) observed that the activity, stability, and substrate specificity of glucose-6-phosphatase is influenced by the phospholipids contained in the enzyme. If the lipids are removed, an inactive form of the enzyme is obtained which can be reactivated by addition of phospholipids, although complete identity of this preparation with the native form of the enzyme is not achieved.

Metabolism and Its Control

S. Granick (U.S.A.) discussed a repressed enzyme system in chicken liver. When 3,5-bisethoxycarbonyl-1,4-dihydrocollidine is added to a 16-day old primary culture of chick embryo liver, porphyrins can be detected in the cells within 3 h. The reason for this is *de novo* synthesis of rate-determining δ-aminolevulinic synthetase. Inhibitors of protein synthesis such as mitomycin C and actinomycin D prevent the formation of the enzyme.

W. E. Knox (U.S.A.) determined the degree of incorporation of [^{14}C]arginine into tryptophan pyrrolase following induction of the enzyme with tryptophan or cortisol. The enzyme was precipitated with antibodies, and its radiocarbon content was determined. Although the amount of enzyme rose after both types of induction, only that formed after induction with cortisol had a higher specific radioactivity in the protein. It therefore follows that only cortisol induces *de novo* syntbesis of the enzyme, whereas tryptophan apparently only slows down the degradation of the pyrrolase.

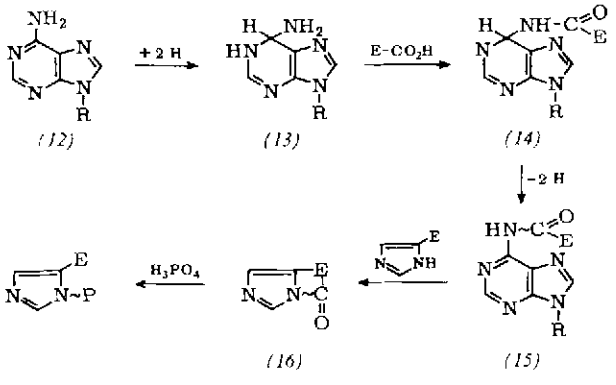
The effects of insulin on carbohydrate metabolism in the liver were studied by *J. S. Bishop* et al. (U.S.A.), who found that intravenous infusions of insulin (0.08–0.2 units/kg/h) into dogs decrease the release of glucose from the liver into the blood by 62 %, increase the glucose uptake of all tissues

threefold, and increase the synthesis in the liver of glycogen from blood glucose eightfold. The uptake of glucose into non-glycogenous liver constituents also increases.

Thyroid hormones influence the activity of mitochondrial enzymes. *B. Kadenbach* (Germany) observed an increase in the activity of glycerophosphate oxidase and succinic dehydrogenase in the mitochondria of rat liver, kidney, heart, muscle, brain, and spleen on passing from the hypo- to the hyperthyroid state. The cytochromes a, b, and c increase by a factor of 1.3–2.0, and DPN-specific isocitric dehydrogenase increases by a factor of 1.4–2.4, but not in brain and spleen mitochondria. On the other hand, TPN-dependent isocitric dehydrogenase, glutamate-oxaloacetate transaminase, and β-hydroxybutyric dehydrogenase in mitochondria from liver, heart, kidney, and muscle have lower activities in the hyperthyroid state. It follows from these results that thyroid hormones increase the activity of the oxidative system of mitochondria by induction of the enzymes of the citric acid cycle and of the respiratory chain, but inhibit the enzymes of the synthetic metabolism.

Bioenergetics

V. P. Skulachev (U.S.S.R.) reported on the function of adenine nucleotides in the respiratory chain. It appears that adenine nucleotides *(12)* not only function as energy-rich compounds (ATP) but, as the formulae show, are also substrates for redox reactions. The pyrimidine ring is first reduced to *(13)*, which is acylated at its amino group by the free carboxyl group of an enzyme (E–CO_2H) to give *(14)*, which is then reoxidized to *(15)*. The aromatic ring withdraws electrons from the amide nitrogen and thus increases the energy content of the amide bond. The energy from this bond could be utilized by imidazole catalysis for the formation of ATP.



The coupling factors involved in mitochondrial oxidative phosphorylation were discussed by *G. Webster* (U.S.A.). He isolated three proteins from the soluble protein fraction of mitochondria and found that these function as coupling factors, each being specific for a single coupling site. The DPNH coupling factor, which is required for phosphorylation in the DPNH-flavoprotein region, was obtained in crystalline form; it is homogeneous and has a molecular weight of about 30000. The QH_2 factor (specific for phosphorylation in the coenzyme Q-cytochrome b region) was highly purified and separates into two components in the ultracentrifuge. The coupling factor for reduced cytochrome c is homogeneous and has a molecular weight of about 35000.

It appears that all of these factors have a part to play in reaction sequences which may be written as follows:

a) Substrate + Particle → Particle ~ Substrate

b) Particle ~ Substrate + Factor → Factor ~ Substrate + Particle

c) Factor ~ Substrate + P_i → Factor ~ P + Oxidized substrate

d) Factor ~ P + ADP → Factor + ATP

The compounds Factor ~ Substrate (= DPNH ~ Factor) and Factor ~ P were isolated from the phosphorylation step coupled to DPNH oxidation. The Substrate ~ Particle component for the phosphorylation step coupled to cytochrome c oxidation was also isolated; it is labile above 5 °C. The compound Factor ~ Substrate (for cytochrome c) is red, has a molecular weight of about 50000, and appears to consist of 1 mole of factor and 1 mole of reduced cytochrome c. It reacts with orthophosphate to form colorless Factor ~ P with liberation of cytochrome c. The Factor ~ P compound is stable at neutral pH but decomposes at acid and alkaline pH. It reacts with ADP to form ATP. Inhibitors of oxidative phosphorylation affect various steps of the four-stage reaction sequence: 2,4-dinitrophenol and bicoumarol cause rapid disintegration of the Particle ~ Substrate complex, and oligomycin inhibits the formation of ATP from Factor ~ P.

Organic Photochemistry

The International Union for Pure and Applied Chemistry held an International Symposium on Organic Photochemistry in Strasbourg (France) on July 20th–24th, 1964. The conference was supported by NATO and admirably organized by *G. S. Hammond* and *J. Levisalles*, and was preceded by an introductory seminar lasting three days.

W. A. Noyes dealt with problems of the radiationless deactivation of excited molecular states with or without change in multiplicity (*i.e.* "intersystem crossover" or "internal conversion", respectively). In the case of diacetyl or benzene, all or nearly all molecules in the gas phase that are excited to the first singlet state are regarded as assuming the triplet state, unless they are previously stabilized by emission of fluorescence. There are indications, however, that the singlet-triplet-conversion requires only a low activation energy; in any case, deuteration of benzene increases the fluorescence yield considerably. This yield is not independent of the wavelength of the incident light; it approaches zero at 2350 Å. Presumably, a competing deactivation process plays a part, possibly an isomerization, which proceeds faster than the dissipation of the excess of vibrational energy, particularly if the latter is very large in the excited state.

Little has been done so far to investigate the radiationless transition: triplet → ground state; beyond its existence in principle, not very much is known. Here, isomerization may again play a role in the deactivation.

A survey of chemiluminescence in solution was given by *E.J. Bowen*. Chemiluminescence reactions are phenomena in which a potentially fluorescent molecule is excited by means of chemical energy into an electronically excited state. As a rule, typical radical reactions are involved, because the energy required per light emission in the visible region is 40–70 kcal/mole. Two of the most brilliant emissions are observed in the oxidation of the cyclic 3-aminopbthaloyl hydrazide and dimethyldiacridylium nitrate. In both cases, the final products (*viz.* aminophthalic acid or methylacridone) are the emitting species. In concentrated solutions of acridone, an energy transfer to the reacting molecules also appears possible. Organic hydroperoxides may be decomposed thermally to ketones; if a fluorescent organic molecule containing an

extended conjugated system is present, this is first oxidized in a one-electron process, and is then reduced in a second stage, with simultaneous conversion into the excited singlet state that is responsible for the luminescence. At least two additional, although less effective, mechanisms are possible. The mechanism of light emission that occurs in the thermal dissociation of cyclic peroxides of molecules containing conjugated systems (*e.g.* the peroxide of diphenylanthracene) is still not clear. The simple dissociation process

$$AO_2 \rightarrow A + O_2$$

does not provide sufficient energy for a visible quantum. Possibly the reaction

$$AO_2 \rightarrow {}^3A + {}^3O_2$$

is followed by

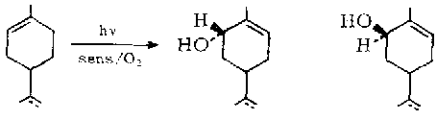
$${}^3A + {}^3A \rightarrow {}^1A^* + {}^1A$$

The subject of a survey by *G. Porter* was the reactivity of $n \rightarrow \pi^*$-, $\pi \rightarrow \pi^*$-, and charge-transfer states in benzophenone derivatives. It is wellknown that the photopinacolization of triplet-benzophenone is strongly influenced by substituents: certain *ortho*-substituents inhibit this reaction, due to intermediate tautomerization. The fact that *meta*- and *para*-substituents also exert a profound influence on the reactivity must be ascribed to their effect on the electronic energy levels. It has not yet been explained exactly how these effects operate. In particular, no explanation is yet available which accounts for the effectiveness of NH_2-substituents, for the lack of influence of halogens, or for the considerable reactivity of the *p*-methoxy derivative, and the contrasting inertness of the *p*-hydroxy derivative. An unequivocal interpretation of these phenomena is provided by new measurements of absorption and phosphorescence spectra, of quantum yields, and of lifetimes, together with new studies of intermediates by means of flash-photolysis. In addition to $n \rightarrow \pi^*$- and $\pi \rightarrow \pi^*$-states, charge-transfer states play a part in derivatives with electron-donating substituents (OH, OCH_3, NH_2); reactivity is always small when the charge-transfer levels are lowest, because in these cases the carbonyl group possesses a high electron density. The divergent effects of hydroxy and methoxy substituents is due to the rapid deprotonation of the hydroxy group in the excited state. This interpretation is supported by pK-measurements in the ground, triplet, and excited singlet states.

Confirmation of this interpretation of the different tendency of substituted benzophenones to photopinacolization is provided by the influence of solvents on the relative positions of the $n \rightarrow \pi^*$-, $\pi \rightarrow \pi^*$-, and charge-transfer transitions, and on the reactivities dependent thereon. Thus, certain photosensitized benzophenone derivatives abstract hydrogen from paraffins, but not from alcohols.

Results of recent investigations by *G. O. Schenck* and his coworkers were reported by *K. Gollnick*: The effectiveness of fluorescein (and its tetrabromo-, tetraiodo-, and tetraidotetrachloro derivatives) as sensitizers in the oxygen transfer to dimethylfuran: Spectroscopic data provide the basis for calculations of absolute rate-constants, and hence half-lives of the sensitizers in the excited singlet and triplet states, and for the computation of the quantum yields of the fluorescence, of the $^1S(O)$-transition and the oxygen-transfer reaction. Substitution by halogen in the sensitizer has practically no influence on the life-time of the excited singlet state, but increases considerably both the $^1S(O) \rightarrow S_0$- and the $^1S(O) \rightarrow {}^3S(O)$-transitions. Consequently, the quantum yield of triplet formation is considerably increased in fluorescein by heavy halogens. This effect is due to spin-orbit coupling. Because of the very short life-time of $^1S(O)$, the O_2-transferring species is formed almost exclusively by the reaction of $^3S(O)$ with oxygen.

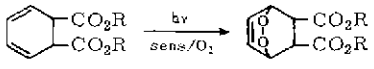
The mechanism and stereospecificity of the O_2-transfer to olefins having isolated double bonds and allylic hydrogen atoms, sensitized by methylene blue or Rose Bengal: oxygen transfer to (+)-limonene and (+)-carvomenthene *(1)* affords, in each case, after reduction of the hydroperoxides, six optically active alcohols. The fact that simultaneous inversion of configuration results in levorotatory *cis/trans*-carveoles and *cis/trans*-carvotanacetoles *(2)*, excludes direct O_2-insertion into the allylic C—H-bond, and emphasizes the contrast with thermal autoxidation. The actual composition of the product deviates from the statistical distribution and is interpreted in terms of the preferential removal of the quasi-axial hydrogen atoms. The stereoselectivity of the photo-oxidation of 1,1-dimethyl-2-alkylethylenes is ascribed to the same cause.



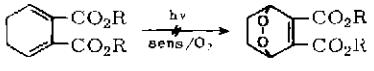
(+) (−) (−)

(1) *(2)*

The directive influence of very bulky substituents is demonstrated by (+)-Δ^3-carene (exclusive *trans*-attack), while the effect of purely electronic factors is shown by the cyclohexadiene derivatives *(3)* and *(4)*, and by various alkyl-substituted ethylene and cylohexene derivatives.

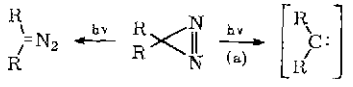


(3)



(4)

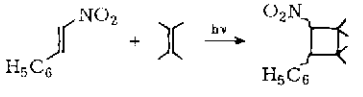
According to *H. M. Frey*, the photolysis of diazirines involves two primary reactions: the main reaction is the direct elimination of nitrogen with formation of a carbene *(6)*; in a parallel reaction, the diazirine is isomerized to the open-chain diazo compound *(7)*.



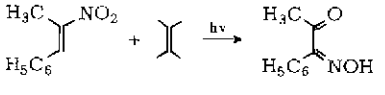
(7) *(6)*

The existence of a carbene intermediate is indicated by the composition of the hydrocarbon mixture originating in Reaction (a); this agrees satisfactorily with the result of the base-catalysed or thermal decomposition of *p*-toluenesulfonylhydrazones. However, attempts to trap carbenes in the photolysis of diazirines were unsuccessful.

New results concerning the photochemistry of unsaturated nitro compounds have been provided by *O. L. Chapman*. Irradiation of β-nitrostyrene in olefins results in the formation of 1:1-adducts in good yields; tetramethylethylene, for example, affords *(8)*. Surprisingly, β-methyl-β-nitrostyrene *(9)* does not add onto olefins, product *(10)*, isomeric with *(9)*, being obtained in 79 % yield.



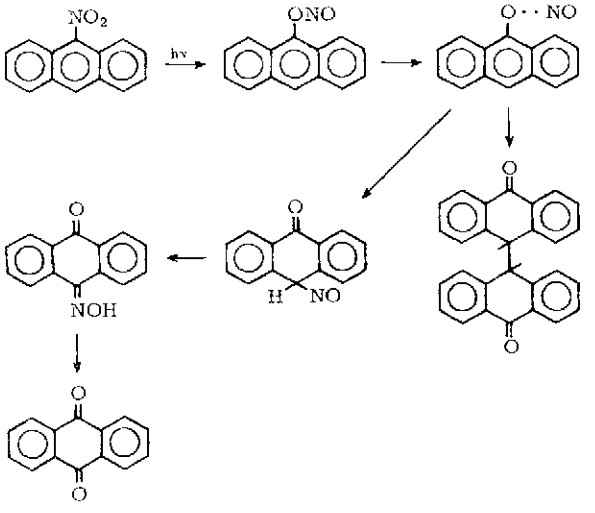
(8)



(9) *(10)*

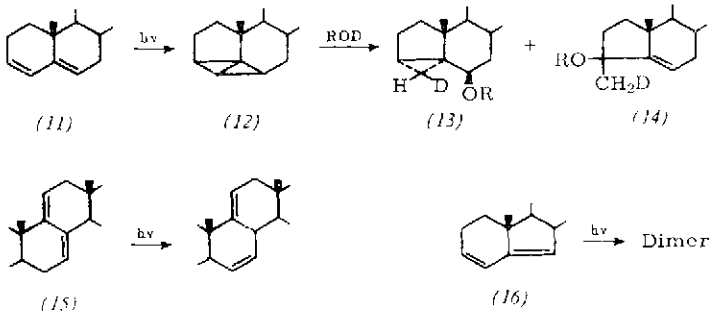
The mechansim of this rearrangement is closely related to photochemical transformations of aromatic nitro compounds. 10,10'-Bisanthrone, anthraquinone and its monoxime are the photochemical products of 9-nitroanthracene. Since anthraquinone arises also in the absence of oxygen, it is not the

product of a photo-oxidation (*Dufraisse*). On irradiation in the presence of nitric oxide, anthraquinone is formed in up to 77 % yield. These observations are interpreted by the following sequence of reactions:



A similar mechanism accounts for the isomerization of *(9)* to *(10)*.

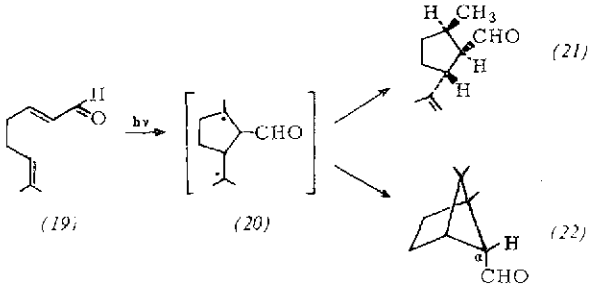
According to recent investigations by *W. G. Dauben*, the rigid *trans*-diene *(11)* is isomerized by irradiation in a hydrocarbon solvent to the [1,1,0]-bicyclic system *(12)* which reacts stereospecifically with protonic solvents to yield *(13)* [OR axial] and *(14)*.



Accordingly, in aqueous dioxane, the final photo-products are the appropriate alcohols. Sensitization by fluorscein causes dimerization of *(11)*. The sensitivity of the formation of the [1,1,0]-bicyclic system towards geometric factors is illustrated by examples *(15)* and *(16)*: hydrogen transfer or dimerization are the preferred reactions even in 10^{-4} M solution.

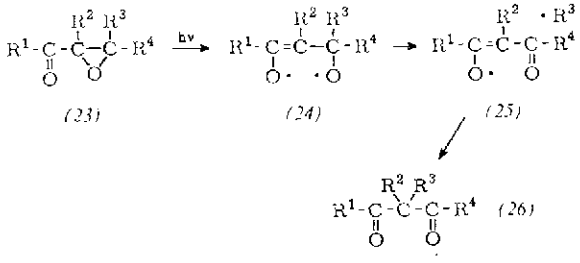
Mechanistic problems of photochemical reactions, particularly of carbonyl compounds, were the subject of a paper by *H. E. Zimmermann*. New sensitization studies suggest the high probability of a triplet mechanism for the rearrangement of the dienone *(17)* to *(18)*.

Spectroscopic data, measured in ethanol/petroleum ether at 77 °K, show that the reaction involves an $n \rightarrow \pi^*$-, and not a $\pi \rightarrow \pi^*$-triplet-state: the phosphorescence spectrum of *(17)* greatly resembles that of benzophenone in fine structure and in the position of the bands. For benzophenone the $n \rightarrow \pi^*$-character has been conclusively shown. The half-life of 0.5 msec measured at 77 °K is in agreement with this assignment.

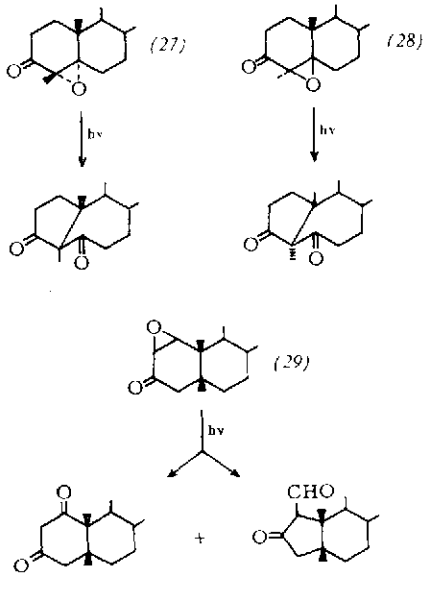


The mechanistic interpretation of photochemical reactions is often based, at least partially, upon stereochemical results. The reliability and limitations of such relationships were discussed by *R. C. Cookson*, with special emphasis on certain reactions of ketones, including the elimination of carbon monoxide, intramolecular ene-synthesis, and cleavage to ketenes. He stressed that stereospecificity is not an absolute proof of a synchronized process. The aldehydes resulting from the $n \rightarrow \pi^*$-excitation of citral *(19)* have configurations *(21)* and *(22)*. The *trans*-configuration of the alkyl groups in *(21)* and the α-position of the aldehyde group in *(22)* suggest the existence of a common intermediate *(20)* as singlet or triplet.

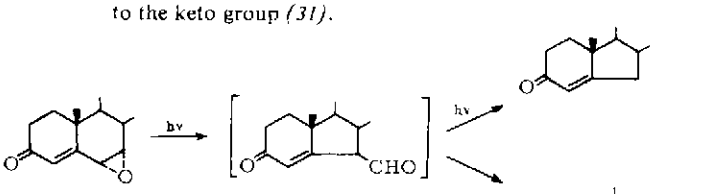
The importance of light-induced transformations of α,β-epoxyketones and related carbobyl systems in organic synthesis was demonstrated by *O. Jeger*. The isomerization of α,β-epoxyketones to β-diketones may be represented by formulae *(23)*–*(26)*.



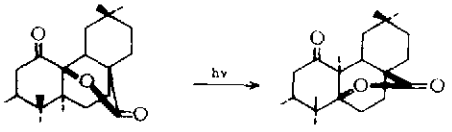
Ultraviolet irradiation of numerous steroid α,β-epoxyketones illustrated the general nature of this photo-isomerization. Depending on the structure, it results in a 1,2-rearrangement of the carbon skeleton or in a 1,2-hydrogen migration. The reactions of *(27)*–*(29)* proceed stereospecifically.



α,β-Unsaturated γ,δ-epoxyketones *(30)* also undergo epoxyketone rearrangement. The function of the epoxy oxygen atom may be exerted by other oxygen functions in α-position to the keto group *(31)*.



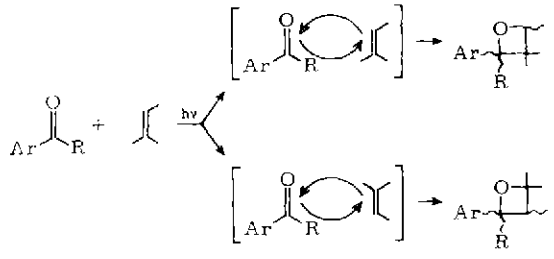
(30)



(31)

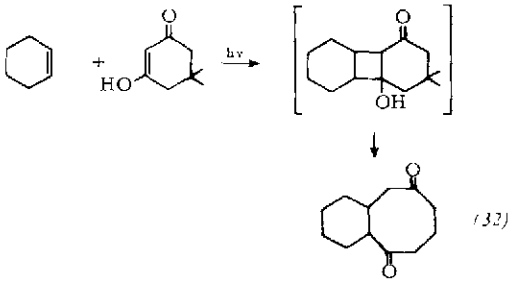
In addition to the C(α)-O bond, the C(α)–C(β) link may be cleaved during ultraviolet irradiation of α,β-epoxyketones. A process of this type is regarded to be operative in the photofragmentation of *O*-acetyljervine.

A paper by *N. C. Yang* dealt with new aspects of the Paterno-Büchi reaction. The oxetane mixture, isolated in 64 % yield in the photo-addition of benzaldehyde to 2-methylbut-2-ene, contains all four isomers, as expected. Attack by the carbonyl oxygen atom (which is electron-deficient in the excited state) at the C=C bond with formation of the most stable carbonium ion is more probable by a factor of 1.6.



Oxetane formation, occurring with a quantum yield of 0.45 ± 0.05, is suppressed by paramagnetic salts. The addition of benzophenone and acetophenone proceeds far more selectively: the two isomers of the favored addition are formed in yields exceeding 90 %. 1- and 2-Naphthaldehyde, 2-benzoylnaphthalene, and 9-anthraldehyde are employed with comparably good results, but the quantum yields are considerably lower than with benzaldehyde; however, 1- and 2-acetylnaphthalene and 9-acetylanthracene are inert. The use of α,β-unsaturated carbonyl compounds (*e.g.* cinnamic or crotonic aldehyde) results in 1,2-addition to the C=C and C=O bonds, but not in 1,4-addition to dihydropyran derivatives.

P. de Mayo dealt chiefly with photochemical cycloadditions of dicarbonyl compounds; their applicability to the synthesis of mono- and bicyclic systems is illustrated by the following examples. Dimethyl maleate reacts with cyclohexene to yield,

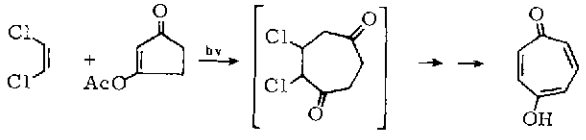


(33)

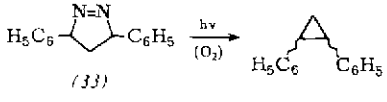
in addition to cyclohexenylsuccinic acid and bicyclohexenyl, at least four isomeric bicyclo[4,2,0]octanedicarboxylic esters. Two of these bicyclic products have the *trans*-configuration; this requires a two-stage process for the formation of at least these two compounds. The ratio of the *cis*/*trans* isomers is temperature-dependent, *i.e.* an intermediate is in thermal equilibrium with its environment. Since sensitizers (acetophenone, benzene) affect the result only slightly, the occurrence of triplet states (possibly of the $n \rightarrow \pi^*$-type) is possible.

The cycloaddition of cyclohexene to dimedone or of acrylic esters to cyclohexane-1,3-dione affords derivatives of cyclooctane-1,5-dione *(32)*; the perhydroazulene system is formed from cyclohexene and cyclohexane-1,3-dione.

One of three stereoisomeric addition products of dichloroethylene to the enol acetate of cyclopentane-1,3-dione yields γ-tropolone after methanolysis and treatment with bases.

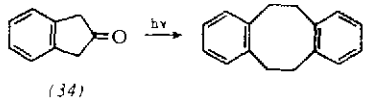


According to *G. Quinkert*, the most important types of photochemical reactions of saturated ketones in solution (epimerization, at least two modes of isomerization, elimination of carbon monoxide, and oxidative cleavage) probably proceed by way of intermediate acyl/alkyl biradicals which arise as dissociation products in the primary photochemical stage. Compared to monoradicals, these biradicals exhibit a considerably decreased intermolecular reactivity, particularly towards oxygen. Accordingly, the result of the photolysis of cyclic azo compounds such as *(33)* is not affected by oxygen.

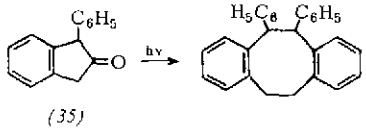


(33)

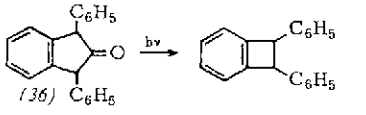
Intramolecular recombination of these biradicals causes reversible epimerization of the ketones. In suitable environments, this recombination is inhibited by intramolecular hydrogen migration: the products of this photo-isomerization are open-chain ketenes (acids) and unsaturated aldehydes. The readiness of photo-decarbonylation – a valuable preparative method for the synthesis of certain hydrocarbons in the gas phase – depends in the liquid phase on the π-electron stabilization of the radicals formed.



(34)

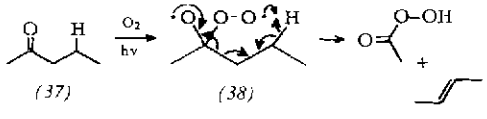


(35)



(36)

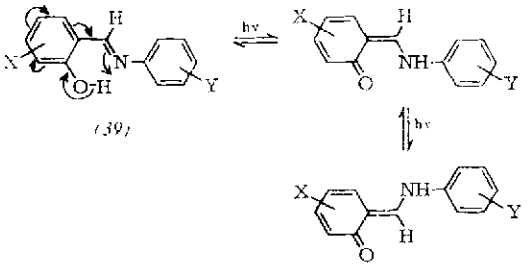
Thus, for example, *(34)* loses less than 10 % CO during irradiation, while *(35)* and *(36)* are almost completely decarbonylated.



(37) *(38)*

As shown by formulae *(37)* and *(38)*, all ketones containing a hydrogen atom in the β-position and in *cis*-configuration with respect to the carbonyl group, should be capable of undergoing this photo-oxidative cleavage.

Numerous photochemical reactions proceed differently in the solid state and in solution, possibly due to the high viscosity or the particular geometry of the crystal; in the latter case "topochemically controlled" reactions are involved. Two examples of this kind were discussed by *M. D. Cohen*. Photochromism (*i.e.* the reversible light-induced color change) of anils of salicylic aldehyde *(39)* may be ascribed to a two-stage process, *viz.* migration of hydrogen, followed by isomerization.



(39)

Crystallographic data account for the fact that photochromism and thermochromism are mutually exclusive in the case of these anils. When the crystal structure favors the hydrogen transfer, isomerization is prevented in the thermochromic crystals. The crystal lattice also determines the course of the photochemical reaction of cinnamic acids. Thus, the *trans*-acid will only dimerize when the distance between active centers is less than about 4 Å. [VB 865/172 IE]

Vth International Symposium on Gas Chromatography

The Fifth International Symposium on Gas Chromatography was held in Brighton (England) from September 8th to 10th, 1964. These symposia follow each other in alternate years, an interval which is too short for far-reaching advances to be expected from each symposium. This year the outstanding contributions were predominantly those extending knowledge and understanding of already known phenomena on the basis of critical and generalized examinations. The assimilation of innovations into established techniques of gas chromatography found expression in an extensive exhibition of apparatus.

Part of the proceedings showed that with the increasing technical perfection of gas-chromatographic apparatus, the production of rapid and high-efficiency columns has become a major problem, and that much effort will he required before the advantages inherent in gas-solid chromatography can be widely utilized.

The contributon by *I. Halász*, *K. Hartmann*, and *E. Heine* (Frankfurt/M.) on "Column types in gas chromatography" was of great theoretical and practical interest in this respect. The authors showed that column types are not sufficiently characterized on the basis of plate numbers. Of equal importance are permeability or the drop in carrier gas pressure at a given flow rate, which influence the time required for a given separation. The stability of the column and the technical difficulties involved in its preparation are also of practical importance. In a further development of the Golay performance index, *Halász* et al. propose a performance parameter (PP) for use in the characterization of column properties:

$$PP = h^2 \frac{(1+k')^5}{(k')^4} \cdot \frac{\eta}{K \cdot j'} \cdot \left(\frac{6 \cdot r_{12}}{r_{12}-1}\right)^4 = \Delta P_{ne} \cdot t_{ne}$$

(where ΔP_{ne} = pressure drop; r_{12} = relative retention; t_{ne} = analysis time; η = viscosity of the carrier gas; K = permeability; j' = pressure drop correction coefficient; k' = capacity factor; h = height equivalent of theoretical plate).

The authors attempted to combine the advantages of capillary columns (open tubular columns, low pressure drop) with those of packed columns (large surface area, small V/V_t-value), which has led to packed capillary columns and other transitional types.

C. Landault and *G. Guiochon* (Paris) described the preparation and properties of a packed capillary column. Like *Halász* et al., they used a capillary column (50 m long; 0.5 mm internal diameter; 1.5 mm external diameter) filled with firebrick C-22 (particle size from 100 to 250 μ, various packing densities). The liquid phase was applied as in the classical capillary column technique. With squalane as stationary phase a complete separation of the isomeric hexanes, including separation of the pair 2,3-dimethylbutane and 2-methylpentane, which is difficult, was obtained within 8 minutes.

Gas-solid chromatography has distinct advantages over gas-liquid chromatography only in the field of hydrocarbon separations, for which alone it is possible to obtain linear isotherms without the use of extremely high operating temperatures. *C. G. Scott* and *C. S. G. Philips* (Oxford) stated that:

1. Gas-solid elution chromatography can accomplish the same separations of hydrocarbons and relatively non-polar substances as can gas-liquid elution chromatography.
2. The selectivity of gas-solid chromatography can equal, if not surpass, that of gas-liquid elution chromatography.
3. A combination of gas-solid displacement chromatography and gas-liquid elution chromatography is a powerful method for trace analysis.
4. Gas-solid displacement chromatography has considerable use in preparative chromatography.

A. V. Kiselev (Moscow) discussed types of intermolecular interaction. Compounds which are not capable of specific interactions contain only π-bonds or have a symmetrical electron density distribution; while molecules capable of specific interactions have local concentration of positive or negative charge (lone-pair electrons, π-bonds, active hydrogen). On this basis adsorbents were classified into four groups:

1. Adsorbents with a chemically saturated surface (*e.g.* graphited soot). The surface contains no ions, functional groups, or π-bonds. The operative forces are dispersion forces, depending only on the geometry of the molecule. On such surfaces the energies of adsorption of water, ammonia, alcohol, etc. are smaller than their energies of condensation, because the surface coverage is so sparse that the adsorbed molecules do not interact with one another. Gas-solid chromatography columns employing graphitized carbon black as stationary phase were first used by *Halász* and *Horvath*. High adsorption energies are disadvantageous as they require very high working temperatures.
2. Adsorbents with local concentrations of positive charge (protons, small-radius cations). They adsorb molecules with lone-pair electrons and π-bonds.
3. Adsorbents with π-bonds and anions of small ionic radii.
4. Non-specific adsorbents bearing cations and anions.

J. J. Kirkland (Wilmington, Del.) described investigations with boehmite-modified firebrick carriers, treated with stearic acid. Dibutyl maleate (1 %) was used as liquid phase. As compared with a column containing dibutyl maleate (20 %) as

liquid phase on normal firebrick, a better separation of the low boiling fractions of a fluorinated hydrocarbon mixture, and a marked reduction of bleeding as a result of adsorption of the dibutyl maleate on the (active) boehmite, was obtained. Similar boehmite-modified carrier surfaces were produced by *Kirkland* on glass beads and in glass capillaries, for which purpose coatings with silicone oils were generally used.

A. B. Littlewood (Newcastle-upon-Tyne) calculated (according to *Giddings*) the increase in width of gas-chromatographic zones over the whole cross-sectional area of a packed column, resulting from non-uniform flow. The results obtained were confirmed on intentionally badly-packed columns, and the effects with alkaline or acidic vapors were made visible by the use of indicators. The effect is also observed in properly packed columns, and here also the theory is compatible with the experimental results. *Littlewood* found that inhomogeneity of the flow profile decreases the separating efficiency especially in preparative columns of diameters between 3 and 10 cm.

In their contribution on "The theory and design of preparative-scale columns", *C. M. C. Higgins* and *J. F. Smith* (Welwyn Garden City, Herts.) discussed the difficulties involved in obtaining definite and reproducible packings of preparative columns. The authors favor what they term a "mountain-packing" method of column filling, where the stationary phase is slowly introduced through a narrow tube so as to form a mound in the center of the column. This method of filling leads to a strong fractionation of particle sizes across the column, which is advantageous in smoothing the flow profile. Particular attention was given by the authors to overloading phenomena in gas-chromatographic columns. On the basis of their observations they propose the following requirements in preparative gas chromatography:

1. A stable liquid phase with a low γ_0-value must be chosen.

2. The carrier material should consist of a very narrow sieve fraction and be as uniformly coated as possible. Of all the carriers examined, firebrick had the best properties (good mechanical durability, easy to coat, easy to pack).

3. Carrier and packing technique should be chosen so that a high radial diffusivity and, as far as possible, a flat intrinsic-profile is obtained.

4. The heat conductivity and specific heat of the packing should be greater than that of the apparatus (column, injection block, etc.).

5. A change of carrier gas has no great influence on separation. Only the time necessary for a given separation is dependent on the diffusivity of the carrier gas.

6. The method of sample injection should allow for control of the sample volume in order that a good compromise between sample size and overloading phenomena can be obtained.

7. The detection system should be rapid in operation and have a large dynamic range.

K. P. Hupe and *E. Bayer* (Tübingen) dealt with problems of temperature programming of preparative columns. In large-diameter columns considerable temperature differentials arise between the walls and the center of the column. These influence the separation very unfavorably and make rapid temperature programming over a large temperature range impracticable. Temperature profiles were calculated by the method of *Giddings*. In large-diameter columns the experimental findings did not agree with the calculations.

According to *R. P. W. Scott* (Sharnbrook, Bedford) flow programming is superior to temperature programming for the shortening of analysis time in the following respects:

1. Flow programming can be used with any chromatograph without regard to oven construction.

2. The thermal stability of the liquid phase is not important.

3. The long cooling-down period after temperature programming is avoided.

Finally, flow programming has a very favorable effect on overloading phenomena and makes "preparative" loads possible even on analytical columns.

Two contributions described new detector systems for liquid-solid chromatography. In both methods an endless metal wire is run past the end of the column where it is moistened by the eluate. The wire then runs into an oven where the solvent is evaporated, leaving only the non-volatile material. In the experimental arrangement of *A. T. James* et al. (Sharnbrook, Bedford) the material on the wire is then led into a pyrolysis oven and cracked. The cracked gases are detected in an argon macrodetector. In the arrangement reported by *E. Haahti* et al. (Turku, Finland) the wire is led directly into the flame of a flame-ionization detector.

Finally, the presentation of gas-chromatographic data was discussed. New recommendations of the Gas Chromatography Discussion Group are that:

1. Relative retentio data should only be derived from chromatograms containing a standard substance.

2. As far as possible n-alkanes should be used as standard substances.

3. Where this is not possible, secondary substances whose retention data relative to n-alkanes are known should be used.

4. All data should be corrected for the dead volume of the apparatus.

5. The retention of an unknown substance x relative to a n-alkane with N C-atoms should be indicated as R_{xN}, and the relative retention should be regarded as the primary unit.

6. Relative retention data should be published preferably in the form of *Kovat*'s retention indices or as R_{x9} values. It has been shown that the Kovats' retention index shows the least variation from a standard value.

7. The gradient b of the linear plot of log R against C-number of the n-alkane, determined from at least three alkanes, should be given together with the retention data.

8. Full experimental details of the apparatus used should be given.

The exhibition of apparatus provided a survey of new developments. Prominent among these were a microcoulometric detector (Messrs. Dohrmann), which can be used with any chromatograph for the analysis of halogen-, phosphorus-, and sulfur-containing compounds, and a flow-programming apparatus (designed by *Scott*) (Messrs. Pye). In the integration field, a new digital integrator (Messrs. Infotronics) for use in amino-acid analysis, and a digital integrator (Messrs. Siemens), were shown. An important development is the Atlas curve-evaluator (patented for Farbenfabriken Bayer) which achieves the integration of a recorded chromatogram by means of an optical tracer system. This apparatus also gives the results in digital form. [VB 862/167 IE]

German version: Angew. Chem. 77, 104 (1965)

Under the joint auspices of the Czechoslovakian Chemical Society and the University of Prague, a "Symposium on the Chemistry of Organic Sulfur Compounds" was held in the Castle of Liblice, near Prague, between June 15 and 17, 1964.

From the agenda:

O. Exner, Prague, surveyed the attempts to gain semiquantitative relations for the originally qualitative concepts of the inductive, mesomeric, and steric effects. These effects were studied on model compounds, and relative data were obtained either from kinetic data or from equilibrium constants. The (-I) effect of alkylthio groups is significantly weaker than that of alkoxy groups. However, groups containing multivalent sulfur are strong electron-acceptors. The (-I) effect decreases in the order:

$$SO_2Cl > SO_2F > SO_2CF_3 > SO_2OC_2H_5 \approx SO_2NH_2 \gg SO_2O^-.$$

The (+M) effect of the SR-group is about half as great as that of the OR-group.

The application of infrared spectroscopy to the investigation of organic sulfur compounds was discussed by *M. Horac*, Prague. He dealt especially with the "insulation effect" due to the relatively great mass of sulfur. Empirical relations were found between the vibration frequencies of the SO and SO_2 groups on the one hand, and the effects of polar substituents on the other. The force constants of these groups were estimated. The intermolecular interaction of different S-containing compounds in donor-acceptor systems was examined in detail. The ability to take up protons is about the same for sulfides as for ethers, while the SH group forms appreciably weaker hydrogen bonds than the OH group.

According to *E. A. C. Lucken*, Geneva (Switzerland), investigations of the nuclear magnetic resonance and the nuclear quadrupole resonance of organic sulfur compounds are restricted by the relatively low occurrence of the natural ^{33}S isotope (0.75 %); nevertheless, the halogen coupling constants of sulfur-containing halogen compounds can be used for structural investigations.

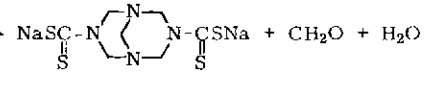
H. W. Prinzler, Leuna-Merseburg (Germany), discussed the formation of the sulfur compounds present in petroleum. Evidently, sulfur compounds were formed simultaneously with the formation of the crude oil by anaerobic microbial reduction of sulfates. With progressive exhaustion of the sulfur content of the mineral deposits, disproportionation occurred with a hydrogen transfer, as a result of which some H_2S escaped and the sulfur content of the crude oil decreased. The hydrogen deficient fraction then gave rise to the sulfur-containing fused compounds found in crude oil today.

P. Zuman, Prague, illustrated the application of polarographic methods to the investigation of organic sulfur compounds. The C–S–R bond is cleaved reductively when activating groups, such as phenacyl, are present, or when the sulfur is in the form of a sulfonium salt. Aryl sulfones are reduced to aryl sulfines and aryl sulfoxides form aryl thioethers. On the other hand, in α,β-unsaturated sulfones the C=C bond is reduced preferentially. In disulfides, 1,2-disulfones, and thiosulfates, the S–S bond is reduced. Homolytic or heterolytic reactions occur, depending on the potential and the structure of the compounds.

According to *J. Cech*, Ustí (Czechoslovakia), the reaction of carbon disulfide with hexamethylenetetramine in alkaline medium gives pentamethylenetetraminebisdithiocarboxylates *(1)*. The ammonium salt can also be prepared from a mixture of aqueous ammonia, CS_2, and formaldehyde. The heavy metal salts of the acid are distinguished by characteristic colors.

According to *W. Fürst*, *W. Kretzschmann*, and *W. Göbel*, Dresden (Germany), pyridine-3-sulfochloride can now be prepared in 70 % yield since pyridine-3-sulfonic acid is obtainable in more than 90 % yield from pyridine and SO_3 at 180 °C.

$$2\ CS_2 + 2\ NaOH + N_4(CH_2)_6$$



(1)

J. Gosselck, Gießen (Germany), found that the inductive and mesomeric effects of the hetero-atoms O, S, and Se may be estimated from the differences in the C=O bond-frequencies $[\Delta\nu_{CO}\ (A-B)]$ and p_k values of isologous carboxylic acids and esters of the general formula $R-C_6H_4-X-CH_2-COOR'$ (A) and $R-C_6H_4-CH_2-X-CH_2-COOR'$ (B), where R = H, NO_2; R' = H, OC_2H_5; X = O, S, Se. Resonance between the limiting structures $Ar-X- \leftrightarrow \overset{\ominus}{Ar}=\overset{\oplus}{X}-$ decreases in the direction O > S > Se in the ratio 8:3:1. The chemical shift of the α-methylene protons in the NMR spectrum is proportional to the C=O frequency of the same compounds.

J. Horac, Prague, investigated the reaction between trichloromethanesulfenic acid (and its derivatives) with alkoxides and aliphatic or aromatic thiolates, which leads (a) to orthocarbonates and (b) to trithiocarbonates, respectively.

$$\text{(a)}\quad CCl_3SX + 4\ RO^{\ominus} \rightarrow C(OR)_4 + S + 3\ Cl^{\ominus} + X^{\ominus}$$

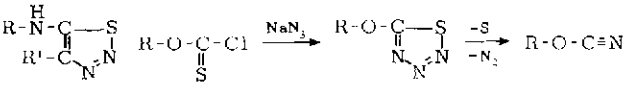
$$\text{(b)}\quad CCl_3SX + 4\ RS^{\ominus} \rightarrow SC(SR)_2 + R-S-S-R + 3\ Cl^{\ominus} + X^{\ominus}$$

The first step in the reaction is the bimolecular nucleophilic substitution of the Cl atoms of the CCl_3-group. In phenyl esters on the other hand, the first step is substitution at the sulfur:

$$CCl_3SOAr + RO^{\ominus} \rightarrow CCl_3SOR + ArO^{\ominus}$$

G. Kresze, München (Germany), has shown that the nitrogen-sulfur bond in *N*-sulfinyl compounds and especially in *N*-sulfinylsulfonamides, is capable of cycloaddition to multiple bonds (C=C, C–O, N=O) to form four-, five-, or six-membered rings. Compounds of the form HX (alcohols, mercaptans, amines) can also be added.

According to *D. Martin*, Berlin-Adlershof (Germany), the reaction between isothiocyanates and diazo compounds yields amino-substituted 1,2,3-thiadiazoles *(2)* by an 1,3-dipolar addition. The corresponding 1,2,3,4-thiatriazoles *(4)*, which are formed from chlorothioformates *(3)* and sodium azide, undergo exothermic decomposition to give nitrogen, sulfur, and aryl cyanates *(5)*, which so far had not been described.

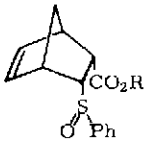


(2) *(3)* *(4)* *(5)*

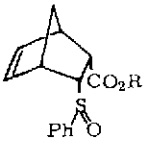
According to *R. Mayer*, Dresden (Germany), carbonyl compounds or their analogues do not yield thiols or thioketones with hydrogen sulfide, if electron-attracting groups are in positions adjacent to the carbonyl group. Instead, reduction products, *viz.* –CH(OH)– or $-CH_2-$, are formed quantitatively. Compounds of the type R–S–X can be similarly desulfurized to give R–X. Numerous examples illustrate the range of application of this reaction.

F. Montanari, Modena (Italy), has described methods for the preparation of optically active sulfoxides, *e.g.* by oxidation of sulfides R–S–R' with optically active peroxyacids.

Relationships can be established between the absolute configuration of the sulfur atom in the enantiomer formed in excess and the optically active reagent used. Diastereomeric sulfoxides are reduced by hydrogen iodide at different rates. Diene syntheses with α-ethylenesulfoxides yield isomeric adducts *(6)* and *(7)* differing only in the configuration of the sulfur atom. The syn- and anti-forms have been distinguished by means of NMR and infrared spectroscopy.

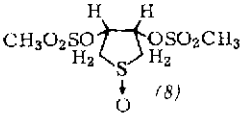


(6), syn

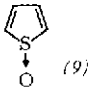


(7), anti

By kinetic studies on the oxidation of sulfoxides to sulfones with peroxyacids in alkaline medium, *G. Modena*, Bari (Italy), has shown that nucleophilic attack by the peroxyacid on the SO group occurs besides the known electrophilic oxidation. The positive ρ-value (*Hammett*) for the reaction indicates that oxidation is favored by an increase in charge density on the SO group brought about by substituent effects. In its dependence on steric effects, the oxidation in alkaline media does not differ appreciably from that in neutral or acidic media.



(8)

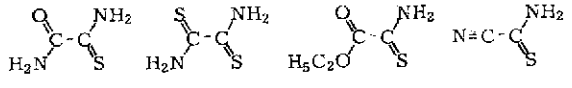


(9)

M. Procházka, Prague, obtained thiophene 1-oxide *(9)* by the action of sodium methoxide on the bis-methanesulfonate of 3,4-dihydroxytetrahydrothiophene 1-oxide *(8)*. The product *(9)* is a very reactive diene and dimerizes or trimerizes in concentrated solutions.

M. Rajsner, Prague, reported on the reactions of lactones of the phthalide type with mercapto compounds. The bicyclic 4,9-dihydrobenzo[e]thieno[2,3-*b*]thiepin-4-one, formed by ring closure from 2-(2'-thienylthiomethyl)benzoic acid, gave the strongly anti-histaminic 4-(3-dimethylaminopropylidene)-4,9-dihydrobenzo[e]thieno[2,3-*b*]thiepine ("Dithiadene") by reaction with 3-dimethylaminopropylmagnesium chloride, followed by dehydration.

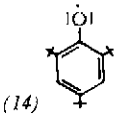
D. H. Reid, St. Andrews (Great Britain) reported on the synthesis of pyrrolo[2,1-*b*]thiazoles. These compounds are thermally stable and form stable charge-transfer complexes. They are protonated reversibly on C-5 and can undergo electrophilic substitution on the same carbon atom. Their spectroscopic behavior corresponds to that of hetero-aromatic compounds. *J. Sandström*, Lund (Sweden), obtained information by spectroscopic methods on conjugation and steric effects in the amide of thiooxalic acid and related compounds. According to this work, *(10)* and *(12)* exist in the trans-form. The effects brought about by conjugation in *(10)*, *(12)*, and



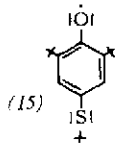
(10) *(11)* *(12)* *(13)*

(13) are in satisfactory agreement with the results of LCAO calculations. The spectra of *N*-monomethyl compounds resemble those of the amides, while those of dimethylamino compounds exhibit considerable hypsochromic shifts of the $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ bands; this behavior is attributed to bond displacement and consequently decreasing conjugation.

K. Scheffler and *H. B. Stegmann*, Tübingen (Germany), demonstrated the participation of sulfur in the free-radical state of aroxyls, by the determination of the g-factor from EPR spectra and by the examination of the EPR hyperfine structure (HFS). The g-factor of the sulfur-free aroxyl *(14)* has a value of 2.00447, whereas that of *(15)* is 2.00529. Since g should be 0.0129 when only the $-\overset{\oplus}{\underset{\cdot}{S}}-$ structure is present, the actual participation of the S-radical form can be estimated at 6.3 % from the difference in the g-factors of *(14)* and *(15)*.



(14)



(15)

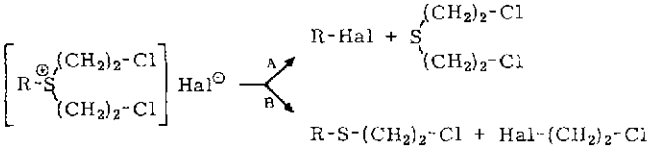
Similarly, a certain free-electron density on the sulfur emerges from the hyperfine structure investigations. If groups capable of conjugation ($-\overset{\alpha}{C}H=\overset{\beta}{C}H-R$) are introduced and the molecule is deuterated a spin density can be detected in the α- and β-positions. The compounds are therefore mesomeric O–C–S radicals.

E. N. Prilezhaeva et al., Moscow, investigated the steric course of the addition of thiols and alcohols to *cis*-1-alkylthio-1-butene-3-ynes and to *cis*-1-alkoxy-1-butene-3-ynes. Thiolate ions add stereospecifically to the triple bonds of the alkylthio compounds forming *cis,cis*-1,4-bisalkylthio-1,3-butadienes. The addition of alkoxide ions to the alkoxy compounds leads to propiolaldehyde acetals.

•SR-Radicals add non-stereospecifically to the triple bond of the en-yne system to give 1,4-disubstituted *cis,cis*- and *cis,trans*-butadienes. PCl_4^+ is added to the triple bond when the en-yne system reacts with PCl_5.

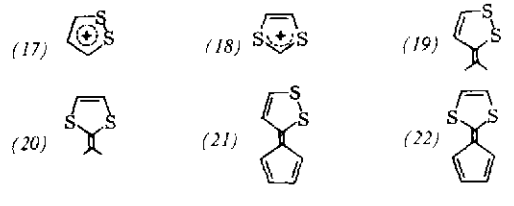
The decomposition of the primary complex results in the formation of the chlorides of 1-alkoxy- or 1-alkylthio-3-chloro-1,3-butadiene-4-phosphinic acid, respectively.

To improve the cytostatic activity of tris-(β-chloroethyl)-sulfonium salts, *A. Lüttringhaus* and *J. Ringhartz*, Freiburg (Germany), reacted cholestanethiols with two moles of ethylene bromohydrin and obtained the corresponding bis-(β-hydroxyethyl)sulfonium salts. Chlorination with thionyl chloride, however, gave β-chloroethyl sulfides instead of the



expected bis-(β-chloroethyl)sulfonium salts. It has been shown that the sulfonium salts *(16)*, with R = benzyl or alkyl, decompose according to (A) exclusively. If, on the other hand, R = t-butyl or cyclohexyl, the decomposition partly follows route (B). Br^- or I^- ions increase the tendency to decompose by route (B).

Comparative proton resonance measurements were carried out on 1,2- and 1,3-dithiolium salts by *H. Prinzbach*, *E. Futterer*, *H. Berger*, and *A. Lüttringhaus*, Freiburg (Germany).



(17) *(18)* *(19)* *(20)* *(21)* *(22)*

Compounds *(17)* and *(18)* are iso-π-electronic with the tropylium ion, while the dithiafulvenes *(19)* and *(20)* and the dithiafulvalenes *(21)* and *(22)* are analogous to heptafulvene and sesquifulvalene.

The chemical shifts of the proton signals of *(17)* and *(18)* reflect the marked local electron deficiency at the corresponding carbon atoms. From the influence of substituents in the 3- and 4-positions in *(17)*, or in the 4-position in *(18)*, on the chemical shift of H-4 and H-5 or H-2 it can be deduced that a cyclic delocalization of the π-electron system occurs in *(17)* and *(18)*, involving in each case a pair of p_π-electrons of the ring sulfur atoms.

The H-signals in the analogously substituted compounds *(19)–(22)* are displaced diamagnetically by about 2–2.5 ppm. These data are compatible only with extensively localized bond systems, dipolar structures having no importance.

Translated by Express Translation Service, London

Structure and Properties of Coordination Compounds

In connection with the Eighth International Conference on Coordination Chemistry in Vienna from September 7th to 11th 1964, the Czechoslovakian Chemical Society, together with the Slovakian and the Czechoslovakian Academies of Sciences and the Slovakian Technical University, Bratislava, arranged a Symposium on the Structure and Properties of Coordination Compounds in Bratislava (Czechoslovakia) from September 2nd to 4th, 1964. The congress had about 200 participants, and 80 lectures were given in Englisch (55 %), German (35 %), or Russian (10 %).

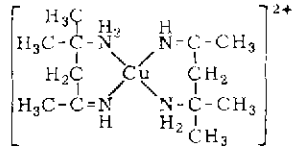
Investigations of Crystal Structure

L. Kutschabsky (Berlin, Germany) showed that $SrB_2O_4 \cdot 4\,H_2O$ consists of discrete $[B(OH)_4]^-$ tetrahedra and Sr^{2+} ions.

H. Dunken and *W. Haase* (Jena, Germany) examined the polytetrafluoroarsenates $(MAsF_4O)_n$ prepared by *L. Kolditz* and coworkers and found dimeric units $(As_2F_8O_2)^{2-}$ consisting of two octahedra with common oxygen edges. Shielding of the susceptible As–O bond leads to a remarkable stability of the complexes.

By passing NH_3 into a solution of $Cu(NO_3)_2$ in acetone, condensation and complex formation occur. In the violet chelate complex *(1)* the octahedral coordination of the copper is achieved through the nitrate groups (*F. Hanic* and *G. Lundgren*, Bratislava).

(1)



In $Cu(SCN)_2(NH_3)_2$ (*J. Garaj* and *J. Gažo*, Bratislava), which always crystallizes in the *trans*-form from aqueous solution, the Cu atom is surrounded by four nitrogen atoms in a distorted square; the two sulfur atoms complete the coordination polyhedron to form an inclined bipyramid.

According to *B. Hajek* (Prague, Czechoslovakia) fluoroscandates always contain ScF_6 octahedra, which are discrete units in M_3ScF_6 and are joined at the corners to form two-dimensional layers in $MScF_4$.

J. Zemann (Göttingen, Germany) reviewed the stereochemistry of tellurites and tellurates. While in tellurites the lone-electron pair occupies a coordination site, TeO_5-octahedra are present in tellurates. They are joined to form chain-complexes having common edges in $KTeO_3(OH)$ and common corners in $KTeO_2(OH)_3$.

From structural investigations on pentacarbonylmanganese hydride and other hydrides *J. A. Ibers* (Upton, N.Y., U.S.A.) concluded that the metal-hydrogen distance was the length for a covalent bond and that the hydrogen atom completed the coordination polyhedron, having a definite position in it.

K. Dornberger-Schiff (Berlin, Germany) investigated the structure of $Sr_3(GeO_3)_3$ as a model for β-wollastonite. It consists of layers of $(GeO_3)_3$ rings, between which Sr atoms with an eightfold coordination are located.

In lithium *o*-chlorobenzoate, $ClC_6H_4COOLi \cdot H_2O$, lithium is surrounded tetrahedrally by three carboxyl-oxygen atoms and a hydrogen atom. One carboxyl-oxygen atom is always common to two tetrahedra (*H. H. Worch*, Berlin, Germany).

New Complexes

Biphosphines, $R_2P{-}PR_2$, according to *K. Issleib* (Halle, Germany) react not only with metal salts to form complexes, but also with metal carbonyls by substitution. In this way compounds of the types *(2)* to *(5)* result.

$$(R_2P\text{-}PR_2)MX_2 \quad (2) \qquad (R_2P\text{-}PR_2)_2MX_2 \quad (3)$$

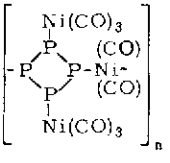
$$(R_2P\text{-}PR_2)\underset{X}{Cu}(R_2P\text{-}PR_2)\underset{X}{Cu}(R_2P\text{-}PR_2) \quad (4)$$

$$(CO)_nM(R_2P\text{-}PR_2)M(CO)_n \quad (5)$$

With M = Ni, Co, Pd, and others the halogen-containing complexes (X = halogen) are more easily formed when R is aliphatic than when it is aromatic. The stability of CO-containing complexes with M = Ni, or Fe does not depend on the nature of R. $Fe(CO)_5$ and $Ni(CO)_4$ react also with tetraorganylcyclotetraphosphines. Highly polymerized complexes *(6)* and *(7)* are probably formed. Alkali metals add onto cyclophosphines without cleavage of the P–P bonds.

$(RP)_4[Fe(CO)_4]_2$ *(6)*

(7)

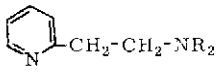


M. H. B. Stiddard (London, England) obtained diphosphine carbonyl complexes with M = Mn, and prepared diarsine carbonyl complexes with M = Re. The central atoms can be oxidized to Mn^+, or Re^{3+} and Re^{4+}.

G. Schwarzenbach (Zurich, Switzerland) spoke about complex formation with mercaptophosphines $R_{3-x}P(CH_2{-}CH_2{-}SH)_x$ [x = 1, 2, and 3]. 1:2, 2:4 and 3:4-complexes result with Ni, Pd, and Pt. If the sulfur atoms are not coordinated they can take up protons and the usual acidity of mercaptans is found. The protons can be replaced by CH_3Hg-groups. The 1:2-complexes, having *trans*-configuration according to their dipole moments, dissolve in aqueous $NiCl_2$ solution to form 3:4-complexes and are converted into *cis*-1:2-complexes by addition of EDTA. In this way polynuclear complexes with different central atoms can also be obtained.

If in Pt complexes P or As together with olefinic groups are present in a ligand such as $CH_2=CH-CH_2-(CH_2)_2-L$ [L = $As(CH_3)_2$ or PPh_2], then, according to *M. A. Bennett* (London, England) the double bond is only weakly held by the platinum atom. When the $-CH_2-$ bridge in the ligand is replaced by a phenylene group, the double bond no longer participates in complex formation, but increased reactivity results.

E. Uhlig (Jena, Germany) reported on the formation of complexes *(8)* with NiX_2 (X = halogen). If R is large,



(8)

Ni(amine)X_2 complexes result, which are tetrahedral or octahedral and polymeric. If R = H or at the most CH_3, then octahedral compounds Ni(amine)$_2X_2$ form; with X = iodide a yellow tetragonal and a dark green tetrahedral isomer exist.

Phthalocyanines of Ni, Co, Fe, and Mn, according to *R. Taube* (Greifswald, Germany), can be reduced in four stages by Li or Na in tetrahydrofuran. The Li salts from the first two stages were obtained on a preparative scale.

K. Madeja (Greifswald, Germany) found that $[Fe(phenanthroline)_3]^{2+}$ in hot pyridine easily loses a ligand to form $[Fe(phenanthroline)_2X_2]$. The magnetic properties of these complexes markedly depend on the nature of X.

Alkylchromium compounds of various compositions can be obtained, according to *E. Kurras* (Jena, Germany), by reaction of Grignard or organolithium compounds with $CrCl_3$ and $CrCl_2$.

R. Ripan (Cluj, Rumania) reported on salts *(9)* and *(10)* of two new heteropolyacids.

$(NH_4)_6\,[Co_2(II)W_{12}O_{42}]\,[Ni(II)(NH_3)_2(H_2O)_2]\cdot x\,H_2O$ *(9)*

$(NH_4)_7\,[Co(III)W_{12}O_{42}]\cdot x\,H_2O$ *(10)*

α-Amino acids as bidentate ligands can replace four nitro groups in hexacobaltates(III) according to *M. B. Celap* (Belgrade, Yugoslavia).

Physicochemical Investigations

T. Šramko (Bratislava, Czechoslovakia) made a spectrophotometric investigation of various $NiClO_4$/thiourea systems and confirmed the existence of $[Ni(thiourea)_6]^{2+}$. *Z. Valtr* (Bratislava) proved the existence of cyanato complexes $K_2[M(OCN)_4]$ with M = Cu, Fe, Ni, and Mn in methanolic solution. *V. Holba* (Bratislava) followed the course of hydration of *trans*-$[Cr(en)_2(SCN)_2]^{2+}$ and *M. Bartušek* and *L. Sommer* (Brno, Czechoslovakia) studied the complex formation of UO_2^{2+} ions with ligands containing phenolic hydroxy groups.

By polarographic examination *E. Fischerová* (Brno, Czechoslovakia) found that Cr(III) and Cr(II) complexes with ethylenediamine behave analogously to the cobalt complexes. *D. I. Bustin* and *A. A. Vlček* (Prague, Czechoslovakia) observed near the first reduction step for the $[Cr(CN)_5(NO)]^{3-}$ ion a second and a third step at lower pH values. *V. Novák*, *M. Svičekova*, and *J. Majer* (Bratislava) determined the stability constants of the lanthanide complexes of 2,3-diaminobutane-N,N,N′,N′-tetra-acetic acid.

The reduction of $[Cu(CN)_4]^{2-}$ complexes in methanolic solution at −45 °C is slowed down so much that *J. Bjerrum* and *R. Paterson* (Copenhagen, Denmark) could determine the complex-formation constants potentiometrically.

The proton magnetic resonance spectrum of σ-cyclopentadienyl complexes of Si, Ge, Sn, and Pb contains, according to *H. P. Fritz* (Munich, Germany), at high temperatures only one signal, indicating that valence-tautomeric systems are probably present.

[VB 858/165 IE]

German version: Angew. Chem. 77, 44 (1965)

VIIth European Peptide Symposium

The Seventh European Peptide Symposium was held from September 3rd to 8th, 1964 in Budapest (Hungary).

From the agenda:

Protective Groups

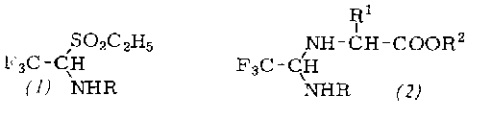
T. Wieland (Frankfurt/Main, Germany) emphasized that even today further new protective groups, selectively removable under mild conditions, are needed in peptide chemistry. Starting from the observation that some *Amanita* toxins are cleaved [1] specifically at the γ-hydroxyleucyl bond even by aqueous trifluoroacetic acid at room temperature, the γ-hydroxyisocaproyl residue (HIC-residue) was used as an amino-protective group. HIC-amino acids may be prepared by heating amino acids with γ,γ-dimethylbutyrolactone in the presence of imidazole. After peptide synthesis the protective group can be split off with dilute acids, *e.g.* in the case of HIC–Gly–L–Leu–OBz (Bz = benzyl) with 50 % trifluoroacetic acid (20 °C, 2 h) [2].

m-Nitrophenoxycarbonylamino acids can be deacylated by irradiation with a mercury lamp (λ > 300 mμ) (1 mmole in 2–3 h) or even with triethylamine/water at room temperature. Unfortunately, hydantoins are always formed in the deacylation of peptide derivatives, so that the protective group is not suitable for peptide syntheses.

K. and *H. Medzihradszky* (Budapest, Hungary) found that with Z-peptides (Z = carbobenzoxy), which do not contain *N*-terminal methionine, the carbobenzoxy residue may be removed by hydrogenation, if the fourfold amount (by mole) of cyclohexylamine is added and about 0.1 to 1 times the amount by weight of catalyst is used. In the presence of sensitive ester groups, triethylamine can also be added as base. The method fails with carbobenzoxydipeptide esters, since here diketopiperazines are formed.

F. Weygand, *W. Steglich*, and *I. Lengyel* (Munich, Germany) reported on a new CF_3-containing protective group. 2,2,2-Trifluoro-1-ethylmercaptoethylamine hydrobromide [3], easily accessible from 2-trifluoromethylpseudooxazol-5-one and ethyl mercaptan in HBr/glacial acetic acid, can be acylated on the nitrogen atom and oxidized to the sulfone *(1)*.

Compound *(1)* exchanges the sulfonyl residue easily for other nucleophilic groups like −OR, −SR and −NHR. If a



(1) *(2)*

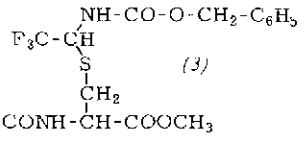
(a): R = F_3CCO-

(b): R = $H_5C_6CH_2$-O-CO-

[1] *T. Wieland*, Helv. chim. Acta *44*, 919 (1961).

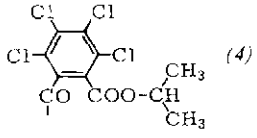
[2] Cleavage of a peptide bond under mild conditions: *T. Wieland* and *D. Rehbinder*, Liebigs Ann. Chem. *670*, 149 (1963).

sulfone like *(1a)* or *(1b)*, that contains a removable acyl residue, is used, then derivatives of the type *(2a)* or *(2b)*, respectively, are obtained by reaction with amino-acid esters. Compound *(3)* is formed in good yield from *N*-trifluoroacetyl-L-cysteine methyl ester and *(1b)* in presence of triethylamine (1 mole) at room temperature.



(3)

S. Guttmann and *J. Pless* (Basel, Switzerland) used acyl residues for the reversible protection of the guanidino group of arginine. The tetrachloroisopropoxyphthaloyl group (TIP-group) *(4)* and the *p*-nitrobenzyloxycarbonyl group [Z(NO_2)-group] proved particularly suitable.



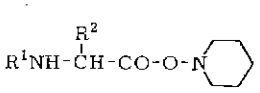
(4)

For the preparation of Z-(ω-TIP)-L-arginine, Z-L-arginine was treated with TIP-2,4,5-trichlorophenyl ester. The TIP-residue can be split off quantitatively with aqueous acetic acid at 100 °C. It is stable to HBr/glacial acetic acid, trifluoroacetic acid and H_2/Pt. Z-[ω-Z(NO_2)]-L-arginine is also suitable for peptide synthesis. The guanidino-protective group, which may be selectively removed by controlled catalytic hydrogenation, is exceptionally stable to HBr/glacial acetic acid and caustic alkali.

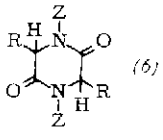
p-Chlorobenzyl esters of *N*-carbobenzoxyamino acids are attacked less than benzyl esters in the cleavage of the Z-residue with HBr/glacial acetic acid, as *L. Kisfaludy* and *N. Löw* (Budapest, Hungary) found. With 17 % HBr/glacial acetic acid, the Z-di-*p*-chlorobenzyl esters of aspartic and glutamic acids may be converted in more than 60 % yield into the di-*p*-chlorobenzyl ester hydrobromides. If instead of HBr/glacial acetic acid, 1 N NaOH in dioxane is used, Z-aspartic acid β-*p*-chlorobenzyl ester or Z-glutamic acid γ-*p*-chlorobenzyl ester are obtained in 60 and 33 per cent yield, respectively.

Formation of the Peptide Bond, Racemization

Of special interest for peptide chemistry are the *N*-acylamino acid 1-piperidyl esters *(5)* investigated by *I. Antonovics*, *S. Beaumont*, *B. O. Handford*, and *G. T. Young* (Oxford, England).



(5)



(6)

Z = $H_5C_6CH_2$-O-CO-

They may be prepared from the *N*-acylamino acids and 1-hydroxypiperidine with dicyclohexylcarbodiimide (DCC). While Z-L-Leu-O-Pip (Pip = piperidyl) and Gly-OC_2H_5 afforded Z-L-Leu-Gly-OC_2H_5 in good yield only after 5 days, 84 % of the dipeptide derivative were obtained 36 h after addition of 1 mole of glacial acetic acid. If the glycine ester was liberated from the hydrochloride with water-containing sodium acetate, the dipeptide derivative (85 % yield) was formed even after 2 h. In these cases, as well as in the synthesis of benzoyl-L-Leu-Gly-OC_2H_5 under different conditions, no racemization could be found (detection limit about 2 % DL-compound). Also from free glycine and 1 mole of base in dioxane/water, optically pure benzoyl-L-Leu-Gly was formed in high yield. In chloroform/triethylamine benzoyl-L-Leu-O-Pip showed no racemization and no oxazolone formation, in contrast to the *p*-nitrophenyl ester.

As *E. Taschner*, *A. Kuziel*, *T. Vajda* and, *B. Rzeszotarska* (Danzig) showed, the amount of dicyclohexylcarbodiimide determines what kind of products are formed in the reaction with Z-amino acids. While according to *Schüssler* and *Zahn* [4], Z-amino-acid anhydrides are formed with 1/2 mole of DCC, a mixture of *N*-acylurea and the bisbenzyloxycarbonyldiketopiperazine derivative *(6)* was obtained using 1 mole of DCC in ethyl acetate at 20 °C in addition to dicyclohexylurea (45–100 %). Anhydrides or oxazolones could not be detected.

E. Taschner, *B. Rzeszotarska*, and *A. Kuziel* (Danzig) recommend bromoacetonitrile in place of the customary chloroacetonitrile [5] for the preparation of cyanomethyl esters. The esters are formed already at room temperature and can be reacted, without isolation, with amino-acid esters. The addition of 0.2 equivalents of glacial acetic acid markedly decreases the reaction time. The dipeptide derivatives *(7)* and *(8)* were examined for racemization by paper chromatography (For = formyl, TFA = trifluoroacetyl, tBu = t-butyl).

	activation with	DL-dipeptide [%]
For-L-Val-L-Val-OtBu *(7)*	$ClCH_2CN$	30
	$BrCH_2CN$	< 1
TFA-L-Phe-L-Val-OtBu *(8)*	$ClCH_2CN$	40
	$BrCH_2CN$	25
	$BrCH_2CN$ + 0.2 equiv. AcOH	< 1

B. Liberek and *A. Michalik* (Danzig) used Z-β-cyano-L-alanine to study the degree of racemization in the synthesis of Z-dipeptide esters. Although in the reaction with glycine methyl ester by the *p*-nitrophenylester, DCC-, phosphorazo- and phosphorus oxide chloride-methods, no racemization occurred (even 2 % racemate detectable), it was observed in considerable amount in the reaction of the thiophenyl ester.

The degree of racemization greatly depends on the solvent: it is highest in dimethylformamide (DMF) and dimethylsulfoxide and lowest in tetrahydrofuran (THF). The degree of racemization increases with greater dilution. While *Beyerman*'s bifunctional catalysts [6] have no influence in DMF, and while acetic acid reduces the degree of racemization only slightly, the racemization in ethyl acetate is lowered from 27 to 2 % DL-compound by 2-hydroxypyridine or acetic acid.

D. G. Knorre and *T. N. Shubina* (Novosibirsk, U.S.S.R.) reported on peptide syntheses in aqueous solution without isolation of intermediate peptides. An activated intermediate (probably *O*-acylurea) is formed in the reaction of formylamino acids with water-soluble carbodiimides in water in a narrow pH range with an optimum at pH 5. In addition, a non-reactive product, presumably the *N*-acylurea, is formed. After the addition of amino-acid ester, peptides are formed at pH 7.

Since all by-products are easily removed with ion exchangers, the formyldipeptide produced can be used afresh for synthesis without isolation after hydrolysis of the ester. The method was used for preparing simple tetrapeptides; the yields amounted to 60–85 % at each step. It is of advantage to work with a 2- to 5-fold excess of carbodiimide.

M. Brenner (Basel, Switzerland) studied the rate of the aminodiacylhydrazine rearrangement [7] in which *e.g.*

[3] *F. Weygand*, *W. Steglich*, and *H. Tanner*, Liebigs Ann. Chem. *658*, 128 (1962).

[4] *H. Zahn* and *H. Schüssler*, Chem. Ber. *95*, 1076 (1962).

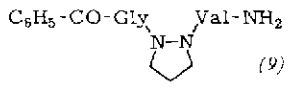
[5] *R. Schwyzer*, *M. Feurer*, *B. Iselin*, and *H. Kägi*, Helv. chim. Acta *38*, 80 (1955).

[6] *H. C. Beyerman* and *W. Maassen van den Brink*, Proc. chem. Soc. (London) *1963*, 266.

[7] *M. Brenner* and *W. Hofer*, Helv. chim. Acta *44*, 1794 (1961).

Z-Gly-Gly-Phe-NH-NH_2 is formed from Z-Gly-Gly-NH-NH-Phe. Only those acids, which carry a doubly bound oxygen atom and an OH-group on the same atom, *e.g.* carboxylic acids, phosphoric acid and sulfuric acid, act as catalysts. Pivalic acid is by far the best catalyst; activity decreases in the series propionic acid > acetic acid > formic acid.

The rate of rearrangement strongly depends on the solvent. It decreases in the series THF, dimethoxyethane, methanol. Besides, it depends markedly on the constitution. While *e.g.* benzoyl-Gly-NHNH-Phe in 10 % propionic acid in THF at 40 °C rearranges within 25 min, Z-Val-NHNH-Val required 40 days under similar conditions. Substitution of the hydrazine-hydrogen atoms by alkyl groups increased the rate of rearrangement. Derivatives of the type *(9)* rearrange instantaneously. Unfortunately the NH-group liberated can no longer be acylated.



(9)

New results on the effects of bifunctional catalysts were communicated by *H. C. Beyerman* and *W. Maassen van den Brink* (Delft, Holland). With slow reactions, *e.g.* the reaction of Z-Gly-OCH_2CN with cyclohexylamine at 20 °C, the yield of amide amounts to 11 % after 30 min without catalyst, but to more than 60 % after addition of pyrazole, 1,2,4-triazole or 2-hydroxypyridine. A mixture of phenol and pyridine showed no effect. Also, in the reaction of Z-Gly-OCH_3 with cyclohexylamine in boiling acetonitrile, bifunctional catalysts increased the yields of amide 10- to 12-fold. In peptide synthesis with cyanomethyl esters, *p*-nitrophenyl esters and vinyl esters, no racemization occurred in the presence of 1,2,4-triazole, while imidazole yielded some racemate in most cases.

A. T. Moore and *H. N. Rydon* (Exeter, England) polymerized ε-TFA-Lys-Gly-Glu-(γ-OCH_3)-Gly and ε-TFA-Lys-Gly-Gly-Glu-(γ-OCH_3)-Gly-Gly with DCC in DMF obtaining as main products the protected octa- and dodecacyclopeptides, respectively. It was shown that even with peptides containing an even number of amino acids the dimerizing cyclization is the main reaction. The possibility for the non-parallel arrangement of the initial peptide appears, therefore, to be more important for the course of the reaction than the stabilization of the end product by hydrogen bonding.

Synthesis of Natural Peptides

R. A. Boissonnas and *E. Sandrin* (Basel, Switzerland) prepared many eledoisine analogues and showed that the *C*-terminal amino acids are responsible for the biological action [8].

K. Lübke (Berlin) found that on degrading eledoisine from the amino-end, the octapeptide (amino acids 4–11) still exhibited 50 % activity, and on passing to the pentapeptide (amino acids 7–11) the activity decreased further [9].

S. Guttmann, J. Pless, and *R. A. Boissonnas* (Basel, Switzerland) reported on the synthesis of ACTH analogues (ACTH = adrenocorticotropic hormone). For this purpose, in the case of arginine, the tosyl- and, in the case of lysine, the formyl-residue was used for protection of the ω-amino groups, so that cleavage of the Lys-Pro bond was avoided on reduction with sodium in liquid ammonia. Here, however, partial cleavage of a Tyr-Pro bond was observed. *M. Löw* and *L. Kisfaludy* (Budapest, Hungary) constructed an ACTH-sequence using hydroxysuccinimide esters. As novel protected amino-acid derivatives Z-Asp-(β-OtBu)-OSU, Z-Glu-(γ-OtBu)-OSU, Z-(ε-BOC)Lys-OSU, and Z-(OBz)Tyr-OSU were prepared (SU = succinimidyl, BOC = t-butyloxycarbonyl). On reaction of these with higher peptides the reaction times increased considerably. An excess of hydroxysuccinimide ester was then used, which after reaction with $NH_2-CH_2-CH_2-N(CH_3)_2$, could be easily removed by dissolving in acid.

K. Poduska (Prague, Czechoslovakia) described the synthesis of the partial trypsin sequence Asp(NH_2)-Ser-Cys-Glu(NH_2)-Gly-Gly-Asp-Ser-Gly-Pro-Val-Val-Cys-Ser-Gly-Lys (which, however, according to the latest findings is slightly different in trypsin). The required intermediate, Z-Ser-(OtBu)-Gly-OCH_3, was prepared directly from the Z-dipeptide ester and isobutylene in the presence of some sulfuric acid. Apparently the etherification succeeds only, if glycine is adjacent to serine [10].

D. Theodoropoulos (Athens, Greece) synthesized the peptide part of cytochrome c. For this, Try-(imBz)His-Thr-Val-Gu-$(OBz)_2$ [imBz = imidazole benzyl], after saponification with 2 equivalents of caustic alkali, was converted into the *p*-nitrobenzyl ester by warming with *p*-nitrobenzyl tosylate and triethylamine in acetone or DMF. In the synthesis of glutamine-containing peptides, ring closures to pyroglutamic or glutamic imide derivatives occurred as side reactions.

The hormone stimulating the secretion of stomach juice consists of the closely related gastrins I and II. Gastrin II is a heptadecapeptide [11]: pyroGlu-Gly-Pro-Try-Met-Glu-Glu-Glu-Glu-Glu-Ala-Tyr-Gly-Try-Met-Asp-Phe-NH_2. *R. C. Sheppard* (Liverpool, England) reported on the synthesis of this peptide from *(10)*, *(11)*, and *(12)*.

pyroGlu-Gly-Pro-Try-Met-OCH_3 *(10)*

Z-Glu-(OtBu)-Glu-(OtBu)-Glu-(OtBu)-Glu-(OtBu)-Glu-(OtBu)-Glu-(OtBu)-Ala-Tyr-Gly-OCH_3 *(11)*

Try-Met-Asp-(OtBu)-Phe-NH_2 *(12)*

After splitting off the protective groups the peptide proved to be physiologically fully active, but was identical in its chemical and physical behavior with Gastrin I; this contradiction has not yet been explained.

Special Problems

C. Nicot and *E. Bricas* (Paris, France) were able to protect *meso*-diaminopimelyl-(D)L-alanine with carbobenzoxy chloride in 47 % yield selectively at the L-center of the *meso*-diaminopimelic acid. The compound is a useful intermediate for the synthesis of unsymmetrical tripeptides of *meso*-diaminopimelic acid.

The acylation of substituted hydrazines employing methods common to peptide chemistry was investigated by *H. Niedrich* (Berlin-Buch, Germany). Reaction of hydrazinoacetic ester with t-butyloxycarbonyl *p*-nitrophenolate afforded a mixture of the two isomeric BOC-compounds, which may be separated by distillation. Both could be acylated with carbobenzoxyglycine and DCC on the free NH-group; after removal of the protecting group, one compound gave the *N*-aminodipeptide *(13)* and the other gave the hydrazinopeptide *(14)*.

Z-Gly-CO-$\overset{\overset{NH_2}{|}}{N}$-$CH_2COOC_2H_5$ *(13)*

Z-Gly-CO-NHNH-$CH_2COOC_2H_5$ *(14)*

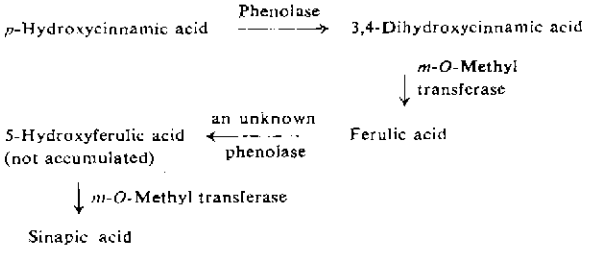
An international symposium "sur la Chimie et la Biochemie de la Lignine, de la Cellulose et des Hemicelluloses" was held in the Ecole Francaise de Papeterie, Grenoble (France), from June 29th–July 4th, 1964.

K. Freudenberg, Heidelberg (Germany), used selected data from the work carried out over the past 15 years on the biosynthesis, degradation, and analysis of lignin [1] to construct a schematic structural formula for lignin comprising 18 main and 7 alternative C_6–C_3 units; this formula is able to account for all the properties of lignin both qualitatively and quantitatively [2]. Spruce lignin can be formed *in vitro* by enzymatic dehydrogenation of a mixture of *p*-coumaryl alcohol, coniferyl alcohol, and sinapyl alcohol (14:6:80) via di-, tri-, tetra-, and oligolignols, many of which have been isolated and identified. Diverse reactions of quinone methides, which occur as intermediates in this polycondensation process, contribute significantly to molecular growth. The three major dilignols (dehydrodiconiferyl alcohol, (±)-pinoresinol, and guaiacylglycerol-β-coniferyl ether) have been isolated from spruce wood by chemical degradation of its lignin. The elemental composition of pure lignin from any woody plant fits the formula – based on C_9 – $(C_9H_{8-}OCH_3O_2(H_2O)_{0\ 1}(OCH_3)_{0-1.5}]_n$, *i.e.* about 2 atoms of hydrogen have been abstracted from every C_9 unit during the formation of lignin. For thioglycolic acid lignin, the group $(C_2H_{3.33}O_{1.67}S)_{<1}$ per C_9 unit has to be added.

E. Adler et al., Göteborg (Sweden), acidolysed spruce lignin (0.2 N HCl, dioxane:water 9:1, 4 h reflux) and obtained crystalline monomeric [3] and dimeric products after chromatography on Sephadex columns; these proved the presence of dehydrodiconiferyl-alcohol and guaiacylglycerol-β-coniferyl-ether groupings in lignin. Cleavage of the guaiacylglycerol-β-coniferyl-ether entities in lignin is promoted by S^2 ions during cooking of wood with $NaOH/Na_2S$ [4]. During kraft pulping, some of the phenylcoumaran structures in lignin are converted via quinone methides into stilbenes, with liberation of HCHO. This reaction was examined on dehydrodiisoeugenol as a model.

F. F. Nord and *W. J. Schubert*, Fordham University, New York (U.S.A.), treated softwood lignins and lignin models with various white-rot fungi [5]. About 15 substances, including vanillin, vanillic acid, *p*-hydroxybenzoic acid, ferulic acid, 4-hydroxy-3-methoxyphenylpyruvic acid, *p*-hydroxycinnamic acid, guaiacylglycerol, coniferaldehyde, *p*-hydroxycinnamaldehyde, and guaiacylglycerol-β-coniferyl ether were detected as degradation products by paper chromatography. A hitherto unknown etherase is thought to be responsible for the liberation of the ether (yield from ultraviolet measurements 0.1 %).

S. A. Brown, Peterborough, Ont. (Canada), reviewed work on the biogenesis of the C_6–C_3 alcohols [6] from which lignin arises by dehydrogenative polycondensation. His latest labelling experiments with wheat have revealed the following paths for some of the steps:



The acids are reduced to the alcohols via their CoA derivatives. When radioactive coniferyl alcohol is administered to wheat, it is partly converted into dehydrodiconiferyl alcohol and (±)-pinoresinol.

T. Higuchi, Gifu (Japan), and *F. Barnoud*, Grenoble (France), studied lignin formation from labelled precursors and the requisite enzyme systems in plant tissue cultures. Tyrase was detected in numerous Gramineae and phenylalanine deaminase in many higher plants. These enzymes catalyse the transformation of the amino acids into the correspondingly hydroxylated cinnamic acids during the biosynthesis of the C_6–C_3 alcohols. It appears that only peroxidase is responsible for the phenol dehydrogenation reactions involved in lignification in tissue cultures.

J. C. Pew, Madison, Wis. (U.S.A.), dehydrogenated 4-propylguaiacol and other guaiacyl derivatives with peroxidase/H_2O_2 as simple models for lignification. Apart from biphenyl compounds [7], he found *inter alia* diphenyl ethers, quinone methides, 1-guaiacylpropan-1-ols, and guaiacyl ethyl ketones as dehydrogenation products. Dehydrogenation of eugenol gives rise to a quinone methide which adds on a molecule of water to form coniferyl alcohol; this explains the formation of the lignin-like products obtained by *S. M. Siegel* [7a] on dehydrogenation of eugenol. In the discussion, *J. M. Harkin*, Heidelberg (Germany), pointed out that these dehydrogenations lead not only to *o*- and *p*-quinone methides, but also to benzoquinones, diphenoquinones, quinhydrones, and semiquinones. When embedded in the lignin macromolecule, these structures are restrained from undergoing the addition and polymerization reactions observed with simple models. These groups serve to explain part of the carbonyl and free radical (term "caged radical" proposed by *K. Kratzl*; cf. [8]) contents of lignin.

K. Sarkanen et al., Seattle, Wash. (U.S.A.), prepared specifically deuterated and tritiated guaiacols, veratrols, and creosols and used these to study the reactivities of the various positions in the aromatic ring towards electrophilic attack, *e.g.* by Cl_2, NO_2, H^+, or HCHO. C–6 in lignin units reacts faster than C–5 or C–2. [2,6-$^3H_2$]Glucovanillin is incorporated into the lignin of the middle lamellae when administered to spruce.

A. von Wacek, Graz (Austria), attempted to work out a micromethod for the determination of lignin in wood using its total methoxyl content and applying corrections for the carbohydrate methoxyl content determined by liberation of methanol with alkali. However, it was found that methanol is also liberated by alkali from certain lignin models and from similar structures in natural and in *Freudenberg*'s artificial lignin via quinone methide intermediates. This complicates the determination of the sugar methoxyl content.

T. Enkvist and *J. Turunen*, Helsinki (Finland), reported on attempts to obtain low molecular-weight products from spent sulfite liquor by means of demethylation and degradation. The liquor is treated with fresh Na_2S/NaOH at 250 to 295 °C for 15–60 min [9], but now at normal pressure or *in vacuo*. A simple S_N2 reaction with HS^- or CH_3S^- effects specific cleavage of certain ether and C–C linkages. The products include phenol, alkylphenols, catechol, alkylcatechols, phenolic carboxylic acids, $(CH_3)_2S$, and $(CH_3)_2S \rightarrow O$.

K. Kratzl and *E. Risnyovszky*, Vienna (Austria), conducted alkaline hydrolyses of about 20 model substances in order to obtain information of the reaction mechanisms involved in the anaerobic alkaline cleavage of lignosulfonic acids from gymnosperms. The sulfonic acid grouping is absolutely necessary for reaction to occur. Sulfonic acids derived from aldols give rise to ketones; those derived from acyloins yield carboxylic acids. A twofold β-elimination is assumed to explain the reaction. Considerable yields of vanillin, acetaldehyde, acetovanillone, and formaldehyde were obtained in this way from lignin.

C. de Choudens and *R. A. Quiles*, Grenoble (France), oxidized 2 % solutions of lignin in NaOH at 100 °C and 5–30 atm of oxygen. CO_2, formic and acetic acids, acetovanillone, vanillin, *p*-hydroxybenzaldehyde, syringaaldehyde, and the corresponding acids were detected as products by chromatography.

Studies of the influence of the physical properties, particularly the melting point, of lignin either as such or in sawdust of various grain size on the speed of sulfonation at 70, 95, and 135 °C and pH 3 or 7 were carried out by *A. Björkman*, Copenhagen (Denmark). Chemical reactions are not rate-determining. Kinetic expressions for the rate of dissolution of the lignin – a first-order process – were evolved. About 10 % of isolated lignin dissolves immediately, however. Methylated lignin or lignin reduced with $NaBH_4$ dissolves slower than untreated lignin.

D. A. I. Goring, Montreal (Canada), determined the molecular weights and molecular configuration of 5 fractions of lignosulfonate from spruce. The values obtained by light-scattering and sedimentation-pattern measurements lay between 5000 and 130000. $M_w/M_n = 3.1$, *i.e.* there is a wide range of molecular weights present. Dialysis through graded micropore filters gave 9 subfractions with molecular weights between 37000 and 1270000. The molecules are spherical aggregates of random coils. Electron micrographs indicate a molecular diameter of 60 Å; the dialysis experiments suggest 47 Å. Heating of the molecules does not bring about any greater change in molecular weight, *i.e.* the random C_9 chains must be interlinked by covalent bonds, and the spherical aggregates are not merely micelles.

Annual Conference of the German Mineralogical Society

The Deutsche Mineralogische Gesellschaft held its session of lectures in Wiesbaden (Germany) from September 7th to 10th, 1964.

From the agenda:

H. Kirsch (Gummersbach, Germany) reported on the examination of tubes from high-pressure steam-power stations. The crystallites of layers of magnetite, formed by corrosion inside the tubes, grow at the area of contact with one of their octahedral faces orientated on the metal crystallites. The degree of orientation and the density of these magnetite layers depend on the amount of oxygen dissolved in the water, on the temperature and on the rate of flow of water or steam in the tubes. Since well-orientated and defect-free magnetite layers effectively protect the tubes against further corrosion, the conditions in the first hours after installation of new tubes are very important as regards resistance to corrosion.

J.-H. Hiller (Stuttgart, Germany) carried out X-ray investigations on rusting of sheet iron in sea air, woodland air, and in the air (containing SO_2) of industrial regions, and showed that fresh rust originally contains an amorphous component which is transformed in a few hours into γ-FeOOH, lepidocrocite, which sometimes forms hexagonal platelets 0.5 mm across. The lepidocrocite is transformed, while retaining its external crystal form, into α-FeOOH (goethite) or magnetite (Fe_3O_4). Magnetite forms rapidly, especially in moist industrial air, but only very slowly in woodland air.

Another problem in industry is the quantitative X-ray determination of cristobalite, which is difficult due to the different degrees of order of the crystals. According to *I. Patzak* (Bonn, Germany) the "disorder number", which is defined as the ratio of the half-widths of two of the closest possible adjoining X-ray interferences and is easily determined experimentally, is a measure of the degree of order of the cristobalite under investigation. Calibration curves, obtained by using cristobalite of a known "disorder number", permit determination of the relative state of order and also of the quantity of cristobalite contained in a mixture.

The importance of the electron microprobe for microanalytical work and for chemical phase analysis was mentioned in two papers. *E. F. Stumpfl* and *A. M. Clark* (London, Great Britain) found that orientated lamellar crystals in naturally occurring linneite, Co_3S_4, were not of the common hexagonal CoS type, but a cubic phase of composition Co_9S_8 ($a_0 = 9.928 \pm 0.001$ Å). Furthermore, the authors found new rhodium-platinum minerals in South African platinum ores, which had escaped detection till then, since they occur only in very small quantities in the ores and are of small particle size. The work of *D. D. Klemm* (Munich, Germany) on zonally formed skutterudites (Fe, Co, Ni)As_x, where $x = 2.0$ to 3.5, gave some indication of the limits of this method due to limitations in the resolving power of the microprobe. The resolving power is determined by the diameter of the electron beam which in this case is about 1 μ.

H. Schloemer (Saarbrücken, Germany) has studied the effect of alkali concentration and species of alkali ions on the properties of boehmite γ-AlOOH, which had been precipitated using purest aluminum powder (5 ppm impurities) with 0.1, 0.01, and 0.001 N alkali-metal hydroxide solutions and triply distilled water. He observed that the crystallite size and state of order of the boehmite increased not only with increasing alkali concentration but also in the order H_2O, CsOH, KOH, LiOH, as precipitating agent, while the specific surface area decreased in this order. The observed decrease in magnitude of the lattice constants of the boehmite with increasing radius of the alkali ion used needs further investigation.

While nowadays it is usually assumed that precipitation of silica dissolved in sea-water proceeds *via* its incorporation into the shells and skeletons of marine organisms, the experiments of *H. Harder* (Münster, Germany) show that deposition of dissolved silica is possible by precipitation

of aluminum hydroxide. The SiO_2 content of the amorphous hydroxide precipitate is higher, the lower the temperature during precipitation. With a high $Al_2O_3:SiO_2$ ratio in solution the dissolved silica is almost completely precipitated. The pH of the solution has only a slight effect on the $Al_2O_3:SiO_2$ ratio of the precipitate. When using sea water, the X-ray amorphous precipitates contain other ions, especially magnesium; this could be of significance in the diagenesis of clay minerals from these hydroxide-silica precipitates.

On attempting to prepare the dihydrate $MgSO_4 \cdot 2\ H_2O$ (sanderite) *R. v. Hodenberg* and *R. Kühn* (Hannover, Germany) repeatedly obtained two hydrate phases, of still uncertain composition, whose crystals grew together with the same orientation. For one of the two phases the lattice constants $a_0 = 12.35$ Å, $b_0 = 12.40$ Å, $c_0 = 13.25$ Å, $\beta = 91.5°$ (C2/c) were found. Moreover, the authors prepared an orthorhombic trihydrate $MgSO_4 \cdot 3\ H_2O$, not described before, with lattice constants $a_0 = 8.18$ Å, $b_0 = 10.93$ Å, $c_0 = 12.42$ Å (Pbca, $\rho_{exp.} = 2.06$ g cm^{-3}).

W. Eysel, M. Behruzi, and *T. Hahn* (Aachen, Germany) investigated the system $LiGaSiO_4/LiGaGeO_4/LiAlGeO_4/LiAlSiO_4$. While $LiAlSiO_4$ has the β-quartz structure at normal pressure, the first three compounds crystallize as the phenakite type and are completely miscible. Cd_2GeO_4 is isotypic with γ-Ca_2SiO_4 and γ-Ca_2GeO_4 (olivine type); however, Cd_2SiO_4 crystallizes as the Na_2SO_4 (V)-type. Therefore, at high temperatures only limited mixed-crystal formation between the two cadmium compounds was observed. Cd_3SiO_5 is orthorhombic-pseudotetragonal and structurally related to Ca_3SiO_5; however, Sr_3SiO_5, Ba_3SiO_5 and Ba_3GeO_5, K_3BeF_5 and Rb_3BeF_5 possess full tetragonal symmetry. Sr_3GeO_5 and Cd_3GeO_5 could not be synthesized.

G. H. Moh (Heidelberg, Germany) investigated the binary system tin/sulfur and found that Sn_2S_3 and SnS_2 exist as stable phases as well as Sn, SnS, and S. The hexagonal layer structure of the disulfide is transformed sluggishly at 692 °C into the cubic structure which is stable up to the melting point. Also Sn_2S_3 has a transition point at 738 °C and melts incongruently at 758 °C. Knowledge of the stability relationships finally brought about the discovery of Sn_2O_3 in Bolivian tin ores.

An investigation of cadmium titanate at high pressures (up to 50×10^3 atm) by *J. Liebertz* (Aachen, Germany) and *C. J. M. Rooymans* (Eindhoven, Netherlands) lead to the unexpected result that the temperature of transition from the low-temperature form α-$CdTiO_3$ (ilmenite type) to the high-temperature form β-$CdTiO_3$ (perovskite type) decreased with increasing pressure. This implies that α-$CdTiO_3$ is less dense than the β-form. While the phase transition $\alpha \rightarrow \beta$ in air above 925 °C is irreversible and very slow, the reverse reaction can be observed under hydrothermal conditions at 850 °C.

G. Bayer and *W. Hoffmann* (Zurich, Switzerland) prepared, by solid state reactions, compounds with the formulae $Na_x(B_yTi_{8-y})O_{16}$ where B = Mg, Co, Ni, Zn, Al, Ti(II), Ti(III), Cr(III), Fe(III), and Ga. The range of phases extended, for the compounds with trivalent B ions, from $Na_2B_2Ti_6O_{16}$ to $Na_{1.33}B_{1.33}Ti_{6.67}O_{16}$, and for those with bivalent B ions from $Na_2BTi_7O_{16}$ to $Na_{1.6}B_{0.8}Ti_{7.2}O_{16}$. All these compounds are isotypic with the titanium bronzes Na_xTiO_2, described by *Wadsley*. The Ti and B ions are statistically distributed over the octahedral sites in the crystal lattice, while the Na ions are surrounded by eight oxygen atoms for valence reasons. Substitution for Na by K, Rb, and Ba leads eventually to non-stoichiometric compounds isotypic with priderite.

The painstaking investigation of the structure of the mineral denningite (Mn, Ca, Zn, Mg)Te_2O_5 by *E. M. Walitzi* (Graz, Austria, and Göttingen, Germany) gives information concerning the structure of tellurites. In this structure the Te atom forms a trigonal pyramid with three oxygen atoms. Two such TeO_3 pyramids are joined by a common oxygen atom into a Te_2O_5 group, such that the Te–O distance within the Te_2O_5 group is, on average, 1.92 Å. The coordination of each Te atom is completed by a fourth oxygen atom, at a distance of 2.36 Å, belonging to another Te_2O_5 group. The coordination of the Te atoms as well as the Te–O–Te bond angle of 120° indicate considerable covalent character of the Te–O bond.

$Li_2ZnCl_4 \cdot 2\ H_2O$ contains, according to *H. Jacobi* and *B. Brehler* (Clausthal-Zellerfeld, Germany), $[ZnCl_4]^{2-}$ tetrahedra, while each Li^+ ion is surrounded by four Cl^- ions and two H_2O molecules. In half of the $[LiCl_4(H_2O)_2]^{3-}$ octahedra the water molecules occupy the *cis*-positions, and in the other half they occupy the *trans*-positions.

S. Ghose, M. Fehlmann (Zurich, Switzerland) and *J. J. Finney* (Golden, Colorado, U.S.A.) found two types of copper polyhedra in the crystal structure of cornetite, $Cu_3PO_4(OH)_3$. Two thirds of the Cu atoms have tetragonal-pyramidal [4 + 1]-coordination, and the others have very distorted tetragonal-bipyramidal [4 + 2]-coordination. These polyhedra are combined by common corners and edges into a three-dimensional network, in which the $[PO_4]$ groups are found.

Of great interest was a comprehensive paper by *W. Gentner* (Heidelberg, Germany) on the determination of the age of planetary materials, in which he showed that, contrary to popular opinion, methods by which the concentration of a gaseous decomposition product is measured (K–Ar methods, U/Th–He methods) offer advantages over those using solid decomposition products, because the isotopic composition of the original lead is unknown, while the original rare gases are practically no longer available on Earth. Measurement of the K–Ar age of a large number of chondrites frequently showed that they had an age of ca. 0.5×10^9 or ca. 4×10^9 years. Presumably then, these stony meteorites from our planetary system originated from two heavenly bodies which solidified 0.5×10^9 and 4×10^9 years ago. The so-called "radiation age", obtained by examination of the outer crust of the meteorite which has been exposed to cosmic radiation, enables the point of time of disintegration of a heavenly body to be established. For stony and for iron meteorites the "radiation age" is usually 2×10^7 to 3×10^7 and 5×10^7 years, but the small number of meteorites examined yields little definite information about how many cosmic catastrophies the meteorites which reach Earth have passed through. There has been much controversy as to whether tektites are glasses of volcanic or of meteoric origin. The determination of their "radiation age" gave $(14.9 \pm 1) \times 10^6$ years for tektites from the Nördlinger Ries, and $(14.8 \pm 0.6) \times 10^6$ years for the moldavites found in Czechoslavakia, which, together with other findings, indicates a genetic linkage between the two. The isotopic composition of argon contained in the many blow-holes in the tektites indicates that the material is terrestrial matter which probably melted when striken by a meteor.

Synergic Effects in Solvent Extraction

H. Irving, Leeds (England)

Synergism in the liquid-liquid extraction of inorganic cations, *i.e.* the phenomenon wherehy a mixture of two reagents produces a larger value for the extraction coefficient than either reagent taken alone, was originally believed to occur only with uranium(VI) and certain mixtures of phosphorus-containing extractants. In 1959, *Irving* predicted that the effect would be much more general and demonstrated the very large synergic effect in the extraction of uranium(VI) by mixtures of TTA (thenoyltrifluoroacetone) and TBP (tributylphosphate) or TBPO (tributylphosphine oxide). The effect was later demonstrated with other actinides in various

oxidation states, with lanthanides, with transition metals of the first series, and even with alkaline earths.

In the lecture, examples were given of synergism in the solvent extraction of indium, protactinium, and plutonium by various combinations of reagents and solvents. An account was also given of other unpublished work on the uses of heterocyclic amines and diamines to promote the extraction of copper(II) by acetylacetone, cobalt(II) by TTA, and nickel by diacetylbisbenzoylhydrazone. The compositions of the extractable adducts have been determined in various ways and a reduction of the synergic effect caused by α-substitution in pyridines can be attributed to steric hindrance of coordination.

Where the solvent extraction of the bischelate CoT_2 [*] is enhanced by either of two bases A or B due to the formation of the extractable adducts CoT_2A_2 and CoT_2B_2, an additional synergic effect may arise from a mixed complex CoT_2AB, and evidence for such mixed complexes can be obtained in this way.

[*] T=Thenoyltrifluoroacetone.

SELECTED ABSTRACTS

An apparatus for maintaining the pH of unbufferd solutions has been constructed by *C. W. Cotman* and *D. M. Smith*. A pH-meter with a simple combination of a glass electrode and a reference electrode gives a signal indicating any change in pH through a servo system which, depending on the sign of the pH difference relative to the desired constant value, discharges strong acid or strong base (of a concentration dependent upon the pH value to be maintained) from one of two syringes. The instrument can maintain any pH value between 2 and 10 constant to better than ±0.05 unit for 48 h, provided that the temperature of the unbuffered solution is kept constant. / Rev. sci. Instruments *41*, 561 (1964) / –Hz.

[Rd 110/297 IE]

Pure difluoroborane HBF_2 has been prepared for the first time by *T. D. Coyle, J. J. Ritter*, and *T. C. Farrar*. HBF_2 was already suspected as an intermediate in the reaction of diborane with fluoro-olefins; here it is best obtained from BF_3 and dialkoxyboranes at 0 °C; the product is frozen out as a mixture with BF_3 and a little diborane. The products are separated by vacuum distillation, but this leads to considerable loss of HBF_2. The compound disproportionates gradually at room temperature into BF_3 and diborane; addition of diborane slows down the disproportionation. HBF_2 reacts smoothly with ethylene at room temperature to give ethylboron difluoride. / Proc. chem. Soc. (London) *1964*, 25 / –Gn.

[Rd 145/332 IE]

Novel complexes of metallocenes with π-acceptors were isolated by *J. C. Goan, E. Berg*, and *H. E. Podall*. (1:2)-Nickelocene-*p*-chloranil *(1)* is formed from its components in benzene in 76 % yield as a dark brown solid which is stable in air and up to 350 °C under argon; it is soluble in water and benzene. (1:1)-Cobaltocene-*p*-chloranil *(2)* [92 % yield] is olive green and decomposes at 105–110 °C; the (1:2)-complex *(3)* [78 % yield] is dark green and decomposes at 228 °C. (1:1)-Cobaltocene-1,3,5-trinitrobenzene *(4)* [95 % yield] is brown and stable in air; its m. p. is 125 °C. Ferrocene forms complexes in the melt and in some solvents with *p*-benzoquinone, tetrachlorophthalic anhydride, 1,2,4,5-tetracyanobenzene, *etc.*, but these cannot be isolated.

$\pi\text{-}Cp_2Ni^{2\oplus}CA^{2\ominus}CA$ *(1)*

$\pi\text{-}Cp_2Co^{\delta\oplus}CA^{\bullet\delta\ominus}$ *(2)*

$\pi\text{-}Cp_2Co^{\delta\oplus}TNB^{\delta\ominus} \rightleftharpoons \pi\text{-}Cp_2Co^{\oplus} + TNB^{\bullet\ominus}$ *(4)*

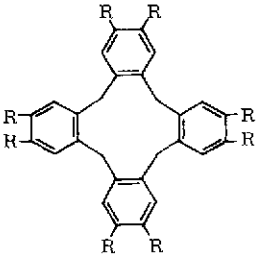
$\pi\text{-}Cp_2Co^{\oplus}CA^{\bullet\ominus}CA$ *(3)*

Cp = Cyclopentadienyl, CA = p-Chloranil,
TNB = 1,3,5-Trinitrobenzol

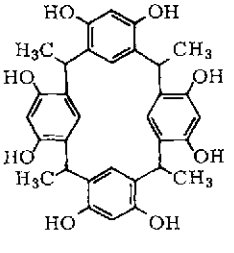
Complexes of this kind are the intermediates sought for in the preparation of metallocinium salts of aromatic acids by oxidation of metallocenes, *e.g.* with benzoquinone in the presence of acid [1]. Infrared and ultraviolet spectra reveal that it is the central metal ion and not a π-cyclopentadienyl ring which functions as π-electron donor. This ion combines with the aromatic radical anion (detected by ESR spectroscopy) to form either a charge-transfer complex with partial charge separation such as *(2)* or *(4)* – which can dissociate into ions in polar solvents such as methanol – or a charge-transfer radical ion salt such as *(3)*. Because of the weakness of its ESR signal, *(1)* is formulated as a nickelocinium salt in which the primary radical ions have undergone disproportionation. / J. org. Chemistry *29*, 975 (1964) / –Bi.

[Rd 156/343 IE]

The structures of macrocyclic condensation products obtained from veratrole and resorcinol with aldehydes were elucidated by *H. Erdtman, F. Haglid*, and *R. Ryhage*. Acid-catalysed condensation of veratrole with formaldehyde affords two crystalline compounds. It was confirmed by mass spectrometric and NMR studies that one of these does in fact possess the structure already assumed by *Lindsey* [2] with three veratrole rings and a "crown" conformation of the nine-membered ring. The second compound has the structure *(1)*. A crystalline product obtained by condensing resorcinol with acetaldehyde in the presence of sulfuric acid has the



R = OCH_3 *(1)*



(2)

structure *(2)*. / Acta chem. scand. *18*, 1249 (1964) / –Ma.

[Rd 150/337 IE]

Prismatic samples can give wrong transparency values in the infrared, as *A. L. Olsen, K. B. LaBaw*, and *L. W. Nichols* have found. The prismatic form of the sample causes the beam of light that has passed through it to enter the monochromator at an oblique angle and therefore disturbs the conditions of the optical beam balance. The magnitude of the error in the transparency is given in terms of the angle of the prismatic layer and index of refraction of the sample; the error increases with increasing prism angle and with increasing refractive index. / J. opt. Soc. American *54*, 813 (1964) / –Hz.

[1] Cf. *G. Wilkinson* et al., J. Amer. chem. Soc. *74*, 2125 (1952).

[2] *A. S. Lindsey*, Chem. and Ind. *1963*, 823.

A new Landoldt reaction which is catalysed by vanadium(V), iron(III), or osmium(VIII) has been discovered by *J. Bognár* and *O. Jellinek*. The reaction can be used for the detection and semiquantitative estimation of small amounts of these ions.

$$ClO_3^{\ominus} + 6\ Br^{\ominus} + 6\ H^{\oplus} = Cl^{\ominus} + 3\ Br_2 + 3\ H_2O \qquad (a)$$

$$Br_2 + C_6H_8O_6\ (1) = 2\ Br^{\ominus} + 2\ H^{\oplus} + C_6H_6O_6 \qquad (b)$$

$$ClO_3^{\ominus} + 3\ C_6H_8O_6\ (1) = Cl^{\ominus} + 3\ C_6H_6O_6 + 3\ H_2O \qquad (c)$$

Reaction (b) goes faster than Reaction (a), so that bromine is reduced by ascorbic acid *(1)* as soon as it is formed. It is only when the ascrobic acid has been entirely consumed by Reactions (b) and (c) that bromine formed by Reaction (a) remains in the solution and is indicated by its brown coloration with *o*-toluidine. The time required for the bromine to appear is shortened by the catalytic effect of traces of some elements; this phenomenon can be used to detect 0.1 μg of V(V), 0.5 μg of Fe(III), or 0.2 μg of Os(VIII) in 5 ml of solution. An excess of Ti(IV), Mo(VI), and Cu(II) interferes with the test by causing additional catalysis. / Mikrochim. Acta. *1964*, 317 / –Gn. [Rd 147/334 IE]

A gravimetric procedure for estimating cyclopentadiene and the cyclopentadienyl anion has been worked out by *G. W. Watt* and *L. J. Baye*; the method is based on the reaction with $HgCl_2$ [1]. A few milligrams of C_5H_6 or KC_5H_5 in anhydrous methanol are mixed with an excess of a 40 % solution of $HgCl_2$ in methanol and saturated methanolic sodium acetate. A yellow precipitate separates almost immediately and is completely coagulated after 16 h. Dilution of the supernatant with water precipitates another small quantity of $C_5(HgCl)_6$. The precipitate is filtered off and washed. The solid gives no X-ray diffraction diagram. In unbuffered solutions C_5H_5HgCl, contaminated with a little Hg_2Cl_2 is precipitated. From buffered solutions $C_5(HgCH_3COO)_6$ and a minute amount of CH_3COOHg are obtained almost quantitatively. / J. inorg. nuclear Chem. *26*, 1531 (1964) / –Kr. [Rd 119/306 IE]

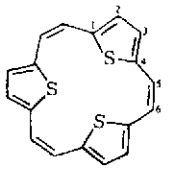
A rapid determination of CO_2, particularly for purposes of organic elemental analysis, can be achieved using relative conductometric procedures according to *W. Bartscher* and *W. Schmidts*. The ratio of the conductivities of a solution of sodium hydroxide used to absorb CO_2 and of an unaltered standard solution is measured; the relationship of these ratios to the CO_2 content is non-linear, but a suitable circuit is used to achieve a linear response when the sample cell and reference solution are kept at the same temperature. The concentration of the sodium hydroxide solution must be kept low in order to estimate small amounts of CO_2; this can lead to incomplete absorption in the solution. However, this difficulty can be avoided by addition of the enzyme carboanhydrase to the solution or by buffering it with amino compounds, *e.g.* aminoethanol. The increase in accuracy obtained in this way makes it possible to determine carbon in organic substances, for example, in samples of even less than 1/mg with the precision of conventional methods. / Z. analyt. Chem. *203*, 168 (1964) / –Gn. [Rd 146/ 333 IE]

A covalent metal-metal bond in mixed metal carbonyls was proven by *R. F. Bryan* using X-ray analysis. In the complex $(C_6H_5)_3SnMn(CO)_4P(C_6H_5)_3$, which crystallizes in a monoclinic ($P2_1/n$) lattice (a = 10.453; b = 26.477; c = 12.646 Å; β = 99°34'), the three atoms Sn, Mn, and P are in a linear arrangement with the interatomic distances $d_{Sn-Mn} = 2.55 \pm 0.02$ and $d_{Mn-P} = 2.36 \pm 0.02$ Å. / Proc. chem. Soc. (London) *1964*, 232 / –Jg. [Rd 157/344 IE]

[1] *K. Issleib* and *A. Brack*, Z. Naturforsch. *11b*, 420 (1956).

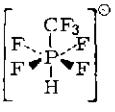
The structure of [18]-annulene trisulfide was made the subject of HMO calculations by *C. A. Coulson* and *M. D. Poole* (in order to compare its aromaticity with that of [18]-annulene itself). Working on the assumptions of a planar D_{3h} molecule, equality of all α_c, and of $\beta_{cc} = \beta_0$, they varied two parameters: $\alpha_s - \alpha_c = 1.5(2.0; 1.5)\beta_0$; and $\beta_{cs} = 1(1.0; 0.8)\beta_0$. The π-bond order [S–(C–1): 0.368; (C 1)–(C–2): 0.630; (C–2)–(C–3): 0.658; (C–4)–(C–5): 0.548; (C–5)–(C–6): 0.715] and π-charge densities: [S: 1.776; C–1: 1.009; C–2: 1.067; C–5: 1.037] given for the third case differ only slightly from those obtained for the first and second assumptions. The most important result is that the (C–5)–(C–6)

(1)



honds have a significantly higher double-hond character than the other C–C bonds. The trisulfide *(1)* is thus less aromatic than [18]-annulene, being more like three thiophene rings coupled by olefinic double bonds; this result is supported by the ultraviolet spectrum of *(1)*. The thiophene rings may be twisted somewhat out of the common plane. / Proc. chem. Soc. (London) *1964*, 220 / –Jg. [Rd 158/345 IE]

The hydridotetrafluoro(trifluoromethyl)phosphate anion *(1)* has been detected and characterized by NMR and infrared spectroscopy by *R. G. Cavell* and *J. F. Nixon*.



(1)

Its dimethylammonium salt *(2)* is formed as follows:

$$3\ F_3C{-}PF_2 + 3\ HN(CH_3)_2 \rightarrow 2\ F_3C{-}PF{-}N(CH_3)_2 + (H_3C)_2NH_2^{\oplus}[F_3C{-}PF_4H]^{\ominus}$$

(2)

Dry *(2)* is stable at room temperature; on alkaline hydrolysis, it forms a quantitative yield of fluoroform. / Proc. chem. Soc. (London) *1964*, 229 / –Jg. [Rd 159/346 IE]

Fluorinated imines were studied by *W. J. Middleton* and *C. G. Krespan*. Perfluorinated ketones do not yield imino derivatives under the usual conditions. The reactive imine *(1)* was, however, obtained in 70 % yield from hexafluoroacetone by treating it with NH_3 and then with $POCl_3$ in pyridine. *N*-Alkylimines are obtained if primary amines are used instead of the NH_3. The synthesis is generally applicable for the preparation of fluorinated imines from fluoro ketones. Compound *(1)* reacts with ammonia or amines to give adducts such as *(2)*. With hydrazine it forms the aminohydrazine *(3)*, which is converted into the hydrazone *(4)* by P_2O_5. The adducts *(5)* and *(6)* are obtained with HCN and HN_3, respectively. Cyclopentadiene, too, gives an adduct. The lithium salt of the imine can be converted into the bromo derivative, which reacts with the Li salt to form the azine *(7)*.

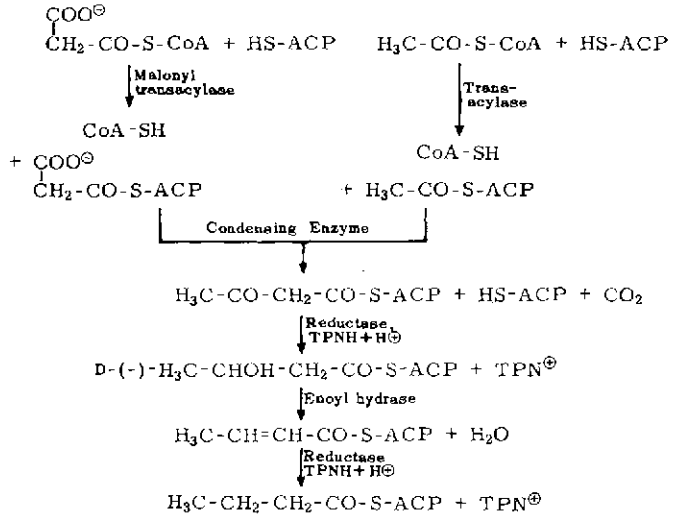
Abstracts, 148th Meeting Amer. chem. Soc. 1964, 24 K / –Ma. [Rd 148/335 IE]

The protein carrier responsible for the biosynthesis of fatty acids has been isolated from *Escherichia coli* by *P. J. Majerus, A. W. Alberts*, and *P. R. Vagelos*. Since the coenzyme A derivatives of the intermediates in the β-oxidation of fatty acids are not the same as those of the intermediates in fatty acid synthesis, it was assumed that all these intermediates are linked to a protein. This thermostable protein, previously called enzyme II, is now termed acyl-carrier protein (ACP) and was concentrated 410-fold by heating incubates at 80 °C, followed by precipitation with 0.1 N HCl, treatment with streptomycin, and repeated chromatography on DEAE-cellulose and DEAE-Sephadex. The protein was practically pure and has a molecular weight of 9500; its amino-acid composition was also determined. It contains a mercapto group which can bind an acyl residue as a thioester grouping. The carrier protein from *E. coli* does not appear to be species-specific. The synthesis of fatty acids in *E. coli* proceeds by the following scheme:



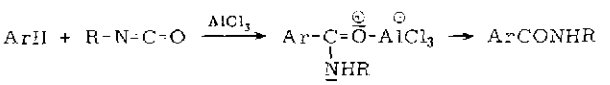
Proc. nat. Acad. Sci. USA *51*, 1231 (1964) / –Sch. [Rd 136/323 IE]

An asymmetric synthesis of optically active alcohols from carbonyl compounds was achieved by *S. R. Landor, B. J. Miller*, and *A. R. Tatchell* using $LiAlH_4$. An asymmetric complex is prepared in ether from a suspension of $LiAlH_4$ with 1,2-*O*-cyclohexylidene-D-glucofuranose *(1)* or methyl 4,6-*O*-benzylidene-α-D-glucopyranoside *(2)*, and the ketone to be reduced is added to this dropwise with stirring.

Ketone	Yield of alcohol [%]	Stereo-specificity [%]	$LiAlH_4$-complex with
C_6H_5–CO–CH_3	66	14.3	*(1)*
	58	7.6	*(2)*
$(H_3C)_2C$=CH–CO–CH_3	60	9.6	*(1)*
	56	3.9	*(2)*

The method is simple and cheap to apply. It is hoped that higher stereospecificity will be achieved with cyclic asymmetric complexes in which the aluminum hydride portion can approach closer to the center of asymmetry. / Proc. chem. Soc. (London) *1964*, 227 / –Jg. [Rd 160/347 IE]

The Friedel-Crafts reaction of isocyanates and benzene derivatives was investigated by *F. Effenberger* and *R. Gleiter*. Isocyanates react with aromatic compounds according to the scheme



to form *N*-substituted benzamides. The reactivity of the aromatic compounds decreases along the series anisole ≈ mesitylene > toluene > benzene ≈ fluorobenzene > chlorobenzene > *m*-dichlorobenzene. The heat of formation of the alkyl isocyanate complexes is greater than that of the aryl complexes, but the alkyl isocyanate/$AlCl_3$ complexes are less reactive than the aromatic complexes. Di-isocyanates give rise to bis-anilides. The highly reactive compound *p*-toluenesulfonyl isocyanate yields the diphenylsulfone derivative as well as the amide. Aromatic compounds with second-order substituents, *e.g.* acetylmesitylene, dimesitylsulfone, and nitromesitylene, do not react to give anilides. Some of the reactions give quantitative yields. / Chem. Ber. *97*, 472 (1964) / –Ma. [Rd 6/283 IE]

Intermolecular association of liquid nitriles is indicated by the temperature dependence of their dielectric constants, according to *W. Dannhauser* and *A. F. Flueckinger*. The equation of *Cole* [Equation (a)] derived from the Kirkwood-Frohlich theory was used to calculate the correlation factor, g, which is a measure of short-range dipole-dipole interaction.

$$\varepsilon_0 \varepsilon_\infty + \frac{3\varepsilon_0}{2\varepsilon_0 + \varepsilon_\infty}\left(\frac{\varepsilon_\infty + 2}{3}\right)^2 \frac{4\pi N \rho \mu_0^2}{3MkT} \cdot g \qquad (a)$$

[ε_0 = experimental dielectric constant at $\nu = \infty$ (as a measure of the polarization), ρ = density, μ_0 = dipole moment in vacuo, M = molecular weight]

If the association is assumed to be due merely to the dimerization of molecules of antiparallel dipole, an equilibrium constant $K = (1-g)/g^2$ can be calculated. The values calculated from the temperature dependence of K and the ranges of ε_0 are given in the table.

Nitrile	$K^\circ_{25\,°C}$	$\Delta H^\circ_{25\,°C}$ [kcal/mole]	$\Delta S^\circ_{25\,°C}$ [e.u.]	Range of T [°C]	Range of ε_0

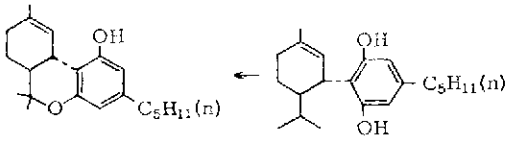
J. physic. Chem. *68*, 1814 (1964) / –Jg. [Rd 118/305 IE]

Ozone is stabilized by strong bases, according to a report by *L. J. Heidt* and *R. Landi*. The half-life of ozone at room temperature is 2 min in 1 N NaOH, 40 min in 5 N NaOH, and 83 h in 20 N NaOH. In addition, ozone does not decompose explosively in strongly alkaline solutions. The causes of these effects are still unknown. It is also unexplained why the half-life of ozone decreases about 18-fold on passing from 10^{-6} to 10^{-4} N NaOH and then increases again in stronger NaOH. / Chem. Engng. News *42*, No. 30, p. 38 (1964) / –Kr. [Rd 120/307 IE]

The effect of sodium γ-hydroxybutyrate on the activity of anesthetics in mice was studied by *L. A. Serebryakov*. Sodium γ-hydroxybutyrate intensifies the anesthetic action of hexobarbital, sodium thiopental, and ethanol two- to three-fold and of diethyl ether and fluorothan to a smaller extent. The lethal dose of sodium γ-hydroxybutyrate applied by intraperitoneal injection is 3.7 g/kg. Simultaneous application of sodium γ-hydroxybutyrate and either hexobarbital or ethanol did not increase the toxicity of either substance. / Pharm. and Toxicol. USSR *3*, 275 (1964) / –Kr. [Rd 121/308 IE]

The isolation, structure, and partial synthesis of an active constituent of hashish (marihuana) are described by *Y. Gaoni* and *R. Mechoulam*. Δ^1-3,4-*trans*-Tetrahydrocannabinol *(1)* was isolated by chromatography of a hexane extract of hashish on florisil. The structure of *(1)* was derived from the properties of its crystalline derivatives, from its ultraviolet, infrared, and NMR spectra, and from its partial synthesis by refluxing cannabidiol *(2)* in ethanol plus HCl. Compound *(1)* exhibits high activity in the ataxia test on dogs.



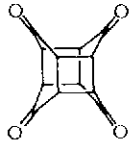
(1) *(2)*

J. Amer. chem. Soc. *86*, 1646 (1964) / –Sch.
[Rd 139/326 IE]

Cystathionine is absent from the brains of patients suffering from homocystinuria, as *T. Gerritsen* and *H. A. Waisman* showed for several persons. Homocystinuria is a congenital disturbance of the metabolism of amino acids containing sulfur, its symptoms including mental retardedness. The human brain normally contains 0.022–0.056 % cystathionine, which is formed in the liver from homocysteine and serine through the action of cystathionine synthetase. Homocystinuria is thought to be caused by a lack of cystathionine synthetase. In earlier studies no cystathionine synthetase could be detected in the liver of a homocystinuria patient. Since a very minute excretion of cystathionine in urine was observed after administration of L-serine and since the excretion of homocystine was reduced, the pathogenic symptoms are probably due only to a strongly inhibited formation of cystathionine, and not to complete blockage of the process. / Science (Wahington) *145*, 588 (1964) / –De. [Rd 107/294 IE]

A quantitative separation of inorganic orthophosphate from pyrophosphate and organic phosphates was achieved by *Y. Sugino* and *Y. Miyoshi*. Addition of ammonium molybdate and triethylamine hydrochloride to an acidic solution of the phosphates (0.05–1.0 N at pH 0.5–2.0) gives a precipitate consisting of orthophosphoric acid, ammonium molybdate, and triethylammonium chloride (1:2:3). Inorganic pyrophosphate, sugar phosphates, and nucleoside phosphates remain in the supernatant. Acid-labile phosphates are partially hydrolysed. Concentrations of orthophosphate ions down to 5×10^{-6} M can be removed. / J. biol. Chemistry *238*, 2360 (1964) / –Sch. [Rd 138/325 IE]

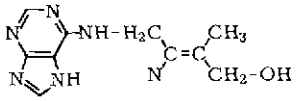
A three-dimensionally bonded dimer of *p*-benzoquinone *(1)* was obtained by *D. Bryce-Smith* and *A. Gilbert* by ultraviolet irradiation of *p*-benzoquinone in molten maleic anhydride; the yield was 30 mg or 0.2 % after 1 h at 60–65 °C. The same pale yellow dimer *(1)*, m.p. 248 °C, is formed when molten benzoquinone is irradiated, although the yield is lower. Irradiation of benzoquinone in cyclohexane yields *(1)* as by-product and



(1)

quinhydrone as main product. Surprisingly, no photoadduct of *p*-benzoquinone onto benzene, naphthalene, anthracene, or phenanthrene was found. Irradiation of a mixture of *p*-benzoquinone and acenaphthylene afforded a copolymer with the approximate formula (*p*-benzoquinone)$_{14}$(acenaphthylene)$_{15}$. / J. chem. Soc. (London) *1964*, 2428 / –Kr.
[Rd 122/309 IE]

Zeatine, a factor which induces cell division, has been isolated in crystalline form (1 mg from 70 kg of grain) by *D. S. Letham*, *J. S. Shannon*, and *I. R. McDonald*. Zeatine *(1)* was identified on chromatograms as a purine derivative; its oxidation with HNO_3 or MnO_2 yielded adenine. Physical investigations and



(1)

its identity with zeatine synthesized by *G. Shaw* and *D. V. Wilson* from γ-bromotiglate (m.p. 207–208 °C) led to structure *(1)* for the compound. As little as 0.1 μg/l of the substance suffices to activate cell division. / Proc. chem. Soc. (London) *1964*, 230, 231 / –De. [Rd 106/293 IE]

The repressor for the alkaline phosphatase in Escherichia coli is a metabolically unstable protein, judging from the results of studies by *J. Gallant* and *R. Stapleton* on the synthesis of the alkaline phosphatase in an *E. coli* mutant in which repression by inorganic phosphate increases with decreasing temperature. The repression depends on the presence of a specific amino acid which is essential for the mutant, and can be eliminated by chloramphenicol (an inhibitor of protein biosynthesis), but is not affected by 5-fluorouracil (an inhibitor of RNA biosynthesis), and occurs even in the absence of the DNA constituent thymine. This indicates that the repressor is a protein, and since a *de novo* synthesis is essential following every derepression, it must be a metabolically unstable protein. Inorganic phosphate appears to be required as corepressor for its synthesis. / J. molecular Biol. *8*, 431 (1964) / –Sch. [Rd 140/327 IE]

The size of the binding site of messenger RNA on ribosomes was determined by *M. Takanami* and *G. Zuber* by degrading polyribosomes containing the synthetic messenger poly(uridylic acid) [poly-U] with ribonuclease. Since only free poly-U is degraded rapidly by the enzyme, it was to be expected that the nucleic acid in or at the 30-S subunit of the ribosome would not be attacked. The isolation and characterization of a relatively homogenous oligonucleotide fraction consisting of heptadecameric UMP suggests that sequences of about 17 bases of the messenger RNA are attached to the ribosomes. When stretched, an oligonucleotide of this type is 184 Å long and is thus just as large as the diameter of the 30-S subunit of the ribosomes (160–180 Å). Poly-U has no secondary structure; it forms polyribosomes immediately on mixing with a ribosome preparation. All other types of RNA require preincubation or denaturation. The attachment to the ribosomes therefore occurs in the stretched form. / Proc. nat. Acad. Sci. USA *51*, 834 (1964) / –Sch. [Rd 143/330 IE]

The entropy of micelle formation in aqueous potassium perfluorocaprylate has been evaluated by *K. Shinoda* and *K. Katsura*. The entropy in solutions free from foreign electrolytes can be calculated from the critical micelle concentration c^0 using Equation (a), for example, assuming that the micelle behaves as a separate phase.

$$\Delta S = \Delta H/T = -(1 + k)RT \cdot d \ln c^0/dT \quad (a)$$

c^0 is obtained from the electrical conductivity; the constant k is found by adding a foreign salt (KNO_3); c_3 is the concentration of the counter-ion belonging to the surfactant per-

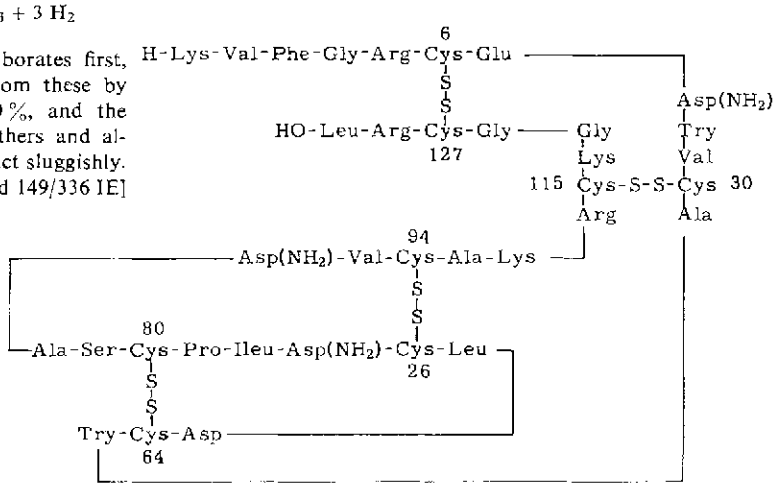
fluorocaprylate anion. / J. physic. Chem. *68*, 1568 (1964) / –Jg. [Rd 115/302 IE]

A new method for preparing organic iodides has been described by *G. F. Freeguard* and *L. H. Long*. Compounds of the type R–O–R′, where R = alkyl, substituted alkyl, R′ = H, alkyl, aryl, or another organic ligand, react with iodine in the presence of small amounts of diborane (or other boranes) to form organic iodides.

$$6\ R{-}O{-}R' + 3\ I_2 + B_2H_6 \rightarrow 6\ RI + 2\ B(OR')_3 + 3\ H_2$$

Cyclic ethers, *e.g.* epoxides, form iodinated borates first, but the iodo compounds can be liberated from these by hydrolysis. The yields are generally over 70%, and the products obtained are very pure. Diphenyl ethers and alcohols with vicinal halogen atoms generally react sluggishly. / Chem. and Ind. *1964*, 1582 / –Ma. [Rd 149/336 IE]

The positions of the disulfide bridges in lysozyme from hen's egg-white were determined by *P. Jollès*, *J. Jauregui-Adell*, and *J. Jollès* by isolating the four peptides containing cystine after hydrolysis of the native protein with pepsin and chymotrypsin. The protein molecule is a chain consisting of 129 amino acids [1] and can be represented schematically as follows:



C. R. hebd. Seances Acad. Sci. *258*, 3920 (1964) / –Sch. [Rd 144/331 IE]

Addition of sodium alkyl sulfates to water alters the chemical shift of the signals of water protons in the NMR spectrum; *J. Clifford* and *B. A. Pethica* observed that the resonance is shifted to higher field strengths. The first four methylene groups in the alkyl chain have but little influence; here the effect of the sulfate group on the structure of the water still predominates. With alkyl sulfates containing (4 + n) methylene groups, the shift is proportional to n. As soon as micelles are formed, the effect disappears, since contact between water and the alkyl chains is lost; micelles produce the same shifts as an equivalent number of free sulfate groups. The results can be interpreted by assuming that the dissolved alkyl chains break hydrogen bridges. / Trans. Faraday Soc. *60*, 1483 (1964) / –Hz. [Rd 111/298 IE]

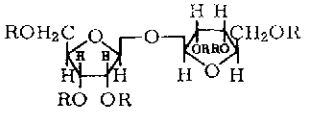
Ion-pair formation in aqueous solutions was detected by *H. Lee* and *J. K. Wilmshurst* using Raman spectroscopy. Degenerate natural vibrations of nitrates, sulfates, carbonates, perchlorates, and ammonium salts are resolved at high concentrations. It is thought that the ion-pairs which can be observed in this fashion share one molecule of water between the anion and cation in the first hydration shell. Attention is called to the difference between the high "spectroscopic" and low "kinetic" concentration of ion-pairs, which is due to the fact that the time of observation involved in vibrational spectroscopy is of the order of 10^{-12} sec. / Austral. J. Chem. *17*, 943 (1964) / –Hz. [Rd 109/296 IE]

The formation of negative ions in alkali halide vapors has been investigated by *H. Ehinghaus* using mass spectrometry. Ions of the form $M^{\ominus}$, $X^{\odot}$, $MX^{\ominus}$, and $M_2X^{\odot}$ were found, where M = Li, Na, K, and Cs and X = F, Cl, Br, and I. Some of the ions are formed from dimers M_2X_2. The results of the measurements were used to evaluate the electron affinities of the alkali metal atoms; the values obtained lie around 0.5 eV and agree well with those obtained by quantum-mechanical calculations. The electron affinities of the MX molecules were calculated to be 1.1–1.5 eV, but these values are to be considered as minima. / Z. Naturforsch. *19a*, 727 (1964) / –Hz. [Rd 114/301 IE]

A protein as the product of a regulator gene was isolated by *A. Garen* and *N. Otsuji*. A protein which is absent in mutants of *Escherichia coli* effecting constitutive synthesis of alkaline phosphatase, but which is present in a wild strain whose enzyme is repressed by phosphate was identified by electrophoresis and isolated by precipitation with ammonium sulfate and repeated chromatography on DEAE-cellulose. The amino-acid composition of the protein was determined. Its biosynthesis is dictated by one of the three genes which regulate the alkaline phosphatase, *viz.* the R2b locus. Like the phosphatase, it is subject to genetic regulation, and is therefore not the repressor as such, though it is probably essential for formation of the latter. / J. molecular Biol. *8*, 841 (1964) / –Sch. [Rd 141/328 IE]

β-Galactosidase subunits have no enzymatic activity, as *S. Lederberg*, *B. Rotman*, and *V. Lederberg* found from estimations of individual enzyme molecules on active ribosomes. In non-induced *E. coli* cells, there is one molecule of β-galactosidase for 4×10^7 ribosomes, *i.e.* less than one molecule per 100 cells. Molecules with intermediate activity could not be detected; the subunits or enzyme fragments are therefore enzymatically inactive. Galactosidase antibodies double the activity bound to ribosomes in experiments *in vitro*, but do not affect the activity of the free enzyme. The antibody becomes attached to an allosteric center on the enzyme and appears to form a model for the hypothetical protein which produces the active enzyme from inactive β-galactosidase *in vivo* by altering the conformation of the latter. / J. biol. Chemistry *239*, 54 (1964) / –Sch. [Rd 65/353 IE]

A new diriboside synthesis developed by *J. A. Zderic* has led to the first preparation of crystalline β-D-ribofuranosyl-β-D-ribofuranoside *(1b)*. 1-*O*-Acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranoside was treated with boron trifluoride etherate in benzene to give *(1a)*. Removal of the benzoyl group with sodium



(1a) R = CO-C_6H_5
(1b) R = H

methoxide in methanol and recrystallization from ethanol afforded *(1b)*, m.p. 158–160 °C, $[\alpha]_D = -102°$ (c = 0.47 in water). The β,β′-configuration was proved by NMR spectroscopy. / Experientia (Basel) *20*, 48 (1964) / –Re. [Rd 133/320 IE]

Justus von Liebig in eigenen Zeugnissen und solchen seiner Zeitgenossen (Justus von Liebig in his own Memoirs and those of his Contemporaries). Edited by *Hertha von Dechend*, with a foreword by *W. Hartner*. Verlag Chemie, Weinheim/Bergstrasse, 2nd revised edition, 1963. 159 pp., 4 plates, DM 14.80 (about $ 3.75).

Much has been written about *Liebig* in the past, and numerous are the works in which his correspondence with certain of his contemporaries such as *Berzelius*, *Merck*, *Mohr*, *Reuning*, *Schönbein*, or his friend *Wöhler* has appeared in print. Like so many eminent figures who ardently defended that which was recognized as right, during his lifetime he had not only admirers but also sworn adversaries; it therefore speaks highly of *Liebig*'s fascinating personality that, in the ninety years which have elapsed since his death, contributions have continually appeared dealing with his life or certain of his ideas and achievements. The present book, issued by the Frankfurt Institute for the History of Natural Sciences and first published in 1953 by the Giessen Society of the Liebig Museum to commemorate the 150th anniversary of *Liebig's* birth, is a further proof that "he who has once been seriously involved with him will never escape him". The book opens with *Liebig*'s autobiographical notes, first published in 1926 by *E. Esselhorn*; the main section, arranged in chronological order, consists of his discourses on scientific, personal, or political questions alongside comparison with the opinions of his friends or adversaries. From the discourses and discussions, there thus ensues a very impressive picture of the personality of this scientist and of the period in which he lived. This is better suited to following *Liebig*'s pathway than a biographical presentation which is always influenced by the temperament of its author.

W. Ruske [NB 217/96 IE]

Zonenschmelzen (Zone Melting). By *H. Schildknecht*. Monograph No. 75 of "Angewandte Chemie" and "Chemie-Ingenieur-Technik". Verlag Chemie, GmbH., Weinheim/Bergstraße, 1964. 1st Edit., XII + 226 pp., 220 figs., 29 tables, linen, DM 26.– (about $ 8.50) [*].

Although originally developed for the purification of semiconductors because of the high demands placed upon their purity, the technique of zone melting has also earned an important status within the past few years in preparative inorganic and organic chemistry. Not unimportant in this connection is the fact that this process can frequently be applied to separate mixtures even of chemically related compounds with good success and yields without requiring chemical transformations. Once a suitable apparatus is available, the main advantage of the method, namely its low demand of man-hours, is fully accrued.

In the present monograph, the author has given a concise and very comprehensive review of the process of zone melting and its applications.

The fundamentals of the subject are dealt with in a general section. The liquid-solid phase equilibrium, eutectic systems, and the formation of solid-solutions are described, and the behavior of these systems on zone melting is discussed in pregnant but justifiably terse terms. The author intentionally does not place too much emphasis on a mathematical analysis of the phenomenon of zone melting in the various systems; instead, he restricts his treatment to the most important formulae, and in keeping with this general policy, allots only a qualitative treatment to a few complicated cases. In the second instrumentation section, apparatus for zone melting and the various methods of heating and cooling are described. This section will provide many a valuable suggestion especially to the organic chemist engaged in preparative work.

In the third specialized section, the author goes into the subject of the purification by zone melting of semiconductor elements and compounds, of metals, and of organic, aromatic and aliphatic compounds, *etc.* The relatively extensive treatment of organic compounds here – about half of this section – is not surprising considering that the author himself is a prominent worker in this field who has published a number of important fundamental articles on the subject and has contributed significantly to the applications of zone melting, *e.g.* for the isolation of natural products. In addition, the importance which this separatory procedure has attained for the preparation of organic compounds and the possibilities which are still open for extending its use in this direction are impressively revealed.

The monograph is written in a clear and lucid style and from its content and organization is directed primarily towards the practical chemist.

Anyone who desires to learn about this elegant purification technique is advised to acquire this book. Even those who are already working in this field will find the volume to be profitable reading.

In conclusion, it should be pointed out that an extensive literature coverage (360 references) and author index are provided to facilitate research into specialized literature on this topic.

Th. Renner [NB 318/156 IE]

Die coulometrische Analyse (Coulometric Analysis). By *K. Abresch* and *I. Claassen*. Monograph No. 71 of "Angewandte Chemie" and "Chemie-Ingenieur-Technik". Verlag Chemie GmbH., Weinheim/Bergstraße 1961. 1st Edit., 228 pp., numerous illustrs., paperback, DM 24.– (about $ 6.00).

The significant advances that have been made within recent times in electrochemical analytical procedures thanks to electronics have only partially been recorded in German scientific literature. It is therefore all the more welcome that the present volume has appeared to fill a gap in one branch of this discipline.

No exceptionally great knowledge of theoretical principles is required in order to understand coulometric analysis. The method is based solely upon Faraday's laws, and the only prerequisites for determining the end points are knowledge of the Nernst equation for an electrode potential and some familiarity with the treatment of transport processes. Accordingly, this book concentrates upon the technical execution of the various procedures and gives illustrations with practical examples which at the same time indicate the limits of detection and the accuracy of the method. An extensive table is given in which almost all of the procedures developed to date are listed. The book is thus an excellent source of information for anyone who wishes to solve a special analytical problem using this technique. The text is easy to read and orderly arranged, so that the book can be warmly recommended to the experimenting analyst.

H. Gerischer [NB 314/172 IE]

Medizin und Chemie, Vol. VII (Medicine and Chemistry). Essays from the medical-chemical research laboratories of Farbenfabriken Bayer AG. Verlag Chemie, Weinheim/Bergstr. 1963. 1st Edit., 822 pp., 122 illustr., 135 tables, 12 color plates, half-leather, DM 45.– (about $ 11.50).

The new (VIIth) volume of the series "Medizin und Chemie" has been published for the centenary of Farbenfabriken Bayer AG and dedicated to the memory of *Fritz Mietzsch*. The scientific contributions are arranged according to their content in 10 groups following a survey of the history of Farbenfabriken Bayer, especially of the pharmaceutical division

[*] An English edition will be published jointly by Verlag Chemie and Academic Press in 1965.

founded 75 years ago after the discovery of phenacetin. The first group, "Pharmacology", is the most extensive. A substantial part of the papers report on drugs with effects on the nervous system. Other contributions include the application of the Mann-Whitney test to the examination of pharmacological activities. In the field of chemotherapy, reports are given on thiochromes with schistomicidal activity and 8-hydroxyquinoline derivatives with activity against *Trypanosoma cruzi* infections. A series of articles deals with the production, properties, and activities of semisynthetic penicillins, *e.g.* the preparation of 6-aminopenicillanic acid by enzymatic cleavage of penicillin G. In the salicyl anilide series, parallelism between cestocidal activity and the uncoupling of oxidative phosphorylation was observed. One of the contributions of the virus research group describes the cultivation of the foot-and-mouth-disease virus in kidney-cell cultures for obtaining antigen. Three contributions are concerned with the synthesis of ethyleneiminoquinones, their toxicity and effect on tumor cells. Chemical papers on a new vitamin A synthesis and a determination of the vitamin B_{12} components in injectable liver extract follow. The 47 contributions provide a clear picture of the range and intensity of research in the laboratories of Bayer's pharmaceutical division. Several contributions not only describe special results, but also sketch the current status of the knowledge and problems of the fields concerned, so that they offer information to a wider circle of interested scientists.

M. Kiese [NB 190/83 IE]

Advances in Inorganic Chemistry and Radiochemistry, Vol. 5. Edited by *H. J. Emeléus* and *A. G. Sharpe*. Academic Press Inc., New York 1963. 1st Edit., IX + 429 pp., numerous illustrs. and tables, linen, $ 14.50.

The book "Modern Aspects of Inorganic Chemistry" by *H. J. Emeléus* and *J. S. Anderson* published for the first time in 1938 was received with great enthusiasm by professional colleagues, research chemists, and even by students, for it gave short pregnant summaries of various special fields of the then current research in inorganic chemistry, called attention to deficiencies and probable errors, and provided numerous directives and incentives. It is clear that this undertaking, which was started under the influence of the youthful zeal and dedication of the main author, would surpass his capacities as the extent of his non-scientific duties increased. The only alternative available for him was to act as editor of a series of monographs in which prominent research chemists would report on the newest developments in their particular fields. It was with this background that the series on "Advances in Inorganic Chemistry and Radiochemistry" was commenced in 1959; the fifth volume of the series has now appeared. In the first five years of its existence, the series has achieved high recognition, and it is probably nowhere lacking in institutes dealing with problems of inorganic chemistry or in the libraries of academic teachers and research workers associated with the fields discussed.

It is perhaps seemly, now that 39 articles covering about 2000 pages of text have appeared, to give a critical survey of the complete work. By applying a loose classification, eleven monographs on the chemistry of non-metals, six on the chemistry of complexes, three on organometallic compounds, three on structural chemistry, eight on nuclear chemistry and radiochemistry, three on physical inorganic chemistry, and five on inorganic systems in unusual states (fused oxides, gaseous hydroxides, *etc.*) can be differentiated; naturally there are often no sharp distinctions between the individual groups of topics. Striking omissions include discourses on systems and structures of metals and alloys, the chemistry of semiconductors, and the inert gases. These lapses will certainly be compensated in later volumes.

There are a few factors which have an unfavorable influence on the quality of the series. For example, there is generally an interim of two years between compilation of the manuscripts and the appearance of the printed volumes, and articles on rapidly advancing subjects give the impression of being outdated despite the insertion of important addenda during proof - reading. Again, the editor may perhaps not always have been able to secure the services of the most knowledgeable experts or at least of the most gifted authors on certain subjects for the "Advances"; there are pronounced differences in the quality of the individual monographs. It detracts from the homogeneity of the work that the editor has tended to allow the authors to describe their fields from their own viewpoint and has handled the articles with magnanimous tolerance: nomenclature, physical symbols, *etc.* often vary from monograph to monograph. Furthermore, restriction of the pages allocated to each monograph to approximately 50 sometimes incites the authors to communicate only superficial or abridged information on their fields. The expert soon recognizes that such monographs cannot be complete, while on the other hand, those who wish to become acquainted with only the main themes of a specialized field are shied off by the maze of abundant and disordered information. In effect, therefore, the "Advances in Inorganic Chemistry and Radiochemistry" are not essentially different from review journals. The hope that the "Modern Aspects of Inorganic Chemistry" would evolve into a promising 3000-page textbook of specialized inorganic chemistry in the "Advances" series seems as far from fulfillment as that of the timely appearance of updated – or at least only three years outdated – volumes of Gmelin's Handbook. It appears as if we shall probably have to forbear any survey over the whole of modern inorganic chemistry, even only in broad outline, and no one is spared the task of undertaking strenuous literature searches for information on more limited research topics.

The principle benefit of the "Advances" is to be culled from their use for preparing lecture series on specialized subjects and for preliminary literature work for commencement in new fields. Careful perusal of the articles will call so many gaps, discrepancies, and parallels in our knowledge to the attention of the reader that many may feel inclined to start off their own research studies at such points.

Volume 5 of "Advances in Inorganic Chemistry and Radiochemistry" contains eight monographs: 1. "The Stabilization of Oxidation States of the Transition Metals" (40 pp., 77 references) by *R. S. Nyholm* and *M. L. Tobe*, an article written with fluent (too fluent?) a style; 2. "Oxides and Oxyfluorides of the Halogens" (49 pp., 211 refs.), in which *M. Schmeisser* and *K. Brändle* have incorporated numerous unpublished results from their own and other research into a chapter on classical preparative chemistry – [here inclusion of the compounds O_3ClOF and O_2NOF in the treatment would have been desirable; moreover, the krypto-ionic approach adopted, whereby compounds such as $ClONO_2$ ("chloronitrate", which has a Cl–O bond) or $ClNO_2$ ("nitryl chloride", which has an N–Cl bond) are written simply as $ClNO_3$ and NO_2Cl, is somewhat confusing]; 3. "The Chemistry of Gallium" (44 pp., 310 refs.,) in which *N. N. Greenwood* describes unusual chemical properties of this element, but principally its adducts with halides; 4. "Chemical Effects of Nuclear Activation in Gases and Liquids" (80 pp., 349 refs.) by *J. G. Campbell*, for those interested in radiochemistry; 5. "Gaseous Hydroxides", where *O. Glemser* and *H. G. Wendlandt* give a supreme description of hydroxides of Li, Na, Be, B, Al, Si, Zn, Mo, and W in the gas phase at high temperatures (up to 2000 °C); 6. "The Borazines" (47 pp., 197 refs.) by *E. K. Mellon* and *J. J. Lagowski*, where about 200 derivatives of the borazole ring system [the nomenclature preferred by these authors, viz. "borazines", is just as trivial as the name "borazoles" and is not derived systematically] are described, stressing the differences between the aromatic system of benzene and that of borazole; opinions are expressed which appear to be derived more from studies of the pertinent literature and from theoretical estimations than from the authors' own experimental work; 7. "Decaborane-14 and its Derivatives" (39 pp., 88 refs.) by *M. F. Hawthorne* is a stimulating and informative chapter, whose length for the description of a

single compound shows the enormous development of boron hydride chemistry; and finally 8. "The Structure and Reactivity of Organophosphorus Compounds" (52 pp., 192 refs.) by *R. F. Hudson*, which ought to interest the organic chemist more than the inorganic or organometallic chemist.

Without wishing to depreciate the value of the other contributions, the reviewer finds that the treatises by *Schmeisser*, *Glemser*, and *Hawthorne* will prove to be most the fruitful reading for the inorganic chemist, for whom the series is actually intended. The quality of this fifth volume is not only in the same high class as that of its predecessors, but it can compete favorably with the best of them.

A few errors might be quoted in conclusion. Page 43, line 3: O_4F_2 is not an oxide; page 51: read $Cl_3Ti\ Cl^{\delta-}$ and $ClO-Cl^{\delta+}$ instead of Cl_3Ti-Cl^- and $ClO-Cl^-$; page 63: the rearrangement equilibrium $O_2NNO_2 \rightleftharpoons NO^+NO_3^-$ is incorrectly formulated; page 66, line 17: $FClO_3$ was prepared in a pure state for the first time in 1952 by *Engelbrecht* (ref. 52); *Bode* (1951) formulated his product as $FOClO_3$, but he was actually dealing with a mixture of $FClO_2$ and $FClO_3$; page 69, line 29: O_3ClF and O_3ClO^- are not isosteric; page 219, Figure 3: there should be ⊕ instead of OH; page 268, line 14: $(R-C\equiv H-NBRH)_3$ is inconceivable; page 274, line 21: potassium thiocyanate is $K^{\oplus}[\overline{N}=C=\overline{S}]^{\ominus}$, not K[CNS] (= thiofulminate); the reaction of KNCS with $\rangle BCl$ can lead only to $\rangle B\ \overline{N}=$ or $\rangle B-\overline{S}-$, never to $\rangle B\ C\equiv$ bonds.

U. Wannagat [NB 300/159 IE]

Neutronenaktivierung als analytisches Hilfsmittel (Neutron Activation as an Analytical Tool). By *Werner Schulze*, in co-operation with *W. Bock-Werthmann*. Vol. 50 of the series "Die chemische Analyse" edited by *G. Jander*. Ferdinand Enke Verlag, Stuttgart 1962. 1st Edit., X + 323 pp., 28 figs., numerous tables, linen, DM 79.-- (about $20.00).

Following a short introduction explaining the principle and modes of application of activation analysis, the authors describe the methods of producing neutrons, the nuclear reactions that can be effected by neutrons, and procedures for irradiating samples with neutrons. Further chapters deal with modes of decay, scaling methods, and the principles of radiochemical separations. The second part of the book contains important measuring data and an extensive collection (with 1010 references) of known applications of activation analysis.

Despite the vast amount of material covered, the authors have succeeded in giving a lucid representative survey of the field. The diversity of the various aspects of the subject naturally requires fuller consideration of certain topics. Thus, for example, the counting methods might have been discussed more critically in order to help users of the book to decide which method best fits his particular needs. A more intensive discussion of the precision of the analytical methods would have been useful. In addition, some corrections are necessary; for example, the activity measured for an infinitely thick sample is proportional to the specific activity, and not to the weight of the sample. Despite these slight flaws, the book can be recommended as an introduction to the methods of activation analysis. The book contains many tables and these will make it a valuable work of reference for the specialist in this field.

H. Münzel [NB 253/111 IE]

Non-stoichiometric Compounds. Edited by *L. Mandelcorn*. Academic Press, New York-London 1964. 1st Edit., xiii + 674 pp., numerous illustrations and tables, linen, $22.50.

This monograph surveys the properties of organic and inorganic compounds having slight deviations from stoichiometric proportions of their constituent atoms and of compounds having no definite connections with the laws of stoichiometry. The boundaries between these two groups are naturally not always clear-cut. The first group includes numerous inorganic oxides and chalcogenides, the second group includes inorganic addition, inclusion, and complex compounds, *e.g.* the zeolites. Organic representatives of the latter group include some molecular compounds and adducts, *e.g.* clathrates.

The book is divided up as follows. *J. M. Robertson* discusses the analysis of the structures of these compounds using X-ray diffraction methods. *H. Eyring* and *D. Henderson* consider statistical thermodynamics and the theory of absolute rates of reaction, particular attention being paid to non-stoichiometric compounds. A comprehensive survey of the lattice structures of inorganic compounds that exhibit deviations from stoichiometric composition is given by *A. D. Wadsley*. *O. M. Katz* and *E. A. Gulbransen* report on the dissolution and occlusion of gases, particularly hydrogen, in metals. A contribution by *E. C. Subbarao* is devoted to the physical properties of non-stoichiometric inorganic compounds. *R. M. Barrer* reports on iorganic inclusion complexes. The next three chapters are allotted to non-stoichiometric organic compounds, *H. M. Powell* reporting on clathrates, *L. P. C. Fetterly* on organic adducts, and *F. R. Senti* and *S. R. Erlander* on hydrates of carbon. *L. A. K. Stavely* then deals with the physical, thermodynamic, and chemical properties of organic molecular compounds in a chapter entitled "The Physics and Chemistry of Inclusion Compounds".

This book will stimulate the interest of everyone who works with non-stoichiometric compounds.

H.-J. Engell [NB 248/106 IE]

From Vital Force to Structural Formulas. By *O. T. Benfey*. Classic Researches in Organic Chemistry. Houghton Mifflin Co., Boston-New York-Atlanta-Geneva, Ill.-Dallas-Palo Alto 1964. 1st Edit., xi + 115 pp., 4 figs., paperback, $1.95.

For the young student who finds that his textbooks present only the current position of his science, this book uses narrative style to impress upon him the answer to the question how it came about that a particular structural formula was allotted to each particular compound. The approach adopted in describing this evolution which culminates in the structural formulae proposed by *Kekulé* and *Couper*, is didactically very clever: references to original publications, indications of sources of more detailed discussions – mostly articles in the Journal of Chemical Education – on particular questions for the interested reader, and the author's fluent mode of expression combine to give the beginner the impression of participating in the construction of the edifice of organic chemistry upward from the foundations that were laid by the "great" chemists. In a country like Germany, where the history of science is regarded mainly as a "hobby" for emeritus professors, it should be pointed out that the author wrote his mansucript during a sabbatical year. The book belongs to the series "Classic Researches in Organic Chemistry" edited by *H. Hart*. The idea of bringing the student of chemistry into contact with classical investigations in this way is certainly a most welcome innovation.

W. Ruske [NB 258/116 IE]

Fortschritte der Arzneimittelforschung (Advances in Drug Research) Vol. 6. Edited by *E. Jucker*. Birkhäuser Verlag, Basel-Stuttgart, 1963. 1st Edit., 423 pp,. 35 illustr., numerous tables, linen, DM 108.– (about $27.50).

Vol. 6 of this series once again contains detailed reviews on particular aspects of drug research. "Metabolism of drugs and other foreign compounds by enzymatic mechanisms" is reviewed by *J. R. Gilette* (60 pp.). The principal mechanisms for the conversion of foreign substances in the body are first described by means of instructive examples, and then the agents, either inherent in or foreign to the body, which enhance or inhibit such metabolism, are discussed (413 references).

The next review, by *R. V. Heinzelman* and *J. Szemuszkevicz*, is entitled "Recent studies in the field of indole compounds"

(76 pp.). The authors supplement the earlier reviews by *Cerletti* in Vol. 2 and *Erspamer* in Vol. 5 with discussions of the synthesis and biological activity of tryptamine derivatives, the conversion of tryptamines into β-carbolines, the enzyme-inhibiting activity of 3-(2-aminobutyl)indoles, indole compounds with ketonic and alcoholic side-chains, and indole derivatives containing sulfur. Finally, syntheses of tetrahydrobenzindole, bufotenine and uroroseine are described (218 references and numerous tables).

H. G. Leemann, K. Stich, and *M. Thomas* provide a detailed review (128 pp.) of "Physico-chemical methods in pharmaceutical chemistry. I. Spectrofluorometry". After a theoretical discussion of the basic principles of fluorometry, examples of the relationship between fluorescence and chemical constitution are discussed. The main section of the report reviews the relevant work published in about 400 journals during the period 1950–1961. The wavelengths of the exciting and fluorescent light, the detection limits, and literature references are presented in tabular form.

The "Biological activity of the terpenoids and their derivatives" is reviewed by *M. Martin-Smith* and *Towhida Khatoon*. After an introduction on classification, some terpenoids with specific activities, those used in clinical and non-clinical practice, and the role of active groups are discussed. The fate of terpenoids in the body and their side effects are briefly described (867 references).

"Neue Arzneimittel" (New drugs), by *W. Kunz*, covers in 60 pp. materials introduced since publication of the earlier reviews in Vols. 2 and 3, classified according to field of indication (365 references).

A detailed subject index again makes the volume a useful work of reference, and the numerous structural formulae substantially contribute to its usefulness. The presentation is once again excellent.

O. Schaumann [NB 221/98 IE]

Progress in the Science and Technology of the Rare Earths. Vol. 1. Edited by *LeRoy Eyring*. Pergamon Press, Oxford London-New York-Paris 1964. 1st Edit., 532 pp., numerous illustrations and tables, linen, £6.0.0 (about $16.00).

Interest in the rare earths was reawakened about 20 years ago, because these elements were found to be products from the nuclear fission of uranium, and secondly because they held promise as good models for predictions about the actinides. Furthermore, thorium had gained importance because of its use as a source of nuclear energy. During the isolation of thorium from monazite sand, several times its weight of rare earths are obtained as by-product and – as in *Auer von Welsbach*'s time – are lying in vast stock-piles until some profitable method of utilizing them is discovered. Hence industry is also now interested in extending basic research in this field. In the USA, congresses concerned exclusively with the chemistry and metallurgy of these elements are held from time to time, and in Russia, a whole institute is devoted to the study of them.

Bearing this in mind, it is understandable that the editor and publishers are planning to produce a series of monographic reports on the rare earths. This first volume covers publications which appeared between the years 1955 and 1961 and reproduces in 500 pages 16 excellent articles written by experts from six different countries. The topics dealt with range from geochemistry and the technical recovery and separation of rare earths to their alloys and organometallic compounds. One contribution gives an 85-page review of potential applications, and two other articles evaluate Russian literature in this field.

The survey volume presented here is to be followed annually by other volumes of the series, a highly useful practice that has already been adopted in some other fields. This practice may evolve into the future form of abstract literature and thus replace the classical abstract journals which threaten to become too expensive and too extensive to read.

Werner Fischer [NB 244/102 IE]

Methoden der organischen Chemie (Houben-Weyl-Müller) [Methods in Organic Chemistry], Vol. VI, Part 2: Sauerstoffverbindungen I (Oxygen Compounds). Georg Thieme Verlag, Stuttgart, 1963. 4th Edit., edited by *Eugen Müller*. xlviii + 952 pp., 4 figs., 1 portrait, 161 tables, price per volume DM 220.– (about $ 56.00).

This is the first part of the projected volumes VI/2 and VI/3 on organic oxygen compounds. Its first chapter contains methods for preparing metal alkoxides, enoxides, and phenoxides and also an appendix (20 pp.) on the most important chelates, including a section on the technically interesting technique of "oxidative coppering of azo dyes". This is followed by chapters on the preparation of organic derivatives of silicic and boric acids. It is of great advantage to the reader that terms are defined in the preliminary chapters, thus avoiding confusion and ensuring consistency throughout the book. The authors have taken the trouble to record the names of the compounds in accordance with the old and new rules of nomenclature – occasionally with references to the English names.

The procedures for preparation of the numerous compounds described are based mainly on a few fundamental chemical operations such as partial and complete solvolysis of readily available halogeno derivatives, comproportionation and disproportionation reactions, and esterification and transesterification, all of which are arranged in orderly fashion. Next come chapters that are organized in a similar manner on organic derivatives of oxyacids of nitrogen, arsenic, antimony, sulfur, and halogens, followed by chapters on the production of β-lactones and on the preparation and reactions of other lactones. The recency of the closing date for literature coverage varies; it is only in the chapter on organic boric acid derivatives that the deadline of 1962–1963 mentioned in the preface has been respected.

After careful perusal [*] of the whole volume applying highly critical standards, the reviewer considers it worthwhile to call attention to the following points.

1. The trimethylsilazadichloralane formed fromh examethyldisilazane and aluminum trichloride (p. 167/2) is apparently dimeric [cf. *M. Schmidt* and *H. Schmidbauer*, Angew. Chem. *74*, 372 (1962); Angew. Chem. internat. Edit. *1*, 327 (1962)].

2. In connection with the reaction of N_2O_5 with cycloparaffins (p. 346), the publication by *F. Asinger* [Chem. Ber. *94*, 84 (1961)] in which he corrects earlier erroneous reports should have been cited.

3. Since attention is called to the sensitivity towards light of alkyl nitrites (p. 338), it would have been useful to have gone into the preparatively important Barton reaction [J. Amer. chem. Soc. *82*, 2640 (1961)], which has proved to be of great value as a method for the synthesis of steroids. Another regrettable omission is the lack of reference to the photolysis of alkyl hypohalides among the decomposition reactions on pp. 499–500.

4. The bicyclo[2,2,1]heptane and bicyclo[2,2,2]octane systems should have been depicted uniformly throughout the whole volume in the manner shown on p. 710, which corresponds to the internationally accepted convention and which simultaneously conveys a more precise image of the structure of the molecule.

5. In addition, the steric structure of molecules has been disregarded in most formulae. It may be that the stereochemistry is unknown or uncertain in individual cases, and this is probably why references to orginal literature are given. However, when the discussion in the text is concerned with stereoisomeric compounds or reaction products, the steric relationships should be presented more clearly in the formulae. Thus, for example, it would have been better to intimate that the β,δ-dimethylsorbic acid of m.p. 67.5 °C described on p. 822 has the Δ^2-*cis*-structure.

6. The preparation of terebinic acid (p. 637) involves a photosensitized addition of isopropanol onto fumaric acid with

[*] Thanks are due to Dr. *H. D. Scharf* for his generous support in this task.

benzophenone as sensitizer. The expression "chemically sensitized" used in the book does not convey much information to the reviewer. Moreover, the publications of *G. O. Schenk* [Angew. Chem. *69*, 177 (1957)] should have been cited, for he described this addition earlier. The same applies to the photodimerization of coumarins (p. 758), for again there is no reference to *G. O. Schenck*'s work [cf. Chem. Ber. *95*, 1409 (1962)], although he discovered the relationships between the substrate, sensitizer, and sterochemistry of the photodimerized coumarins.

7. *R. Kothe* (not *Kohte*) does not deal with dehydrogenation of diols in his paper cited in footnote 5 on p. 718, but with the production of dialkyl phthalides.

8. Why is it that "Krystalle" and "krystallisieren" have been spelled with "y" throughout the book? The procedures given on pp. 491 and 806 contain the old-fashioned method of expressing quantities in "Teilen" or "Tl" (parts); these procedures can perhaps be modernized in a later edition.

On the whole, however, the book represents a magnificent feat for which the authors, the editor, and the publisher can all be equally congratulated. It succeeds in coordinating results which are strewn throughout inorganic and organic literature and in organizing them according to both methods and materials into a lucid arrangement; it will thus form an extremely useful advisor for the organic chemist engaged in preparative work. Even for a chemist who has worked for a long time in one special field, *e.g.* lactone chemistry, this volume is an extraordinarily rich treasure trove. *F. Korte* [NB 294/152 IE]

Inorganic Polymer Chemistry. By *F. G. R. Gimblett*. Butterworths & Co., Ltd., London 1963. 1st Edit., x + 452 pp., numerous illustr. and tables, linen, £4.10.0 (about $12.50).

The field of polymeric inorganic compounds has undergone an unforeseen development within the past few years. It is therefore a great credit to the author that he has devoted himself to presenting the essential features of this field in a systematic treatment. His main aim has been to approach the principles governing the formation and structure of inorganic polymers particularly from the physico-chemical standpoint and thus to afford incentives for further developments in this field. The basis for his systematic arrangement is formed by the methods for obtaining the polymers: 1. condensation reactions and 2. addition reactions. The reviewer agrees that this is the best basis for dealing with the subject, for it permits a readily surveyable systematic treatment.

In the introduction, the nature of the bonding in inorganic polymers is discussed and compared with that of the bonds in organic polymers. This is followed by a discourse on condensation processes at high temperatures (with a relatively detailed treatment of polyphosphates and metaphosphates and of silicates), and then cationic aggregation processes in aqueous and non-aqueous solutions are described. Next comes a special chapter on "Coordination Polymerization", which deals with polymers whose formation is due more or less to the tendency of a cation to coordinate, *e.g.* in the complex incorporation of Be^{2+} into a bis-1,3-diketone. The next section deals with anionic aggregation processes in aqueous solution, such as the formation of iso- and heteropolyacids, and includes a short description of the condensation of dialkylsilanediols to give silicones. The relatively few cases of addition polymerizations (S, Se, Te, and phosphorusnitrile chlorides) are then discussed. A relatively large chapter is devoted to the structures of crystalline and glass-like polymers; this deals with borides of transition elements and with nitrides (*e.g.* BN), *etc.* The phenomenon of depolymerization is also described in detail. In conclusion, the latest developments in the chemistry of inorganic polymers are presented, and a very clever selection is made from the numerous publications by *Andrianov*, for example.

The book is very easy to read and conveys the general impression that the author is well acquainted with the material and has thought it all over carefully. Its topics are stimulating and can be heartily recommended especially to those who want to start work in the field of inorganic polymers.

O. Schmitz-DuMont [NB 297/155 IE]

Einkristalle. Wachstum, Herstellung und Anwendung (Single Crystals – Growth, Production, and Use). By *A. Smakula*. Volume 14 in the series: Technische Physik in Einzeldarstellungen, edited by *W. Meissner* and *M. Näbauer*. Springer, Berlin-Göttingen-Heidelberg 1962. 1st Edit., VIII, pp. 431, 240 illustr., 160 tab., linen, DM 76.– (about $19.00).

The author has set out to give a comprehensive review of the present status of the knowledge of crystal growth and of the methods for the growth of single crystals. This intention is most welcome, since as yet there have been only few books of this kind, and important work scattered throughout the literature can be found only with difficulty.

The first part, about one-third of the book (*Aufbau und Abbau der Kristalle*), deals with the properties of crystal structural elements, crystal structure, nuclei formation, crystal growth, crystal analysis, dislocations, and theories of crystal growth. The second part, about half of the text (*Methoden der Kristallherstellung*), deals with the preparation of crystals, *i.e.* crystal growth from solution, high temperatures and their measurement and control, crystal preparation from melts, and flame-fusion, vapor-phase recrystallization, and electrolytic methods, as well as with "whiskers". The short third part (*Anwendung der Einkristalle*) is devoted to the applications and manipulation of single crystals.

The book is written simply and intelligibly, maintaining the correct balance between theoretical and empirical considerations; owing to the variety of experimental possibilities here, this approach is especially suitable for treatment of the subject. The text is illustrated with numerous flow-sheets, sketches of apparatus, and diagrams; about a quarter of the illustrations are photographs – enough to assist comprehension of the text, but not so many that the result is a "picture book". One can overlook the one or two minor points of error, for example the designation of crucible floating zone purification as "flotation" (this designation should be reserved, as has hitherto been customary, for the action of foam on solids) or the omission of a discussion on the fundamental work on zone melting by *G. Schreiber* and *R. Schubert* [Z. physik. Chem. *206*, 102 (1956)]. A book of this scope on a specific topic must naturally develop into a reference book; as such it can be thoroughly recommended to the novice or the expert, and to the physicist, chemist, or engineer alike.

G. Matz [NB 220/89 IE]

Applications of Neutron Diffraction in Chemistry, by *G. E. Bacon*. Topic 11, Vol. 1 of: International Encyclopedia of Physical Chemistry and Chemical Physics. Published by Guggenheim/Mayer/Tompkins. Pergamon Press, Oxford-London-New York-Paris 1963. First edition. xi + 141 pp., 82 illustrations, some Tables, linen, £2.2.0.

Neutron diffraction has two advantages, besides a number of disadvantages, as a method for studying the spatial arrangement of atoms in solids. Because of the irregular variation of the neutron scattering amplitude with atomic weight, it is possible to fix the positions of light atoms even in the presence of many heavy ones and to distinguish between neighboring elements. Moreover, because of the interaction between the magnetic moments of neutrons and unpaired electrons, information can be obtained on the location, orientation and magnitude of the magnetic moments in ferro-, antiferro- and ferri-magnetic materials. It is not surprising, therefore, that neutron diffraction has led to highly important results in the field of structure chemistry, and this book is an account of them. As one would expect of Dr. Bacon, it is very competently written. The theoretical and experimental background is treated only very briefly, and the reader in

search of more detailed information in this direction should turn instead to the same author's "Neutron Diffraction" (2nd Edition, 1963, Oxford); the two books overlap to some extent. The newer book is shorter, but it could easily have been made shorter still, simply by cutting down the size of many of the eighty-two figures and condensing their somewhat lengthy and repetitive legends.

J. D. Dunitz [NB 251/109 IE]

Classical Thermodynamics of Non-Electrolyte Solutions. By *H. C. van Ness*. Pergamon Press, Oxford-London-New York-Paris 1964. 1st Edit., VIII + 166 pp., 38 figs., 2 tables, linen, £2.0.0 (about $ 5.50).

On the basis of the fundamental equations of thermodynamics, a discussion is given of the thermodynamic properties of liquids, the alterations of these properties on mixing, and the partial molar quantities. Systems of equations are developed which can be used to calculate thermodynamic data from measured quantities in order to apply the former to the solution of practical problems.

As an example of the broad scope of application of the systems of equations, vapor-liquid equilibria are dealt with, in accordance with their importance for distillation, but without going into the theory of distillation. The author restricts his discussion to simple systems at low pressures. After studying the monograph, the reader should be in a position to acquaint himself easily with the thermodynamics of multicomponent systems.

The presentation of the subject matter is terse and abstract, and the equations derived are only rarely illustrated in the text or in graphic presentations by practical examples. In consequence, the book will probably not be easy to read for the practical experimenter. However, anyone who enjoys grappling with the formal and logical skeleton of thermodynamics will be amply rewarded for perusal of this book.

Cyclic Compounds as Configurational Models for Stereoregular Polymers

BY DR. M. FARINA, DR. M. PERALDO, AND PROF. DR. G. NATTA
ISTITUTO CHIMICA INDUSTRIALE POLITECNICO, MILAN (ITALY)

It is possible to draw analogies between linear polymers and cyclic compounds. Stereochemical considerations developed in this connection led to the recognition of new aspects of importance for the systematic classification of both classes of compounds; for example, asymmetric structures can be predicted which had hitherto never been suspected. – The concept of "diasteric centers" is introduced, and the definition of an "asymmetric center" is expressed in more general terms.

Determination of the crystal structure of many stereoregular polymers has led to an independent formulation of the principles for configurational and conformational analysis of polymers with respect to other types of organic compounds [1].

This approach is possible because linear polymers can be considered essentially as monodimensional molecules, *i.e.* the order necessary for a crystalline structure to develop is determined in one dimension by the succession rules existing within the macromolecule, In addition, the configurational sign (D or L) often loses its meaning; instead, the relationship between the configurations (no matter how defined) of atoms belonging to the same macromolecular chain becomes important.

In this paper, a method is outlined for considering polymeric structures from a configurational point of view. An attempt is made to point out analogies between macromolecules and the low molecular-weight molecules usually considered in classical organic stereochemistry. In particular, some analogies between the configurational properties of linear macromolecules and those of cyclic compounds are described.

1. Polymeric Chains, Their Lengths, and Cyclic Models

Studies of the configurational properties of polymers are remarkably simplified by considering polymeric chains of infinite length [2]; from several points of view, this extrapolation seems justified and useful. Various parameters in macromolecular chemistry, such as melting and transition points [3a] depend asymptotically on the molecular weight, *i.e.* above certain molecular weights their value is constant and practically equal to that of a polymer of infinite chain length. The configurational properties of polymers also exhibit this asymptotic dependence on molecular weight, as shown below.

The tertiary carbon atoms in an ideal isotactic polymer of infinite length derived from a vinyl monomer cannot be considered as asymmetric [2]. An isotactic vinyl polymer chain of finite length with identical end groups is usually considered as a *meso*-form, having two sequences of atoms with opposite configurations (DDD...DDLL...LLL). In reality, there is no sharp transition in the central region, since each asymmetric atom differs from the preceding one and becomes less asymmetric the nearer it is to the center of the molecule ($D_1D_2D_3 \ldots D_{n/2}L_{n/2} \ldots L_3L_2L_1$). The data reported in the literature concerning the influence exerted by the length of a substituent on the optical activity of an asymmetric atom show that such influence diminishes rapidly and that the molar optical activity soon tends to constant values (possibly zero).

This is illustrated in Figure 1, where Curve I represents schematically the situation occurring in compounds of the tartaric acid type (*meso*-forms with only two asymmetric atoms), Curve II represents that of a *meso*-compound having four or more similar asymmetric atoms, and Curve III refers to an isotactic vinyl polymer. Here the major portion of the macromolecule has no measurable asymmetry and can therefore be described by the model of infinite length (Curve IV).

The model of infinite length may be conveniently replaced by a cyclic model, if the concept of an unlimited chain is taken instead of that of an infinite chain.

A line closed on itself, in particular a circumference, has the property in common with an infinite straight line of being unlimited. The straight line is infinite and unlimited (in one dimension), while a circumference is a finite though unlimited figure. Analogous remarks apply to a segmented line

[3a] *P. J. Flory*: Principles of Polymer Chemistry. Cornell University Press, Ithaca, N.Y., 1953, p. 571.

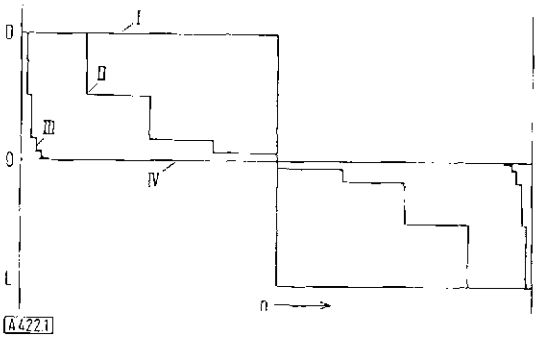

Fig. 1. Schematic representation of the asymmetry of each asymmetric atom in *meso*-tartaric acid (I), in a *meso*-compound with several homo-substituted atoms (II), in an isotactic polymer with equal terminal groups (III), and in an isotactic polymer of infinite length (IV).

Abscissa: number of carbon atoms.
Ordinate: asymmetric character

with an infinite number of segments and to a polygon. On this basis, it is possible, to use a cyclic model to describe and to make predictions about polymers.

The concept of a polymer as an unlimited structure without end groups has recently also been developed by other authors: "In a strict sence, only a macrocyclic compound is a real polymer" [4]. Only a cyclic polymer can consist exclusively of one type of structural unit; a linear polymer of finite length always contains end groups with a structure different from those in the chain. For linear polymers, the monomeric units are all the same only when the chains are of infinite length.

Analogies between the physical properties of cyclic compounds and those of linear polymers can be observed only when the cycles are large enough. For instance, it has long been known that macrocyclic hydrocarbons crystallize in long straight segments similar to linear hydrocarbons [5]. It can also be expected that cyclic and linear compounds, whose molecules have the same distance between subsequent folds of the chain in the crystals will have similar melting points.

It must be remembered that, although compounds consisting of small cycles differ in their physical properties from those consisting of large cycles, the configurational properties of both are the same. It thus follows that the configurational properties of linear polymers can be predicted very simply by considering cyclic structures comprising only a few structural units either equal or equivalent to those in the corresponding linear polymer.

It is interesting to note that the hypothesis of cyclic structures for polymers was long supported by a number of workers owing to the difficulty in distinguishing by chemical means between linear macromolecules and cyclic compounds – even of small size – with analogous structures [3b].

2. Types of Representation and Symmetry Elements

In order to facilitate the configurational analysis proposed, simple and consistent representations of the two series of compounds (cycles and chains) must be chosen.

We have therefore chosen a regular plane polygon for the cyclic compounds and Fischer projection formulae for the chains [6a]. Complete rotation of substituents around the bonds is admitted, so that they can be symbolized by a letter and treated in symmetry operations as spheres, unless they are asymmetric, when the mirror image of the generic substituent D is then L.

Passage from one series of compounds to the other, *i.e.* from cycles to chains and *vice versa*, involves transformation of the symmetry elements inherent in the type of representation selected and valid only from a configurational point of view. Table 1 reports the relationships existing between the symmetry elements of a cyclic model with n sides and of the corresponding polymeric chain represented according to the Fischer convention.

Table 1. Correlation among the symmetry elements of a linear polymer chain (represented according to the Fischer convention) and of its cyclic models.

Cyclic model with n sides	Fischer projection
m-fold rotational axis perpendicular to the ring	Repetition period equal to n/m
Two-fold axis in the plane of the ring	Two-fold axes normal to the projection, placed at a distance of n/2 from each other
Mirror plane in the plane of the ring [a]	Mirror plane containing the chain axis and normal to the projection [a]
Mirror plane normal to the ring (one-fold alternating axis)	Mirror planes normal to the chain axis, placed at a distance of n/2
Center of symmetry (two-fold alternating axis)	Glide plane containing the chain and perpendicular to the projection, with a period of n/2
Four-fold alternating axis	Glide plane containing the chain and perpendicular to the projection, with a period of n/4

[a] Absence of stereoisomerism in both series.

It can be observed that no independent symmetric element corresponding to the four-fold alternating axis exists in linear polymers: a cyclic model containing such an axis, can always be reduced to one half; in this case it has a center of symmetry.

The relationships indicated in Table 1 suggest that the conditions for predicting the optical activity in low molecular-weight compounds, *i.e.* the absence of alternating axes of the 1st, 2nd and 4th order [6b,7], must be modified in the case of linear macromolecules. Here, the existence of configurational enantiomorphous forms is in fact connected with the absence, in the Fischer projection, of mirror planes normal to the chain axis and of glide planes containing the chain and being perpendicular to the projection.

These conclusions complete and put into a systematic form some considerations recently made by *Arcus* [8].

3. Models of Stereoregular Structures and "Diasteric" Centers

cis-Hexamethylcyclohexane, *cis*-1, 3, 5 - trimethylcyclohexane, and *cis*-1,4-dimethylcyclohexane are configurational models of isotactic polymers (Fig. 2); *trans*-hexamethylcyclohexane, *trans*-1,4-dimethylcyclohexane, and *trans*-tetramethylcyclobutane are models of syndiotactic polymers [*].

All the models contain at least a plane of symmetry, the *trans*-models also possess a center of symmetry or a four-fold alternating axis; correspondingly, all the polymers have symmetry planes normal to the chain, and the syndiotactic polymers also have glide planes parallel to the chain.

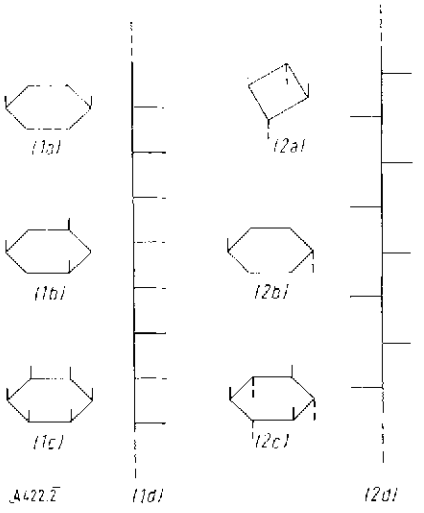

Fig. 2. Cyclic models and Fischer projection formulae of isotactic *(1)* and syndiotactic polymers *(2)*.

The tertiary carbon atoms of the models are not asymmetric: we therefore deduce that the tertiary atoms of the macromolecule are not asymmetric either. In both cases, however, these atoms are centers of diastereoisomerism in the sense that inversion of the disposition of the substituents at some of these centers leads to a different stereoisomer, which is not enantiomorphous with the original compound. This is the situation involved in the transition from *cis*- to *trans*-substituted cyclohexanes, or from isotactic to syndiotactic polymers.

These diastereoisomerism phenomena are not necessarily connected with the presence of asymmetric or pseudo-asymmetric atoms, as can be seen from the models already discussed. It is proposed that the general term "diasteric" (*i.e.* capable of diastereoisomerism) be used to describe an atom, independently of its asymmetry, when interchange of two substituents on this atom causes the molecule to be transformed into one of its diastereoisomers (non-enantiomorphous stereoisomers). It can be shown that if a diasteric carbon atom is neither asymmetric nor pseudo-asymmetric, it must necessarily be part of a cycle or of an infinite chain.

A case similar to that of the vinyl polymers is that of the di-isotactic and di-syndiotactic polymers obtained from 1,2-disubstitued ethylenes of the type CHA=CHB.

[*] For a correlation of the terms isotactic and *cis*, and syndiotactic and *trans*, see [1].

Figure 3 shows the cyclic models for all possible forms (*erythro*- and *threo*-di-isotactic, and di-syndiotactic polymers).

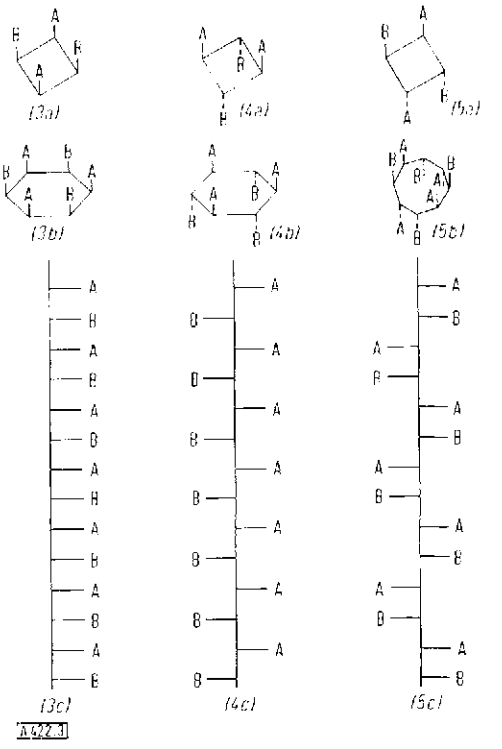

Fig. 3. Cyclic models and Fischer projection formulae of *erythro*-di-isotactic *(3)*, *threo*-di-isotactic *(4)*, and di-syndiotactic polymers *(5)*.

It must be observed that no planes of symmetry exist in the models of di-syndiotactic polymers, but only a center or a fourfold alternating axis of symmetry. In the corresponding polymer chain, in agreement with the correlations reported above, there is only a glide plane parallel to the chain axis.

Incidentally, it is noteworth that the octagonal model in Figure 3 represents the simplest cyclic compound with no asymmetric substituents which possesses an alternating axis of the fourth order as the only alternating configurational axis.

4. Optical Activity in Polymers

The symmetry of the structures just examined excludes the possibility of the existence of optical antipodes for all isotactic, syndiotactic, di-isotactic, and di-syndiotactic macromolecules. This fact is widely known [2, 8–10], but even recently some misunderstandings have arisen with regard to this question. Several classes of optically active polymers have been obtained to date: poly(propylene oxide) [11], poly-(3-methylpentene) and other polyolefins with asymmetric substituents [12], polysorbates and other substituted poly(pentadienoic

[9] *G. Natta, M. Farina*, and *M. Peraldo*, J. Polymer Sci. *43*, 289 (1960); Chim. e Ind. *42*, 255 (1960); Makromolekulare Chem. *38*, 13 (1960).

[10] *C. Schuerch*, J. Polymer Sci. *40*, 533 (1959).

[12] *P. Pino, G. P. Lorenzi*, and *L. Lardicci*, J. Amer. chem. Soc. *82*, 4745 (1960).

esters) [13], polybenzofuran [14], polypentadiene [15], *etc.* Examination of the polymeric structures and cyclic models of all of these compounds reveals the absence of planes or centers of symmetry and alternating axes of the fourth order in the models, and of perpendicular planes and glide planes of symmetry parallel to the chain in the polymers.

Such optically active polymers are of two types: 1. polymers of the vinyl type with asymmetric substituents, and 2. compounds with asymmetric atoms in the main chain.

In the former type, the tertiary atoms in the chain are diasteric, but not asymmetric. Some polymers of the latter type are derived from monomers that contain asymmetric atoms, *e.g.* propylene oxide, others are obtained by asymmetric synthesis from monomers that do not contain centers of optical stereoisomerism, *e.g.* 1-monosubstituted or 1,4-disubstituted butadienes and cyclic olefins [13, 16].

Using cyclic models, it can be seen that neither cyclobutene nor 1,5-cyclooctadiene, which are models of the 1,4-polybutadiene chains, possess configurational asymmetry [*].

The recent isolation of the antipodes of *trans,trans*-1,5-cyclooctadiene by *Cope* [18] does not invalidate this observation because here the stability of the asymmetric conformations is due solely to steric hindrance to rotation around the C—C bonds.

Figure 4 shows some optically active substituted cyclobutenes and 1,5-disubstituted cyclooctadienes and the corresponding isotactic and di-isotactic polymeric forms. The active forms are of the *threo*-type if the substituents are equal, and of both the *erythro*- and *threo*-type if they are different.

Analogously, it is possible to predict the existence of enantiomorphous forms for di-isotactic polymers of cyclic olefins: of the *threo*-type *(10)* for cycloolefins with identical substituents, and of the *erythro*- *(12)* and *threo*-type *(11)* for the more general case of different substituents (cf. Fig. 5) [16]. Figure 5 also shows the corresponding polycyclic compounds: *trans-anti-trans (10b)* for cycles with identical substituents, and *trans-anti-trans* and *cis-syn-cis* for cycles with different substituents. It is difficult to find examples of these models as the polycyclic compounds represented in Figure 5 are not well known.

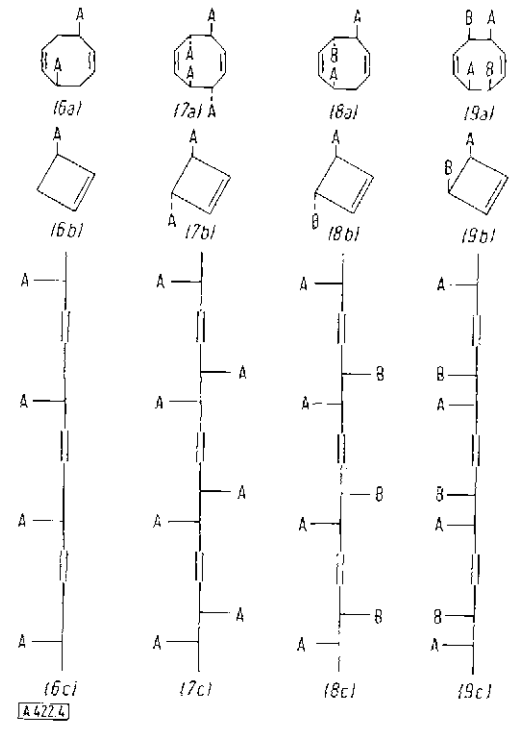

Fig. 4. Optically active polymers. Models and Fischer projection formulae of substituted 1,4-polybutadienes: isotactic 1-substituted polybutadiene *(6)*, *threo*-di-isotactic 1,4-disubstituted polybutadienes *(7)* and *(8)*, *erythro*-di-isotactic 1,4-disubstituted polybutadiene *(9)* (only one antipode is shown).

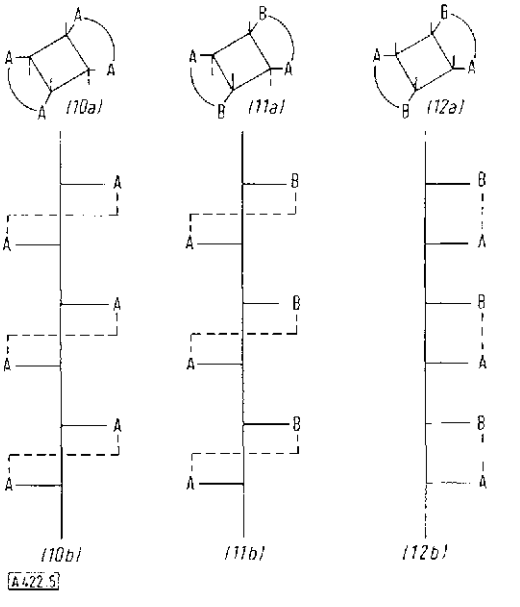

Fig. 5. Optically active polymers. Models and Fischer projection formulae of polymers of cyclic olefins: *threo*-di-isotactic polymers *(10)* and *(11)*, and *erythro*-di-isotactic polymers *(12)*.

From what has been stated so far it may seem impossible to obtain optically active polymers from α-olefins and from 1,2-disubstituted ethylenes which are not cyclic and which do not contain asymmetric groups. However, this is true only for simple repetitions, either isotactic or syndiotactic, but not if more complex structures are taken into account. Here the usefulness of the cyclic model is clearly seen. It is known that homocyclic compounds with 3, 4, or 5 atoms which are all equally substituted are optically inactive. Optically active isomers of this type exist only in the cyclohexane and

[16] *C. L. Arcus*, J. chem. Soc. (London) *1955*, 2801.

[*] Cyclobutene is not only a model of the polybutadiene chain but 1,4-polybutadiene can actually be obtained from it [17]. In this reaction and all other polymerizations involving ring opening, the symmetry properties of the monomer can be transferred to the polymeric chain using the rules already developed, provided that the configurational repetition period is equal to only one monomeric unit, and that there are no inversions of configuration during the polymerization.

[18] *A. C. Cope, C. F. Howell*, and *A. Knowles*, J. Amer. chem. Soc. *84*, 3190 (1962).

higher series, *e.g.* inositols [see Fig. 6, *(13a)*]; the corresponding polymeric chains are also asymmetric, *e.g.* *(13b)*. This type of structure can actually be obtained with six monomeric vinyl units, or with three units derived from monomers of the CHA=CHA type.

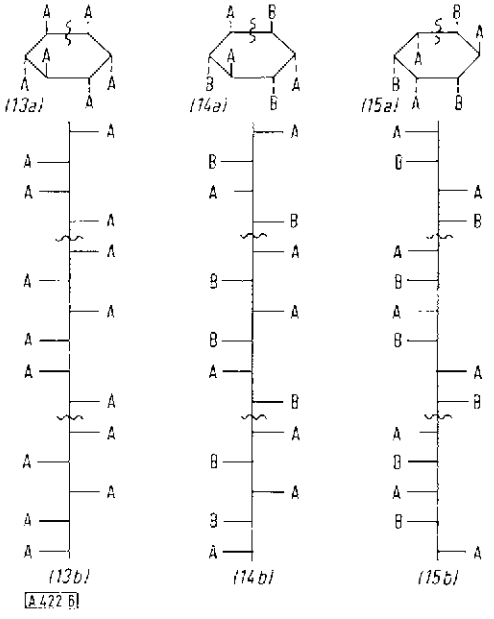

Fig. 6. Optically active polymers. Models and Fischer projection formulae of polymers derived from non-cyclic olefins.

It is also possible to foresee the existence of enantiomorphs for structures derived from monomers of the CHA=CHB type: the simplest have a configurational repetition period of three monomeric units and are represented in Figure 6. Structures *(14)* and *(15)* have an *erythro-/threo*-relationship. The *threo*-structure *(14b)* is analogous to the active structure obtained from monomers of the CHA=CHA type. It can be observed that the *erythro*-isomer *(15b)* has real asymmetry only when the *threo*-form is asymmetric and the substituents of the adjacent asymmetric atoms are different (Figs. 4, 5, and 6); otherwise, the *erythro*-form can be identified with a *meso*-form. In the optically active polymers of Fig. 6 all the tertiary carbon atoms are asymmetric, since the two chain portions bound to each atom are diastereoisomeric.

5. Polymeric Chains as Models of Cyclic Compounds

The formal analogy between polymeric substances and cyclic compounds has also contributed to the knowledge of certain classes of cyclic compounds.

Examination of the symmetry properties of the atoms in the chain of polybenzofuran shows that the definition of the asymmetric carbon atom commonly used is insufficient here [19], for each carbon atom of the polymeric chain is bonded to two substituents which are effectively identical if considered separately (Fig. 7). Such atoms seem to possess substitution of the C_{abdd} type. However, they differ substantially from the C_{abdd} atoms (*e.g.* a-CH_2-b) usually considered. In fact, in the structure under examination, the two substituents d are different

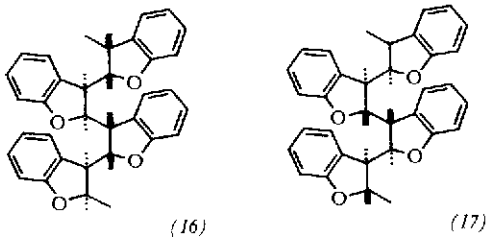

Fig. 7. Optically active polybenzofuran: *erythro*-di-isotactic *(16)* and *threo*-di-isotactic structures *(17)*.

in their relationships to the atom considered: one belongs to the same cycle (*endo*-), whercas the other belongs to a different cycle (*exo*-) [14]. This therefore leads to a more general definition of the asymmetric carbon atom: the four substituents must be different either in themselves or at least in their relationships to the atom considered (*e.g. exo*- or *endo*-) [19].

The above discussion can be applied to the analogous cyclic compounds shown in Figure 6. As already mentioned, the chemistry of homocyclic or heterocyclic saturated compounds of this type is not well developed.

We have therefore synthesized one of these models, the *trans-anti-trans-anti-trans* isomer of perhydrotriphenylene [20]. It is a crystalline compound melting at 128 °C, and its configurational and conformational structure is

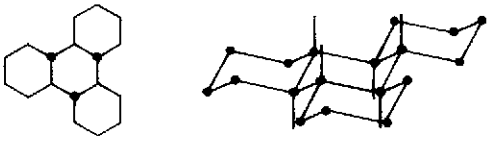

Fig. 8. Structural and conformational formulae of (*R*)-*trans-anti-trans-anti-trans*-perhydrotriphenylene.

given in Figure 8. In spite of its high symmetry (1 threefold axis and 3 two-fold axes), it does not possess alternating axes of any order, hence it exists in two enantiomorphous forms, one of which is shown in Figure 8. The symmetry properties of the tertiary atoms are analogous to those of the tertiray carbons in polybenzofuran, of which perhydrotriphenylene represents the best model available at present. By applying the rule "*endo* precedes *exo*" recently proposed [19,21] to extend the Cahn-Ingold-Prelog nomenclature [22] to this compound, one finds that the six asymmetric atoms of the isomer shown in Figure 8 have all an absolute *(R)*-configuration.

6. Conclusions

The discussion of the analogies between cyclic and polymeric compounds reveals a substantial unity between classical organic and macromolecular stereochemistry. In our opinion, previous misunderstandings can easily be cleared up by adopting a cyclic model rather than by trying to extrapolate the configurational properties of macromolecular compounds from those of the low molecular-weight linear compounds.

Structure and Crystallization Behavior of Glasses [*]

BY DR. W. VOGEL

SAALE-GLAS GMBH., JENA (GERMANY)

Almost all optical and technical glasses contain micro-heterogeneities which can be seen using an electron microscope. These heterogeneous regions are shaped like small drops, and their size (20 to 500 Å) depends on the construction of the glass, on its temperature-history, on the field strength of the cations, and also on the adjacent gas atmosphere. – Preparation of valuable ultramicrocrystalline ceramics for industrial use from ordinary and photosensitive glasses involves controlled phase-separation processes and subsequent crystallization.

I. Classical Views on the Structure of Glasses

When a batch of frit is melted, the crystalline raw materials are converted into a viscous melt which solidifies to an amorphous glass on rapid supercooling. The energy absorbed in fusion is not entirely liberated on solidification. Consequently, all glasses are considerably richer in energy than the crystalline materials from which they are formed, so that the glass state is metastable. This energy reserve provides the driving force for many processes which can take place, controlled or uncontrolled, in the glass.

Various views on the fine structure of glasses have been developed during the past 40 years. *Tammann* [1] was the first to compare the structure of glass to that of liquids. Owing to the high viscosity of glass melts, the liquid structure is probably largely retained and fixed during rapid supercooling. *Goldschmidt* [2] concluded from his chemical studies of the crystalline state that the ability of a simple compound to solidify readily to a glass after fusion depends on the size ratios of the ions. An oxide or a simple compound should be capable of forming a glass only if the ratio of the radii of the cation and the anion ($r_C : r_A$) is between 0.2 and 0.4. This condition is fulfilled by the principal glass-forming compounds such as SiO_2, B_2O_3, and P_2O_5. The theory is convincingly verified by the fact that BeF_2, which also satisfies the above condition, solidifies to a glass. Furthermore, the laws governing the formation of a glass structure should be the same as those which apply in crystal chemistry.

A. Network Theory

Whereas previous attempts had been directed mainly towards the classification and explanation of the known properties of glasses by means of a theory of the structure of glasses, *Zachariasen*'s hypothesis (1932) [3], which was confirmed by the X-ray investigations of *Warren* in 1933 [4], brought about a revolutionary advance. For the first time it became possible, to a limited extent, to calculate the properties of glass from data concerning the constituent ions. The Zachariasen-Warren hypothesis is based on the principle that, for example, the $[SiO_4]$-tetrahedron is the smallest structural unit in an SiO_2-glass. It is thought, however, that these tetrahedra are not linked uniformly to give a three-dimensional network, such as that found by *Bragg* in crystalline silicates, but that they are rather linked in an irregular manner. The very large increase in the viscosity of glass melts on cooling is easily explained by the formation of an irregular infinite three-dimensional network from building units with small coordination numbers, *e.g.* C.N. = 4 in the $[SiO_4]$ tetrahedron of the SiO_2 glasses, or C.N. = 3 in the planar trigonal $[BO_3]$ group of B_2O_3 glass.

According to the network theory of *Zachariasen* [3] and *Warren* [4], the formation of low-order space lattices, *i.e.* the vitrification of the simple compounds SiO_2, B_2O_3, P_2O_5, GeO_2, As_2S_3, BeF_2, *etc.*, is governed by the following selection rules:

a) An oxide or other compound will tend to form a glass if it readily forms polyhedral groups as the smallest building units.

[4] *B. E. Warren*, Z. Kristallogr., Mineralog. Petrogr. *86*, 349 (1933).

b) Not more than one corner may be shared by any two such polyhedra.

c) An anion, *e.g.* O^{2-}, S^{2-}, or F^-, must not be linked to more than two central atoms of polyhedra. Thus the anions form bridges between pairs of polyhedra in all simple glasses.

d) The number of corners of a polyhedron must be less than six.

e) At least three corners of a polyhedron must be linked to adjacent polyhedra *via* anion bridges.

If large cations are incorporated (*e.g.* by fusing SiO_2 together with Na_2O or CaO) into simple glasses which obey the selection rules, the bridges will be broken. The anion, introduced with the large cation, will then occupy the free corner of one of the two separated tetrahedra, while the large cation will be accommodated in the enlarged cavity resulting from rupture of the network. Rupture of the network and incorporation of the large cations should occur in a random manner. This leads to continuous changes in the properties of glasses.

Zachariasen further classified all the cations capable of participating in glass formation into three groups:

a) Network formers such as Si, B, P, Ge, As, and Be (as BeF_2) mostly having coordination numbers of 3 or 4.

b) Network modifiers such as Na, K, Ca, and Ba, generally having coordination numbers ≥ 6.

c) Intermediate oxides with cations such as Al, Mg, Zn, Pb, Be, Nb, and Ta, generally having coordination numbers from 4 to 6.

The intermediate oxides occupy an intermediate position between the network formers and the network modifiers. In a multi-component glass, these substances can either strengthen the glass structure by forming tetrahedra (with C.N. = 4), or, acting like network modifiers, further loosen the basic structure (with C.N. = 6 to 8), depending on the composition.

The Zachariasen-Warren principle readily accounts for most of the properties of glasses, and permits prediction of these properties within certain limits. It brought about the greatest advance to date in the investigation of glass structure. Nevertheless, even this concept fails to explain certain characteristics as, for example, the discontinuities in the curves relating glass properties to composition.

A further significant advance was made by *Dietzel* [5] (1942). Whereas *Goldschmidt* considered the size-ratios as being the principal property that affects glass formation, *Dietzel* also took into account the field strengths of the ions. This enabled him to explain phenomena which cannot be explained by the Zachariasen-Warren hypothesis alone.

As the melt of a binary silicate cools, the two cations compete for the oxygen ions, trying to surround themselves with the latter in the closest possible packing. If the field strengths of the two cations are equal, separation into two phases generally takes place. If, however, the field strengths of the cations differ, the oxygen ions will arrange in the closest packing, mainly around the cation with the higher field strength. The cation with the lower field strength then becomes linked, with a higher coordination number, to the resulting anion complex (*e.g.* $[SiO_4]^{4-}$). According to *Dietzel*, compound formation and crystallization occur at a difference in field strength above $\Delta F = 0.3\ Z/a^2$ [*] while phase-separation occurs when $\Delta F = 0\ Z/a^2$; glass formation readily occurs when $\Delta F > 1.33$.

The best glass-forming substances are SiO_2, B_2O_3, and P_2O_5. However, melts of any two of these (SiO_2/P_2O_5; B_2O_3/P_2O_5) generally solidify in the crystalline form, although the Zachariasen-Warren conditions for glass formation are satisfied. This deviation from *Zachariasen*'s concept is easily explained by *Dietzel*'s results. Since the field strength of B^{3+} in $[BO_3]$ is $1.63\ Z/a^2$, that of Si^{4+} in $[SiO_4]$ is $1.57\ Z/a^2$, and that of P^{5+} in $[PO_4]$ is $2.1\ Z/a^2$, the differences in field strength are greater than $\Delta F = 0.3\ Z/a^2$, and this explains the crystalline solidification of the SiO_2/P_2O_5 and B_2O_3/P_2O_5 melts.

Phase separation should occur in the SiO_2/B_2O_3 system, when $\Delta F = 0.06\ Z/a^2$. Instead glass-formation is observed. This fact does not represent a deviation from *Dietzel*'s results, since electron-microscopic investigations have in fact shown a microphase separation in B_2O_3–SiO_2 glasses [23, 24, 35, 36]. *Dietzel*'s field-strength relationships, which enable us to assess both the stability and the number of possible compounds in melt systems, represent a significant advance of the network theory.

Similar progress has been brought about by the theories of *Smekal* [6] (1949), and *Weyl* [7] (1958). According to *Smekal*, glasses are characterized by mixed bonding. Substances with purely ionic or purely homopolar bonding are low-melting, have a low hardness and crystallize easily. On the other hand, substances with mixed bonding such as quartz, are very hard, high-melting, very viscous in the melting range, and readily solidify to form glasses after fusion. Moreover, they all exhibit conchoidal fracture.

According to *Smekal*, heteropolar bonding is accompanied by about 50 % of homopolar bonding in rock crystal, about 44 % in B_2O_3, and about 60 % in Al_2O_3. In the beryllium fluoride model-glasses first prepared by *Goldschmidt*, on the other hand, the homopolar bonding component is only about 21 % [8, 9].

Weyl's shielding theory [7] considers in particular the residual valence forces resulting from polarization and deformation. These forces are responsible for the polymerization of the coordination groups, such as $[SiO_4]$, $[BO_3]$, $[PO_4]$, and $[BeF_4]$, into irregular networks.

B. The Crystallite Theory

The development of the network hypothesis was paralleled by that of *Lebedev*'s crystallite theory [10] which was supported by X-ray investigations by *Randall*, *Rooksby*, and *Cooper* [11], and by *Valenkov* and *Poray-Koshits* [12]. The crystallite theory was originally described as the antithesis of the network hypothesis. Whereas the latter is characterized by the random

distribution of large cations in a disordered basic glass network, the crystallite theory assumes considerable ordering of the cations, owing to the existence of crystallites in the glass. According to *Lebedev* [10], glasses may be regarded as aggregates of microcrystalline structures, *e.g.* of SiO_2 and silicates in the case of silicate glasses. Even pure quartz glass is assumed to be constituted in this way.

In particular, the crystallite hypothesis explains discontinuities in the curves of properties of glass systems where the network hypothesis offers no satisfactory interpretation. In this manner, for example, *Tudorovskaya* [13] has traced the discontinuous change in the refractive index of a sodium silicate glass with increasing temperature to α-β transitions of the SiO_2 crystallites.

From theoretical calculations based on X-ray diffraction patterns, *Valenkov* and *Poray-Koshits* [12] have established that the structure of a crystallite is most regular in the center, where it is practically the same as that of a crystal. The degree of order of the crystal lattice decreases towards the periphery of the crystallite. This results in the formation of a highly amorphous intermediate layer, which links all the crystallites together. The diameters of the crystallites were found to be 8 to 15 Å in most cases. These dimensions correspond to only a few unit cells, and so are very close to the limits beyond which the lattice concept is no longer valid.

Lebedev finally modified his original crystallite theory to the extent of taking the emphasis from the expression "crystallite". In his opinion, glass contains disordered as well as ordered regions in the form of definite chemical compounds. According to *Lebedev*, this concept of the glass state greatly diminishes the contradiction between the crystallite and the network theories.

II. The Development of New Structural Concepts

A. Micro-Heterogeneities in Glass

A number of authors determined the interionic distances in glass from X-ray diagrams which are generally very indistinct, and reached certain conclusions concerning the short- and the long-range order. *Hoffman* and *Statton* [14] (1955), as well as *Poray-Koshits* and *Andreyev* [15] (1959), measured the small-angle X-ray diffraction of several glasses, and established that glass is neither as homogeneous in structure as is required by the network theory, nor does ist possess such a high degree of order as the crystallite theory ascribes to it; on the contrary, it is characterized by "micro-heterogeneities". These findings agree with the results obtained previously by electron microscopy.

Thus *Slayter* [16] (1952) as well as *Prebus* and *Michener* [17] (1954) have shown, by electron microscopy, that silicate glasses contain structural inhomogeneities, the dimensions of which are by one order of magnitude greater (20 to 200 Å) than those required for the crystallites (8 to 15 Å) in the crystallite theory. *Šelyubsky* [18] (1954) and *Oberlies* [19] (1956) were the first to use the replica process in electron microscopy for the study of glass, and independently came to the same conclusion as *Slayter*, *Prebus*, and *Michener*.

In 1955, following the network theory, we began a series of systematic investigations on beryllium fluoride glasses. According to *Goldschmidt* [2], crystalline fluoroberyllates may be regarded as the crystallochemical models of crystalline silicates. A model structure is produced when two substances crystallize in the same lattice, and their ions have identical or similar radii but different charges. The model and the original then differ only in their lattice forces.

Owing to the difference in the charges of oxide and fluoride ions on the one hand, and silicon and beryllium ions on the other, the bonding forces in the BeF_2 model are only $^1/_4$ as large as those in the SiO_2 original. By virtue of the weaker bonding forces in beryllium fluoride glasses, processes of structure formation may be expected to take place in a more discernible manner.

In the course of a preliminary investigation of binary alkali beryllium fluoride glasses by physicochemical methods, opalescent turbidity was observed in composition ranges in which it was not expected. This phenomenon was first attributed to secondary or glass defects and disorders, but these could not be identified by optical microscopy or by X-ray crystallography. However, extensive electron-microscopic studies showed that the opalescent turbidity was caused by regions of phase separation in the form of droplets.

Since small drop-shaped regions with a diameter of 300 to 600 Å could be definitely detected even in model glasses which showed no Tyndall effect, it was assumed that the processes of phase separation are closely associated with the formation of the glass structure and are of general validity.

B. Factors Affecting the Dimensions of the Drop-Shaped Microphases

The presence of drop-shaped regions of phase separations was subsequently established in many different glasses, such as optical, technical, and laboratory-ware glasses, and became recognized as an essential structural feature [20–28]. These results were later confirmed by numerous electron-microscopic studies [29–40].

Control of the microphase separation is important, *e.g.* in preventing defects during the production of glass and in the development of new types of glass. The recent manufacture of novel ceramic or semi-ceramic products from glass is based on controlled microphase separation. The following factors have so far been shown to influence the dimensions of the drop-shaped microphases in glass:

1. *The Concentration of the Principal Constituents of Glass* [20]

The phase separation taking place during cooling of a glass melt tends to form one microphase with a higher concentration of network formers, and another with a higher concentration of network modifiers, the phase with the greater surface tension forming droplets. A change in the concentration of the glass components will favor phase separation in one direction or the other. Figure 1 shows the dependence of the phase separation in the model system on concentration.

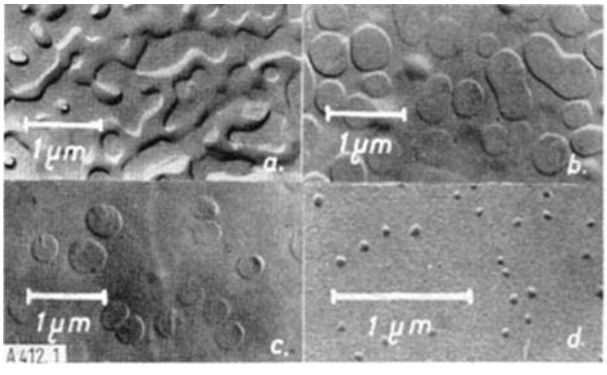

Fig. 1. The effect of concentration on phase separation in binary $LiF-BeF_2$ glasses containing (a) 15, (b) 25, (c) 35, and (d) 45 mole-% of LiF. The droplet size clearly decreases. Glass (d) does not show any Tyndall effect.

2. *Previous Thermal Treatment of the Glass* [23]

Glasses are not in a state of minimum energy, but are characterized by the fact that the order present in the melt is "frozen in". The ordering process can be reinitiated by subsequent thermal treatment. The phase separation in binary sodium borate glasses is shown in Figure 2. All processes of phase separation occurring in glasses depend on temperature; further heat-treatment results in the formation and aggregation of droplets.

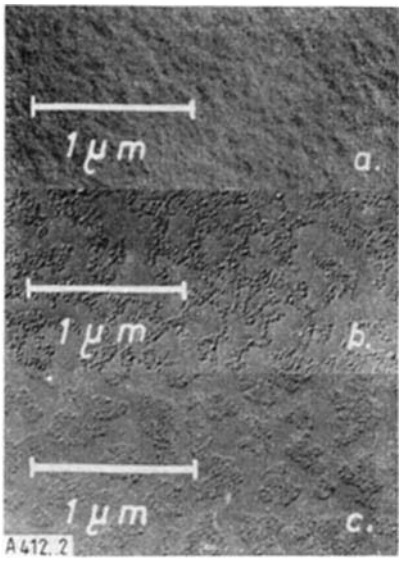

Fig. 2. The effect of temperature on phase separation in binary $Na_2O-B_2O_3$ glasses containing 16 mole-% of Na_2O. (a) Strongly quenched, (b) normally cooled, and (c) annealed at 500 °C for 2.5 hours after cooling. Formation and aggregation of droplets increase in those glasses which do not show the Tyndall effect.

3. *The Field Strength of the Cations* [20]

The field strength of the cations affects the tendency not only towards crystallization, but also towards phase separation in a glass melt. In binary alkali beryllium fluoride glasses containing *e.g.* 15 mole-% of NaF, KF, or RbF the droplet size rapidly decreases in this order.

4. *Trace Additives* [26, 28]

It has been found from experimental studies, and in particular from observations on the day-to-day operation of the melting plant of a glass works, that phenomena of phase separation are considerably altered by the presence of certain ions even in small quantities. Microphase formation may be either suppressed or increased by the deliberate introduction of trace additives. This fact is of great significance in the manufacture and development of glass. A striking practical example is shown in Figure 3, where traces of $[SO_4]^{2-}$ have caused the growth of the microphases in an originally clear optical glass to such an extent as to cause visible turbidity.

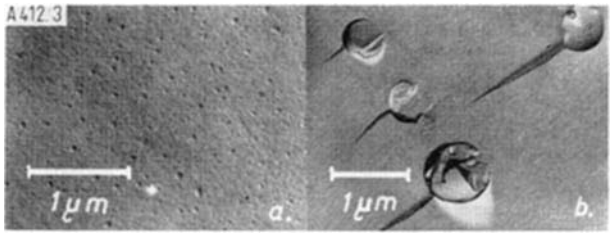

Fig. 3. The effect of trace impurities on phase separation. The microphases (a) in an optical titanium silicate glass containing fluoride are so greatly increased by traces of $[SO_4]^{2-}$ (0.01 % by weight) as to cause turbidity (b).

5. *The Surrounding Gas Atmosphere*

It has been found recently that the size of the droplets appears to be influenced by the surrounding gas atmosphere. The surface tensions of two glass phases of different compositions do not change to the same extent when the surround-

ing gas atmosphere is changed. This can result in appreciable changes in the difference between the surface tensions of the two microphases at the glass/gas interface and in acceleration of the phase separation in this region. Liquation of SiO_2-rich phases on the surfaces of the melts and the substantially greater difficulty in melting of silicate glasses with high lead contents in SO_2-rich atmospheres can evidently be attributed to processes of this kind.

C. Special Problems of the Micro-Heterogeneous Structure of Glass with Particular Reference to the Li_2O—SiO_2 System [41—45]

Figures 4a and 4b represent an example of the micro-heterogeneous structure of most glasses. They are electron micrographs of a completely clear binary lithium-silicate glass which exhibits no Tyndall effect,

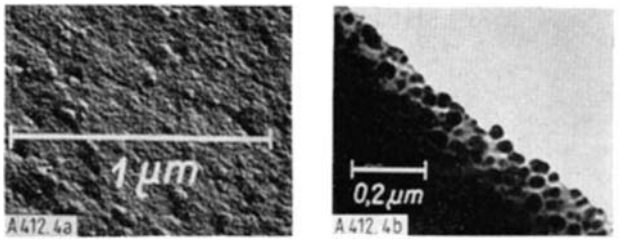

Fig. 4. Binary lithium silicate glass (28.6 mole-% of liquid Li_2O) which is completely free of Tyndall effect, showing drop-shaped microphases about 450 Å in diameter. (a): Electron micrograph obtained by the replica method, (b): direct exposure. The droplets are richer in Li_2O than their surroundings.

but Figure 4a was obtained by the replica process, and Figure 4b by direct exposure. The micro-heterogeneous structure of this glass can be clearly recognized in both cases. The detection of the drop-shaped regions of phase separation, the dependence of the droplet size on several factors, the very uniform sizes of the regions, and the crystallization behavior of the droplets (see Section III), led to the question: are the regions of phase separation due to purely random aggregations of ions, or does the phenomenon conceal some fundamental regularities, *e.g.* the formation of relatively uniform structural groups in the form of definite chemical compounds?

Analogies concerning the distribution of the network modifiers in glasses can be drawn from the distribution of the guest component in mixed crystals. *Laves* [45] has illustrated the problems of mixed crystal formation in terms of the

Fig. 5. Distribution of black and white squares according to *Laves* [45]: (a) statistical, (b) better than, and (c) worse than statistical.

possible distribution of 50 % black and 50 % white squares (see Figure 5). The distribution of the guest component in a mixed crystal is almost random, *i.e.* it lies between the state shown in Figure 5a and that in Figure 5c. The diagrammatic representation shows that even a random distribution permits a certain formation of aggregates and clusters.

It is suggested that the formation of clusters of ions during the cooling of a glass melt, which may be regarded as preliminary to the separation of the drop-shaped micro-heterogeneities, may quite possibly also lie within the scope of statistical considerations. In American hyalogical literature such aggregations are termed "cluster formations". In our opinion, however, these relationships can no longer be explained by statistical considerations in so far as an ion cluster begins to separate from the rest of the glass by formation of a phase boundary.

The results which we have obtained with glasses of the Li_2O—SiO_2 system may contribute to the elucidation of some unsolved problems of the structure of glass. The lithium silicate glasses, which were prepared under constant conditions, contain regions of phase separation whose dimensions greatly depend on the composition of the glass. Figure 6 may serve as an example for the series of glasses obtained.

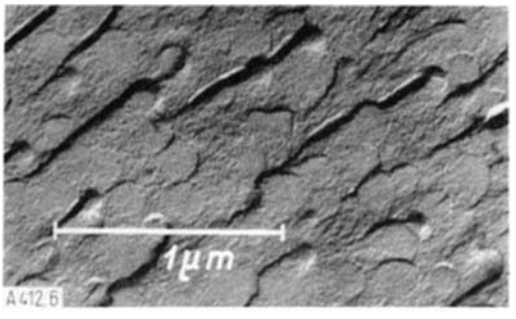

Fig. 6. Binary lithium silicate opal glass (20 mole-% of Li_2O and 80 mole-% of SiO_2). The drop-shaped phase-separation zones, the composition of which approximates that of lithium silicate, are embedded in a SiO_2 rich matrix glass.

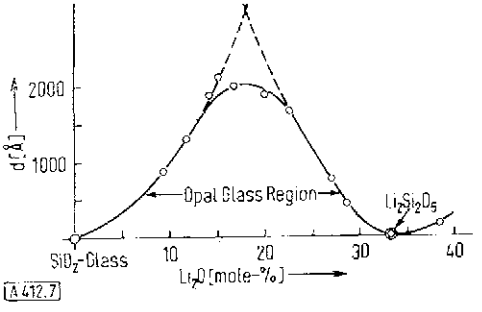

Fig. 7. Dependence of the diameter d of the droplets on the composition of the glass in the system Li_2O—SiO_2.

The entire course of phase separation is reproduced in Figure 7. While pure quartz glass has a homogeneous structure, a phase-separation maximum occurs between 0 and 33.3 mole-% of Li_2O. Glasses with compositions corresponding to the first possible compound ($Li_2Si_2O_5$, lithium disilicate) in the crystallization diagram are again homogeneous. A lithium content which exceeds the disilicate ratio (Li_2O > 33.3 mole-%) tends to cause

phase separation to increase again. However, the trend of the curve leads us to assume that the droplet phase is a silicate with a high Li_2O content. Since the droplet size falls to zero in the case of 33.3 mole-% of Li_2O, the glass of the droplets should tend towards the disilicate composition. The identification of the droplets as a phase with a high Li_2O content may be considered as certain.

At 1300 °C, a glass with the disilicate composition has a surface tension which is by 37.2 dyne/cm greater than that of pure SiO_2-glass. The disilicate glass must therefore take the form of droplets at this temperature [46–49].

Figure 4b also shows that regions of high Li_2O content, which are denser than the SiO_2-rich glass, stand out as dark regions in the electron microscope.

When small quantities of Li_2O (< 10 mole-%) are incorporated into quartz glass, it must be assumed that the lithium ions are randomly distributed in the $[SiO_4]$ lattice, in accordance with the network theory. When the Li_2O content is increased, however, clusters of lithium ions are formed and finally separate out as drop-shaped microphases. After the glass of the droplets has reached the disilicate composition (about 16 mole-% of Li_2O in the glass as a whole), Li_2O is preferentially incorporated into the surrounding glass phase until the latter attains the same composition as the droplet phase. This is accompanied by a decrease in the size of the droplets, until they finally disappear when the overall composition of the glass corresponds to that of the disilicate. At this point, therefore, we have again a glass with a homogeneous basic structure of evidently uniform disilicate building units, to which the network theory applies.

The same process which occurs between 0 and 33.3 mole-% of Li_2O begins to recur when the Li_2O content is increased beyond 33.3 mole-%. The continuous glass phase now consists only of disilicate, while the composition towards which the droplets tend, suddenly changes from disilicate to metasilicate.

Curves similar to those in Figure 7 have also been obtained during the investigation of other glass systems. It is therefore by no means possible to speak of a uniform structure of glass, even in the case of glasses within the same system. Both the network and the crystallite theories should be treated as limiting cases. Most glasses possess micro-heterogeneous structures. If the drop-shaped microphases had the cluster character which is statistically possible, the composition of the cluster would have to change continuously with, and in the same direction as the overall composition of the glass. According to Figure 7, however, this is not the case.

In the case of binary lithium silicate glasses with low Li_2O contents (up to 15 mole-%), the droplets which have not yet attained the disilicate composition can be dissolved out of the almost pure SiO_2 glass with dilute hydrofluoric acid (Figure 8). This is because SiO_2 glass is substantially less soluble in HF than glass containing Li_2O.

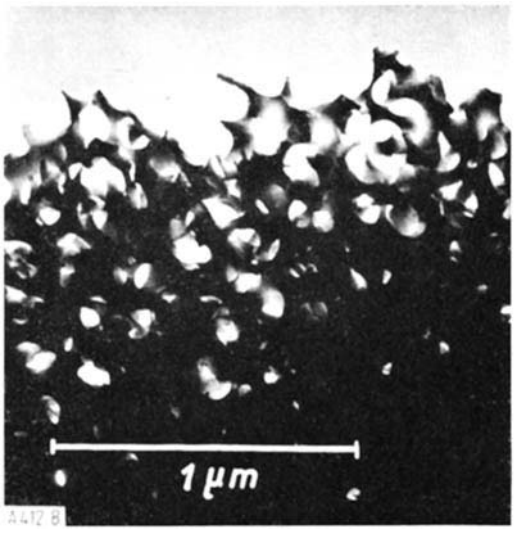

Fig. 8. Fragment of a binary lithium silicate glass (9.5 mole-% of Li_2O and 90.5 mole-% of SiO_2) after brief treatment with 2.5 % hydrofluoric acid. Direct electron micrograph. The Li_2O-rich droplet phase has been dissolved out leaving behind an almost pure SiO_2 glass phase.

At the phase-separation maximum (see Figure 7) stronger tensile forces at the spherical phase boundaries of the disilicate droplets lead to a secondary phase-separation and formation of very small metasilicate droplets within the macro-droplets. This process, which takes place even at relatively low temperatures, corresponds completely to the incongruent melting of the crystalline lithium disilicate

$$Li_2O \cdot 2\,SiO_2 \xrightarrow{1033\,^{\circ}C} \begin{cases} Li_2O \cdot SiO_2 \\ SiO_2 \end{cases}$$

Thus, in the secondary phase-separation in the macro-droplet glass-phase an SiO_2 glass phase is formed which is purer than the LiO_2-containing but SiO_2-rich surroundings of the large droplets.

Hydrofluoric acid dissolves the surroundings of these large droplets first, so that the droplets remain behind. At the same time the metasilicate is extracted from the peripbery of the large droplets. Figure 9 shows a photograph of a sample obtained by accident. The

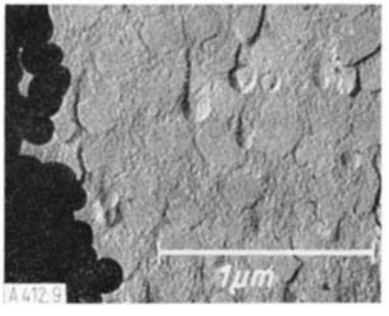

Fig. 9. Binary lithium silicate glass (20 mole-% of Li_2O and 80 mole-% of SiO_2) as in Figure 6. In the electron-microscopic preparation, the carbon replica was removed with hydrofluoric acid, and small glass splinters were etched at the same time. In contrast to the analogous etching process in Figure 8, the droplet zones (black) were isolated in this case. They were accidentally transferred to the replica film. Direct electron micrograph. The isolated droplet zones had the same dimensions as those appearing in the replica.

replica film here was loosened from the glass using dilute hydrofluoric acid. The droplets were thus isolated and collected on the replica film. Electrons directly passed through the sample during subsequent electron microscopy. The photograph can thus be regarded as the image and mirror-image of the droplets. Isolation of the droplets (see Figure 10) then allowed various investigations to be carried out on the separated microphases. These confirmed the views which have already been advanced concerning the structure of lithium silicate glasses.

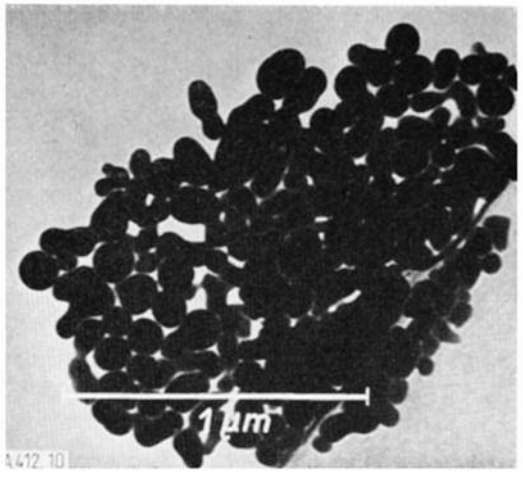

Fig. 10. Isolated droplets from a binary lithium silicate glass. Glass powder with a particle size of between 1 and 2 µm was treated with 2% hydrofluoric acid for 15 minutes and placed on a lacquer-film support. Direct electron micrograph.

Homogeneous glasses of disilicate composition are uniformly attacked by hydrofluoric acid, as is shown by the fact that the luster remains almost constant.

Secondary phase separation during the solidification of glass melts has only recently been detected [43,44] [*]. The significance of these processes for heterogeneous crystal-nucleus formation in connection with the production of novel semi-ceramic products from glass will be discussed in Section III.B. Theoretical considerations concerning the mechanism of cluster formation and phase separation [43,44] in glass will not be dealt with here.

Originally the network theory and the crystallite theory were opposing concepts. However, *Hartleif* [50] and *Dietzel* [5] were the first to discuss network modifiers as being distributed in clusters instead of being distributed statistically throughout the lattice of the parent glass. The original crystallite concept has also been modified, especially by *Lebedev*'s school in Leningrad, as indicated in particular by the work of *Markin* [51], *Yevstropev* [51], and *Poray-Koshits* [51].

Basically the new ideas on the micro-heterogeneities in connection with compound formation in glass were expressed as early as 1940 by *Botvinkin* [51,52]. The theoretical conclusions from other investigations

[*] These phenomena have also been observed in the case of glasses of alkaline earth silicates. *Toropov*, personal communication, Fourth Soviet Conference on Glass Structure (1964).

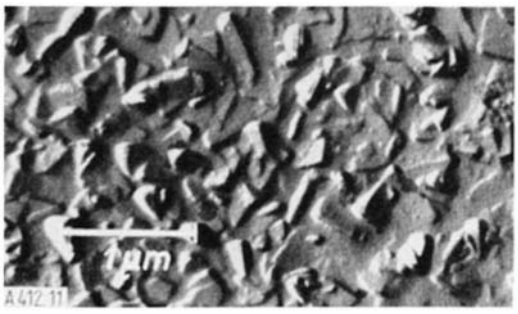

Fig. 11. Binary magnesium phosphate glass (58 mole-% of MgO and 42 mole-% of P_2O_5), which is free of Tyndall effect, with numerous crystallites of considerable dimensions. These evidently have roughly the same refractive index as the surrounding glass. This glass can serve as a model for *Lebedev*'s crystallite theory.

[53–61] point in the same direction, although the aggregates in glasses are denoted by terms such as "structones", "vitrones", "micelles", and "microphases". Disregarding border-line cases in which excellent agreement is found even with the original extreme interpretations of the network and crystallite theories (see especially Figure 11), experimental evidence for a long time did not permit acceptance of the new structural concepts. Decisive progress was essentially due to the use of electron microscopy.

III. Controlled Crystallization in Glass [44,62,63]

A. Crystallization as a Glass Defect and as a Basis for the Production of Novel Materials

The solidification of a melt to form a glass leads to a metastable state. The state with the lowest energy, *i.e.* the normal state, would result from crystallization.

The conditions which are necessary to inhibit crystallization in glass have been investigated particularly by *Tammann* [1] and his school. Crystallization represents the principal source of defects in the manufacture of glass. There are many examples, both in science and in technology, of defects, undesirable reactions, and other phenomena which lost their "horror" and acquired a new, unsuspected significance when their nature was understood, and man had learned to master them. A similar development is still in progress in the case of crystallization in glass, and this has led to the production from glass of valuable ultramicrocrystalline ceramic materials and of photosensitive

glasses [64]. The principal problem here is the production of minute dimensionally homogeneous crystals in the glass.

In order that crystallization may begin, crystal nuclei must be present. In this respect the transition range between the melt and the crystalline state, in which the nuclei are formed, is of special importance.

Kleber [65] and *Roy* [66] have described the conditions for nucleation. According to *Kleber*, the frequency of nucleation is chiefly determined by two factors:

a) by the actual work of nucleation, which may be defined as the energy required for the formation of a nucleus, if its building units are already present at the site of the nucleus, and

b) by the activation energy required to bring the building units of the nucleus to the site of its formation [65].

The work of nucleation is the difference between two energy terms. One term is the work consumed in the creation of a new nuclear surface by overcoming the surface tension of the surroundings. The second term is the energy liberated during the formation of the nucleus, when an amorphous region changes to the ordered state of a crystal lattice. This term is volume-dependent. If we assume that the building units of a nucleus are already present at the site of nucleation, *i.e.* that factor (b) is zero, the work of nucleation will be small and nucleation will proceed particularly readily when the stoichiometric composition of the amorphous region of nucleation corresponds to the composition of the nucleus. In this case, the difference between the two energy terms contributing to the work of nucleation is determined mainly by the energy liberated in the ordering process. The energy required to overcome the surface tension of the surroundings will be very small in this case and will be determined solely by the different degrees of order.

B. Homogeneous Nucleation

A nucleus will develop preferentially at a site where the composition of the glass corresponds to that of the nucleus. In glasses with homogeneous basic structures (according to *Zachariasen*) nucleation must follow statistical laws. This means that the first nuclei formed can develop into crystals of appreciable dimensions before the critical nucleus size is reached elsewhere, *i.e.* before other nuclei can start to grow. Thus the nuclei formed first enjoy relatively unhindered growth until the growth fronts of two crystals meet. The dimensions of the resulting crystals are rather large. Figure 12 shows a crystalline lithium silicate phase ($Li_2Si_2O_5$) formed in a binary lithium disilicate glass of homogeneous basic structure.

In a glass of micro-heterogeneous basic structure, the compositions of the microphases tend to correspond to those of definite compounds ("pre-crystalline state" [21,25,26]). On annealing, nucleation and crystallization will therefore begin preferentially in the microphases which are in a pre-crystalline state. Whether the microphase which is richer in network modifiers or that which is richer in the network former will take the form of droplets as the melt cools, depends on which has the higher surface tension. Normally the phase which is

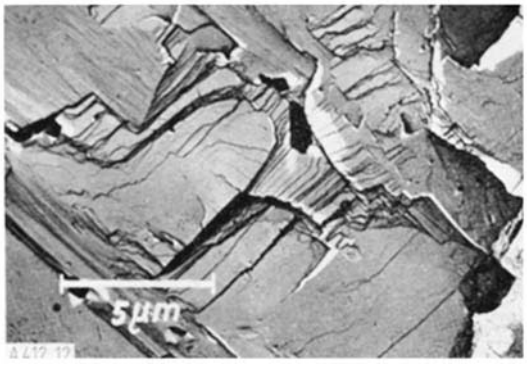

Fig. 12. Crystallization in a binary lithium silicate glass of disilicate composition (33.3 mole-% of Li_2O and 66.6 mole-% of SiO_2) and of homogeneous structure. A macroscopic $Li_2Si_2O_5$ crystal phase is formed

richer in network modifiers has a greater tendency to crystallize, since here the greatest proportion of network bridges are broken, so that the network is loosened and ions are most mobile. Theoretically, therefore, crystallization should sometimes occur preferentially in the droplet phase, and sometimes in the surrounding glass phase. Both cases have been detected. In Figure 13, nucleation and crystallization occurred in the droplet phase, and crystal growth terminated at the phase boundary, since the composition of the surrounding glass was dissimilar. In contrast, Figure 14 shows a beryllium fluoride glass in which crystallization occurred mainly in the surroundings of the droplets, so that the amorphous droplet-phase is finally embedded in a completely crystalline glass-phase.

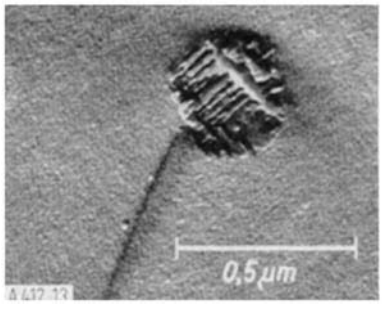

Fig. 13. Drop-shaped phase separation zones with a barbed fracture in a fluorosilicate glass. The drop-shaped glass phase is just beginning to crystallize.

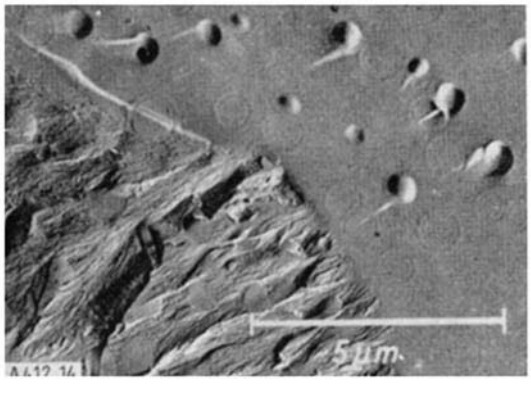

Fig. 14. Induced crystallization in a binary lithium beryllium fluoride opal glass (40 mole-% of LiF and 60 mole-% of BeF_2). The crystallization front is advancing into the two-phase glass and surrounds the vitreous, BeF_2-rich drop-shaped phase-separation zones.

[64] German Patent 962110 (1954), 1045056 (1957), 1090397 (1959), US.-Pat. 2515275 (1950), 2515937 (1950), Corning, Glassworks, Inventor: *S. D. Stooky*.

[65] *W. Kleber*, Silikattechnik *13*, 5 (1962).

Whereas the last case is of more theoretical interest, glasses in which the droplet phase has the greater tendency towards crystallization are of great practical importance. This type of crystallization is the basis of the new ultramicro-crystalline ceramic or semi-ceramic materials of the "Pyroceram" type [62–64]. In the "Pyroceram" process, the article is first formed from a clear glass which has a tendency towards phase separation; the phase separation to form droplets is developed further during the first annealing stage (at the nucleation temperature). Crystallization of the micro-phases is then brought about in the second annealing stage at a higher temperature, *i.e.* the glass is converted to an ultramicro-crystalline ceramic product.

Since all microphase separation-processes occurring in glass result in the formation of droplets with very uniform dimensions and compositions, a very large number of sites are thus created each having the same starting conditions for homogeneous nucleation and crystallization at the higher temperature. A further dimensional equalization results from the temporary interruption of crystal growth at the boundaries of the droplets (see Figure 13). The diffusion of the network modifier, which becomes more intense at high temperatures, enables the crystals formed in the droplet-shaped microphases to pass beyond the phase boundary, until growth is finally stopped by contact with other spherulites. Figure 15 shows an original "Pyroceram" glass in which this stage has been reached at a number

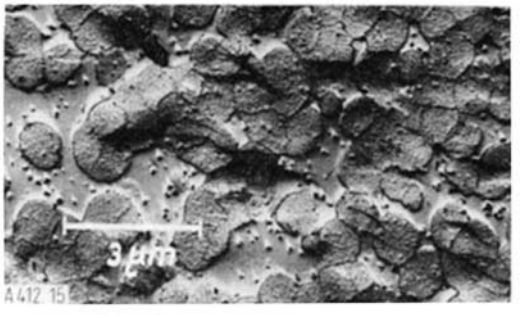

Fig. 15. "Pyroceram" glass annealed at 760 °C for 30 minutes. Crystallization has started in all the drop-shaped phase-separation zones and has already passed beyond the droplet boundary. Growth ceases when the spherical crystal-growth fronts come into contact with each other.

of points. The uniform dimensions of the crystallites are particularly noticeable. It should also be noted that the crystallization occurring after homogeneous nucleation in a glass with a homogeneous basic structure is fundamentally different from that occurring in a glass with a heterogeneous structure (compare Figure 12 to Figure 15).

C. Heterogeneous Nucleation

Whereas in homogeneous nucleation the composition of the primary nuclei does not differ from that of the main crystalline phase, in heterogeneous nucleation the crystallization of the glass is induced by foreign nuclei.

In photosensitive glasses arbitrarily chosen sections can be converted to sharply limited crystalline zones by ultraviolet irradiation followed by heating, while the surrounding parts, which have not been irradiated, are completely unaffected. In this way it is possible to produce permanent scales and designs in glass, or using a subsequent etching process, to produce miniature precision ceramic components for the electronics industry.

In general, glasses can be made photosensitive by the addition of small quantities of Cu^+, Ag^+, or Au^+ ions (ca. 0.001 mole-%), and of Ce^{3+} ions (ca. 0.01 mole-%). The mechanism of the reduction of silver by ultraviolet irradiation is assumed to be as follows:

$$Ce^{3+} \xrightarrow{h\nu} Ce^{4+} + e^-$$

$$Ag^+ + e^- \longrightarrow Ag^0$$

In the absence of Ce^{3+} ions, glasses containing Ag^+ ions are not sensitive toward ultraviolet irradiation. They are, however, sensitive toward X-rays, which have a higher energy. In this case, annealing of the glass following irradiation leads to the formation of silver nuclei and initiation of crystallization of the surrounding glass phase.

As in homogeneous nucleation, the formation of the primary silver nuclei depends on the fine structure of the parent glass. In a homogeneous silicate parent-glass, the silver ions are statistically distributed. However, this makes it difficult for the silver nuclei to reach the critical dimensions at an infinite number of sites in the glass. The fact that the critical size of the silver nuclei is attained only at relatively few sites results in the formation of rather large glass crystals. It is obvious therefore that only relatively coarse images can be obtained in glasses with homogeneous basic structures.

In micro-heterogeneous silicate glasses, the Ag^+ ions accumulate, together with other network modifiers, in the droplet phase. This results in a higher photosensitivity. The silver nuclei formed in the droplets by irradiation initiate the ordering process in the droplet phase, which by itself has a greater tendency towards crystallization. In micro-heterogeneous glasses, it is therefore possible to obtain lines down to 0.01 mm thick.

In connection with heterogeneous nucleation, brief mention must again be made of the production of new ceramic materials of the "Pyroceram" type. The formation of these materials has so far been attributed to homogeneous nucleation. However, titanium dioxide, which is only required in relatively low concentrations in the parent glass, separates out as minute droplets in the macro-droplet phase in a secondary phase-separation [44, 67]. According to their degree of order, these secondary TiO_2-rich ultramicro-droplets must already be regarded as nuclei. The same phenomenon was observed in the case of lithium silicate glasses by X-ray studies. It seems therefore correct to attribute the formation of "Pyroceram" to heterogeneous nucleation. The TiO_2 nuclei formed in the secondary phase-separation act in the same way as the Cu, Ag, or Au nuclei formed by ultraviolet irradiation in photosensitive glasses.

[67] *W. Vogel*, Z. Chem. *3*, 313 (1963).

D. Epitaxy as the Process Initiating Controlled Crystallization [44,63]

The initiation of the crystallization of a glass phase by foreign nuclei suggests an epitaxial interaction, *i.e.* the oriented deposition of material on foreign nuclei with similar lattice dimensions. This assumption is the more probable, since the nature of the crystals formed in a glass by heterogeneous nucleation may be specific for the nucleus-forming substance [62]. An experiment which confirms these assumptions will now be described.

In the case of photosensitive glasses, the surfaces of Cu, Ag, or Au nuclei have an orienting effect on the structural elements of the glass which are deposited on them. Metals (*e.g.* Pt or Ir), carbon, or SiO are frequently evaporated onto the samples in the preparation of electron-microscopic replicas. If Cu, Ag, or Au are evaporated onto photosensitive glass in which controlled crystallization is induced by nuclei of the same metal, the deposition of the metal on the glass crystals should also be oriented. In Figure 16, silver was evaporated onto a sodium beryllium fluoride glass whose basic structure was very similar to that of the glass in the lower part of Figure 14, and in which crystallization had been induced by silver nuclei. As can be seen from Figure 16, the crystalline silver particles are deposited on the micro-crystalline $NaBeF_3$ phase in the form of a string of pearls.

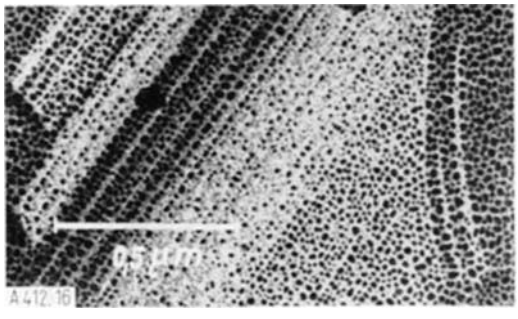

Fig. 16. The $NaBeF_3$ crystalline phase in a glass of the type shown in the lower part of Figure 14, having silver evaporated onto it, showing oriented deposition of the silver particles in the form of a string of pearls.

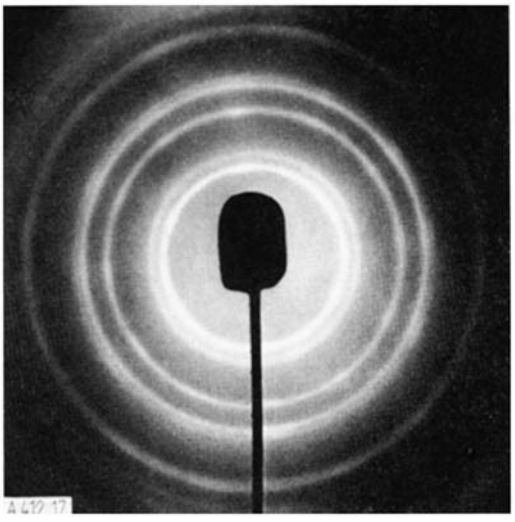

Fig. 17. Electron-diffraction diagram (direct radiation technique) of the carbon replica-film prepared after evaporation of silver (see Figure 16). The resolution of the diffraction rings into single reflections indicates the two-dimensional orientation of the silver particles on the $NaBeF_3$ crystal.

Figure 17 is an electron-diffraction photograph (direct) of the deposited silver particles. The incipient resolution of the diffraction rings into individual reflections is clearly recognizable. The two-dimensional orientation detected in this way rules out the possibility of a stepwise induction exerted on depositing silver particles, and shows that epitaxy must play a decisive part in heterogeneous nucleation in glass.

Strained Polycyclic Systems Consisting of Three- and Four-Membered Rings

BY DR. D. SEEBACH

INSTITUT FÜR ORGANISCHE CHEMIE
DER TECHNISCHEN HOCHSCHULE KARLSRUHE (GERMANY)

Polycyclic compounds consisting of small rings have been known for several years. Their chemical and physical properties, which are of both theoretical and practical interest, are discussed, and methods of preparation of a few examples are illustrated. The carbon skeletons of tetrahedrane, Dewar benzene, prismane, and cubane are discussed in greater detail, since the preparation of these compounds has now been achieved, or has at least been made possible.

I. Introduction

A few years ago it was still possible to discuss the entire chemistry of three- and four-membered ring compounds in a single review [1]. Since then this field has become so large that an exhaustive treatment would require an extensive monograph.

In recent years a theoretically and preparatively interesting group of compounds has become accessible, consisting of polycyclic compounds containing only three- and/or four-membered rings. These highly strained systems form the subject of the present review. (Accord-

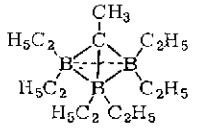
[1] *E. Vogel*, Angew. Chem. *72*, 4 (1960); Fortschr. chem. Forsch. *3*, 430 (1955).

ing to their reactions, bicyclic compounds containing condensed three-/five- and four-/five-membered rings are not included in this group.) Some notable representatives of the compounds under discussion are tetrahedrane *(1)*, tne dimer of acetylene which has not yet itself been prepared although the structure has been almost built up, prismane *(10)*, and "Dewar benzene" *(11)*, which are trimers of acetylenc, and cubane *(12)*, a tetramer of acetylene.

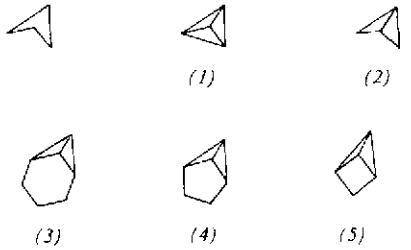
II. Classification and Properties of Strained Polycyclic Compounds [*]

A. Bicyclobutane

The most highly fused system comprising only small rings is the tetrahedron *(1)* [2]. The only structure of this type which could be hitherto synthesized contains three boron atoms (as carborane, spherical bond system) [2a].



The tetrahedron consisting of four carbon atoms is a cyclobutadiene isomer [3], but may be thought of as being formed from two molecules of acetylene [5] or by interlinking of opposite corners of a four-membered ring [4]. However, its relationship to acetylene is not purely formal, as has been shown by the most remark-



(1) *(2)* *(3)* *(4)* *(5)*

able properties of compounds with the structures *(2)* to *(5)* which are already known: the tertiary protons at the bridgehead positions, like the protons of acetylene, are acidic in character.

To explain this, it is necessary to examine the character of tne bonds in the three-membered carbon ring, which was considered as early as 1949 in a theoretical publication by *Coulson* and *Moffit* [6]. The angles between the lines joining the carbon atoms are 60 °, while those between the orbitals cannot be distorted from the tetrahedral angle (109 °) to such small values. The smallest theoretically possible angle between orbitals of carbon is 90 °, *i.e.* the angle between pure p-orbitals. Consequently, the center of gravity of the bonding electron cloud does not lie on the line joining the carbon atoms, and the resulting bonds are "bent bonds".

The most important properties of the three-membered carbon ring result from its tendency to attain the greatest possible overlap of the orbitals with resultant stabilization of the system. This is achieved:

1. by shortening of the C–C distance from the normal value of 1.540 Å to 1.524 Å,

2. by reduction of the tetrahedral valence angle (to 105 ° according to calculations by *Coulson* and *Moffit)*; this is made possible by partial change in the state of hybridization: the ring bonds assume higher p-character, and the exocyclic bonds consequently acquire higher s-character,

3. by delocalization of electrons [6] as a result of the higher p-character of the ring bonds, leading to stabilization of the entire bond system and to a kind of ring current in the plane of the three carbon atoms.

The fact that the C–C internuclear distance in the three-membered ring is reduced has been known for some time [4]. The increased p-character of the ring bonds explains why three-membered rings react with reagents which attack double bonds. It also explains the conjugative effect of three-membered rings coupled to double bond systems [7] The increased s-character of the exocyclic bonds has now been confirmed for many examples (Table 1). Recent NMR investigations by *Roberts* [7a] prove the cyclic delocalization of electrons.

The degree of hybridization of a C–H bond, a factor of interest in connection with the acidic character of the protons on the bridgehead carbon atoms in bicyclobutanes, can be measured using nuclear magnetic resonance [7b]. Natural carbon contains 1.1 % ^{13}C which has a nuclear spin $J = {}^1/_2$. The coupling of ^{13}C nuclei, present at the natural concentration in organic compounds, with the protons bonded to them can be measured by high-resolution NMR spectrography. The coupling constant (125–250 cps) depends on the disposition of the electrons in the bond, *i.e.* on the bond order. Using the coupling constants measured for a given compound, the s- and p-components of the C–H bond in question can be read off directly from a calibration curve [7b, 7c, 10]. A few values are listed in Table 1.

Since the maximum residence probability of an s-electron lies closer to the nucleus than that of a p-

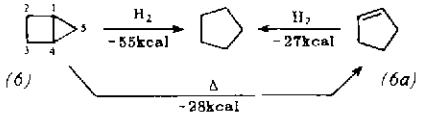
electron, the acidity of protons increases with increasing s-character of the C–H bond. In fact, bicyclobutanes of structures *(3)* and *(4)* react [10,31] just like other substances with highly mobile hydrogen atoms. Thus, the protons on the bridgehead carbon atoms of *(3)* are exchanged for deuterium with $(H_3C)_3C{-}OD$ in the presence of $(H_3C)_3C{-}OK$ [10]. This means that the pK_a value of *(3)* is smaller than that of $(H_3C)_3C{-}OH$ ($pK_a \approx 19$).

The C–H valence-band in the infrared spectrum is shifted to short wavelengths because hybridization of the bond in such systems is altered [17a].

B. Systems Consisting of Condensed Three- and Four-Membered Rings

Unsubstituted bicyclopentane *(6)* was first prepared by *Criegee* and *Rimmelin* [12–13b]. *Criegee*'s research group also recently obtained a methylated derivative of



tricyclo[3,1,0,0^{2,4}]hexane *(7)* [9]. The "strain" in such systems is manifest in their reaction with double-bond reagents such as Br_2, H_2, and $Pb(OAc)_4$, which proceeds much more readily than with cyclopropane. The strain may be measured using the heat of hydrogenation.

(7a)

(7b)

Thus, hydrogenation of *(6)* to cyclopentane resulted in liberation of 55 kcal per mole of H_2, the highest heat of hydrogenation measured until that time [13b].

Therefore the heat of combustion of *(6)* must be very high too (the heat of combustion of the reaction $H_2 + {}^1/_2\,O_2 \rightarrow H_2O$ is −58 kcal/mole of H_2), with the result that the use of *(6)* as a rocket fuel has been considered in the U.S.A. By comparison the heat of hydrogenation of cyclopentene is −27 kcal/mole; the bicyclic compound is therefore spoken of as having an extra strain energy of (−55 + 27) = −28 kcal/mole, which also represents the energy for the isomerization *(6)* → *(6a)*.

(8) *(8a)*

Derivatives of the unsaturated compound *(8)* have not yet been prepared, but are postulated as intermediates in several reactions from which cyclopentadienes have been isolated [3,14]. Their high instability is due not only to the increased strain resulting from the double bond in the four-membered ring and the gain in resonance energy of a conjugated system on transition to *(8a)*, but also to the possibility of valence-bond isomerization [15], a concept which can be explained by comparing *(6)* with *(8)*. Both compounds isomerize to give five-membered rings; whereas *(6)* must be heated above 300 °C (activation energy: 45 kcal/mole [14a]), *(8)* isomerizes so readily that the five-membered ring is already formed at −78 °C. To transform *(6)* into cyclopentene, a proton must migrate, while in the case of *(8)* only a cyclic electron-displacement is required with no great change in the position of any atom. This cyclic electron-displacement is the characteristic feature of valence-bond isomerizations which are encountered with all the following compounds.

If the free corners of the two three-membered rings of *(7b)* are linked by a methylene group, quadricyclene *(9)* is obtained, a highly symmetrical compound consisting of two five-, one four-, and two three-membered rings, which was prepared independently by *Dauben*, *Hammond*, and *Prinzbach* [16]. It exhibits the

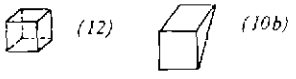
typical properties of strained three-membered ring compounds, *viz.* reaction with acids, bromine, and hydrogen, as well as ready thermal isomerization to its valence-bond isomer norbornadiene *(9a)*, from which *(9)* was prepared by irradiation

Like tetrahedrane *(1)* and cubane *(12)*, a hydrocarbon prismane *(10)* containing six tertiary carbon atoms is a very interesting compound.

(10) *(11)*



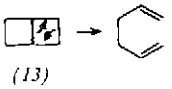
(12) *(10b)*

Since *(10)* is an isomer of "Dewar benzene" and of benzene, it is not surprising that in the first experiment in which prismane was probably an intermediate [17], only the corresponding benzene derivative could be isolated [17a].

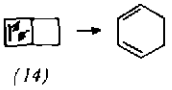
A compound closely related to prismane is the tricyclic carbohydrate *(10b)* [17b] which contains "only" one C–C linkage less than prismane.

C. The Bicyclo[2,2,0]hexane Skeleton

The simplest compound containing only four-membered rings is bicyclo[2,2,0]hexane *(13)*, which isomerizes at 200 °C (activation energy: 36 kcal/mole [14a]) to 1,5-hexadiene, a reaction corresponding to the pyrolysis of cyclobutane into two molecules of ethylene [18, 19]. Introduction of a double bond into *(13)* leads



(13)



(14)

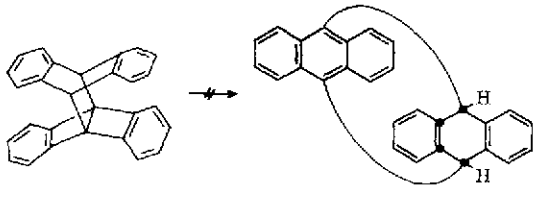
to the bicyclohexenes *(14)*, which readily undergo valence-bond isomerizations to cyclohexadienes. The first compound with a bicyclo[2,2,0]hexane structural element was isolated more than 20 years ago by *Windaus* [20], and its true structure was discussed; however it was only in 1959 that this structure was proved by *Dauben* and *Fonken* [20]. With two double bonds in *(13)* the so-called Dewar benzene, bicyclo[3,3,0]hexadiene *(11)*, is obtained. This compound does not have the benzene structure *(15)* suggested by *Dewar* (which is planar and is included in the description of benzene by the valence-bond theory) but is the non-planar molecule

(15)

formed by two cyclobutene rings with a 1,4-σ-bond. Bicyclohexadienes naturally isomerize readily to benzene derivatives, with release of the strain and liberation of the resonance energy which, being 36 kcal/mole, is so great that it is surprising that a molecule such as *(11)* can be prepared at all. Three means of stabilization of such molecules may be quoted.

1. Bracket Effect

Eschenmoser and *Vogel* [21] found with norcaradiene that an unstable structure can be stabilized if, for example, a "five-membered ring bracket" is inserted to link the two atoms between which the labile bond is situated. Meanwhile this principle was also applied to the bicyclohexane derivative *(16)*. This "Dewar benzene" derivative [22c] is so stable that it can be recovered 63 % unchanged even after 1.2 h at 360 °C, while the unsubstituted "Dewar benzene" is extremely labile [$\tau_{1/2}$ (20 °C) = 2 days] [22a].



(16) *(16a)*

The six-membered "clamp" holds the bicyclic system together. A cyclophane-type linkage of the 9,10-sp^2-hybridized valences of anthracene through the four carbon atoms indicated in *(16a)* is impossible. This agrees with the fact that the only products which are isolated on pyrolysis of *(16)* are anthracene and bianthryl.

2. Steric Hindrance

Labile structures can also be stabilized by bulky groups which would hinder each other to a greater extent in the structurally more stable isomeric molecule or which would have to move past one another in the course of isomerization of the less stable species. This effect

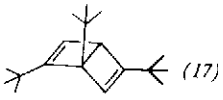
played a part in the preparation of the first derivative of "Dewar benzene" by *van Tamelen* [22b].

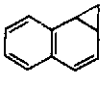


(17)

The bicyclic compound *(17)* is formed on irradiation of 1,2,4-tri-t-butylbenzene; in contrast to unsubstituted "Dewar benzene" [22a], *(17)* is perfectly stable at room temperature. The photocatalysed rearrangement is largely due to the strain produced by the three t-butyl groups in the benzene derivative. Assuming that the two sp^3-hybridized bridgehead carbon atoms in *(17)* exhibit their normal valence angles, the planes containing the two bulky groups in the bicyclic compound lie at an angle of about 55 °C to each other [4,50]. The mutual repulsion of the t-butyl groups prevents reversion of the isomerization at normal temperatures.

3. Benzene Resonance

If a benzene ring is fused to a molecule that isomerizes easily, in such a way that the ring adopts a quinonoid structure through valence-bond isomerization, *i.e.* that on cyclic electron shift the resonance energy of benzene is lost, then this molecule is rendered stable. An example is the norcaradiene system: the unsubstituted cycloheptatriene appears as a seven-membered ring, the amount of valence-bond isomeric norcaradiene present being too low to be detectable by NMR spectroscopy [7b]; on the other hand, the valence-bond isomeric benzocycloheptatriene cannot be detected in benzonorcaradiene *(17a)* [23,23a] [cf. also *(57)*].



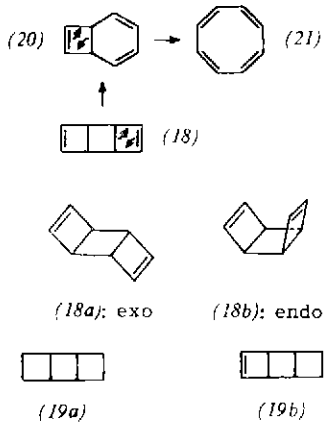
(17a)

D. The Tricyclo[4,2,0,$0^{2,5}$]octane Skeleton

Tricyclic compounds consisting of three *ortho*-condensed four-membered rings are nearly all derived from dimeric cyclobutadienes *(18)*.

Little is yet known about the saturated system *(19a)* and the mono-unsaturated system *(19b)*.

Isomerization of the dimeric cyclobutadienes *(18)* to cyclooctatetraenes proceeds *via* the bicyclo[4,2,0]octatrienes *(20)* [40,48,49,51][*], which are valence-bond isomers of cyclooctatetraene *(21)* and derivatives of which were first prepared in this manner [40,47,49]. The



tricyclic compounds can exist in the *endo*- (*syn*) or *exo*- (*anti*-) forms; representatives of both configurations have been obtained during numerous attempts to prepare cyclobutadienes.

E. Cubane

It can be seen that the *endo*-form *(18b)* is very similar to the structure of cubane *(12)* which could result from cycloaddition of the mutually opposed double bonds of the tricyclic compound. It has been calculated [5] that this cube of eight carbon atoms should be less stable by 80 kcal per mole than its isomer cyclooctatetraene. Experiments with tetraphenylcyclobutadiene readily led to a compound which was described as having the octaphenylcubane structure [24]; it was recently shown, however, to be octaphenylcyclooctatetraene [24a]. *Eaton* and *Cole* have prepared unsubstituted cubane [24b,54].

All five possible cyclobutadiene dimer structures C_8H_8 appear to have been isolated: cubane *(12)*, *exo*- and *endo*-tricyclooctadiene *(18a)* and *(18b)*, bicyclooctatriene *(20)*, and cyclooctatetraene *(21)*.

III. Synthesis of the Strained Ring Systems

The methods used for the preparation of the strained systems can be divided up into a few groups. The principles of the reactions, some of which are novel [25], are briefly discussed in the following Sections.

A. Reaction Types

α) Transannular elimination: In this reaction a new transverse C–C bond is formed in an existing ring by thermal or photolytic elimination of N_2 or CO, by elimination of HX with strong bases, or by elimination of X_2 with alkali metals.

[25] *J. J. Bloomfield, R. G. Todd*, and *L. T. Takahashi*, J. org. Chemistry *28*, 1474 (1963).

β) Intramolecular carbene reaction: Here use is made of the high reactivity of carbenes which, in the absence of other coreactants, can undergo intramolecular C–H insertion or C=C addition reactions to form highly strained systems.

γ) Intramolecular photolytic reaction: Olefinic systems isomerize on absorption of light (often in the presence of a sensitizer). The isomers no longer absorb in the spectral region of the light used for irradiation.

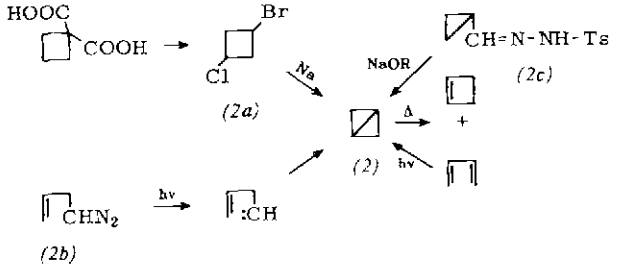
δ) Cycloaddition of highly reactive olefins: Highly activated olefins (fluoro-olefins and polycyano-olefins) undergo 1,2-additions onto double bonds even when the resulting molecules are strained. The olefins can also be activated photochemically; they then yield, in contrast to (γ), intermolecular addition compounds.

ε) Reactions of cyclobutadienes: This method is only a special case of reaction (δ) with cyclobutadiene as the reactive olefin. During attempts to prepare cyclobutadienes under the mildest possible conditions, secondary or side reactions [3] led to the formation of strained four-membered rings which are stable under the experimental conditions.

B. Examples

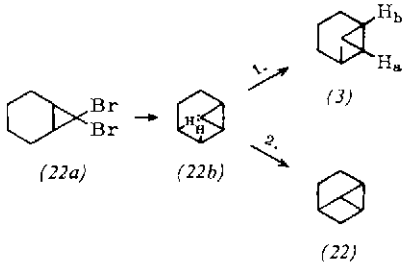
1. Bicyclobutanes

The first compound with a bicyclobutane structure was prepared in 1959 by *Wiberg* [26], who subsequently also succeeded in obtaining unsubstituted bicyclobutane *(2)* on a preparative scale from 1-bromo-3-chlorocyclobutane *(2a) via* reaction type (α) [27].



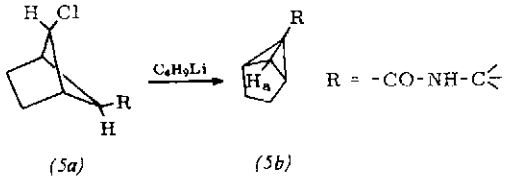
Compound *(2)* is also formed from diazobutene *(2b)* [28] *via* an intramolecular carbene addition reaction and from the tosylhydrazone *(2c) via* an intramolecular carbene insertion reaction [28a] [reaction type (β)]. Pyrolysis of *(2)* yields cyclobutene and butadiene. Under certain conditions bicyclobutane can be obtained on irradiating butadiene [28b]. This reaction is of practical importance in that, despite low yields (5 to 6 %), the bicyclic compound is produced in one step from commercially available starting material. Polymerization of *(2)* occurs readily, according to *Wiberg*, the C–C dissociation energy being so low that this compound possesses pseudo-olefinic character [26].

Carbene insertion into the C–H bond led *Moore* to the trimethylene-bridged bicyclobutane *(3)* mentioned above [29]. Elimination of bromine from the dibromide *(22a)*, which is readily available from cyclohexene and dibromocarbene, leads to the formation of a carbene *(22b)* which reacts further in two ways: insertion into the C–H bond in the α-position yields the bicyclobutane derivate *(3)* (NMR spectrum for H_a: $\tau = 8.33$; for H_b: $\tau = 8.55$ ppm); alternative insertion into the C–H bond in the β-position yields the bicyclopentane derivative *(22)* [29, 30].



As in all bicyclobutane derivatives, hydrogenation of *(3)* results in cleavage of both three-membered rings; here methylcyclohexane is formed.

By transannular elimination of HCl from the bicyclohexane derivative *(4a)*, *Meinwald* [31] prepared the bicyclobutane derivative *(4b)*, which is bridged by only two methylene groups [reaction type (α)].



The proton H_a bonded to the bicyclobutane bridgehead carbon atom is "acidic": it can be readily replaced by metal atoms, and a wide variety of groups can then be introduced by reaction with CO_2 or organic halides.

Ketocarbenes, formed by heating or photolysing diazoketone derivatives of cyclopropenes *(4c)* and *(5a)*, can react by intramolecular addition across the double bond [*cf. (2b)* → *(2)*]; compound *(4d)* [31a] is formed in 53 % yield, and when heated at 180 °C yields 3,4,5-triphenylphenol. The hydrogenation product of the tricyclic compound *(5b)* [31b] is *cis*-3,4-diphenylcyclopentanone; *(5b)* resembles the tetrahedron *(1)* more closely than any other known tricyclic compound.

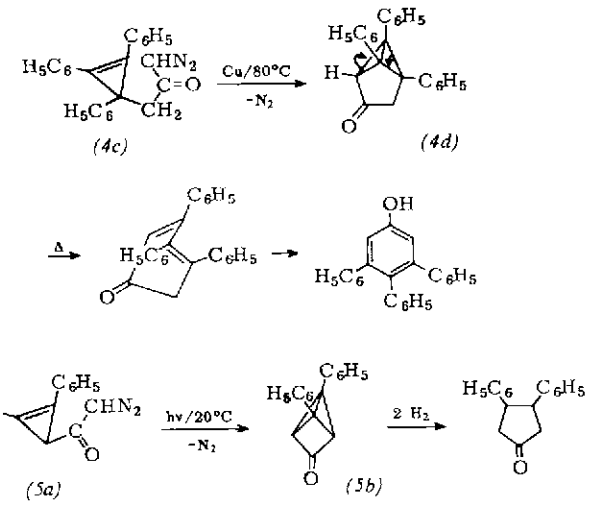
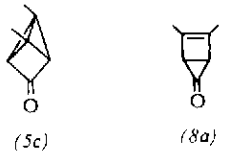
[31b] *S. Masamune*, J. Amer. chem. Soc. *86*, 735 (1964).



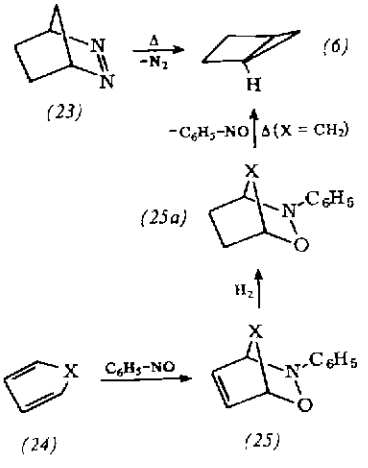
Doering and *Pomerantz* [31c] isolated *(5c)* with methyl substituents instead of phenyl substituents in 1 % yield by the same method (NMR spectrum of *(5c)*: two maxima with an intensity ratio of 3:1 at τ = 7.95 and 8.17 ppm). Hydrogenation yields *cis*- and *trans*-dimethylcyclopentanone.



According to the authors structure *(8a)* is not inconsistent with the spectral data for compounds *(5b)* and *(5c)*. From experimental observations on valence-bond isomerization of cyclobutenes ([38, 38a]; see also Section II.B), a cyclobutene of type *(8a)* containing a fused three-membered ring should isomerize readily to the dimer of cyclopentadienone *via* its monomer.

2. Systems with Bicyclopentane Groupings

Hydrocarbon *(6)* was prepared in 1957 from the bicyclic compound *(23)* by pyrolytic elimination of nitrogen [12]. However, a recent publication [32] reports its synthesis by a similar, more generally applicable



[31c] *W. v. E. Doering* and *M. Pomerantz*, Tetrahedron Letters *1964*, 961.

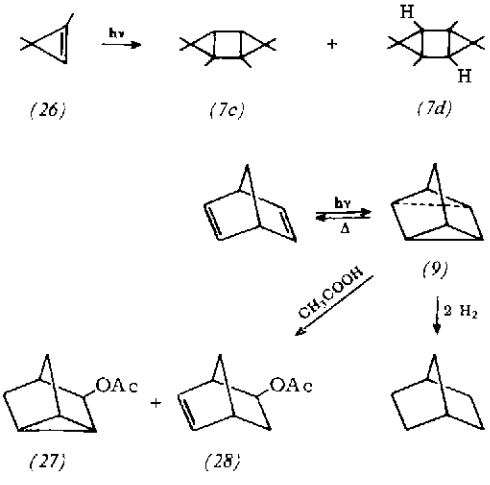
[32] *C. E. Griffin, N. F. Hepfinger*, and *B. L. Shapiro*, J. Amer. chem. Soc. *85*, 2683 (1963).

reaction [type (α)]. This involves the use of a cyclic diene *(24)* [*e.g.* X = $(CH_2)_n$; n = 1–4], which is converted into the Diels-Alder adduct *(25)* with nitrosobenzene; the double bond is then hydrogenated to give *(25a)*, and the nitrosobenzene is thermally eliminated. This yields *(6)* when X = CH_2.

Tricyclic compounds containing the bicyclopentane skeleton, *e.g. (22)*, can also be prepared starting from the norbornane system [30].

Tricyclohexane derivatives of type *(7)*, *e.g. (7c)* and *(7d)* (NMR spectrum for tertiary H: τ = 9.0 ppm), are formed in a novel reaction, namely photosensitized cyclodimerization of cyclopropene *(26)* [9, 33].

Quadricyclane *(9)* has a methylene-bridged tricyclohexane structure and has been known now for some years; its chemistry has therefore been investigated more thoroughly [16]. Its reactions result in the cleavage of one or both strained bonds. The reaction of *(9)* with acetic acid leads to the formation of the acetoxy



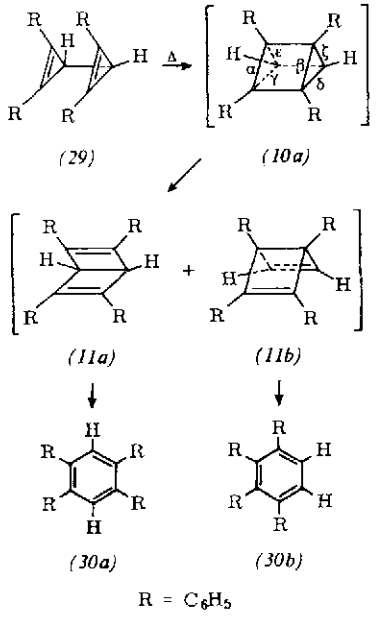
compounds *(27)* and *(28)*; catalytic hydrogenation yields norbornane, and heating to 200 °C gives the valence-bond isomer norbornadiene. Polycyclic compounds such as *(9)* which are built up of three- and four-membered rings are generally extremely sensitive to acids.

Evidence pointing to the existence of prismane, which is also tetracyclic, has recently been obtained for the first time [17, cf. 17a]. The two tetraphenylbenzenes *(30a)* and *(30b)* were isolated from *(29)* following a reaction similar to the dimerization of cyclopropene *(26)*.

The simplest explanation for this is the intermediate formation of tetraphenylprismane *(10a)* which, according to *Breslow*, may be imagined to react further through the isomeric "Dewar benzenes" *(11a)* and *(11b)* to form the tetraphenylbenzenes *(30a)* and *(30b)*, depending on whether bonds α and β or γ and δ (ε and ζ) in *(10a)* are broken.

Tricyclo[2.2.0.$0^{2,6}$]hexane *(10b)*, mentioned already, was obtained by *Lemal* and *Shim* [17b] in 30 % yield

[33] The lines here and in the remainder of the paper indicate methyl groups.



(29) (10a) (11a) (11b) (30a) (30b)

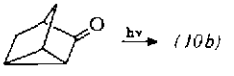
from the tricyclanone *(10c)* *via* mercury-sensitized liberation of carbon monoxide in a flow apparatus.

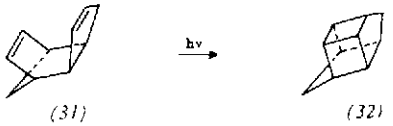


(10c)

3. The Bicyclo[2,2,0]hexane Skeleton

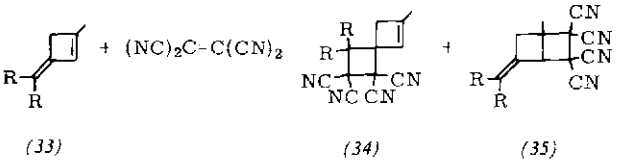
a) Bicyclohexanes

The parent hydrocarbon *(13)* was first prepared in small yields (< 5 %) by *Cremer* and *Srinivasan* in Hg-sensitized photoreactions in the gaseous phase [18]. It can now be prepared according to *Griffin* in 60 % yield from cheap starting materials [cyclohexadiene *(24)* with X = $(CH_2)_2$ and nitrosobenzene, cf. the formation of *(6)* from *(24)*]. The saturated bicyclohexane skeleton is formed, built into cage-like compounds [34], on exposure of dimeric cyclopentadienes to light. Thus, in the photosensitized cycloaddition [reaction type (γ)] of unsubstituted *(31)*, *Schenck* and *Steinmetz* [35] obtained the pentacyclic compound *(32)*. Compound *(32)* is stable at temperatures above 400 °C, in contrast to simple bicyclobutane derivatives, which isomerize at temperatures as low as 200 °C [14a, 18]; the compound differs from cubane in the insertion of a methylene group into two of the bonds. The key compound *(69)* for cubanedicarboxylic acid *(12a)* [24a] arises from the dimeric bromocyclopentadienone *(68)* *via* the same reaction.



(31) (32)

Cycloaddition of a highly reactive olefin onto a double bond [36] with formation of a bicyclohexane compound is exemplified by the reaction of tetracyanoethylene with methylenecyclobutenes *(33)* [reaction type (δ)].



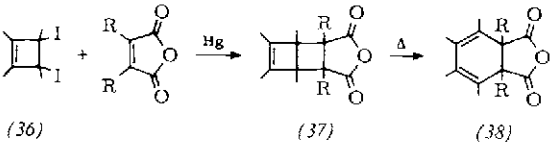
(33) (34) (35)

When R = H, the reaction leads simply to formation of the less strained spirane *(34)*; however, with greater steric hindrance of the exocyclic double bond (R = CH_3), the principal product is the bicyclic compound *(35)*.

Fluoro-olefins also add onto double bonds in the same manner at elevated temperatures to form polycyclic compounds with four-membered rings (cf. [37]). X-Ray studies showed that the supposedly perfluorinated tricyclo[4,2,0,$0^{2,5}$]octane is indeed the [3,3,0,$0^{2,6}$]-isomer having only one four-membered ring [37a].

b) Bicyclohexenes

Reaction type (ε) found its first application with the bicyclohexenes. According to *Criegee*, the only adducts of a "cyclobutadiene" with olefins so far isolated are the compounds *(37)* [3, 38] which are obtained by dehalogenation of the diiodide *(36)* with Hg in the presence of maleic anhydrides (attempts to trap other cyclobutadienes led directly to the isomeric cyclohexadienes [39]).



(36) (37) (38)

R = H, CH_3, Cl, Br, I

Chemical changes in the anhydride grouping [*] result in the formation of bicyclohexene derivatives *(37)* [38], which undergo valence-bond isomerization to yield cyclohexadiene derivatives [e.g. *(38)*] at about 200 °C (stabilizing influence of the methyl groups [40]). The dibromide *(37)* (R = Br) is the starting material in the preparation of "Dewar benzene" *(11d)* [22d].

A very thermolabile bicyclohexene *(39a)* [38a] is formed in 50 % yield by illuminating butyne in the presence of an ester of cyclobutenedicarboxylic acid [reaction type (δ)]. Under the additional influence of both carboxyl groups, isomerization to cyclohexadiene can be achieved

[34] *O. L. Chapman* et al., J. Amer. chem. Soc. *85*, 2031 (1963).

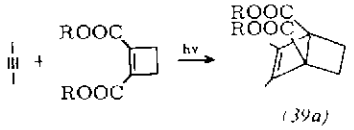
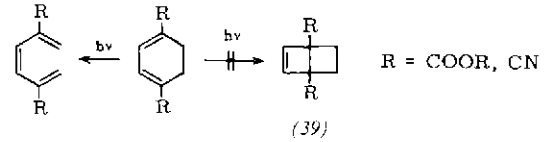
even at 80 °C ($\tau_{1/2}$ = 4.2 h; activation energy = 30.6 kcal/mole).



(39a)

Conversely, bicyclohexenes can be formed from cyclohexadienes by the action of light [reaction type (γ)]. Besides the examples mentioned in the interesting studies on sterols [20] and terpenes [41a], in which cyclization is facilitated by the sterically fixed proximity of the double bonds in the polycyclic skeleton, this photoisomerization has also been achieved with simple cyclohexadienes [22a, 41d].

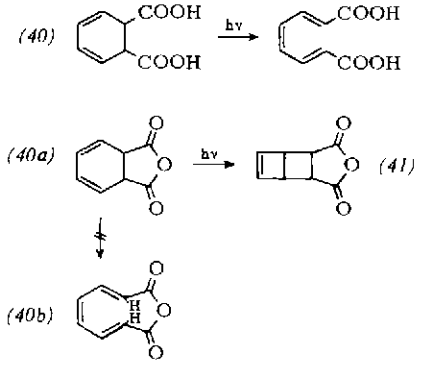
According to *Barton* [41], the "normal" photoreaction of the cyclohexadienes is ring-opening to yield extremely reactive hexa-1,3,5-trienes.



(39)

Meanwhile doubt has been thrown [41c] on the structure of the bicyclohexenes *(39)* described by *Prinzbach* [41b].

Another method of isomerizing cyclohexadienes has been demonstrated by *van Tamelen* [41d, 22a]. Whereas the six-membered ring of the dicarboxylic acid *(40)* is opened by the action of light, dihydrophthalic anhydride *(40a)* undergoes ring closure to form bicyclohexane *(41)* [22a]. A kind of bracket effect was proposed as the explanation for this: the monocyclic anhydride *(40b)* is not formed owing to steric hindrance of the hydrogen atoms indicated in the formula (cf. Section II.C.1).



The anhydride *(41)* is the starting material for a surprisingly simple preparation of the unsubstituted "Dewar benzene" *(11)*.

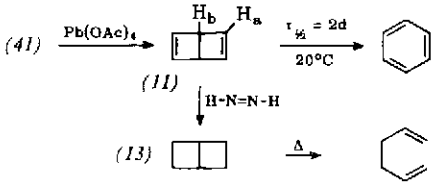
[41c] *H. Prinzbach*, personal communication.

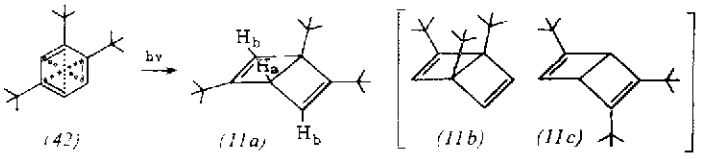
[41d] *G. J. Fonken* and *W. Moran*, Chem. and Ind. *1963*, 1841; *G. J. Fonken* and *K. Mehrotra*, ibid. *1964*, 1025.

Van Tamelen and *Pappas* have shown [22a], that a solution of "Dewar benzene" *(11)* [NMR spectrum for H_a: τ = 3.45; H_b: τ = 6.16 ppm] can be obtained in about 20 % yield by reaction of *(41)* with $Pb(OAc)_4$ in pyridine.



In addition to its spectra, the chemical reactions of *(11)* provide clear evidence for its structure: hydrogenation with diimide [*] yields bicyclo[2,2,0]hexane *(13)*, which is converted into 1,5-hexadiene by heating (both substances were identical with authentic samples [18]). "Dewar benzene" isomerizes to benzene at room temperature with a half-life of 2 days.

A much more stable "Dewar benzene" derivative (see Section II.C.2) had been prepared a year previously (1962). On irradiation of 1,2,4-tri-t-butylbenzene *(42)*, 1,4-ring closure could theoretically lead to formation of the three products *(11a)*–*(11c)* [reaction type (γ)]. Of these, only *(11a)* [NMR spectrum for H_a: τ = 6.80; H_b: τ = 3.90 ppm] no longer contains two t-butyl groups in a single plane together with the carbon atoms connecting them. The two groups on the bridgehead atoms in *(11b)* lie in a single plane, those on the double bond do in *(11c)*. Thus, the formation of *(11b)* and *(11c)* would involve no reduction in steric hindrance compared to *(42)* [**]. Compound *(11a)* was in



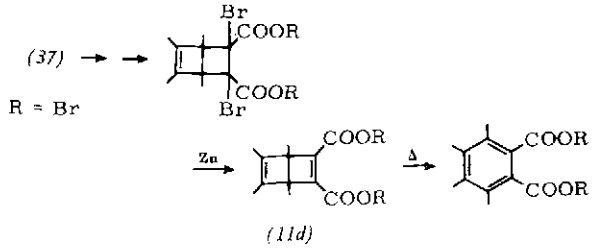
fact isolated as the first bicyclohexadiene. It can be vacuum distilled (10^{-7} mm) and is so stable that heating for 15 min at 200 °C is necessary to effect reversal of the isomerization.

Thus, although the unsubstituted compound *(11)* is very unstable and has not yet been isolated, while its derivative *(11a)* has been prepared in only very small amounts, *Criegee* and *Zanker* [22d] succeeded in synthesizing the "Dewar benzene" derivative *(11d)* on a preparative scale and in good yields from the dibromide *(37)* (R = Br) *via* the dicarboxylic acid ester.

[*] Diimide hydrogenates only non-polar double bonds [42].

[**] 1,2,3-Tri-t-butyl-4,5,6-trifluorobicyclohexadiene was recently isolated by *H. G. Viehe* et al., Angew. Chem. *76*, 922 (1964); Angew. Chem. internat. Edit. *3*, 755 (1964).

[42] Most recent publications with references to all earlier papers: *S. Hünig*, *H. R. Müller*, and *W. Thier*, Angew. Chem. *75*, 298 (1963); Angew. Chem. internat. Edit. *2*, 214 (1963); *E. J. Corey* and *W. L. Mock*, J. Amer. chem. Soc. *84*, 685 (1962); *E. E. van Tamelen* and *R. J. Timmons*, ibid. *84*, 1067 (1962).



(11d)

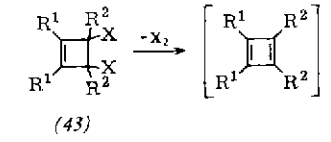
At room temperature compound *(11d)* is stable, but at 90 °C it isomerizes to the ester of tetramethylphthalic acid ($\tau_{1/2}$ = 4.7 h), in which the stabilizing influence of methyl substitution on an unstable valence-isomer can again be seen [3,40].

4. The Tricyclooctane Skeleton

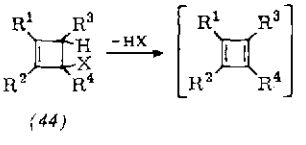
So far there is scarcely a reaction known [43,44] in which a tricyclooctane skeleton with three *ortho*-fused four-membered rings is formed, other than dimerization of cyclobutadienes [reaction type (ε)]. Only a brief description of the tricyclooctadienes, their formation, and their properties will therefore be given. Moreover, reviews have already been published on some parts of this field, such as the dimers of tetramethylcyclobutadiene and of benzocyclobutadiene (*cf. Criegee* [3] and *Cava* [45]). Besides these two workers, *Freedman* and *Nenitzescu* have also investigated the chemistry of the cyclobutadienes.

a) Generation of Cyclobutadienes

The reaction most frequently used for the generation of cyclobutadienes is the elimination of halogen from dihalogenocyclobutenes *(43)*. The elimination of hydrogen halides is less frequently used [47,48,50], owing to the greater difficulty involved in obtaining monohalogenocyclobutenes *(44)*.



(43)



(44)

$R^1 = R^2 = H$; X = Cl [46]
$R^1 = R^2 = CH_3$; X = Cl, I [3]
$R^1 = R^2 = C_6H_5$; X = Br [39]

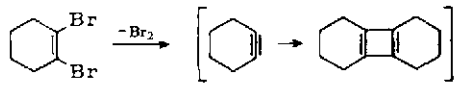
$R^1 = R^4 = H$; $R^2 = R^3 = C_6H_5$; X = N< [50a]

Wittig and *Mayer* [51] obtained a cyclobutadiene derivative *(47)* by an entirely different reaction during the preparation of cyclohexyne *(46)* from 1,2-dibromo-1-cyclohexene *(45)*.

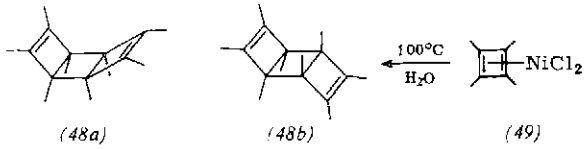


(45) (46) (47)

b) Secondary Products

The dimer of cyclohexyne *(47)* itself dimerizes like other cyclobutadienes to give the corresponding tricyclooctadiene [cf. *(18)*]; a tricyclooctadiene derivative is invariably the first secondary product formed from all cyclobutadienes.

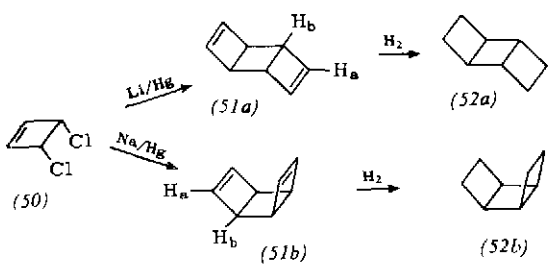
The *syn*- and *anti*-isomers of a tricyclooctadiene derivative were prepared and their structures proved and assigned for the first time by *Criegee* et al. [3]: the permethylated *syn*-tricyclic compound *(48a)* is formed by elimination of chlorine from the corresponding dichloride *(43)*, while the *anti*-tricyclic compound *(48b)* results from decomposition of the cyclobutadiene-nickel complex *(49)*.



(48a) (48b) (49)

Subsequently, unsubstituted analogues *(51a)* [NMR spectrum for H_a: τ = 3.52; H_b: τ = 7.06 ppm] and *(51b)* [NMR spectrum for H_a: τ = 4.05; H_b: τ = 6.92 ppm], catalytic hydrogenation of which leads to the saturated tricyclic hydrocarbons *(52a)* and *(52b)*, were also prepared by *Nenitzescu* [46].

Compound *(51a)* is formed from the dichloride *(50)* with Li/Hg, and *(51b)* with Na/Hg. A surprising specificity similar to that observed in the formation of *(48)* and



(50) (51a) (51b) (52a) (52b)

[48] *M. P. Cava* et al., Tetrahedron Letters *1961*, 140.

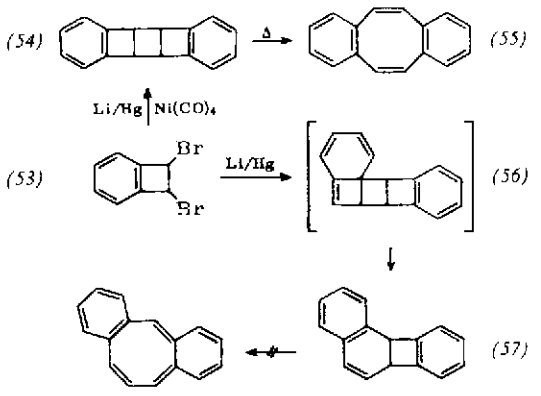
[49] *C. D. Nenitzescu* et al., Chem. and Ind. *1959*, 257; *1962*, 555; Chem. Ber. *93*, 1789 (1960); Tetrahedron *19*, 309 (1963).

[50] *J. D. Roberts* et al., J. Amer. chem. Soc. *82*, 3106 (1960); *86*, 449 (1964); *Ch. Fritchie jr.* and *E. W. Hughes,* ibid. *84*, 2257(1962).

[50a] *E. H. White* and *H. C. Dunathan,* J. Amer. chem. Soc. *86*, 453 (1964).

[51] *G. Wittig* and *U. Mayer,* Chem. Ber. *96*, 342 (1963).

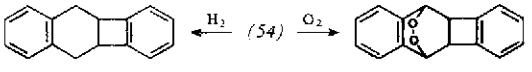
(51) is found in the dimerization of benzocyclobutadiene. Whereas benzocyclobutadienes generally



undergo angular dimerization leading to compounds of structure *(57)* [47,48], the reaction of the dibromide *(53)* with Li/Hg in the presence of $Ni(CO)_4$ yields a linear dimer *(54)* [49]. This specificity suggests that free cyclobutadiene compounds do not exist as intermediates in all cases [3].

Later however, experiments by *Skell* and *Petersen* [51a] indicated that free tetramethylcyclobutadiene exists in the gas phase for some period of time; the formation of the *syn*-tricyclic compound *(48a)* could be proved, Thus is seems no longer necessary to describe cyclobutadiene as being only a hypothetical compound.

In *(54)*, resonance is retained in both benzene rings; hence the compound can be isolated as such and is converted into the valence-bond isomer *(55)* only on heating. On the other hand, one of the benzene rings is present in an *ortho*-quinonoid form in the primary product *(56)* of the angular dimerization; consequently, *(56)* cannot be obtained as such, and instead the more stable product *(57)* is isolated. Compound *(57)* was the first derivative of bicyclo[4,2,0]octatriene to be isolated (see also [40]); it cannot isomerize to the eight-membered ring *(58)*, since this would again result in the formation of an *ortho*-quinonoid ring [see also Section II.C.3].

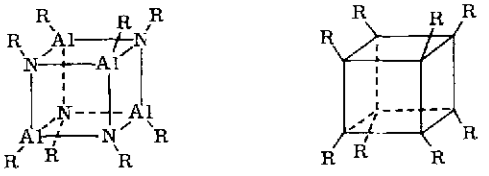


(59) *(60)*

The strain in the system consisting of three condensed four-membered rings is manifest in the reactions of *(54)* with hydrogen to yield bicyclo-octadiene *(59)* and with oxygen to yield the *endo*-peroxide *(60)* [49].

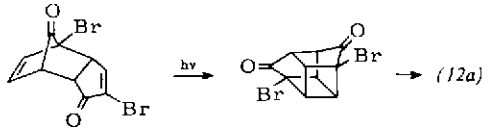
5. Cubane

Following the success of reactions leading to quadricyclene *(9)*, prismane *(10a)*, and the pentacyclic compound *(32)*, it also seemed possible to prepare the cubane skeleton from an *endo*-tricyclooctadiene such as *(48a)*. However, this tricyclic compound could not be converted into cubane either by exposure to light or at a pressure of several thousand atmospheres [38]. The first compound whose structure was known with certainty (from X-ray analysis) to be based on the cubane structure was the octaphenyl-Al-N cube *(61)* [52].



According to *Freedman* [24,39,53], the dimer of tetraphenylcyclobutadiene (m.p. 430 °C) seemed to have an octaphenylcubane structure *(62)*. However, it turned out to be octaphenylcyclooctatetraene [24a].

As already mentioned, *Eaton* and *Cole* have synthesized the cubane skeleton [24b,54]. The pentacyclic compound *(64)* is converted to cubanedicarboxylic acid *(12a)* using boiling 50 % aqueous KOH, the overall yield of *(12a)* obtained from the dimer of bromocyclopentadienone *(63)* being 30 %.



(63) *(64)*

The reaction is assumed to be a Favorskii rearrangement following the mechanism of the semi-benzilic acid rearrangement. The data hitherto available (see, for example, Table 1) favor the proposed structure *(12a)*. Further examination of *(12a)* and of the parent hydrocarbon C_8H_8 [54] should yield interesting results.

I am sincerely grateful to Professor R. Criegee for his interest in this review.

Reactions of Metal Acetylacetonates

BY PROF. DR. J. P. COLLMAN

CHEMISTRY DEPARTMENT, UNIVERSITY OF NORTH CAROLINA, CHAPEL HILL, NORTH CAROLINA (U.S.A.)

Certain metal acetylacetonates undergo reactions characteristic of aromatic systems. Outstanding among these are electrophilic substitutions and the formation of a stable diazonium fluoroborate. Unsymmetrically substituted chelates have been prepared by stepwise substitution of trifunctional complexes. Chemical and physical properties of such mixed-ring complexes provide evidence for intramolecular interannular electronic effects transmitted through the metal ion.

I. Introduction

Although the physical properties of metal acetylacetonates have been studied extensively over many years, until recently very little attention was given to the chemical reactivity of this heterocyclic ring system. In 1925 *Reihlen* et al. reported bromination of chromium(III) acetylacetonate and assigned the correct structure to the bromination product [1]. As we were beginning our own work in 1958, *Djordjevis, Lewis*, and *Nyholm* described nitration of copper(II) acetylacetonate with N_2O_4 [2]. Since then metal acetylacetonate chemistry has developed extensively [3]. This account reviews our work in this field.

In order to minimize degradation of these acid-labile chelates, our studies have been largely restricted to relatively inert tris-acetylacetonates of chromium(III), cobalt(III), and rhodium(III) *(1)*. These metals confer individual differences on their chelates so that certain reactions or physical properties are more conveniently studied in one case than another. The rhodium(III) chelate is by far the most stable to acids, bases, or thermal treatment. On the other hand the chromium(III) and cobalt(III) chelate rings are much more reactive towards electrophiles than is the rhodium(III) complex. Almost all reducing agents quickly degrade the cobalt(III) complexes by producing labile cobalt(II) species. $NaBH_4$ or B_2H_6 quickly reduce rhodium(III) in these chelates to rhodium metal; however, catalytic and other chemical reducing agents do not reduce complexed rhodium(III). By contrast chromium(III) acetylacetonate is inert to all but the most powerful reducing agents. The d^6-cobalt(III) and rodium(III) complexes are diamagnetic and amenable to proton magnetic resonance analysis. The d^3-chromium(III) complexes are strongly paramagnetic so that NMR spectra cannot be determined.

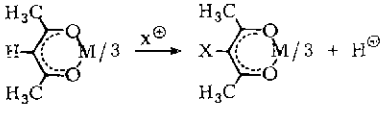
II. Electrophilic Substitution of the Chelate Rings

The central hydrogen atom on these chelate rings *(1)* can be replaced by several groups under apparently electrophilic conditions *(2)*. Because of the acid lability of these complexes, selective reagents must be employed to minimize degradation of the chelate rings. Halogenation [4, 5], thiocyanogenation [6, 7], arylsulfenylation [7], chlorosulfenylation [6, 7], nitration [8], acylation [7], formylation [8], chloromethylation and dimethylaminomethylation [9] have been realized.



(1) *(2)*

X = I, Br, Cl, SCN, SAr, SCl, NO_2, CH_2Cl, $CH_2N(CH_3)_2$, COR, CHO

Because of the trifunctional character of these tris-acetylacetonates an additional factor must be considered.

Mono-, di-, and tri-substituted chelates are formed if the concentration of electrophilic reagent is limited. Furthermore, the entering substituent may deactivate the remaining unsubstituted rings in a molecule so that higher degrees of substitution become progressively more difficult.

Halogenation of these acetylacetonates is best effected by the use of *N*-halogenosuccinimides (NCS, NBS, NIS) in hot chloroform [4, 5]. Excess reagent affords high

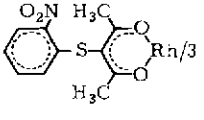
yields of trihalogenated chelates isolated as very stable 1:1-chloroform solvates. Chlorine, bromine, and iodine monochloride also halogenate these complexes; however, yields are lower because of acid degradation by released HX [5]. The rate of reaction decreases in the order NBS > NCS > NIS, and cobalt ≈ chromium > rhodium. Limited amounts of halogenating agents lead to mixtures of incompletely substituted chelates *(3)* which can be separated by chromatography [10]. Further elaboration of these chelates leads to a wide variety of mixed-ring complexes.

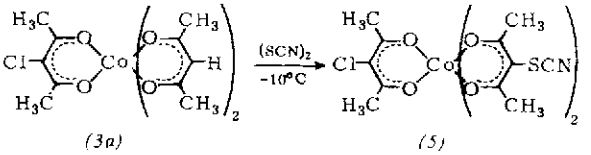
(1) $\xrightarrow{(H_2CCO)_2NX}$ 
(3)

X = I, Br, Cl m = 1, n = 2
M = Rh, Co, Cr m = 2, n = 1
m = 3, n = 0

Sulfur can be introduced into the chelate ring by a number of electrophilic reagents [6,7]. Arylsulfenyl chlorides, sulfur dichloride, and thiocyanogen all react rapidly under mild conditions to form tri-substituted acetylacetonates. The arylsulfide chelates, *e.g. (4)*, form amazingly stable crystalline 1:1-benzene solvates. Mixtures of partially substituted thiocyanato chelates have proven intractable in our hands. Unsymmetrically substituted complexes containing sulfur *(5)* are better prepared from partially halogenated acetylacetonates *(3a)* [11].



(4)



(3a) *(5)*

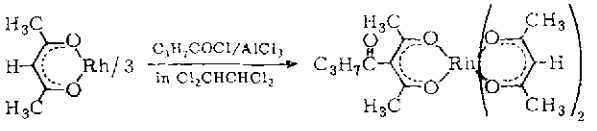
Nitration of metal acetylacetonates cannot be carried out with the usual mixtures of nitric and sulfuric acids since the complexes are rapidly decomposed by strong acid. High yields of nitrated chelates have been obtained using solutions of copper(II) nitrate trihydrate in acetic anhydride [8,12]. If sufficient reagent is employed, trinitrated chelates are formed. On the other hand, lesser amounts of copper(II) nitrate lead to mixtures of partially nitrated acetylacetonate complexes *(6)* which can be separated by chromatography [13].

Friedel-Crafts acylation of these acetylacetonates can be accomplished under carfully controlled conditions [7]. Because of intramolecular deactivation by acyl substituents, each substitution becomes progressively slower, and mixtures result.

(1) $\xrightarrow[(CH_3CO)_2O;\ 10-20^\circ C]{Cu(NO_3)_2\cdot 3\,H_2O/}$ 
(6)

M = Rh, Cr, Co m = 1, n = 2
m = 2, n = 1
m = 3, n = 0

Chromium acetylacetonate yields mono-, di-, and triacetylated chelates when acetic anhydride and BF_3-OEt_2 is the reagent. Under these conditions cobalt acetylacetonate also gives mixtures, but very little triacetylated chelate is formed. The rhodium complex does not react, but acetyl chloride and aluminum chloride effect mono- and diacetylation of this complex (conditions which degrade the cobalt and chromium chelates). Thus a reactivity series chromium>cobalt>rhodium is established. Larger acyl groups can be introduced into rhodium acetylacetonate but these reactions are slower and lead largely to mono-substituted products *(7)*. Ketene or acyl chloride/pyridine mixtures fail to react with any of these chelates, but reaction does occur with the free ligands.



(7)

Formylation of these metal acetylacetonates was carried out using the Vilsmeir reaction [8]. Treatment of the chelates with $POCl_3$ in dimethylformamide afforded mixtures of mono- and di-formyl chelates. Trisubstitution is possible with cobalt acetylacetonate under forcing conditions. Further elaboration of the remaining unsubstituted rings has led to a series of unsymmetrically substituted chelate-aldehydes, *e.g. (8)* [10,11].

(1) M = Co $\xrightarrow[3.\ (SCN)_2]{1.\ POCl_3/DMF\ \ 2.\ NaOAc/H_2O}$ 
(8)

Chloromethylation of metal acetylacetonates is possible, but the reaction is complex [9]. Treatment of unsubstituted tris-acetylacetonates with chloromethyl methyl ether and BF_3-$O(C_2H_5)_2$ yields cross-linked methylene-bridged chelate-polymers. A similar result is obtained

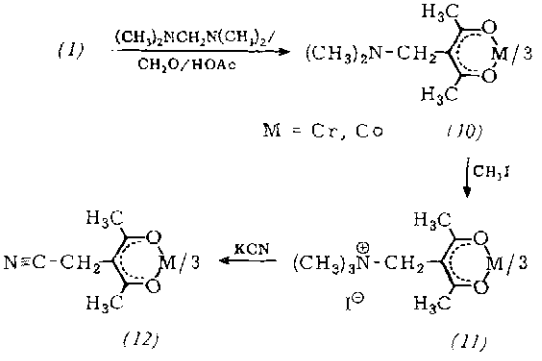
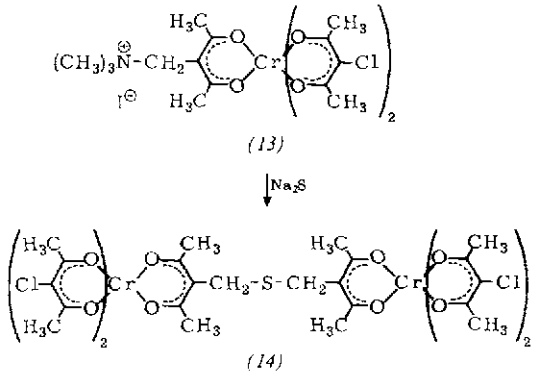
using acetic acid and paraformaldehyde [14]. Starting from dichlororhodium acetylacetonate an intermediate chloromethyl derivative is formed and can be trapped but not isolated. Alcoholysis affords the expected unsymmetrical ether *(9)*.

A modified Mannich reaction introduces dimethylaminomethyl groups into the acetylacetonate ring [9]. Tris-dimethylaminomethyl chelates *(10)* are unusually difficult to purify because of their high solublity in many solvents and because of their hygroscopic nature.

Quaternization of the uncoordinated tertiary amines *(10)* was effected by reaction with methyl iodide; however, the reaction is incomplete and yields intractable mixtures. Further treatment of the impure quaternary ammonium iodides *(11)* with potassium cyanide affords cyanomethylene complexes *(12)* which can be purified by chromatography.

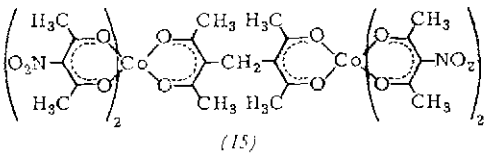


The problems arising on dealing with the polyfunctional reactive chelates *(10)*, *(11)*, and *(12)* can be simplified by using a dichlorinated acetylacetonate complex (one unsubstituted ring). However, some of the chlorine atoms were displaced by the Mannich reagent [9]. Again the amine was quaternized and the quaternary salt *(13)* was then treated with a series of nucleophiles, *e.g.* to yield a sulfur-bridged chelate *(14)*.



Attempted Friedel-Crafts alkylation of these metal acetylacetonates has been unsuccessful [14]. However, paraformaldehyde in glacial acetic acid attacks these chelates to produce methylene-bridged complexes. The dinitrocobalt acetylacetonate complex reacts to form the dimer *(15)*. The mononitro chromium- and cobalt chelates yield soluble polymers but the average molecular weights are not high [14].

[14] *J. P. Collman* and *R. H. Barker*, unpublished results.

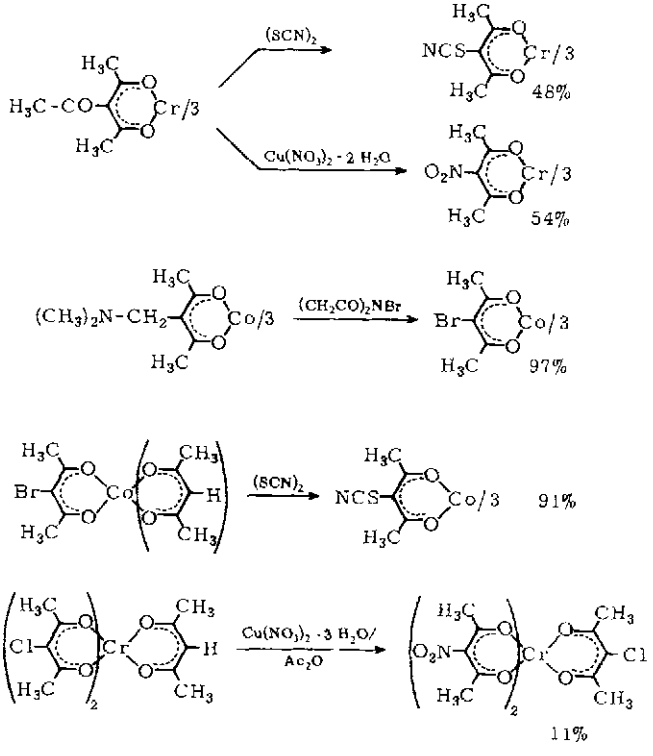


One aspect of the mechanism of these substitution reactions has been examined more closely: The unsymmetric tris-acetylacetonates were partially resolved by chromatography on a column (5 m long) of lactose hydrate, and the partially resolved complexes were then substituted with various electrophilic reagents [15]. Since the products were all optically active, it was presumed that substitution is not accompanied by ring opening.

An interesting sidelight on this work was the discovery of the racemization of cobalt acetylacetonate dnring crystallization [15,16]. This strange phenomenon, apparently the result of a preferential formation of racemic crystals, is being investigated at present.

III. Cleavage of Substituents from Acetylacetonate Rings under Electrophilic Conditions

We have observed a number of instances in which groups other than hydrogen are displaced from the chelate ring under apparently electrophilic conditions. A detailed investigation of this reaction revealed a pronounced selectivity of leaving groups, of electrophilic reagents, and of the metal in the chelate ring [11]. Typical examples of this type of reaction are outlined in Scheme 1.



Scheme 1. Typical examples of electrophilic displacement reactions with acetylacetonate chelates.

[15] *J. P. Collman, R. P. Blair, R. L. Marshall*, and *A. L. Slade*, Inorg. Chem. *2*, 576 (1963).

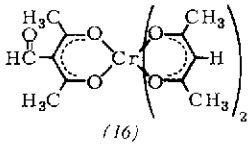
[16] *J. P. Collman, R. P. Blair, A. L. Slade*, and *R. L. Marshall*, Chem. and Ind. *1962*, 141.

The selectivity of substituents as leaving groups seems to parallel their stability as carbonium or halonium ions: $(CH_3)_2NCH_2 > CH_3CO > HCO > R$, and $I > Br > Cl$.

IV. Reactions of Functional Groups on Chelate Rings

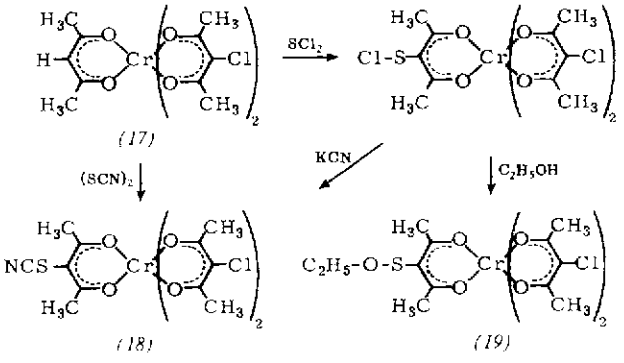
Substituent groups on these metal acetylacetonates sometimes exhibit unusual chemical properties. The high electron-density at the central carbon atom of the chelate ring and the steric shielding of this position by the flanking methyl groups are thought to be responsible for these abnormal properties.

Halogen atoms on chelate rings are unusually resistant to nucleophilic displacements [5]. They can, however, be displaced by electrophiles as described in Section III. All attempts to prepare Grignard or lithium reagents from halogenated chelates have failed. The starting materials were usually recovered unchanged. As illustrated below, the chelate rings are stable to Grignard reagents. An aldehyde group on the chelate ring is surprisingly inert. All attempts to prepare oxime, hydrazone and semicarbazone derivatives failed. The most amazing illustration of this low reactivity is the failure of the chromium-aldehyde chelate *(16)* to react with the methyl Grignard-reagent [17]. The starting material was recovered unchanged. The carbonyl groups in acetyl and ethoxycarbonyl-substituted chelates are similarly inert.



(16)

Sulfide groups on acetylacetonate rings are not oxidized by 30 % hydrogen peroxide [7]. Sulfenyl chloride groups behave quite normally, reacting with cyanide ion to form thiocyanate derivatives, *e.g. (18)* [6, 7], and with alcohols to form sulfenate esters *(19)* [7]. Reactive groups such as this are best studied using monofunctional chelates such as *(17)*.

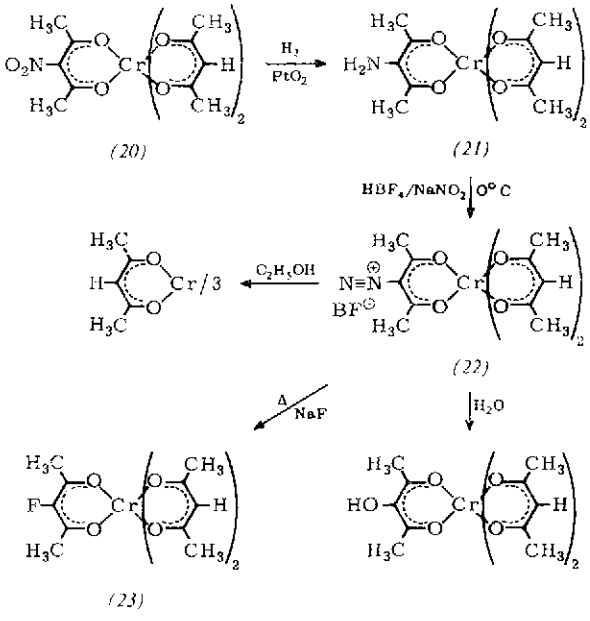


(17) *(18)* *(19)*

[17] *J. P. Collman* and *C. T. Sears Jr.*, unpublished results.

Derivatives with a 3-hydroxymethyl group have not been isolated. This group probably undergoes solvolysis to a carbonium ion with great ease as indicated by the formation of chelate polymers by reaction of metal acetylacetonates and formaldehyde under acidic conditions.

Nitrated acetylacetonates are resistant to chemical reduction of the nitro group. Catalytic hydrogenation of mononitro chromium acetylacetonate *(20)* affords the amino chelate *(21)* in 65 % yield. The amino chelate is easily autoxidized and should be handled under nitrogen. The amino group behaves like a typical aromatic amine in that it is reversibly protonated (pK_a 5.24 in 1:1 alcohol-water) and can be acetylated. The *N*-acetyl derivative resists hydrolysis. The amino chelate *(21)* is readily converted into a stable diazonium fluoroborate *(22)* which is very reactive. It undergoes reduction with ethanol, coupling with β-naphthol, and solvolysis in water or methanol [13]. The diazonium fluoroborate undergoes a Schiemann reaction with difficulty upon heating with dry, powdered sodium fluoride.



(20) *(21)* *(22)* *(23)*

V. Chemistry of Chelates Related to the Acetylacetonates

Acetylacetonates of other metals can also be substituted by some of the electrophilic reagents mentioned above. However, these complexes are usually more easily degraded by acids. Tris-acetylacetonates of aluminum(III), europium(III) and iron(III) have been brominated and, in the first case, nitrated [18]. Bis-acetylacetonates of copper(II) and palladium(II) [19] have been brominated. *Bailar* has studied reactions of bis-(2,4-pentanediono)-beryllium(II) in some detail [20, 21].

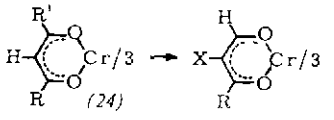
[18] *J. P. Collman* and *M. P. Cooke*, unpublished results.

[19] *J. P. Collman* and *C. Twine*, unpublished results.

[20] *R. M. Klein* and *J. C. Bailar Jr.*, Inorg. Chem. *2*, 1187 (1963).

[21] *R. M. Kelin* and *J. C. Bailar Jr.*, Inorg. Chem. *2*, 1190 (1963).

The malonaldehyde complex, tris-(1,3-propandialato)-chromium(III) *(25)* can be considered as the parent of the 1,3-dicarbonyl chelate systems [22]. So far only the chromium complex of this ligand has been prepared. Cobalt(III) and rhodium(III) cations are reduced by malonaldehyde salts. The malonaldehyde chelate has been brominated, thiocyanogenated, and nitrated. Attempted formylation or acetylation degrades this complex. Of the related formylacetone chromium chelate *(25b)* *cis*- and *trans*-isomers have been prepared. The formylacetone complex also undergoes electrophilic substitutions, but *(25)* and *(25b)* react more slowly and are less stable towards acidic reagents than chromium acetylacetonate. There is no tendency for the aldehydic protons to undergo substitution. It is probable that the methyl groups in acetylacetonate rings sterically retard but electronically enhance substitution reactions and simultaneously shield the oxygen donor-atoms from attack by the electrophiles.

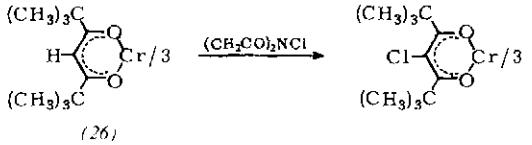


(24)

(25a): R = R' = H X = Br, SCN, NO_2

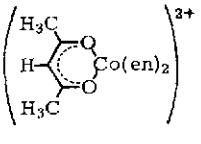
(25b): R = CH_3; R' = H R = H, CH_3(cis + trans)

The effect of massive steric hindrance on chelate reactions is illustrated by the chromium chelate of dipivaloylmethane *(26)*. This chelate undergoes reactions only very slowly under forcing conditions [17]. Chlorination and nitration have been observed. Chelates of dibenzoylmethane can be halogenated but the reactions are slower than with the acetylacetonates [5].



(26)

Electronegatively substituted complexes such as chromium chelates of trifluoro- and hexafluoro-acetylacetone are inert to electrophilic substitution, *e.g.* with *N*-bromosuccinimide [17]. The remarkably volatile hexfluoro complexes can be passed through vapor-phase chromatography columns. Another electron-deficient acetylacetonate ring, the bisethylenediamine-(2,4-pentanediono)cobalt(III) cation *(27)*, resists electrophilic substitutions such as bromination but is slowly deuterated



(27)

[22] *J. P. Collman* and *E. T. Kittleman*, J. Amer. chem. Soc. *83*, 3529 (1961).

on the central carbon atom of the chelate ring in strongly acidic D_2O solution [23].

In a few instances complexes have been prepared in which one of the oxygen atoms in the acetylacetonate rings is replaced by another hetero-atom. Chromium complexes of α,β-unsaturated β-amino ketones *(28)* have been prepared and halogenated [24]. More recently, chelates of monothioacetylacetone have been prepared, but little is known about their reactions [25,26]. In contrast to the acetylacetonate, the nickel thiochelate *(29)* is monomeric and diamagnetic. Chelates of tropolone *(30)* undergo electrophilic substitution of the tropolone ring but complex mixtures result [27].

(29) *(30)*

VI. Physical Properties of Metal Acetylacetonates

1. Chromatography

The tris-acetylacetonates are moderately soluble in organic solvents and thus amenable to purification by chromatography. Thin-layer chromatography is particulary useful in establishing the homogeneity of such substances. Mixtures of unsymmetrically substituted chelates so far can be separated by such techniques only. Mixtures of rhodium complexes are much more difficult to separate than the analogous cobalt or chromium chelates, and in some instances the former are intractable. Melting points are useful in characterizing substituted acetylacetonates but comparative thin-layer chromatography using known standards is more reliable.

2. Infrared Spectra

Infrared spectra are useful in characterizing acetylacetonate complexes. Unsubstituted acetylacetonates exhibit strong bands at 1570 and 1520 cm^{-1}. Substituted acetylacetonates show only weak absorption at 1520 cm^{-1} and the band at 1570 cm^{-1} is shifted to ca. 1550

[23] *J. P. Collman* and *D. A. Buckingham*, unpublished results.

[27] *J. P. Collman* and *M. Yamada*, unpublished results.

cm^{-1}. Thus substitution of the acetylacctonate ring causes the strong doublet in the 1500–1600 cm^{-1} region to apparently merge into one peak [28]. The disappearance of a weak C··H in-plane bending vibration at 1190 cm^{-1} also provides a measure of ring substitution. Infrared vibrations of the different chelate rings in unsymmetrically substituted acetylacetonates are nearly independent of one another. Spectra of analogous complexes of the three metals Rh, Cr, and Co are nearly identical.

Characteristic group-frequencies of substituents on these chelates are useful in determining the type of substitution product. However, certain of these group frequencies are unusual. For example, the uncoordinated aldehyde group in formyl chelates shows a carbonyl stretching frequency at 1670 cm^{-1}.

3. Electronic Spectra

The ultraviolet spectra of these chelates are often complex in that one to four bands or shoulders are found. The principal absorption bands in the ultraviolet region occur at about 256 mμ for cobalt, at about 317 mμ for rhodium, and at 331 mμ for chromium acetylacetonate. These bands probably arise from $\pi \rightarrow \pi^*$-transitions of the ligand [29].

Comparison of ultraviolet spectra of substituted acetylacetonates can be used to indicate the extent of steric inhibition of resonance of the substituents with the chelate ring [22]. Halogen, sulfur, and formyl are the only substituents which produce bathochromic shifts of the intense absorption bands, but in the spectra of formylacetone and malonaldehyde chelates, nitro groups also cause bathochromic shifts. The ultraviolet data for substituted chromium chelates shown in Table 1 indicate

Table 1. Ultraviolet absorption maxima and extinction coefficients of chromium chelates of type *(24)* in chloroform.

R	R'	X	First λ_{max} [mμ]	ε_{max}
CH_3	CH_3	H	335	15800

H	H	NO_2	282	31000

that the two methyl groups in acetylacetonates prevent coplanarity of acetyl and nitro groups with the chelate ring and thus sterically inhibit resonance with the ring. When one or both of these methyl groups are replaced by hydrogen, as is the case with the formylacetone and malonaldehyde complexes, the nitro group becomes conjugated with the ring. This argument becomes important when intramolecular electronic effects are examined.

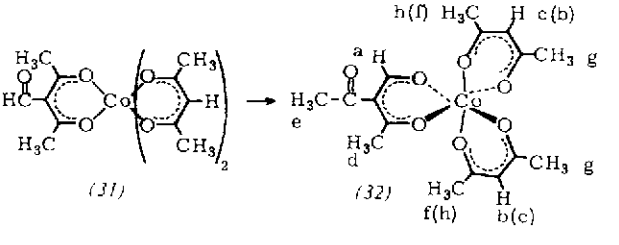
[29] *J. P. Fackler Jr.*, *F. A. Cotton*, and *D. W. Barnum*, Inorg. Chem. *2*, 97 (1963).

4. Nuclear Magnetic Resonance Spectra

Proton magnetic resonance spectra of rhodium and cobalt chelates are very useful for structure determination. These spectra are simplified by the absence of coupling. The unsubstituted acetylacetonates exhibit two proton signals in the ratio of 1:6. Trisubstitution results in disappearance of the lower-field peak and in a shift of the methyl signal to lower fields. The chemical shift of the methyl signals in trisubstituted acetylacetonates depends on the substituent, the metal, and the solvent [11].

Because of the peculiar and rigid geometry of tris-acetylacetonates, the NMR spectra of unsymmetrically substituted chelates exhibit an unexpected chemical shift [10]. The methyl groups on the uniquely substituted ring β of the disubstituted tris-acetylacetonate *(5)* are equivalent and give one sharp signal. However the two methyl groups on each of the two equally substituted rings α are not equivalent and give rise to two sharp signals. Examination of a model of *(5)* reveals that each methyl group on the β-ring is over the symmetry axis of one of the α-rings. On the other hand, chelates in which all three rings are differently substituted exhibit six methyl signals [11]. Over forty examples of this phenomenon have been observed in our laboratory [11].

A striking illustration of the use of NMR spectra for the determination of chelate structures is provided by the coordination isomer *(32)* of cobalt monoformyl acetylacetonate *(31)*. This isomer was formed by intermolecular ligand interchange on heating the formyl chelate in boiling toluene [30]. Models of this complex show 9 different kinds of protons. The NMR spectrum of *(32)* exhibits 8 peaks assignable to hydrogens a (2.08 τ), b (4.37 τ), c (4.40 τ), d (7.32 τ), e (7.65 τ), f (7.77 τ), g (7.79 τ), and h (7.80 τ), in the intensity ratios 1:1:1:3:3:3:6:3. Peak g corresponds to two slightly different methyl groups the signals of which are not resolved. There is no spincoupling. The chemical shifts were unequivocally assigned using model compounds.



(31) *(32)*

VII. Intramolecular Interannular Electronic Effects

1. Chemical Evidence

In a previous section several qualitative observations were reported which could be accounted for by intramolecular interannular electronic deactivation by sub-

[30] *J. P. Collman* and *J. Y. Sun*, unpublished results.

stituent groups. For example, formylation of each of the three chelate rings in the same molecule becomes successively more difficult (using the same concentrations of formylating reagent per number of unreacted rings) [11]. Similar effects were observed during acetylation.

Another example is the failure of the dinitro chromium chelate to undergo a Mannich reaction whereas the dichloro chromium chelate reacts readily under the same conditions. On competitive bromination of equivalent amounts of dichloro and dinitro chromium acetylacetonates, the dichloro chelate is exclusively brominated, but both complexes react if sufficient *N*-bromosuccinimide is present. These competitive brominations were followed by thin-layer chromatography using the pure starting materials and reaction products as internal standards.

2. Physical Evidence

A study of the NMR spectra of partially substituted cobalt and rhodium acetylacetonates showed that the chemical shift of the signal for the central hydrogen atom on the unsubstituted chelate ring depends on the substituents on the other rings. By using the unsubstituted cobalt or rhodium acetylacetonate as an internal standard and repeatedly measuring the separation between the chelate-ring hydrogen-signals on an expanded scale, this difference in chemical shift between unsubstituted and partially substituted chelates was measured with great precision. These shifts were then correlated by the Hammett equation (cf. Fig. 1 for the Co(III)-complexes) [11]. However, correlations were possible only when the NMR shifts were plotted versus σ_{para} constants for groups capable of resonance interaction (chloro, bromo, formyl) and versus σ_I constants for groups not capable of resonance (acetyl and nitro). As illustrated in Figure 1, the data are additive, even for complexes containing two different substituents. These correlations are considered to be "satisfactory to excellent" fits by the correlation coefficient criterion defined by *Jaffe* [31].

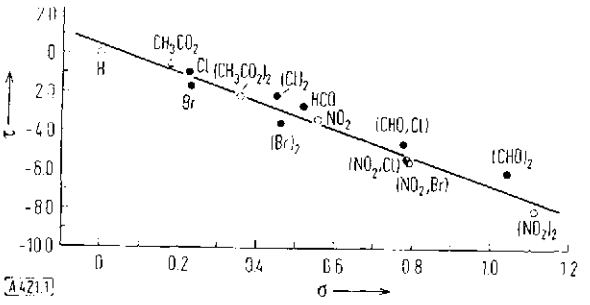


Figure 1. Correlation of proton-NMR shifts and σ constants for partially substituted cobalt(III) acetylacetonates in benzene [cobalt(III) acetylacetonate as internal standard].

○ = σ_I values

Abscissa: σ-Values

Succesful application of Hammett linear free-energy functions to partially substituted metal acetylacetonates implies that significant interannular intramolecular electronic effects are transmitted through the central metal ion. The slope of the regression line for partially substituted rhodium acetylacetonates is *ca.* 10 % less than that of the line for the corresponding cobalt series. This implies that intramolecular interannular electronic effects are transmitted to a lesser extent through the rhodium ion. This result is opposite to that expected from atomic polarization.

Recent Results of Configurational Research [*]

BY DR. W. SCHLENK, JR.

AMMONIAKLABORATORIUM, BADISCHE ANILIN- UND SODAFABRIK AG., LUDWIGSHAFEN/RHEIN (GERMANY)

The problems involved in configurational research differ from those of many of the currently important fields of general chemistry. Consequently, many chemists are less familiar with recent developements in this field than, for example, with those of the generally important modern ideas on valence and reaction mechanisms. A survey of new methods and recent results of configurational studies is attempted in this review, some unpublished experimental findings by the author being included. However, no attempt has been made to present an exhaustive review, nor to give a detailed treatment of individual problems which may interest the specialist.

I. Absolute Configuration

The foundations of configurational stereochemistry rest on three great achievements of the last century: the discovery of the optical activity of organic compounds by *Jean Baptiste Biot* (1815), the discovery of optical isomerism by *Louis Pasteur* (1860), and the hypothesis of the tetrahedral arrangement of the substituents on saturated carbon atoms by *Jacobus Henricus van't Hoff* (1874).

The most important development in recent years in configurational chemistry, and at the same time one of the most important ever in this field, was the discovery by *Bijvoet*, *Peerdeman*, and *van Bommel* in 1951 of a physical method for determining absolute configurations [1]. This method is based on X-ray structural analysis with rays of anomalous phase difference, and led first to the elucidation of the absolute configuration of tartaric acid [2] and thereby to the establishment of the absolute configurations of all compounds which had been related to tartaric acid. Somewhat later it led to the elucidation of the configuration of isoleucine [3], and hence to a knowledge of the absolute configurations of all the other naturally occurring α-amino acids.

Long before *Bijvoet* made his discovery, theorists had tried to relate the rotation of plane-polarized light to absolute configuration and to predict the absolute configuration of an optically active compound from the direction of its rotation [4]. Similarly, detailed theories had been developed for the mechanisms of substitution at asymmetric carbon atoms, the practical value of which culminated in the empirical rule that Walden inversion always occurs when a bimolecular mechanism can be detected by kinetic measurements in the case of nucleophilic substitution (S_N2 rule) [5]. The main significance of the determination of absolute configuration (*Bijvoet*'s method is the only one yet known) lies in the fact that it is the basis and a criterion for the verification and development of any theory of optical activity [6], and of the Walden inversion [5].

Knowledge of absolute configurations is still only of hypothetical importance for the as yet unsolved problem of the origin of optical activity in living organisms. So far, only hypothetical answers to this question exist, and these fall into two categories. On the one hand, it is contended that the optically active substances in nature could have arisen by chance, although chemists have never succeeded in preparing an optically active substance from an inactive substance by a chemical reaction without the aid of a directing agent. On the other hand it is thought that a directional influence was present at the original production of the first optically active substance. A noteworthy attempt to show that the original production of optically active substances may have been due to the recently discovered non-validity of the law of parity for elementary particles has been abandoned for the present [7].

Important reference compounds whose absolute configurations have been elucidated with the aid of X-rays of anomalous phase-difference are, in addition to tartaric acid and isoleucine, bulbocapnine [8] (an atropisomeric biphenyl derivative), dihydro-β-erythroidine [9] (which has an asymmetric spiro-carbon atom), the tri-isopropylenediaminecobalt(III) ion [10], strychnine [11], and α-naphthylphenylmethylsilane [8] (a compound with an asymmetric silicon atom).

The compounds investigated by *Bijvoet* included sodium chlorate and sodium bromate which, like quartz, are optically active only in the crystalline state. Here the activity is not due to the shape of the molecule, but to the asymmetric arrangement of the structural units in the crystal lattice. The two salts are isomorphous. They form a continuous series of mixed crystals. The arrangement of the ions in the lattice is in principle identical, the only difference being that the dimensions of the elementary cell of the bromate lattice are slightly greater than those of the chlorate lattice.

It is therefore extremely surprising to find that the sign of the optical rotation of the bromate crystals [12] is opposite to that of the chlorate crystals [13] of the same configuration. No reliable explanation for this phenomenon has yet been given. *Bijvoet* himself put forward a tentative explanation, but despite careful checking, has so far found no experimental evidence to support it.

Since the two salts have almost identical lattices and form a continuous series of mixed crystals, it was to be expected that seeding of a saturated or slightly supersaturated solution of sodium chlorate with sodium bromate crystals would lead to the growth of sodium chlorate crystals with the same configuration as the seed crystals, and vice versa. In fact, numerous seeding experiments showed, without exception, that sodium bromate crystals always stimulate the growth of sodium chlorate crystals, with a sign of rotation opposite to that of the seed crystals. Similarly, sodium chlorate crystals only cause the growth of bromate crystals with the opposite sign of rotation. Despite initial difficulties, it also became possible to study the rotation of mixed crystals of sodium chlorate and sodium bromate. The results again confirmed that sodium chlorate and bromate of the same configuration rotate polarized light in opposite directions [14].

II. Nomenclature

At a time when only relative configurations could be determined, it was sufficient to use a few reference compounds to characterize configurations. Hydroxy compounds were related to optically active glyceraldehyde, and amino acids to optically active serine; one of the two possible steric formulae of these reference substances was assigned by convention to one of the enantiomorphs, and the prefixes D or L were appended to the names to indicate structural similarity of the compounds in question to D-(+)-glyceraldehyde or L-(−)-serine. Configurational relationships in steroid chemistry were denoted by the symbols α and β [15].

A new method of denoting configurations proposed by *Cahn*, *Ingold*, and *Prelog* [16] does not require a reference compound but expresses directly the absolute configuration of the active form in question. The two stereoisomeric forms are denoted by letters *R* and *S* according to the following principles: Sequence rules are used to establish an order of precedence for each of the four different substituents on the carbon atom. The asymmetric carbon atom is then oriented so that the substituent with the lowest precedence is turned away from the observer, and the other three lie on a circle perpendicular to the line of vision. If the order of precedence of the three ligands decreases in a clockwise direction, the asymmetric carbon atom is given the designation "*R*" (Lat. rectus = right), while if the class decreases in an anticlockwise direction, the designation "*S*" (Lat. sinister = left) is given.

The nomenclature of *Cahn*, *Ingold*, and *Prelog* also applies to atropisomerism and to the optical isomerism of allenes and spiro-compounds. One of the great advantages of this method of designating configurations is that it is absolutely unambiguous; consequently, there should be no future danger of confusion or disagreement as to notation.

III. Correlative Determinations of Configuration

In order that *Bijvoet*'s method may be applied, the asymmetric compound should contain an atom the eigen-frequency of which is similar to that of the X-rays used. This is not the case, for example, with hydrocarbons or alcohols. However, it is sufficient that the X-ray method has given and will continue to give the absolute configurations of reference compounds, A large number of asymmetric compounds can be related to these standards by the methods of "relative configurational analysis", thus yielding "absolute" configurations by an indirect route. A survey of recent methods and results in relative configurational analysis is given in the following Sections.

1. The Quasi-Racemate Method

This method originated in an investigation by *Timmermanns* in 1929 [17] and was developed mainly by *Fredga* [18]. It involves determination of the configuration of

[12] *G. Beurskens-Kerssen, J. Kroon, H. J. Endeman, J. van Laar,* and *J. M. Bijvoet,* in *G. N. Ramachandran:* Crystallography and Crystal Perfection, Proc. Sympos. Madras (January 14–18th, 1963). Academic Press, London-New York 1963, p. 225ff.

[13] *G. N. Ramachandran* and *K. S. Chandrasekaran,* Acta crystallogr. *10*, 671 (1957).

[14] Unpublished work by the author. Seeding methods of this type had already been attempted unsuccessfully over a century ago by *H. Marbach* who discovered the optical activity of the chlorate and bromate. The direction of rotation of bromate crystals, whose growth had been induced by chlorate, could not be determined owing to "lamellar polarization"; in the case of chlorate seeded with bromate, *Marbach* claimed that the directions of rotation of the "nucleus and the crust", *i.e.* of the seed crystal and of the crystals grown on it, were sometimes similar and sometimes opposite [Poggendorfs Ann. Physik Chemie, 4th Series, *H. Marbach*, *9*, 459 (1856)].

[16] The first postulate of this new mode of designating configurations was published shortly before the determination of the absolute configuration of tartaric acid, and was based on D-(+)-glyceraldehyde as standard: *R. S. Cahn* and *C. K. Ingold,* J. chem. Soc. (London) 1951, 612. The second published version was based on absolute configurations: *R. S. Cahn, C. K. Ingold,* and *V. Prelog,* Experientia *12*, 81 (1956). Most recent publications: *R. S. Cahn,* J. chem. Educat. *41*, 116 (1964); *R. S. Cahn, C. K. Ingold,* and *V. Prelog,* Angew. Chem. and Angew. Chem. internat. Edit., in the press.

[17] *J. Timmermans,* Recueil Trav. chim. Pays-Bas *48*, 890 (1929).

[18] Summary: *A. Fredga,* Tetrahedron *8*, 126 (1960).

an optically active compound, *e.g.* (−)-bromosuccinic acid, by comparison with another active compound of similar molecular structure, *e.g.* (+)-chlorosuccinic acid, the configuration of which is known or is taken as a standard. A melting point *vs.* composition diagram of mixtures of the standard and the test sample is plotted. If the sample has the same configuration as the standard, the phase diagram is that of a solid solution; if the configurations are opposite, the compounds form a "quasi-racemate". Like a true racemate [*e.g.* a 50:50 mixture of (+)- and (−)-chlorosuccinic acids], a quasi-racemate [*e.g.* (+)-chlorosuccinic acid and (−)-bromosuccinic acid] is reflected in the phase diagram by a special branch of the curve with a maximum at 50 mole-%. Even when an optically active substance forms a solid solution with one of the enantiomorphs of the standard and an ordinary eutectic instead of a quasi-racemate with the other, an assignement can still be made [19]. The compound under investigation has the same configuration as its partner in the solid solution.

The results achieved by this method include the correlation of methyl-, chloro-, mercapto-, and hydroxysuccinic acids [18]. Very recent results regard the configurations of an asymmetric silicon compound [20] and an asymmetric germanium compound [21].

Conclusions based on the quasi-racemate method are extremely reliable; no case is known so far in which a result has subsequently heen shown to be wrong. However, the method is subject to certain restrictions. The substances must be crystalline and a reference substance of known configuration with a molecular structure similar to that of the test substance must be available. Occasionally, although rarely, the optically active substance forms quasi-racemates with both enantiomorphs of the reference compound [21a]; no conclusion can then be drawn.

2. Asymmetric Synthesis

The term "asymmetric syntheses" is used here [22] to denote syntheses in which a non-asymmetric starting material, *e.g.* an α-ketocarboxylic acid, is temporarily linked to an optically active compound of known configuration, *e.g.* is esterified with an optically active secondary alcohol. The keto ester is reduced or condensed with a Grignard reagent to yield a hydroxy ester, thus creating a second optically active carbon atom in the molecule. One of the two diastereoisomeric compounds to be expected is formed in excess, and hence subsequent saponification does not lead to a racemic but to a partially optically active β-hydroxycarboxylic acid. The configuration favored at the second asymmetric center depends on the configuration of the carbinol carbon atom of the original alcohol, and can be predicted by *Prelog*'s method [23] from the space requirements of the three substituents on this carbon atom. Conversely, if the configuration of the preferentially formed β-hydroxycarboxylic acid is known, the configuration of the active alcohol can be found [24]. This method led to the establishment of the configurations of, for example, atrolactic acid [25] and various triterpene alcohols [24] (α-amyrin, eupbol, dihydrolanosterol).

3. The Cotton Effect (Rotatory Dispersion and Circular Dichroism)

Within the past eight years, optical rotatory dispersion in the ultraviolet has rapidly become an important aid to configurational research. The principle is not new, as can be seen from the fundamental work of *Werner Kuhn* [26]. However, it has only become widely used since ultraviolet polarimeters became available. Credit for this is due to the pioneering work on steroids by *Djerassi* and his co-workers, which stimulated industrial production of the first ultraviolet polarimeter in the U.S.A.

The theory and results of the method can be only briefly indicated here [27,28]. Many optically active organic compounds, including saturated hydrocarbons, alcohols, fatty acids, and amino acids, show a monotonic increase in optical rotation, which obeys the simple Drude equation, on passing from longwave to shortwave light regions (down to ca. 260 mμ) [29].

However, if an asymmetric molecule contains a chromophore in the direct vicinity of the asymmetric center, a phenomenon known as the Cotton effect can be observed in the dispersion curve: the specific rotation passes through a maximum on the steep side of the absorption band, this is followed by a sudden drop, and finally reversal of the sign of rotation occurs. A change in sign with decreasing wavelength from (+) to (−) is termed a positive Cotton effect; if the change is from (−) to (+), the Cotton effect is termed negative.

It has been found that structurally similar compounds of the same configuration give Cotton effects of the same sign. This is the vital point in this "analogy" method for configurational analyses, which has proved useful especially in the investigation of steroid ketones and halogenated cyclic ketones.

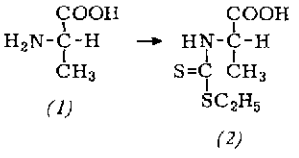
Kuhn* on optical activity, and a list of the first 76 publications (up to the end of 1962) by *C. Djerassi et al.* on optical rotatory dispersion.

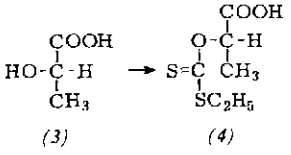
[29] A plot of $[\alpha]_D$ against λ gives the so-called optical rotatory dispersion curve.

It is significant that this method can also be applied to compounds which do not show the Cotton effect within experimentally accessible wavelength regions, provided that a chromophore can be introduced into the molecule close to its asymmetric center. For example, ethyldithiocarbamidocarboxylic acids *(2)*, which are readily prepared from amino acids *(1)* by successive treatment with carbon disulfide and ethyl bromide [30], have an absorption maximum at 345 mμ; as expected, they also exhibit a Cotton effect at this wavelength, the signs being the same for similar configurations [31].



(1) *(2)*

Optically active hydroxycarboxylic acids *(3)* were investigated by rotatory dispersion in the form of their xanthates *(4)* which are structurally very similar to the ethyldithiocarbamidocarboxylic acids *(2)* [32]. Once again, the rule was confirmed: identical configurations give Cotton effects of the same sign.



(3) *(4)*

Besides rotatory dispersion, the related phenomenon of circular dichroism is gaining practical importance in connection with problems of configurational analysis. Here, too, the basic principles were laid in the thirties [33], but an instrument for the measurement of circular dichroism [34] became commercially available only in 1961. Consequently, organic chemists are only now beginning to measure and make use of circular dichroism, the principle and the importance of which were discussed recently in detail [35]. It is especially important that circular dichroism can frequently be measured at wavelengths at which polarimetry can no longer be used, owing to high molar extinction.

4. Inclusion Method

The principle of the inclusion method [36] is the following: The hexagonal urea lattice can be regarded as a system of parallel channels. It can occur in two stereoisomeric forms: in one of these the urea molecules, representing the walls of the channels, are arranged in the form of a right-handed helix; in the other they form a left-handed helix. If crystallization is left to chance, right-handed and left-handed crystals are formed together. However, methods have been found by which one of the two helical lattices can be grown exclusively.

If such configuratively homogeneous crystals, *e.g.* right-handed crystals, are allowed to grow in the solution of a racemate, *e.g.* ethyl α-methylbutyrate, whose molecules can form urea adducts, it is found that one of the two enantiomorphs, *e.g.* ethyl (+)-α-methylbutyrate, is preferentially taken up by the right-handed crystals, since by virtue of its shape, the dextrorotatory molecule fits better into the urea helix than the enantiomorphic levorotatory molecule does. If the preferential inclusion of (+)-α-methylbutyrate is determined by its shape, it could be expected, that of other racemates with structures similar to that of ethyl α-methylbutyrate the enantiomorph with a similar shape, *i.e.* with the same configuration as (+)-α-methylbutyrate, would be taken up preferentially, too. This is in fact the case. Table 1 shows the results of such relative configuration studies for four sets of sterically related compounds.

Table 1. Configurative relationships of steric series found by the urea inclusion method (see text).

Carboxylic acid	Urea inclusion lattice
(+)-2-Methyl fatty acids (−)-2-Chloro fatty acids (−)-2-Amino fatty acids (−)-2-Mercapto fatty acids	Enantiomeric form A [a]
(−)/(−)-3-Methyl fatty acids (+)/(−)-3-Chloro fatty acids (+)-3-Mercapto fatty acids	Enantiomeric form A
(+)-Aspartic acid (−)-Malic acid (−)-Thiomalic acid (−)-Chlorosuccinic acid (−)-Methylsuccinic acid	Enantiomeric form A
(+)-Glutamic acid (−)-2-Hydroxyglutaric acid (−)-2-Chloroglutaric acid (+)-2-Methylglutaric acid	Enantiomeric form A

[a] As the absolute configuration of the lattice is not yet known, the enantiomeric forms are distinguished as "form A" and "form B".

The enantiomorphs bracketed together are taken up preferentially by the same helical lattice; these enantiomorphs should, therefore, have the same configuration. The (+)/(−) signs shown together for the 3-methyl and 3-chloro fatty acids are a result of the reversal of sign of configuration in this series: for a given configuration, the lower members of the series are dextrorotatory, while the higher members are laevorotatory. The results obtained with this method agree with the now generally accepted scheme of configurational relationships developed from the results of many methods during the last thirty years.

Like all methods based on analogy – (with the exception of X-ray, chemical, and mathematical methods, all methods of configuration analysis are based on analogy) – the inclusion method must be used with care. Detailed investigations have shown that the configuration of a molecule is not always the

only factor governing the preferential uptake of one or the other enantiomorph by the urea lattice. For example, introduction of an ether oxygen or sulfur atom into a carbon chain of a molecule can cause reversal of its configurative relationship to the inclusion lattice, although the configuration of the derivative is the same as that of the parent molecule and the geometry of the latter is scarcely altered by the hetero-atom. Such anomalies are useful for studies of the forces existing between the urea lattice and included molecules, but present an obstacle to routine configurational analysis.

5. Investigation of the Configuration of Optically Inactive Asymmetric Substances — A Problem of Biogenetic Triglycerides

Normally enantiomorphs can be recognized by their ability to rotate the plane of polarized light, one enantiomorph causing rotation to the right, and the other an equal rotation to the left. However, enantiomorphs can also be optically inactive, *i.e.* inactive for our methods of measurement Only one example of this is known at present, *viz.* the triglycerides of the higher fatty acids, which form the major constituents of natural fats.

All triglycerides with three different acid components or two different acid components in the 1- and 3-positions have an asymmetric carbon atom in the 2-position of the glycerol residue. However, no triglyceride with measurable optical activity has ever been isolated from natural fats. Glycerides containing optically active acids (*e.g.* ricinoleic acid) are not considered here. All the aliphatic triglycerides prepared by syntheses which should have yielded optically active products were also inactive. *Fischer* and *Baer* suggested that the absence of measurable optical activity despite an asymmetric structure was characteristic of triglycerides which contain only aliphatic acid residues, and that, although natural triglycerides do not exhibit rotatory power, they are not necessarily racemates, but may be present in one of their two enantiomorphic forms [37].

The first of these assumptions is not generally valid. With regard to the second point, it has been shown that certain triglycerides occurring in natural fats do not in fact exhibit measurable activity in their enantiomorphic form. It has also been shown how such optically inactive enantiomorphs can be distinguished from their racemates, and how their absolute configurations can be determined. Finally, it has been shown for one triglyceride isolated from natural material that it is a racemate and not an enantiomorph [38].

In natural glycerides, the fatty acid residues in the 1- and 3-positions are generally very similar, *e.g.* palmitoyl and stearoyl residues, and hence the asymmetry of the molecule is very slight. This is true of all the aliphatic triglycerides made by *Fischer* and *Baer*, which exhibited no rotation.

We assumed that optical activity would be observed only if the fatty acid residues in the 1- and 3-positions differed considerably in size and shape, and so we prepared a number of such triglycerides (starting in each case with an optically active monoglyceride), *e.g.* 1-trimethylacetyl-2,3-di-n-valerin, 1-myristo-2,3-diisovalerin, 1-palmito-2,3-diisovalerin, 1-lauro-2,3-dibutyrin, 1-myristo-2,3-dibutyrin, and 1-lauro-2,3-dipalmitin. All these triglycerides were found to be optically active, the first five in the visible region, the last only in the ultraviolet (the C_{12} and C_{16} residues are relatively large and differ only slightly). On the other hand, glycerides with large acid residues, *e.g.* 1-palmito-2-oleo-3-stearin, which were prepared by the same method, exhibit no measurable activity, even in the ultraviolet. A method for distinguishing between enantiomorphs and racemates in such molecules was based on the piezoelectricity of the triglyceride crystals.

When crystals belonging to one of the 21 classes without centers of symmetry are subjected to mechanical pressure in a direction of structural polarity, they acquire an electrical charge. All crystals consisting of one enantiomorph of asymmetric molecules must exhibit the piezoelectric effect. Thus, if asymmetric triglycerides are enantiomorphs and not racemates, they should be piezoelectric. In crystals of racemates, on the other hand, the absence of a center of symmetry, and hence the existence of a piezoelectric effect, is not entirely ruled out, but is unlikely. We know of no case in which a true racemate crystallizes in an asymmetric lattice.

With the aid of the piezoelectrometer recently developed by *Bergmann* [39], it was indeed possible, to detect the piezoelectric effect in glycerides which, according to their synthesis, should have been enantiomorphs, even though they did not exhibit optical activity. Moreover, as expected, the effect was not observed with racemates (Table 2).

Table 2. Piezoelectric measurements of glyceride crystals.

Triglyceride	Piezoelectric effect
Act. 1-lauro-2,3-dipalmitin	present
Racem. 1-lauro-2,3-dipalmitin	absent
Act. 1-stearo-2,3-dipalmitin	present
Racem. 1-stearo-2,3-dipalmitin	absent
Act. 1-palmito-2-oleo-3-stearin	present
Racem. 1-palmito-2-oleo-3-stearin	absent
Act. 1-oleo-2-palmito-3-stearin	present
Racem. 1-oleo-2-palmito-3-stearin	absent

Another method for distinguishing between racemates and enantiomorphs in the absence of measurable optical activity was afforded by comparative X-ray investigations. For every triglyceride examined, it was found that the "active" glycerides, even those which do not exert a measurable rotation, always crystallize in a lattice different from that of the corresponding racemates.

As an example, the X-ray diagrams for the two enantiomorphs of 1-lauro-2,3-dipalmitin are shown in I and II of Figure 1; these diastereoisomeric forms are naturally identical on X-ray examination, and the X-ray diagram of the racemate shown in III can be distinguished from these at a glance.

Diagram IV confirms that I and II represent enantiomorphs and that III represents the racemate, since IV is derived from the crystals obtained from a solution

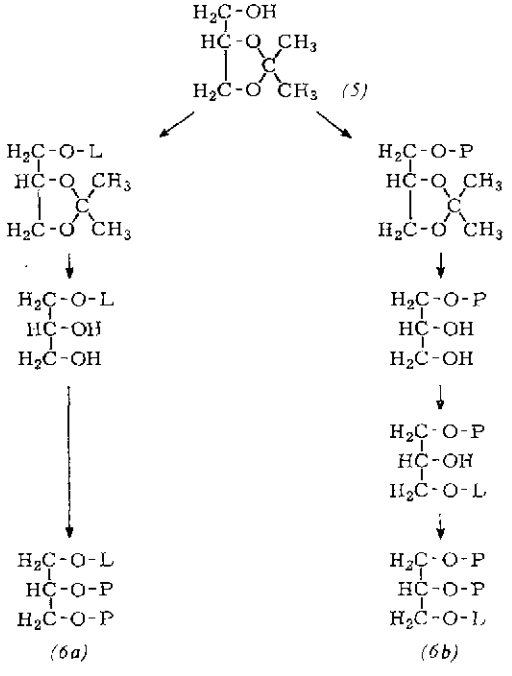
containing equal quantities of the two enantiomorphs. It is clear that the racemate IV, which was obtained by mixing the enantiomorphs, is identical with the racemate prepared directly.

The preparative routes leading to the two enantiomorphs of 1-lauro-2,3-dipalmitin, both starting with the same optically active raw material, *viz.* D-(+)-1,2,*O*-isopropylideneglycerol *(5)*, are shown in Scheme 1.



Scheme 1. Synthesis of the two enantiomorphs *(6a)* and *(6b)* of 1-lauro-2,3-dipalmitin (L and P denote the lauroyl and palmitoyl residues, respectively).

The configurations of the two compounds are predetermined by the synthesis and are represented in the projection formulae. Since the absolute configuration of the starting material is known, the two formulae also represent the absolute configurations of the two triglycerides, (−)-*(S)*-1-laurodipalmitin *(6a)* and (+)-*(R)*-1-laurodipalmitin *(6b)*.

On the basis of these results, the question, whether a sample of a given triglyceride of known constitution, *e.g.* 1-stearo-2,3-dipalmitin, is an enantiomorph or a racemate, can be resolved experimentally by synthesizing the respective racemate and one of the antipodes of the compound in question and comparing the X-ray diagrams of these three samples. If the X-ray diagram of the sample to be tested is the same as that of the racemate, the problem is solved. On the other hand, if the X-ray diagram of the sample to be tested is the same as that of the enantiomorph, it is an enantiomorph itself, though it cannot be said which one it is, since the X-ray diagrams of the enantiomorphs are identical.

Which enantiomorph is present, can then be resolved as follows: Some of the substance in question is mixed with an equal amount of the synthetic enantiomorph, and the X-ray diagram of the crystals of the mixed product is measured [40]. If the X-ray diagram remains unchanged, the enantiomorph in question is the same as that synthesized, the configuration of which is known. On the other hand, if the diagram is that of the racemate, the substance being examined is the enantiomer of the sample used for comparison.

Experience gained with synthetic materials make it possible to determine whether naturally occurring glycerides are optically active or racemic.

An investigation of this type was carried out on 1-palmito-2-oleo-3-stearin, a major constituent of cocoa bean oil. The glyceride was extracted from cocoa butter, from fermented unroasted cocoa beans, and from fresh germinable seeds of cocoa fruits harvested a few days before processing [41], since denaturation of the fat was possible during the technical preparation of the cocoa butter, or even during the fermentation of the beans.

The glyceride was isolated under mild conditions (extraction with ether, fractional crystallization from acetone) so that no racemization was to be anticipated on the basis of experience gained with synthetic glycerides exhibiting measurable optical activity. The glyceride obtained in all three cases was found to be a racemate.

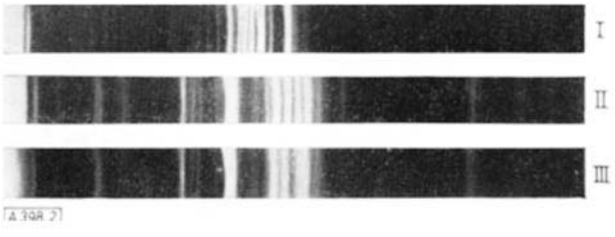


Fig. 2. X-ray diagram of 1-palmito-2-oleo-3-stearin (Cu-K_α radiation, Guinier). Active (I), racemic (III), and glyceride isolated from cocoa beans (II).

In the center of Figure 2, the X-ray diagram for the 1-palmito-2-oleo-3-stearin isolated from the natural fat is shown; above this is the diagram for the corresponding active glyceride, and below is that of the racemic form, both of which were synthesized. The central diagram is clearly identical with the lower one and not identical with the upper one. The racemic configuration of a biogenetic triglyceride was proved in this way for the first time. *Holman* [42] recently showed that the

[40] Mixed crystals of the sample and the synthetic enantiomorph are prepared by dissolving equal amounts of both substances in ether or in acetone/petrol ether and crystallizing them at a low temperature.

[41] We are indebted to Messrs. Schokinag, Mannheim (Germany), for procuring the fresh fruit from Nigeria.

[42] *R. T. Holman*, Fall Meeting of the American Oil Chemists' Society, J. Amer. Oil Chem. Soc. *40*, No. 9, 9 (1963). Prof. *Holman* kindly allowed the author to peruse the manuscript.

seed fat of two *Euphorbiaceae* [43] probably contains asymmetric triglycerides of measurable, and quite appreciable, optical activity ($[\alpha]_D \approx 19°$). The specific rotation is many times higher than that of the most unusual optically active triglycerides so far prepared by us. *Holman*'s view that the strong rotation may be due to the 2,4-hexadienecarboxylic acid which has been detected in the fat and which could act as a chromophore, is quite plausible. We prepared a triglyceride containing sorbic acid and found it to exhibit a relatively high specific rotation [44].

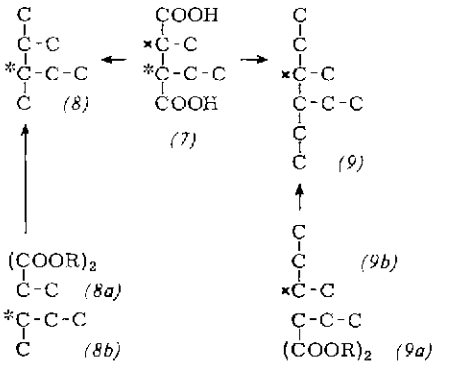
Naturally, these first findings on the configuration of fats cannot be generalized: neither the fact that the l palmito-2-oleo-3-stearin of cocoa butter is racemic, nor the supposition that glycerides of *Sapium sebiferum* and *Sebastiana lingustrina*, both of which contain 2,4-decadienoic acid, are produced in nature as enantiomorphs. If both findings are correct, then glycerides can be synthesized both stereospecifically and non-stereospecifically in nature.

6. Chemical Reactions

Despite the evolution of new physical methods of configurational analysis, the classical method of correlating asymmetric compounds by chemical reactions has certainly not become less valuable. With the exception of X-ray structural analysis, the chemical method has the advantage over all other methods in being invariably accurate. Its limitation is that the asymmetric carbon atom must not be affected by the reaction, *i.e.* none of the four bonds attached to it may be broken unless it is known with certainty whether or not Walden inversion occurs. A recent example of the remarkable achievements obtained using the chemical method is the success in relating the asymmetric tertiary carbon atom of (−)-dihydroshikimic acid to the asymmetric center of secondary hydroxy compounds, *e.g.* glucose, by oxidative ring cleavage of (−)-dihydroshikimic acid and reduction of the cleavage product to (+)-3-methylhexane [45].

This is the first case in which two steric series with different substituents on the asymmetric carbon atom have been related by chemical methods, without the asymmetric center itself being affected.

Of the many other examples the determination of the configuration of atropisomeric biphenyl derivatives using the chemical method [46] is noteworthy. The configuration of adjacent, non-equivalent, tertiary carbon atoms has also been determined by chemical methods [47]. The principle is shown in Scheme 2 for 2-ethyl-3-methylsuccinic acid.



Scheme 2. Chemical determination of the configuration of 2-ethyl-3-methylsuccinic acid.

The two asymmetric centers of the acid *(7)* are indicated by an asterisk and a cross. The acid is reduced to the hydrocarbon *(8)*, whereby the asymmetric center × is lost, while the asymmetric center * is retained. The hydrocarbon *(8)* can also be prepared in a sterically controlled reaction [48] from methylmalonate *(8a)* and optically active 2-bromobutane *(8b)*. This gives the configuration at the asymmetric center *.

The acid *(7)* can also be converted into the hydrocarbon *(9)* by chain extension followed by reduction. In this reaction the asymmetric center × remains intact, while center * disappears. The hydrocarbon *(9)* can be prepared in a sterically controlled reaction [48] from ethylmalonate *(9a)* and optically active 2-bromobutane *(9b)* by condensation, elimination of CO_2, chain extension, and reduction. This gives the configuration at the asymmetric center ×.

The configurations of both the active *threo*-form and the active *erythro*-form of the acid *(8)* were determined by this method. Any other 2,3-dialkylsuccinic acid can obviously be studied in exactly the same manner.

The method is simpler for 2,3-dialkylsuccinic acids with two identical alkyl residues, since the acid need be converted into only one hydrocarbon, and only this hydrocarbon need be synthesized from the malonic ester, because it contains two equivalent asymmetric carbon atoms.

The author is grateful to the management of Badische Anilin- und Sodafabrik for permitting him to devote time to work in this field. Thanks are also due to Dr. H. U. Lenné for the X-ray diagrams of the triglycerides, and to the author's colleagues of many year's standing, namely Josef Strubel, Herbert Esswein, Friedrich Schmidt, Günther Riewe, Edith Henn, and Johanna Wahl for the experimental results reported from the Ammonia Laboratory.

Reduction of Acid Bromides to Aldehydes by Irradiation in a Hydrogen Donor [1]

By Prof. Dr. Ulrich Schmidt

Chemisches Laboratorium
der Universität Freiburg/Brsg. (Germany)

The acyl-bromine bond of acylbromides is homolytically split by radiation from a low-pressure mercury lamp. Aldehydes are produced in the presence of a hydrogen donor since the dissociation energy of the acyl-hydrogen bond is similar to or larger than that of the carbon-hydrogen bond of the hydrogen donor. The hydrogen donor is dehydrogenated or hrominated.

Benzaldehyde in 80 % yield was produced on irradiation of henzoylbromide (0.2 mole) in 100 ml ether for 30 h with a low-pressure mercury lamp (10 watts at 254 mμ). The irradiation of acetyl bromide in cumene led to acetaldehyde (isolated as the dinitrophenylhydrazone in 25 % yield) and to 2,3-diphenyl-2,3-dimethylbutane, the dehydrogenation product of cumene. In the absence of light but in the presence of radical initiators no reaction took place. The irradiation of valeroyl bromide in cyclohexane produces small amounts of n-butyl bromide (identified by gas chromatography) which may be formed by decarbonylation of the valeroyl radical and subsequent combination with bromine.

8,8-Disubstituted Xanthines – a Novel Group of Purine Derivatives

By Dipl.-Chem. E. Bühler and Prof. Dr. W. Pfleiderer

Institut für Organische Chemie
der Technischen Hochschule Stuttgart (Germany)

Fading or decomposition of various 5-nitroso-4-alkylaminouracils during melting point determination [1–4] are due to imidazole ring formation. This has recently been confirmed by other authors [5].

We have found that the presence of a substituent on N-3 or activation of the methylene group adjacent to the nitrogen in the 4-alkylamino side-chain is necessary for the reaction to occur; the cyclization proceeds either on heating the substances neat or on refluxing them for a short time in high-boiling solvents such as n-butanol, dimethylformamide, or *N*-methylpterolidone.

Novel purine derivatives *(3)* and *(4)* are obtained in this way from 1,3-dimethyl-5-nitroso-4-aminouracils whose 4-amino group is substituted by a secondary carbon atom; examples are shown in the formulae.

[a] Determined by spectroscopy. – [b] Values in parentheses: shoulders.
[c] C = cation, N = neutral molecule. – [d] Measured in water.

The *o*-quinonoid structures of the 8,8-disubstituted theophylline derivatives *(3)* and *(4)* led us to expect that these compounds would behave like masked alloxan derivatives. The reaction of *(3)* with the dihydrochloride of *o*-phenylenediamine in aqueous solution did in fact proceed smoothly to give 1,3-dimethylalloxazine *(5)*.

Because of the *o*-quinonoid structures, the long-wave absorption bands in the ultraviolet spectra of *(3)* and *(4)* are bathochromically displaced relative to those of coffeine and isocoffeine. The weakly basic properties resulting from these structures are reflected in the extremely low basic pK_a values of *(3)* and *(4)*.

Organometallic Derivatives of Cobaloximes and of Vitamin B_{12}

By Priv.-Doz. Dr. G. N. Schrauzer and Dipl.-Chem. G. Kratel

Institut für Anorganische Chemie
der Universität München (Germany)

Bisdimethylglyoximatocobalt(III) compounds of the type $X-(CoD_2H_2)B$ [1], where X = halogen, B = base, and D = the dianion of dimethylglyoxime, are coordination analogues

of vitamin B_{12}. We designate these compounds as "cobaloximes" [2]. On reduction, *e.g.* with $NaBH_4$ in methanol, they give blue to blue-green derivatives ("cobaloximes$_s$") which correspond to vitamin B_{12s} and can be regarded as hydrolysed salts of the weak acid $H-Co(D_2H_2)B$. Cobaloxime$_s$ compounds react with alkylating agents to form alkylcobaloximes $R-(CoD_2H_2)B$, or with organometal halides R_nMX to yield crystalline complexes of composition $R_nM-(CoD_2H_2)B$, where M can be Si, Ge, Sn, Pb, As, Sb, or Bi (see Table). With a few exceptions, these compounds are stable towards oxygen, soluble in organic solvents such as CH_2Cl_2, $CHCl_3$, benzene, and acetone, and resistant to alkali. They are decomposed by strong acids.

Compound [3]	Behavior on heating [4]	Color
$(C_6H_5)_3Si-(Co)-Py$	decomp. at 135–145 °C	yellow-orange
$(C_6H_5)_3Ge-(Co)-Py$	decomp. at 172–180 °C	orange
$(C_6H_5)_3Sn-(Co)-Py$	decomp. at 194 °C	red-orange
$(C_6H_5)_3Pb-(Co)-Py$	decomp. at 190–195 °C	dark brown
$(C_6H_5)_3Pb-(Co)-P(n\text{-}C_4H_9)_3$	m.p. 167–168 °C	brown
$(C_6H_5)_3Sn-(Co)-P(n\text{-}C_4H_9)_3$	m.p. 145–147 °C	orange
$(C_6H_5)_3Sn-(Co)-Sb(CH_3)_3$	decomp. at 164–168 °C	red-orange
$(C_6H_5)_2Sb-(Co)-Py$	decomp. at 185–195 °C	brown
$(C_6H_5)_2Bi-(Co)-Py$	decomp. at 225–230 °C	brown
$(CH_3)_3Sn-(Co)-Py$	decomp. at 172–178 °C	red

The presence of M–Co bonds in these complexes follows from their elemental analyses and from degradation reactions, which proceed by oxidative (*e.g.* with bromine) or by reductive (*e.g.* with $NaBH_4$) cleavage of the M–Co bond. The thermal stability of the compounds containing elements of the fourth and fifth main groups of the periodic table generally rises with increasing atomic weight of the element. Hence, for example, it has so far not been possible to isolate a tritylcobaloxime. Triphenylsilylpyridinatocobaloxime is very sensitive to air and decomposes at a lower temperature than the corresponding derivatives of Ge, Sn, and Pb. The stability of the complexes also depends upon the base component B and upon the effective ligand strength of the nitrogen atoms of the dioxime. Vitamin B_{12s} behaves very similarly to cobaloximes. Solutions possibly containing trialkyltin- and dialkylarsine derivatives of vitamin B_{12} have been obtained on reaction of vitamin B_{12s} with trialkyltin- and dialkylarsenic chlorides. However, these solutions are extremely sensitive to air and the desired compounds could not yet be isolated.

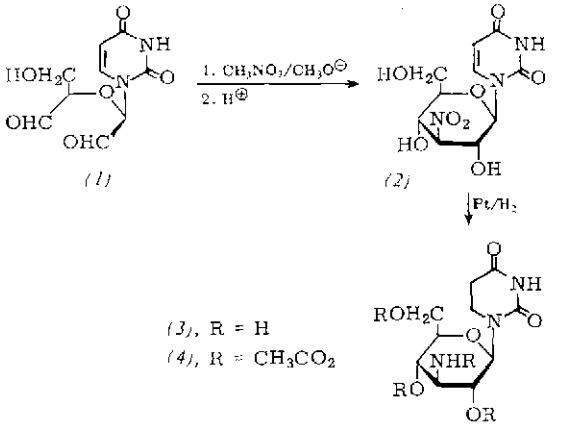
Cyclization of "Nucleoside Dialdehydes" with Nitromethane

By Doz. Dr. F. W. Lichtenthaler, cand. chem. H.P. Albrecht, and Gertrud Olfermann

Institut für Organische Chemie
der Technischen Hochschule Darmstadt (Germany)

Application of the cyclization of dialdehydes with nitromethane [1] to the "uridine dialdehyde" *(1)* obtained from uridine by oxidation with periodate [2] led to a mixture of 3-nitrohexosides when *(1)* was condensed with nitromethane plus sodium methoxide in methanol and the reaction mixture was subsequently neutralized with methanolic hydrochloric acid. Due to its low solubility in water, 3-(3′-deoxy-3′-nitro-β-D-glucopyranosyl)uracil *(2)* could be isolated from this mixture in 40 % yield as the monohydrate, m.p. 162–164 °C, $[\alpha]_D^{20} = +36°$ in water. On catalytic hydrogenation of *(2)* over platinum the nitro group and the 4,5-double bond in the uracil moiety are reduced; the product obtained is 3-(3′-amino-3′-deoxy-β-D-glucopyranosyl)-4,5-dihydrouracil *(3)*, which was characterized in the form of its hydrochloride (decomposes above 180 °C, $[\alpha]_D^{20} = +20°$ in water) and its tetra-acetate *(4)*, m.p. 281 to 283 °C (decomp.), $[\alpha]_D^{20} = -7°$ in chloroform.



Proof for the *gluco*-configuration of *(2)* and its derivatives was derived firstly from the NMR spectrum of *(4)*, which has three signals in an intensity ratio of 2:1:1 in the region around 8 τ indicating three equatorial acetoxy groups (7.93 τ and 7.95 τ) and one equatorial acetamido group (8.07 τ) [3], and secondly from the hydrolysis of *(3)* with acid, which leads to 3-amino-3-deoxyglucose, which was isolated as its penta-acetate [4].

Analogous cyclization with nitromethane of the "adenosine dialdehyde" which can be isolated in crystalline form after oxidation of adenosine with periodate [2] afforded a mixture of 3-nitrohexosyladenines. The main product can be isolated from this mixture in crystalline form (decomposes above 150 °C) in 40–45 % yield by chromatography on a column of silica gel with water saturated with n-butanol as eluant, or can be precipitated as its picrate, m.p. 237–240 °C, in 67.5 % yield. According to its NMR spectrum, this product is 9-(3′-nitro-3′-deoxyhexopyranosyl)adenine and has the *gluco*-configuration.

Analogous treatment of "inosine dialdehyde" yields a mixture of 3-nitrohexosylhypoxanthines. This mixture contains one major product, which can be isolated in pure crystalline form [m.p. 194–196 °C (decomp.)] in 20 % yield (based on the inosine) by column chromatography on silica gel. Catalytic hydrogenation and subsequent acetylation of the mixture gives rise to a 9-(tri-*O*-acetyl-3′-acetamido-3′-deoxyhexopyranosyl)hypoxanthine, m.p. 265–268 °C, whose NMR spectrum indicates it to have the *talo*-configuration.

Mass-Spectrometric Investigation of Rhenium Trichloride

By Dipl.-Chem. K. Rinke and Prof. Dr. H. Schäfer

Anorganisch-Chemisches Institut
der Universität Münster (Germany)

In the compound Re_3Cl_9 and in the anions $(Re_3Cl_{12})^{3-}$, $(Re_3Cl_{11})^{2-}$, and $(Re_3Cl_{10})^{-}$, Re_3-groups with particularly short Re–Re distances are present as the main structural elements in the solid state and in solution [1]. In the crystal lattice of rhenium trichloride, the chlorine atoms are so arranged that Re_3Cl_9 units result. We evaporated rhenium trichloride in the mass spectrometer in order to see whether the Re_3Cl_9 group remains intact in the vapor phase [2].

Rhenium trichloride was prepared from its elements [3]. The crystals obtained had the empirical formula $ReCl_{2.92}$ and gave the familiar X-ray diffraction diagram of $ReCl_3$ [4].

The measurements were carried out in a 60° sector field mass spectrometer [a CH 4 model from Messrs. Atlas MAT, Bremen (Germany)]. The substance was evaporated out of a graphite crucible at about 280 °C. The ion-accelerating voltage was 2000 volts up to a mass number of 700, and 1000 volts up to a mass number of 1400. The ionization was effected by bombardment with electrons with an energy of 70 eV, and the spectrum was recorded over a secondary electron multiplier. The ions detected were identified by assignment of mass numbers and by comparison of the calculated and experimental isotope distributions [5].

Ion	Relative abundance [a]	Ion	Relative abundance [a]	Ion	Relative abundance [a]
Re^+	6	Re_2^+	1	Re_3^+	0
$ReCl^+$	4	Re_2Cl^+	2	Re_3Cl^+	1
$ReCl_2^+$	6	$Re_2Cl_2^+$	3	$Re_3Cl_2^+$	1
$ReCl_3^+$	12	$Re_2Cl_3^+$	10	$Re_3Cl_3^+$	2
$ReCl_4^+$	1	$Re_2Cl_4^+$	9	$Re_3Cl_4^+$	2
		$Re_2Cl_5^+$	31	$Re_3Cl_5^+$	4
		$Re_2Cl_6^+$	23	$Re_3Cl_6^+$	3
				$Re_3Cl_7^+$	3
				$Re_3Cl_8^+$	19
				$Re_3Cl_9^+$	100

[a] Based on $Re_3Cl_9^+ = 100$ with allowance for the isotope distribution, but without correction for the (differing) yields of secondary electrons.

The table shows that it is mainly Re_3Cl_9 molecules that are present in the vapor. The Re_3 configuration is therefore very stable.

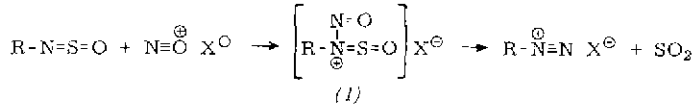
Synthesis of Diazonium Salts from Sulfinyl Imides and Nitrosyl Salts

By Dr. K. Bott

Institut für Organische Chemie
der Universität München (Germany) [1]

Nitrosyl perchlorate or nitrosyl hexachloroantimonate reacts with aromatic sulfinyl imides in ethylene dichloride at −10 to 0 °C to form the corresponding diazonium salts and sulfur dioxide. The salt *(1)* is assumed to be an intermediate but cannot be isolated.



(1)

X = ClO_4, $SbCl_6$

The yields of arenediazonium hexachloroantimonates are 93 % for R = *p*-nitrophenyl, 94 % for R = *m*-nitrophenyl, and 99 % for R = *p*-chlorophenyl. The elemental analyses of the products and comparison of their infrared spectra with those of authentic samples proved the purity of the salts obtained. The diazonium perchlorates are highly explosive and were not isolated, but were coupled in methanolic solution with β-naphthol to give azo dyes.

Synthesis of Tetrakis(trifluorophosphine)cobalt Hydride and Hexakis(trifluorophosphine)tungsten(0) [1]

By Priv.-Doz. Dr. Th. Kruck, Dipl.-Chem. W. Lang, and cand. chem. A. Engelmann

Anorganisch-Chemisches Laboratorium
der Technischen Hochschule München (Germany)

The reaction of FeI_2 or NiI_2 [2] with PF_3 under pressure in the presence of hydrogen-containing compounds hitherto invariably led to the formation of trifluorophosphinemetal(0) complexes. We now found that the reaction of cobalt iodide with PF_3 in a copper-lined autoclave in the presence of only traces of moisture affords tetrakis(trifluorophosphine)cobalt hydride. Quantitative formation of this hydride is achieved by treating a mixture of anhydrous CoI_2 and copper powder in a molar ratio of 1:2 with 250 atm of trifluorophosphine and a slight excess of hydrogen at 190–200 °C.

$$2\,CoI_2 + 4\,Cu + 8\,PF_3 + H_2 \rightarrow 2\,HCo(PF_3)_4 + 4\,CuI$$

$HCo(PF_3)_4$ is a mobile, highly volatile liquid, m.p. −51 °C, b.p. 80 °C/730 mm, with a pale green cast. The infrared spectrum of the diamagnetic compound contains P–F valence vibrations at 961 (w), 917 (vs), 907 (sh), and 867 (vs) cm^{-1} [3]; its proton magnetic resonance spectrum has a broad signal at 12.5 ppm (relative to tetramethylsilane). The hydride remains unaltered in air for some time. Above 250 °C it decomposes with separation of metallic cobalt. In aqueous solution it behaves as a strong monobasic acid. When treated with potassium amalgam, it gives a quantitative yield of colorless crystals of potassium tetrakis(trifluorophosphine)cobaltate(-1), which is relatively stable towards oxygen.

$$2\,HCo(PF_3)_4 + 2\,K/Hg \xrightarrow{\text{ether}} 2\,K[Co(PF_3)_4] + H_2$$

The $[Co(PF_3)_4]^{\ominus}$ anion can be precipitated from aqueous solutions with voluminous cations. During the conversion of $HCo(PF_3)_4$ into $[Co(PF_3)_4]^{\ominus}$, a bathochromic shift of the P–F valence vibrations is observed which is probably due to a reduction in the double-bond character of the P–F bond.

At PF_3-pressures above 200 atm and temperatures above 200 °C, tungsten hexachloride reacts with copper powder as halogen acceptor to form colorless crystals of hexakis(trifluorophosphine)tungsten(0).

$$WCl_6 + 6\ Cu + 6\ PF_3 \rightarrow W(PF_3)_6 + 6\ CuCl$$

$W(PF_3)_6$ completes the series of hexakis(trifluorophosphine) complexes of the chromium group [4]. The new compound, m.p. 214 °C, is completely analogous to the corresponding chromium and molybdenum complexes. It sublimes rapidly in a high vacuum at 40 °C and decomposes only above 320 °C with formation of a tungsten mirror. Its infrared spectrum has P–F valence vibrations at 914 (vs) and 852 (s) cm^{-1} [3] and indicates an octahedral structure of the diamagnetic complex.

On the Preparation of "Free Carbonic Acid"

By Priv.-Doz. Dr. G. Gattow and cand. chem. U. Gerwarth

Anorganisch-Chemisches Institut
der Universität Göttingen (Germany)

In continuation of our studies of chalkogenocarbonic acids [1], we attempted to isolate carbon monoxide bishydroxide $OC(OH)_2$, which in aqueous solution is carbonic acid H_2CO_3. A suspension of 5–10 g of finely pulverized anhydrous Na_2CO_3 in 100–150 ml of dimethyl ether was cooled to about −35 °C, and a solution of 5 N HCl in dimethyl ether (50–60 % of the equivalent amount) at −35 °C was added. The formal reaction

$$Na_2CO_3 + 2\ HCl \rightarrow OC(OH)_2 + 2\ NaCl$$

proceeds almost quantitatively without evolution of gas or alteration of the pressure, provided 1. traces of moisture are present, 2. the HCl solution is added only in minute portions (less than 2 ml) at prolonged intervals (one addition every 30 min), and 3. precautions are taken to ensure efficient removal of the heat of reaction.

The reaction mixture was filtered at about −35 °C, and the dimethyl ether was removed from the filtrate by evacuation at about −80 °C. The residue is a highly viscous solution from which a white crystalline substance precipitates out; this solid was purified from traces of dimethyl ether by evacuation at −80 °C for 2 weeks [2].

On warming, the solid melts at −47 °C to form a liquid which begins to decompose violently at or above 5 °C; the products of this decomposition are water, carbon dioxide, and dimethyl ether. The molar ratio $H_2O:CO_2$ was determined gravimetrically to be 1:1.02, and that of CO_2 to $(CH_3)_2O$ by infrared spectroscopy to be 1:1. It can be concluded from these results, together with the values obtained from measurements carried out on solutions and mixtures of HCl and/or CO_2 in water and/or dimethyl ether that the substance produced in the way described is the monoctherate of carbon monoxide bishydroxide $OC(OH)_2 \cdot O(CH_3)_2$. Interpretable infrared or NMR spectra could not be obtained. We were unable to repeat the preparation of $H_2CO_3 \cdot (C_2H_5)_2O$ already described [4].

The heat of fusion of $OC(OH)_2 \cdot O(CH_3)_2$ is 0.6 ± 0.2 kcal/mole. Its decomposition pressures were measured between −90 °C and +20 °C by isoteniscopy and used together with the known thermochemical data for water [5], carbon dioxide [5], and dimethyl ether [6] to calculate the enthalpy of formation of $OC(OH)_2 \cdot O(CH_3)_2$; at −70 °C, $\Delta H_f = -202 \pm 5$ kcal/mole. Using this value, the enthalpy of formation of solid $OC(OH)_2$ is calculated to be $\Delta H_f = -155 \pm 10$ kcal/mole. This value is in good agreement with the enthalpy of formation calculated by the increments method [7] and estimated from the thermochemical data for carbonates [5, 8] and trithiocarbonates [8, 9].

Stereoisomeric 2,5-Dimethyl-2,3:4,5-dioxidohexanes as the Main Products of the Pyrolysis of Polymeric 2,5-Dimethyl-2,4-hexadiene Peroxide

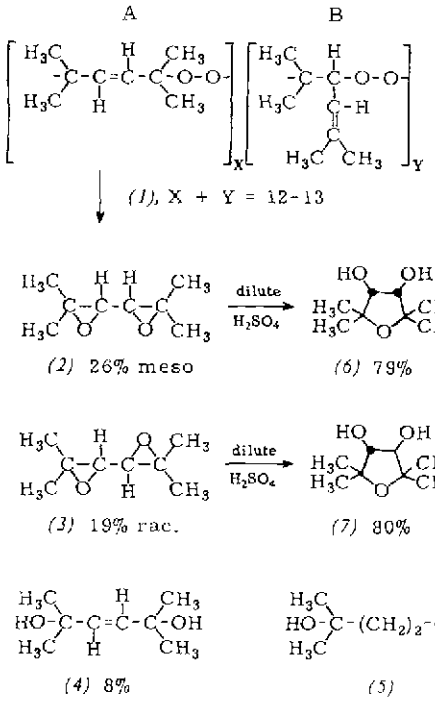
By Dr. G. Bernhardt and Prof. Dr. F. Korte

Shell Grundlagenforschung-Gesellschaft m.b.H.,
Schloß Birlinghoven/Siegkreis (Germany)

We have found that pyrolysis of polymeric 2,5-dimethyl-2,4-hexadiene peroxide *(1)* [1, 2] at 150 °C affords the two stereoisomeric dioxidohexanes *(2)* and *(3)* as the major products. In addition, small amounts of *trans*-2,5-dimethylhex-3-ene-2,5-diol *(4)*, acetone, and β-methylcrotonaldehyde are formed. To our knowledge, the occurrence of diepoxides during the thermal decomposition of polymeric peroxides has never been observed before. The formation of compounds *(2)*, *(3)*, and *(4)* requires that the –O–O– bridges in *(1)* be between the 1- and 4-positions.

The *meso*-diepoxide *(2)*, m.p. 60 °C, can be separated from the liquid racemate *(3)* [3], b.p. 62 °C/12 mm, by crystallization. Both isomers have characteristic infrared absorptions [4]: the epoxide bands of *(2)* are at 1237, 899, and 802 cm^{-1}; those of *(3)* are at 1241, 897, and 810 cm^{-1} [5]. Chemical proof of the structures of *(2)* and *(3)* is supplied by reduction with $LiAlH_4$ to give *(5)*, and by hydrolysis with acid to give the stereoisomeric tetrahydrofuran-2,3-diols; here *(2)* yields the *cis*-form *(6)*, and *(3)* leads to the *trans*-compound *(7)* [6].

Since only the *trans*-form *(4)* of hexene-1,4-diol, m.p. 93–94 °C, is formed, a *trans*-structure seems to be indicated for (A), which has recently been proved by an independent method [1].



The formation of acetone and β-methylcrotonaldehyde can be explained by cleavage of 1,2-peroxo-linked structures (B) [7]. Since the amount of acetone formed is 5%, it can be concluded that the ratio of $C_8H_{14}O_2$ units in *(1)* with a 1,4-peroxo structure (A) to units with a 1,2-peroxo link (B) is about 7:1.

The Influence of the Interfacial Energy of Organic Solvents on the Photochemical Dimerization of Thymidylyl-(3′→5′)-thymidine

By Prof. Dr. A Wacker and Dr. E. Lodemann

Institut für therapeutische Biochemie
der Universität Frankfurt/Main (Germany)

Irradiation of single-stranded deoxyribonucleic acid (DNA) with light of 254 mμ wavelength in aqueous solution produces more thymine dimer (T_D) than analogous irradiation of native double-stranded DNA [1]. However, when the irradiation is carried out in 96–100% ethylene glycol, single-stranded DNA gives less T_D than double-stranded DNA does in aqueous solution [2].

We have irradiated the model compound thymidylyl-(3′→5′)-thymidine (TpT) [3] in various solvents with light of 280 mμ wavelength and found that for equal radiation doses, the yield of T_D is greatest in water as solvent. When other solvents are used, the yields of T_D decrease in the series glycerol > formamide > ethylene glycol > n-butanol > methanol > ethanol > t-butanol.

Sinanoglu and *Abdulnur* [4] recently showed that the interfacial energy of the solvent is of decisive importance, in addition to van der Waals forces, for the formation of double-stranded DNA. If the percentage of T_D formed (determined by measuring the decrease in extinction at 267 mμ) in the various solvents is plotted against the change in free energy ΔF^0 of the TpT molecule [5] during its conversion from a form with mobile thymine bases into a form with stationary adjacent bases (which is suitable for dimerization) in each solvent, a linear relationship results [6].

Solvent	ΔF^0 [kcal/mole]	Formation of T_D [%]
t-Butanol	− 2.9	5
Ethanol	− 4.2	5.5
Methanol	− 4.5	6
n-Butanol	− 4.7	7.5
Ethylene glycol	−11.3	19
Formamide	−16.3	21
Glycerol	−16.5	33
Water	−22.3	35

This observation also explains the diminished thymine dimerization in single-stranded DNA with ethylene glycol as solvent [2]. Moreover, it can be concluded that the double helix of DNA is held together to a large extent by van der Waals forces (electrostatic and dispersion forces) and by solvation forces and only to a lesser extent by hydrogen bonds between the purine and pyrimidine bases [4].

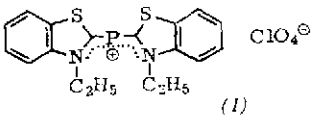
The Crystal Structure of a Phosphacyanine

By Dr. R. Allmann

Mineralogisches Institut
der Universität Marburg/Lahn (Germany)

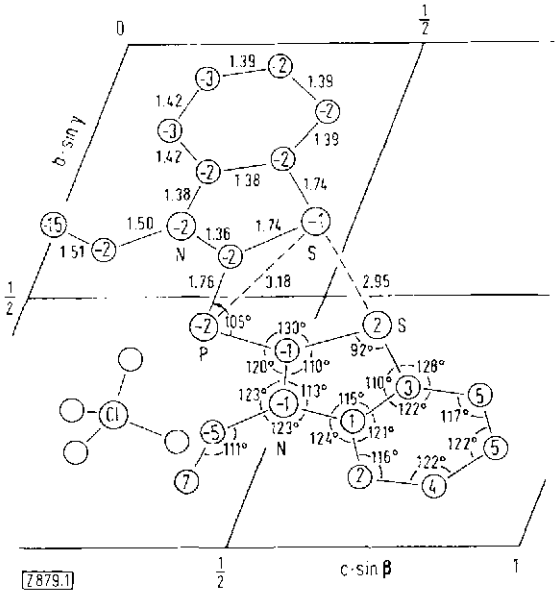
X-Ray analysis of *N*-ethyl-2-[(*N*-ethylbenzothiazolin-2-yl-idene)phosphino]benzothiazolium perchlorate *(1)*, which was recently prepared by *Dimroth* and *Hoffmann* [1], gave results that are in complete agreement with the constitution assumed.



(1)

The two C–P distances are 1.76 Å and are thus significantly shorter than those for C–P single bonds; the C–P–C angle is 105° (for comparison, $(H_3C)_3P$: 1.87 Å and 100° [2], and $(C_6H_5)_3P$: 1.83 Å and 103° [3]).

The planes of the two benzothiazole systems form an angle of only 3°. The two sulfur atoms are 2.95 Å apart and are thus relatively close together.



The figure shows the Y,Z-projection of a perchlorate anion and of a phosphacyanine cation with averaged interatomic distances in Å and averaged bond angles. The distortions out of the plane $2x + y + 2z = 2$ are given in tenths of an Ångstrom in the circles.

The phosphacyanine perchlorate *(1)* forms orange-red needles which belong to the space group $P\bar{1}$. Its lattice constants are [4]:

$a = 8.412 \pm 0.006$ Å	$\alpha = 107°17' \pm 15'$
$b = 11.673 \pm 0.009$ Å	$\beta = 66°41' \pm 15'$
$c = 11.713 \pm 0.011$ Å	$\gamma = 95°32' \pm 15'$

The density calculated for *(1)* from the volume of its unit cell (1008 Å³) and its molecular weight (456.9) is $D_x = 1.51$ g/cm³; the value found by experiment was $D_m = 1.50$ g/cm³. A total of 3634 intensities were estimated visually from Weissenberg photographs. The coordinates of the four heavier atoms (2 S, P, and Cl) were derived from a Patterson synthesis. The positions of the remaining light atoms (18 C, 2 N, and 4 O) were then obtained from a Fourier synthesis with the phases of the heavier atoms. After five cycles of refinement, the R factor (*i.e.* the mean difference between observed and calculated structural factors) was reduced to 16.4 %. From the error in the coordinates of about 0.01 Å, there results a mean error of about 0.02 Å for the interatomic distances and of 1–2° for the bond angles. Within the limits of these errors both halves of the molecule have identical structures.

New Heterocyclic Ring Systems Containing Boron and Nitrogen

By Prof. Dr. F. Umland and Dipl.-Chem. C. Schleyerbach

Anorganisch-Chemisches Institut der Universität Münster (Germany) and
Institut für Anorganische Chemie der Technischen Hochschule Hannover (Germany)

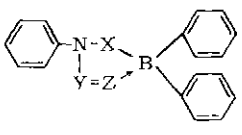
We have succeeded in preparing a series of five-membered heterocyclic ring systems containing a boron atom together with one to four nitrogen atoms in the ring:

1,1,3,4-tetraphenyl-1-bora-2,5-dioxa-3-aza-4-cyclopentene *(1)*, m.p. 153 °C (prepared from *N*-benzoyl-*N*-phenylhydroxylamine).

1,1,3-triphenyl-1-bora-2,5-dioxa-3,4-diaza-4-cyclopentene *(2)* [1], m.p. 102 °C (prepared from *N*-nitroso-*N*-phenylhydroxylamine).

1,1,3,5-tetraphenyl-1-bora-2-oxa-3,4,5-triaza-4-cyclopentene *(3)*, m.p. 139 °C with decomposition (prepared from 1,3-diphenyl-3-hydroxytriazene [2]).

1,1,3,5-tetraphenyl-1-bora-2,3,4,5-tetraaza-4-cyclopentene *(4)*, m.p. 130 °C with decomposition (prepared from 2,4-diphenyltetrazene [3]).



(1), X = O, Y = C_6H_5-C, Z = O
(2), X = O, Y = N, Z = O
(3), X = O, Y = N, Z = C_6H_5-N
(4), X = NH, Y = N, Z = C_6H_5-N

β-Aminoethyl diphenylborinate, Flavognost®, and equimolar amounts of the starting materials named above were dissolved separately in the smallest possible volume of ethanol or a 1:1 mixture of ethanol/benzene. The solutions were combined and a few drops of acetic acid were added to each mixture. To obtain *(1)* and *(2)*, the reaction mixtures were refluxed for 30 min, but short boiling sufficed to form *(3)* and *(4)*. The products crystallized out on cooling and were recrystallized from the same solvents, or *(3)* and *(4)* preferably from methanol. If Cupferron® (the ammonium salt of *N*-nitroso-*N*-phenylhydroxylamine) is used for preparing *(2)*, a little more than an equimolar amount of glacial acetic acid must be added.

All four compounds are yellow and stable in air. Their stability in solution decreases in the series *(1)* > *(2)* > *(3)* > *(4)*. The diphenylboryl group can be replaced by a heavy metal atom with aqueous solutions of heavy metal salts. However, only those metal ions participate in this reaction which form stable complexes with the chelate-forming compounds involved in *(1)*–*(4)*. Hence the new compounds, especially *(1)* and *(2)*, are selective analytical reagents.

Dichlorotrinitrosylvanadium $[V(NO)_3Cl_2]_n$

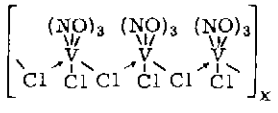
By Priv.-Doz. Dr. W. Beck, Dr. K. Lottes, and cand. chem. K. Schmidtner

Anorganisch-Chemisches Laboratorium der Technischen Hochschule München (Germany)

When nitric oxide is passed into a 0.2 M solution of VCl_4 in anhydrous CCl_4, dehalogenation of the vanadium occurs and dichlorotrinitrosylvanadium is obtained in almost quantitative yield.

$$VCl_4 + 5\ NO \rightarrow V(NO)_3Cl_2 + 2\ NOCl$$

The product is a light- to dark-brown solid depending on its grain size; it is sensitive to moisture and is practically insoluble in all the common organic solvents. In contrast to the nitrosyl chlorides of iron [1] and cobalt [2], the new compound cannot be sublimed and is therefore probably polymeric in nature. Its infrared spectrum in Nujol contains N–O absorptions at 1924 (s), 1761 (vs) cm^{-1} [3] plus two bands at 309 and 261 cm^{-1} which can be assigned to V–Cl stretching vibrations. Comparison of the infrared spectrum with those of other nitrosylmetal chlorides [3] showed that $[V(NO)_3Cl_2]_n$ has probably a polynuclear structure *(1)* with terminal and bridging chloro ligands. This structure contains sixfold coordinated vanadium with an inert-gas configuration



(1)

and has a trigonal bipyramidal arrangement of the NO groups; these features are in agreement with the fact that the compound is diamagnetic and gives only two N–O absorptions in the infrared.

Synthesis of Dichlorogallane $HGaCl_2$

By Priv.-Doz. Dr. H. Schmidbaur, Dipl.-Chem. W. Findeiss, and cand. chem. E. Gast

Institut für Anorganische Chemie
der Universität Marburg/Lahn (Germany)

Trimethylsilane reacts at −20 °C with equimolar amounts of gallium trichloride to form trimethylchlorosilane (99.5 % yield) and pure dichlorogallane.

$$(H_3C)_3SiH + GaCl_3 \rightarrow (H_3C)_3SiCl + HGaCl_2$$

When the chlorosilane is pumped off at −30 °C, a residue of $HGaCl_2$ is obtained in 95 % yield as colorless crystals which dissolve well and without decomposition at low temperatures in anhydrous solvents such as benzene, cyclohexane, or diethyl ether [1].

Cryoscopic determinations of the molecular weight revealed that $HGaCl_2$ like $GaCl_3$ is dimeric in benzene. It cannot be kept unlimited at room temperature without decomposition, but rapid decomposition with evolution of hydrogen begins only at its melting point of 29 °C [2]. Pyrolysis of the compound at 150 °C gives a quantitative yield of hydrogen and gallium chlorogallanate ("gallium dichloride" $GaCl_2$).

$$(HGaCl_2)_2 \rightarrow H_2 + Ga[GaCl_4]$$

The infrared spectrum of dichlorogallane has a somewhat broadened but very intense band at 2018 cm^{-1} which is due to the Ga–H valence vibration. This band is at much higher frequencies than that for $GaH_3{\cdot}N(CH_3)_3$ [3] (1852 cm^{-1}) and indicates the higher force constant of the Ga–H bond in dichlorogallane. The proton resonance spectrum of $HGaCl_2$ in benzene has no proton signal between −33 and +16 ppm (relative to tetramethylsilane), but this is understandable in view of the high spin and quadrupole moments of the gallium isotopes.

When trimethylamine is passed into a solution of $HGaCl_2$ in benzene, colorless crystals of an adduct $HGaCl_2{\cdot}N(CH_3)_3$ precipitate. This melts at 70 °C and is more stable than the starting material. Here the Ga–H valence vibration lies at 1986 cm^{-1}, and the PMR signal for the trimethylamino group is observed at 5.01 ppm (in benzene and relative to benzene as standard). Here, too, no H–Ga signal could be detected.

Received: December 15th, 1964 [Z 882/703 IE]
German version: Angew. Chem. 77, 170 (1965)

[1] Neither H_3CGaCl_2 nor $(H_3C)_2SiHCl$ could be detected by spectroscopy in the products; these compounds might have resulted from a reaction analogous to that of tetramethylsilane with gallium trichloride [cf. *H. Schmidbaur* and *W. Findeiss*, Angew. Chem. *76*, 752 (1964); Angew. Chem. internat. Edit. *3*, 696 (1964)].

[2] GaH_3 which is not stabilized by coordination decomposes far below room temperature [3].

Heterosiloxanes and t-Butoxy Compounds of Aluminum, Gallium, and Indium

By Priv.-Doz. Dr. H. Schmidbaur

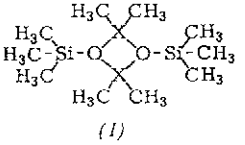
Institut für Anorganische Chemie
der Universität Marburg/Lahn (Germany)

We have succeeded in preparing organoheterosiloxanes with Ga–O–Si and In–O–Si structural units [1,2]. Trimethylgallium and trimethylindium etherates react fast even below room temperature with equimolar amounts of trimethylsilanol to form the desired gallosiloxane and indosiloxane, respectively, with liberation of methane.

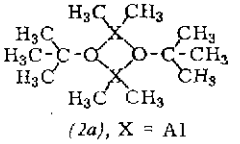
$$Me_3SiOH + Me_3X{\cdot}OEt_2 \rightarrow Et_2O + CH_4 + Me_3SiOXMe_2$$

(1a), X = Al [3]
(1b), X = Ga
Me = CH_3; Et = C_2H_5 *(1c)*, X = In

The yields are almost quantitative. The products *(1a)–(1c)* occur only as dimers, having the four-membered ring structure *(1)*, which probably has C_{2h} symmetry judging from infrared and NMR data [3]; compounds *(1b)* and *(1c)* are surprisingly stable toward oxidation and hydrolysis.



(1)



(2a), X = Al
(2b), X = Ga
(2c), X = In

When anhydrous t-butanol is used instead of trimethylsilanol, the corresponding t-butoxydimethylmetal compounds are formed. This type of reaction had already been described for other alcohol components [4,5]. It is remarkable that

	M.p. [°C]	B.p. [°C/mm]	NMR [6] δ_{CH_3Si}, C	NMR [6] δ_{CH_3X}
(1a)	45.5	35/1 [a]	−12.0	+49.0

Trimethylaluminum Trimethylphosphorus Oxide and Trimethylarsenic Trimethylgallium Oxide

By Dr. F. Schindler, Priv.-Doz. Dr. H. Schmidbaur, and cand. chem. G. Jonas

Institut für Anorganische Chemie
der Universität Marburg/Lahn (Germany)

Trimethylphosphine oxide reacts rapidly in benzene with trimethylaluminum etherate to form a 1:1 adduct with a P–O–Al bond.

$$(H_3C)_3PO + (H_3C)_3Al \cdot O(C_2H_5)_2 \rightarrow (C_2H_5)_2O + (H_3C)_3P{-}O{-}Al(CH_3)_3 \quad (1)$$

The homologous ethyl compounds *(2)–(4)* are also formed readily, and so is the analogous compound *(5)* with an As–O·Ga grouping obtained from trimethylarsenic oxide and trimethylgallium etherate.

$$(H_3C)_3AsO + (H_3C)_3Ga \cdot O(C_2H_5)_2 \rightarrow (C_2H_5)_2O + (H_3C)_3As{-}O{-}Ga(CH_3)_3 \quad (5)$$

The chemical and spectroscopic properties of *(1)–(5)* indicate them to be isosteric with the hexaalkyldisiloxanes $R_3Si{-}O{-}SiR_3$ *(6)* and hexaalkyldigermoxanes $R_3Ge{-}O{-}GeR_3$ *(7)*. All the new compounds are surprisingly stable to heat and exhibit no tendency to dissociate or to undergo intramolecular redox reactions up to about 150 °C. Cryoscopic and osmometric determinations of their molecular weights in benzene revealed that they are all monomeric. Because the polarity of the P–O–Al grouping is much stronger than that of Si–O–Si or Ge–O–Ge bridges, the melting and boiling points of the new oxides lie by more than 100 °C above those of the corresponding disiloxanes or digermoxanes. The solubilities of *(1)–(4)* in non-polar solvents other than benzene are also lower than those of *(6)* or *(7)*. However *(5)* is much more soluble in such solvents than *(1)–(4)*, but cannot be distilled without decomposition.

The number, multiplicity, and area ratios of the proton signals in the nuclear magnetic resonance spectra [1] of the new compounds were invariably in accordance with the theoretical expectations. The isosterism of the new oxides with *(6)* and *(7)* is particularly obvious on comparison of the coupling constants $J(^1H{-}^{13}C)$. For *(1)* and for *(5)*, the arithmetic mean $\bar{J}$ of the two coupling constants is almost exactly equal to the values found for the isosters: hexamethyldisiloxane: 118.0; hexamethyldigermoxane: 125.5 cps [2, 3].

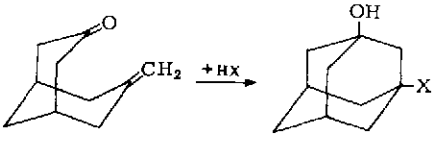
New Syntheses of the Adamantane Ring System

By Prof. Dr. H. Stetter, Dipl.-Chem. J. Gärtner, and Dr. P. Tacke

Institut für Organische Chemie
der Technischen Hochschule Aachen (Germany)

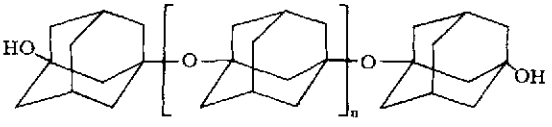
3-Methylenebicyclo[3,3,1]nonan-7-one *(1)* [1] readily undergoes cyclization in the presence of acids to give 1-hydroxyadamantane derivatives substituted at the 3-position.



(1) *(2)*, X = OH *(5)*, X = NH–Ac
(3), X = Cl *(6)*, X = NH_2
(4), X = OC_2H_5

1,3-Dihydroxyadamantane *(2)* is obtained in almost quantitative yield from *(1)* with dilute sulfuric acid. Treatment of *(1)* with hydrochloric acid produces 1-chloro-3-hydroxyadamantane *(3)*, m.p. 205.5 °C, while acids in ethanol lead to 1-ethoxy-3-hydroxyadamantane *(4)*, m.p. 77.5 °C. Acetonitrile reacts with *(1)* under the conditions of a Ritter reaction to give 1-acetamido-3-hydroxyadamantane *(5)*, m.p. 220 °C. The reaction of *(1)* with aqueous ammonia in a sealed tube at 130 °C yields 1-amino-3-hydroxyadamantane *(6)*, m.p. 267 °C.

The same principle can be applied to prepare polyethers *(7)* of adamantane by treating *(1)* with acids in inert solvents.

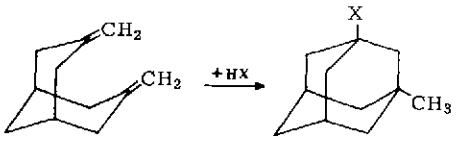


(7)

The same approach can be used to prepare adamantane derivatives from 3,7-dimethylenebicyclo[3,3,1]nonane *(8)*, m.p. 75 °C, which can be obtained from *(1)* in a Wittig reaction; ring closure of *(8)* with acids gives 1-methyladamantanes containing substituents at the 3-position.

Thus, 1-hydroxy-3-methyladamantane *(9)*, m.p. 131 °C, and 1-methyl-3-methoxyadamantane *(10)*, b.p. 99–100 °C/13 mm,

are readily obtained from *(8)* in water or methanol by acidic catalysis. Similarly, 1-acetamido-3-methyladamantane *(11)*, m.p. 112 °C, and 1-methyl-3-(*p*-methoxyphenyl)adamantane *(12)*, b.p. 145 °C/5 mm, are obtained with acids in acetonitrile and anisole, respectively.



(8) *(9)*, X = OH *(11)*, X = NH-Ac
(10), X = OCH_3 *(12)*, X = C_6H_4-OCH_3

It seems remarkable that the hydrocarbon *(8)* forms π-complexes with metal salts; the complex formed with CuCl, m.p. 196–198 °C, is unusually stable.

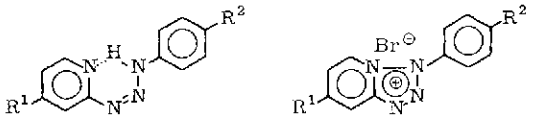
Synthesis of 3-Phenyltetrazolopyridinium Bromides and 3-Phenyl-6-bromotetrazolo[5,1-a]-isoquinolinium Bromide

By Dr. A. Messmer and Dipl.-Chem. A. Gelléri

Central Research Institute of Chemistry, Hungarian Academy of Sciences, Budapest (Hungary)

We have found that 1-(α-pyridyl)-3-aryltriazene *(1a)*, R^1 = R^2 = H [1], is dehydrogenated in ethyl acetate at room temperature by 2,4,4,6-tetrabromocyclohexadien-1-one [2] to give 3-phenyltetrazolopyridinium bromide *(2a)*, R^1 = R^2 = H, m.p. 278–280 °C, in 87% yield; the $BF_4^\ominus$ salt of *(2a)* melts at 246 °C.



(1) *(2)*

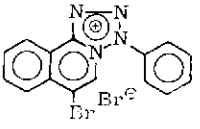
Further derivatives *(1b)–(1f)* of compound *(1)* were prepared by azo coupling of α-aminopyridines and the corresponding benzenediazonium salts.

(1b), R^1 = H, R^2 = OCH_3, m.p. 188–189 °C, 48%
(1c), R^1 = H, R^2 = Cl, m.p. 195–196 °C, 42%
(1d), R^1 = H, R^2 = Br, m.p. 206–207 °C, 39%
(1e), R^1 = CH_3, R^2 = H, m.p. 209–210 °C, 29%
(1f), R^1 = CH_3, R^2 = Br, m.p. 206–208 °C, 46%

All these compounds contain an intramolecular hydrogen bond (characteristic broadening of the infrared bands between 2600 and 3100 cm^{-1}) and on cyclodehydrogenation yield the following derivatives *(2b)–(2f)*:

(2b), m.p. > 360 °C, 89%; $BF_4^\ominus$ salt: m.p. 179 °C
(2c), m.p. 306–307 °C, 85%; $BF_4^\ominus$ salt: m.p. 227 °C
(2d), m.p. 310–311 °C, 84%; $BF_4^\ominus$ salt: m.p. 249 °C
(2e), m.p. > 360 °C, 78%; $BF_4^\ominus$ salt: m.p. 198 °C
(2f), m.p. > 360 °C, 92%; $BF_4^\ominus$ salt: m.p. 228 °C

The compounds *(2)* are all soluble in water. If 5–10% solutions of *(2)* in water are mixed with an equal volume of a 40% solution of HBF_4, beautiful crystals of the tetrafluoroborates precipitate out. None of the compounds *(2)* absorbs between 2600 and 3100 cm^{-1}. Their maxima in the ultraviolet are at shorter wavelengths than those of the compounds *(1)*, *e.g.* for *(2a)*, λ_{max} = 293 mμ, log ε = 3.55, whereas for *(1a)*, λ_{max} = 339 mμ, log ε = 4.32 in ethanol. The triazenes *(1)* can be reobtained from *(2)* by treatment with $Na_2S_2O_4$ in alkaline solution.



(3)

By analogy to the reaction of *(1)*, dehydrogenation of 1-phenyl-3-(1-isoquinolyl)triazene, m.p. 136 °C, λ_{max} = 397 mμ, log ε = 4.28 in ethanol, leads to a 53% yield of 3-phenyl-6-bromotetrazolo[5,1-*a*]isoquinolinium bromide *(3)*, m.p. 292 °C, λ_{max} = 293 mμ, log ε = 3.95 in ethanol. To our knowledge, compound *(3)* is the first tetrazolo[5,1-*a*]isoquinoline prepared.

Synthesis of β-Thioxo Ketones by Condensation of Ketones with Thionic Esters

By Doz. Dr. E. Uhlemann and Dipl.-Chem. Helmut Müller

Institut für Anorganische Chemie der Universität Leipzig (Germany)

Thio derivatives of β-dicarbonyl compounds can be obtained by acid- or base-catalysed reaction of the oxygen compounds with hydrogen sulfide [1,2]. With highly unsymmetrical β-dicarbonyl compounds, the point of attack of the hydrogen sulfide is largely determined by the constitution of the starting material, whereas for β-diketones with only slightly different substituents two isomeric thio derivatives are to be expected.

We have found that β-thioxo ketones of uniform structure can be readily obtained by a Claisen-type condensation of ketones with dithioic esters or thionic esters. Yields of over 50% are obtained.

Monothiodibenzoylmethane

Acetophenone (40 g or 0.33 mole) is added slowly with stirring to a suspension of 13 g of sodamide (0.33 mole) in 200 ml of ether. After 15 minutes, a solution of 24 g of *O*-methyl thiobenzoate (0.16 mole) in 50 ml of ether is added dropwise. The mixture is stirred for 3 h at room temperature and left standing overnight. The precipitate is dissolved by adding ice-water, and the aqueous solution is extracted with ether. On passing carbon dioxide into the aqueous solution, monothiobenzoylmethane separates out in the form of shiny red crystals, m.p. 82–83 °C. The yield is 26 g or 68%.

Effect of Steroids on the Activity of DNA-Dependent RNA-Polymerase

By Prof. Dr. A. Wacker, Dr. J. Drews, Dr. W. B. Pratt, and P. Chandra

Institut für Therapeutische Biochemie der Universität Frankfurt/Main (Germany)

Dedicated to Professor Gustav Erhart on the occasion of his 70th birthday

We allowed *Pseudomonas testosteroni* to grow for 4–5 h in the presence of tritium-labelled testosterone and then isolated from the cells the fraction which contained radioactivity. Cells grown in the absence of testosterone were processed in the same fashion: Moist cells (0.7–0.8 g) were homogenized by shaking with glass beads. The suspension was centrifuged for 10 min at 1500 g. The cell-free extract was then centrifuged at 105000 g for 45 min and the supernatant was fractionated on a column (2 cm in diameter and 42 cm long) of Sephadex G-100 using 0.06 M phosphate buffer (pH 7.5) as eluant. The first fraction which showed absorption at 280 mμ was used for the further experiments.

Both fractions, *i.e.* that from cells grown in the presence and that from cells grown in the absence of testosterone, inhibited the DNA-dependent RNA-polymerase in a cell-free system synthesizing m-RNA, but the degree of inhibition was higher with the fraction from cells grown without testosterone (Table 1). If testosterone is subsequently added to this fraction, its inhibitory effect falls off to equal that of the fraction from cells grown in the presence of testosterone. Additions of cortisone are without effect [1].

Table 1. Effect of a fraction isolated from cells grown in the presence (IF) or in the absence (NIF) of testosterone on the activity of the DNA-dependent RNA-polymerase. The reaction mixture (0.38 ml at pH 7.5) contained: 100 mμmoles each of GTP, CTP, UTP, and [^{3}H]-ATP; 10 μmoles of tris; 0.25 μmole of $MnCl_2$; 1.0 mμmole of $MgCl_2$; 1.0 μmole of β-mercaptoethanol; 2 optical units of DNA from salmon sperm; and 20 μg of RNA-polymerase from *Escherichia coli* [2].

System	[^{3}H]-ATP incorporated [mμmole]
Complete	0.455
– Polymerase	0.004
+ NIF	0.192
+ IF	0.245
+ NIF + Testosterone	0.255
+ NIF + Cortisone	0.145

The different effects of testosterone and cortisone are also observed *in vivo* (Table 2): although testosterone induces in growing cells of *P. testosteroni* a maximum activity of Δ^5-3-ketosteroid isomerase (and of 3α- and 3β,17β-hydroxysteroid dehydrogenase) cortisone has almost no effect. Parallel results *in vivo* and *in vitro* are obtained for other steroids as well (Table 2). It appears particularly remarkable that m-RNA synthesis is inhibited by cortisone, which has an antianabolic and catabolic action, but is promoted by methenolone, which has an anabolic effect.

Table 2. Effect of various steroids on the activity of DNA-dependent RNA-polymerase *in vitro* (cf. Table 1) and upon Δ^5-3-ketosteroid isomerase *in vivo*. Reaction mixture as in Table 1.

System	[^{3}H]-ATP incorporated [mμmole]	Δ^5-3-ketosteroid isomerase [units/ml of bacterial suspension][a]
Complete + NIF	0.080	0.3 [b]
+ Testosterone	0.125	15.6
+ Menthennlone [c]	0.108	11.6
+ Substance S [d]	0.100	11.2
+ Progesterone	0.090	
+ Cnrtisone	0.065	0.55

[a] One unit of enzyme isomerizes 1 μmole of Δ^5-androstene-3,17-dione to Δ^4-androstene-3,17-dione within one minute.
[b] Control experiment without steroid.
[c] 1-Methyl-Δ^1-androsten-17β-ol-3-one (Primobolan®).
[d] 11-Deoxycortisone.

Preliminary studies (incubation with enzymes, inactivation by heat) suggest that the fraction isolated from *P. testosteroni* contains a protein which reacts with the steroids; this protein possibly is a repressor of RNA-polymerase, such as postulated by *Jacob* and *Monod* [3].

Phosphinoalkanoic Acids [1]

By Prof. Dr. K. Issleib, Dipl.-Chem. R. Kümmel, and Dipl.-Chem. H. Zimmermann

Institut für Anorganische Chemie der Universität Halle/Saale (Germany)

The procedure for preparing tertiary carboxyalkylphosphines from alkali diorganophosphides MPR_2 and halogenoalkanoic esters [2] in tetrahydrofuran or ether cannot be used directly to synthesize primary or secondary carboxyalkylphosphines, since here side reactions such as metal-halogen and metal-hydrogen exchange or nucleophilic attack of the phosphide anion at the ester group occur to a significant extent. However, when the anhydrous sodium salts of the halogenoalkanoic acids are used instead of the esters, a smooth reaction occurs and good yields of the sodium salts of the primary and secondary carboxyalkylphosphines are formed. The free phosphinoalkanoic acids *(1)*–*(8)*, which can be regarded as phosphorus analogues of the amino acids, are readily obtained from the sodium salts with dilute sulfuric acid.

$$MPHR + X\text{-}\underset{|}{(CH)_n}\text{-}COO^{\ominus} \rightarrow MX + RHP\text{-}\underset{|}{(CH)_n}\text{-}COO^{\ominus}$$

X = Cl or Br; M = Na or K

Compound	B.p. [°C/mm] or m.p. [°C]	Yield [%]	Derivative	B.p. [°C/mm]
(1), H_2P-CH_2-COOH	70–72/6	82	$H_2P-CH_2COOCH_3$	27–28/10
(2), $H_2P-CH(CH_3)-COOH$	73–74/5	85	$H_2P-CH(CH_3)COOCH_3$	33–34/13
(3), $H_2P-CH(C_2H_5)-COOH$	87–89/6	76	$H_2P-CH(C_2H_5)-COOCH_3$	39–41/10
(4), $H_2P-CH_2-CH_2-COOH$	86–87/6	69	$H_2P-CH_2-CH_2-COOCH_3$ [5]	37–38/10
(5), $C_6H_5HP-CH_2-COOH$	35–37	70	$[H_3P^{\oplus}-CH_2-COOH]I^{\ominus}$	m.p. 112 °C from C_2H_5OH
(6), $c\text{-}C_6H_{11}HP-CH_2-COOH$	oil	70	–	
(7), $C_2H_5HP-CH_2-COOH$	oil	75	–	
(8), $C_6H_5HP-CH(CH_3)-COOH$	29–31	57	–	

The reactions are carried out in liquid ammonia, in which the majority of the alkali phosphides MPH_2 and MPHR dissolve without decomposition owing to the difference in pK_a between phosphine and ammonia [3]. The alkali phosphides are prepared in liquid ammonia from sodium or potassium and PH_3 [4] or a primary phosphine (color change to yellow). The sodium salt of the halogenocarboxylic acid is then simply added to the solution.

The carboxylic acids *(1)–(4)* are colorless liquids with a characteristic odor; they decompose in air but can be distilled unchanged *in vacuo* and form colorless crystals slightly below room temperature. Vacuum distillation of *(5)–(8)* is not recommended. Compounds *(1)–(4)* dissolve in ether and in water with an acidic reaction, but *(5)–(8)* dissolve in organic solvents only. Polarographic studies revealed that *(1)–(8)* have a partially zwitterionic structure. Almost quantitative yields of the corresponding methyl esters (see Table) are obtained from *(1)–(4)* with diazomethane in ether; the esters are colorless, low-boiling liquids which ignite spontaneously when finely divided in air. Analogous derivatives are obtained from *(5)–(8)*. The phosphine portions of *(1)–(8)* can be quaternized with hydrogen iodide.

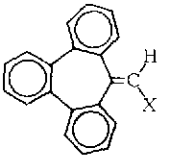
An Optically Active Derivative of Methylenetribenzocycloheptatriene

By Dr. W. Tochtermann and Dr. H. Küppers

Organisch-Chemisches Institut der Universität Heidelberg (Germany)

Inversion of the seven-membered ring occurring in the nonplanar boat form is more difficult in di- and tribenzocycloheptatrienone acetals than in cycloheptatriene [1]. Suitable substituted tribenzocycloheptatriene derivatives ought therefore to be separable into optically active antipodes.

To test this prediction, we prepared bromomethylenetribenzocycloheptatriene *(1a)*, m.p. 127–129 °C, by bromomethylenation [2] of tribenzocycloheptatrienone (yield: 75%) and treated it with lithium in dimethoxymethane [3] at –20 to –25 °C to form the lithio compound *(1b)*. Carboxylation of *(1b)* and subsequent hydrolysis produced a 60% yield of 1-carboxymethylenetribenzo[*b,d,f*]cyclohepta-2,4,6-triene *(1c)*, m.p. 249–251 °C. The structure of *(1c)* was proved by its



(1a), X = Br
(1b), X = Li
(1c), X = COOH

elemental analysis, molecular weight, NMR, ultraviolet, and infrared spectra, and by its oxidation with potassium permanganate to tribenzocycloheptatrienone.

The carboxylic acid *(1c)* was resolved *via* its brucine salt into its optical antipodes, which were quite stable and exhibited specific rotations ($[\alpha]_{546}^{25} = +31.7°$ and $[\alpha]_{546}^{25} = -30.9°$, c = 0.026 g/cm³ in acetone) which were strongly dependent on the solvent used. No loss of the optical activity was observed even on prolonged standing of solutions of the optical antipodes at room temperature [*].

Racemization of the optical isomers in diethylene glycol dimethyl ether at 139 °C showed that the rotations decrease by a first order mechanism with $k_{exp} = 1.1 \times 10^{-4}$ sec^{-1} on the average. Thus, since $k_{inversion} = 0.5\ k_{exp}$ [4], a free energy of activation $\Delta F^{\neq} = 31$ kcal/mole is calculated for the inversion at 139 °C. Thus racemization caused by inversion of the seven-membered ring appears to proceed somewhat slower than the racemization of bromodibenzocyclooctatetraenedicarboxylic acid [5].

CONFERENCE REPORTS

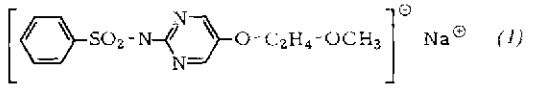
Therapy Congress and Pharmaceutical Exhibition

The lectures delivered at the 16th German Therapy Congress, which took place in Karlsruhe (Germany) from August 30th to September 5th, 1964, dealt *inter alia* with the therapy of liver and bile-passage ailments, the treatment of thyroid disorders, the application of tissue extracts, the treatment of cardiac and circulatory diseases, the therapy and prophylaxis of thromboembolic illnesses, and physical therapy during convalescence. – A seminar lasting several days was held to discuss disorders of the water-electrolyte balance as an adverse factor influencing therapeutic treatments.

The exhibition of pharmaceuticals had products from about 250 companies on display. Of the many new preparations introduced, only those which contain hitherto unknown chemical compounds or substances which are appearing for the first time on the German market are listed in the following report.

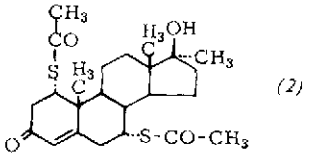
A new oral antidiabetic, Redul®, was developed jointly by Farbenfabriken Bayer and Schering AG. Its ingredient does not belong to the sulfonylurea group but is a representative of a class of substances which is new in diabetes therapy, namely sulfapyrimidine derivatives. Redul contains the sodium salt of 2-benzenesulfonamido-5-(methoxyethoxy)-pyrimidine *(1)* – generic name: glycodiazine – which is readily soluble in water and methanol; its molecular weight

is 331, its m.p. 221–226 °C. Redul stimulates the β-cells of the Langerhans islets and thus evokes a greater physiological incretion of insulin, which in turn results in a reliable depletion of blood sugar. It is degraded rapidly and completely in the organism but maintains its full antidiabetic activity during the first stage of its catabolism.



(1)

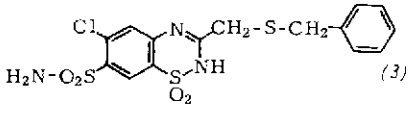
Emdabol® is a hormone preparation for promoting protein synthesis introduced by E. Merck AG., Darmstadt (Germany); it is for oral administration and consists of 1α,7α-bis-acetylthio-17β-hydroxy-17α-methyl-4-androsten-3-one *(2)*, a new substance, m.p. 205–206 °C, $[\alpha]_D = -66°$ in dioxane. Its anabolic activity is twice that of 17α-methyltestosterone. It has an extremely favorable anabolic/androgenic index and is said to exhibit no gestagenic or mineralocorticoid side-effects. Emdabol is indicated for all consumptive illnesses and for cachectic states, *etc.*



(2)

New saluretics were introduced by several companies:

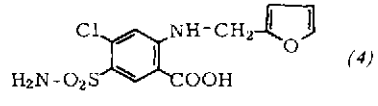
Exosalt® is a new preparation of the benzothiadiazine group issued by Farbenfabriken Bayer and consists of 3-benzylthiomethyl-6-chloro-7-sulfamyl-1,2,4-benzothiadiazine 1,1-dioxide *(3)* – generic name: benzothiazide – a white crystalline



(3)

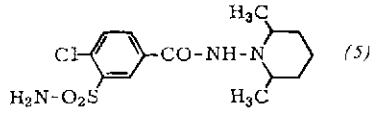
substance, m.p. 238–239 °C, molecular weight 432. It induces a high excretion of sodium and chloride ions in equivalent amounts and is remarkable for the rapidity of its action: diuresis commences within two hours after ingestion of the drug. In animal experiments, Exosalt had about ten times the activity of chlorothiazide.

Although the saluretic called Lasix® developed by Farbwerke Hoechst is also a sulfonamide derivative, its structure differs from those of the benzothiadiazines frequently employed. It consists of 4-chloro-*N*-(2-furylmethyl)-5-sulfamylanthranilic acid *(4)* – generic name: fursemide. Lasix leads to an increased excretion of water and sodium chloride in cases where a diuretic effect cannot otherwise be achieved; it is therefore assumed that *(4)* has a mode of action different from that of the diuretics currently in use.



(4)

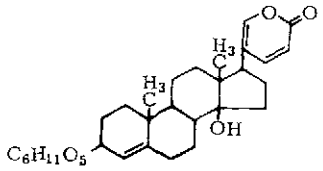
Brinaldix® from Sandoz AG., Nürnberg (Germany), is another new sulfonamide diuretic. Chemically, it is a derivative of 3-sulfamyl-4-chlorobenzoic acid, namely *N*-(*cis*-2,6-dimethyl-1-piperidyl)-3-sulfamyl-4-chlorobenzoamide *(5)*, a solid of m.p. 244–245 °C. Brinaldix is characterized by its



(5)

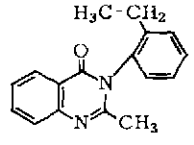
reliable and rapid induction of excretion of sodium and chloride ions and particularly by its broad therapeutic range. It produced no toxic symptoms in animals which were given 100000 times the normal dose.

Proscillaridine, a glycoside long known to occur in *Scilla maritima var. alba*, has now undergone clinical testing and has been introduced into practical therapy as Talusin® bei Knoll AG., Ludwigshafen (Germany), and as Caradrin® by Asta-Werke, Brackwede (Germany). Proscillaridine is 3β-rhamnosido-14β-hydroxy-$\Delta^{4,20,23}$-bufatrienolide *(6)*, m.p. 219–222 °C, $[\alpha] = -92°$ C in methanol, and acts as rapidly as strophanthin, but can be administered *per os*. Since it does not accumulate in the organism and has a broad therapeutic spectrum, the drug is easy to dose.



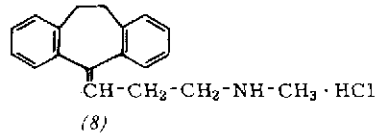
(6)

A new daily sedative and mild soporific is Aolan®, which is produced by P. Beiersdorf & Co. AG., Hamburg (Germany); it is recommended for normalizing disturbances in the functions of the central and vegetative nervous systems due to overstimulation. It consists of 2-methyl-3-(*o*-ethylphenyl)-4-quinazolone *(7)* – generic name: ethinazone.



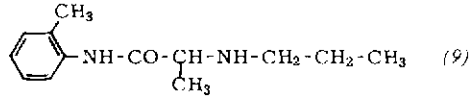
(7)

A new psychopharmaceutical for treating fits of depression, psychosomatic disturbances, *etc.* is marketed by Troponwerke, Köln-Mühlheim (Germany), under the name Nortrilen® and by Eli Lilly GmbH., Gießen (Germany), as Acetexa®. It is composed of 5-(3-methylaminopropylidene)-dibenzo[*a*,*d*]-[1,4]cycloheptadiene hydrochloride – generic name: nortryptiline – a white powder, m.p. 216–219 °C, which dissolves in water, chloroform, or alcohol but not in other organic solvents. Its molecular weight is 299.86. Nortryptiline differs from another long-known antidepressant, amitryptiline, by the absence of a methyl group.



(8)

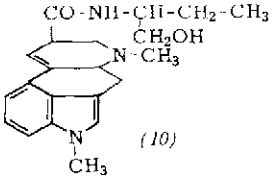
A new local anaesthetic called Xylonest® being marketed by Pharma-Stern AG., Wedel/Holstein (Germany), has already been tested abroad, where it is sold under the trademark Citanest. The structure of Xylonest is closely allied to that of Xylocaine. It contains racemic α-propylamino-2-methylpropionanilide *(9)*, a base which is only slightly soluble in water but readily soluble in alcohol, ether, and acetone, in the form of the water-soluble hydrochloride (molecular weight 256.8, m.p. 167–168 °C). Xylonest is reputed to anaesthetize as well as Xylocaine but to exhibit more prolonged blockage of the nerve fibres.



(9)

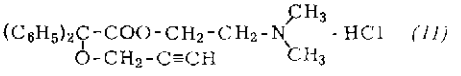
A drug called Deseril® for prophylactic treatment of migraine was introduced by Sandoz AG., Nürnberg (Germany). Its active principle is *N*-[(+)-1-hydroxymethylpropyl]-1-methyl-D-lysergamide *(10)* – generic name: methysergide – which has proved to be the strongest serotonin antagonist known to date. Deseril is incorporated into retarder tablets as its dimaleate. Deseril is applicable for the treatment of all

illnesses with symptoms which arise owing to the participation of serotonin, and can therefore be given for migraine headaches, allergies, and carcinoid syndromes.



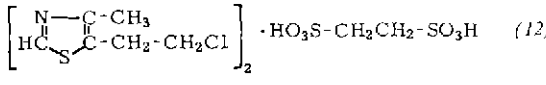
(10)

Ventrinerval®, a new preparation for the treatment of stomach disorders from Rhein-Pharma GmbH., Heidelberg (Ge many), contains aluminum glycinate plus a new spasmolytic benzilic ester, β-dimethylaminoethyl α,α-diphenyl-α-propargoxyacetate, in the form of its hydrochloride *(11)*. This is a white crystalline substance, m.p. 162- 163 °C, molecular weight 373.89, which effects neurotropic and musculotropic spasmolysis plus central analgesia and anaesthetizes the mucous membranes, inhibits secretion, and reduces intestinal motility.



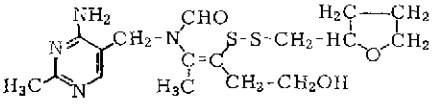
(11)

An anticonvulsive, hypnotic, and sedative agent long known abroad as Hemineurine has now been brought to the German market under the mane of Distraneurin® by Pharma-Stern AG., Wedel/Holstein. It consists of the thiazole moiety of thiamine (vitamin B_1) in which the hydroxyl group has been replaced by a chlorine atom. This 4-methyl-5-(β-chloroethyl)thiazole is administered as the salt *(12)* of ethanedisulfonic acid, a crystalline, relatively stable substance which dissolves easily in water. Distraneurin is a reliable tranquillizer for application particularly in psychomotoric schizophrenia following acute alcoholic intoxication or after abrupt deprivation of alcohol during *delirium tremens*, or for paranoid states due to cerebral sclerosis.



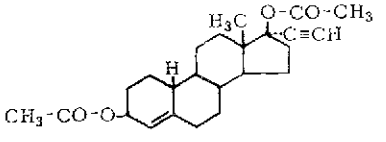
(12)

Another interesting derivative of thiamine (vitamin B_1) developed by Takeda Chemical Industries Ltd., Osaka (Japan), was presented by M. Woelm, Eschwege (Germany), under the name of Judolor®. This comprise the open-ring form of thiamine-tetrahydrofurfuryl disulfide, TTFD *(13)*, which was discovered during attempts to find a better resorbable form of thiamine. Even when large doses of vitamin B_1 are given, a maximum of only 5 mg is absorbed by the organism, whereas Judolor is fully effective when taken orally. The concentration of the cocarboxylase required for metabolism can thus be increased in the tissues by about 100 %. Judolor has analgetic, antiphlogistic, and spasmolytic activity and is recommended for treating neuralgias, neuritis, myalgias, rheumatism, and myocardial defects, as well as for hepatopathy.



(13)

Ovulen® is a new contraceptive drug containing Mestranol as estrogenic component plus a new gestagenic principle developed by Searle, Chicago, Ill. (U.S.A.), and tested in cooperation with C. F. Boehringer GmbH., Mannheim (Germany), *viz.* the diacetate of 17α-ethynyl-4-estrene-3β,17β-diol *(14)* – generic name: ethynodiol diacetate – a white, odorless, crystalline compound, which is insoluble in water but soluble in oil. The diacetate *(14)* proved to be one of the most effective and best tolerable gestagens; a dose of only 1 mg daily ensures reliable contraception.



(14)

A new special corticoid for dermatological use is Locacorten® from Ciba AG., Wehr/Baden (Germany); its active constituent is a newly developed pharmaceutical called flumethasone, *i.e.* 6α,9α-difluoro-11β,17α-dihydroxy-16α-methyl-21-trimethylacetoxy-1,4-pregnadien-3,20-dione *(15)*, as its pivalate. This substance exerts a rapid inhibitor effect on inflammation due to dermatitis, especially from eczemas, and has antiallergic, antiexudative, and antipruriginous activity.

Advances in Electron Microscopy

The Third European Regional Conference on Electron Microscopy was held in Prague (Czechoslovakia) from August 26th to September 3rd, 1964. This was the first international meeting on this topic to be held in a socialist country. In consequence, the number of participants from socialist countries was significantly higher than in corresponding symposia in western European countries. The reports thus presented an excellent survey of the research topics being studied in eastern Europe and of the quality of the work being done there, and hence aroused great interest on the part of visitors from western countries.

Advances in applied electron microscopy can be made mainly by increasing the resolving power of the microscopes, by adaptation of the instruments for special tasks without loss of their electron-optical resolution, and by introducing new methods of preparation and investigation.

All reports on the theory and practical aspects of the limits of resolution of electron microscopes confirmed the opinion that the highest theoretically attainable resolution is almost achieved on current commercial high-resolution instruments (maximum beam potential 100000 volts). Some of the differences in the values quoted for the limit of resolution are probably the consequence of different measuring techniques.

A remarkable demonstration was the direct projection by *T. Komoda*, Tokyo (Japan) of lattice network planes in single crystals of gold, where the lattice planes were 2.35 Å apart. The gold sample was 40 Å thick and was prepared by epitactic sublimation; the electron beam impinged upon its surface at an angle such that the central beam and diffracted beam (111 reflection) lay symmetrical to the optical axis of the microscope.

Although this resolution demonstrates the potentialities of modern electron microscopes, a value as low as 2.35 Å cannot be expected from other preparations and other modes of examination. *J. Heydenreich*, *H. Bethge*, and *U. Ruess*, Halle/Saale (Germany) proposed a method for the first time for objective evaluation of resolution test exposures using equidensitometry according to *Lau* and *Krug*. If their proposal achieves general acceptance, then it would at last be possible to compare data for the resolving power of electron microscopes which were determined in different laboratories with different instruments.

In order to adapt electron microscopes for special purposes, it is essential to be able to exert clearly defined physical or chemical influences on the specimens. Several lectures were devoted to the description of suitable appliances. *K.-H. Herrmann* and *W. Loebe*, Berlin (Germany) reported on a method for cooling the sample chamber in the Siemens & Halske Elmiskop I which prevents contamination of the sample due to decomposition of hydrocarbons in the electron microscope. *U. Valdre*, Bologna (Italy) and *R. M. J. Cotterill*, Illinois (U.S.A.) reported on their independent work concerning the development of techniques for cooling the sample chamber in electron microscopes down to the temperature of liquid helium. Devices of the kind described are important for the observation of radiation damage and of superconductors. *M. J. Goringe* and *U. Valdre*, Bologna (Italy) described the application of sample-cooling devices for the investigation of superconducting lead with the electron shadow microscope: a magnetic field was applied normal to the electron beam, and alterations in magnetic field on attaining a critical temperature could be observed in the electron shadow image.

It is well known that the preparation of sufficiently thin sections (*e.g.* for direct transmission of electron beams through metals) still entails considerable difficulties. *G. Dupouy*, *F. Perrier*, and *L. Durrieu*, Toulouse (France) showed that good quality photographs of metals and metal alloys could still be obtained with beam potentials of 1×10^6 volts even if the thickness of the sample is 6 μ or 9 μ.

Numerous lectures dealt with precipitation processes, phase changes, nucleation processes, dislocations, and stacking defects in metals and metal alloys. Almost without exception it was the method of direct transmission through thin etched metal foils that was used. Again it was apparent that this aspect of metal-physical research is popular mainly in English-speaking countries. Only a few of the numerous reports on this subject can be mentioned here and these because of their mainly chemical interest. *S. A. Jansson*, Stockholm (Sweden) reported on the continual observation of the oxidation of a stainless chrome-nickel steel made possible by passing gases through a special sample chamber during observation. The partial pressure of the oxygen during observation was approximately 10^{-2} mm. The rate of oxidation varied widely from one grain of metal to another. Diffraction photographs showed two kinds of oxide nuclei which could be differentiated by their sizes and orientations. In addition, oxide nuclei could often be seen at the ends of dislocations.

M. H. Lewis and *J. W. Martin*, Oxford (England) discussed the growth of oxide particles during internal oxidation of copper alloys. The dispersed oxides (MgO, BeO, Al_2O_3, and ZrO_2) had progressively smaller particle sizes as the distance of the particles from the surface increased.

The detection of lattice defects by transmission electron microscopy is still restricted to metallic samples. For ionic crystals, the metal decoration (shadow casting) procedure introduced by *H. Bethge*, Halle/Saale (Germany) has been developed into a powerful tool. Thus, for example, after deformation of a sodium crystal glide steps with a height of 2.8 Å could be made visible. It also proved possible to resolve dislocation lines 50 Å apart in a replica specimen by using palladium decoration to obtain micrographs of small-angle grain boundaries with a large dislocation density on the surface of NaCl crystals. Finally, *M. Krohn* and *H. Bethge*, Halle/Saale (Germany) gave an explanation for the occurrence of growth spirals with a large step-height: these spirals are made up of approximately round growth lamellae whose centers do not overlap. A high step then forms to cover up the ends of a host of these circular lamellae, but the fine structure of the step cannot be resolved in a light microscope.

Several lectures dealt with the properties of thin semiconducting layers. *V. E. Yurasova* et al., Moscow (U.S.S.R.) reported on their production of single crystal samples by cathodic atomization. A plasma of these samples (InSb or GaAs) at 10^{-3} mm is bombarded with positive ions. In order to observe the dynamic processes occurring in p-n junctions, *V. G. Diikov* et al., Moscow (U.S.S.R.) fitted an emission electron microscope with a stroboscopic attachment. A basic impulse is directed onto the p-n junction to be studied and a second impulse of much shorter duration onto an ion cannon, which induces the emission of electrons from the sample. Since the phase of the second impulse can be displaced relative to that of the basic impulse, stationary images of the p-n junction can be observed on the screen of the microscope at various times after release of the first impulse. *A. D. G. Stewart* et al., Cambridge (England) observed the images of a p-n junction using a scanning electron microscope.

M. Schulz, Berlin-Teltow (Germany) found that defects in the lattices of single crystals of germanium were preferred nuclei for the start of oxide formation. Extensive outgrowths of oxide particles occur at the breakthrough points of individual dislocations; smaller outgrowths indicate the distribution of the doping agent. The method used is remarkable, for no undesirable chemical or thermal strains are applied to the material being examined. *G. I. Distler* et al., Moscow (U.S.S.R.) described a new method for the chemical decoration of active regions in crystal surfaces, where chemical reactions leading to crystallization cause the decoration effect. An example given was the crystallization of PbS caused by the slow decomposition of lead acetate with thiourea. This decoration method was used for single crystals of silicon; here the decoration became attached in strips corresponding to the inclusion of impurities inside the crystal.

The influence of various impurities on the growth of Fe_2O_3 whiskers was examined by *R. A. Ploc* and *J. P. Chilton*, Cambridge (England), who found that every impurity has a characteristic effect on the crystal size and shape. Silver produces prismatic needles of the oxide, indium causes a grass-like structure to form, and zinc gives a mixture of fine needles and platelets.

J. A. Gard, Aberdeen (England) gave a typical example for the study of a chemical reaction using the electron microscope. The calcium fluoride crystals formed by the action of sodium fluoride on calcite appear as pseudomorphoses of calcite. This reaction could be followed in detail by carbon replication, and it was shown that the $(10\bar{1}2)$ surface of the calcite becomes the (110) surface of the fluoride.

Following the magnificent successes which transmission electron microscopy has achieved in metallurgy – particularly in the field of the physics of metals – it was an obvious next step to apply this investigational technique to inorganic, non-metallic substances. Naturally considerable difficulties with regard to preparation techniques had to be overcome in order to acquire sufficiently thin samples for transmission.

O. E. Radczewski and *E. Wanderer*, Aachen (Germany) applied the thin-section method to study single asbestos fibers and managed to observe the cross-sectional shape of individual fibers and simultaneously to record their electron diffraction diagrams. *D. H. Warrington* and *M. H. Lewis*, Sheffield (England) investigated extremely fine inflated glass foils. Various different phases could be differentiated in the resultant electron micrographs. Different phases can also be distinguished by coupling a special etching prodecure with replication techniques, as *T. L. Tran* and *C. Sella*, Paris (France) were able to show. The main difficulty involved in direct transmission and replica electron microscopy is the interpretation of the pictures obtained. [VB 869/177 1E]

Glycosaminoglycans, Glycoproteins, and Glycolipids

At the suggestion of *R. W. Jeanloz* the Retina Foundation of Boston organized an international symposium on the chemistry of the three title substances at Swampscott, Mass. (U.S.A.) from July 22nd to July 25th, 1964. The following topics were discussed: 1. the sugar sequences in glycolipids and glycoproteins; 2. the degradation of glycosaminoglycans and glycoproteins by redox systems and radiation; 3. the physicochemical properties and biological importance of glycosaminoglycan and glycoprotein solutions; 4. the covalent bonds between amino acids and sugars in glycoproteins; and 5. the biosynthesis of the carbohydrate portion of glycoproteins and glycolipids.

1. Sugar Sequences in Glycolipids and Glycoproteins

Richard Kuhn (Heidelberg, Germany) reported on the isolation of a chromatographically pure glycoliposialoprotein (mucolipid A) which gave a uniform sedimentation pattern in the analytical ultracentrifuge and exhibited high acetylcholine esterase activity. After mild treatment with chloroform plus methanol, this afforded a ganglioside-rich component. All the analyses carried out on this product to date indicate an ester-like and/or lactone-like linkage between the gangliosides.

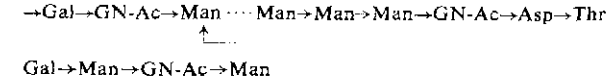
E. Klenk (Köln, Germany) reported on the occurrence of Tay-Sachs gangliosides in normal brain.

P. Stoffyn (Belmont, Mass., U.S.A.) reported on a general method for estimating the α- or β-configuration of the glycosidic bond in cerebrosides. Hydrolysis and hydrogenation of phrenosine affords psychosine which was oxidized with $NaIO_4$, the palmitaldehyde formed being extracted with ether and estimated by gas chromatography. The aldehydes from the aqueous phase were compared with the products obtained from control substances. In the case of phrenosine, they agreed with the aldehydes obtained from 1-D-glyceryl β-D-galactoside, indicating a β-linkage. The method cannot be applied to disaccharides.

G. T. Barry (Knoxville, Tenn., U.S.A.) hydrolysed the glycopeptides from *Citrobacter Freundii* with acid and obtained an amino acid which gave a yellow coloration with ninhydrin and had the same R_f-values on paper chromatograms as synthetic 4-hydroxyleucine. This is formed during the hydrolysis from L-fucosamine, which has thus been detected for the first time in Gram-negative bacteria. *G. F. Springer* (Evanston, Ill., U.S.A.) carried out the isolation and partial characterization of specific haptenes from M and N blood group substances. NN- and N-like blood group substances from erythrocytes and meconium have the structure hexosamine-sialic acid-methylpentose as long as they are still biologically active. *H. Hotta* (Evanston, Ill., U.S.A.) called attention to the high content (33–34 %) of sialic acid in N-active haptenes. *G. M. W. Cook* (Los Angeles, Calif., U.S.A.) achieved a successful separation of M and N blood group glycoproteins by treatment with pronase and subsequent chromatography on Sephadex and DEAE-cellulose. Preliminary identification of the cleavage products indicated that their primary structures are different.

F. Egami (Tokyo, Japan) found the acidic heteropolysaccharides hovatin-sulfuric acid and hovaminic acid in the liver of marine gastropods; these acids contain fucose, mannose, glucose, galactose, and galactosamine; the former also contains sialic acid. But hovaminic acid also reacts with thiobarbituric acid.

On hydrolysis of ovomucoid, *J. Montreuil* (Lille, France) obtained 15 cleavage products which led to the following tentative structure for ovomucoid [*]:



R. G. Spiro (Boston, Mass., U.S.A.) degraded thyreoglobulin by four different methods into two glycoproteins with molecular weights of 1250 and 4100. The smaller fraction contains no sialic acid.

2. Degradation of Glycosaminoglycans and Glycoproteins by Redox Systems and Radiation

L. Sundblad (Stockholm, Sweden) and *W. Pigman* (New York, U.S.A.) spoke about the effect of X-rays on the viscosity of hyaluronic acid and on the redox depolymerization of the same substance and other polymers. The viscosities of solutions containing polysaccharides or synthetic polymers are reduced both by irradiation and by the action of autoxidants such as ascorbic acid or cysteine. Chemical bonds are cleaved by the free radicals formed. *G. O. Philips* (Cardiff, Britain) was able to show that the same radiation dose had different effects, depending on the state of aggregation (crystalline, freeze-dried) of the substrate. *K. S. Dogson* (Cardiff, Britain) irradiated the 6-*O*-sulfates of various monohexoses with X-rays and found that the glucose ester was the most stable.

3. Physicochemical Properties and Biological Importance of Glycosaminoglycan and Glycoprotein Solutions

M. B. Mathews (Chicago, Ill., U.S.A.) reported on the molecular evolution of connective tissue. Although its content of chondroitin sulfate C has remained unaltered, that of chondroitin sulfate A is much higher in evolutionary primitive animals and decreases on rising in the evolutionary scale.

L. Sundblad (Stockholm, Sweden) studied the ratios of some proteins and mucoproteins in the synovial fluid and serum of patients with and without arthritis. In those with rheumatic arthritis only alterations in the proteins were observed.

H. Faillard (Köln and Bochum, Germany) reported on the effect of enzymes on the physiological activity of intrinsic-factor mucoids. The loss of activity after treatment with neuraminidase could be compensated by the addition of strongly acidic ion exchangers. Both its bonded sialic acid and the ion exchanger make the mucoid trypsin-resistant. Its bonding capacity for vitamin B_{12} is not affected by the treatment with neuraminidase.

4. Covalent Bonds between Amino Acids and Sugars in Glycoproteins

A. Dorfman (Chicago, Ill., U.S.A.) found that patients suffering from gargoylism do not have chondroitin sulfate B attached in the normal fashion to a protein; instead, it is extremely soluble. *L. Rodén* (Chicago, Ill., U.S.A.) studied the sugar-protein bond in acidic mucopolysaccharide/protein complexes and isolated xylosylserine and galactosyl-xylosylserine from heparin; this shows the significance of xylose as the bonding unit for attaching the mucopolysaccharide to the protein. The following structure was proposed:

[*] GN = glucosamine, Ac = acetyl.

5. Biosynthesis of the Carbohydrate Portion of Glycoproteins and Glycolipids

The intermediates in the biosynthesis of plasma glycoproteins were discussed by *R. J. Winzler* (Chicago, Ill., U.S.A.). [^{14}C]Glucosamine is rapidly removed from the plasma and converted by microsome fractions from liver homogenates into UDP-*N*-acetylglucosamine *via* a series of still unknown intermediates. The product transfers the acetylglucosamine residue to an acceptor (peptide chain). Since no radioactive oligosaccharides were found, it is assumed that oligosaccharide units are formed by interlinking of individual sugars. *S. Roseman* (Ann Arbor, Mich., U.S.A.) gave an excellent survey of the investigations being carried out in his laboratories. Four enzyme systems catalyse the transfer of sialic acid (as CMP-sialic acid) to acceptors: 1. *E.coli* extracts (transfer to colominic acid); 2. mammary tissue from lactating rats (transfer to low molecular-weight β-D-galactosides, *e.g.* lactose); 3. an enzyme from the submaxillary glands of sheep (transfer to sheep mucin and fetuin treated with neuraminidase); and 4. a soluble enzyme from goat colostrum, which incorporates sialic acid into high and low molecular-weight substances. With the last enzyme and lactose as substrate, 2→3-sialyllactose is not formed as with the enzyme from the mammary tissue of lactating rats, but the 2→6-isomer is formed instead. The isolation of nucleotides with the general structure sialic acid→Gal→GN-Ac→UDP makes it again appear less likely that the transfer of sialic acid is the last step in the biosynthesis of the carbohydrate chains in glycoproteins.

[VB 864/168 IE]

German version: Angew. Chem. 77, 176 (1965)

4th International Congress on Detergents

The 4th International Congress on Detergents was held in Brussels (Belgium) from September 7th to 12th, 1964 [*]. The program was divided into three main groups: The chemistry of detergents (Section A), the physics of detergents (Section B), and applications of detergents (Section C).

The world output of surfactants in 1963 was 2×10^6 tons, according to *W. Hagge*, Leverkusen (Germany). The increase in production of detergents since 1958 lies above the average increase for the overall production of chemicals and approaches the rate of increase of plastics production. If the index of 100 is taken for the year 1958, then the index for the world output of surfactants in 1963 is 177, for plastics it is about 200, and for the average of all chemical products it is about 155.

G. G. Eberhardt and *W. A. Butte*, Marcus Hook, Pa. (U.S.A.), reported on a catalytic telomerization using aromatic hydrocarbons as telogens and ethylene as taxogen; this process leads to liquid or wax-like products, depending on the partial pressure of the ethylene. The catalyst for the reaction is an organolithium compound, *e.g.* butyl-lithium in hexane, which is chelated by a tertiary amine such as triethylenediamine or *N,N'*-tetramethylethylenediamine. Catalytic systems of this type accelerate the rates of chain propagation and transmetallation so much that the telomerization can proceed under mild conditions. The amine component must not contain any active hydrogen (including aromatic, allylic, or benzylic hydrogens). This is why tertiary aliphatic amines are used; moreover, an excess must be used, since the equilibria (a) and (b) must be displaced to the right as much as possible.

$$LiR + NR_3 \rightleftharpoons R_3N{\cdot}LiR \qquad (a)$$

$$R_3N{\cdot}LiR + NR_3 \rightleftharpoons (R_3N)_2{\cdot}LiR \qquad (b)$$

The telomerization can only be carried out with ethylene as taxogen, for all other olefins tend to act preferentially as telogens because of their acidic allylic hydrogens. If benzene is used as telogen, then 1-phenylalkanes are obtained with alkyl chain lengths in statistical distribution. In contrast, with toluene, the transmetallation occurs in the side chain. Here, too, a statistical distribution results, the products being 90 % 1-phenylalkanes with uneven numbers of carbon atoms and 10 % 1-(*m*-methylphenyl)alkanes. The optimum temperature for the reaction lies between 105 and 115 °C.

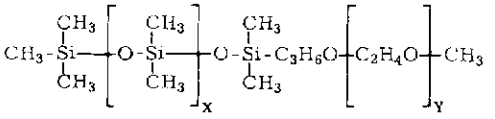
Two lectures were devoted to alkylation of aromatics. *H. M. Friedman*, Cranford, N.J. (U.S.A.), described the reaction of naphthalene with nonene (propene trimer), which is carried out as a discontinuous process. The catalyst used consists of 50 % BF_3 in 85 % H_3PO_4 and has the advantages over conventional Friedel-Crafts catalysts such as H_2SO_4 and 96 % Al_2Cl_6 or $AlCl_3$·HCl [cf. the lecture by *R. Martinez-Gayol*, Madrid (Spain), on the production of dodecylbenzene by alkylation of benzene with propene tetramer] of affording higher yields of monoalkylated naphthalenes and of yielding products of better color. The highest yields of monoalkylnaphthalenes are obtained between 45 and 50 °C (0.8 mole plus 0.03–0.05 mole of dialkylnaphthalenes and 0.15 mole of unchanged naphthalene). Increase in the concentration of catalyst from 8.1 to 15.0 % does not result in any significant increase in the yield of monoalkylated product. The olefin: naphthalene ratio used is 1:1; this is remarkable, since in all other alkylation reactions the aromatic component must be used in excess.

Another important topic dealt with was the synthesis of non-ionic detergents. *W. T. Weller*, Port Sunlight, Cheshire (England), isolated pure poly(ethylene glycols) of formula $HO(C_2H_2O)_nH$, where $n = 1-6$, by fractional distillation of a complex mixture of polyglycols (SHELL PEG 200); the purity of the products was checked by gas chromatography. The monosodium salts of the pure glycols were then treated with the *p*-toluenesulfonate of a fatty alcohol; this led to non-ionic detergents of general formula $RO(C_2H_4O)_nH$, where $R = C_{10}H_{21}$ or $C_{12}H_{25}$, and $n = 1-6$. *R. Celades*, Barcelona (Spain), and *C. Paquot*, Bellevue (France), reported on the preparation of esters of poly(ethylene glycols) by alcoholysis (transesterification) of fatty acid methyl esters with the polyglycols.

G. L. Hollis, Billingham, Durhamshire (England), spoke about some regularities in systems containing ethylene-oxide condensation products. Straight-chain and branched primary alcohols and branched alkylphenols were condensed with ethylene oxide, and the surfactant properties of the products were investigated. These properties vary with the content of ethylene oxide, but nonetheless in every series there is a limiting value for the hydrophobic chain length beyond which no improvements in surfactivity can be obtained independent of the ethylene-oxide content. Examples were given of how the incorporation of propylene oxide into the chains can improve the surfactant properties.

D. L. Bailey, *J. H. Petersen*, and *W. G. Reid*, Tonawanda, N.Y. (U.S.A.), considered siloxane/alkylene oxide copolymers as an unusual class of non-ionic detergents. The properties of methylsiloxane/alkylene oxide copolymers(1) were compared with those of conventional surfactants.

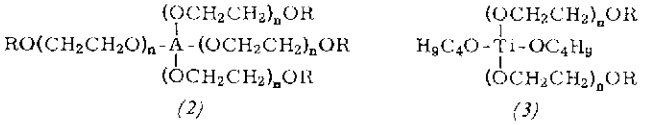
[*] The reports given at the Congress are to be published in three volumes by Gordon and Breach, Science Publishers, Inc., 150 Fifth Avenue, New York 11, N.Y. (U.S.A.), by the middle of 1965.



(1)

Copolymers of this type lead to extremely low values for the surface tension ($\sigma \approx 20$ dynes/cm) in their solutions, even at very high dilutions. They are excellent wetting agents for polyethylene and other hydrophobic surfaces and, in contrast to most other organic products, they exhibit surfactivity in non-aqueous polyglycol systems; this explains their commercial importance as stabilizers for polyurethane foams.

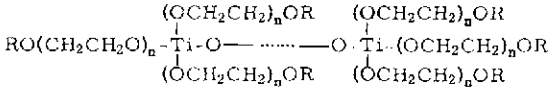
K. Meguro and *M. Ochi*, Tokyo (Japan), prepared organometallic surfactants and examined their suitability as dispersing agents. They synthesized surface-active poly(ethylene oxide) titanates and silicates of general formulae *(2)*, *(3)*,



(2)

A = Ti, Si

(3)



(4)

and *(4)* by the reaction of titanium tetrabutoxide or silicon tetraethoxide with higher oxethylated alcohols. These esters are soluble in water and in many organic solvents and have good dispersing effects on inorganic pigments.

R. Heusch, Leverkusen (Germany), dealt with the surface tension σ of alkylphenol polyglycol ethers. The curves of σ *vs.* temperature for aqueous solutions of alkylphenol polyglycol ethers with alkyl and polyether chains of varying lengths were used to construct σ *vs.* c curves [*] for a measuring time of 90 min; the latter were then used to derive the molecular surface requirements in the interface with the aid of the Gibbs equation. The logarithm of the saturation concentration taken from the σ *vs.* c curves is plotted against the number of carbon atoms in the alkyl residue or against the number of moles of ethylene oxide and the resultant curves used to estimate the energy relationships in the interfaces for hydrophobic and hydrophilic films. The interfacial phenomena were contrasted with the behavior of the molecules in solution.

B. Mitev, Montreal (Canada), and *G. Khanzada*, Montreal (Canada), described the synthesis and properties of biologically degradable detergents based on wheat gluten which had been partially hydrolysed in the presence of alkali at high temperatures under pressure; the resultant polypeptides were acylated with fatty acid chlorides. Further lectures dealt with surfactant 2-alkyl-2-imidazolines [*J. Tornquist*, Stenungsund (Sweden)], the rates of reaction of primary and secondary hexadecyl chlorides with pyridine [*M. Kajl*, Warsaw (Poland)], the synthesis of alkylphenol polyglycerol ethers and their effects on photographic emulsions [*K. Koda* and *S. Kikuchi*, Tokyo (Japan)], and with the removal of electrolytes from a mixture of detergents [*R. C. Mast*, Cincinnati, Ohio (U.S.A.)]. Another interesting topic dealt with was the sulfonation of alkylbenzenes, fatty alcohols, condensates of fatty alcohols and alkylphenols with ethylene oxide, *etc.* to give anionic surfactants.

M. Brunier and *M. Carlotti*, Bonneuil/Marne (France), investigated the effect of various sulfonating agents such as sulfuric acid or oleum plus SO_3 and of different sulfonating conditions on the properties of the sulfonates obtained. During sulfonation with SO_3, the reaction conditions must be maintained much more exactly than with other conventional sulfonating agents. The effect of temperature is one determinant factor, for at high temperatures partial degradation can occur and at low temperature the proportion of non-sulfonated material increases. It could be shown that alkylates with straight side-chains are easier to sulfonate than those with a branched side-chain.

W. Fricke, Frankfurt/Main (Germany), spoke about "Advances in the production of surfactant detergents by sulfonation using SO_3 gas" and discussed a batch process and a continuous multistep process as well as a continuous short contact-time process used by the Chemithon Corporation. The advantages of this method are as follows. The surfactant material is more soluble in liquid detergents because of its lower salt content; fatty alcohols and their condensates with ethylene oxide can be treated to give up to 90 % conversion without discoloration; working costs are reduced because storage and starting-material costs are less even though the power consumption is higher; by-products such as 78 % sulfuric acid and hydrochloric acid are not produced; using a Chemithon plant, for example, straight-chain and branched alkylbenzenes, C_4 to C_{18} fatty alcohols, oxethylated fatty alcohols, and oxethylated alkylphenols can be sulfonated. These advantages are counterbalanced by higher investment costs and – especially in the case of sulfonation of alkylbenzenes – by a higher free-oil content than in the sulfonation with oleum.

A. Davidsohn, Haifa (Israel), talked about practical aspects of sulfonations using SO_3 gas. Following sulfonation experiments with tetrapropylenebenzene, both straight-chain and slightly branched alkylated products were sulfonated. Sulfonation with SO_3 gas appears to offer especially great advantages over conventional methods particularly for these types of substrate; it is only necessary to maintain a lower temperature (about 50 °C towards the end of the reaction). The proportion of non-sulfonated material is estimated as follows. A solution of 5 % sulfonic acid in 50 % aqueous alcohol causes turbidity in a mixture of methyl alcohol and diacetonyl alcohol if the content of non-sulfonated product is greater than 1.5 % based on 100 % detergent. Fatty alcohols or synthetic alcohols (alfols) can also be sulfonated. Another factor of great importance is the possibility of sulfonating toluene and alkylbenzenes in admixture, since as little as 5–10 % toluenesulfonate confers better properties on alkylbenzenesulfonates. In addition to toluene and higher alkylbenzenes, polynuclear aromatics, *e.g.* naphthalene, can also be sulfonated. Petroleum fractions, *e.g.* that boiling between 180 and 240 °C, can also be sulfonated with SO_3 gas.

M. Crauland and *A. Courtier*, Anthony/Seine (France), and *J. Bolle*, Vert-le-Petit (France), lectured on the influence of structure on detergent action and the biological degredability of some alkyl sulfates, alkylbenzenesulfonates, and alkanesulfonates. They reported the syntheses of 1. sodium n-dodecylbenzenesulfonate, 2. a sodium dodecylbenzenesulfonate which was prepared in three different ways and which in contrast to 1. had a branched side-chain; 3. the sodium salts of 2-pentyl-1-nonyl sulfate, 9-heptadecyl sulfate, octadecyl sulfate, and of the sulfates of the products obtained by condensing 2-n-pentyl-2-nonanol, n-heptadecanol, and octadecanol with 2 moles of ethylene oxide; 4. the product of a sulfochlorination of a gasoline fraction with an average of 12 carbon atoms; this product is a sulfonate obtained by addition of $NaHSO_3$ onto 1-dodecene; 5. tetrapropylenebenzene as standard for comparison. The abilities of these products to act as foaming and wetting agents and as detergents and to undergo biological degradation were determined. The sulfates of oxethylated alcohols are better foaming agents than the sulfates of the simple alcohols. The foaming and wetting properties and the stability of the resultant foams increase when the hydrophobic portion of

[*] c = log of concentration.

the detergent is branched. The detergent action was determined by washing artificially soiled natural silk in distilled water at 40 °C containing 1.75 g of detergent per liter. None of the compounds examined attained the detergent action of myristyl sulfate or Marseille soap, which were taken as standards. The biological degradability is significantly facilitated by the oxethylated side-chains, since bacterial growth is apparently promoted by groupings of this type. Thus, for example, condensates of alcohols with ethylene oxide are extremely susceptible to biological degradation.

J. H. McAteer, Linden, N.J. (U.S.A.), and *L. M. Kinnard*, East Hendred, Wantage-Berkshire (England), reported on the dependence of the properties of sodium alkanesulfonates on the molecular weights. A mixture of hydrocarbons consisting of straight-chain paraffins with 12 to 20 carbon atoms per molecule was separated into sharp fractions each containing about 90–95 % of molecules with an equal number of carbon atoms. These fractions were converted into their sulfonates by irradiation with γ-rays. The $-SO_3H$ groups are distributed statistically over the whole molecule. The sulfur content was 1.3 atoms per mole. The decrease in solubility with rising molecular weight was determined at 25 °C. The solubility of the C_{18} sulfonate is similar to that of n-dodecylbenzenesulfonate. Subsequently, the surface tension, critical micelle concentration, foaming action in soft and hard water, and the detergent action of the products were determined. These properties increase as the carbon content per molecule rises from 13 to 17. The detergent action of a sulfonate containing 15 carbon atoms is roughly equivalent to that of tetrapropylenebenzene under the same conditions. The biological degradability of each product was determined by the method of *M. S. Kenecky*, *R. I. Kelly*, *J. M. Symonds*, and *P. L. McCarty* ["The Determination of the Biodegradability of Detergents, Esso Research Biodegradation Test", presented at the 36th Annual Meeting of the Water Pollution Control Federation, Seattle, Wash. (U.S.A.), October 1963]. All the products are readily degradable, the sodium alkanesulfonates of higher molecular weight requiring about 10 days for complete degradation, *i.e.* about the same time as for 2-phenyldodecanesulfonate.

Organic Semi-Conductors and Inorganic Semi-Conductors with Molecular Lattices

A meeting of the "Semi-Conductor Chemistry" Group of the Gesellschaft Deutscher Chemiker was held in Munich (Germany) on October 12th and 13th, 1964. As *G. M. Schwab* emphasized in the introduction, the meeting should provide a survey of the state of work carried out in recent years in the field of organic semi-conductors. The lectures were concerned not only with methods of measurement and mechanisms throwing light on conductivity in molecular lattices, but also with the possible uses of organic semi-conductors.

In the first plenary lecture *O. Le Blanc, jr.* (New York, U.S.A.) considered the problem of electronic transport in organic crystals on the basis of results obtained by the impulse-photoconductivity procedure developed by him and *Kepler* (1960). Since this procedure makes it possible to follow through the crystal the migration of charge-carriers, which are released by a flash of light of 1 μsec duration at the crystal surface, information can be obtained about mobility, trapping processes and the mechanism of charge-carrier formation (quantum yield *etc.*). By these means it was established that in anthracene crystals the mobilities of holes and electrons, of the order of 1 $cm^2/V/sec$, decreased with increasing temperature, a result which is in accordance with the band model. The change in mobility from 1 $cm^2/V/sec$ observed in pyrene on transition from the solid to the liquid state indicates that a "jump process" replaces the band-model mechanism in this transition. Measurements of the lifetime τ of electrons and defect-electrons in tetracene gave values of up to 10 μsec. A marked increase in the time of transit T for holes on doping was observed, which ranged from 50 μsec in undoped anthracene to 5000 μsec after adding 2 p.p.m. of naphthacene. The dependence on wavelength of the number of charge-carriers released by a flash of light conforms with the absorption spetrum. The number of negative carriers in anthracene is about ten times that of the positive ones. The relationship between the number of charge-carriers formed by irradiation and the intensity of the light is linear.

To explain the results it is assumed that the charge-carriers (electrons, holes) formed by irradiation at the surface of the crystal result from disintegration of an "exciton" which has diffused to the surface; the transport through the crystal can apparently be described in terms of the band model.

Ph. Traynard (Grenoble, France) in his paper on "Catalysis and Organic Semi-Conductors" – reported by *Nechtschein* – referred to the possible technical uses of organic polymers on the basis of their surface-catalytic activity. Eka-conjugated polymers (*e.g.* polybenzimidazoles) were shown to catalyse the decomposition of N_2O and the cleavage of hydrogen from alcohols and formic acid. The close correlation between the number of unpaired electrons determined by measurements of the paramagnetic resonance and the catalytic activity is worthy of note. In accordance with this, the catalytic activity of the polymers is enhanced by addition of radicals. A relationship between the catalytic activity and the chemical structure of the polymers could so far not be found.

H. Meier and *W. Albrecht* (Bamberg, Germany) reported on "The Problem of Doping Organic Photoconductors". It was shown that the dark- and photoconductivity of p-type dyes purified by high-vacuum sublimation (merocyanine, phthalocyanine) can be increased by a factor of up to 1.7×10^3 or 5×10^4, respectively, by addition of electron-acceptors (iodine, tetraiodophthalic anhydride, tetracyanoethylene *etc.*). Acceptor concentrations of 10^{-7} M were effective. The dark conductivity of high-resistance phthalocyanines was of the order of 0.02 $ohm^{-1}\,cm^{-1}$ after doping. To explain the effect of doping it was assumed that after addition of acceptors the concentration of electron-deficiencies in the p-type dye increases on irradiation due to charge-transfer processes and a simple acceptor action between dye and doping material somewhat as in inorganic semi-conductors.

As evidence for the validity of this mechanism, which assumes that theories used for inorganic semi-conductors are applicable to organic photoconductors, some experimental results were discussed: mobilities of the order of 100 $cm^2/V/sec$ (*Delacote* and *Schott* et al.), ESR measurements (*Kearns*, *Tollin*, *Calvin* et al.), quantum yields > 1 on doping, enhancement of the photovoltaic effect of inorganic/organic semi-conductor combinations (CdS/phthalocyanine, *etc.*) of the order of 300 to 400 mV on doping the dye component.

J. Voitländer (Munich, Germany) spoke about the "Dark- and Photoconductivity of Ferrocene" – reported by *Eichhorn*. In ferrocene single-crystals purified by vacuum sublimation, the specific dark-resistance, of the order of 7×10^{13} ohm·cm, obeys the equation $\log R = (E/kT)\log R_0$ with an energy of activation $E = 0.61 \pm 0.02$ eV. The current-potential characteristic shows an ohmic relationship up to 5000 V/cm, above 5000 V/cm, however, the relationship between dark current and voltage is $i = \sinh(bV)$. By comparing the intensity functions of the photoelectric current on positive and negative polarity of the electrodes of the sand-

wich cell used, a ratio $i_+/i_- = 2.3$ is obtained. The dependence of photoelectric current on wavelength (using filters for measurement) shows that the photoelectric current is produced by photons of wavelength 2025 Å. Thus the transition of iron at 2700 Å does not contribute to the photoconductivity of ferrocene. The mobility of the electron-deficiencies is 0.43 $cm^2/V/sec$, that of the electrons 0.36 $cm^2/V/sec$.

In explaining the photoconductivity it is assumed that on absorption of light excitons result, which diffuse to the surface and dissociate into electrons and defect-electrons. On the basis of the ratio $i_+/i_- = 2.3$, holes were considered to be the major carriers.

"New Polymers of Aromatic and Heterocyclic Compounds and their Electrophysical Properties" was the subject of the paper by *H. Naarmann* and F. *Beck* (Ludwigshafen, Germany). They prepared insoluble, infusible, deep-colored, high-molecular compounds by reductive polymerization of aromatic and heterocyclic compounds (benzene, naphthalene, thiophene, Cu-phthalocyanine, *etc.*) in the presence of Friedel-Crafts catalysts. The degree of polymerization obtained from infrared measurements is about 60 for the polymerisation of benzene, but depends on the reaction temperature and the components used. The interference with polymerization by oxygen and the varying activities of the dehydrogenating agents, which in the series $CuCl_2 < FeCl_3 < PdCl_2$ cause an increase of the degree of polymerization, is noteworthy.

Conductivities of the order of 10^{-1} to 10^{-15} $ohm^{-1}\ cm^{-1}$ (25 °C) for powders at a pressure of 300 atm increase with temperature; the Arrhenius plots gave activation energies between 0.025 and 0.96 eV. The specific conductivity of the compounds increases with the temperature of polymerization (*e.g.* from 10^{-11} $ohm^{-1}\ cm^{-1}$ at 20 °C to 10^{-6} $ohm^{-1}\ cm^{-1}$ at 300 °C) while the energy of activation of the conductivity decreases. Since this effect was recently connected with the relationship between conductivity and chain-length, the connection between conductivity and type of dehydrogenating agent, as well as the effect of the oxygen content of the species to be polymerized, is understandable. On using $PdCl_2$ as the dehydrogenating agent for polymerization a conductivity of 10^{-2} $ohm^{-1}\ cm^{-1}$ is obtained, while with $CuCl_2$ the conductivity is 10^{-11} $ohm^{-1}\ cm^{-1}$; on decreasing the oxygen content the conductivity increases. From the sign of the thermal e.m.f. (which is of the order of up to 125 $\mu V/°C$) it is concluded that the polymers, which also exhibit photoconductivity, are p-type conductors.

In the second plenary lecture *N. Riehl* (Munich, Germany) spoke on "Protonic Semi-Conductors". Since the conductivity of these semi-conductors is due to transitions of protons from one site to another, especially substances with hydrogen bonds, in which the proton can occupy various positions, behave as protonic semi-conductors.

Ice was chosen as the model substance for investigating protonic conductivity. In ice proton transitions account for the high diclectric constant (DK). The activation energy (0.6 eV) of these transitions was determined from the variation of dispersion frequency with temperature. It agrees with the activation energy of conductivity from which it is concluded that the conductivity, too, can be accounted for by proton transitions.

The values recently found for the proton concentration in ice yielded information about the mobility of the protons. It is about fifty times higher than in water and is about 0.1 $cm^2/V/sec$, *i.e.* of the same order as the mobility of electrons in some organic semi-conductors. This result is of great significance for the charge-transfer mechanism in organic molecules of biological importance since hydrogen bonds are present in these as in ice.

J. Mulder (Eindhoven, Netherlands) reported on "The Photoconductivity of Perylene Crystals". The investigations, in which aqueous solutions were used as electrodes, showed that the quantum yield of the photoelectric current of the metastable β-modification of perylene is similar to that for anthracene, namely 10 %, while the value is markedly lower (<2 %) for the stable α-perylene. The spectral sensitivity of the photoelectric current bears a great resemblance to the absorption spectrum. There is a shift in the spectral sensitivity on adsorption of rhodamine B at the positively charged crystal faces.

The ratio of the photoelectric currents with positive or negative polarity of the illuminated electrode ($i_+/i_- > 100$) indicates a preferential hole current in the crystals. Presumably the charge carriers are formed from excitons which diffuse to the positive crystal faces.

The paper by *K. Hauffe* (Frankfurt/Main, Germany) was concerned with "The Influence of Gaseous Atmospheres on the Dark- and Photoelectric Current of Some Phthalocyanines". Measurements of the conductivity of metal-free phthalocyanine and Cu-, Zn-, Ni-, and Fe-phthalocyanines in O_2, NO, NO_2, NH_3, and in vacuum (10^{-5} mm) between 20 and 150 °C gave the following results: O_2 causes a reversible increase in conductivity; by the influence of NO or NO_2 the conductivity is irreversibly increased by 5 to 6 powers of 10, but on subsequent treatment with NH_3 the original value is restored. The influence of the central metal atom on the conductivity is slight; also the effect of the gas is not influenced by the metal atom.

In the third plenary lecture, *J. Kommandeur* (Groningen, Netherlands) dealt with "Donor-Acceptor Effects in Organic and Inorganic Molecular Crystals", which determine the electrical behavior of numerous organic semi-conductors. As examples, pyrene-iodine complexes *(1)* and perylene-iodine complexes *(2)* display high conductivities [specific resistance of *(1)*: 75 ohm·cm, of *(2)*: 8 ohm·cm] and energies of activation for dark conductivity which are of the same order of magnitude as kT at room temperature [*(1)*: 0.07 to 0.14 eV, *(2)*: 0.019 eV]. The energy of activation obtained from the temperature-dependence of conductivity is in good agreement with that derived from ESR measurements, showing a connection between concentration of unpaired spins and concentration of charge-carriers.

The electrical behaviour of donor-acceptor crystals can be discussed in terms of the molionic lattice. These lattices contain ion-pairs (donor-acceptor pairs) together with molecules and, owing to the polarizing action of the ions, are much more stable than purely molecular lattices.

H. Hoegl (Carouge-Genève, Switzerland) reported on the "Photoconducting Properties of Poly-*N*-vinylcarbazoles", determined by electrophotographic methods or by measurement of the light-induced decrease in potential of layers charged by corona discharge. The results from the electrophotographic methods at the same time indicated a potential use of the photoconductors examined in electrophotography. The investigations showed that the spectral sensitivity of thin films (2 to 10 μ) of polyvinylcarbazoles can be shifted by the addition of sensitizers (rhodamine B, *etc.*). Moreover, the photoconductivity is much increased by doping with electron acceptors. The following electron acceptors were effective: Lewis acids (*e.g.* BF_3, $AlCl_3$); nitro compounds (1,3,5-trinitrobenzene, 2-nitroindane-1,3-dione), cyano compounds (tetracyanoethylene; 1,5-dicyanonaphthalene); carboxylic acid anhydrides (tetrachlorophthalic anhydride, *etc.*); esters (tetraethyl ethylenetetracarboxylate); halogen compounds (triphenylchloromethane, *etc.*); quinones (*p*-chloroaniline, *etc.*); keto compounds (benzil, pyrene-3-carboxaldehyde); aza compounds (acridine, *etc.*). Similarly, using electron acceptors as the basic material marked increases of photoelectric sensitivity are measured after doping with electron donors.

An obvious relationship exists between the concentration of electron acceptors and the photoelectric sensitivity of the doped polyvinylcarbazoles. To explain the formation of charge carriers in the doped layers it is assumed that a light-induced electron transition occurs between the vinylcarbazole residues and the acceptor-defects.

In a discussion on the problem of semi-conductor properties of phthalocyanines, *C. Haman* (Dresden, Germany) pointed

to the fact that differing results by different authors were probably due to their disregarding the differing electrical properties of phthalocyanine modifications. For example, measurements of thermal e.m.f. gave the following values: β-form: +50 μV/°C; α-form: +1100 μV/°C; α'-form: +1350 μV/°C; γ-form: +900 μV/°C. A mixture of β- and α-forms gave a negative thermal e.m.f. of −70 μV/°C. While the α'-modification is formed by precipitation from H_2SO_4, the β-modification results from heating the α-form at 280 °C. The γ-modification is obtained by mechanical treatment of the β-form, *e.g.* by grinding with phthalic anhydride.

Structure and Function of the Red Blood Cells

The Institute for Physiological Chemistry and the Institute for Pharmacology and Toxicology of the Humboldt University were the organizers of the IVth International Symposium on Structure and Function of the Red Blood Cells that was held in Berlin (Germany) from August 25th to 27th, 1964 under the auspices of the Gesellschaft für experimentelle Medizin der DDR. Of the 130 participants 34 were foreign guests. The scientific program was organized by *S. Rapoport* and *F. Jung*. Problems of transport through membranes, of metabolic regulation, and of the structure of red blood cells were of foremost interest.

W. Wilbrandt (Bern, Switzerland) described the three possibilities for transport of substances (free diffusion, mediated diffusion, exchange diffusion with active transport). He dealt particularly with sugar transport with the participation of carriers and was able to show that the speed of transport under conditions of constant concentrations within and without the membrane decreased with increasing absolute concentration. The kinetics of transport mediated by carriers did not correspond to enzyme kinetics. The transport of one substrate (D-glucose) occurring in high concentration, is competitively accelerated by a second substrate (D-mannose). This acceleration changes to competitive inhibition at saturation with the second substrate. Investigations and calculations, jointly with *Kotyk* (Prague), indicate a mechanism involving 1 carrier molecule per 2 substrate molecules.

W. F. Widdas (London) dealt with the irreversible inhibition of glucose transport by 2,4-dinitrofluorobenzene (DNFB) and *N*-ethylmaleimide. ^{14}C-Labelled DNFB was recovered in the butanol-soluble lipid fraction. The mechanism of this transport inhibition is not yet clear.

K. Repke and *H. J. Portius* (Berlin, Germany) reported that the inhibitory action of steroid lactones on transport-ATPase and the ion transport in erythrocytes depends on the presence of a conjugated unsaturated lactone ring occurring in the 17β-position. Ca^{2+} acts synergistically, K^+ antagonistically. According to *Steinbrecht* (Magdeburg, Germany), the permeation of 2-deoxy-D-ribose into rabbit erythrocytes is a simple diffusion process with a large entry velocity.

F. Müller (Leipzig, Germany) found that the inhibition by strophantin of galactose and ion transport is counteracted by fructose. Whether a true coupling between monosaccharide and ion transport is involved has not yet been elucidated. Iodoacetate and 2,4-dinitrophenol inhibit the transport.

S. Rapoport (Berlin, Germany) described the following principles for the regulation of the metabolism of the red blood cell: 1. Regulation by synthesis and breakdown of enzymes. Red blood cells are unsuitable for the investigation of genetic control of enzyme induction and repression because of the lack of DNA. On the other hand, they have proved to be particularly suitable for the investigation of metabolic regulation by enzyme degradation which is characteristic of the process of maturation. – 2. Regulation by changes of enzyme activity without participation of substrates, cofactors and metabolites. In this connection, the formation of active enzymes from precursors, changes in activity through polymerisation or depolymerization, and unmasking of enzymes was discussed. At the same time reference was made to the regulation by compartmentization, *i.e.* to the limitation of metabolism by membranes. – 3. Regulation by the effect of immediate or later metabolites and cofactors on the enzyme (comparable with the allosteric effect).

The contributions on the regulation of glycolysis led from different starting points to concordant conclusions:

1. Glucose transport is not limiting for glycolysis. *Augustin* and *Häcker* (Magdeburg, Germany) came to this result from a comparison of maximal glycolysis capacity and maximal transport capacity. *L. Garby* and *C. H. de Verdier* (Uppsala, Sweden) concluded the same from the fact that the glucose gradient at the membrane changes only slightly with marked alterations of the external glucose concentration.

2. The rate of glycolysis is influenced in some species by the phosphate concentration. *L. Garby* and *C. H. de Verdier* found an increase of glycolysis with increasing phosphate concentration and on addition of EDTA. They explain this effect by a fall in the actual Ca^{2+} concentration and a consequently higher activity of Mg^{2+} ions on hexokinase.

G. Jacobasch and *J. Syllm-Rapoport* (Berlin, Germany) found the same effect of inorganic phosphate with erythrocytes from patients with short-term vitamin D deficiency rickets. Triose phosphate dehydrogenase is discussed as the enzyme involved.

Investigations on the relationship between amino acid breakdown, respiration and carbohydrate metabolism showed that the amino acids, as endogenous substrates of respiration, participate to different degrees in the total CO_2 formation (*M. Schultze* and *J. Scholz*, Berlin). The participation of some amino acids changes during maturation. Among the free amino acids of the reticulocyte, glycine occurs in the greatest concentration, and at the same time, plays the biggest role in CO_2 formation (*R. Buchmann*, Berlin). The concentrations of free amino acids decrease in the course of maturation. The same occurs on short term incubation. Addition of α-ketoglutarate or glucose keeps the concentrations of free amino acids low for longer incubation times, so that a prolonged synthetic activity must be assumed. The same may be observed with 2,4-dinitrophenol. The cause in this case certainly is a reduced amino acid liberation from the stroma since this is energy-dependent.

[u-^{14}C]Serine and [3-^{14}C]serine yield hydroxylamine and glycine (*M. Schultze* and *M. Müller*, Berlin), which are used in the biosynthesis of purines and porphyrins and form CO_2 to a large extent. In addition, serine forms pyruvate which again yields CO_2. As the addition of glutamine leads to an increased glycine concentration, glutamine causes either an enzyme inhibition or brings about a regression of the Shemin cycle. Addition of methylene blue increases amino acid breakdown in the soluble phase, whereby CO_2 formation, from the substrates of the citric acid cycle, is diminished.

L. Ababei (Bucharest, Rumania) showed that no equilibrium is established between lactate and pyruvate in the erythrocyte. The reason lies in the presence of NADH- and NADPH-oxidases, which were enriched. Besides, two lactic dehydrogenases with different coenzyme specificities (NAD and NADP) were detected in erythrocytes.

In investigations on the 2,3-diphosphoglycerate-splitting enzyme of human erythrocytes, the question of the importance of the diphosphoglycerate cycle in erythrocyte glycolysis was taken up again.

H. Roigas (Berlin) was able to show that addition of ADP and NADH in physiological concentrations can increase the small 2,3-PGase [1] activity in haemolysates up to five-fold. This effect is interpreted as the degradation in the direction pyruvate-lactate of accumulated 3-phosphoglycerate, which inhibits the 2,3-PGase competitively. *G. Sauer* and *D. Scholz* (Berlin), who purified erythrocyte 2,3-PGase up to 220 times, came to the same conclusions. The findings indicate a preference for the diphosphoglycerate pathway in intact erythrocytes. *C. H. de Verdier* (Uppsala, Sweden) confirmed the presented data in a detailed discussion from his own investigations with purified PGase from human erythrocytes. The existence of two isoenzymes seems probable. It can be assumed that the 2,3-PGA [2] pathway is only of small significance for red blood cells (sheep erythrocytes) which contain only traces of 2,3-PGA (*G. Jacobasch* and *S. Rapoport*, Berlin).

S. Rosenthal, *K. Jagemann*, and *G. Heinemann* (Berlin) reported on enzymatic determinations of the purity of reticulocyte ribosomes (rabbit) and characterized a ribosomal RNase. Pure ribosome preparations (50 % protein, 50 % RNA) contain only 0.1 % (referred to the whole haemolysate) or less of acid phosphatase. Such pure ribosomes possess an RNase, which is activated at pH 7.5 by monovalent cations (tris, collidine, K^+, Na^+, Li^+) at varying degrees.

[VB 870/174 IE]

German version: Angew. Chem. 77, 138 (1965)

[1] 2,3-PGase = 2,3-diphosphoglyceratase.

[2] 2,3-PGA = 2,3-diphosphoglycerate.

The Chemistry of Carbohydrates

An international symposium on the chemistry of carbohydrates was held from July 13th to 17th, 1964 in Münster (Germany). Participants from nineteen countries heard almost fifty lectures on problems from the fields of mono- and polysaccharides, amino sugars, and the biochemistry of carbohydrates.

From the lectures:

K. Freudenberg, Heidelberg (Germany), reported on the linkage between lignin and carbohydrates in plants. During the formation of lignin by dehydrogenation of *p*-hydroxycinnamyl alcohols, *p*-quinone methides occur as intermediates which can combine, for example, with one or two molecules of sucrose to give aliphatic ether-type compounds which again undergo phenol dehydrogenation and are condensed into the growing lignin molecule. Lignin is grafted onto the polysaccharides in wood by the same mechanism.

G. G. S. Dutton and *A. M. Unrau*, Vancouver (Canada), investigated the structures of synthetic polysaccharides (glucosans, xylans, mannans, and arabans) which had been prepared by *Mora* et al. by polymerization of monosaccharides at 120 °C using phosphoric acid as catalyst. The structures of the products were found by hydrolysis of their methyl derivatives, reduction with $NaBH_4$, oxidation of the sugar alcohols with periodate, and renewed reduction with $NaBH_4$. The products of this series of operations were separated by gas chromatography and revealed that all the polysaccharides are strongly branched and that their monosaccharide constituents are mainly in the furanoid form.

E. Husemann and *G. M. J. Müller*, Freiburg/Breisgau (Germany), polycondensed 2,3,6-tricarbanilylglucose with P_4O_{10} in chloroform/dimethylsulfoxide. The products obtained had degrees of polymerization of 200–600 and could be converted by alkaline hydrolysis into compounds which were comparable with strongly degraded celluloses. After partial hydrolysis, cellobiose and cellotriose were obtained. The polymers are therefore β-1,4-polyglucosans and can be degraded by *Acetobacter xylinum*, for example, but not with amylase.

P. S. O'Colla and *E. E. Lee*, Galway (Ireland), reported on the polymerization of β-1,2,3,4-tetra-*O*-acetylmannose and -galactose with $ZnCl_2$ as catalyst. The mannose derivative yields oligosaccharides and a polymer. Degradation of the polymer with periodate and subsequent methylation revealed that it consists mainly of an α-1,6-mannan with a degree of polymerization of 10.

E. J. Bourne et al., London (England), studied the structures of branched dextrans by hydrolysis with acid, acetolysis, methylation, and oxidation with periodate. Catalytic oxidation and hydrolysis afforded α-D-glucuronido-D-glucoses which represent the points of branching in the dextrans. α-1,3-Branched dextrans submitted to oxidation with periodate, reduction, and partial hydrolysis yielded α-D-glucosidoglycerol and α-isomaltosidoglycerol. The degradation products supply information on the size and distribution of the side chains in the dextrans.

The structure of the plant gum from *Sterculia* species was studied by *G. O. Aspinall* et al., Edinburgh (Scotland). The gum is a partially acetylated polysaccharide, containing D-glucuronic acid, D-galacturonic acid, D-galactose, and L-rhamnose. Isolation of the products of hydrolysis of the methylated polysaccharides indicated the type and extent of branching in the gum.

E. Percival, Englefield Green (England), isolated a β-1,3-linked glucosan and a mannan containing 27 % uronic acid and 7.5 % sulfate esters from *Phaeodactylum tricornutum*, a marine alga. The glucuronidomannan containing sulfuric acid is the first polymer of this type that has been encountered in nature.

I. Bremner and *K. C. B. Wilkie*, Old Aberdeen (Scotland), extracted the stems of *Pteridium aquilinum*, a species of fern, and isolated two hemicellulose-type polymers, a water-soluble xylan, and a branched glucomannan, in which mannose and glucose in a ratio of 4:1 are linked by β-1,4-linkages. The xylan consists of β-1,4-linked xylose residues, some of which are etherified glycosidically in the 2-position with 4-methyl-D-glucuronic acid residues.

A. S. Perlin and *W. Klöker*, Saskatoon (Canada), investigated the carbohydrates from the spores of *Puccinia graminis tritici*, the fungus which causes wheat-rust. The polysaccharides extracted contained D-mannose linked by β-1,4- and occasionally by β-1,3-linkages, together with smaller amounts of D-glucose and D-galactose. Numerous mono- and oligosaccharides including xylose, ribose, and glucosamine were isolated after partial acetolysis and hydrolysis of the residue.

V. C. Barry and *J. E. McCormick*, Dublin (Ireland), oxidized simple glycosides with periodate and treated the products obtained with isonicotinylhydrazine and thiosemicarbazide. They thus obtained condensation products which had previously been isolated after oxidation of polysaccharides with periodate. Hence the two aldehydic groups in the oxidized sugar react with only one molecule of the hydrazine compound to form a cyclic derivative and not a bis-hydrazone.

G. Henseke and *G. Hanisch*, Freiberg/Sachsen (Germany), used dimethylsulfoxide for oxidations in the sugar series. If 1,2-*O*-isopropylidene-6-*O*-tosyl-D-glucose is converted into its 5,6-epoxide, the latter can be oxidized with dimethylsulfoxide in the presence of boron trifluoride to give the 1,6-dialdose. Analogously, α-methyl 2,3-epoxy-4,6-*O*-benzylidene-alltopyranoside can be oxidized to the corresponding mannopyranosidc. Simultaneously, migration of the formyl residue into the interior of the sugar chain occurs with formation of 1,5:2,6-dianhydro-3,4-D(L)-*threo*-hexodiulose.

B. Lindberg, Stockholm (Sweden), treated carbohydrates, *e.g.* glucose, with sulfite at various temperatures and pH values. This results in oxidation of hydroxyl or aldehydic groups, and rearrangements and sulfonations occur.

H. Zinner, Rostock (Germany), reported on the synthesis and reactions of di-*O*-benzylidenepentonic acids, which are prepared by oxidation of the di-*O*-benzylidenepentoses with chromic oxide in dimethylformamide. The acids yield the methyl esters with diazomethane; when treated with ammonia or hydrazine hydrate in methanol, the esters give rise to the di-*O*-benzylidenepentonamides and the corresponding hydrazides. Reduction of these three derivatives of the acids with $LiAlH_4$ yielded the dibenzylidenepentitols and their 1-deoxy-1-amino and 1-deoxy-1-hydrazino derivatives. The structures of the dibenzylidene compounds all correspond to the rules set forth by *R. M. Hann* and *C. S. Hudson* for the formation of cyclic acetals of polyhydric alcohols.

The last two unknown 3-*O*-methyl-6-deoxyhexosides with the *allo*- and *gulo*-configurations have been synthesized by *H. Kaufmann* and *T. Reichstein*, Basel (Switzerland). Of the eight possible stereoisomers with two antipodes each, six isomers are known either from natural sources or from syntheses. The 3-*O*-methyl-6-deoxy-D-allose was made by partial methylation from 3-methyl 6-deoxy-D-allopyranoside. For the synthesis of the 3-*O*-methyl-6-deoxy-D-gulose, β-methyl D-glucopyranoside was converted into β-methyl 6-deoxy-3,4-anhydro-D-galactopyranoside, which was treated with sodium methoxide to yield the D-gulo derivative by diaxial opening of the epoxide ring.

N. K. Kochetkov, Moscow (U.S.S.R.), reported on a new synthesis of glycosides. 1,2-Alkylidene orthoacetates of acetylated monosaccharides react with alcohols in the presence of $HgBr_2$ in nitromethane to give 1,2-*trans*-glycosides. Di- and oligosaccharides can be synthesized using the same reaction.

M. Schulz, Berlin-Adlershof (Germany), treated α-acetobromoglucose *(1)* with t-butyl hydroperoxide in benzene in the presence of silver carbonate and obtained t-butyl tetra-*O*-acetylperoxyglucoside. The reaction of *(1)* and t-butyl hydroperoxide in nitromethane/collidine, on the other hand, yielded tri-*O*-acetyl-1,2-[t-butylperoxyortho-*O*-acetyl]-α-D-glucose. The carbon atom in position 1 of the sugar is split off from the peroxyglucoside with 0.01 N sodium methoxide in ethyl formate. This reaction is a new sugar degradation of general applicability.

V. Prey, Vienna (Austria), treated di-*O*-isopropylideneglucose and -fructose with trimethylchlorosilane, dimethyldichlorosilane, and methyltrichlorosilane and obtained the corresponding methylsilyl compounds containing one, two, or three molecules of sugar. Similar derivatives are formed with $SiCl_4$ in which one silicon atom is linked to four molecules of sugar.

R. Bognár, Debrecen (Hungary), reported on the synthesis and properties of onic acid derivatives. Acetylated onic acids can be converted with dichloromethyl methyl ether into the acid chlorides, which are suitable as acylating agents for amines, phenols, and monosaccharides with only one free hydroxy group; 1- and 6-gluconyl-D-glucose were prepared in this way. Tetra-*O*-acetylgalactonyl chloride reacts with NaN_3 to form the azide, which reacts with acetic anhydride to yield *N*-[D-galactopenta-*O*-acetyloxyamyl]acetamide. The latter can be degraded with ammonia to D-lyxosyldiacetamide or with HCl to D-lyxose.

B. R. Baker et al., Buffalo, N.Y. (U.S.A.), studied the conditions under which *cis*-2,3-diamino sugars are formed with regard to neighboring group effects and conformation. α-Methyl 2-*O*-mesyl-3-deoxy-3-amino-4,6-*O*-benzylidene-D-altroside (with a *trans*-diaxial conformation of the substituents on C-2 and C-3 and with a urea, thiourea, guanido, or nitroguanido residue instead of the amino group, if desired) undergoes cyclization under strongly alkaline conditions to give an aziridine derivative, with formation of an anion as an intermediate. In the presence of an acid acceptor, *e.g.* pyridine, an oxazolidine, imidazolidine, or thiazolidine derivative is formed. By contrast, β-methyl 2-*O*-mesyl-3-deoxy-3-thioureido-4,6-*O*-benzylidene-D-glucoside, which has a *trans*-diequatorial conformation of the substituents, does not form an aziridine but yields only a thiazolidine derivative under both sets of conditions.

The synthesis and properties of epimino sugars were studied by *L. Hough* et al., Bristol (England). α-Methyl 2-deoxy-2-acetamido-3-*O*-mesyl-4,6-*O*-benzylidene-D-altroside reacts with sodium ethoxide in ethanol with inversion of the configuration at C-3 to give a mixture of an *N*-acetylepimino sugar (an aziridine derivative) and an oxazoline derivative. *trans*-Diaxial ring opening of the *N*-acetylepimine with hydrogen halide leads to a mixture of the 2-halogeno-3-acetamido and 2-acetamido-3-halogeno derivatives of altrose.

R. D. Guthrie and *D. Murphy*, Brighton (England), treated α-methyl 2,3-dideoxy-2,3-epimino-4,6-*O*-benzylidene-D-alloside and the corresponding mannoside with azide to form the corresponding aminoazido sugars. Subsequent reduction yielded the same 2,3-diaminoaltroside from both starting materials, hence *trans*-diaxial opening of the epimino ring has occurred here, too.

H. Paulsen, Hamburg (Germany), reported on the reactions of 5-aminopentoses and 5-aminohexoses, which occur mainly in the form of piperidinoses and readily lose three molecules of water to yield derivatives of 3-hydroxypyridine. In addition, an Amadori rearrangement of the piperidinoses can also take place leading to derivatives of 4,5-dihydroxy-3-oxopiperidine. This reaction proceeds via a Δ^1-piperideine which rearranges to the final product.

In connection with the work by *Paulsen*, *Hanessian*, and *Haskell*, the investigations of *W. A. Szarek* and *J. K. N. Jones*, Kingston, Ont. (Canada), are of interest. These authors oxidized 1-deoxy-1-acetamido-D-rihitol carefully with periodate and obtained 4-deoxy-4-acetamido-L-erythrose, a sugar with nitrogen as hetero-atom in a five-membered ring. 4-Deoxy-4-acetamido-D-threofuranose has an analogous structure. 2-Oxopentose derivatives, *e.g.* 5-deoxy-5-acetamido-D-*threo*- and -L-*erythro*-2-oxopentose, on the other hand, do not form a five-membered nitrogenous heterocycle.

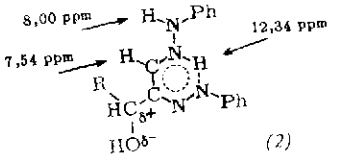
R. L. Whistler, Lafayette, Ind. (U.S.A.), reported on syntheses of pyranoses containing sulfur as hetero-atom in the ring (reaction of 5-*O*-tosylpentofuranose derivatives with sodium benzylmercaptide to give 5-mercapto sugars and cyclization to thiapyranoses) and on attempts to prepare thiafuranoses and hexose derivatives with a seven-membered ring containing sulfur. Thus, for example, 1,2-*O*-isopropylidene-5-*O*-tosyl-6-*O*-tritylglucofuranose reacts *via* an olefinic intermediate to give 5-deoxy-6-mercapto-D-glucose, which undergoes ring closure to yield a glucosan-type compound containing sulfur.

J. E. Hodge et al., Peoria, Ill. (U.S.A.), examined the degradation products obtained from sugars that had been prepared by Amadori rearrangement with secondary amines. L-Rhamnose yielded diacetyl and a reductone containing nitrogen which is derived from hydroxydiacetyl, together with 2,5-dimethyl-4-hydroxy-3(2*H*)-furanone. Maltose and lactose give rise respectively to 2-acetyl-3-hydroxyfuran and 2-methyl-3-hydroxy-1,4-pyrone. Under the conditions used,

all the aldo- and ketohexoses examined afforded betaine-like aminohexose reductones, *i.e.* methyl derivatives of reductinic acid containing nitrogen. It is assumed that the formation of these compounds starts with 2,3-enolization of the products of the Amadori rearrangement. The olefinic diols are in equilibrium with the tautomeric 3-oxo compounds, from which the nitrogen is eliminated to form α-diketone intermediates.

There is a close connection between the work by *Hodge* and the studies by *H. Simon* and G. *Heubach*, München (Germany), on the formation of alicyclic and open-chain reductones containing nitrogen from hexoses and secondary amines. The mode of formation of *N*-[1-methyl-1,2,3-trihydroxycyclopent-2-en-4-ylidene]piperidinium betaine, an aminohexose reductone, was clarified further by its synthesis from diacetylformoin and piperidine. The structure of the nitrogenous reductone derived from hydroxydiacetyl that was found by *Hodge* was proved by its synthesis from diacetyl bromide or D-erythrose and an amine.

L. Mester, Paris (France), spoke about the structure of sugar osazones. Long-range spin-spin coupling between the proton on C-1 and the non-chelated NH proton was detected in the nuclear magnetic resonance spectra of sugar osazones using the double resonance technique. The weak resolution ($J \approx 1$ cps) of the signal for the proton on C-1 disappears on deuteration of the non-chelated NH proton, whose position is identical with that of the methyl group in 1-methyl-1-phenyl-2-phenylosazones. These results indicate a quasi-aromatic chelate structure for sugar osazones such as is expressed by Fieser's chelate formula *(2)*.



(2)

The course of osazone formation was studied by *F. Micheel* and *I. Dijong*, Münster (Germany), starting from 4,6-*O*-benzylidene-D-glucose. They found that the reaction is initiated by partial decomposition of phenylhydrazine by disproportionation into aniline, ammonia, benzene, and nitrogen, transamination of the 4,6-*O*-benzylidene-D-glucose phenylhydrazone initially formed to give phenylamino-4,6-*O*-benzylidene-D-glucoside, and Amadori rearrangement of the latter compound. The phenylhydrazone of the product of the Amadori rearrangement reacts further with phenylhydrazine in acidic solution to give the osazone. The dehydrogenation occurring during osazone formation was studied using [^{14}C]-phenylhydrazine. This dehydrogenation is not part of an intramolecular redox reaction; instead, the phenylhydrazone formed from the product of the Amadori rearrangement is dehydrogenated by free phenylhydrazine.

J. O. Deferrari, Buenos Aires (Argentina), reported on the reaction of methanolic ammonia with acylated disaccharides. Ammonolysis of octa-*O*-benzoylcellobiose produced mono-*O*-benzoylcellobiose together with a mixture of cellobiose, *N*-benzoylcellobioside, and an *N,N'*-dibenzoyl derivative. Following the analogous treatment of hepta-*O*-benzoylmaltose, however, only partially debenzoylated derivatives could be isolated and no nitrogenous products were detected.

D. Horton, *M. L. Wolfrom* et al., Columbus, Ohio (U.S.A.), examined the properties of 1-thio derivatives of aldoses and amino sugars. Condensation of 2-deoxy-2-amino-acetohalogeno sugars with thiourea leads to 2-[2-deoxy-2-amino-β-D-glucosido]-2-isothiourea derivatives, which undergo an intramolecular rearrangement in neutral solution to 1-thio-2-deoxy-2-guanidinoaldose derivatives. Thio sugars of this kind can be used to produce acetohalogeno sugars or non-acetylated halogeno sugars under mild conditions. They may also be of importance as radiation-protecting substances.

P. F. Lloyd and *S. Peat*, Bangor (Wales), carried out a number of syntheses starting from 2-deoxy-2-[2,4-dinitrophenylamino]-D-glucose. The corresponding acetobromo derivative *(3)* reacts with alcohols to give either α- or β-glycosides, depending on the conditions used. These reactions were used to synthesize disaccharides and to elucidate the structures of aminopolysaccharides. For example, 6-[2-deoxy-2-amino-α(β)-D-glucosido]galactose can be prepared from *(3)* and 1,2:3,4-di-*O*-isopropylidene-D-galactose with pyridine as catalyst.

I. Jezo, Bratislava (Czechoslovakia), studied the reaction of sucrose with aqueous solutions of ammonia, methylamine, ethylenediamine, and ethanolamine at elevated temperatures. The sucrose is first hydrolysed, and then derivatives of D-glucosamine, D-fructosamine, *N*-glucosides, and *N*-fructosides are formed. Intermolecular or intramolecular condensation of these amino sugars and subsequent dehydrogenations or isomerizations then lead to the formation of pyrazine and imidazole derivatives.

H. Weidmann, Graz (Austria), prepared ulononitriles by dehydration of uronamides or ω-aldoaldoside oximes with dibromotriphenylphosphorane, benzenesulfonyl chloride, sodium borohydride, or trifluoroacetic anhydride.

J. Montreuil et al., Lille (France), investigated the structure of ovomucoid. Mild hydrolysis led to numerous sugars. Enzymatic degradation of ovomucoid afforded three glycoproteins; one of these contained only aspartic acid, the second aspartic acid and threonine in a 1:1 ratio, and the third aspartic acid and cystine in a 1:1 ratio. There is probably a general structural scheme for the carbohydrate moiety of these three glycoproteins.

E. D. Kaverzneva and *V. H. Lupac*, Moscow (U.S.S.R.), proved that, in contrast to the arrangement in ovalbumin, there are various types of bonding between the sugar and peptide chains in ovomucoid. The carbohydrate fraction in ovomucoid (21 %) is much higher than that in ovalbumin (3.15 %). Treatment of ovomucoid with hydroxylamine did not yield any free polysaccharides, but only high molecular-weight glycopeptides and low molecular-weight peptides. Glycopeptides were also obtained by the action of anhydrous hydrazine, but again, no free polysaccharides were released. It appears from these results that there are no ester linkages between the protein and carbohydrate.

F. Cramer et al., Göttingen (Germany), studied the rates of hydrolysis of protecting groups for hydroxy groups and phosphoric acid derivatives, since selective protecting groups which can be removed under mild conditions are required for the stepwise synthesis of oligonucleotides. Substituted benzaldehydes are suitable for protecting 2'- and 3'-hydroxy groups, while t-butyl and benzhydryl groups are acid-resistant protecting groups for phosphoric acid derivatives.

K. Onodera, Kyoto (Japan), synthesized numerous purine and pyrimidine nucleosides from 1-trichloroacetyl sugars. 1-*O*-trichloroacetyl-2,3,4,6-tetra-*O*-acetyl-α-D-glucose reacts with purine bases in the presence of $ZnCl_2$ to give *trans*-nucleosides (C-1'-C-2' *trans*). A mixture of the *cis*- and *trans*-derivatives is formed with 6-benzamidopurine and acidic catalysts. *trans*-Nucleosides are also obtained with pyrimidines from the 1-*O*-trichloroacetyl derivatives of D-glucose and D-xylose in the presence of acidic catalysts (*p*-toluenesulfonic acid).

L. Vargha and *J. Kuszmann*, Budapest (Hungary), condensed 6-benzamido-9-chloromercurypurine with 1,2-dideoxy-1,2-dichloro-3,5-di-*O*-acetyl-D-arabofuranose and obtained a mixture of α- and β-9-[2'-deoxy-2'-chloro-3',5'-di-*O*-acetyl-D-arabofuranosido]benzoyladenine, which can be separated into its components after Zemplen hydrolysis. Catalytic hydrogenation then gives either α- or β-[2'-deoxy-D-ribofuranosido]adenine. Both anomers react with sodium methoxide to give the α- and β-2',3'-epoxy-D-ribose compounds, whose specific rotations are not in accordance with Hudson's rule.

J. E. Courtois et al., Paris (France), studied trehalose and the properties of trehalases. In order to obtain information about the behavior of these enzymes, chemical or biochemical methods were used to prepare derivatives of α,α-trehalose in which the symmetry of the molecule relative to the glycosidic bond is disturbed. The purification of 6-*O*-monotosyl- and 6-*O*-monomesyl-trehalose required extensive chromatographic separations. α-D-Galactosido-6-trehalose was made by biosynthesis.

J. Kiss, Basel (Switzerland), reported on the chemical synthesis of thiamine-activated aldehydes, hydroxyaldehydes, and α-ketocarboxylic acids. These carbonyl compounds form a covalent bond with C-2 of the thiazole ring in thiamine. The products act as activated derivatives and are therefore particularly suitable for use in biochemical reactions. 2-Hydroxymethyl-4-methyl-5-[β-hydroxyethyl]thiazole was converted by oxidation into the 2-formyl compound ("activated formaldehyde"), which produces derivatives of methanol with Grignard reagents. These methanol derivatives can be converted into homologues of activated formaldehyde.

Z. Nikuni, Sakai (Japan), reported on some unusual illnesses. In 1960, a material, which gave with iodine the blue coloration typical of starch, was extracted for the first time from the granulates of wounds in a female patient. Systematic clinical, pathological, microbiological, enzymatic, and chemical investigations revealed that the material isolated was in fact starch which could be separated into amylose and amylopectin fractions. There are only slight differences in the absorption maxima of the iodine complexes formed from this human starch and potato starch. The infrared spectrum of human starch is identical with that of rice starch. No differences were observed in the degradation products obtained with α-amylase from human and potato starch. At approximately the same time, a "cotton-producing disease" was discovered, during which cellulose is formed in wound granulates in humans. The cellulose fibres are 1–3 cm long. Following acetylation and hydrolysis, octa-*O*-acetylcellobiose was isolated in 36–40 % yield.

M. L. Wolfrom, Columbus, Ohio (U.S.A.), reviewed the elucidation of the structure of heparin. New investigations were conducted in which the polysaccharide was partially desulfurized, reduced with diborane, and partially hydrolysed with acid. Two disaccharides were isolated: α-D-glucosido-1,4-α-D-glucosamine and α-D-glucosaminido-1,4-α-D-glucose. Every tetrasaccharide unit in heparin (made up of two amino sugar and two uronic acid residues) contains five sulfuric acid groups, two of which are attached to the nitrogens. Two sulfato groups are probably attached at C-6 of the two amino sugars and one sulfato group is at C-2 of one of the two uronic acid residues.

A. Klemer, Münster (Germany), reported on chemical studies of chondroitinsulfuric acid-protein complexes in connection with investigations of arteriosclerosis and ageing processes. No difference was observed in the nature of chromatographically pure chondroitinsulfuric acid-protein complexes isolated from the water-soluble fraction (which amounts to one-third of the fresh weight) of normal and arteriosclerotic human aortas. There was only a difference in yield, which was about twice as high from diseased aorta (0.25 %) as from healthy aorta (0.13 %). Extraction of the water-insoluble residue with an aqueous solution of calcium chloride gave another fraction containing mucopolysaccharides. The chondroitinsulfuric acid A-protein complexes isolated from this fraction (0.4 % from normal and 0.1 % from diseased aorta) had no differences in chemical composition or molecular weight.

In order to explain rearrangement reactions of unsaturated carbohydrate derivatives, *H. Isbell*, Washington, D.C. (U.S.A.), in 1943 proposed an electron transfer from positions of high to positions of low electron density in the molecule. This electron transfer would be coupled with the addition and liberation of ions. The same hypothesis may serve to interpret the rearrangement of phenylhydrazones of inositol derivatives into olefinic and aromatic phenylazo compounds.

A. B. Foster et al., Birmingham (England), determined the absolute configurations of 2-phenyl-1,3-dioxane and -1,3-dioxolane derivatives using NMR spectroscopy. The bonding shift δ of the signal of the benzyl proton is 4.98–5.25 ppm for 2-phenyl-1,3-dioxane derivatives with equatorial substituents in the 4-, 5-, 4,5- and 4,6-positions. 2-Phenyl-1,3-dioxolane (with *cis*-orientation of the benzyl proton and the hydrogen atoms at C-4 and C-5) exhibits only one signal at δ = 5.34. Products substituted at C-4, on the other hand, give signals at δ = 5.33–5.38 and 5.48–5.54 ppm (for *cis*- and *trans*-orientation of the benzyl proton and the substituents at C-4). These data were used to determine the absolute configurations of diastereoisomers of benzylidene derivatives of carbohydrates.

C. T. Greenwood et al., Edinburgh (Scotland), investigated the influence of ions on aqueous solutions of starch. The molecular size of the starch components can be estimated by viscosity measurements in alkaline solution. However, the viscosity number of potato amylose depends largely on the hydroxyl ion concentration, because this polysaccharide behaves as a polyelectrolyte. Additions of KCl eliminate alterations in the viscosity number. Light-scattering and sedimentation measurements showed that these changes in the viscosity number are due to alterations in the conformation of the molecules.

H. Scharmann, Hamburg (Germany), described the mass spectra of numerous derivatives of mono- and disaccharides. Permethylated sugars are best suited for mass spectroscopy, and the combination of this technique with gas chromatography permits investigation of minute amounts of material. Comparison of the mass numbers of the fragmentation products obtained from unlabelled and specifically deuterated monosaccharides proved an aid to the derivation of the fragmentation mechanism involved. The results can largely be applied to disaccharides as well. [VB 850/189 IE]

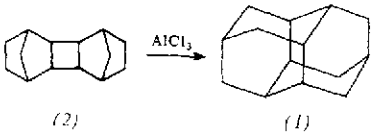
The Synthesis of Pentacyclo[7.3.1.1^{4,12}.0^{2,7}.0^{6,11}]tetradecane

P. v. R. Schleyer, Princeton, N.J. (U.S.A.) [1]

The preparation of "congressane" *(1)* (pentacyclo-[7.3.1.1^{4,12}.0^{2,7}0^{6,11}]tetradecane), a relative of adamantane also possessing the diamond structure, was reported. The name "congressane" comes from the use of *(1)* as the official Emblem of the XIXth International Congress of Pure and Applied Chemistry, held in London in July, 1963 [2]. The method used to make the compound was analogous to the isomerization of tetrahydrodicyclopentadiene to adamantane by the action of strong Lewis acid catalysts [3]. Norbornene was converted photochemically in the presence of photosensitizing agents to stereoisomeric dimers of structure *(2)*. When treated with $AlCl_3$ some isomers of *(2)* gave large quantities of tar, but others gave a cleaner reaction. From these reactions small amounts of a high melting substance were isolated [4].



(2) *(1)*

[1] At present (1964–1965) Fulbright Research Fellow, Institut für Organische Chemie der Universität München (Germany).

[2] See *V. Prelog*, Pure appl. Chem. 6, 545 (1963).

[3] Review: *R. C. Fort, Jr.* and *P. v. R. Schleyer*, Chem. Reviews 64, 277 (1964).

[4] Coworkers: *C. Cupas*, Princeton University; *D. J. Trecker*, Union Carbide Corporation, West Virginia (U.S.A.).

The properties of this new material, very similar to those of adamantane [3], were consistent with those expected of congressane *(I)*: melting point 236–237 °C; very simple infrared spectrum with only 6 bands in the 5000–700 cm^{-1} region; a relatively sharp (w_h *ca.* 3 cps) single peak in the nuclear magnetic resonance spectrum (at 8.32 τ); and a mass spectrum indicating a very stable ring skeleton, since the parent peak at m/e = 188 not only was the base peak, but its intensity was more than three times greater than that of any other ion. The congressane structure *(I)* was proven for the new material by X-ray analysis [5].

The Effect of Magnetic Susceptibility on Proton Resonance; Magnetic Measurements on New Organic Radicals

H. J. Friedrich, Würzburg (Germany)

Owing to magnetic susceptibility, proton resonance signals measured in cylindrical cells are shifted by $(\Delta H/H)_S = c \cdot \Delta\chi_V$. The susceptibility shift factor c was estimated from the proton resonance shifts of tetramethylsilane in solvents of varying volume susceptibility and from the proton resonance shifts of various standard substances produced by Goldschmidt's radical $(H_5C_6)_2N-\dot{N}-C_6H_2(NO_2)_3$ in various solvents [1]; the value found was 2.09 ± 0.1. It agrees with that derived from theory, *viz.* c = 2 π/3. Interfering effects on the susceptibility shift may be exerted by magnetic anisotropy and by electrical polarization of the medium and when the unpaired electron has a spin density on the resonating proton.

This method can be used to estimate the magnetic susceptibility of organic free radicals [2]. The radical cations prepared by *Hünig* [3] were examined in this way. The susceptibilities measured are indicative of monomeric free radicals with one unpaired electron [4]. Of the verdazyl radicals prepared by *Kuhn* and *Trischmann* [5], 1,3,5-triphenylverdazyl and 1,3,5,6-tetraphenylverdazyl gave susceptibility values for monomeric radicals with one unpaired electron in the concentration range from 3 to 12 mg/l.

The Synthesis of Molecularly Uniform Polymers

G. V. Schulz, Mainz (Germany)

The synthesis of uniform polymers, *i.e.* of macromolecules with all chains of equal length, by stepwise addition or condensation has so far led into molecular-weight ranges of only a few thousand. To get into the range $M = 10^5$–10^6, chain reactions can be used under the following conditions: chain initiation and termination must be regulated in such a way that the *duration of growth* is exactly the same for all molecules; in addition, concentration and temperature must be controlled so that the *rate of growth* is equal for all molecules. However, even under ideal conditions, a narrow distribution in the molecular weights is unavoidable (Poisson distribution). Two series of experiments were described which aimed at attaining such a Poisson process; one involved a free-radical, the other an anionic polymerization.

According to *Bianchi*, *Price*, and *Zimm*, a free-radical Poisson process exists in emulsion polymerization when the chain-initiating and chain-terminating radicals are produced by intermittent irradiation. Analysis using a Baker-Williams column of the distribution of molecular weights during polymerization of styrene (*J. Romatowski* [1]) showed, however, that this method does not succeed. Reasons are: a low concentration of radicals leads to a spectrum of polymers, whose preferential degrees of polymerization correspond to whole multiples of the exposure time (*i.e.* some of the growing free-radical chains initiated during the first exposure are not terminated during the second exposure, but only during a third, fourth, or later exposure); a high concentration of radicals, on the other hand, produces polymers of random chain-length in the aqueous phase.

Anionic polymerization can give rise to a Poisson process if the initiator (sodium + naphthalene) and the monomer (styrene) are brought together very rapidly by means of a jet mixer, if the mixture is driven through a tube with turbulent currents at a definite rate, and if the polymerization is quenched at the end of the tube by injection of the polymerization-terminating reagent through a second jet. Control of the flow conditions in the tube (*G. Löhr* [2]) and limitation of the polymerization to a one-way mechanism (*R. V. Figini* and *H. Hostalka* [3]) by suppression of dissociation [by addition of $KB(C_6H_5)_4$] so that only ion pairs react, make it possible to come very close to a Poisson distribution.

The biosynthesis of uniform macromolecules apparently does not proceed via Poisson processes but instead by mechanisms controlled by matrices, as has been shown for cellulose (*M. Marx-Figini* [4]).

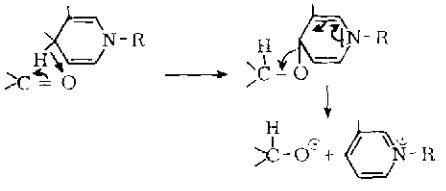
SELECTED ABSTRACTS

The production of pure xenon hexafluoride was achieved by *I. Sheft*, *T. M. Spittler*, and *F. H. Martin* via its addition compound with sodium fluoride. XeF_6 produced by fluorination of xenon with excess fluorine always contains some $XeOF_4$, XeF_4, and XeF_2. In order to purify the hexafluoride, 10 g of the crude product is condensed in a nickel vessel containing 10g of NaF, heated for 2h at 50°C, and left standing overnight at room temperature. Fractionative evaporation is then carried out: the $XeOF_4$ is evolved first at room temperature followed by mainly the XeF_2 and XeF_4 at 50–55 °C. Extremely pure XeF_6 is then obtained as the third fraction at 125 °C; the yield is 8 g or 80 %. The XeF_6 is white but turns yellow at 43–43.5 °C and melts at 47.7 ± 0.2 °C to form a yellow liquid, which recrystallizes to a white solid on recooling. NaF dissolves in excess XeF_6 to form a yellow solution; when the latter is concentrated at 50 °C *in vacuo*, a pale yellow residue of the XeF_6/NaF adduct is left. / Science (Washington) *145*, 701 (1964) / –Ko. [Rd 162/349 IE]

A solution of an intermetallic compound, Li_3Bi, in a molten salt was observed for the first time by *M. S. Foster, C. E. Crouthamel, D. M. Gruen*, and *R. L. McBeth*. An Li–Bi alloy containing 70 atom-% Li forms clear, deep red solutions in an LiCl–LiF eutectic at 100–600 °C under helium. The Li/Bi ratio in the dissolved compound is 3:1. The spectrum of the red solution at 525 °C has a characteristic intense absorption band whose long-wavelength edge lies at 16300 cm^{-1} (2 eV). / J. physic. Chem. *68*, 980 (1964) / –Ma.
[Rd 72/356 IE]

An NADH model which reduces carbonyl groups almost quantitatively and non-enzymatically has been described by *D. C. Dittmer* and *R. A. Fouty*. These authors stirred 2 equivalents of hexachloroacetone and 1 equivalent of 1-benzyl-1,4-dihydronicotinamide in formamide at room temperature for 2 h and obtained hexachloroisopropanol in 97% yield. Addition of radical scavengers had no effect on the reaction.



A mechanism is proposed in which a hydrogen atom from C-4 is transferred to the carbonyl carbon directly in a charge-transfer complex formed from the carbonyl compound and the dihydropyridine derivative. / J. Amer. chem. Soc. *86*, 91 (1964) / –Sch. [Rd 66/354 IE]

New trisilyl compounds have been prepared by *E. Amberger* and *H. D. Boeters*. They isolated $HC(SiH_3)_3$, which is formed according to Equation (a) with $LiAlH_4$ as catalyst, $P(SiH_3)_3$ and $As(SiH_3)_3$, which are formed below 100 °C in dimethyl ether according to Equation (b), and $Sb(SiH_3)_3$, which is produced according to Equation (c) by reaction in dimethyl ether.

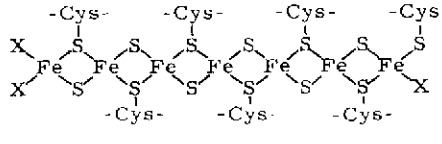
$$9\,LiH + HC(SiCl_3)_3 \rightarrow HC(SiH_3)_3 + 9\,LiCl \quad (a)$$

$$3\,KElH_2 + 3\,SiH_3Br \rightarrow El(SiH_3)_3 + 2\,ElH_3 + 3\,KBr \quad (b)$$
(El = P or As)

$$Li_3Sb + 3\,SiH_3Br \rightarrow Sb(SiH_3)_3 + 3\,LiBr \quad (c)$$

No mono- or disilyl compounds are formed. The trisilyl compounds are colorless liquids which ignite spontaneously on exposure to air; they are decomposed by 33% sodium hydroxide solution to give $HC(SiO_2Na)_3$ and hydrogen plus PH_3, AsH_3, or Sb and by-products. $Sb(SiH_3)_3$ decomposes on prolonged standing. / Chem. Ber. *97*, 1999 (1964) / –Gn.
[Rd 164/351 IE]

A model for the active center of ferredoxin has been proposed by *D. C. Blomstrom, E. Knight, W. D. Phillips*, and *J. F. Weiher*. The seven iron atoms in the protein having a molecular weight of 6000 are responsible for electron transfer during photosynthesis, and occur in two structurally different environments. Comparisons with the known structures of *Roussin*'s red salt and of polymeric $KFeS_2$ led to the assumption of structure *(1)* for the active center.



(1)

Electron transport along this iron-sulfur chain could proceed by a mechanism similar to that proposed by *D. W. Urry* and *H. Eyring* for the imidazole-pump model of the respiratory chain. / Proc. nat. Acad. Sci. U.S.A. *51*, 1085 (1964) / –Sch.
[Rd 137/324 IE]

Optically pure L-homocystine has been prepared in 92% yield by *D. B. Hope* and *J. F. Humphries*. Charges of up to 30 g of L-methionine can be rearranged with sodium in liquid ammonia:

$$H_3CSCH_2CH(NH_2)COOH \rightarrow HSCH_2CH_2CH(NH_2)COOH \quad (1)$$

The base-catalysed racemization which occurs in other processes is completely suppressed here by addition of ammonium chloride. The L-homocysteine *(1)* obtained in this way is oxidized with $K_3Fe(CN)_6$ to L-homocystine, $[\alpha]_D^{20} = -77.0°$ (c = 1 in 1 N HCl). / J. chem. Soc. (London) *1964*, 869 / –Rc.
[Rd 134/321 IE]

The addition of formamide onto terminal olefins to give carboxamides *(1)* was found by *D. Elad* and *J. Rokach* to proceed particularly well by photochemical initiation in acetone according to Equation (a); thus, up to 90% of 1:1 adducts were obtained from $HCONH_2$ and olefin in t-butanol/acetone mixtures at 20–30 °C within a few hours with $\lambda > 300$ mμ; steps (b) and (c) are chain reactions.

$$HCONH_2 \xrightarrow{h\nu} \cdot CONH_2 \quad (a)$$

$$RCH{=}CH_2 + \cdot CONH_2 \rightarrow R\dot{C}H{-}CH_2{-}CONH_2 \quad (b)$$

$$R\dot{C}H{-}CH_2{-}CONH_2 + HCONH_2 \rightarrow RCH_2{-}CH_2{-}CONH_2 + \cdot CONH_2 \quad (c)$$
(1)

$$R\dot{C}H{-}CH_2{-}CONH_2 + RCH{=}CH_2 \rightarrow R\dot{C}H{-}CH_2{-}RCH{-}CH_2{-}CONH_2 \quad (d)$$

$$R\dot{C}H{-}CH_2{-}RCH{-}CH_2{-}CONH_2 + HCONH_2 \rightarrow RCH_2{-}CH_2{-}RCH{-}CH_2{-}CONH_2 + \cdot CONH_2 \quad (e)$$

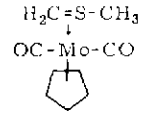
e.g. with $R = H_3C{-}(CH_2)_n{-}$, where n = 3–8, or with $R = H_3COOC{-}(CH_2)_n{-}$ or $H_2N{-}CO{-}(CH_2)_n{-}$, where n = 2–8.

Reactions (d) and (e) yield a few percent of 2:1 telomer. This amidation of olefins can be used to produce carboxylic acids and amines from cheap starting materials. The amides *(1)* crystallize well and are easy to purify. / J. org. Chemistry *29*, 1855 (1964) / –Jg. [Rd 117/304 IE]

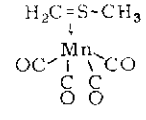
Di- and tripeptides from amino esters and hydroxamic acid dervatives of *N*-carbobenzoxyamino acids were obtained by *E. Hoffmann* and *I. Faiferman*. First *N*-Cbo-amino esters are converted into their hydroxamic acid derivatives with hydroxylamine in 70% yields. On boiling these derivatives with amino esters in dioxane or dioxane/ethanol, hydroxylamine is eliminated affording peptide esters in 30–80% yields. The peptide esters can in turn be activated with hydroxylamine and extended further. Compounds prepared include ethyl *N*-benzoyl- and *N*-Cbo-diglycylglycinate, and di- and tripeptide esters from glycine and alanine. / J. org. Chemistry *29*, 748 (1964) / –Rc. [Rd 93/363 IE]

Lipotropin, a new hypophyseal hormone, was discovered by accident in sheep pituitary by *Y. Birk* and *C. H. Li* while trying to work out a better method for isolating ACTH. The new hormone has a molecular weight of 6600 and consists of a single peptide chain containing 59 amino acids, with glutamic acid at the *N*-terminal and lysine at the *C*-terminal end. The new hormone appears to induce degradation of solid depot fat and thus to mobilize it for energy production. It was therefore termed lipotropic hormone (LPH) or lipotropin. The authors also succeded in detecting this biologically active peptide in the blood stream. / J. biol. Chemistry *239*, 1053 (1964) / –Sch. [Rd 67/366 IE]

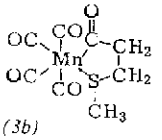
The production of carbonyls of transition metals which are stabilized by π-bonds between sulfur and the metal is described by *R. B. King* and *M. B. Bisnette*. Carbonyl anions and chloroalkyl methyl sulfides lead to the carbonyls *(1a)* to *(4a)*, which lose a carbonyl group on heating at 70 °C or on irradiation with ultraviolet light. On the basis of NMR and infrared spectra, structures were proposed for the carbonyls *(1b)* and *(2b)* in which the $H_3C-S=CH_2$ group and one alkyl group both contribute three electrons to the π-bond with the metal.



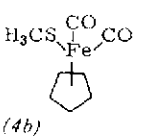
(1b)



(2b)



(3b)



(4b)

The very strong band in the infrared spectrum of the carbonyl *(3b)* at 1622 cm^{-1} is probably due to one carbonyl group being present as an acyl residue. Irradiation of *(4a)* leads to the carbonyl *(4b)*, which is the first example of a methylthio derivative of a transition metal in which the sulfur is coordinated with only one metal atom. / J. Amer. chem. Soc. *86*, 1267 (1964) / –Re. [Rd 92/362 IE]

***cis*-9-Octadecen-12-ynoic acid (crepenynic acid)** *(1)* is the first non-conjugated unsaturated acetylenic fatty acid of natural origin and was found by *K. L. Mikolajczak, C. R. Smith, M. O. Bagby*, and *I. A. Wolff* as 60 % of the seed oil of *Crepis foetida* L.

(1) $H_3C-(CH_2)_4-C\equiv C-CH_2-CH=CH-(CH_2)_7-COOH$

Hydrogenation of the methyl ester over platinum oxide yielded methyl stearate and over Lindlar catalyst afforded 71.4 % methyl linoleate plus 11.1 % unchanged starting material, 3.1 % conjugated triene, and 14.4 % low molecular-weight fragments. Epoxidation of the free acid with peroxyacetic acid produces an 85.5 % yield of the epoxyacetylenic acid, m.p. 37.5–38 °C, which on hydrolysis yielded *threo*-9,10-dihydroxyoctadec-12-ynoic acid, m.p. 72–75.5 °C. Hydrogenation of the latter over platinum oxide afforded *threo*-9,10-dihydroxystearic acid, m.p. 92–93 °C. Crepenynic esters undergo autoxidation extremely readily, even on storage at –18 °C. / J. org. Chemistry *29*, 318 (1964) / –W. [Rd 78/371 IE]

Biradical intermediates were detected by *L. K. Montgomery, K. Schueller*, and *P. D. Bartlett* during the cycloaddition of 1,1-dichloro-2,2-difluoroethylene *(1)* onto the stereoisomers of 2,4-hexadiene. When conditions were used (16.3 h at 80 or 100 °C) under which neither 2,4-hexadiene nor its adducts with *(1)* underwent stereoisomerization, the *cis,cis*-diene yielded two adducts, the *trans,trans*-diene yielded two adducts, and the *cis,trans*-diene afforded a mixture of all four adducts, whose structures were elucidated. During the addition partial isomerization of an intermediate occurs, but the ratio 82 % *trans*-:18 % *cis*-form of the cyclobutane derivative finally formed is never completely attained. It was calculated from the composition of the reaction mixture and from kinetic data that the internal rotation in the intermediate from *cis*- to the *trans*-form proceeds about ten times faster than the cyclization, that the half-life of the bifunctional intermediate is about 10^{-10} sec, and that the activation energy is very low. These results can be explained only by the occurrence of a biradical intermediate. / J. Amer. chem. Soc. *86*, 622 (1964) / –W. [Rd 79/372 IE]

The cycloaddition of 1,1-dichloro-2,2-difluoroethylene onto dienes was investigated by *P. D. Bartlett, L. K. Montgomery*, and *B. Seidel*. Butadiene and *cis*- and *trans*-piperylene react with an excess of 1,1-dichloro-2,2-difluoroethylene *(1)* at 80 °C in a sealed tube in the presence of a polymerization inhibitor such as hydroquinone to give exclusively 1,2-adducts. 1,2- and 3,4-cycloadducts were obtained in a ratio of 5.4:1 from isoprene, and in a ratio of 4:1 form chloroprene. Cyclopentadiene reacts with a fourfold excess of *(1)* to give the 1,4-adduct 2,2-dichloro-3,3-difluorobicyclo[2,2,1]-hept-5-ene in 44 % yield in addition to 9 % of the 1,2-adduct 6,6-difluor-7,7-dichlorobicyclo[3,2,0]hept-2-ene and 47 % *endo*-dicyclopentadiene. The butadiene, isoprene, and chloroprene adducts were degraded by mild oxidation to 2,2-dichloro-3,3-difluorocyclobutane-1-carboxylic acid, which is transformed readily by acids into 2-chloro-3,3-difluoro-1-cyclobutene-1-carboxylic acid, and by alkali into 2-chloro-3,3-difluoro-1-cyclobutene. NMR and infrared spectra prove that the chlorine atoms lie adjacent to the unsaturated side-chain; this confirms the theory of a biradical intermediate in the cycloaddition. / J. Amer. chem. Soc. *86*, 616 (1964) / –W. [Rd 80/373 IE]

Complexes of trivalent silver can be produced from AgO according to a report by *G. L. Cohen*. A mixture of KOH, KIO_3, and AgO is boiled in water and filtered. On addition of 40 g of NaOH, $Na_5H_2Ag^{III}(IO_6)_2 \cdot 16\,H_2O$ separates out as a voluminous orange precipitate.

$$6\,AgO + 2\,H_2O + 8\,OH^{\ominus} + 2\,IO_3^{\ominus} \rightarrow 5\,Ag(OH)_2^{\ominus} + Ag(IO_6)_2^{5\ominus} + 2\,H^{\oplus}$$

The Ag(III) apparently originates from the AgO, which according to recent findings is to be regarded as silver(I) silver(III) oxide. It is assumed that the first step in the reaction is the oxidation of iodate to periodate by Ag(III) and that this is followed by combination of further Ag(III) with the periodate formed to give the stable complex ion $Ag(IO_6)_2^{7\ominus}$. / Chem. Engng. News *42*, No. 16, p. 52 (1964) / –Ko. [Rd 84/369 IE]

Reactions of perfluoroallene which proceed via ionic intermediates have been investigated by *R. E. Banks, R. N. Haszeldine*, and *D. R. Taylor*. In contrast to perfluoro-olefins, perfluoroallene *(1)* combines smoothly with hydrogen halides in the absence of light, catalysts, and solvents to form quantitative yields of 1:1 adducts.

$$\underset{(1)}{F_2C=C=CF_2} + HX \rightarrow F_2XC-CH=CF_2 \quad X = F\ (2),\ Cl,\ or\ Br$$

When *(1)* is kept in an autoclave at –72 °C with excess HF for 12 h and subsequently heated to 20 °C, 2*H*-pentafluoropentene *(2)* is formed in 99 % yield; HCl at 20 °C gives 99 % 3-chloro-1,1,3,3-tetrafluoropropene, and HBr at –45 °C gives 89 % 3-bromo-1,1,3,3-tetrafluoropropene. Allene reacts rapidly with HCl at –78 °C in the presence of $BiCl_3$ to form a mixture of $H_3C-CCl=CH_2$ and $H_3C-CCl_2-CH_3$ in quantitative yield. When treated with excess chlorine in the dark at –72 °C for 12 h and then warmed up to 20 °C and left for 7 days, *(1)* gives 99 % $F_2ClC-CCl=CF_2$; in sunlight at 25 °C for 6 h, only 5 % of this compound is formed alongside 92 % $F_2ClC-CCl_2-CF_2Cl$. Like perfluoro-olefins, *(1)* also undergoes nucleophilic reactions, *e.g.* with moist CsF at 100 °C to form *(2)*:

$$F^{\ominus} + F_2C=C=CF_2 \rightleftharpoons F_3C-C-CF_2\,H_2O \xrightarrow{H_2O} F_3C-CH=CF_2 \quad (2)$$

$H_3C-O-CF_2-CH=CF_2$ is formed with methanol at –24 to 20 °C. It therefore follows that in reactions which proceed via ionic intermediates, *(1)* is present in the polarized form $F_2\overset{\delta+}{C}=\overset{\delta-}{C}=CF_2$. / Proc. chem. Soc. (London) *1964*, 121 / –Ma. [Rd 69/368 IE]

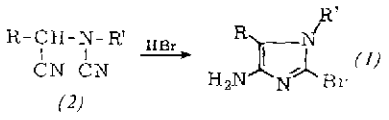
Spectra in the far infrared (down to 200 μ) for 12 organic liquids have been taken by *H. R. Wyss, R. D. Werder,* and *H. H. Günthard.* The compounds studied were benzene, chlorobenzene, bromobenzene, toluene, carbon tetrachloride, chloroform, methylene chloride, carbon disulfide, Nujol, n-hexane, cyclohexane, and pyridine. Band assignments were made for the spectra of the first eight liquids; the absorption curves indicate that all of these substances are suitable as solvents for spectroscopic studies in the far infrared. Suitable materials for sample cell windows include CsI (down to 170 cm^{-1}) and teflon or quartz for longer wavelengths. Although polyethylene is also transparent in this region, it generally swells in organic solvents. / Spectrochim. Acta *20*, 573 (1964) / –Hz. [Rd 59/365 IE]

An apparent prolongation of the half-life of radioactive nuclides has been demonstrated by *S. L. Ruby, R. R. Ferber, R. V. Babcock, L. M. Epstein,* and *Kuan H. Sun* using the Mössbauer effect. A radiation source with ^{119}Sn or ^{57}Fe (in their excited states) as emitter was enclosed in a jacket containing the same nuclides in their ground states. The γ-quanta emitted from the source are partially absorbed in the jacket (resonance absorption). The excited nuclei produced in the jacket in this way disintegrate with their characteristic half-lives leading to an overall prolongation of the half-life of the complete preparation by 2–3 %. The half-life of the excited nuclei originally present in the emitting source has, of course, remained unaltered. / Chem. Engng. News *42*, No. 25, p. 43 (1964) / –Ko. [Rd 85/370 IE]

The protein components of the tail T 2 bacteriophages were examined by *N. Sarkar, S. Sarkar,* and *L. M. Kozloff,* who succeeded in isolating the contractile protein from the sheath of the phage tail. The complete sheath has a molecular weight of 8×10^6 and consists almost exclusively of amino acids, comprising 144 subunits with molecular weights of about 55500 each. Each subunit contains a histidine residue to which ATP probably becomes attached to initiate contraction. The core of the tail is also a protein which was isolated. It has a molecular weight of 487000 and is in the form of a stiff hollow tube about 1000 Å long and 100 Å in diameter consisting of five intertwined peptide chains. The five SH groups of the core protein probably lie at the ends of the peptide chains and appear to be of importance for its attachment to the end-plate. The function of the core is not absolutely clear. It may be a prop which falls out on contraction of the sheath, but on the other hand, the hollow in its cable-like structure is just large enough to permit the DNA filament of the phage – which is 24 Å thick – to glide through. / Biochemistry *3*, 511, 517 (1964) / –Sch. [Rd 64/367 IE]

Crystalline polyvinylcyclobutane and polyvinylcycloheptane have been synthesized by *C. G. Overberger* and coworkers. Vinylcyclobutane was prepared from cyclobutanecarbonyl chloride in an overall yield of 13 % and purified by preparative gas chromatography. Polymerization with tri-isobutylaluminum / $TiCl_4$ (2:1) as catalyst for 7 days at 75 °C gave 24 % of a polymer of high crystallinity and with a softening point of 228 °C. Vinylcycloheptane, b.p. 160 °C, $n_D^{25} = 1.4589$, was synthesized for the first time from cycloheptyl bromide in 40 % yield. Its polymerization with tri-isobutylaluminum/$TiCl_4$ (3:2) as catalyst for 7 days at 72 °C led to 9.8 % of a highly crystalline polymer, m.p. 300 °C. / J. Polymer Sci. A *2*, 755 (1964) / –Re. [Rd 94/374 IE]

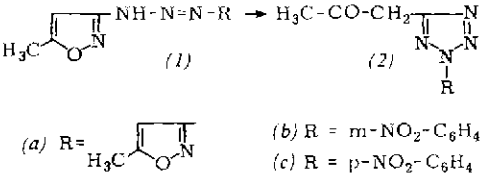
A new synthesis of imidazoles is described by *F. Johnson* and *W. A. Nasutavicus.* When treated with anhydrous HBr in inert solvents, dinitriles of general formula R'N(CN)CH(CN)R *(2)* undergo cyclization to form 2-bromo-4(5)-aminoimidazoles *(1)*. If R and R' are aryl residues, then the amino compounds can be isolated as the free bases; otherwise they



(2) *(1)*

are isolated as their *N*-acetyl derivatives. The dinitriles required for the synthesis, *i.e.* α-cyanoalkylcyanamides, can be prepared by the reaction of a monosubstituted cyanamide with an α-halogenoalkyl cyanide or an α-(*p*-toluenesulfonyl)-alkyl cyanide in anhydrous dimethylformamide in the presence of triethylamine. / J. org. Chemistry *29*, 153 (1964) / –Ma. [Rd 73/357 IE]

A novel conversion of 3-diazoaminoisoxazoles into tetrazoles is described by *H. Kano* and *E. Yamazaki.* 1,3-Bis-(5-methyl-3-isoxazolyl)triazene *(1a)*, which is obtained from 5-methyl-3-aminoisoxazole and $NaNO_2$ in 10 % HCl, undergoes an exothermic reaction on warming in alkaline solution to form

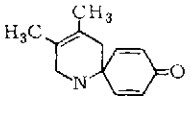


(1) *(2)*

(a) R = *(b)* R = m-NO_2-C_6H_4 *(c)* R = p-NO_2-C_6H_4

2-(5-methyl-3-isoxazolyl)-5-acetonyltetrazole *(2a)*, m.p. 147 to 149 °C, in 81 % yield. Analogously, *(1b)* gives *(2b)* in 94.5 % yield, and *(1c)* gives *(2c)* in 56 % yield. / Tetrahedron *20*, 461 (1964) / –Ma. [Rd 74/358 IE]

The action of light on the Diels-Alder system *p*-benzoquinone/2,3-dimethyl-1,3-butadiene was examined by *J. A. Barltrop* and *B. Hesp.* Irradiation of an oxygen free solution of benzoquinone in dimethylbutadiene at less than 0 °C with light of $\lambda > 300$ mμ or preferably of $\lambda > 400$ mμ and separation of the products by chromatography gave a fraction whose main component was a 1:1 adduct of the quinone and diene. This had a m.p. of 39–42 °C and on the basis of its NMR and infrared spectra was allocated the spiropyran structure *(1)*.



(1)

The yield was 33 %. This adduct is formed by excitation of the $n \rightarrow \pi^*$ carbonyl transition of the benzoquinone. / Proc. chem. Soc. (London) *1964*, 195 / –Ma. [Rd 75/359 IE]

BOOK REVIEWS

Ullmanns Encyklopädie der technischen Chemie (Ullmann's Encyclopaedia of Chemical Technology). 3rd Completely revised edition. Edited by *W. Foerst,* now edited by *Hertha Buchholz-Meisenheimer.* Vol 14: Pilzinfektionen bis Ruß (Fungal infections to soot). Verlag Urban & Schwarzenberg, München-Berlin 1963. xii + 810 pp., linen DM 128.– (about $ 32.25).

This new volume of Ullmann's encyclopaedia contains 48 articles arranged under alphabetical key-word headings. About 32 % of its content consists of the chemistry of high molecular-weight materials: polymers (203 pp.), polyesters (27 pp.), polyurethanes (26 pp.), polyamides (17 pp.), polyethers and polyacetals (16 pp.), press-moulding compositions (14 pp.), polycarbonates (4 pp.), and proteinoid plastics

(4 pp.). Other longer articles include: odoriferous substances (86 pp.), reproduction technology (33 pp.), proteins (33 pp.), reaction mechanisms (33 pp.), platinum and the platinum metals (29 pp.), polymethine dyestuffs (28 pp.), mercury (23 pp.), reduction and hydrogenation (19 pp.), soot (17 pp.), pyrotechnics (15 pp.), and rocket fuels (13 pp.). The remaining 176 pp. are filled by 29 shorter articles dealing mainly with topics from organic chemistry, *e.g.* pyridine and its derivatives, reactive dyes, pyrazolones, and purines and purine derivatives.

The authors of this volume comprise 78 experts, including eight collaborators from abroad (U.S.A., Great Britain, Italy, Switzerland, and Austria). Twenty-three contributers come from technical colleges, and the remainder are employeyd in the chemical industry. The reviewer observes with satisfaction that "Ullmann" is enjoying more and more interest and support from industrial foundations. Closer perusal of the staff of coauthors reveals that industry has frequently its acknowledged experts available. Thanks to their cooperation and the highly differentiated presentation of the text, the information offered is up-to-date and complete.

Nineteen authors have combined in the compilation of the long article on polymers. In the introduction (30 pp.), *H. Fikentscher* deals with the mechanism, technology, and peculiar features of polymerization, and thereby reveals the quintessence of his decades of industrial research work on polymerizations. High-pressure polyethylene (10 pp.) and the Phillips process for polyethylene (5 pp.) are described by BASF chemists, low-pressure polyethylene made by the Ziegler process (12 pp.) by chemists from Farbwerke Hoechst, and polypropylene, amorphous ethylene/olefin copolymers and isotactic polybutene (16 pp.) by *G. Natta*. All the other sections on polymers, polycondensates, and polyadducts are well written, and thus "Ullmann" gives the best presentation of the essentials of this subject available at present.

In the article on odoriferous substances (86 pp.), 106 complex perfumes of natural origin (23 pp.) and 164 chemically uniform compounds or classes of compounds with odoriferous properties are described. The introduction to this chapter (8 pp.) gives a short historical survey, an instructive section on odor and constitution, and a brief but interesting review of the specialized technology used in the production of odoriferous substances. This whole article is well done.

The article on furs deals with the production of tanned and prepared pelts. One of the admirable features of "Ullmann" is that it includes also borderline aspects of technological chemistry and presents them for comparative examination. – The article on soot is compiled by a team from the firm Degussa and gives a readily surveyable review of the development and present-day technical status of the production of amorphous carbon. Unfortunately no economic data are given.

It should be remarked that on the whole, far too little consideration has been given to economic data in the present volume, although they are essentially the decisive factors for all considerations about the technical production of chemical products. Of the 48 articles included, only seven quote economic data, which are sometimes even too short and general, *e.g.* as in the article on quartz and quartz glass. A short but lucid economic review with numerical data is given in the article on mercury. In addition, the comparisons given of various procedures which lead to the same product would have been more valuable if economic aspects such as the ratio of plant-construction costs to operational costs had been discussed. It should have been stressed that the question of costs does not arise solely in the commercial evaluation of the products of technical chemical processes but already participates decisively in determining the aims and structure of chemical technology as a whole.

The article on photomechanical reproduction techniques affords good insight into a new and rapidly developing field. A section on "reprography" describes the procedure for phototechnical production of permanent copies of originals. – Further well-written sections which deserve mention are those on fungal infections, rocket fuels, hydrogenation and reduction, and proteins.

Under the headings "Radicals" and "Reaction mechanisms", the physical chemist expects to find information on the theoretical fundamentals and practical applications of reaction kinetics, but will be amazed to find that physical chemistry has no part in these articles, and that gaseous systems are also entirely neglected. It is to be hoped that this basic field which has become so important in practice since the development of petrochemistry will be awarded the treatment it deserves in another part of the encyclopaedia.

The reviewer's critical remarks are not intended to obscure his general impression that this 14th volume of "Ullmann" maintains the excellent standard of its predecessors, so that it is to be wished that the undertaking can reach a speedy and successful conclusion.

H. Sachsse [NB 284/142 IE]

Die Entwicklung neuer insektizider Phosphorsäure-Ester (The Development of New Insecticidal Phosphoric Esters). By *G. Schrader*. Verlag Chemie, GmbH., Weinheim/Bergstr., 1963. 3rd Revised edit., VII, 444 pp. linen DM 44.– (about $11.–).

At the start of the fifties, a monograph on the development of new insecticidal organic fluorine and phosphorus compounds appeared in two editions and caught the attention of those working in the field. The impressive extension and broadening of developments in this field has led the author to prepare a revised edition; this is to be welcomed, for who could give better coverage than he, who not only had the honor and credit of having initiated this development but who has contributed to it in such an extraordinarily effective way, as a glance at the author index shows?

The originally small monograph has meanwhile become a distinguished and sizeable volume. It starts with an introduction to the general development of organophosphorus compounds, followed by 49 excellent chapters on important individual compounds. Each chapter gives complete details of the methods of preparation, and of the chemical, physical, toxicological, and insecticidal properties of the compound in question. Analytical problems, compounds of closely related structure, and the commercial importance are also discussed. In many cases (*e.g.* for TEPP, DDVP, and Rogor), a detailed historical commentary is included. Hence, because the subject is so intimately related with the experience of the author, and described from his experience, the book makes enthralling reading for the interested reader, a commendation which can seldom be conferred upon the current flood of relevant literature. *Gerhard Schrader* and Verlag Chemie deserve our praise and congratulations for producing this excellent volume.

E. Knüsli [NB 216/93 IE]

Einführung in die Arzneibereitung (Introduction to the Preparation of Pharmaceuticals). By *F. Gstirner*. Wissenschaftliche Verlagsgesellschaft mbH., Stuttgart, 2nd revised edit. 1963, XVII, 419 pp., 108 illustrs., cloth, DM 49.50 (about $12.50).

This modernized edition of the original book has erradicated the failings but retained the character of an introduction to methodology despite its extension by 77 pages. This is greatly to the credit of the author, who has at the same time made the terminology used more "scientific" and placed the emphasis on process technology. Naturally, in order to keep the book within reasonable limits, some topics, such as tissue preparations, vaccines, dialysates, and the isolation of active ingredients, are not included.

The book is divided strictly into sections on the preparation of synthetic, natural, and homeopathic drugs. A new appendix deals briefly with sterilization techniques, dressings, and surgical sutures. This last section is, as is emphasised in the text, only a brief resumé. It is clear that the contents in almost

all the chapters have been completely revised, *e.g.* the chapter on emulsions has increased from 30 to 56 pp. and the chapter on ointments includes references to silicone bases, hydrocortisone ointments, *etc.* Modern techniques in such classical fields as the preparation of pastes, powders, soaps, suppositories, pills, syrups, capsules, tablets, and dragees are dealt with. The particularly important practical section on tabletting faults provides an excellent basic introduction to the methodology. Treatments more suitable for a textbook are to be desired in some sections, *e.g.* that on solutions for injection. The sections on the preparation of natural drugs is particularly valuable, since their therapeutic use has been greatly undervalued in face of the abundance of chemical pharmaceuticals. The same applies to the section on homeopathic pharmacy. The completely new illustrations might have been supplemented by technological flow-sheets for the preparation of pharmaceuticals.

This is a book which will be useful not only to the student of pharmacy, but also to practising chemists in the pharmaceutical industry.

S. Balke [NB 219/97 IE]

Fortschritte der Strukturforschung mit Beugungsmethoden (Advances in Structural Analysis using Diffraction Methods). Edited by *R. Brill*. Vol. I. Friedrich Vieweg & Sohn, Braunschweig; Interscience Publishers, a division of John Wiley & Sons, New York-London 1964. 1st Edit., VIII + 221 pp., 102 figs., linen DM 48.– (about $ 12.25).

The appearance of this new series on "advances in structural analysis using diffraction methods" has closed a gap between the numerous original publications in journals and extensive monographs on the subject. In this first volume of the series, individual topics selected from this vast field are discussed by acknowledged experts (*G. E. Bacon*, *B. K. Vainshtein*, *J. Karle*, *W. Hoppe*, *H. Jagodzinski*, and *A. Niggli*). In addition to two articles on the application of neutron and electron diffraction to the determination of structures, particularly the determination of the positions of hydrogen atoms, there is a review of methods for measuring phase angles. Two further sections are devoted to thermal background variations and to the interpretation of the diffuse interferences occurring in crystals with dislocations. Finally, a short discourse on some symmetry problems is given. Every user of this book will be grateful for the instructive examples and mathematical derivations included. The numerous references given will also prove a great aid for the perusal of original publications.

G. Habermehl [NB 245/103 IE]

Chemie und Technologie aliphatischer fluororganischer Verbindungen (The Chemistry and Technology of Aliphatic Organofluorine Compounds). By *D. Osteroth*. Collection of Chemical and Chemical Technological Reviews. New Series 59. Founded by *F. B. Ahrens*, edited by *R. Pummerer*, *L. Birkofer*, and *F. Goubeau*. Ferdinand Enke Verlag, Stuttgart 1964. 1st Edit., VIII, 195 pp., 8 figs., 41 tables, linen DM 58.– (about $15.00).

The author has attempted to provide a survey of the development of the chemistry and technology of aliphatic fluorine compounds up to the year 1961. The book deals with syntheses of fluorinated hydrocarbons, alcohols, ethers, aldehydes, ketones, carboxylic acids, and compounds containing nitrogen and sulfur, as well as with their chemical reactions. In view of the rapid development and vastness of fluorine chemistry, no single author can reasonably be expected to give a complete critical account of the whole field. The reviewer thus looked in vain among the literature cited for numerous references to methods of preparative importance. For example, the synthesis of monofluorocarboxylic acid esters or monofluoroketones is covered better by the publications of *E. D. Bergmann*. Fluorination by perchloryl fluoride is not mentioned, nor are cycloaliphatic fluorine compounds, such as the pharmaceutically important fluoro steroids. Interactions of *N*-bromoacetamide and hydrogen fluoride with olefins, and reactions with difluorocarbene or fluorochlorocarbene have also been overlooked. Reaction mechanisms are hardly touched upon, but patents and technological aspects are more fully covered.

H. Machleidt [NB 233/90 IE]

Mathematik für Naturwissenschaftler und Chemiker (Mathematics for Scientists and Chemists). By *H. Sirk* and *M. Draeger*. Completely revised by *M. Draeger*. Verlag Theodor Steinkopff, Dresden-Leipzig 1963. 9th Edit., xii + 385 pp., 132 figs., linen DM 25.20 (about $6.50)

The value of "Sirk" is demonstrated by its many editions, and now it has appeared in a new edition completely revised by *M. Draeger*. Despite radical alterations, the character of the book has been maintained, and on the whole, the presentation – as well as the typographical appearance – of the volume are clearer. This has been achieved partly by a reorganization of the material. The elementary mathematics hitherto appended at the end now appears together with one section each on combinations and determinants in the new first part of the book. Infinite series and approximation procedures are discussed in a new fifth part. The practical examples in thermodynamics are now gathered together in a single chapter in the third part (functions with several variables). In addition, even more effort has been made here than in previous editions to conveying a lucid and intelligible appreciation of mathematical concepts in order to simplify understanding of the methods described. In this connection, the section on the basic number e, the detailed discussion of the geometrical interpretation of simple, first-order differential equation as a vector field and of its general integral as a one-parameter series of curves, the clear treatment of the method of the integrating factors, and the section applied to differentiating between the concepts of "necessary" and "sufficient" conditions can be cited as examples. Furthermore, the illustrative examples given in the text are supplemented by numerous problems whose solutions are given in the appendix. There is a brief summary at the end of each chapter to assist rapid orientation.

A few sections had to be shortened to make room for these welcome additions and innovations. Thus, treatment of the method for calculating errors by the law of least squares and of Taylor series has been omitted, and elimination of the section on the Schrödinger equation has consequently led to the lack of mention of boundary conditions, eigenvalues, and eigenfunctions of a differential equation. In view of the increasing importance of electronic computers, a somewhat more extensive treatment of iteration procedures would have been desirable.

This new edition of "Sirk/Draeger" is an exceptionally lucid and well-planned introduction to the fundamentals of higher mathematics and can therefore be earnestly recommended to every student of chemistry. Here not only will he find the mathematical basis of classical physical chemistry, but he can also acquire the background which will facilitate his explorations into specialized fields of modern physical and theoretical chemistry.

M. Klessinger [NB 250/108 IE]

Carl Wilhelm Scheele. Apotheker - Chemiker - Entdecker. By *O. Zekert*. Vol. 27 of the series "Grosse Naturforscher" edited by *H. Degen*. Wissenschaftliche Verlagsgesellschaft m.b.H., Stuttgart 1963. 1st Edit., 142 pp., 23 illustrations, linen DM 15.80 (about $4.00).

Carl Wilhelm Scheele (1742–1786) was one of the most prominent chemists during the transition from the phlogistic to the antiphlogistic eras; his biography and achievements are recounted in the present volume. Many of the results of his investigations can be regarded as the beginnings from which organic chemistry developed into an independent science. Even though *Wöhler*'s synthesis of urea is generally accepted as the starting point of synthetic organic chemistry nowadays, it should not be forgotten that, during his investigations of "the coloring material in Berlin blue", *Scheele* prepared hydrogen

cyanide as early as 1782 and even tested its "unusual odor and taste" in complete unawareness of the toxicity of the compound. However, *Scheele*'s name will remain famous mainly because of his discovery of oxygen around 1771, *i.e.* before the work of *Priestley* in 1774, although *Scheele* did not publish his findings until later in his book "Chemische Abhandlung von der Luft und dem Feuer" (Chemical Discourse on Air and Fire) in 1777. According to *J. R. Partington* a report on *Scheele*'s work had actually been published beforehand in 1775 by *Bergman*. "There can hardly be another scientist", writes *Zekert*, "who, within the brief span of only two decades, has created something so meaningful and of lasting value as has *Scheele*", and hence it now seems almost incredible that all his scientific work was carried out within the confines of a laboratory attached to his pharmacy.

The volume closes with a table giving a synopsis of the important dates in *Scheele*'s life in relation to world events of that time. This book will perhaps induce its readers to interest themselves further in this fascinating scientist and in the effects of his work on the development of organic chemistry.

W. Ruske [NB 257/115 IE]

Mass Spectrometry of Organic Ions. Edited by *F. W. McLafferty*. Academic Press Inc., New York-London 1963. 1st Edit., xii + 730 pp., numerous illustrations and tables, linen, $ 24.00.

In recent years mass spectrometry has assumed an important position in chemical research. In this collective volume several authors review their particular fields. The topics dealt with are intended for chemists and physicochemists and include both theoretical and practical aspects of mass spectrometry. The result is a multifarious treatment that will be inspiring and useful to all interested in the subject.

The sections on the quasi-equilibrium theory and appearance potentials are written clearly and with discerning criticism. Several instructive chapters are devoted to the application of mass spectrometry to the study of ion-molecule reactions, free radicals, electrical discharges, and flames, and abundant data are given on experimental techniques, equipment, and previous results. A section on the mass spectra of negative ions is also included.

The second part of the book, which is dedicated to the correlation of mass spectra with molecular structure, will undoubtedly be of greatest interest to the organic chemist. A brief but excellent recapitulation of the general principles involved is followed by chapters in which the techniques and results of mass spectrometry are illustrated by way of examples. Investigations of numerous fatty esters made it possible to detect the fragmentation paths and to elucidate the structures of some natural products. Extensive studies of alkylbenzenes revealed very surprising information about the structures of some ions. Both chapters distinguish in exemplary fashion between proven and postulated fragmentations.

The next section (on the elucidation of the structures of amino acids and alkaloids) illustrates how complicated natural materials can be successfully investigated by combining chemical and mass-spectroscopic results. The success in studying complex mixtures of similar compounds is demonstrated by taking petroleum as an example. A section on high-resolution spectrometers indicates the vast potentials of this method. The chapter on terpenes is unfortunately not satisfactory. In contrast to the rest of the book, here the individual compounds are dealt with too summarily; the fragmentations are few and are all unproved. In addition, there are several errors here, *e.g.* the fragmentation of myrcene on page 653.

On the whole, however, the book is to be highly recommended. Its individual articles are excellent and describe the whole field of mass spectrometry; repetitions have been almost invariably avoided. The literature has generally been evaluated till spring 1962. All results and findings have been critically reviewed; this and the abundant use of tables and illustrations deserve particular praise.

W. Benz [NB 254/112 IE]

Air Chemistry and Radioactivity. By *C. E. Junge*. International Geophysics Series, Vol. 4, edited by *J. van Mieghem*. Academic Press, New York-London 1963. 1st Edit., xii + 382 pp., 83 figs., 66 tables, linen $ 13.50.

Publications on the chemistry of the atmosphere are scattered throughout many scientific journals. The author is therefore to be highly commended for this survey of the present state of research on this subject, which is now developing rapidly. The concentrations of oxygen, nitrogen, and most of the inert gases in the atmosphere can be regarded as being constant with respect to space and time, and hence are not dealt with in the book. The distributions with space and time of the other gaseous components of the atmosphere – over a dozen are known – are described (Chapter 1). These data are important not only because of their influence on organic life (*e.g.* owing to their absorption of sunlight), but also for the investigation of atmospheric circulation and exchange processes. In the second chapter, the physical and chemical properties of aerosols are discussed, together with their distribution in the troposphere and stratosphere. Aerosols have the property of concentrating material from their environment in various ways, and so their structure and composition are continuously changing; they are largely responsible for atmospheric static, atmospheric optics, cloud formation, and the chemistry of the atmosphere.

The most important rainfall processes, which are responsible for the clearing of the atmosphere, are nucleation within clouds and scrubbing by rainfall underneath the clouds. There are also numerous other processes by which materials can be removed from the atmosphere: sedimentation, fixation by objects on the earth's surface, adsorption of gases, chemical reactions, and escape into outer space. General rules for these processes are derived here from a large number of observations (Chapter 4). The most important topic in this connection is the chemical composition of rainfall.

Impurities in the air are mainly due to industrial factories and roadway traffic. In the fifth chapter, a general discussion on the composition of these impurities, their distribution, and their removal from the atmosphere is given. Atmospheric radioactivity is discussed in the third chapter; this arises from three sources: the natural radioactivity of the earth's crust, which leads to the emanation of radon and thoron, the radioactive isotopes produced in the upper troposphere and lower stratosphere by cosmic rays (of these, ^{14}C and ^{3}H have acquired particular importance), and the nuclides formed by nuclear explosions, which are now of general interest because of the danger of radiation damage due to radioactive fall-out. Much attention is given to a description of the distribution of these isotopes in the atmosphere and of their importance for studying circulatory and separatory processes.

This book by *Junge* links together chemistry, nuclear chemistry, and meteorology. It will provide a valuable aid to all scientists interested in problems associated in the widest sense with the atmosphere.

W. Groth [NB 260/118 IE]

Anorganische Chemie (Inorganic Chemistry), Volume III. By *I. Náray-Szabó*. Akademie-Verlag, Berlin and Verlag der Ungarischen Akademie der Wissenschaften, Budapest 1963. 1st Edit., pp. 669, 21 illustr., 4 tabl., linen DM 48.– (about $12.00).

With this third and last volume, the German edition of "Anorganische Chemie" is now completed. The first three chapters deal with the metals and compounds of the copper, zinc, and gallium groups and the fourth, very extensive chapter is devoted to the chemistry of the iron and platinum groups of metals. In addition, the rare gases are discussed, and the rare gas fluorides and oxygen-containing xenon compounds discovered during the last two years are mentioned. A comprehensive account of the properties of the elements and a short section on geochemistry and cosmic chemistry complete this volume.

As in the preceding volumes [1] the author has compiled with remarkable care much physical data and extensive chemical factual material. Unfortunately, especially in the chapter on the metals of group 8 of the periodic system, this is not always up-to-date and outmoded structures and formulae are given, *e.g.* for cyano complexes and halogenocarbonyls. Many new types of compounds of the iron and platinum metals have not been mentioned, *e.g.* the reader will search in vain for a reference to sandwich compounds of the ferrocene type or to the numerous co-ordination compounds of these metals with anomalous oxidation numbers which have been isolated and structurally analysed during the last fifteen years and which are of bonding and sterochemical interest. On the other hand, many a compound stated to be "non-existent" could have been left out. Despite these reservations and certain deficiencies in the coverage of the latest developments, the third volume of *Náray-Szabó* will also serve its purpose as a handbook in many instances. Its carefully compiled subject and formula indices contribute significantly to its efficiency.

R. Nast [NB 218/88 1E]

Friedel-Crafts and Related Reactions. Edited by *G. A. Olah*. Vol. I: General Aspects. Interscience Publishers, a Division of John Wiley & Sons, New York-London 1963. 1st Edit., XXXIV + 1031 pp., numerous illustrs. and tables, linen £ 11.0.0 (about $ 30.50).

Volume I of this series of four volumes (6 books with about 4000 pp.) begins with a survey over the vital, even dramatic period around the discovery of the reaction, which is particularly well illustrated by numerous facsimile reproductions, including extracts from the laboratory notebooks written together by *Friedel* and *Crafts*. (Chapter I: *G. A. Olah* and *R. E. A. Dear*). In Chapter II, *G. A. Olah* defines the range and limitations of the "Friedel-Crafts and Related Reactions" (120 pp.) thereby including any substitution reaction, isomerization, elimination, cracking reaction, polymerization, or addition that is catalysed by Lewis or protonic acids. – This is followed in Chapter III by a short but poignantly lucid discourse by *R. J. Gillespie* on "Brønsted and Lewis Acids" in which the influence of structural parameters upon the acid strength and the importance of strong protonic acids as solvents is stressed. – Under the heading "Catalysts and Solvents" in Chapter IV, *G. A. Olah* no longer describes simply Lewis acids of the metal halide type but includes metal alkyls, metal alkoxides, acidic oxides and sulfides, cation exchangers, and even cation-forming substances such as $AgClO_4$ or $AgBF_4$ in his scheme without constraint. A detailed discussion is given of the part that cocatalysts play in Friedel-Craft reactions; here the importance of small amounts of water or oxygen is given particular attention.

The role of Lewis catalysts in non-aqueous systems is dealt with by *M. Baaz* and *V. Gutmann* in Chapter V. One of the particularly valuable features of this chapter is to be found in its orderly tabular collection of reactions given with the Lewis acid used, the solvent employed, the ionization of the donor-acceptor complex, *etc.*, which is probably unmatched elsewhere. – In Chapters VI and VII, the coordination compounds of boron halides and aluminum halides are discussed respectively by *D. R. Martin* and *J. M. Canon*. Although the authors are to be awarded due commendation for the admittedly arduous task of compiling a summary, for example, of all the boron halogen compounds known (one table contains no less than 464 compounds!), it would probably be more beneficial to the ease of surveyance of the complete work if this chapter (150 pp.) were either radically abbridged or – even better – reorganized to appear as a separate monograph for those interested in this topic.

Chapter VIII by *G. A. Olah* and *M. W. Meyer* again makes good reading, for it records all the intermediates of Friedel-Crafts reactions known to date. The intelligibility of this chapter is aided to no mean extent by the exact definitions given of π-, σ-, and n-complexes, which arise by the interaction of the following coreactants a) catalyst/cocatalyst, b) catalyst/substrate, c) catalyst/reagent, d) catalyst/product, and e) catalyst/solvent. The profound knowledge of the editor in this field in particular makes possible a critical appraisal of chemical and physical methods for detecting such intermediate complexes. In supplementation, Chapter IX by *D. Cook* gives a summary of spectroscopic experiments designed to convey information on the nature of the donor-acceptor complexes occuring as intermediates in Friedel-Crafts reactions. This description includes, for example, the complexes of ketones, which are formed as reaction products, with Lewis acids and the complex formation of Lewis acids with solvents (*e.g.* nitrobenzene). It is understandable that the major accent has been placed upon nitronium and acylium ions and their complexes, for these are relatively easy to secure and are very important. Here again well presented tables enable the reader to obtain a good idea of the current status of knowledge, which, however frequently needs confirmation by other independent methods, particularly X-ray crystallography.

In Chapter X, *R. M. Robert* and *G. J. Fonken* describe vividly how labelled compounds have been applied with great profit in the field of Friedel-Crafts reactions for mechanistic studies, particularly of technically interesting alkylations, dealkylations, rearrangements, and fragmentations. In comparison with the abundance of experimental material, the theoretical evaluation of the results, which is built up on a remarkably critical attitude, is rather scant. – In Chapter XI on "Reactivity and Selectivity", *G. A. Olah* shows that the overall effect of a catalyst/cocatalyst system must always be regarded as the complex result of a number of combining and opposing factors, including the different electronegativities of the halogeno ligands in Lewis acid halides, the dissociation energies of dimeric metal halides, the electronegativities of the molecules acting as donors, the bond lengths and strengths within the donor-acceptor complexes, lattice and solvation energies, and steric effects. This chapter in particular can be consulted by the reader with profit, for it is one of the richest and gives empirical sequences for the relative reactivities of catalysts, cocatalysts, acyl halides, *etc.* in the most important types of reaction. If a compound contains more than a single reactive group, then Friedel-Crafts reactions are subject to considerable limitations on account of the frequently observed lack of specificity of the Lewis acids used. Numerous cleverly selected examples are given to illustrate the various possibilities for procuring a selective course of a Friedel-Crafts reaction on polyfunctional compounds. Both the theorist and experimenting chemist will be interested by the detailed treatment given in this connection to questions of the positional selectivity observed in electrophilic substitutions of aromatic compounds.

A brief introduction to the thermodynamic approach to Friedel-Crafts reactions is given by *D. R. Stull* in Chapter XII. Calculations on the course of ten reactions – mainly alkylations and acylations – are presented and will enable the organic chemist who is not fully competent in this field to find easy access to the subject, especially since complicated reactions have been wittingly avoided and all the thermodynamic constants required for the operations are presented in orderly tables in the appendix. – The carbonium ion mechanism for the Friedel-Crafts reaction, which proabably enjoys general acceptance today, finds additional support in the more or less complete racemization observed when the corresponding optically active alkylating agents are used. The none too numerous findings that have been accumulated to date from stereochemical studies in this field have been admirably collected together by *H. Hart* in the last chapter, which fortunately waives any all too broad theoretical background.

It is certainly to be expected that this first volume of the series, which is so good as to make its user look forward to the coming volumes, will assume its merited and indispensible position in academic and industrial laboratories.

J. Gosselck [NB 298/157 IE]

[1] Cf. review of Vols. I and II in Angew. Chem. *75*, 695 (1963); Angew. Chem. internat. Edit. *2*, 404 (1963).

Friedel-Crafts and Related Reactions. Edited by *G. A. Olah*. Vol. II: Alkylation and Related Reactions. Part I and Part II. Interscience Publishers, a Division of John Wiley & Sons, New York-London-Sydney 1964. 1st Edit., Parts 1 and 2 together, 1362 pp., numerous tables, linen £ 18.18.0 (about $ 52.50).

Volume I of this series placed the general aspects of this subject in the forefront, and now the discussion of "Alkylation and Related Reactions" is continued in greater detail. The intense interest that has been shown by researchers – particularly in industrial laboratories – in the alkylation of aromatics ever since its discovery by *Friedel* and *Crafts* has resulted in such a vast amount of literature reports that the subject can only be covered with great effort. The editor and his co-authors are to be awarded high commendation for undertaking the none too easy task of introducing an orderly principle here. Scientific and patent literature is covered up to 1961 – sometimes up to 1962 – and the references cited are mainly from publications that have appeared within the past 15 years, although frequently (*e.g.* on pp. 2, 475, and 979) references are given to important reviews of earlier investigations.

In Part I, the following topics are discussed in sequence: Methods of alkylating aromatics using alkenes and alkanes (Chapter XIV, *S. H. Patinkin* and *B. S. Friedman*), using dienes and substituted alkenes (Chapter XV, *R. Koncos* and *B. S. Friedman*), using alkynes (Chapter XVI, *V. Franzen*), using halogenated alkanes (Chapter XVII, *F. A. Drahowzal*), using alcohols and ethers (Chapter XVIII, *A. Schriesheim*), with aldehydes and ketones (Chapter XIX, *J. E. Hofman* and *A. Schriesheim*), and finally with inorganic esters and alkylarenesulfonates (Chapter XX, *F. A. Drahowzal*). Part II deals with halogenoalkylation (Chapter XXI, *G. A. Olah* and *W. S. Tolgyesi*), cycloalkylation of aromatics (Chapter XXII, *L. R. C. Barclay*), dehydrogenative condensation (the Scholl reaction, Chapter XXIII, *A. T. Balaban* and *C. D. Nenitzescu*), isomerization of aromatic hydrocarbons (Chapter XXIV, *D. A. McCauley*), alkylation of saturated hydrocarbons (Chapter XXV, *L. Schmerling*), the condensation of halogenoalkanes with alkenes and halogenoalkenes (Chapter XXVI, *L. Schmerling*), the alkylation of alkenes with carbonyl compounds (Chapter XXVII, *C. W. Roberts*), the isomerization of saturated hydrocarbons (Chapter XXVIII, *H. Pines* and *N. E. Hoffman*), hydrogen exchange in aromatic compounds (Chapter XXIX, *V. Gold*), and polymerization (Chapter XXX, *D. C. Pepper*).

Both parts of Volume II are apparently intended for use mainly as handbooks, for it has been attempted to reproduce as much experimental material as possible in tabular form (there are over 320 full-page tables) in order to enable the reader to acquire speedy information on the reaction he is interested in. In general, detailed theoretical considerations such as appeared in large sections in Volume I and conferred upon it the nature of a textbook have been disregarded here; only a few are included, for example in Chapter XXIX (hydrogen exchange) and Chapter XXX (polymerization; here the Ziegler-Natta polymerization has been intentionally excluded).

The outlay and appearance of the two books is good. They are intended primarily for the use of the experimenting chemist, who, the reviewer earnestly believes, will soon find that he would not like to be without them.

J. Gosselck [NB 299/158 IE]

Electronic Charges of Bonds in Organic Compounds. By *G. V. Bykov*, translated from the Russian by *J. T. Greaves*, edited by *R. W. Clarke*. Pergamon Press, Oxford-London-New York-Paris 1964. 1st Edit., viii + 191 pp., 16 figs., 39 tables, linen £3.0.0 (about $8.25).

In this monograph, where a summary of his publications appearing between 1951 and 1960 are presented, *G. V. Bykov* attempts to develop a purely empirical treatment of the electronic structures of organic compounds. The starting point for this approach is the linear relationship between the physical properties of a compound and the charge densities in its bonds. The charge densities evaluated in this manner are used to derive values for the electronegativity of the atoms, this concept being defined in a new way. The author states that the aim of this book is to coordinate the publications in this field and to make them available to all chemists. Unfortunately, this aim is not attained. Instead of relating the various – mostly quantum mechanical – theories of charge density to one another the author's theory is presented in such an unsystematic manner that it is difficult to distinguish between the assumptions and the results of the theory.

The translation does not give an account of the developments that have taken place since the appearance of the Russian edition and does not contribute to an easier understanding of the text. By a slight stretch of imagination, it can be seen from the context that "frequencies of valence fluctuations of the CH-bonds", for example, means C–H valence vibrational frequencies and that "super-conjugation" means hyperconjugation. Since there are about a hundred errors spread out evenly over the text and formulae, it is advisable to check all derivations and formulae carefully. If the reader wishes to peruse some of the original literature cited, he will be surprised to learn that references to Pauling's "Nature of the Chemical Bond" and to Hückel's "Theoretische Grundlagen der organischen Chemie" are based on the Russian editions of these two books.

M. Klessinger [NB 249/107 IE]

Elimination Reactions. By *D. V. Banthorpe*. Vol. 2 of a series: Reaction Mechanisms in Organic Chemistry, edited by *E. D. Hughes*. Elsevier Publishing Co., Amsterdam-London-New York 1963. 1st Edit., viii + 215 pp., 17 tables, linen DM 25.– (about $6.30).

D. V. Banthorpe has investigated elimination reactions, and using his wide experience in this field has written this very readable book. With its 482 references the work reflects the state of this subject at the beginning of 1962. The selection and presentation of the material discussed illustrate the author's subjective approach, stressing the classical examples of β-eliminations from saturated systems. Four sections are devoted to a discussion of the mechanism of olefin formation, the influence of structure on the course of elimination reactions, orientation rules and their interpretation, and eliminations from cyclic systems where base-catalysed reactions are emphasized. Two chapters are devoted to acid-catalysed and pyrolytic eliminations.

It is well-nigh impossible to find a better presentation of this subject matter; however, in the reviewer's opinion, the standpoint adopted in the book is sometimes too "classical", and the chapter on "Less Usual Elimination Reactions" is too short, even though references to reviews by other authors are given. Thus, for example, eliminations from olefins are allowed only three pages and fragmentations receive only two pages of text. A little more space is allotted to α-eliminations, but this certainly does not correspond nowadays to the importance to be attached to the mechanisms pertinent here. An extended treatment of the latter and the inclusion of important results published after completion of the manuscripts would be desirable in any subsequent edition of the work. Nevertheless the book can be highly recommended to advanced students and to anyone interested in reaction mechanisms.

G. Köbrich [NB 255/113 IE]

Technique of Organic Chemistry, edited by *A. Weissberger*. Vol. XI: Elucidation of Structures by Physical and Chemical Methods, Part II. Edited by *K. W. Bentley*. Interscience Publishers, a division of John Wiley & Sons, New York-London 1963. 1st Edit. ix + 537 pp., numerous tables, linen £7.7.0 (about $20.00).

The second part of Vol. XI of this series contains ten interesting articles written by prominent organic chemists. *Z. Valenta* demonstrates in his article that distillation over zinc

dust is still an extremely useful method in structural investigations when known rearrangements are borne in mind. *B. C. L. Weedon* reviews the applications of alkali fusion and the reactions that occur thereby. Relatively unknown reactions, such as the alkyl transfer to ketones, special dehydrogenations of alkoxides, and the demethylation of methoxylated phenols are mentioned. *J. K. N. Jones* and *M. B. Perry* discuss methods for degrading polysaccharides and methylated polysaccharides. *K. W. Bentley* describes the application of conventional methods of cleaving C–O and C–N bonds mainly in the alkaloid series. The reviewer welcomes the inclusion of the little known cleavage of $N-CH_3$ bonds with azodicarboxylic esters discovered by *O. Diels* and of the β-elimination with $LiAlH_4$. *E. Y. Spencer* gives a thirty page review of methods for the hydrolytic degradation and elucidation of the structures of polypeptides and proteins, including a discourse on oxidative procedures. *K. T. Potts* illustrates the application of known methods of cleaving C=C bonds with examples from the chemistry of natural products. The interesting cleavages that occur with alkaline H_2O_2 are relatively unknown. A second article by *K. W. Bentley* on C=C fission reports mainly on common methods; the examples given of abnormal cleavage with ozone are highly instructive. The chapter by *N. Polgar* on methods for shortening side chains and long-chained compounds is also very useful as it describes relatively unfamiliar reactions.

Here brevity does not permit a closer appraisal of the excellent article (150 pages) by *B. Belleau* on the allocation of steric configurations to natural products using chemical methods. This article also describes the latest data on reaction mechanisms and can be recommended as the basis of lectures on stereochemistry. In the final article, *P. de Mayo* writes a most intriguing review of rearrangement reactions that occur with natural products. Only one (see p. 1095) of the few printing and formulae errors is not immediately recognizable: here an attacking proton is drawn directly above an angular methyl group. This volume deserves a hearty recommendation.

Infrared Band Handbook. Edited by *H. A. Szymanski*. Plenum Press, New York 1963. 1st Edit., xii + 484 pp., linen $7.50.

This book is a catalogue of over 8500 infrared bands in the region between 3610 and 617 cm^{-1}, measured on over a thousand substances. In the main part of the volume, the bands are arranged in order of decreasing wave-number. The information for each band comprises, as far as possible, substance, nature of sample measured, resolution of instrument, type of vibration, band intensity, and reference. The book contains also a substance index and correlation tables for methyl deformation vibrations and C–N valence vibrations, since these vibrations are not included in the main section. The literature references have been restricted to 25 sources covering the period up to 1961. The principal source evaluated is the American Petroleum Research Institute, Project 44 catalogue. Annual supplements costing $7.50 are planned to cover the region down to 250 cm^{-1}. The book is a valuable aid for the identification of unknown substances and for the solution of problems of band assignment.

E. Lippert [NB 261/119 IE]

Oxydation des Métaux (Oxidation of Metals). Vol. I: Processus Fondamentaux (Fundamental Processes). Edited by *J. Bénard*. Gauthiers-Villars et Cie., Paris 1962. 1st Edit., 465 pp., numerous illustrations, linen, NF 55.– (about $11.50).

Over the past few years, experiments on the oxidation of metals have been carried out increasingly under carefully controlled conditions and with highly purified starting materials. The time therefore seemed ripe for reassessment of existing theories and for development of more refined concepts. In this first of two volumes on the "Oxidation of Metals" *J. Bénard* and a number of collaborators have attempted to give a detailed account of the fundamental principles involved, without omitting any relevant material. A brief glance at the contents of the various chapters may serve to illustrate this point. Chapters 1–5: Metal surfaces, adsorption equilibria, the kinetics of adsorption and chemisorption, the structure of chemisorption layers and their influence on the properties of the underlaying metal (*J. Bénard*). Chapters 6–8: Nucleation processes, the growth of thin layers and their orientation (*J. Bénard, J. Bardolle*, and *F. Bouillon*). Chapters 9–11: Thicker layers, methods of investigation and results, diffusion theory of layer formation (*G. Valensi*). Chapters 12–15: Thermodynamics and kinetics of the oxidation of alloys, internal oxidation (*J. Moreau* and *J. Bénard*). Chapter 16: Real structure of oxides, mechanical properties, dislocations, *etc.* (*M. Cagnet*). Tables of crystallographic, thermal, and mechanical properties of metal oxides are also given.

The individual contributors do not always adopt the same approach to their readers. Thus, for example, a detailed derivation of the law of diffusion is given (p. 228), but sometimes simply the results of rather complex theorems are given, *e.g.* for internal oxidation. Nevertheless, the book offers an excellent provocative and modern survey of the subject, and topics that are all too frequently neglected (*e.g.* the morphological and mechanical properties of metal/metal oxide systems) are considered, as is to be expected from this editor and his coworkers. English, French, and German literature has been covered thoroughly and uniformly until 1960 (1052 references).

W. Jaenicke [NB 268/125 IE]

Steroid Reactions: An Outline for Organic Chemists. Edited by *C. Djerassi*. Holden-Day, Inc., San Francisco 1963. 1st Edit., vi + 657 pp., linen $9.75.

C. Djerassi maintains that the increasing profusion of publications connected with the field of steroids has led many chemists who are not familiar with this subject to abandon the practice of reading articles devoted to it. This is regrettable insofar as there is hardly a chemical reaction that has not been applied to steroids. Furthermore the reactions applied have frequently led to particularly lucid results because of the relatively precise knowledge of the structures, conformations, and reactivities of steorid derivatives. In order to break the soil of this fallow field and make it available even to non-steroid chemists, 16 post-graduate students at Stanford University undertook to arrange 14 special aspects of the subject into order in the form of formulae schemes under *Djerassi*'s guidance; the appropriate reaction conditions, yields, and literature references are given for each reaction. The data include the protection of carbonyl and hydroxyl groups, selective oxidation of polyhydroxysteroids, the introduction of fluorine into the steroid system, the production and dehydrohalogenation of α-bromo, α-chloro, and α-iodo ketosteroids, *etc.* Apart from short introductions before the chapters, written text has been completely replaced by formulae and reaction schemes. Thus it is simple for the user of the book to survey the general picture, and this helps him to find any desired reaction rapidly. Since the work done by the students has been checked and supplemented by experienced steroid chemists in large American firms, the result is an excellent review volume which undoubtedly fully achieves its aim of providing a rapid guide to the entire subject and which will therefore soon acquire many friends. The book fills an obvious gap, even though it is not completely free from errors; one must expect this when one considers the abundance of material discussed. However, the reviewer doubts whether it will influence many non-steroid chemists into investigating the ever increasing amount of steroid literature. In any case, it will certainly be often consulted by the specialist in this field.

Recent Advances in the Total Synthesis of Steroids

BY PROF. DR. L. VELLUZ, DR. J. VALLS, AND DR. G. NOMINÉ
CENTRE DE RECHERCHES ROUSSEL-UCLAF, PARIS (FRANCE)

In the total synthesis of steroids on the industrial scale, three factors are important: stereoselectivity of the reactions used, resolution of racemic intermediates at the earliest possible stage, and convergence of the synthesis. Theoretical advances and wider practical experience in the chemistry of polycyclic compounds have recently led to the development of the first syntheses which are suitable for the industrial production of steroid hormones.

c) Development of Synthetic Routes

Introduction

The object of the total synthesis of steroids is to build up polycyclic compounds containing several centers of asymmetry. If the molecule contains n asymmetric centers, it is possible to obtain 2^n isomers; in the case of steroids, only one of these is of biological importance. Consequently, the reactions used in the total synthesis of steroids must be highly stereoselective. The starting materials for these reactions are unsaturated cyclic compounds containing C=C double bonds, a keto group, or an enol function, *i. e.* compounds with one or more trigonal carbon atoms. The stereochemical problem of the total synthesis of steroids therefore consists in the stereoselective conversion of trigonal carbon atoms belonging to five- or six-membered rings.

In addition to this chemical problem, there is an economic problem: The production of an optically active steroid in high yield by a total synthesis involving a large number of steps requires early resolution of racemic intermediates and convergence of the stepwise synthesis of the ring system [*].

All of these requirements present obstacles to the development of a total steroid synthesis suitable for large-scale production. Following the first total syntheses by *Bachmann* (1939), no solution to the problem was found for a long time, in spite of many, often extremely elegant attempts. Recently, however, the advance of conformational analysis and new findings in the chemistry of polycyclic compounds have led to new solutions.

As a basis for a review of the developments of the past 10 years, we shall first consider the theoretical principles involved in the stepwise synthesis of the steroid skeleton.

I. Theoretical Principles

1. Reactivity and Stability

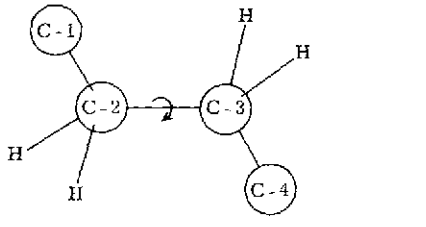
Since the elucidation of the geometry of the cyclohexane ring by *Hassel* in 1943, our knowledge of the reactivities of the ring systems occurring in steroids has greatly in-

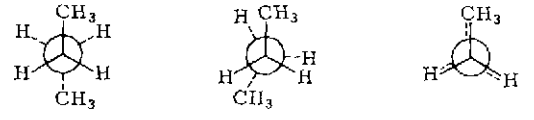
[*] A converging synthesis is one in which several parts of the molecule are prepared first, and these are then joined together to form a single intermediate.

creased, particularly as a result of the development of conformational analysis.

Cyclohexane

According to *Klyne* and *Prelog* [1], the conformations resulting from rotation about a single bond can be described by the magnitude of the dihedral angles. Thus the conformations of butane are staggered *(1)*, skew *(2)*, or eclipsed *(3)*, depending on the dihedral angles $\alpha = \sphericalangle$ C(1)-C(2)-C(3)-C(4). These conformations give rise to the interactions and strains which determine the energy content of a structure. Conformation *(1)* corresponds to the minimum potential energy, and *(3)* to the maximum.



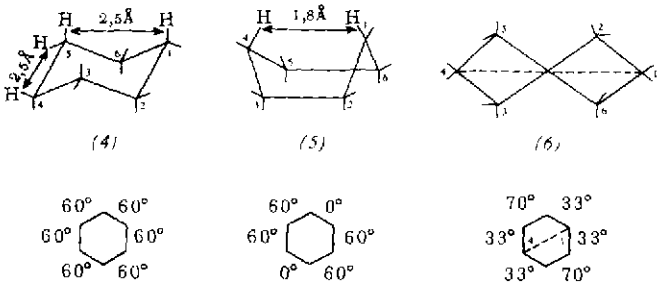


(1), $\alpha = 180°$ *(2)*, $0° < \alpha < 180°$ *(3)*, $\alpha = 0°$

The cyclohexane ring can to some extent be regarded as a cyclic combination of butane units, each of which contributes its own conformational problem. The conformation of cyclohexane is therefore defined by the six dihedral angles in the ring. The potential energy is determined by the steric interactions of atoms which are not directly bonded to one another, and by strains resulting from these interactions.

The chair conformation *(4)*, with its three-fold axis of symmetry, has six equal dihedral angles of 60° each, and steric interactions within the molecule are reduced to a minimum. This is the reason for the great stability of this conformation.

The boat form *(5)*, with two dihedral angles of 0° and four of 60°, contains two pairs of eclipsed interactions and a 1,4-bow-stern interaction. Consequently, this form is less stable by about 6.5 kcal/mole than the chair conformation.



(4) *(5)* *(6)*

The potential energy of the twist conformations, *e. g. (6)*, is somewhat lower than that of the boat form *(5)* [2].

Among the non-bonded interactions in the chair form of cyclohexane, the 1,3-interactions between axial substituents and the 1,2-interactions between equatorial substituents are particularly important. Conformational analysis shows that the distance between two axial hydrogen atoms or between two adjacent equatorial hydrogen atoms in the chair conformation *(4)* is about 2.5 Å.

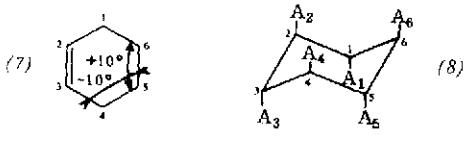
Slight changes in the distances between axial hydrogens have no appreciable effect on the interactions. This is not the case, however, with substituents larger than hydrogen. Thus the energy of interaction between 1,3-diaxial methyl groups is about 5.5 kcal/mole greater than that for two equatorial methyl groups. An example of this is the reflex effect described by *Ourisson* [3].

The eclipsed interactions are also appreciable, and may result in conformational changes (*e. g.* the *gem*-dimethyl effect [4]) or affect the intermediate states of various reactions (see p. 191).

In all cyclohexanes, steric interactions lead to deformation of the ring. Conversely, changes in the dihedral angle affect the distance between atoms which are not directly linked together, *i. e.* steric interactions and conformational changes are closely related.

Little systematic study has so far been devoted to conformational changes in cyclohexane rings. Exceptions, however, are vectorial investigations, particularly those by *Corey* and *Sneen* [5, 6]. Their methods have recently been improved by *Bucourt* [7, 8], working in our laboratory.

Deformations of the cyclohexane ring can be analyzed by determining the deviations of the dihedral angle from an assumed normal value of 60° [7, 8]. Thus on comparison of the half-chair form of cyclohexane *(7)* with the chair form, we find that the "*para*" dihedral angle C(4)-C(5)-C(6)-C(7) has been opened up [*], while the "*meta*" dihedral angle C(3)-C(4)-C(5)-C(6) has been closed, the difference from the normal angle being of the order of 10° in each case [7, 8].



(7) *(8)*

Conversely, deformation of a dihedral angle alters the geometry of a chair cyclohexane, and hence also the distances between axial substituents. The axial substituents A_2, A_4 and A_3, A_1 *(8)* on the C-atoms of the deformed dihedral angle C(1)-C(2)-C(3)-C(4) approach one another when this angle opens up, and move apart when the angle closes.

[8] *R. Bucourt*, Bull. Soc. Chim. France *1963*, 1262; *1964*, 2080.

[*] The expressions "opening" and "closing" refer to the widening or narrowing of the dihedral angle from a standard value of 60 °C.

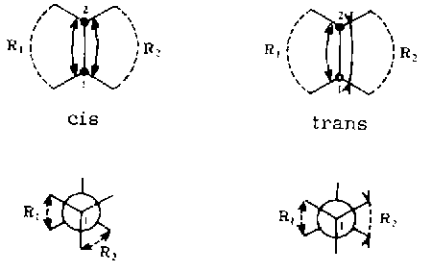
If all carbon atoms of the ring carry only hydrogen atoms, the deformation energy is about 1 kcal/mole for 10° and is practically independent of the sign of the deformation, provided that the magnitude of the latter is small. If, on the other hand, the molecule contains a bulky axial substituent, such as a methyl or methylene group, the change in the interaction energies is no longer negligible.

The effect is greatest when a substituent is attached to one of the carbon atoms which form the vertex of the dihedral angle, *i. e.* attached to C-2 or C-3 in the case of the angle C(1)-C(2)-C(3)-C(4). Opening of the dihedral angle then causes an increase in the energy of interaction, while closing causes a decrease.

b) Polycyclic Compounds

If several rings are fused together as in the steroids, additional interactions arise, depending on the structural elements of the rings and on the type of ring fusion *(cis* or *trans)*. The polycyclic skeleton is fairly rigid, *i. e.* the fusion of the rings results in a mutual interdependence of all steric and conformational effects. Any analysis of the behavior of polycyclic compounds must take into account the transmission of steric and conformational interactions over the entire structure ("conformational transmission" [9]) and should not overlook the stability of the *cis*- or *trans*-fusion of the rings.

Bucourt's analysis [7, 8] of conformational deformations on the basis of changes in the dihedral angles permits to study how deformations are transmitted between two *ortho*-fused rings. Consider two rings R_1 and R_2 (Scheme 1) with a common bond. If the dihedral angle about



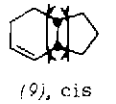
Scheme 1. Behavior of the dihedral angle about the common bond of two *cis*- or *trans*-fused rings R_1 and R_2. In the lower figures the upper figures are viewed along their axes (C-1)—(C-2). The arrow ↔ denotes opening, and › ‹ denotes closing of the dihedral angle.

the common bond is deformed in R_1, the dihedral angle in R_2 also suffers a deformation of the same magnitude. The two deformations have the same sign when the rings are *cis*-fused and opposite signs when the rings are *trans*-fused. In other words, if the dihedral angle about the common bond of two *cis*-fused rings opens in one of the rings, it will also open in the other. If the rings are *trans*-fused, on the other hand, opening of the angle in one ring results in closing of the corresponding angle in the other.

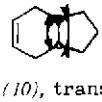
[9] *D. H. R. Barton, A. J. Head*, and *P. J. May*, J. chem. Soc. (London) *1957*, 935.

α) *Tetrahydroindanes*

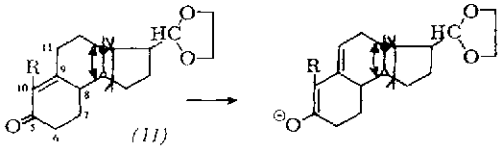
In the tetrahydroindanes *(9)* and *(10)* the deformations at the common bond, which are produced by the five-membered ring and the double bond, lead to *cis*-fusion in *(9)* and to *trans*-fusion in *(10)*. The structures *9* and *10* are the most stable, both theoretically and experimentally. This could explain, for example, the observation that alkylation on C-10 of the tricyclic C/D *trans*-compound *(11)* does not require preliminary blocking of position 6, although this is necessary if ring D is six-membered [10].



(9), cis



(10), trans

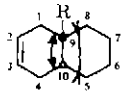


(11)

β) *Octalins*

The Δ^2- and Δ^3-isomers *(12)* and *(13)* of *trans*-octalin with no substituent on C-9 (R = H) exhibit practically no difference in stability, since there are no axial substituents other than hydrogen. A marked difference is observed, on the other hand, if C-9 carries an angular methyl group ($R = CH_3$). Analysis by *Bucourt*'s method shows that the steric pressure exerted by the methyl group on the axial hydrogen atoms of ring B (H-atoms on C-5 and C-7) is greater in the presence of a 3,4-double bond *(12)* than with a 2,3-double bond *(13)*. Thus when $R = CH_3$, *(13)* is more stable than *(12)*.

(12)



(13)

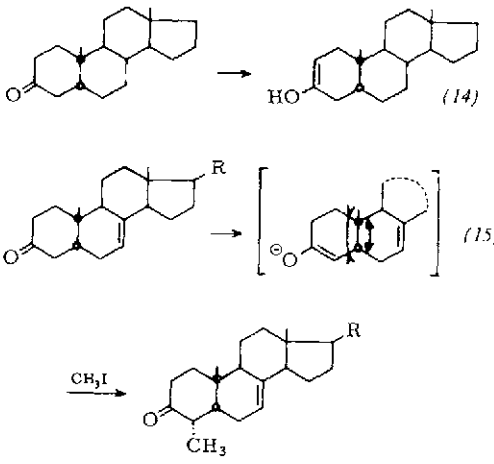
These facts are in excellent agreement with *Corey* and *Sneen*'s theory [5] and with *Djerassi*'s observation [11] that for steric reasons 3-oxo-A/B-*trans* steroids preferentially form Δ^2-enols *(14)*. An additional 7,8-double bond, on the other hand, leads to the formation of a Δ^3-enol *(15)*, since only this structure is compatible with the deformation of the dihedral angle caused by the 7,8-double bond [12].

The fact that a 3,4-double bond in *cis*-octalin *(17)* is more stable than a 2,3-double bond *(16)* is also explained by a decrease in the steric pressure. This decrease is greater for removal of the axial hydrogen atom on C-4 [which interacts with the axial hydrogens on C-6 and C-8, cf. *(19)*] than for removal of the axial hydrogen on C-2 (which interacts only with the axial hydrogen on C-8). However, a conformational effect also contributes

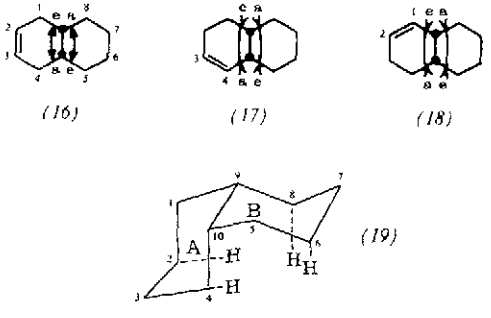
[10] *L. B. Barkley, W. S. Knowles, H. Raffelson*, and *Q. E. Thompson*, J. Amer. chem. Soc. *78*, 4111 (1956).

[11] *B. Berkoz, E. P. Chavez*, and *C. Djerassi*, J. chem. Soc. (London) *1962*, 1323.

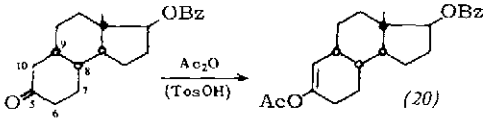
[12] *Y. Mazur* and *F. Sondheimer*, J. Amer. chem. Soc. *80*, 6296 (1958).



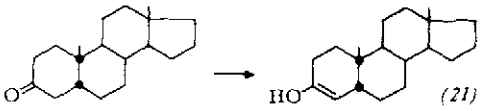
to the lower stability of the 2,3-double bond: in ring B this double bond causes opening of the dihedral angle at the ring junction, and so increases the interactions between the C-4 methylene group [C-4 is axial with respect to ring B, cf. *(19)*] and the two axial hydrogen atoms on C-6 and C-8. For the same reason, the 2,3-double bond *(16)* should be less stable than a 1,2-double bond *(18)*: by closing the dihedral angle at the ring junction in ring B, a 1,2-double bond reduces the interactions between the C-4 methylene group and the axial hydrogen atoms on C-6 and C-8. Thus the difference in the stabilities of the structures *(16)* and *(18)* is entirely due to the conformational effect of ring B, and the stabilities of the three compounds decrease in the order *(17)* > *(18)* > *(16)*. It should be pointed out, however, that the difference in stability between *(17)* and *(18)* becomes appreciable only when the *cis*-octalin is part of a polycyclic system which prevents conversion to the other conformation.



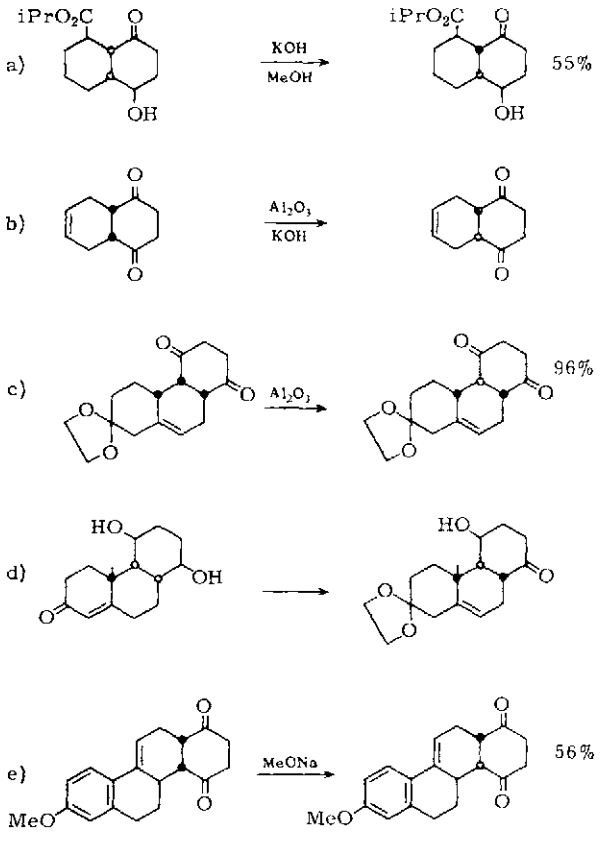
The difference in the stabilities of structures *(16)* and *(18)* manifests itself in the acetylation of 17 β-benzoyloxy-5-oxo-des-A-8α-estrane, which leads exclusively to the $\Delta^{5(10)}$-enol acetate *(20)* [13].



The competition between structures *(16)* and *(17)* may be compared to the enolization of the 3-oxo-A/B-*cis* steroids, in which the angular methyl group (which is axial with respect to ring B) reinforces the conformational effect. These 3-oxo steroids form Δ^4-enols *(21)* in preference to Δ^2-enols.



It is not possible in the present paper to review the whole of our knowledge regarding the relative stabilities of polycyclic systems (cf. [14]). We shall therefore confine ourselves to a few examples which show that differences in stability arising from the ring fusion in a polycyclic system have been utilized in the total synthesis of steroids to effect the epimerization of asymmetric centers adjacent to carbonyl functions. Thus the greater stability of the *trans*-1-decalone and the *trans*-1,4-dioxo-$\Delta^{6(7)}$-octahydronaphthalene made possible the inversions shown in Equations (a) to (e) [15–19].



In his synthesis of epiandrosterone [20, 21] from hydrochrysene, *Johnson* made use of the stability of the *trans-anti-trans* system *(22)* for the isomerization at C-13. Owing to the greater stability of the 2,3-double bond in *trans*-octalins (cf.

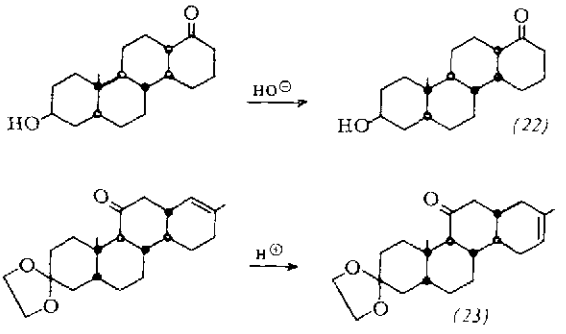
p. 193), it was possible to isomerize a 17,17a- to a 16,17-double bond *(23)* [22].



2. Attack at Trigonal Carbon Atoms

In steroid chemistry, asymmetric centers are generally formed by additions to carbonyl groups or olefinic double bonds and by attack on enol functions, *i. e.* by reactions with unsaturated groups containing one or more trigonal carbon atoms. They result in the conversion of trigonal sp^2 carbon to the tetragonal sp^3 state. Owing to the unsaturated character of these groups and the fact that they form part of a six-membered ring structure, these transitions depend on the following steric factors:

α) perpendicularity of the attack,

β) accessibility of the reaction center,

γ) energy of the intermediate states.

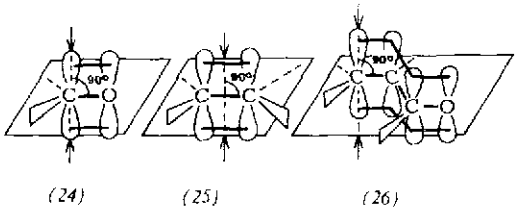
a) Steric Factors

α) *Perpendicularity of the Attack*

Any transformation which permits delocalization of electrons is favored by the gain in energy associated with delocalization. Application of this fact to the transition state of a reaction leads to the principle of maximum overlap of reacting orbitals. According to this principle, a reagent attacks an unsaturated function in such a way as to give the maximum possible overlap between the reacting orbital of the reagent and the π-orbital of the unsaturated function [23]. The electron density of the π-orbital is greatest in the direction perpendicular to the plane which contains the atoms involved in the double bond. The reactant must therefore approach the reaction center from this direction. If the reaction is reversed, the reactant will depart in the same direction, in accordance with the principle of microreversibility.

Toromanoff [24,25], in his contribution to our investigations, stressed that the stereoelectronic principle of perpendicular attack and departure is a very general one and is applicable to a wide variety of unsaturated groups: carbonyl functions *(24)*, olefinic and enolic double bonds *(25)*, α,β-unsaturated carbonyl functions *(26)*, allylic and homoallylic structures, *etc.*

The principle of perpendicular attack and departure is referred to as a stereoelectronic principle [23], since it describes both the electronic (delocalization of the electrons) and steric (orthogonality) features of the reaction. It stipulates a certain orientation of the attacking species



(24) *(25)* *(26)*

as the latter approaches the substrate, and so introduces steric limitations which define the accessibility of the reaction center. It also places restrictions on the geometry of the transition state, which will be discussed later (see Section γ).

β) *Accessibility of the Reaction Center*

The reactant may approach the plane containing the atoms involved in the double bond perpendicularly either from above or form below. Which side is preferred depends on the accessibility, *i. e.* on steric and polar peculiarities of both the cyclohexane structure and the reactant. Steric hindrance by the cyclohexane structure may arise from various causes, an important factor being the presence of axial substituents in the *meta* position relative to the attacked carbon atom.

The concept of accessibility is extremely important. It was developed by *Dauben* [26] under the name "steric approach control" for attack at ring carbonyl groups, and has subsequently been applied or criticized by numerous authors [27–33]. In steroid chemistry, the reaction of carbonyl or enol functions in cyclohexane systems may be greatly influenced by the accessibility of these groups. It should be noted that the accessibility of the reaction center favors the formation of the kinetically controlled product, and can therefore have a decisive effect on the stereochemical result of a reaction only under non-equilibrating conditions.

γ) *Energy of Intermediate States*

The steric course of a reaction also depends on thermodynamic factors, *i. e.* on the energies of the intermediate states through which the ring passes in the course of the reaction. One of these states, namely the transition state, determines the energy barrier which the system must surmount for the reaction to take place. The energy of a transition state is governed primarily by the structures of

the reactants. The transition state may resemble either the starting material (where the carbon atom under attack is trigonal in reactions involving doubly bonded C-atoms) or the end product (where the carbon atom under attack is tetragonal). It is practically impossible, however, at least in the case of cyclohexanes, to describe accurately the degree of rehybridization of the attacked carbon atom in the transition state.

In keto-enol reactions which have been studied in detail, both theoretical [34, 35] and experimental [36, 37] findings indicate that the transition states closely resemble the enol forms. For other reactions of enols or enoxides, it is assumed, explicitly or implicitly, that the transition state lies closer to the enol form than to the keto form. However, it is not purely enolic, *i. e.* the carbon atom under attack already possesses some tetragonal character. The extent of this rehybridization depends on several factors, including the nature of the carbonyl derivative and the electrophilic character of the reagent attacking the enol [23].

The course of the *C*-alkylation of cyclohexenoxides is the subject of controversy. From theoretical considerations, it seems that the transition state should be similar to the ketone formed (tetragonal carbon) [38–40], whereas experimental results are generally interpreted as indicating a similarity between the transition state and the enolic starting material (trigonal carbon). We have therefore attempted to analyse transformations of trigonal carbon atoms by assuming that the intermediate states are rings in which the reacting carbon atom already has appreciable tetragonal character, *i.e.* in which the end products are preformed. (Naturally these intermediate states do not necessarily correspond to true transition states.) The energy of an intermediate state is governed by geometrical factors. These, in turn, are the result of stereoelectronic, steric, conformational, and polar factors, *i.e.* of specific properties of the ring which is being attacked. The reaction will proceed only if, during its course, the ring can assume a conformation which satisfies the various structural requirements. The direction of attachment of the reagent will correspond to this conformation.

These considerations by no means disregard the energies of the more trigonal intermediate states; in fact, the analysis of the accessibility is nothing else than the investigation of the factors which determine the energy levels of more trigonal intermediate states.

It can be seen, therefore, that in analysing the stereochemistry of an attack the two parameters "accessibility" and "energy of the tetragonal intermediate states" must be taken into account. Each of these parameters defines a steric orientation of the substituent being introduced. If both orientations are similar, or even equal, then the stereochemistry of the attack is unambiguously defined. If, on the other hand, they are different, it is necessary to estimate the importance of mutually opposing effects in order to establish the stereochemistry of the reaction.

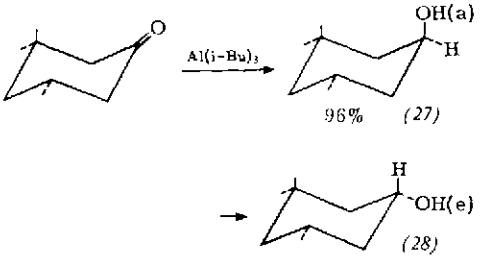
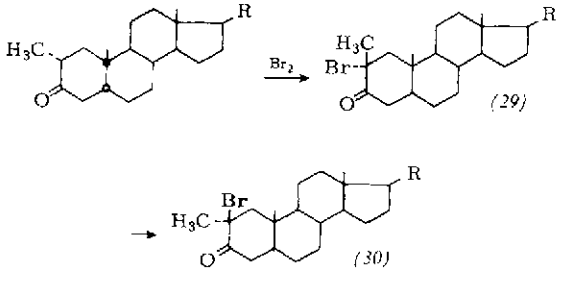
The various factors influencing the stereochemistry of attachment to a trigonal carbon atom may cause the substituent introduced to assume a position which is not the most stable one thermodynamically. The attachment may then lead initially to an unstable product, which under equilibrating conditions is converted to a thermodynamically more stable isomer. This observation can be made in the case of reversible non-equilibrating reactions, in which the substituent is intially fixed, but then detaches itself from the molecule, to form another bond which yields a stable isomer. For example, the kinetically controlled reduction of 3,3,5-trimethylcyclohexanone leads to an axial alcohol *(27)*, which in the presence of excess ketone is converted to the thermodynamically more stable equatorial isomer *(28)* [41].



The bromination of a 2-methyl-3-oxo steroid first yields a 2α-bromide *(29)*, which then isomerizes to the 2β-bromide *(30)* [42, 43].



These two examples illustrate the effects of accessibility and of thermodynamic stability. The thermodynamic factor plays a role only in reversible reactions under equilibrating conditions.

Another example is the migration of a 5α-halogen to the 7α-position in 6-oxo steroids *(31)* [44].

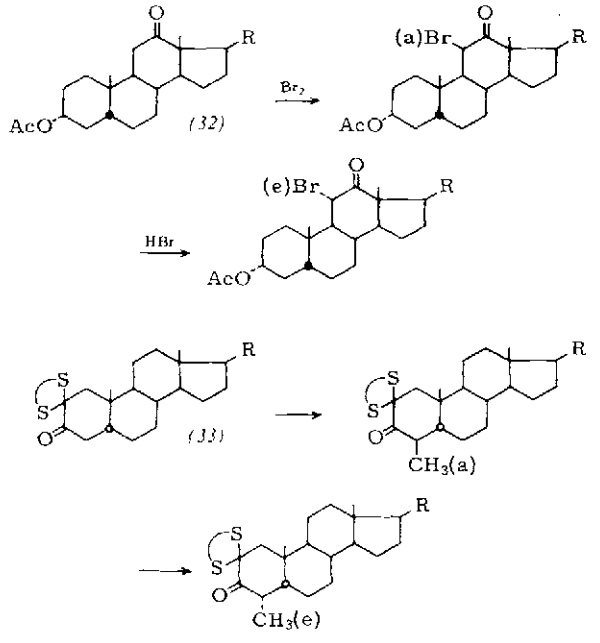
[44] *E. J. Corey*, J. Amer. chem. Soc. *76*, 175 (1954).

Equilibrations may also result from epimerization *via* enol functions, *e. g.* in the bromination of 12-oxo steroids *(32)* [44] or in the methylation of 3-oxo steroids *(33)* [45].

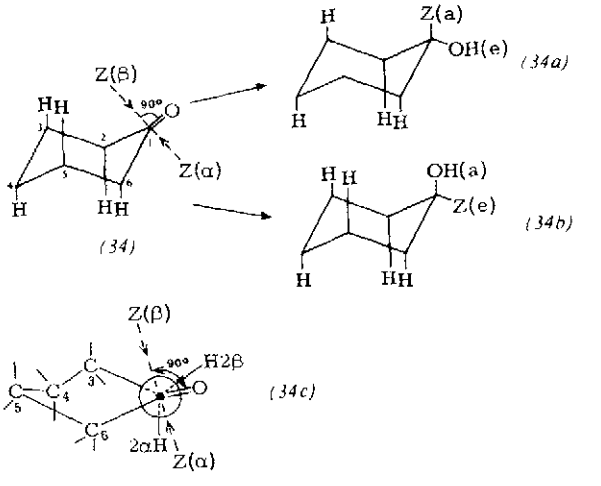


b) Application to Specific Functions

α) *Ketones* ($sp^2 \rightarrow sp^3$)

When applied to reactions of the carbonyl group [24], the principle of perpendicular attack expresses *Cram*'s rule in electronic terms. This rule was originally derived for linear carbonyl derivatives from purely steric considerations [46, 47].

In the case of a chair cyclohexanone *(34)*, perpendicular attack of a reagent Z can take place from either side of the plane C(2)-C(1)-C(6). Accordingly, the resulting hydroxyl group will occupy either an equatorial [β-attack *(34a)*] or an axial [α-attack *(34b)*] position.

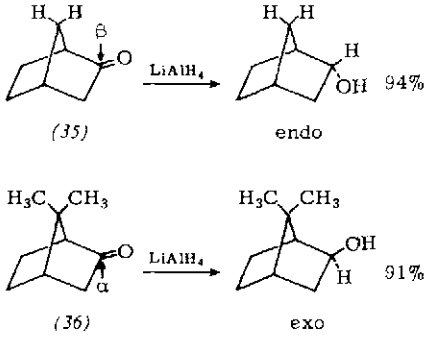


[45] *J. L. Beton, T. G. Halsall, E. R. H. Jones*, and *P. C. Phillips*, J. chem. Soc. (London) *1957*, 753.

[46] *D. J. Cram* and *F. A. A. Elhafez*, J. Amer. chem. Soc. *74*, 5828 (1952).

[47] *J. L. Mateos* and *D. J. Cram*, J. Amer. chem. Soc. *81*, 2756 (1959).

The side from which attack takes place depends primarily on the accessibility of the carbonyl group [cf. formula *(34c)* in which *(34)* is viewed along the axis (C-1)-(C-2)]. Reactions of a carbonyl which is shielded on one side have been studied by *Dauben* [26]. For example, the stereochemistry of the reduction of bicyclo[2,2,1]heptanone *(35)* with complex hydrides is reversed by the introduction of two methyl groups at C-7 *(36)*.



The accessibility of a carbonyl group is particularly affected by axial substituents on the two β-C-atoms [26]. Thus the reduction of 11-oxo steroids with complex hydrides leads exclusively to the 11β-alcohols, *i. e.* attack from the β-side is prevented by the two angular 1,3-diaxial methyl groups. The introduction of a 13β-methyl group into a 17-oxo steroid also causes formation of the 17β-alcohol on reduction.

However, the accessibility of the carbonyl group also depends on the reactant used, and in particular on its bulk, which is often difficult to define owing to solvation [32, 49].

In addition, carbonyl reactions of the type $sp^2 \rightarrow sp^3$ are controlled by the nature of the transition states, about which little is known at present. According to *Dauben*, the transition states in the reduction of cyclohexanones with complex hydrides are assumed to have a hybridization between sp^2 and sp^3. The partly tetragonal character of the carbon atom under attack brings into play those factors which determine the stability of the final product. This leads to a rule formulated by *Barton* [50], according to which an unhindered ketone will yield the thermodynamically more stable epimer (*Dauben*'s "product development control").

This view has been criticized in particular by *Kamernitzky* and *Akhrem* [32]. According to these authors, reactions of the carbonyl group are controlled not only by the accessibility but also by a polar orientation factor, which leads to axial attachment of the reactant. This attachment is claimed to be much more strongly influenced by the kinetics of the reaction than by the thermodynamic stability of the product. *Kamernitzky* and *Akhrem* base their arguments on the relative volumes of the substituents. However, this theory is to be regarded with certain reservations, since the true volume of the hydroxyl functions, which may be solvated or complexed, is unknown [48].

This lack of accuracy is not the only complication in the problem of carbonyl reactions; there is also some uncertainty regarding the active part of the reactant which attacks the carbonyl group, and as to whether or not the reaction proceeds by a concerted mechanism. Further discussion of this subject [32, 51] is beyond the scope of the present paper.

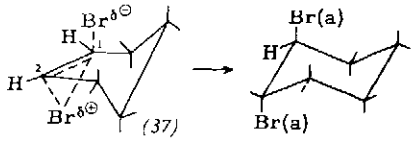
β) *Olefinic Double Bonds* (2 $sp^2 \rightarrow 2\ sp^3$)

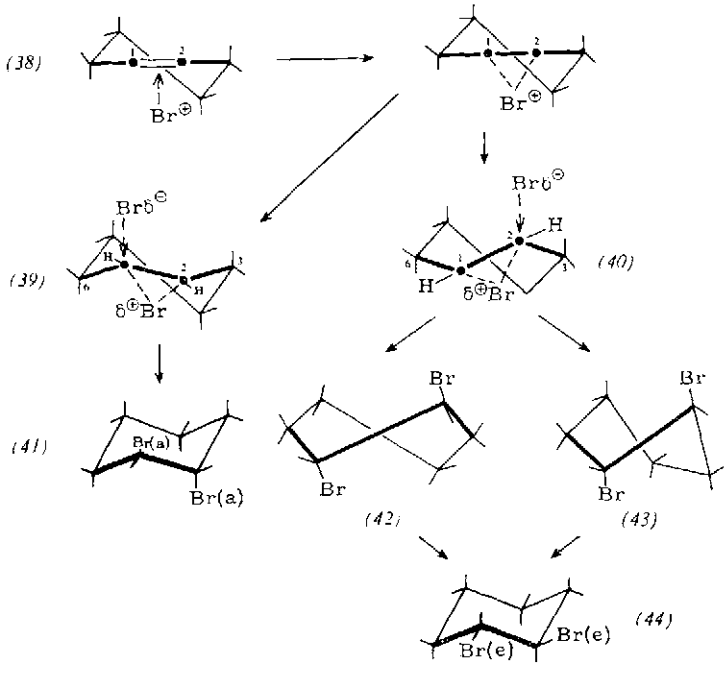
Perpendicular attack of an electrophilic reagent (*e. g.* Br_2) on a cyclic olefin leads to *trans*-diaxial attachment of the new substituents [52, 53]. The electrophilic portion (Br^+) and the anion (Br^-) must lie in the plane of maximum electron density and on opposite sides of the double bond. This is illustrated by the bromination of a cyclohexane in the half-chair form *(37)*.



(37)

The intermediate formation of a bridged bromonium ion demonstrates the analogy between the *trans*-diaxial addition and the diaxial cleavage of epoxides, which forms the basis of *Fürst* and *Plattner*'s rule.

Whether the electrophilic portion (Br^+) attacks from the β- or the α-side is mainly determined by the accessibility of the double bond. In the absence of electronic effects, the anionoid portion of the reactant (Br^-) may become attached to either of the two doubly bonded carbon atoms. To satisfy the principle of perpendicular attack, and in accordance with an analysis applied to the half-chair form *(38)* by *Valls* and *Toromanoff* [27], these two modes of attachment may be regarded as "pre-chair" *(39)* and "pre-twist" *(40)* forms [*]. Chair *(41)* and twist *(42)* conformations are already preformed in these intermediate states, and under certain circumstances the twist form can be converted to the chair form *(44)*.



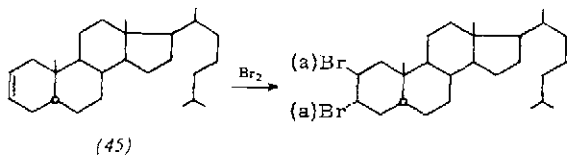
[52] *G. H. Alt* and *D. H. R. Barton*, J. chem. Soc. (London) *1954*, 4234.

[53] *D. H. R. Barton* and *R. C. Cookson*, Quart. Reviews (Chem. Soc. London) *10*, 44 (1956).

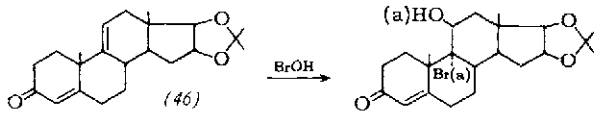
[*] The intermediate state *(40)*, which we originally called the "pre-boat" form [27], is in fact a flexible "pre-twist" conformation. Analysis of the dihedral angles shows that it is a "twisted" conformation with the axis of symmetry passing through the C-3 and C-6 vertices, which leads to the least possible distortion of the original structure.

Whether the Br^- will become attached to C-1 or to C-2 will depend on the relative energies of the two intermediate states. In general, energy factors favor the "pre-chair" form in preference to the "pre-twist" form.

Although a few exceptions are known (particulary in the case of the hydrogen halides), the principle of *trans*-diaxial addition has been shown to be of wide applicability particularly in the steroid series, both with symmetrical (Br_2) and with unsymmetrical (HOBr) reagents, as is shown by examples *(45)* and *(46)*.



(45)



(46)

In the addition of HOBr to *(46)*, accessibility permits attack of the electrophilic Br^+ ion only from the α-side. Attachment of this ion in the 11α-position would require a flexible intermediate state of very high energy; attachment in the 9α-position, on the other hand, passes through the much more favorable "pre-chair" form. It is interesting to note that the 9α-Br,10β-OH addition of HOBr proceeds in opposition to the inductive and electromeric effects (Markownikoff's rule).

In addition to accessibility, a polar substituent in the neighborhood of the double bond can determine the direction of attack. This is true for reactions of carbenes with cyclopentenols [54] and cyclohexenols [55], and for the epoxidation of cyclohexenes, which has been investigated by *Henbest* [56] and *Takeda* [57]. According to these authors, hydroxyl or nitrile groups can affect the stereochemistry of epoxydation in two ways: by binding the reactant in the transition state, or simply by dipole interactions.

One particular aspect of accessibility manifests itself in the catalytic hydrogenation of cyclohexene derivatives, which corresponds to the *cis*-addition of two hydrogen atoms. The molecule must be fixed at the surface of the catalyst with the least hindered side of its double bond. The steric orientation of the two hydrogen atoms to be added is then governed principally by 1,3-diaxial interactions in the unsaturated molecule. *Hadler* [58] has referred to these as "primary steric factors"; they are thought to be responsible for the stereochemistry of the catalytic hydrogenation of Δ^4- and Δ^5-steroids.

Here again, the experimental results cannot be explained by differences in accessibility alone, but intermediate states with almost tetrahedral carbon atoms must also be considered. For example, hydrogenation of the 1-methyl derivatives of *(47)* and *(48)* proceeds three times as slow as hydrogenation of the unsubstituted compounds, al-

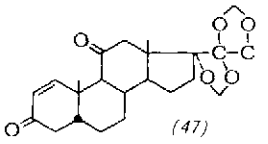
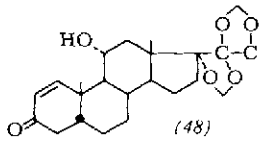
though the extra substituent does not alter the accessibility of the β-side [59].



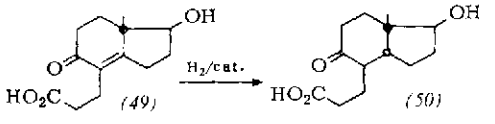
(47)



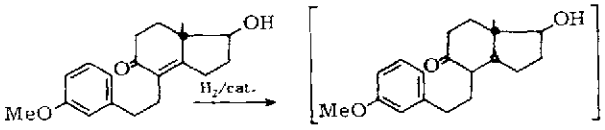
(48)

Polar substituents can also exert a directing influence on catalytic hydrogenation [60]. Catalytic *cis*-hydrogenations are extremely important in the total synthesis of steroids for the formation of asymmetric centers, particularly that in position 14 (cf. p. 195) [51]. $\Delta^{14(15)}$-Steroids are mainly hydrogenated from the α-side, since the β-side is shielded by the C-18 methyl group. The yield is greater in the hydrogenation of a 17β-hydroxy-$\Delta^{14(15)}$-steroid than for a 17-ketone [61] (cf. p. 196).

A difficult stereochemical problem is encountered in the catalytic hydrogenation of bicyclic intermediates with an 8,14-double bond (cf. p. 195). *Velluz*, *Nomine* et al. [62] solved this problem by using a bicyclic derivative *(49)* with an alkyl side-chain on C-8. They obtained mainly the product of α-hydrogenation, *i. e.* the *trans*-hydrindane structure *(5)*. An analogous reaction [*(51)* → *(52)*] has been described by other authors [136].



(49) (50)



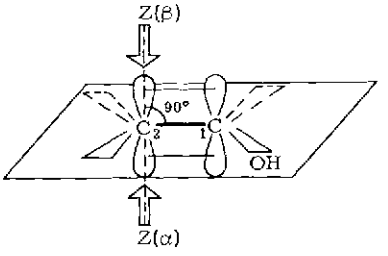
(51) (52)

γ) *Enol Functions* (2 $sp^2 \rightarrow sp^3 + sp^2$)

Reactions, such as halogenation or alkylation of a carbon atom adjacent to a carbonyl group, require preliminary enolization, and so correspond to reactions with enol functions. They are greatly different from the reactions of cyclohexenes in which attack can take place on either of the doubly bonded carbon atoms. In the case of enols, the positive electromeric effect (+E) directs the reaction completely towards the carbon atom which does not carry the OH group *(53)*.

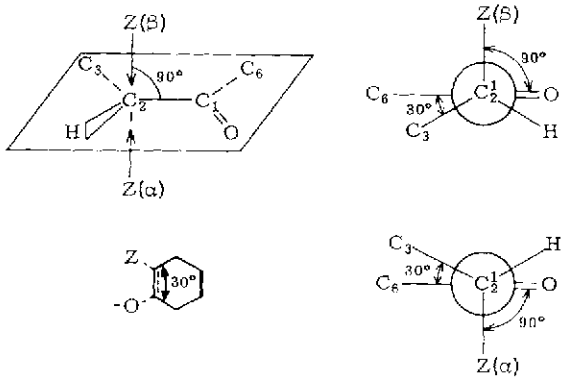
Viewed from another angle, addition to an olefin requires the conversion of two trigonal into two tetragonal carbon atoms (2 $sp^2 \rightarrow 2\ sp^3$), whereas attack at an enol function requires rehybridization of only one trigonal carbon atom, the other remaining trigonal as part of the carbonyl group (2 $sp^2 \rightarrow sp^3 + sp^2$). As a result, the stereoelectronic factor becomes particularly important in reactions involving cyclohexenols.

The attacking reagent obeys the principle of maximum overlap of the participating orbitals by perpendicularly approaching the plane of the atoms which constitute the enol function *(53)*.



(53)

The steric course of the reaction is largely determined by the accessibility of the molecule from the α- and from the β-side. Another important factor is the energy of the transition state. For reasons mentioned on p. 186, we shall assume that the transition state resembles the ketonic product ($sp^3 + sp^2$). In an intermediate state of this type, the bond which is being formed is perpendicular to the plane defined by the carbonyl function and the adjacent C-atoms. Consequently the dihedral angle O-C(1)-C(2)-Z must be 90° and the dihedral angle C(6)-C(1)-C(2)-C(3) becomes 30° (Scheme 2). Thus the stereoelectronic factor leads to a new restriction on the geometry of the transition state, and may strongly affect the steric course of the reaction [*].



Scheme 2. Attack of a reagent Z at a carbon atom adjacent to a carbonyl group. The figure on the upper right shows the attack from the β-side, the figure on the lower right that from the α-side. In both cases the molecule is viewed along its (C-2)–(C-1) axis.

In accordance with the principle of micro-reversibility, the discussion of the attack of Z also applies to the reverse process.

It follows directly from the principle of perpendicular attack that attack and departure will be axial in the chair form of cyclohexanone: the geometry of a chair cyclohexanone *(54)*, as viewed along the C(1)-C(2) bond *(55)*, is defined by the dihedral angles O-C(1)-C(2)-H(2β) = 117°, O-C(1)-C(2)-H(2α) = 3°, and C(6)-C(1)-C(2)-

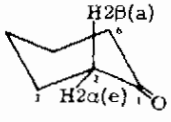
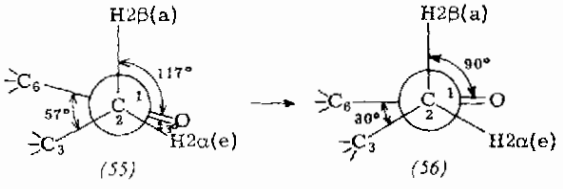
[*] We have assumed, for simplicity, that while the reactant is being attached to C-2, it is not also bonded to the oxygen of the carbonyl group which is being formed; in fact, however, both steps may proceed simultaneously [24].

C(3) – 57° [*]. Now enolization of the carbonyl function requires a hydrogen atom at C-2 to assume a position perpendicular to the plane C(6)-C(1)-C(2). This change must take place with the least possible distortion of the cyclohexane structure. It is obvious [*(55)* → *(56)*] that the axial 2β-hydrogen atom can assume the perpendicular position (117° → 90°) more readily than the equatorial 2α-hydrogen (3° → 90°). The enol is therefore formed preferentially by migration of the 2β-hydrogen atom. In the reverse process (formation of the ketone), the proton becomes attached to C-2 of the enol in such a way that it finally occupies an axial (2β) position [23].



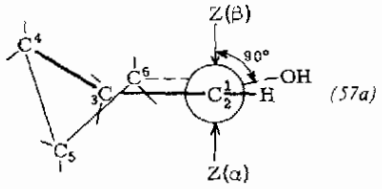
(54)



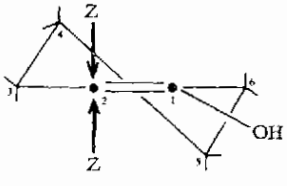
(55) *(56)*

This axial attachment, which is encountered in many reactions of enols (protonation, halogenation, alkylation), has been theoretically interpreted by *Corey*, and is in fact simply a result of the principle of perpendicular attack.

Generalization of the rule of axial attack [27] leads to two possible courses for the perpendicular attack on a cyclohexenol in the half-chair conformation *(57a, b)*. Attack from the β-side leads to a "pre-chair" intermediate, and then to a chair form with Z in an axial (2β) position. Attack from the α-side, on the other hand, gives a "pre-twist" conformation; this in turn yields a flexible ring, with Z in the axial (2a) position, which can finally go over to a chair form with an equatorial (2α) Z. In general, the "pre-chair" form (*i. e.* β-attack) is energetically more favorable than the "pre-twist" form (the formation of which requires greater deformation of the ring) [**].



(57a)



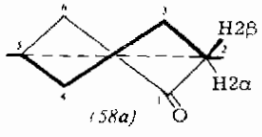
(57b)

[*] The geometry of cyclohexanone is reported to be very similar to that of cyclohexane [64].

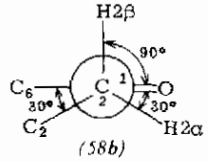
[**] Another interpretation assumes an axial α-attack on the half-boat form of the enol (whereas β-attack would have to occur on the half-chair form) [43].

It follows from the foregoing discussion that equatorial attacks are unlikely from the stereoelectronic standpoint and therefore need no longer be considered [42,43].

It must be emphasized that the rule of axial attack is valid only in the case of the chair form. The principle of perpendicular attack, on the other hand, is far more general and is valid for all possible forms of cyclohexane, including the flexible forms for which the term "axial orientation" may be meaningless. For example, in the twist form *(58a)* with C(2)-C(5) as the axis the 2β-hydrogen atom is in a position favorable for departure, *i. e.* it is perpendicular to the carbonyl group *(58b)*, while it forms an angle of only about 45° with the mean plane of the ring.



(58a)

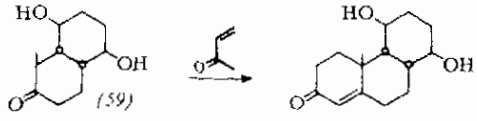


(58b)

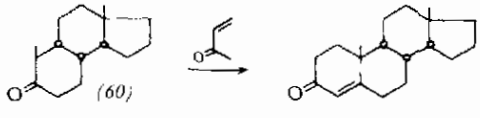
Thus, for conformational analysis of the intermediate states the principle of perpendicular attack is most important. The angle which has as its "hinge" the C-C bond involed in enolization is the corresponding dihedral angle (Scheme 2). The other dihedral angles then must be such as to minimize ring deformation. The potential energy of such a conformation will depend on the deformations of all the dihedral angles and on the steric interactions between atoms which are not directly linked together.

The following examples illustrate the effects of these factors on the stereochemical results of enol reactions:

1. If the accessibility of the enol function and the energy level of the intermediate state favor attack from the same side, the reaction will be highly stereoselective. A good example are the "folded", *i. e. cis*-fused, polycyclic structures *(59)* and *(60)*, which are particularly accessible



(59)



(60)

from the convex α-side. An alkylating agent may enter axially in to a "pre-chair" form, so leading to an intermediate state of low energy (as compared with the "pre-twist" form which would result from β-attack) [18,65,66].

A methyl group makes the "pre-twist" conformation more stable than the "pre-chair" form, and favors attack

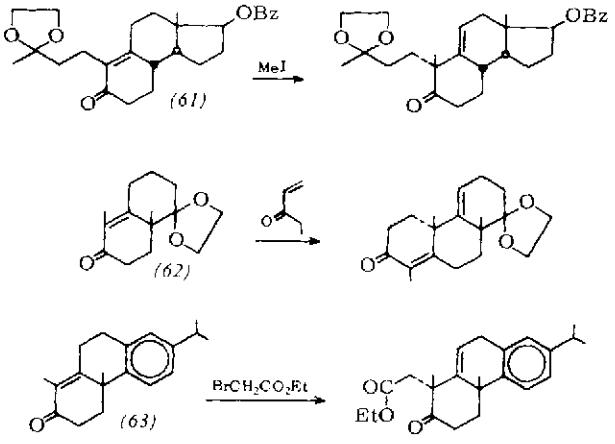
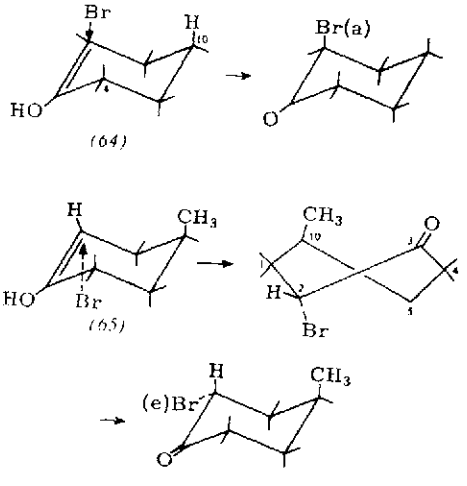
[66] *D. K. Banerjee, V. Paul*, and *S. K. Balasubramanian*, Tetrahedron Letters 1960, No. 12, p. 123.

from the remote side. Whereas on alkylation of *(61)* the main product results from β-attack ("pre-chair" intermediate) [67], an 8β-methyl group [compounds *(62)* and *(63)*, steroid numbering!] permits alkylation from the α-side ("pre-twist" intermediate) [68, 69]. This 8β-methyl group plays a double part: it favors approach from the α-side, and destabilizes the "pre-chair" intermediate resulting from β-attack.



2. If the accessibility of the enol function and the energy level of the intermediate state oppose each other, the product is frequently a mixture of epimers (unless one of the two factors predominates). Examples are found in the bromination of A/B-*trans*-3-oxo steroids: 19-nor derivatives *(64)* take up bromine in the 2β-position ("pre-chair" intermediate), although β-attack is hindered by the axial hydrogen atoms on C-4 and C-10. In *(65)*, on the other hand, β-attack is further hindered by the methyl group on C-10. The bromine cation must therefore approach from the α-side, leading *via* a "pre-twist" intermediate to a chair form with an equatorial 2α-bromine. It should be pointed out that the flexible intermediate can be isolated in the bromination of the 2-methyl derivative of *(65)* [42, 43].

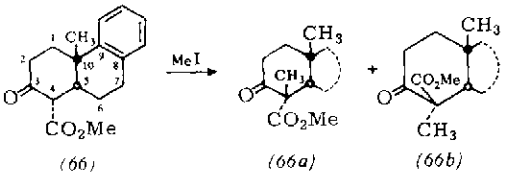


[67] *L. Velluz, G. Nominé,* and *J. Mathieu,* Angew. Chem. *72,* 725 (1960).

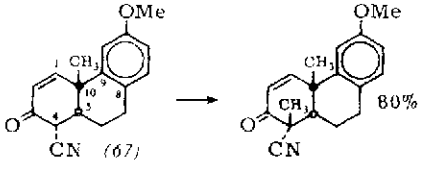
[68] *M. Brown,* Dissertation Abstracts *23,* 4107 (1963).

[69] *G. Stork* and *J. W. Schulenburg,* J. Amer. chem. Soc. *84,* 284 (1962).

Similar observations have been made in the alkylation of enoxides. Thus, methylation of the keto ester *(66)* yields a mixture of the epimeric 4-methyl derivatives *(66a)* and *(66b)* in the ratio 2.4:1 [70]. This result can be explained by considering the opposing effects of the angular 10β-methyl group (which favors accessibility of the α-side) and of the ester function on C-4 (which, owing to its eclipsed interaction with the methylene group on C-6, destabilizes the flexible conformations which would be compatible with the opening of the dihedral angle C(4)-C(5)-C(10)-C(1) caused by the 8,9-double bond).



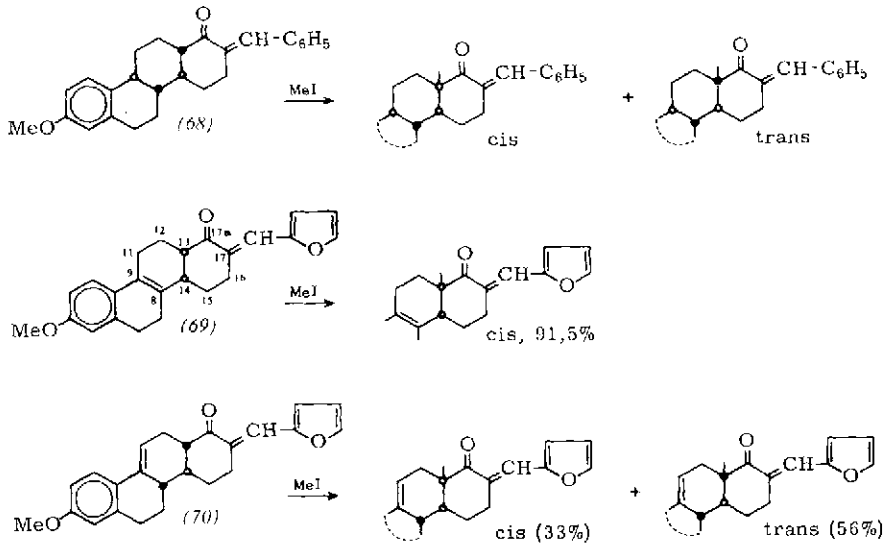
It is interesting to note that the analogous structure *(67)*, which contains a 1,2-double bond, gives only the 4β-methyl derivative, although here β-attack is more strongly hindered [71]. *Stork* [69] has pointed out that the 1,2-double bond in *(67)* is coplanar with the carbonyl function in position 3 only in the chair form of the ring, so that a "pre-chair" intermediate is favored. We believe that, in addition, the conformations resulting from α-attack would be incompatible with the opening of the dihedral angle C(4)-C(5)-C(10)-C(1) caused by the 8,9-double bond.



The above examples, particularly *(66)* and *(67)*, show the importance of the number of double bonds present in the molecule. They affect the dihedral angle at the ring junction and force the reacting ring to assume flexible forms in which the interactions of 1,3-diaxial substituents at the "ring hinge" are modified. A particularly good example of these effects is provided by the work of *Johnson* et al. While the alkylation of compound *(68)* yields a mixture of epimers in which the *cis*-isomer predominates (*cis*:*trans* = 3:1), the introduction of a double bond *(69)* in the *meta*-position relative to the junction dihedron leads to exclusive formation of the *cis*-isomer. After introduction of a double bond in the *para*-position *(70)*, on the other hand, the principal product is the *trans*-isomer.

These results cannot be explained simply by the effect of accessibility [21, 39]. Rather the influence of trigonal carbon atoms on the energy levels of the transition states must also be taken into account. Analysis by *Bucourt*'s method [8] (see p. 182) shows that, in the case of the hexahydronaphthalenes, *cis*-fusion is favored if the two dihedral angles of 0° occupy equivalent positions *(e.g. meta, meta)*. Consider compounds *(69)* and *(70)*: if the 17a-carbonyl function and the double bond at C-17 are

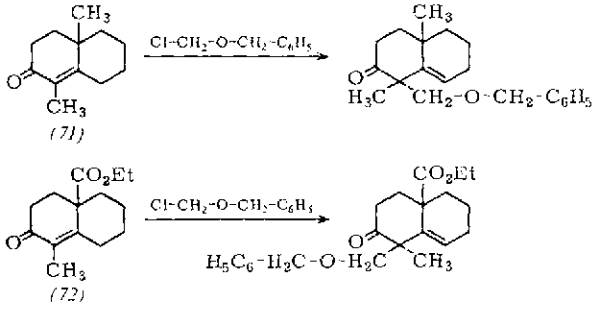
[70] *E. Wenkert* and *A. Tahara,* J. Amer. chem. Soc. *82,* 3229 (1960).



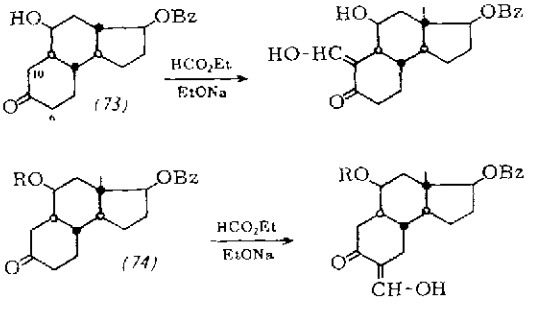
coplanar, the dihedral angles C(13)-C(17a)-C(17)-C(16) and C(14)-C(8)-C(9)-C(11), which are in *meta*-positions relative to the ring junction and which are 0° each, favor the *cis*-product, while in *(70)* the dehedral angles of 0°, *viz.* C(13)-C(17a)-C(17)-C(16) and C(8)-C(9)-C(11)-C(12), are in the *meta*- and *para*-positions, respectively, and thus favor the *trans*-isomer.

3. Finally, there are cases in which the accessibility requires attack from one side, while the energy level of the corresponding intermediate states is so high that the reaction cannot proceed [72, 73] or takes place at another site. This would explain, for example, the bromination of a 3-oxo-5β-methyl steroid at C-2 [40].

Polar factors frequently affect the approach of a reactant and/or the stability of an intermediate state. It has been suggested [74] that effects of this type may be caused by dipole pairing or by solvation of the nascent carbonium ion. In *(72)*, for example, the angular ethoxycarbonyl group reverses the stereochemistry of the alkylation of the enol *(71)* [75].



Similarly, an 11β-hydroxyl group directs the hydroxymethylation of the tricyclic compound *(73)* towards C-10, whereas the reaction occurs at C-6 in the absence or on blockage of the hydroxyl group [76].



II. Practical Considerations

One of the main difficulties in the total synthesis of steroids is the stereoselective introduction of centers of asymmetry by conversion of carbon atoms from the trigonal to the tetragonal state (alkylation of enoxides, hydrogenation of double bonds, epimerization of carbon atoms adjacent to carbonyl groups, *etc.*). In this paper, we shall deal only with the formation asymmetric centers in the angular positions 10 and 13, and in position 14.

a) Formation of a Center of Asymmetry in Positions 13 and 14

The stereoselective synthesis of the 13-alkyl-*trans*-hydrindane *(75)*, corresponding to rings C and D of a steroid, has long been a difficult problem. In fact, most attempts to synthesize *(75)* directly were defeated by the greater stability of the *cis*-hydrindane structure *(76)*.

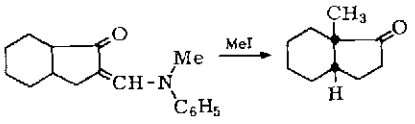
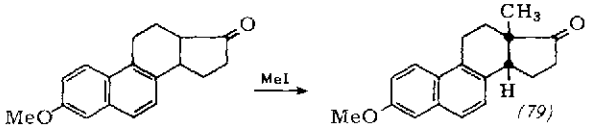
One of the unsuccessful methods was the angular alkylation of hydrindane derivatives. This reaction, which in the case of compound *(77)* yields the cis-isomer *(78)*, had been tried



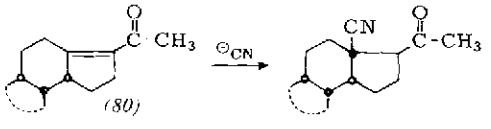
(77) *(78)*, cis

in the tetracyclic series as early as 1938 [77,78]. When applied to the methyl ether of 18-norequilenin (with the 16 position blocked), it gave the *cis*-derivative *(79)* [(±)-iso-equilenin].



(79)

The preferential formation of the *cis*-isomer renders difficult any synthesis which proceeds *via* a hydrindane with no substituent at C-13 [79, 80]. Nevertheless, *Nagata* has recently re-examined this question: under favorable conditions [81] the 1,4-addition of a cyanide ion to an α,β-unsaturated ketone *(80)* leads predominantly to the C/D-*trans*-isomer. This addition is suitable for certain syntheses (aldosterone, conessine), but is too complicated for the introduction of an angular methyl group.



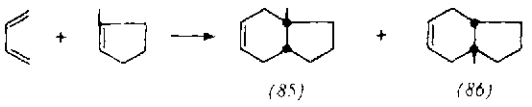
(80)

An attempt has been made to use the Diels-Alder reaction for the direct synthesis of the hydrindane system corresponding to rings C and D. Ring C was prepared by addition of a diene to a cyclopentene, *e.g.* *(81)*–*(84)*, which already contained a methyl group in what was to become the angular position.

(81), R = H *(83)*, R = H

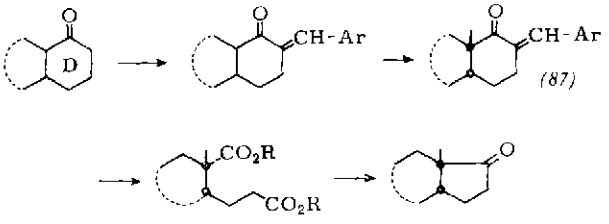
(82), R = CH_3 *(84)*, R = CH_3

The results were not very encouraging, however, since the diene synthesis gave *cis*-fused rings *(85)*, and the changing direction of addition of the diene also led to products with angular methyl groups on C-14 *(86)*. Although this method has been studied very intensively [82–84], it has now been abandoned, except for a few special cases such as the 18-nor-steroids and the D-homosteroids.



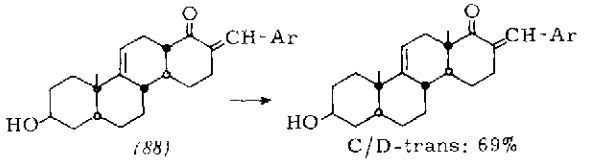
(85) *(86)*

These difficulties led to an investigation of the angular alkylation of decalin structures, which should be more stable in the *trans*-form than the hydrindane structures. The synthesis of rings C and D *via* a D-homosteroid intermediate *(87)* was suggested by *Johnson* and *Allen* ("hydrochrysene syntheses").

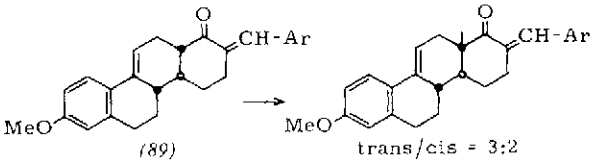


(87)

The stereoselectivity of this reaction was found to be poor. However, *Johnson* et al. [38, 39] observed that the unfavorable *cis*/*trans*-ratio [85, 88, 89] could be reversed by the introduction of a 9,11-double bond *(88)*, *(89)*. The theory underlying this phenomenon has been discussed above (cf. p. 191). The method so modified was used for the synthesis of estrone [86, 87]. However, its value is still limited by the fact that it is not completely stereospecific, and that the final contraction of the six-membered ring D to a five-membered ring proceeds only with low yields.



(88) C/D-trans: 69%



(89) trans/cis = 3:2

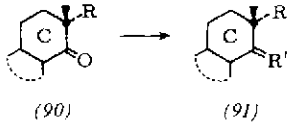
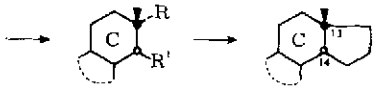
Johnson [90], in his synthesis of aldosterone [91], made use of the fact that the principal product of this method in its original form is the 9-alkyl-*cis*-decalin. The alkyl group introduced at C-13 during formation of the *cis*-decalin system was so chosen that it contained the elements of the future five-membered ring D.

Since no method could be found for the direct synthesis of the 13-alkylhydrindane structure with its two centers of asymmetry (C-13 and C-14), the problem was divided (1) creation of the asymmetric center C-13, and (2) subsequent creation of the asymmetric center C-14.

The asymmetric center C-13 can be formed by either of two routes: by joining ring D onto ring C, which already contains the future angular methyl group *(90)*,

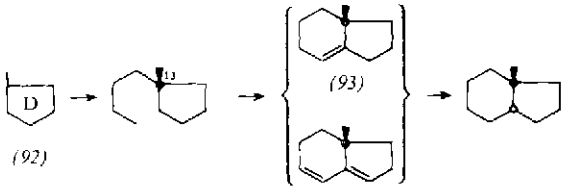


(90) *(91)*



(91a)

or by joining ring C onto a pre-methylated ring D *(92)*.

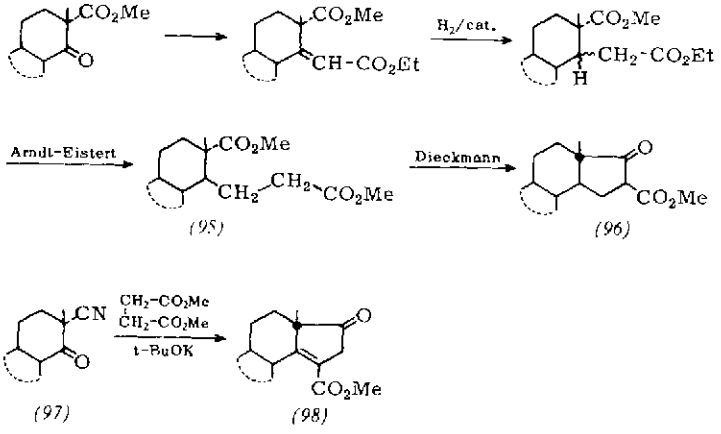


(92) *(93)* *(94)*

The asymmetric center C-14 must then be formed by reduction of a double bond, which may be exocyclic with respect to ring C *(91)*, or endocyclic in ring C *(93)* or ring D *(94)*.

The first of these schemes has been widely used. Ring C of the starting material *(90)* was a cyclohexanone derivative with a center of asymmetry in position 13. One of the substituents on C-13 was a carboxyl or cyanide group, which provided a point of attachment for the synthesis of ring D. The remaining elements of ring D were attached to C-14 by alkylidenation *(91)*. After reduction of the resulting exocyclic double bond, the five-membered ring D was closed by joining the chains attached to C-13 and C-14, using one of the following reactions:

Dieckmann reaction [*(95)* – *(96)*] *(Bachmann, Anner* and *Miescher, Robinson)*, acyloin condensation *(Sheehan)* [92], Stobbe condensation [*(97* – *(98)*] [93, 94], Alkylation *(Sarett)*, alkylidenation *(Wilds, Johnson,* and *Christiansen)*.



(95) *(96)* *(97)* *(98)*

After the desired configuration of the asymmetric center C-13 had been secured in the intermediate *(91)*, the stereochemical problem was to create the asymmetric center C-14. In principle there was no obstacle to the formation of a cyclohexane derivative *(91a)* with *trans*-diequatorial side chains on C-13 and C-14. *Johnson* (catalytic hydrogenation) [95] and *Sarett* (alkali metals/NH_3) [96] investigated the stereochemistry of the reduction *(91)* -> *(91a)*, and found that it was dependent on both the unsaturated compound and the reducing agent. High stereoselectivity can be achieved by correct choice of the reduction conditions.

In the second of the synthetic schemes mentioned above, in which a methylated cyclopentane derivative *(92)* (or its precursor) is used as the starting material [97], ring C is built up in two steps: introduction of a carbon chain at C-13, followed by ring closure to C-14. This scheme, which had been considered as early as 1935 [98], has been frequently used in recent syntheses. There are a number

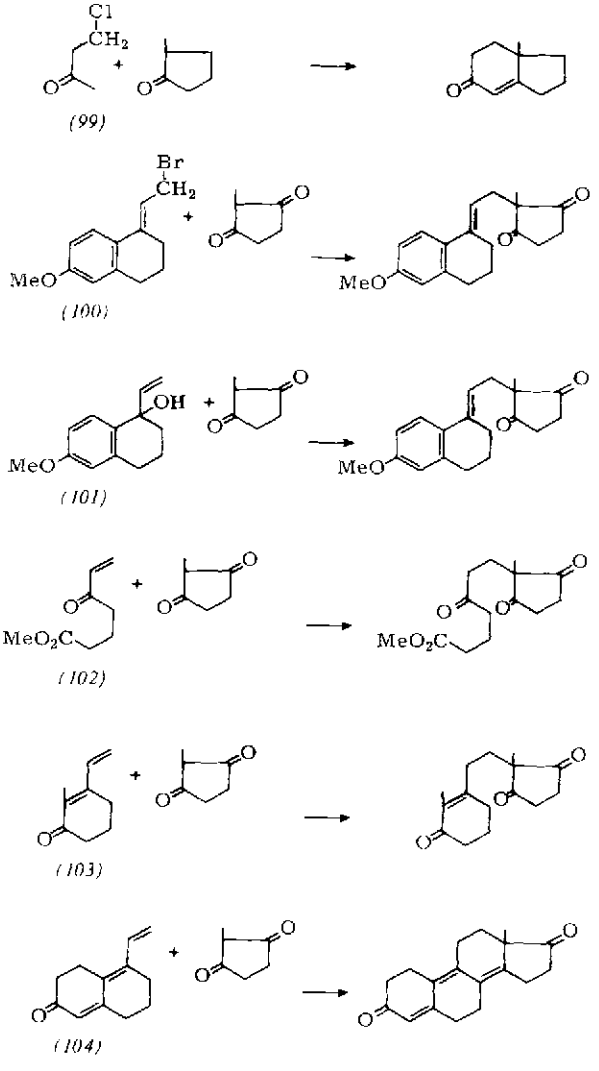
of variants, in which alkylation is achieved with one of the following reagents:

saturated alkyl halides *(99)* [99, 100],

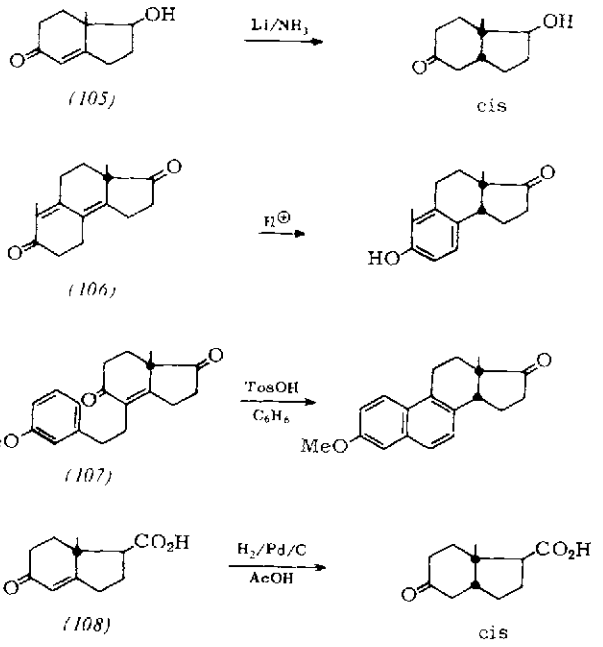
allyl halides *(100)* [101] or allyl alcohols *(101)* [102 to 105],

unsaturated ketones (or their precursors), by 1,4-addition *(102)* [106, 62], 1,6-addition *(103)* [107], or 1,8-addition *(104)* [108].



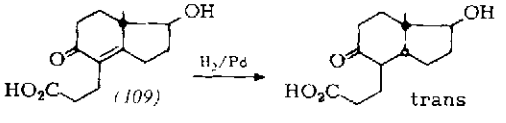
Ring closure is generally effected by alkylidenation, giving rise to an 8,14-double bond *(93)* or a 14,15-double bond *(94)*.

The formation of the asymmetric center C-14 by the reduction of structures *(93)* or *(94)* is stereochemically more difficult than in the case of the exocyclic derivative



(91). Any change allowing the carbon atom to appear temporarily in a form in which it is unable to retain its configuration (*e. g.* as a carbanion, a free radical, or a carbonium ion) may lead to the more stable *cis*-hydrindane system. This is precisely what happens during the reduction of the bicyclic derivative *(105)* [109, 110]. For similar reasons, isomerization of the 8,14-double bond in *(106)* and *(107)* leads to a C/D-*cis*-system [63, 107a]. The same result is obtained on catalytic hydrogenation of *(108)* [109, 110].

Velluz, *Nomine*, and *Amiard* [62] succeeded in solving this problem by using a bicyclic derivative *(109)* with a side chain on C-8. Hydrogenation of this compound is satisfactorily stereoselective and yields the *trans*-hydrindane (cf. p. 189 and [63]).



The presence of an alkyl substituent on C-8 is not the only reason for the stereospecificity of this reduction; the nature of the substituent on C-17 also plays an important part. It was shown that replacement of the 17β-hydroxyl group by a carbonyl group jeopardizes the stereospecificity of the hydrogenation.

If, in the creation of the center of asymmetry in position 14, the starting material has a 14,15-double bond *(110a,b)* or two double bonds in the 8,9- and 14,15-posi-

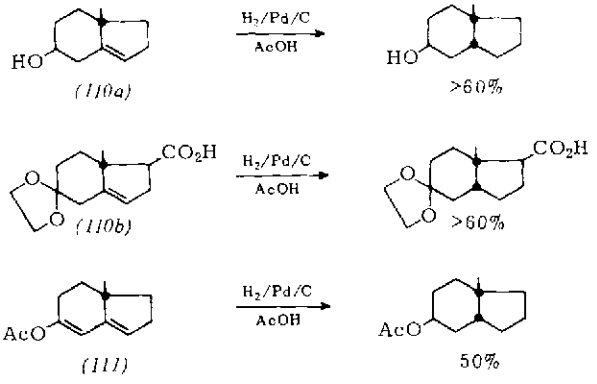
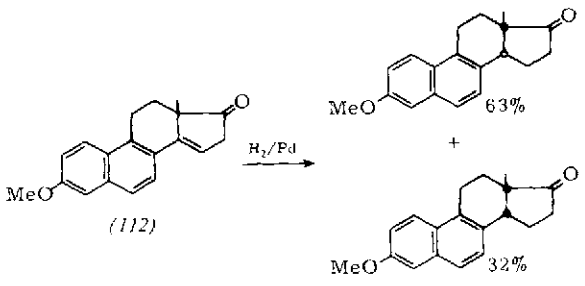
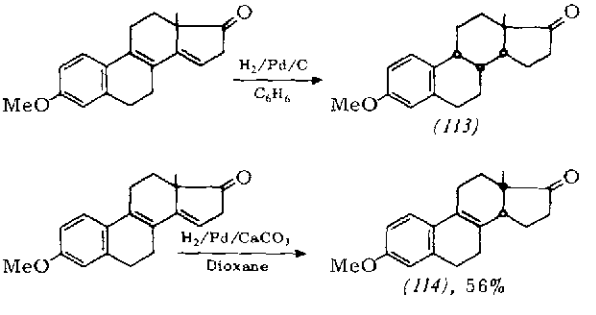
tions *(111)*, the same stereochemical difficulties are encountered as with *(93)*, *i. e.* the reaction leads preferentially to the *cis*-hydrindane derivative [109].



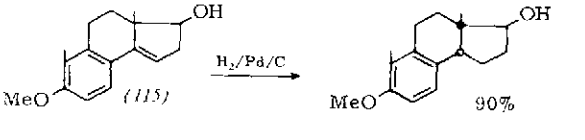
The stereochemistry of these reductions is more complex in the case of tri- and tetracyclic systems. It depends on the reducing agent used, and above all on the nature of the substituent on C-17. For example, the catalytic hydrogenation of the 17-oxo compounds *(112)* leads to mixtures of products [94] (cf. also p. 189).



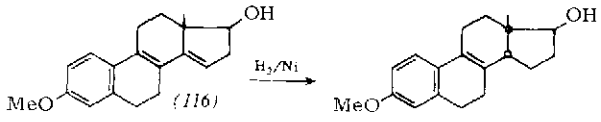
Moreover, the reactant must be sufficiently mild (Raney nickel [106] or $Pd/CaCO_3$ [102]) *(114)* in order to avoid the formation of an 8-iso-center as in *(113)*.



The yield of the reduction is improved if the 17-carbonyl group is converted into a 17β-hydroxyl group *(115)* [61]. This prevents migration of the 14,15-double bond into the 15,16-position to form the more stable *cis*-hydrindane derivative.

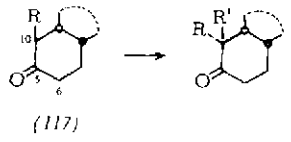


The high stereospecificity of this reaction has been utilized in a number of total syntheses [67, 103], another example being *(116)*.



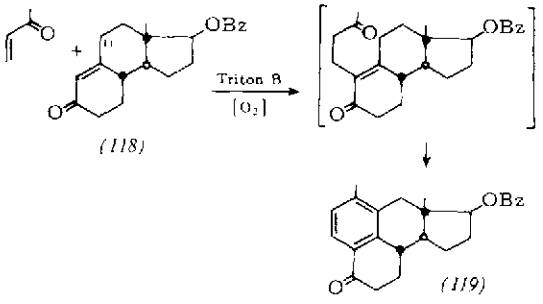
b) Formation of a Center of Asymmetry in Position 10

The center of asymmetry at C-10 is generally formed by alkylation of a cyclohexanone *(117)* which already carries an alkyl group on C-10 (steroid numbering).

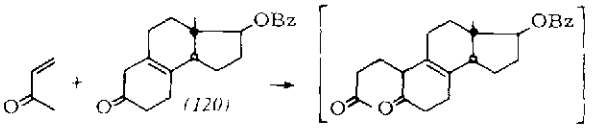


This alkylation can take place on either C-10 or C-6. It is not necessary to block C-6, however, if ring D is five-membered (cf. p. 183).

In cyclohexenones of the type *(118)*, alkylation is also subject to interference from C-11. Thus methyl vinyl ketone condenses with C-11 *(119)* in the presence of Triton B [67] or sodium ethoxide [111].



We were able to avoid this reaction [67] by starting with an unconjugated ketone *(120)*, in which position 11 is no longer activated by a vinylogous double bond, as it is in *(118)*.



A satisfactory alkylation of C-10 can also be achieved by the method recommended by *Stork* [112], in which enamines of conjugated ketones are reacted with 1,3-dichloro-2-butene (or one of its derivatives) [113–115].

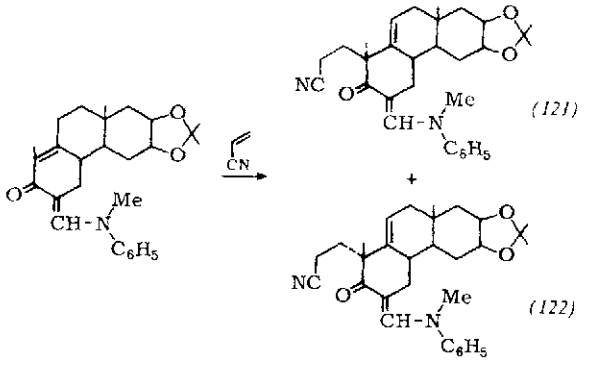
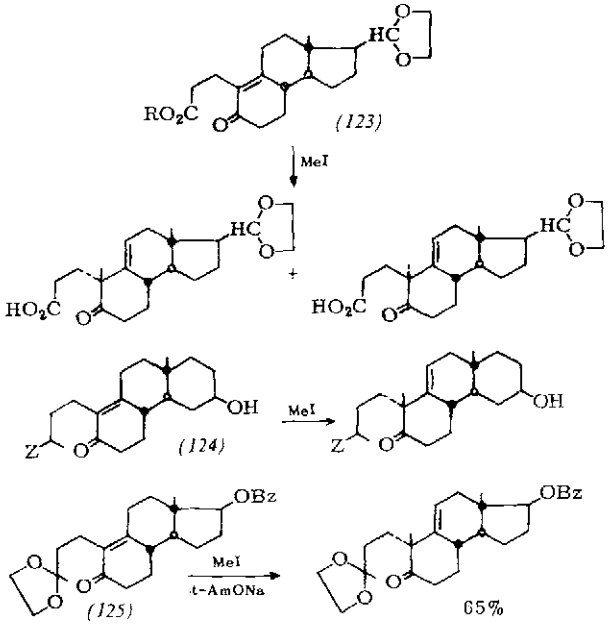
[115] *R. Bucourt, J. Tessier*, and *G. Nominé*, Bull. Soc. Chim. France *1963*, 1923.

The order in which the alkyl groups R and R′ are introduced on C-10 is of some importance to the stereochemistry of this center. If the difference in the accessibility from the α- and from the β-side of the molecule is small, the stereochemistry of the second alkylation at C-10 is governed mainly by the energy of the intermediate state (cf. pp. 185 and 188). Thus the second alkyl residue R′ enters the axial β-position and so directs the first alkyl residue R into the α-position. If access from the β-side is sufficiently hindered, the opposite result is obtained.

The formation of ring A normally fails if ring B already carries the future angular C-19 methyl group, since the chain introduced at C-10 preferentially attacks from the β-side and forces the methyl group into the α-position. This was a weak point in *Woodward*'s total synthesis [116], in which the product contained twice as much 10α-methyl isomer *(121)* as 10β-isomer *(122)*.



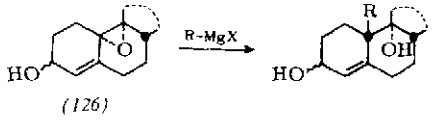
Two solutions have been proposed. One is to use "folded" *cis*-decalin structures, as indicated on p. 190, in which the accessibility of position 10 and the energy of the intermediate state lead to entry of the alkyl group from the α-side. This method has been used by *Banerjee* [66] and *Sarett* [18, 65]. It has the disadvantage, however, that it leads to an 8-iso product, which is frequently difficult to epimerize.



[116] *R. B. Woodward, F. Sondheimer, D. Taub, K. Heusler*, and *W. M. McLamore*, J. Amer. chem. Soc. *74*, 4223 (1952).

The other solution consists in reversal of the alkylation on C-10, *i.e.* in introducing the carbon chain for ring A first, followed by the angular methyl group. The principal product obtained by this method is the 10β-methyl isomer, *e.g.* in the syntheses developed by *Barkley* and *Thompson (123)* [10] and by *Stork (124)* [117]. We have also used this procedure *(125)*.

Finally, the reaction with a 9α,10α-epoxide *(126)* also yields a 10β-alkyl derivative. The alkylating agent attacks from the β-side, and the *trans*-diaxial cleavage of the epoxide ring (cf. p. 188) forces the alkyl group into the 10β-position, while the hydroxyl group appears in the 9α-position. This method has been used for the introduction of an allyl group on C-10 [118].



Tetralin or octalin structures corresponding to rings A and B have also been alkylated on C-10 by the Reimer-Tiemann reaction [119], the vinyl allyl ether rearrangement [120, 121], or by 1,4-addition of cyanide ion [121]. However, these methods have never been used for the introduction of a 10β-alkyl substituent in the total synthesis of steroids.

c) Development of Synthetic Routes

The problems associated with the formation of the asymmetric centers C-13, C-14, and C-10 illustrate the difficulties encountered in the stereospecific total synthesis of steroids. They have influenced the order in which the four rings are built up and restricted the number of useful synthetic routes (despite a large number of theoretically possible combinations). Table 1 shows a few examples illustrating how the synthetic routes used have developed in the course of the last twenty years.

In the first total syntheses, the rings were built up in the sequence A → D, since the object of these syntheses was to prepare steroids containing only a few centers of asymmetry, *i.e.* highly unsaturated structures. The starting materials consisted of an aromatic A or A/B system. Notable examples are the syntheses by *Bachmann* (1939) [122], *Robinson* (1938), *Anner* and *Miescher* (1948) [124], *Johnson* (1945) [93], and *Wilds* (1947).

The order of formation of the rings subsequently changed, but the five-membered ring D still was the last to be formed in all syntheses up till 1958. This was due to the scarcity of methods available at that time for the stereoselective formation of the 13-alkyl-*trans*-hydrindane structure, which made it impractical to start a synthesis with the formation of a C/D-hydrindane system. In order to overcome these difficulties, *Johnson* developed his hydrochrysene synthesis (p. 193) around 1956. This method involved the use of a C/homo-D-decalin system, from which a five-membered ring was produced at the end of the synthesis.

[132] *J. E. Cole* and *W. S. Johnson,* Proc. chem. Soc. (London) *1958,* 114.

The most notable syntheses of this time were those by *Johnson* (1956) [89], *Woodward* (1951), *Sarett* (1952) [65], and *Stork* (1956) [117], as well as the aldosterone syntheses by *Wettstein* (1957–58) and *Johnson* (1958) [132], some of which already exhibited a remarkable degree of stereospecificity (over several stages).

The period following 1958 saw the appearance of syntheses which no longer ended with the formation of the five-membered ring D. These were made possible by the increased stereospecificity of the reactions used for the formation of the asymmetric centers C-13 and C-14. Some syntheses even start with a five-membered ring D, so that the sequence of ring formation becomes D → A (*i.e.* the reverse of that used for the earliest total syntheses).

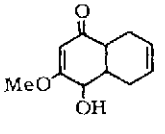
The experimental and theoretical advances, the stereoselectivity of numerous reactions and the choice of synthetic routes became so great in 1959–1960, that it was now possible to attempt a total steroid synthesis which could be used in industry. Until that time, this aim had appeared to be completely Utopian.

There are at least three requirements which must be satisfied by a total synthesis of this type:

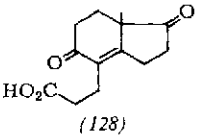
stereoselectivity of each step,
earliest possible resolution of racemates,
convergence of the reaction scheme.

The first of these requirements is obvious, and the problems which it raises have been discussed above, together with the largely satisfactory solutions now available.

The second requirement is related to the cost of production of the optically active end product. Most total syntheses have been carried out with racemates, resolution of the racemic tetracyclic systems being carried out at the end of the synthesis. Resolution at the bicyclic stage offers the advantage of getting early into the active series. The importance of this procedure was recognized in 1954 by the Monsanto group, who tested it with the bicyclic system *(127)*. In 1963, *Velluz, Nominé, Amiard,* et al. made practical use of the resolution of the bicyclic acid *(128)*.



(127)



(128)

The third requirement which must be satisfied by an industrially applicable total synthesis is convergence of the synthetic scheme. In a multistage synthesis, each stage results in a decrease in the overall yield, and involves the loss of increasingly expensive intermediates. This loss is reduced in a converging synthesis, in which two parts of the future steroid are formed initially, and the combination of these fragments to form expensive intermediates is delayed as long as possible. Most of the syntheses achieved prior to 1961 were linear (cf. Table 1, Part 1). The possibility of using the five-membered ring D or a

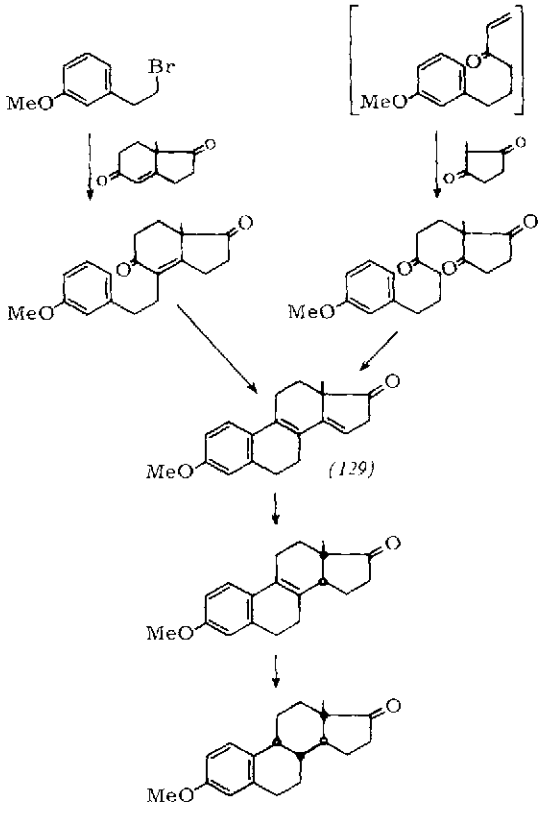
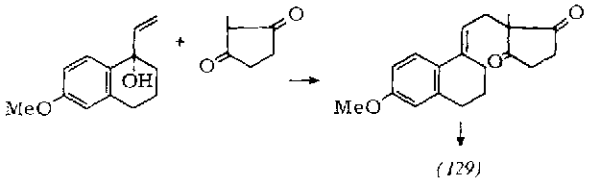
hydrindane system as the starting material then permitted the development of converging syntheses (see Table 1, Part 2).



Scheme 3. Total synthesis of steroids according to *Hughes, Smith*, et al. [135, 137].

It finally became possible to achieve the complete synthesis of steroids by a remarkably short route. Scheme 3 shows the result of investigations by *Hughes, Smith*, et al. [135–137] in the racemic series. Another route (also in the racemic series) used by a number of research groups [101–103, 105, 134, 135] is outlined in Scheme 4.



Scheme 4. Another method of synthesizing compound *(129)* of Scheme 3.

Progress with regard to the stereoselectivity of reactions and the convergence of the synthetic scheme has recently made possible the total synthesis of optically active steroids on the industrial scale. Work carried out in our laboratory initially involved the linear type of synthesis [67, 126–128] (Scheme 5) and corresponded to the sequence BC → Df → A. Resolution of a racemate was achieved at the stage of the tricyclic acid *(130)*, and the synthesis was then completed in the active series.

Recent Developments in the Chemistry of Heterosiloxanes

BY PRIV.-DOZ. DR. H. SCHMIDBAUR

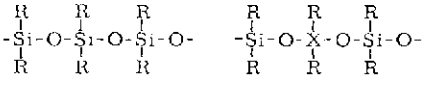
INSTITUT FÜR ANORGANISCHE CHEMIE DER UNIVERSITÄT MARBURG (GERMANY)

Progress in the chemistry of organoheterosiloxanes is reviewed in the light of the latest preparative and spectroscopic results. Attention is focussed on the heterosiloxane structural unit Si–O–X, the bonding in which – depending on the hetero-atom – differs characteristically from that in the siloxane bridge Si–O–Si.

I. Introduction

Following the great success achieved with silicone-based polymers, attempts were made to satisfy the increasing technological demands on inorganic polymers by synthesizing modified silicones. However, since the search for silicone-like polymers was often unsystematic and lacked firm theoretical foundation, these efforts have frequently met with little success. This is also seen from recent monographs on "Inorganic Polymers" [1,2].

Silicone polymers were modified in two ways. Either the residues R bonded to the siloxane skeleton *(1)* were changed, or hetero-atoms were incorporated into the quasi-silicate siloxane chain. The latter change may involve replacement of oxygen by nitrogen [3] or sulfur, or of silicon by other elements X *(2)*.



(1) *(2)*

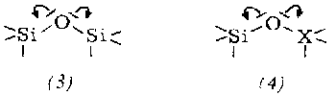
Substances of type *(2)* are termed heterosiloxanes. For many years the main centers of heterosiloxane research have been the schools of *K. A. Andrianov* (Moscow) [4], *D. C. Bradley* (London and Ontario) [1,5], and *M. G. Voronkov* (Leningrad and Riga) [6].

Progress in our understanding of the properties of heterosiloxanes was to be expected only from a better understanding of the bonding. Since investigations of polymers with irregular compositions only rarely yield detailed information, it was necessary to prepare low molecular-weight model substances of definite composition; these should contain all the structural units and building blocks which could be involved in the structures of larger molecules and polymers [7]. The results of work along these lines are reviewed in the present paper.

II. The Siloxane Linkage

Examination of the heterosiloxane linkage, Si–O–X, must be preceded by a discussion of the disiloxane linkage, Si–O–Si.

The unusual thermal and chemical stability of quartz and many silicates led to expect a special type of bonding in the Si–O–Si structural unit; this was later confirmed by the stability of the silicones. Bond energies, force constants, interatomic distances, and valence angles indicate that the Si–O–Si structure *(3)* is a homopolar bond-system with surprisingly little polarization and with unusually high π-bond character [8]. The widely accepted concept of the $d_\pi p_\pi$- or (p → d)π-strengthening of the Si–O σ-skeleton was subjected repeatedly to theoretical calculations and appears to be sufficiently verified [9, 10]. Although this concept may be only one possible interpretation of the experimental findings, it is used in the present paper as a basis for discussion of the bonding in heterosiloxanes.



(3) *(4)*

Replacement of a silicon atom in the Si–O–Si bridge by a hetero-atom, *(3)* → *(4)*, must lead to a fundamental redistribution of the valence electrons; this is determined primarily by the electronegativity and the atomic radius of the atom X, and by the availability of energetically and sterically favorable d-orbitals of X, which, according to molecular-orbital theory, lead to $d_\pi p_\pi$-strengthening of the σ-skeleton by interaction with the p-orbitals of the bridge-oxygen atom. In valence-bond terminology

III. Heterosiloxanes

A. Germanosiloxanes

The most suitable elements for modifying a siloxane skeleton by hetero-atoms are the neighbors of silicon in the periodic system, and in particular its higher homologues; thus, most investigations have so for been concerned with the germano-, stanno-, and plumbo-siloxanes.

1. Preparation

Attempts to prepare germanosiloxane polymers by cohydrolysis of organohalogenosilanes and -germanes met with little success [11]. The first definite germanosiloxanes were obtained by reaction of organosiloxides with organohalogenogermanes [12–14]. Using this method, the parent member *(6)* of the homologous series was prepared in a high yield [Equation (a)].

$$(CH_3)_3SiOLi + ClGe(CH_3)_3 \rightarrow LiCl + \underset{(6)}{(CH_3)_3Si\text{-}O\text{-}Ge(CH_3)_3} \quad (a)$$

More recently, compound *(6)* has also been prepared by the opposite route (h), *i.e.* from lithium trimethylgermoxide and trimethylchlorosilane [15].

$$(CH_3)_3SiCl + LiOGe(CH_3)_3 \rightarrow LiCl + \underset{(6)}{(CH_3)_3Si\text{-}O\text{-}Ge(CH_3)_3} \quad (b)$$

These two synthetic principles also permitted preparation of the higher homologues [13,14,16,17], the most important of which are listed in Table 1. Whereas the germanium atom in *(6)* to *(8)* is only monofunctional (with regard to the siloxane linkage), *(9)* to *(12)* contain di-, tri-, and tetra-functional hetero-atoms, and are thus model substances for linear and branched-chain polygermanosiloxanes.

(7)	$(C_2H_5)_3Si\text{-}O\text{-}Ge(CH_3)_3$		33/1	995	[14]
(8)	$(CH_3)_3Si\text{-}O\text{-}Ge(C_2H_5)_3$		34/1	995	[14]
(9)	$[(CH_3)_3SiO]_2Ge(CH_3)_2$	−61	165/725	1002/952	[13, 14]
(10)	$[(CH_3)_3SiO]_3GeCH_3$		77/10	1020/948	[14]
(11)	$[(CH_3)_3SiO]_4Ge$	−59	198/725	1020/949	[14, 16]
(12)	$[(C_6H_5)_3SiO]_4Ge$	427	400 (subl.)	—	[17]

2. Properties

Chemical behavior of the simplest germanosiloxanes shows that they are less stable than the analogous siloxanes. For example, the Si–O–Ge bridge is more rapidly hydrolysed, both in acidic and in basic media, to form the parent silanols and germanols. Heterolytic cleavage of the germanosiloxane bridge with aluminum chloride has shown that the Ge–O bond is the reactive center of the Ge–O–Si unit, and gives rise to increased reactivity compared to the Si–O–Si structure [18]: the only products are trimethylchlorogermane and trimethylsiloxyaluminum dichloride *(13a)*; trimethylchlorosilane or trimethylgermoxyaluminum dichloride *(13b)* (which is still unknown) are not formed. This

$$\underset{(6)}{(CH_3)_3Si\text{-}O\text{-}Ge(CH_3)_3} + AlCl_3 \rightarrow \begin{cases} (CH_3)_3SiCl + (CH_3)_3Ge\text{-}O\text{-}AlCl_2 & (13b) \\ (CH_3)_3GeCl + (CH_3)_3Si\text{-}O\text{-}AlCl_2 & (13a) \end{cases}$$

indicates that cleavage occurs at the Ge–O bond only. Likewise, germanosiloxanes are more reactive than siloxanes towards other Lewis acids, such as SO_3, CrO_3, SeO_3, $POCl_3$, and $P_2O_3Cl_4$ [19,20].

Destabilization of the siloxane bridge by introduction of germanium atoms is also reflected in the reduced thermal stability of the germanosiloxanes. Thus compounds *(9)* and *(11)* disproportionate above 200 °C to form siloxanes and germoxanes:

$$x\,(CH_3)_3Si\text{-}O\text{-}Ge(CH_3)_2\text{-}O\text{-}Si(CH_3)_3 \rightarrow x\,(CH_3)_3Si\text{-}O\text{-}Si(CH_3)_3 + [(CH_3)_2GeO]_x \quad (c)$$

The polygermoxanes formed still contain terminal siloxy groups.

3. Spectroscopic Investigations

The proton signal of the trimethylsilyl group in the ^1H-NMR spectrum of germanosiloxane *(6)* is shifted towards higher field-strengths as compared to the signal of hexamethyldisiloxane, indicating greater elec-

tron density at the siloxy group of the heterosiloxane [14,21]. This is explained both by the lower electronegativity of germanium as compared to silicon, and by a decrease in the π-bond character of the Ge–O bond as compared to that of the Si–O bond. Both effects tend to strengthen the Si–O bond. Confirmation of this interpretation is provided by comparison with the NMR data for hexamethyldigermoxane. Here, the signal of the trimethylgermyl groups is at a higher field strength than the signal of the trimethylgermyl group in *(6)* (Table 2). The characteristic reduction of the coupling constants $J(^1H-^{13}C)$ and $J(^1H-C-^{29}Si)$ on passing from disiloxane to *(6)* is characteristic of the change in hybridization of the atoms involved [14,21 to

23] and again indicates the increased polarity of the Ge–O bond as compared to the Si–O bond. This agrees with the picture derived from the much more complex spectra of higher germanosiloxanes [14].

As expected, the infrared spectra contain a characteristic Si–O–Ge valence vibration; ν_{as}(Si–O–Ge) is displaced towards longer wavelengths compared to ν_{as}(Si–O–Si), and lies midway between ν_{as}(Si–O–Si) and ν_{as}(Si–O–Sn) [12,14]. The changes in the vibration frequencies of the organometallic residues, on the other hand, are much smaller, but again differ from the values for the "pure" siloxanes or germoxanes (Table 1).

B. Stannosiloxanes

1. Preparation

Publications describing the preparation of organostannosiloxanes and the interpretation of their bonding are much more frequent than in the case of germanosiloxanes [1, 2, 17, 24–28]. The parent member of the stannosiloxane series is easily prepared by a method similar to that used for the germanosiloxanes [12, 29]. In general, alkali-metal siloxides react smoothly with organohalogenostannanes to yield the stannosiloxanes (see Table 3 [29]):

$$(CH_3)_3SiONa + ClSn(CH_3)_3 \rightarrow NaCl + (CH_3)_3Si-O-Sn(CH_3)_3 \quad (d)$$

(14)

The preparation from alkali-metal stannoxides and halogenosilanes is also possible, since these stannoxides are now easily available [30].

$$2\,(CH_3)_3SnOLi + (CH_3)_2SiCl_2 \rightarrow 2\,LiCl + [(CH_3)_3SnO]_2Si(CH_3)_2 \quad (e)$$

(17)

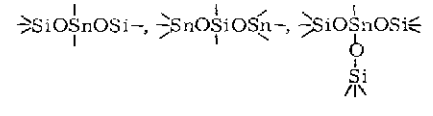
Another method leading quantitatively to stannosiloxanes is the reaction of pseudo-alkali siloxides, such as heptamethylstibiosiloxane with halogenostannanes [31]:

$$(CH_3)_4Sb-O-Si(CH_3)_3 + (CH_3)_3SnCl \rightarrow [(CH_3)_4Sb]Cl + (CH_3)_3Si-O-Sn(CH_3)_3 \quad (f)$$

(14)

Compound *(14)* could not be prepared by cohydrolysis and transesterification [27], but this method can be used to synthesize hexa-alkylstannosiloxanes having longer alkyl residues on the tin atom [27]. Cohydrolysis of trialkylchlorosilanes with dialkyldichlorostannanes also fails to yield simple stannosiloxanes of the type *(19)*, but gives stannoxanes $R_3SiO-[R_2Sn-O-SnR_2O]_n-SiR_3$ containing siloxy end-groups. The structure of these oligomers has been investigated in detail [27, 32].

Numerous phenylstannosiloxanes have recently been prepared, again mostly using the siloxide method [33]. Table 3 covers all types of stannosiloxanes in which the Si-O-Sn unit has been extended to both sides to form straight- or branched-chain polymers [29, 33], *e.g.*



2. Properties

The stannosiloxanes investigated so far are colorless, mostly malodorous, toxic compounds. They are surprisingly volatile and crystallize readily. Molecular-

weight determinations show them to be monomeric. This is in contrast to many distannoxanes which spontaneously oligomerize [27] to form cyclic products (*e.g. (26)*) and indicates a considerable decrease in the donor strength ($d_\pi p_\pi$-bonding) of the stannosiloxane oxygen atoms.

(26)

The thermal stability of alkylstannosiloxanes is generally lower than that of the alkylsiloxanes or alkylstannoxanes. The long-chain compounds *(19)* and *(20)*, in particular, disproportionate above 160 °C to form alkylsiloxanes and alkylstannoxanes:

$$n\ [(CH_3)_3SiO]_2Sn(CH_3)_2 \rightarrow n\ (CH_3)_3Si{-}O{-}Si(CH_3)_3 + [(CH_3)_2SnO]_n \qquad (g)$$

The intermediates in this disproportionation are relatively short stannoxane chains which still contain terminal siloxy groups; the latter can be detected by infrared and NMR spectroscopy.

Stannosiloxanes also differ from siloxanes and stannoxanes in their high reactivity towards nucleophilic and electrophilic reagents. Thus, in contrast to disiloxane (but similar to stannoxane) [34], *(14)* undergoes rapid solvolysis with water, alcohols, amines, mercaptans, *etc.* and is readily cleaved by phenyl-lithium [15], as well as by Lewis acids such as BCl_3, $AlCl_3$, and SO_3 [29,35].

In this respect *(14)* is even more reactive than the germanosiloxane *(6)*. Evidently the chemical behavior of the stannosiloxanes is governed largely by the high reactivity of the Sn-O bond, which undergoes heterolytic cleavage much more readily than the Si-O bond, owing to its higher polarity and lower π-bond character. In agreement with this, an increase in the number of negative substituents on the tin atom has a stabilizing effect on the Sn-O bond, so that compounds of types *(21)* and *(22)* are less sensitive to solvolysis [24–29, 33]. The same effect is achieved for steric reasons by long-chain or branched-chain residues on the tin atom *(17)* [27, 29, 33].

3. Spectroscopic Investigations

The NMR spectra of the stannosiloxanes [21,29] are particularly informative, owing to the presence of the isotopes ^{117}Sn and ^{119}Sn with nuclear spin 1/2; consequently, an interpretation of the spectra after complete assignment of all lines is greatly facilitated [for *(14)*, see Table 2].

The signal of the trimethylsilyl group in *(14)* is shifted towards higher field strenghts than that of hexamethyldisiloxane, and the signal of the trimethylstannyl group towards lower field strengths than that of hexamethyldistannoxane. Similarly, the values of $J(^1H\text{-}C\text{-}^{29}Si)$ and $J(^1H\text{-}C\text{-}^{117,119}Sn)$ are clearly decreased and increased, respectively, compared to those of the siloxanes. A slight effect is even observed for the coupling constant $J(^1H\text{-}^{13}C)$. This indicates an electron distribution in the Si-O-Sn bridge which corresponds to an increased polarity and reduced double-bond character for the Sn-O bond and to a decreased polarity with increased double-bond character of the Si-O bond. For other stannosiloxanes the NMR data indicate a similar situation and a gradation which depends on the number and nature of the alkyl and siloxy groups on the hetero-atom and which corresponds to that observed for germanosiloxanes.

The infrared spectra [25,27,29,33] of stannosiloxanes are characterized by an intense Si–O–Sn valence vibration in the region 950–980 cm^{-1} (Table 3), the position of which depends on the substituents on the silicon and tin atoms. Infrared measurements in the long-wavelength region and Raman measurements remain to be done.

C. Plumbosiloxanes

Until recently, the literature contained practically no detailed information about organoplumbosiloxanes, despite attempts to prepare modified siloxanes with lead and organolead structural elements [1,2].

1. Preparation [36]

Hexamethylplumbosiloxane *(15)*, the simplest organoheterosiloxane having an Si–O–Pb linkage, is rapidly formed in good yield, even at room temperature, from trimethylbromoplumbane and alkali metal trimethylsiloxides in the molar ratio of 1:1.

$$(CH_3)_3SiONa + BrPb(CH_3)_3 \rightarrow NaBr + (CH_3)_3Si{-}O{-}Pb(CH_3)_3 \qquad (h)$$

(15)

Homologues *(27)* to *(29)* can be readily prepared in a similar manner, if care is taken to avoid hydrolysis and oxidation [36].

It has not yet been possible to prepare higher plumbosiloxanes, *e.g.* with Si-O-Pb-O-Si or Pb-O-Si-O-Pb chains. The low solubility of dialkyl-lead dihalides in organic solvents prevents smooth reaction with siloxides. No alkali metal alkylplumboxides are as yet known.

[34] *H. Kriegsmann, H. Hoffmann,* and *S. Pischtschan*, Z. anorg. allg. Chem. *315*, 283 (1962).

[35] *H. Schmidbaur* and *H. Hussek*, unpublished work.

[36] *H. Schmidbaur* and *H. Hussek*, J. organomet. Chem. *1*, 257 (1964).

2. Properties [36]

The hexa-alkylplumbosiloxanes are all very mobile, colorless liquids with an unbearable odor, and presumably very poisonous. Their high volatility and unlimited miscibility with organic solvents is unusual for organolead compounds, such as halides, oxides, sulfides, alkoxides *etc.*, and may be useful for the synthesis of other organolead derivatives. The physical constants of the compounds are shown in Table 4.

It can be seen that *(15)* can be distilled even at normal pressure without decomposition, if the operation is carried out in an atmosphere of a dry inert gas. In the presence of oxygen, explosion occurs at about 140 °C, with evolution of black clouds of lead.

All plumbosiloxanes are highly reactive and very sensitive to heterolytic attack. The Pb–O–Si bridges are hydrolysed even by traces of moisture. Cleavage with Lewis acids (BCl_3, $AlCl_3$, $SOCl_2$) and Lewis bases (CH_3OH, CH_3Li, CH_3SH) shows that the reactive center is the Pb–O bond. The plumbosiloxanes are the most reactive heterosiloxanes of the Group IV elements (*i.e.* the Pb–O bond is the most reactive X–O bond). In addition, the Pb–C bonds are less stable than the analogous C–C–, Si–C, Ge–C, and Sn–C bonds, not only to heterolytic cleavage, but also to oxidation and heat.

3. Spectroscopic Investigations

Hexa-alkylplumbosiloxanes are excellent subjects for NMR spectroscopy [36]. The presence in sufficiently high concentrations of the isotopes ^{207}Pb, ^{29}Si and ^{13}C with nuclear spins leads to NMR spectra which are relatively complex but can be readily interpreted. Table 1 shows the NMR data for compound *(15)*, and Figure 1 shows the experimental (A) and the calculated (B) spectra of *(27)*.

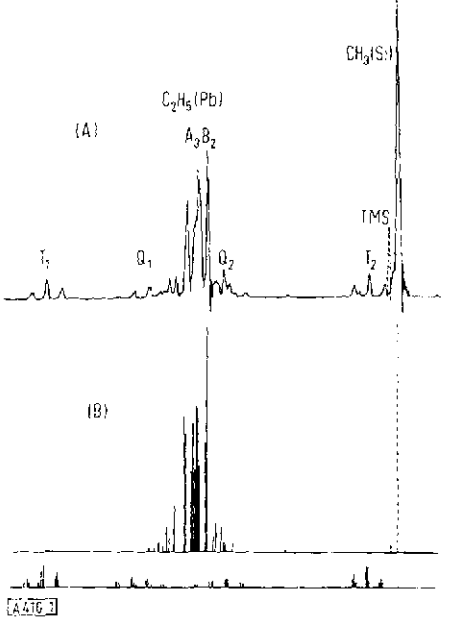

Fig. 1. Experimental (A) and calculated (B) NMR spectra of *Pb*-triethyl-*Si*-trimethylplumbosiloxane *(27)*.

T_1 and T_2 = Triplets from $^1H-C-C^{207}Pb/^1H-C-C-^1H$
Q_1 and Q_2 = Quartets from $^1H-C^{207}Pb/^1H-C-C-^1H$

The plumbosiloxanes occupy an extreme position in the series of heterosiloxanes of the Group IV elements, as regards polarity of the X–O bond and strengthening of the Si–O bond by π-bond character. This was to be expected from the classical electronegativity series C > Si ≈ Ge > Sn > Pb [37]. It is impossible to interpret the experimental findings by other assumptions [38, 39].

Table 4. Physical constants for organoplumbosiloxanes.

No.	Formula	M.p. [°C]	B.p. [°C/mm Hg]	ν_{as} (Si–O–Pb)	Ref.
(15)	$(CH_3)_3SiOPb(CH_3)_3$	−1	172/720	960	[12, 36]
(27)	$(CH_3)_3SiOPb(C_2H_5)_3$		111.5/10	961	[36]
(28)	$(C_2H_5)_3SiOPb(CH_3)_3$		65/1	957	[36]
(29)	$(C_2H_5)_3SiOPb(C_2H_5)_3$		100/1	957	[36]

The infrared bands of the plumbosiloxanes also show, to a first approximation, the gradations expected from the masses and force constants when compared with the infrared bands of analogous heterosiloxanes [12, 36].

D. Alumino- and Gallo-siloxanes

The alumino- and gallo-siloxanes are among the most interesting compounds encountered in heterosiloxane chemistry. Owing to the electron deficiency on the hetero-atom, the structural principles are entirely different, with the result that these compounds contrast significantly with the other types of heterosiloxanes. Moreover, the alumino- and gallo-siloxanes merit attention, since they are related to the purely inorganic aluminosilicates as the siloxanes are to quartz and the silicates. Table 5 lists a number of compounds of this group together with their physical constants.

Table 5. Physical constants of organo-alumino- and -gallo-siloxanes.

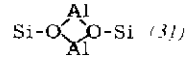
1. Organosiloxyaluminum Halides

Low molecular-weight compounds having Si–O–Al bridges are most readily prepared by cleavage of siloxanes with aluminum halides. In this way, hexaorganodisiloxanes yield triorganosiloxyaluminum halides *(30)* in addition to triorganohalogenosilanes [40–42]:

$$R_3Si{-}O{-}SiR_3 + AlX_3 \rightarrow R_3SiX + R_3Si{-}O{-}AlX_2 \quad (i)$$

X = Halogen *(30)*

Reactions of this type have been known for more than ten years, and their mechanism has recently attracted much interest [43]. For a long time, however, the structures of the products remained unknown. Recent experiments [44,45] have shown that compounds of the type $R_3Si{-}O{-}AlX_2$ always occur as coordination dimers (Figure 2) which are characterized by a planar (or almost planar) structure *(31)*. The planar arrangement of the ligands at the triply coordinated oxygen



(31)

atoms in the four-membered ring appears to be of similar significance as that of the silyl groups on the nitrogen atom in planar trisilylamine [46,47].

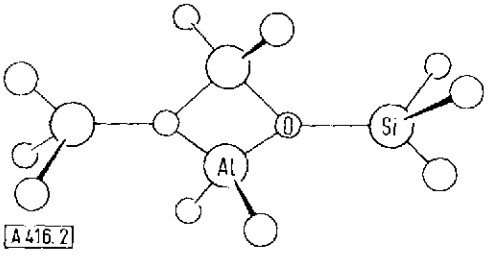


Fig. 2. Structure of the dimeric organosiloxyaluminum halides.

In the light of these results, the course of the cleavage of linear and cyclic diorganopolysiloxanes $(R_2SiO)_n$, n = 3, 4, ∞, with AlX_3 was a surprise: In agreement with Russian authors [48], we have found [49] that the reaction yields $[(CH_3)_2Si]_4Al_3Cl_5O_6$ (m.p. 152–154 °C), which can be crystallized and sublimed, the structure of which, however, is still unknown. Corresponding reactions with $AlBr_3$ and AlI_3 give products of similar composition: $[(CH_3)_2Si]_4Al_3(Y)_5O_6$ [m.p. 159 °C with Y = Br; decomposition point 160 °C with Y = I] [49]. The same heterosiloxanes can be prepared in high yields from octamethyltrisiloxane (trimethylchlorosilane occurs as a by-product; α,ω-dichlorodimethylsiloxanes are also formed in the case of cyclo- and poly-siloxanes [48, 49]). Investigations of these substances are still incomplete [*].

As mentioned above, trialkylsiloxyaluminum dihalides are also formed in the cleavage of heterosiloxanes of germanium, tin, and lead with aluminum halides [18,45], but not from carbosiloxanes [45]. The Si–O–C bridge is always broken at the Si–O bond and never at the C–O bond, so that the products are halogenosilanes and alkoxyaluminum dihalides, as shown in Equation (k).

$$R_3Si{-}O{-}CR_3 + AlX_3 \rightarrow R_3SiX + R_3C{-}O{-}AlX_2 \quad (k)$$

X = Halogen

2. The Reaction of Gallium Halides with Siloxanes [50]

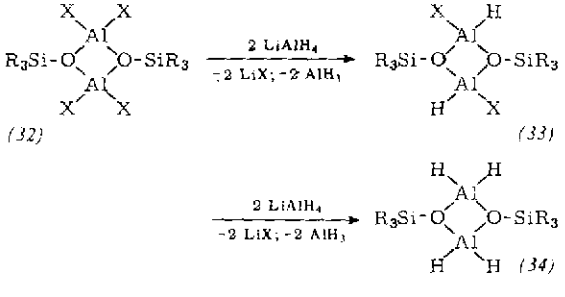
Contrary to expectations, the reaction of gallium halides with organosiloxanes does not yield the desired siloxygallium dihalides. Even under mild conditions, the gallium is always alkylated:

$$(CH_3)_3Si{-}O{-}Si(CH_3)_3 + GaCl_3 \rightarrow CH_3GaCl_2 + (CH_3)_3SiCl + [(CH_3)_2SiO]_n \quad (l)$$

Octamethylcyclotetrasiloxane and $GaCl_3$ give, in addition to CH_3GaCl_2, only a non-volatile methylsiloxane polymer containing halogen. Owing to the favorable reaction conditions, the ease of isolation, and the good yields, this is the best method of preparing methylgallium dihalides [50].

3. Organosiloxyaluminum Halide Hydrides [51]

The halogen atoms on the four-membered aluminosiloxane ring *(32)* can be replaced without opening the ring. Hydrogenation with lithium aluminum hydride leads, *via* a complex aluminum hydride, to trialkylsiloxyaluminum halide hydrides *(33)*, and ultimately to the dihydrides *(34)*.



These aluminum hydrides, which can be readily crystallized and distilled, decompose, at elevated temperatures, with elimination of triorganosilanes:

$$(R_3Si{-}O{-}AlXH)_2 \rightarrow 2\ R_3SiH + 2/n(AlXO)_n \quad (m)$$

Compound *(34)* tends to polymerize and is stable only for a short time as the dimer [52].

Compound *(35)* has the "reverse" configuration, *i.e.* hydrogen on the silicon atom and methyl groups on the aluminum atom; this compound is formed by cleavage of disiloxane with dimethylaluminum bromide:

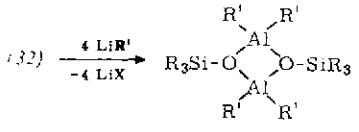
$$2\ H_3Si{-}O{-}SiH_3 + [(CH_3)_2AlBr]_2 \rightarrow [H_3Si{-}O{-}Al(CH_3)_2]_2 + 2\ H_3SiBr \quad (n)$$

(35)

It is very unstable and decomposes spontaneously with the elimination of monosilane [53].

4. Pentaorganoaluminosiloxanes [54]

The parent members of the aluminosiloxanes carrying only organic substituents, $R_3Si{-}O{-}AlR_2$, can be obtained in high yields and in a very pure form by two versatile methods. Substitution of the halogen atoms of the organosiloxyaluminum halides *(32)* with organolithium compounds leads to aluminosiloxanes *(36)* without ring cleavage.



(36)

Another method of preparation is the reaction of diorganohalogenoalanes with alkali metal triorganosiloxides:

$$2\ R'_2AlX + 2\ MOSiR_3 \rightarrow 2\ MX + [R_3Si{-}O{-}AlR'_2]_2 \quad (o)$$

M = Alkali metal *(36)*

In some cases cleavage of siloxanes with trialkylaluminum is successful [55]:

$$2\ (C_2H_5)_3Al + 2\ (CH_3)_3Si{-}O{-}Si(CH_3)_3 \rightarrow 2\ C_2H_4 + 2\ (CH_3)_3SiH + [(CH_3)_2Si{-}O{-}Al(C_2H_5)_2]_2 \quad (p)$$

(36b)

All aluminosiloxanes obtained by these methods are dimeric. Spectroscopic investigations [54] and X-ray structural analyses [56] show that these molecules, like the isosteric silazane *(37)* [57,58], have a planar skeleton. The correspondence of the physical data of *(36a)* and *(37)* is amazing and reflects the largely analogous nature of the bonds [54], in particular the planar arrangement of the ligands on the oxygen and nitrogen atoms. This is confirmed by ^{1}H-NMR spectroscopy [44,54].

Interestingly enough, the corresponding dialkyl-t-butoxyaluminum compounds are also dimeric and have similar structures although they do not contain silicon. However, the planarity of these ring systems has not yet been checked, and an irregular geometry may be found in these cases [59].

The pentaorganoaluminosiloxanes are thermally relatively stable. They decompose above about 180 °C with the elimination of tetraorganosilanes. The Al–C bonds render these compounds very reactive and make them sensitive to oxidation and hydrolysis. Compared to other alkylaluminum compounds, however, they are relatively inert.

5. Tris(triorganosiloxy)-aluminum and -gallium Compounds [60,61]

Complete substitution of the halogen atoms of the aluminum and gallium trihalides by reaction with alkali metal siloxides leads to another class of alumino- and gallo-siloxanes *(38)* in which only siloxy groups are bonded to the metal atoms.

$$2\ MCl_3 + 6\ NaOSi(CH_3)_3 \rightarrow \{[(CH_3)_3SiO]_3M\}_2 + 6\ NaCl$$

M = Al, Ga *(38)*

Compounds of type *(32)* also react with siloxides to form tris(triorganosiloxy)aluminum compounds *(38a)*.

$$(32) + 4\ MOSi(CH_3)_3 \rightarrow 4\ MX + \{[(CH_3)_3SiO]_3Al\}_2$$

(38a)

In some cases silanols react with metallic aluminum to form aluminosiloxanes of type *(38a)*, with liberation of hydrogen [62,63].

Tris(triorganosiloxy)-aluminum and -gallium compounds have a strong tendency to form coordination dimers [60,61,64]. Physico-chemical investigations indicate a structure *(39)* in which the metals carry both bridging and terminal siloxy residues. This is indicated by the two ^{1}H-NMR signals present in both cases. As expected, the bridge-siloxy signals are more strongly shifted towards lower field strengths; this is characteristic of a decreased (p → d)π-stabilization of the Si–O–Al bridges. Similarly, infrared investigations [64] show the presence of two types of siloxy groups. Here, too, the analogous t-butoxyaluminum compounds have similar structures [65].

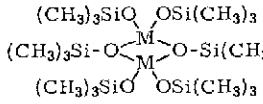
[65] *V. J. Shiner, D. Whittaker,* and *V. P. Fernandez,* J. Amer. chem. Soc. *85,* 2318 (1963).

The compounds *(38)* are relatively stable. They dismutate above 280 °C to form siloxanes and alumina. There is reason to believe that the dimers disappear only above 200 °C, and that it is the monomer which then decomposes. As water-repelling compounds they are fairly insensitive towards hydrolysis. In the presence of organic solvents (alcohol, acetone), however, solvolysis proceeds rapidly even at room temperature.



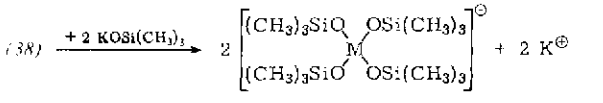
(38)

M = Al, Ga

6. Anionic Alumino- and Gallo-siloxanes [16, 66–69]

The tendency of the oxygen atoms in siloxane and heterosiloxane bridges to form stabilizing (p → d)π-bonds greatly restricts the donor strength of these atoms. Siloxanes and heterosiloxanes therefore are extremely weak Lewis bases. In agreement with this, the four-membered ring systems of type *(38)*, in which the high acceptor strength of the aluminum atoms forces the bridge-oxygen atoms to assume a donor function, are coordinately unsaturated. The tendency of the bridge-oxygen atoms to revert to the two-coordinated state and to form energetically more favorable (p → d)π-systems facilitates the addition of many nucleophilic reagents, and in particular permits the preparation of novel anionic heterosiloxanes.

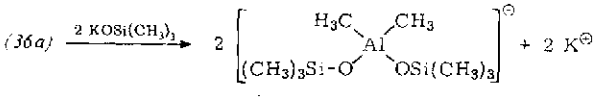
Compounds of type *(38)* react readily and completely with alkali metal siloxides, even at room temperature, to form alkali metal tetrakis(trimethylsilyl)-aluminates and -gallanates *(39)*.



(39)

M = Al, Ga

Similarly, pentamethylaluminosiloxane *(36a)* adds on alkali metal siloxides to form the new alkali metal octamethyldisiloxyalanates *(40)*.



(40)

The anions *(39)* and *(40)* can be regarded as structural units of the purely inorganic aluminosilicates and felspars which have been "monomerized" by organic substituents. (We have also prepared analogous heterosiloxanes of trivalent iron, which have a similar structure [70, 71]).

[66] *H. Schmidbaur*, Chem. Ber. *97*, 459 (1964).

[67] *H. Schmidbaur*, Angew. Chem. *75*, 137 (1963); Angew. Chem. internat. Edit. *2*, 94 (1963).

[68] *H. Schmidbaur*, Chem. Ber. *97*, 842 (1964).

[69] *H. Schmidbaur*, Angew. Chem. *75*, 683 (1963).

[70] *H. Schmidbaur* and *M. Schmidt*, J. Amer. chem. Soc. *84*, 3600 (1962).

[71] *H. Schmidbaur*, Chem. Ber. *97*, 836 (1964).

Substitution of the pseudo-alkali siloxide heptamethylstibiosiloxane *(16)* for the alkali metal siloxides in the reactions leading to *(39)* and *(40)* gives crystallizable products $[(CH_3)_4Sb]^{\oplus}[M(OSi(CH_3)_3)_4]^{\ominus}$ with M = Al, Ga, Fe [68] which are isomorphously orthorhombic (Table 6). According to X-ray analysis, the heterosiliconate anions have the C_{2v}-symmetry shown in Figure 3. The bond lengths and angles [72] as well as the infrared and NMR spectra [68] confirm the assumed stabilization by π-bonding of the Si–O–Al bridges, which thus correspond to those of the aluminosilicates.

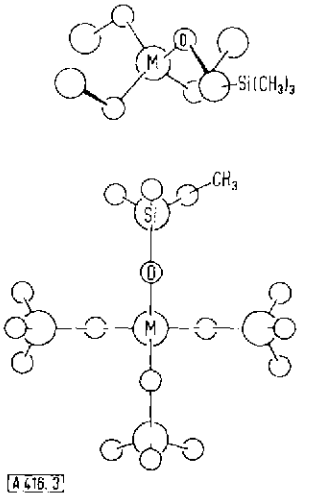


Fig. 3. Structure of the heterosiliconate anions $\{M[OSi(CH_3)_3]_4\}^{\ominus}$

In accordance with this, the compounds have a high thermal stability and decompose only above 250–300 °C. However, their chemical stability is relatively low and is greatly surpassed by that of the corresponding siloxanes and silicates. This is again attributable to the ease of cleavage of the metal-oxygen bonds. Degradations of inorganic silicates, in which Si-O-Si skeletons were "picked out" by simultaneous "saturation" of the functional groups formed with trimethylsilanol, have recently shown [73] that the reactive center in the silicates is again the bond between the hetero-atom and oxygen, and not the Si-O bond.

Heterosiloxanes of thallium have not yet been described. Attempts to cleave siloxanes with $InCl_3$ were unsuccessful [74]; the reaction of $InCl_3$ with alkali metal siloxides led to non-uniform products [74, 74a].

[72] *P. J. Wheatley*, J. chem. Soc. (London) *1963*, 3200.

[73] *Ch. W. Lentz*, Inorg. Chem. *3*, 574 (1964).

[74] *H. Schmidbaur*, *J. A. Perez-Garcia*, and *W. Findeiss*, unpublished work; see also [50].

[74a] Note added in proof: Meanwhile pentamethylgallosiloxane *(36c)* (m.p. 16.5 °C; b.p. 34.5 °C/3 mm) and pentamethylindosiloxane *(36d)* (m.p. 16.5 °C; b.p. 57 °C/3 mm) have been synthesized from trimethylsilanol and trimethylgallium etherate or trimethylindium etherate, respectively:

$$2\ (CH_3)_3M{\cdot}O(C_2H_5)_2 + 2\ HOSi(CH_3)_3 \xrightarrow{-2\,(C_2H_5)_2O} 2\ CH_4 + [(CH_3)_3SiOM(CH_3)_2]_2$$

(36c), M = Ga
(36d), M = In
(36e), M = Tl

Compound *(36d)* is the first indium-containing heterosiloxane that has been prepared. Analyses and molecular-weight determinations as well as infrared and NMR data are consistent with structures analogous to *(36a)*. – Recently pentamethylthallosiloxane *(36e)*, m.p. 98°C, subl. 90°C/1mm, has been prepared from dimethylthallium chloride and sodium trimethylsiloxide.

d_{exp} = Density [g/cm³] determined by flotation.
d_{calc} = Density [g/cm³] calculated from crystallographic data.
U = Size of the unit cell.

E. Arsinosiloxanes

Of the heterosiloxanes containing elements of Group V, those with nitrogen and phosphorus have been deliberately omitted from this paper, since, according to their properties, they should be regarded rather as silyl esters of the oxyacids of these elements than as heterosiloxanes. For the same reason the boron derivatives are omitted from the heterosiloxanes of Group III elements [75].

Arsenic and antimony form a series of heterosiloxane monomers and polymers, in which these elements exhibit various valence states (see Table 7) [1,2,31,76–82].

Table 7. Physical constants of arsino- and stibio-siloxanes.

No.	Formula	M.p. [°C]	B.p. [°C/mm Hg]	Ref.
(42)	$(CH_3)_3SiOAs(CH_3)_2$	−70	116/725	[31,76]
(43)	$[(CH_3)_3SiO]_2As(C_6H_5)$	119–120		[79]
(45)	$(CH_3)_3SiOSb(CH_3)_2$		144/720	[31,76]
(46)	$(CH_3)_3SiOSb(C_6H_5)_2$	59		[76]
(47)	$(CH_3)_3SiOSb(CH_3)_4$	−32	164–165/725	[31,76]
(48)	$[(CH_3)_3SiO]_2Sb(CH_3)_3$	21	210/725	[31,76]
(49)	$(CH_3)_3SiOSb(C_6H_5)_4$	76–78		[76]
(50)	$[(CH_3)_3SiO]_2Sb(C_6H_5)_3$	89	161/1	[76]

1. Preparation

The parent member *(42)* of the arsinosiloxanes with trivalent arsenic is formed in high yield from dimethylchloroarsine and sodium trimethylsiloxide [31,76]:

$$(CH_3)_2AsCl + (CH_3)_3SiONa \rightarrow NaCl + (CH_3)_3Si{-}O{-}As(CH_3)_2 \quad (q)$$
(42)

Phenyl compounds such as *(43)* are also readily obtainable by this method.

Heterosiloxanes with pentavalent arsenic (which, however, has a coordination number of only 4) can be synthesized by oxidation of arsinosiloxanes such as *(42)*, and also from halogenosilanes and metal salts of the corresponding organoarsonic acids [79].

All attempts to prepare arsinosiloxanes with 5-coordinated arsenic have so far failed [76]. The reactions of organoarsenic halides of the types R_4AsX, R_3AsX_2, and R_2AsX_3 with siloxides did not yield the desired products. In the case of the tetra-alkylarsonium halides the reason probably is the insolubility of these (purely ionic [83]) salts in organic solvents. Although the trialkylarsenic dihalides did react owing to more favorable solubilities and structures, the products were trialkylarsenic oxides and siloxanes:

$$(CH_3)_3AsCl_2 + 2\ NaOSi(CH_3)_3 \rightarrow 2\ NaCl + (CH_3)_3AsO + (CH_3)_3Si{-}O{-}Si(CH_3)_3 \quad (r)$$

It may be assumed that *(44)* is formed as an intermediate and decomposes even under mild conditions to give the above products. Thus the coordination number 5 on the arsenic

$$(CH_3)_3SiO\overset{\curvearrowright}{O}{-}As(CH_3)_3{-}\overset{\curvearrowright}{O}Si(CH_3)_3 \quad (44)$$

atoms is avoided by formation of a semipolar double bond to the oxygen atom.

2. Properties

Arsinosiloxanes with trivalent arsenic are stable, colorless, malodorous compounds, and, like the germanosiloxanes, are sensitive to solvolysis. A pronounced sensitivity to oxidation is also noticeable, particularly in the case of the aliphatic derivatives. Thus *(42)* can be distilled in a dry inert-gas atmosphere at 116 °C without decomposition, but is immediately oxidized and hydrolysed in contact with air, ultimately yielding trimethylsilanol and dimethylarsonic acid [76].

Like almost all other heterosiloxanes, the arsinosiloxanes are degraded by thionyl chloride [31,76]; this demonstrates the ease of heterolytic cleavage and can serve as proof of constitution:

$$(CH_3)_3Si{-}O{-}As(CH_3)_2 + SOCl_2 \rightarrow (CH_3)_3SiCl + SO_2 + (CH_3)_2AsCl \quad (s)$$

By contrast, the Si–O–Si bridge in siloxanes does not give this reaction under comparable conditions.

[75] These compounds will form the subject of a review article to be published later.

3. Spectroscopic Investigations

Arsinosiloxanes have so far been investigated by infrared spectroscopy [76, 79] only to establish the characteristic frequencies. The valence vibration ν_{as} (Si-O-As) for derivatives with aliphatic substituents is at 934 cm^{-1}, and that for derivatives with aromatic substituents at 877 cm^{-1} [79]. NMR data are not yet available.

F. Stibiosiloxanes

Our investigations on the heterosiloxanes of antimony were more successful than those on arsinosiloxanes, since many derivatives of the pentavalent element could be obtained easily in this case [76].

1. Preparation

Reaction of dimethylbromostibine with alkali metal trimethylsiloxides leads directly to high yields of the simplest organostibiosiloxane compound *(45)* with trivalent antimony:

$$(CH_3)_2SbBr + (CH_3)_3SiONa \rightarrow NaBr + \underset{(45)}{(CH_3)_3Si{-}O{-}Sb(CH_3)_2} \quad (t)$$

The alkylhalogenostibines $(CH_3)_4SbCl$ and $(CH_3)_3SbCl_2$ also react smoothly with alkali metal siloxides to yield the stibiosiloxanes *(47)* and *(48)* with 5-coordinated antimony:

$$(CH_3)_4SbCl + LiOSi(CH_3)_3 \rightarrow LiCl + \underset{(47)}{(CH_3)_3Si{-}O{-}Sb(CH_3)_4}$$

$$(CH_3)_3SbCl_2 + 2\ LiOSi(CH_3)_3 \rightarrow 2\ LiCl + \underset{(48)}{(CH_3)_3Si{-}O{-}Sb(CH_3)_3{-}O{-}Si(CH_3)_3}$$

Aryl-substituted stibiosiloxanes of both tri- and pentavalent antimony (Table 7) can be synthesized in the same way.

2. Properties

The stibiosiloxane *(45)* is much more sensitive to hydrolysis and oxidation than the arsinosiloxane *(42)*; it explodes in the presence of oxygen at about 40 °C. However, this instability is much less pronounced in the case of the aryl derivative *(46)*. On the other hand, the stibiosiloxanes having pentavalent antimony are stable in the presence of oxygen even at high temperatures, but are all sensitive to hydrolysis.

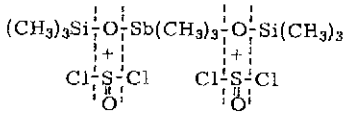
Stibio(V)-siloxanes such as *(47)* are unique pseudo-alkali siloxides. Their pronounced tendency, on heterolytic cleavage to split off the sp^3d-hybridized 5-coordinated antimony atom in tetra-alkylstibonium cations with an sp^3-hybridized antimony atom makes these compounds suitable for many applications [14, 67, 68]. Hydrolysis of *(47)* yields strongly alkaline solutions of tetramethylstibonium hydroxide:

$$(CH_3)_3Si{-}O{-}Sb(CH_3)_4 + H_2O \rightarrow [(CH_3)_4Sb]^{\oplus}OH^{\ominus} + (CH_3)_3SiOH \quad (u)$$

Acid anhydrides convert *(47)* into the stibonium salts. Disiloxanes are formed as by-products:

$$2\,(CH_3)_3Si{-}O{-}Sb(CH_3)_4 + SO_2 \rightarrow [(CH_3)_4Sb]_2^{\oplus}SO_3^{2\ominus} + (CH_3)_3Si{-}O{-}Si(CH_3)_3 \quad (v)$$

Compound *(48)* is one of the thermally and chemically most stable heterosiloxanes. It is solvolysed only slowly by water and alcohols. Degradation with thionyl chloride yields trimethylchlorosilane, trimethyldichlorostibine, and sulfur dioxide:



$$\rightarrow 2\ (CH_3)_3SiCl + (CH_3)_3SbCl_2 + 2\ SO_2 \quad (w)$$

Bis(trimethylsiloxy)triphenylstibine *(50)* is stable up to about 280 °C.

3. Spectroscopic Investigations

The abnormal behavior of *(47)* as a "stibonium siloxide" causes a particularly large chemical shift of the ^{1}H-NMR signal of the trimethylsiloxy group and a distinct reduction of the coupling constants $J(^1H{-}C{-}^{29}Si)$ and $J(^1H{-}^{13}C)$. An electron distribution in the heterosiloxane bridge as shown in *(47a)* evidently facilitates

(47a)

formation of the stibonium cation and rehybridization of the antimony atom. As expected, compound *(48)* does not show these strong shifts (cf. Table 2) [76].

Stibiosiloxanes can be recognized in the infrared spectra by characteristic Si–O–Sb valence vibrations in the region of 940–980 cm^{-1}.

Heterosiloxanes of bismuth are unknown, and, to our knowledge, have not been investigated. Heterosiloxanes containing elements of Groups VI and VII of the periodic table must be classified almost exclusively as silyl esters of the inorganic acids, according to their properties.

These silyl esters, the numerous siloxy derivatives of the transition elements, and the metal siloxides will form the subject of a review article to be published later.

IV. Conclusion

Numerous attempts have been made to prepare from heterosiloxanes new inorganic polymers, which are superior to the silicones in chemical stability. The results, however, have been relatively poor. This seems

understandable in the light of recent investigations. Nevertheless, the incorporation of hetero-atoms may be of advantage in preparing siloxanes for special applications. The properties of the heterosiloxanes synthesized so far clearly show the wide range of possibilities.

The author's own investigations reported in this article were made possible only by the dedicated cooperation of Dr. H. S. Arnold, Dipl.-Chem. W. Findeiss, Dr. H. Hussek, Dr. J. A. Perez-Garcia, and Dr. F. Schindler. We would like to thank Prof. Max Schmidt for his constant and generous support.

Light-Induced Formation of Acids from Cyclic Ketones

BY PROF. DR. G. QUINKERT

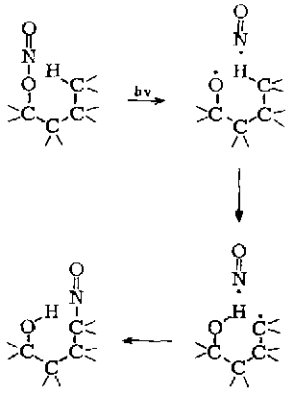
INSTITUT FÜR ORGANISCHE CHEMIE DER TECHNISCHEN HOCHSCHULE BRAUNSCHWEIG (GERMANY)

Ultraviolet irradiation of aqueous solutions of cyclic ketones having a tetrahedral carbon atom in at least one of the two positions adjacent to the light-absorbing carbonyl group results in ring opening accompanied by the formation of a carboxylic acid. Cyclohexadienones which are blocked in the ortho-position are converted to hexadienoc acids. Cycloalkanones give saturated carboxylic acids and, in the presence of oxygen, also some unsaturated ones. The scope of the reactions is illustrated, and favorable conditions are described. The structure of the products and the route by which they are presumably formed are discussed.

I. Introduction

Much work has recently been carried out in the field of organic photochemistry, since both efficient chromatographic methods capable of separating complex mixtures of products, and serviceable light sources [*] are now available.

Photochemical reactions are no longer curiosities, even in the syntheses of natural products. A few examples may serve to illustrate this:



Scheme 1. Principle of the Barton reaction [1].

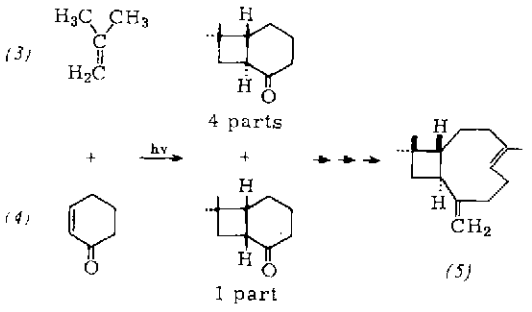
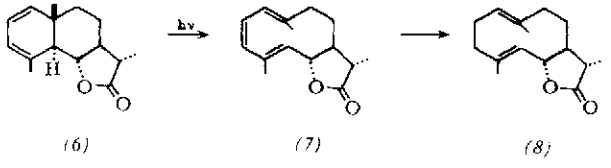
The reaction discovered by *Barton* [1] (Scheme 1) provides a remarkably simple partial synthesis of aldosterone *(2)* from corticosterone acetate *(1)* [2].

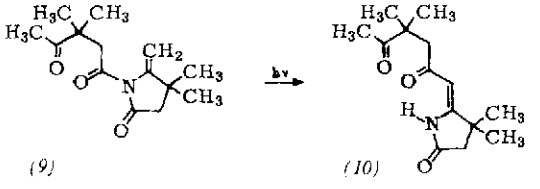
Corey has developed two elegant total syntheses of sesquiterpenes. The synthesis of DL-caryophyllene *(5)* begins with the photochemical addition of isobutylene *(3)* to cyclohexen-2-one *(4)* [3].



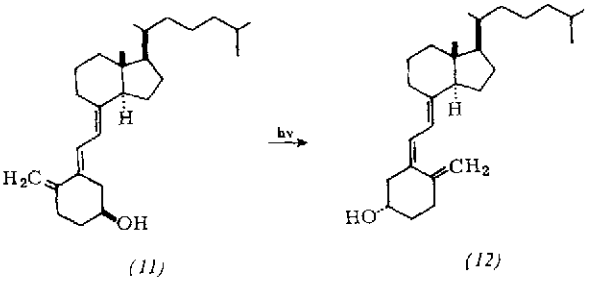
The synthesis of dihydrocostunolide *(8)* involves a light-induced rearrangement of the conjugated cyclohexadiene *(6)* to its valence isomer, the conjugated triene *(7)* [4].



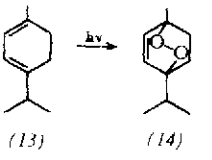
Eschenmoser used a photochemical acyl rearrangement *(9)* → *(10)* in his studies on the synthesis of highly substituted corrin derivatives [5].



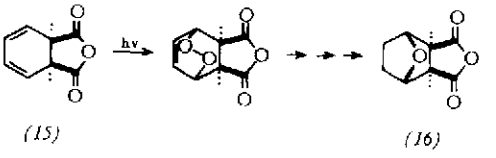
The last step in *Inhoffen*'s total synthesis of vitamin D_3 is the photochemical *trans-cis* isomerization of 5,6-*trans*-vitamin D_3 *(11)* to give the 5,6-*cis*-vitamin D_3 *(12)* [6].



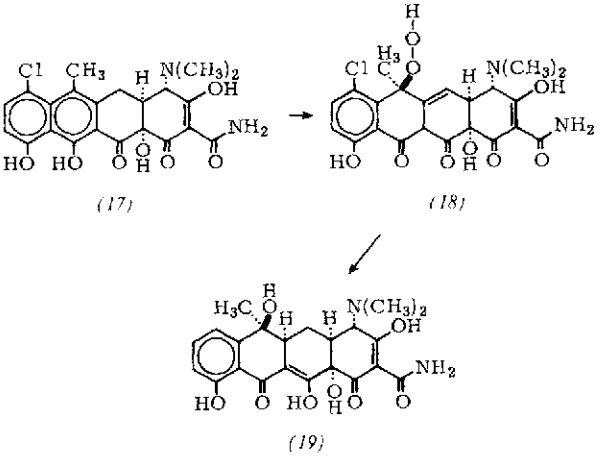
Schenck and *Ziegler* used the photosensitized autoxidation of α-terpinene *(13)* for the partial synthesis of ascaridol *(14)* [7],



and were able to synthesize cantharidin *(16)* from dehydrocantharidin *(15)* using the same reaction [8].



According to *Scott* [9], the unsensitized photo-oxidation of 7-chlorоanhydrotetracycline *(17)* leads to formation of the 6-hydroperoxy compound *(18)* which can be catalytically hydrogenated to tetracycline *(19)*; this reaction sequence provides a partial synthesis of tetracycline.



Finally, the light-induced selective autoxidation of purpurin *(20)* to the ketoaldehyde *(21)* plays an important part in *Woodward*'s synthesis of chlorophyll a *(22)* [10].

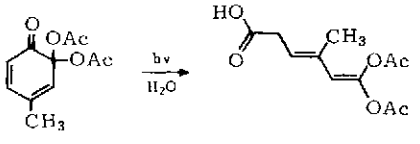
The following review deals with three photochemical reactions which lead to similar results: cyclic ketones are converted to open-chain carboxylic acids by the action of ultraviolet light. Although the mechanisms of the three reactions are not yet fully known, they certainly differ from one another in detail. Nevertheless, a review ought to be useful even at this stage. The following discussion will be deductive, *i. e.* for the sake of clarity the general principle will be explained first and after a provisional interpretation has been given, the experimental facts will be described.

II. Photochemical Formation of Substituted Hexadienoic Acids or Their Derivatives from ortho-Blocked Cyclohexadienones

1. General

If, for example, a solution of *(23)* in ether saturated with water is irradiated with the unfiltered light from a high-pressure mercury lamp, the unsaturated carboxylic acid *(24)* can be isolated after a short reaction-time.



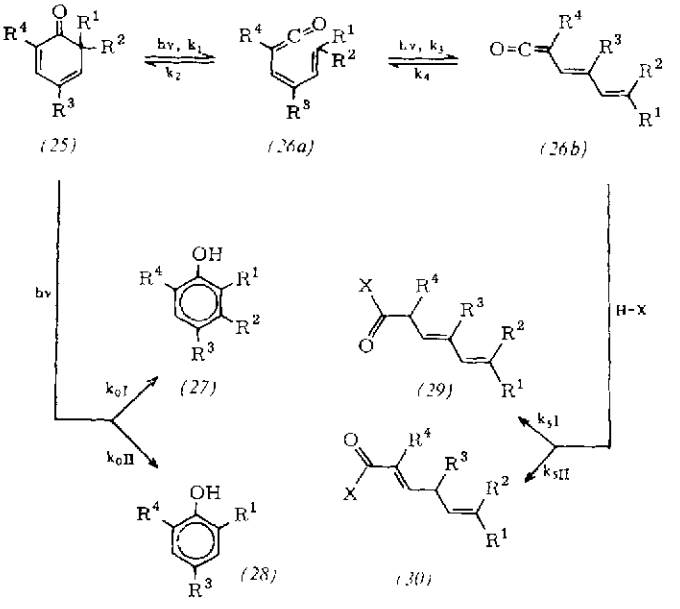
(23) *(24)*

This example is typical of the recently discovered photochemical ring-opening in cyclohexadienones having blocked *ortho*-positions [11], which has already proved to be widely useful (see Table 1). The yield of about 50 % [11a] is certainly not the best possible, since the ketene diacetate grouping in *(24)* is very unstable.

The ease with which the reaction proceeds depends on the number and positions of the substituents in the cyclohexadienone molecule, and on the nucleophilic character of the protonic compound H–X which must be added to the solution.

2. Reaction Mechanism

After the ketone molecule *(25)* [11b] is excited by the absorption of light, it is stabilized by cleavage of the bond between the carbonyl group and the adjacent tetrahedral carbon atom. This results in the formation of a conjugated diene-ketene which can occur in two geometrically isomeric configurations *(26a)* and *(26b)*. In the photostationary state the isomers *(25)*, *(26a)*, and *(26b)* are present together. Their ratio depends on the rate constants k_1, k_2, k_3, and k_4, *i. e.* on the wavelength of the incident light [11c], as well as on the difference between the free energies of *(25)* and *(26a)* on the one hand, and of *(26a)* and *(26b)* on the other. Disturbance of the system leading to a permanent chemical change, can occur either by reaction of the unsaturated ketenes with a nucleophile H–X containing a proton to give the acids or their derivatives, or by irreversible removal of the substituent R^2 from *(25)*. In the latter case, phenols are formed, either by a dienone/phenol photo-rearrangement to *(27)*, or by homolytic photo-dissociation followed by abstraction of hydrogen, *e.g.* from the solvent, to give *(28)*.



(25) *(26a)* *(26b)* *(27)* *(28)* *(29)* *(30)*

Scheme 2. Possible courses for the photochemical reaction of cyclohexadienones having blocked *ortho*-positions.

Assuming that the values of k_1, k_2, and k_4 are relatively large, the extent to which the competing reactions take place is determined by k_{0I} and k_{0II}, and by the sums $(k_3 + k_{5I})$ and $(k_3 + k_{5II})$. Provided that the substituents in *(26b)* do not cause mutual steric hindrance, k_3 is so large that a weakly nucleophilic reactant H–X is sufficient to make the rates of the reactions *via (26b)* considerably greater than the rate of phenol formation. If, on the other hand, mutual repulsion occurs between R^1 or R^2 and R^3, and between R^3 and R^4 in *(26b)*, k_3 decreases and the formation of the acid derivatives *(29)* and *(30)* predominates over the formation of phenols only if a strong nucleophile H–X (*e.g.* a primary amine) is used. With weaker nucleophiles H–X (*e.g.* H_2O), $(k_3 + k_{5I})$ and $(k_3 + k_{5II})$ are comparable to k_{0I} and k_{0II}, and in the extreme case only phenols are formed. This situation always exists when a solution of *(25)* is irradiated with ultraviolet light in the absence of protonic nucleophiles.

[11] *D. H. R. Barton* and *G. Quinkert*, Proc. chem. Soc. (London) *1958*, 197; J. chem. Soc. (London) *1960*, 1.

[11a] The yield determined by ultraviolet spectroscopy of the irradiation product is 86 %.

[11b] The structure of the excited ketones and the mechanism of their physical and chemical stabilization are not considered in this paper.

[11c] The photochemical investigations described here were usually carried out with the unfiltered light from a high-pressure mercury lamp. In glass vessels the reactions are qualitatively the same, though somewhat slower, as those in quartz vessels.

However, in the reactions leading to phenol formation the substituent R^2, which is to be eliminated, must have certain characteristics. The dienone/phenol photorearrangement *(25)* → *(27)* requires R^2 to be a nucleophilic group. The term "dienone/phenol photorearrangement" refers only to the overall reaction; the assumption that polar species are involved in the primary photochemical step [11–13] remains to be proved.

3. Scope of the Reaction

Table 1 contains a list of *ortho*-blocked cyclohexadienones, the photochemical behavior of which corresponds to Scheme 2. Apart from *(41)* (which will be discussed in greater detail below), all *ortho*-blocked cyclohexadienones investigated yield acid derivatives of type *(29)* or *(30)* in the presence of a suitable

Table 1. Photochemical reactions of *ortho*-blocked cyclohexadienones according to Scheme 2.

[e] Deduced by analogy.

[f] Determined by paper chromatography.

[g] Mixture of phenols on irradiation in the absence of nucleophiles.

protonic nucleophile. The strongly nucleophilic cyclohexylamine gives the highest yields, and – with the exception of *(41)* – always leads to the product formed by ring cleavage. Water, being a weaker nucleophile (small values of k_{5I} and k_{5II}), does not form carboxylic acids if there are two 1,3-interactions [cf. *(26b)*] between substituents R^1 (or R^2) and R^3 and between R^3 and R^4. This is the case with, for example, *(37)* and *(38)*. In contrast to *(37)*, compound *(38)* can be converted to phenols. The formation of a phenol in competition with the formation of acid derivatives is noticeable even if only substituents R^1 (or R^2) and R^3 are present, as in *(34)*; up to 10% of phenol are formed in this case [13a]. A number of cyclohexadienones having an acetoxy group on the tetrahedral ring-carbon atom were irradiated in the absence of protonic compounds; they all reacted to form phenols [see *(31)*, *(38)*, *(39)*].

The peculiar behavior of *(41)* can be explained by the fact that one of the two C=C bonds of the cyclohexadienone system belongs to a fused aromatic ring. Consequently, *(41a)* preferentially undergoes dimerization in the presence of water, like an α,β-unsaturated ketone. Even in the presence of cyclohexylamine, no amide could be isolated from *(41b)* [15]; if any was formed, the yield must have been less than 5%. That the fused ring must be aromatic in order to produce the behavior of *(41)* is shown by the irradiation of *(39)*: in aqueous ether, the main product is *(40)*; this is accompanied by a mixture of phenols, in which 1-methyl-5,6,7,8-tetrahydro-2-naphthol has been identified. As expected, therefore, *(39)* behaves like *(34)* [15].

The light-induced conversion of *ortho*-blocked cyclohexadienones to dienecarboxylic acids has also been used in natural-product chemistry. Thus *(43a)* has been obtained from *(42)* which was derived from Ψ-santonin [16], and photosantoninic acid *(47)* has been produced from the recently discovered cyclohexadienone *(46a)* [17, 18], which is itself formed from santonin *(44)*, *via* lumisantonin *(45)*, by the action of light [19].

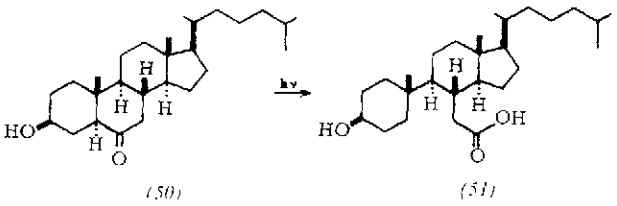
4. Structure of the Reaction Products

A priori it is difficult to predict which of the two diene-carboxylic acids in Scheme 2 [*(29)* and/or *(30)* or their derivatives] will be formed. It is conceivable that the primary product is not the most stable one and undergoes partial or complete isomerization [11], especially in the presence of an amine; however, it is more likely that competing 1,2- and 1,4-additions onto *(26b)* or even onto *(26a)* occur [21a]. The constitution of *(29)* and the configuration of the internal double bond of the conjugated diene portion follow from the characteristic ultraviolet absorption [11].

III. Photochemical Conversion of Cycloalkanones to Open-Chain Saturated Carboxylic Acid Derivatives

1. General

If a solution of 5α-cholestan-3β-ol-6-one *(50)* in acetic acid is irradiated in a quartz vessel under nitrogen with the unfiltered light of a high-pressure mercury-lamp, 5,6-seco-cholestan-3β-ol-6-carboxylic acid *(51)* can be isolated in 54 % yield. This is a typical example [22] of the "photochemical hydrolysis" of unconjugated [22a] open-chain or cyclic ketones, discovered shortly after the turn of the century by *Ciamician* and *Silber* [23–27].



(50) *(51)*

For a long time these reactions have attracted little attention and have only recently found application in the assignment of constitution in terpene chemistry [28,29]. Their mechanism has recently been largely elucidated [30–33]. Investigation of the light-induced formation of carboxylic acids (and their derivatives) from cyclic unconjugated ketones of different ring sizes and different degrees of substitution in the presence of a protonic nucleophile has led to the interpretation shown in Scheme 3.

2. Reaction Mechanism

The ketone molecule *(52)* is excited by the absorption of light and is stabilized by homolytic cleavage of the bond between the carbonyl group and the C-atom which most favors fission owing to the nature and the number of its substituents. The alkyl-acyl diradical *(53)*, which is the primary product of the photochemical reaction [33a], then preferentially undergoes reactions in which both radicals disappear simultaneously.

Recombination leading to the reformation of *(52)* is reflected in the quantum yield. If coupling of the un-

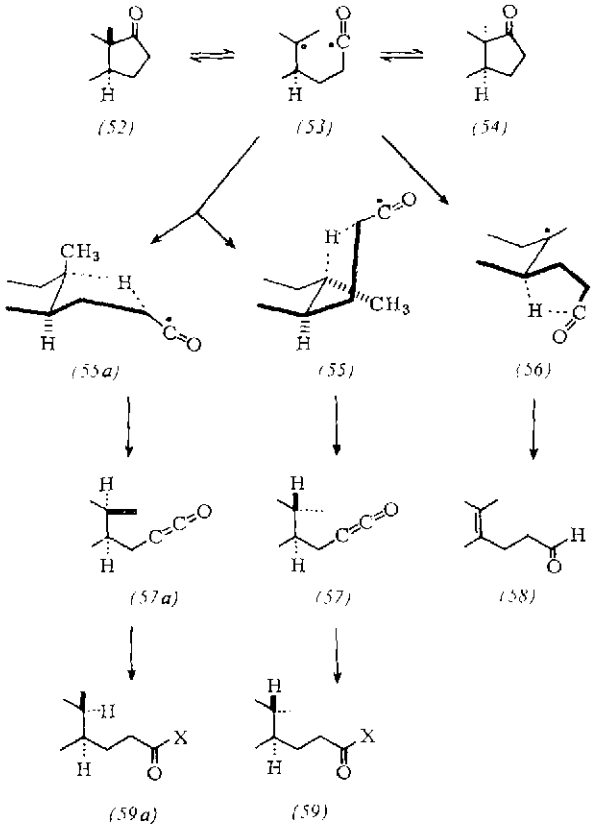
[33a] In contrast to the alkyl-acyl radical pairs formed in gas-phase photolysis of open-chain ketones below 100 °C [40], occurrence of the alkyl-acyl diradical of cyclic ketones has not been experimentally proved. Nevertheless, the light-induced formation of carboxylic acid derivatives from cyclic ketones *via* the alkyl-acyl diradical is discussed here; until formation of this diradical will be experimentally confirmed or refuted, this is justified by analogy with open-chain ketones. Regarding the problem of intermediate diradicals, see [41].

paired electrons leads to the formation of an unsymmetrically substituted center, the epimeric configurations *(54)* and *(52)* may arise. Since both ketones absorb in approximately the same spectral region, the system reaches a photostationary state *via* the diradical. The position of this state depends on the wavelength of the incident light and on the difference between the rates of the competing recyclization reactions.



Scheme 3. Photochemical formation of carboxylic acid derivatives from unconjugated ketones.

In the case of 17-ketosteroids, this photo-epimerization was first observed by *Butenandt* [34]. It was used preparatively in this field [35–38] and was later recognized to be reversible [39]. The photochemical pseudo-equilibrium between *(52)* and *(54)* lies far on the side of *(54)*.

Intramolecular disproportionations of *(53)* (by migration of a hydrogen atom from the position adjacent to the acyl radical to the alkyl radical-site) can lead to the formation of the isomeric ketenes *(57)* or *(57a)*, or to a mixture of both. These react with water to give the carboxylic acids *(59)*, X = OH, and *(59a)*, X = OH; reaction with cyclohexylamine yields the amides *(59)*, X = NH–C_6H_{11}, and *(59a)*, X = NH–C_6H_{11}. When the ketone *(52)* is irradiated in the absence of protonic nucleophiles, the intermediate formation of ketenes can be detected by infrared spectroscopy [32].

A reaction which competes with the formation of ketenes is the formation of the unsaturated aldehyde *(58)*, also by intramolecular disproportionation; in this case, a hydrogen atom migrates from the position adjacent to the alkyl radical to the acyl radical-site. Such ring cleavages of unconjugated cyclic ketones leading to unsaturated aldehydes have been known since the time of *Ciamician* and *Silber* [24–27,42,43]; other examples were described recently [31,44–49].

That the H-migrations leading to the formation of *(57)*, *(57a)*, and *(58)* from *(53)* are intramolecular has been shown with the aid of deuterated ketones, both in the formation of ketenes [31] and of aldehydes [45]. Owing to the competition between both photo-isomerizations of the epimers *(52)* and *(54)*, the yields of *(57)*, *(57a)*, and *(58)* are mutually interdependent. The cyclic transition states of the competing processes can be represented by formulae *(55)*, *(55a)*, and *(56)*. All other factors being equal, the extent to which each disproportionation occurs will be determined by the differences in ring strain [33].

Intramolecular hydrogen shifts are important in the chemistry of free radicals. They may remain unnoticed, or cause branching in a growing polymer chain [50]. A six-membered cyclic transition state seems to be most favorable [51]. This is so in the Hofmann-Löffler-Freytag reaction [52] as well as in the photo-isomerizations described here and in the case of the Barton reaction [1,52a]. In contrast to the formation of the aldehyde *(58)*, there is no uncertainty regarding the source of the migrating H-atom in the formation of the ketenes *(57)* and *(57a)*. If the terminus of the hydrogen shift becomes an unsymmetrical center [as in the case of *(57)* and *(57a)*], its configuration generally cannot be predicted. If the homolytic transfer of the H-atom in *(53)* leads *via* *(55)* and *(55a)* to different reaction products

(57) and *(57a)*, the difference in the ring strains of *(55)* and *(55a)* influences the stereoselectivity of this reaction (see below and especially [33]).

3. Scope of the Reaction

Apart from acetone and methyl ethyl ketone (which give acetic acid together with methane or ethane on irradiation in aqueous solution [23,24]), only cyclic ketones were studied. Table 2 shows a number of examples which illustrate the scope of the reaction and the relationship between the structures of the cycloalkanones irradiated and the resulting carboxylic acids.

Table 2. Photochemical conversion of cycloalkanones to saturated carboxylic acids and their derivatives according to Scheme 3.

Cyclanone	Irradiation product	Ref.
(60)	$HOOC-(CH_2)_5-CH_3$ *(61)*	[25]
 *(62)*	$HOOC-CH_2-\underset{\displaystyle CH_3}{\underset{\vert}{CH}}-(CH_2)_3-\underset{\displaystyle CH_3}{\underset{\vert}{CH}}-CH_3$ *(63)*	[24]
(64)	 *(65)*	[27, 30, 33]
(66)	 *(67)*	[30, 33]
(68)	 *(69)*	[53]
 *(70)*	 *(71)* *(72)*	[31]
 *(73)*  *(75)*	 *(74)* *(76)*	[30–32]
 *(77)*	 *(78)* *(79)*	[33]

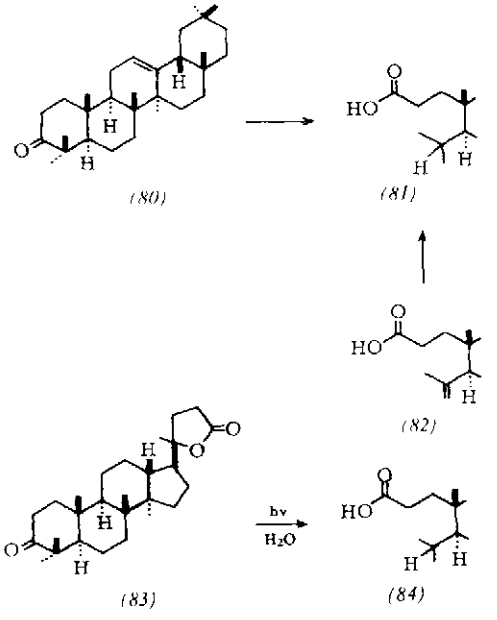
The yields of the acidic products or their derivatives are generally between 30 and 70 %.

In the case of the ketones *(68)* and *(70)* no preferred direction for the α-cleavage is to be expected. While *(69)* gives no nidication of the site of the ring cleavage, the 3-ketosteriod *(70)* yields two carboxylic acids *(71)* and *(72)* by approximately equal cleavage of ring A between C-3 and C-2 and between C-3 and C-4. The other ketones listed in Table 2 are substituted with alkyl groups to varying degrees at the positions adjacent to the carbonyl group. In each case, only the product corresponding to ring cleavage on the side of the more highly substituted α-C-atom was described. The 17-ketosteroids *(73)* and *(75)* have been particularly closley studied with respect to the specificity of the ketene formation [33]: in the presence of water, both *(73)* and

[53] *F. Homburg*, Ph. D. Thesis, Technische Hochschule Braunschweig, 1964.

(75) yield only the primary carboxylic acid *(74)*; the tertiary acid *(76)* is not formed [53a].

The photochemical conversion of unconjugated cycloalkanones into the carboxylic acids by addition of one mole of H_2O has also been used in natural-product chemistry [28]. The ultraviolet irradiation of β-amyrone *(80)* yields the dihydro derivative *(81)* of nyctanthic acid *(82)*. The structure of *(82)* was deduced from this reaction [54]. Likewise, the γ-lactone *(83)* obtained from hydroxydammarenol-II can be converted to *(84)* which was correlated to a reaction product of dammarenolic acid.

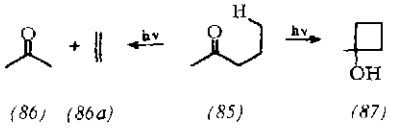


(80) *(81)* *(82)* *(83)* *(84)*

Only very small quantities of an acid derivative are obtained on irradiation of solutions of camphor *(64)* containing a protonic nucleophile. Comparison with homocamphor *(66)* shows that ketene formation increases with the transition from the cyclopentanone ring to the higher homologue. The same is true for the homologues *(73)* and *(77)*. The compound with the cyclopentanone ring *(73)* gives a 28% yield of the carboxylic acid *(74)*, while *(77)* is converted into the corresponding carboxylic acids in a yield of almost 50% [33].

Besides the formation of unsaturated aldehydes, which is related to the formation of ketenes, there are other competing reactions which limit the synthetic usefulness of this method of preparing acids or their derivatives. Such reactions may be due to the structure of the ketone to be irradiated: α,α'-phenyl- [55, 56] or vinyl-substituted [57] ketones undergo rapid light-induced decarbonylation which prevails over the formation of acids (or their derivatives).

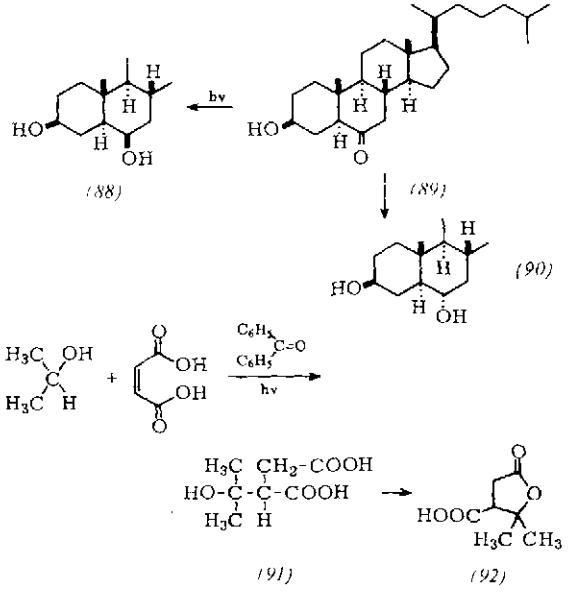
The formation of acids (or their derivatives) can also decrease as a result of photoreduction. If a hydrogen atom occupies a favorable position with respect to the photochemically excited keto group, as in *(85)*, then a photofragmentation [*e.g.* to yield *(86)* and *(86a)*] or a photocyclization [59], *e.g.* leading to *(87)*, may take place. These reactions are initiated by an intramolecular hydrogen shift. Of course, the entire process may occur in a single step [59a].



(86) *(86a)* *(85)* *(87)*

Scheme 4. Photofragmentation and photocyclization of ketones.

If the structural requirements for intramolecular hydrogen transfer to the oxygen atom of the photochemically excited keto group (Scheme 4) are not satisfied, other reactants (particularly the solvent) may assume the role of H-donors. Depending on the nature of the ketone and the coreactant, the products may be alcohols [*e.g.* *(88)* and *(90)* from *(89)*] [31] or alcoholic condensation products [*e.g.* in the addition of isopropanol to maleic acid, photosensitized by benzophenone, to form *(91)* which reacts further to yield *(92)*] [63, 64].



(88) *(89)* *(90)* *(91)* *(92)*

[53a] The absence of *(76)* is consistent with the ketene formation by homolytic hydrogen abstraction from the position adjacent to the acyl radical, since α-cleavage of *(73)* and *(75)* between C-16 and C-17 yields an alkyl-acyl diradical with no hydrogen in the position adjacent to the acyl radical.

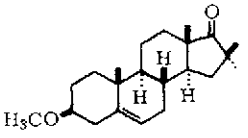
The solvent should have the lowest possible tendency to donate hydrogen atoms to free radicals. This condition is best satisfied by water and benzene; however, these can scarcely be considered as solvents for the formation of carboxylic acids, since ketones usually are not sufficiently soluble in water, and the water required for the reaction is not sufficiently soluble in benzene. Acetonitrile, glacial acetic acid, and alcohols (particularly tertiary alcohols) have been used, whereas aliphatic or cycloaliphatic ethers strongly favor the intermolecular photoreduction.

Finally, a group of unconjugated ketones should be mentioned, from which the light-induced formation of acids or their derivatives is impossible. In fenchone *(93)* and 16,16-dimethyl-3β-methoxy-Δ^5-androsten-17-one *(94)*, neither C-atom adjacent to the light-absorbing carbonyl group carries a hydrogen atom; consequently, these compounds cannot undergo intramolecular hydrogen shift to form a ketene. On irradiation in the presence of water, *(93)* and *(94)* do not yield the carboxylic acids which would arise by incorporation of the elements of water [32,65].

(93)



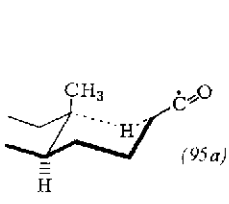
(94)

4. Structure of the Reaction Products

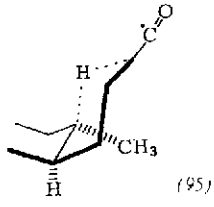
The structure of the carboxylic acids and their derivatives which result from the photochemical reaction of a cycloalkanone [*e.g. (52)*] is determined by constitution-specific cleavage of the ketone ring to yield the most stable diradical [*e.g. (53)*], and consequently depends on the nature of the substituents in the α- and α'-positions. The rule that light-induced cleavage of cyclic ketones takes place on the side of the more highly alkyl-substituted carbon atom was stated by *Ciamician* and *Silber* [24,25,42] and has subsequently been used repeatedly as a guide (*e.g.* [28]) [65a].

Unsaturated substituents, the *p*-orbitals of which overlap with the *p*-orbital of the alkyl radical, favor homolysis and help to determine the site of ring cleavage.

The configuration of the carboxylic acid (or derivative) formed cannot be predicted when a center of asymmetry is involved in the light-induced ring cleavage, as in the case of *(73)* and *(77)*. Comparison of the products obtained in these cases [*(74)* from *(73)*, and *(78)* + *(79)* from *(77)*] shows that the stereoselectivity [67a] decreases as the size of the cycloalkanone ring increases. This can be plausibly explained by assuming that a six-membered ketone gives less ring strain in the cyclic transition state for the formation of ketenes than a five-membered ketone [higher yield of acid from *(77)*



(95a)



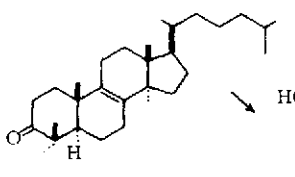
(95)

than from *(73)*], and that the difference between the ring strains of the transition states *(95)* and *(95a)*, which are configurational isomers, is less than in the case of *(55)* and *(55a)*.

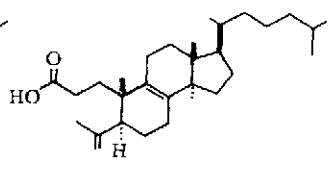
IV. Photochemical Conversion of Cycloalkanones to Open-Chain, Unconjugated, Unsaturated Carboxylic Acids

1. General

If a solution of Δ^8-lanosten-3-one *(96)* and cyclohexylamine in benzene [68a] is irradiated with the unfiltered light of a high-pressure mercury lamp, while oxygen is continuously passed through the solution, a 20 % yield of 3,4-seco-$\Delta^{4(23),8}$-lanostadien-3-oic acid *(97)* can be isolated after 24 hours.



(96)



(97)

This is a typical example of the recently discovered autoxidative ring cleavage of cyclic unconjugated ketones to unsaturated carboxylic acids containing one

[65] *B. Wegemund*, Diploma Thesis, Technische Hochschule Braunschweig, 1960.

[65a] The constitution-specific α-cleavage is not self-evident, since this reaction starts with a photochemically excited molecule. In the gas-phase photolysis, *e.g.* of methyl ethyl ketone, α-cleavage occurs in both possible directions [66]. It seems likely that two different excited species are responsible for the formation of the different reaction products. If the photolysis is carried out in the gas phase at low pressure, the electronically excited molecule reacts from the vibrational state reached in the excitation. In solution, deactivation by a chemical reaction is preceded by thermodynamic equilibration of the vibrational energy with the surroundings; this is shown in the gas-phase photolysis of methyl ethyl ketone by the decrease in specificity of the α-cleavage with decreasing wavelength of the incident light [66]. Apart from the chemical reaction, fluorescent emission also yields information as to the nature of the excited species. Whereas the absorption spectrum of a substance in solution normally shows that the electronically excited molecule is also vibrationally excited, the fluorescent emission spectrum of the same compound in solution shows that the emitting molecule is already in the vibrational ground state [67].

[66] See [40], p. 358.

[67] *T. Förster*: Fluoreszenz Organischer Verbindungen. Vandenhoeck und Rupprecht, Göttingen 1951, p. 133; *A. Ehrenberg* and *H. Theorell* in *M. Florkin*: Comprehensive Biochemistry. Elsevier, Amsterdam 1962, Vol. 3, p. 170.

[67a] The terms "constitution-specific" and "stereoselective" imply a connection between the constitution of the starting material and that of the product, but none between their configurations. Thus, the formation of the carboxylic acid *(74)* with a 13α–CH_3 group from both *(73)* and *(75)* is constitution-specific and stereoselective; see [33,68].

[68] *H. E. Zimmerman, L. Singer*, and *B. S. Thyagarajan*, J. Amer. chem. Soc. *81*, 108 (1959).

[68a] Cyclohexylamine is added to convert the ketenes, which are also formed in the presence of oxygen (see Section III), to cyclohexylamides. This facilitates isolation of the acids formed by autoxidation.

Table 3. Photochemical conversion of cyclic ketones to unsaturated carboxylic acids according to Scheme 5.

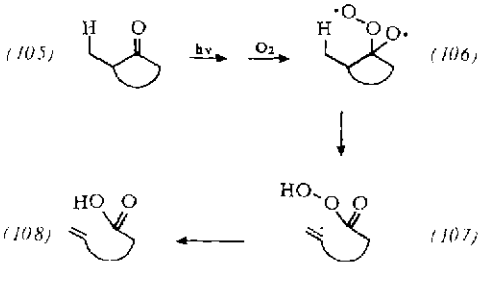
Cyclanone	Acidic photo-oxidation product
(62) [71]	 *(98)* *(99)*
(73) and *(75)* [69,70]	 *(100)*
(80) [69,70]	*(82)*
 *(101)* [69,70]	 *(102)*
 *(103)* [70]	 *(104a)*: R = CH_2OH *(104b)*: R = CH_3

oxygen atom more than the original ketone [69,70]. This reaction has been used in partial syntheses, especially of the 3-ketotriterpenes (see Table 3).

2. Reaction Mechanism

The products assumed or shown to be formed when unconjugated cyclic ketones are irradiated with ultraviolet light in the absence of oxygen (see Section III) are not precursors of the unsaturated carboxylic acids which are formed in the presence of oxygen. The hypothetical diradical, *e.g. (53)*, which has been assigned a key position as the product of the primary photochemical process is also a possible reaction partner for the molecular oxygen. However, such a reaction is ruled out by the structure of the acidic photo-oxidation products [69,70] and by experiments aimed at testing the unknown reactivity of diradicals towards O_2 [72]. For structural reasons, the ketene photoisomer of *(52)*, *e.g. (57)*, cannot be an intermediate of the photo-oxidation, and the other disproportionation product *(58)* of the alkyl-acyl diradical *(53)* can also be ruled out [69,70].

As a working hypothesis it is assumed that the cyclic ketone *(105)* in the photoactivated state reacts with the oxygen molecule [70a]. The postulated hydroxy-hydroperoxy diradical *(106)* undergoes intramolecular rearrangement to yield the unsaturated peroxyacid *(107)* which then forms a carboxylic acid *(108)* in the usual manner (see Scheme 5).



Scheme 5. Photo-oxidation of cyclic ketones to unsaturated carboxylic acids.

Reaction of the photo-oxidation product *(106)* is initiated by an intramolecular hydrogen-shift [cf. the light-induced conversion of *(85)* to *(86)* and *(86a)*]; of course, this reaction may also proceed in a single step. A six-membered cyclic transition state is required for both processes. Thus the cyclic ketone must have at least one H-atom in the β-position with respect to the carbonyl group; furthermore, the orientation of this H-

[69] *G. Quinkert* and *H.-G. Heine*, Tetrahedron Letters *1963*, 1659.

[70] *H.-G. Heine*, Ph. D. Thesis, Technische Hochschule Braunschweig, 1964.

[70a] Photo-oxidations which proceed in the absence of sensitizers, and which do not involve the reaction of radicals formed by photodissociation with O_2, have so far received little attention [see *R. M. Hochstrasser* and *G. B. Porter*, Quart. Reviews *14*, 146 (1960)].

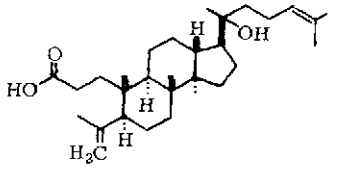
[71] *G. Quinkert* and *H. Oehlschläger*, unpublished work.

[72] *H. H. Rieckert*, Diploma Thesis, Technische Hochschule Braunschweig, 1963.

atom must be such that the centers H-C(β)-C(α)-C–O–O in the hydroxy-hydroperoxy diradical can assume a cyclic arrangement.

3. Scope of the Reaction

Table 3 shows a number of cases studied so far, in which a cyclic ketone is converted to an unsaturated carboxylic acid containing an additional oxygen atom. With the exception of *(62)*, all the ketones contain a CH_3-substituent α to the carbonyl group. In these examples the new C=C double bond, which is formed together with the carboxyl group, is always terminal.



(109)

Consequently, this new photo-oxidation can be used as a step in the partial synthesis of 3,4-seco-triterpene-carboxylic acids with a $\Delta^{4(23)}$-double bond from 3-keto-triterpenes [*e.g. (96)* → *(97)*].

Unsaturated carboxylic acids of this type have very recently been found in nature: dammarenolic acid *(109)* [28], nyctanthic acid *(82)* [28,54], roburic acid *(102)* [73], and canaric acid *(104b)* [74].

Compounds *(102)* and *(82)* have been obtained in 20 % yield by irradiation of α-amyrone *(101)* and β-amyrone *(80)* in the presence of oxygen [69]. Similarly, betulone *(103)* gave the doubly unsaturated hydroxycarboxylic acid *(104a)* [70] which presumably occurs in nature, too.

I obtained my first impressions of photochemistry from the instructive "studies in the vitamin D series" carried out together with Prof. H. H. Inhoffen. I then had the good fortune to witness the development of the study of "photochemical transformations" under Prof. D. H. R. Barton, and subsequently embarked on the investigation of "light-induced reactions" together with capable young colleagues who find a challenge in unsolved problems and who are mentioned by name in the list of references. To all with whom I could work together I am sincerely grateful.

Fused Salts and Their Use as Reaction Media [*]

BY DR. W. SUNDERMEYER

ANORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT GÖTTINGEN (GERMANY)

Apart from being of interest for physicochemical investigations, ionic liquids are a very important supplement to the non-aqueous and water-like solvents. The present discussion of the physical properties and current ideas on the structure of fused salts is followed by a report on the solubilities of gases, salts and metals. Our knowledge of fused salt baths and their use in electrochemical and electrometallurgical processes has recently been considerably expanded. Special attention is drawn to chemical reactions in fused electrolytes. Fused salts can also act as catalysts, so that they may often be advantageous reaction media for synthesis, if not the only media which can be used.

I. Introduction

Most operations in modern preparative chemistry are carried out either in or with the participation of a liquid phase, in which the mobility of the molecules is similar to that in the vapor phase, but where the density of matter is almost the same as that of a solid. However, reactions are not confined to aqueous systems and to solutions in organic solvents, which could also be regarded as "molecular melts". Very profitable use is made, both in the laboratory [1] and in industry, of reaction media which range from condensed gases to melts of predominantly covalent metal halides, and which are characterized by a slight self-dissociation, similar to that of water. Surprisingly, however, we rarely find papers describing the preparative use of ionic liquids as solvents, although the physicochemical properties of these liquids suggest that they should also be useful in fields other than electrochemistry.

Fused electrolytes are generally completely dissociated into ions, and are excellent solvents for salts, metals, and

gases. They are steadily gaining in technological importance, owing to their high thermal stability, low vapor pressure, good electrical conductivity, low viscosity, extremely wide useful temperature range, and the very high temperatures which can be reached. It is not surprising, therefore, that electrochemical [2–7] and physicochemical investigations [8] have recently been intensified with a view to the possibility of general industrial applications of fused salts, particularly in nuclear technology [9]. Growing interest is directed towards new electrometallurgical processes, and to the development of fuel elements with a low internal resistance, or of the "molten salt reactor". However, as can be seen from the increasing number of publications from 1900 to 1960 [10], special attention has been devoted to the structural characteristics of molten salts in the hope of gaining an insight into this extreme form of the liquid state. This as well as the electrochemical and chemical reactions which can be carried out using fused salts as solvents form the subject of the present paper.

II. Physical Properties and Structures of Fused Salts

Silicates, borates, and phosphates [11–13] are omitted from the discussion of molten electrolytes because of the different physical and structural properties of these compounds, which result mainly from the polymeric anion structure. Owing to their high viscosities, the molecules of these compounds are not sufficiently mobile to crystallize on cooling; consequently, they normally solidify in a vitreous state in which the disorder equilibrium of the melt is largely retained. Similarly, fused halides with predominantly covalent bonding (*e.g.* halides of aluminum, arsenic, antimony, and mercury), are discussed only when used in combination with other salts.

Salts which are highly ionic in the crystalline state are expected to dissociate almost completely into ions or groups of ions when fused. Anions and cations cannot be randomly distributed in the melt; instead, each ion is surrounded by a certain number of oppositely charged ions as a result of Coulomb interactions. We thus have a quasi-lattice structure [14], in which random distribution is possible only within the anionic or cationic partial lattice and within the immediate vicinity of a single ion [15, 16]. Although melts have no long-range order such as is present in crystals, the kinetic properties of fused salts can be better discussed in the light of the theory of defects in solids than by comparison with solutions of strong electrolytes.

The validity of this picture of ionic liquids as highly disordered crystals is confirmed by the radial distribution function of the ions in the melt, which can be derived from X-ray or neutron diffraction measurements. The result was surprising. It was found that the degree of order in a melt, at least slightly above the melting point, is similar to that in the solid and does not correspond to the disorder of the gaseous state, as had formerly been assumed. Furthermore, the most probable distance between an ion in the first coordination sphere and a given central ion is up to 9% less than in the crystal lattice (cf. Table 1). This high degree of order is also indicated

Table 1. Coordination numbers (CN) and cation-anion distances in solid and fused alkali metal halides.

Salt	Crystal		Melt at m.p.		Decrease of distance on melting [%]
	CN	Distance [Å]	Mean CN	Distance [Å]	
LiCl	6	2.66	3.7	2.46	7.1
LiBr	6	2.85	5.2	2.68	6.0
LiI	6	3.12	5.6	2.85	8.6
NaI	6	3.35	4.0	3.15	6.0
KCl	6	3.26	3.6	3.10	4.9
CsCl	6	3.57	4.6	3.53	1.0
CsBr	6′	3.72	4.6	3.55	4.4
CsI	6′	3.94	4.5	3.85	2.3

by the fact that the entropy of fusion is only about one quarter of the entropy of vaporization. This agrees with the assumption that at the onset of crystallization extensive preorientation occurs at the melt/crystal interface with the formation of "islands" which are already subject to a certain "ordering" opposing the thermal motion. Crystal growth from the melt can therefore be regarded as a special case of crystalline transitions [17].

Whereas the presence of ordered regions in fused salts slightly above the melting point needs further study, a distinct after-melting effect has been detected by differential thermal analysis, *i.e.* up to 14% of the enthalpy of fusion is absorbed only after completion of the melting process proper [18]. The size distribution of the submicroscopic ordered regions is a function of temperature [19]. On the other hand, the assumption of a quasi-crystalline structure has been refuted in the case of molten metals. The short-range ordering is regarded as a surface effect [20], and the atom distribution in the melt cannot be interpreted in terms of a distorted crystal lattice [21].

At the same time, however, increases of up to 25% in the molar volume have been reported on fusion of salts [22–24] which have a high coordination number in the crystal lattice. This increase in volume can be only partly explained by a structural change in the first coordination spheres [24, 25]. Consequently, the structure of a molten salt must contain a large proportion of empty volumes, on the nature of which there are two different views (see Figures 1a–1c).

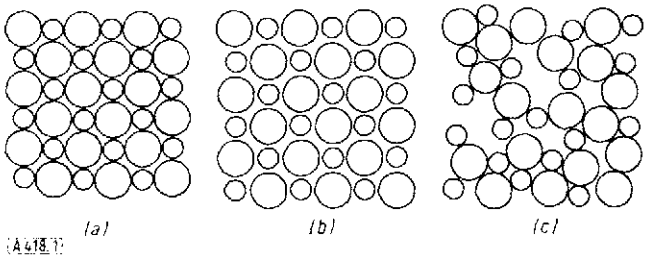

Fig. 1. (a) NaCl crystal; (b) cell model of an NaCl melt; (c) hole model of an NaCl melt.

In the so-called cell model (Fig. 1b) [26], each ion is regarded as an independent linear oscillator vibrating in a three-dimensional cell, the boundaries of which are given by the neighboring ions. The empty volume is thus distributed as free volume between the ions. According to this view the mean coordination number in the melt should correspond to that in the crystal, and the mean interionic distance should increase in parallel with the volume change which occurs on fusion and which should amount to only 6 or 7%; furthermore, electrolytic transport should be due almost exclusively to the smaller cations, which is not confirmed by experiment [27].

The experimental facts rather support the hole model (Fig. 1c) [28–30], according to which the free volume again increases on fusion. However, it has been calculated from the compressibility of molten salts [31] that only about 2% of the total increase in volume can be ascribed to the formation of free volume by an increased amplitude of the vibrations of the ions about their migrating normal positions. The remaining 10 to 20% is attributed to anionic and cationic holes.

This hypothesis is confirmed by the fact that the mean coordination number in fused salts is always appreciably smaller than the maximum value expected from the ratio of the ionic radii (cf. Table 1) [32]. Because of electrical neutrality, however, it is difficult to imagine that, in a quasi-lattice structure, there will always be only one hole with the dimensions of an anion or a cation in one sixth to one fifth of all "lattice sites". Instead, some of the positive holes seem to be discharged by a free electron [33], and almost half of the empty volume appears to consist of neutral cation-anion double holes [34, 35]. This is confirmed by cryometric investigations in fused salts [36]. Since ideal solutions are formed even when salts containing ions of very different sizes are mixed, it can be concluded that holes or gaps are present in the quasi-crystalline lattice.

In a kinetic consideration, it must naturally be assumed that the holes are randomly distributed, not only spatially, but also with respect to their size and shape. Consequently, the term "soft volume" has been coined [37] to avoid references either to a cell or to holes. From the high empty-volume concentration, it is concluded that the forces acting on some of the ions in the melt are no longer symmetrically distributed, so that the formation of ion pairs or molecules is favored. In fact, it is possible to set up a general equation of state for fused electrolytes, one term of which describes the complete formation of molecules (as on vaporization) and the other the ideal solid, and which agrees with the experimental results (*e.g.* the unexpectedly large increase in volume on fusion of ionic crystals) if the individual terms are combined in a certain ratio [38]. However, no conclusion can be drawn from this with regard to the fusion process itself [37].

Provided that a simultaneous structural transition can be ruled out, the sudden large increase in the molar volume on fusion can be explained by the fact that below the melting point the thermal disorder equilibrium reaches an excessively low value as a result of the strong lattice forces and the correspondingly high disorder energy. It is only when the kinetic energy of an individual structural unit has become so large that it can break away completely from the lattice, that the energy required for the formation of a hole decreases spontaneously, and a new thermodynamic disorder equilibrium is set up, with the absorption of a certain quantity of energy (heat of fusion).

Melts of salts with polyvalent cations have not been studied so thoroughly, since here a large number of structural units can be imagined which determine the physicochemical properties of the melt. It is not yet known with certainty to what extent alkaline earth halides, for example, are dissociated, and what complex units they form.

Molten halides of the transition elements form structures such that the melts cannot be described as purely ionic liquids. Whereas beryllium fluoride forms polymeric chains [39], fused zinc chloride may be regarded as consisting of two-dimensionally cross-linked layers [40, 41]. As in the case of the halides of Group III and IV elements (which form water-like molecular melts) these structures dissolve to form complexes only on addition of alkali metal halides. This process corresponds to solvation in other solvents.

Alkali metal salts with anions which are not spherically symmetrical also exhibit irregular properties: groups of associated ions are observed in fused nitrates and nitrites

[42] and the changes in volume are not so pronounced as with the halides, which indicates that the difference between the disorder energies in the crystal and in the melt is less than for alkali metal halides. With fused salt systems containing complexes [23,43], the degree of disorder typical of the liquid state is reached at a lower temperature than with the pure components. Moreover, sudden changes in volume at the melting point are no longer observed. In the case of the thiocyanates, the crystal lattice is so extensively deformed that a pronounced "premelting" occurs [44].

Thermal and electrical transport in melts can hardly be explained unless the presence of holes which can change places with the ions is accepted. Although the transport number, diffusion, and viscosity at a given temperature depend on the size, polarizability, and electrical charge of the ion, they are particularly dependent on the hole concentration; this also explains the high electrical conductivity of fused salts [45]. The objection was made [46] that the electrical conductivity actually decreases when the defect concentration is increased, as in the crystal, by the addition of divalent cations, so that holes seem not to contribute towards transport processes. However, this ignores the fact that larger groups of ions, or even compounds are formed in the melt, which leads to an appreciable decrease in the electrical conductivity [*].

III. Solubility in Fused Salts

A. Gases

Gases often react rapidly and quantitatively in fused salts, although the solubility *e.g.* of inert gases is very low.

While the solubility of helium in fluoride melts between 600 and 800 °C is 10×10^{-8} to 20×10^{-8} mole/cm³ that of xenon is only 0.1×10^{-8} to 2×10^{-8} mole/cm³, *i.e.* the solubility decreases with increasing atomic weight [48–50]. It increases with rising temperature and pressure. The solubility of xenon in a sodium nitrate/potassium nitrate melt between 260 and 450 °C is 8×10^{-8} to 10^{-7} mole/cm³ [51] [**].

The assumptions that the quantity of gas dissolved corresponds to the free volume [53] and that the enthalpy of solution is related to the energy required for the formation of holes were confirmed in the case of molten fluorides [49].

However, if ion-dipole interactions or compound formation takes place between the melt and the gas, the solubility of the gas increases appreciably. This is shown by the strong green coloration occurring near the anode during the electrolysis of fused halides [43]. The solubility of chlorine in alkali metal chlorides was found to be of the order of 10^{-6} mole/cm³, while the solubilities of bromine and iodine in the corresponding alkali metal halides are about ten times greater [54]. The chlorine is probably present as the Cl_3^- ion. It may be assumed that species similar to the chloroiodates are formed on dissolution of iodine in alkali metal chlorides; in any case, iodine has been detected in the valence states of −1, 0, and +1 [55]. Compound formation on dissolution of hydrogen fluoride in NaF/ZrF_4 is well known; as the sodium fluoride concentration increases, the solubility rises from 10^{-5} to 10^{-4} mole/cm³ [56].

B. Salts

Whereas many data are available on the solubility of salts in the melts of other salts [8], information on the solubilities of oxides is less abundant, although these data are important in connection with the corrosion of oxidic container materials. The solubility of magnesium oxide in binary and ternary systems of the alkali metal and alkaline earth halides is less than 0.05% by weight at 800 °C [57] (0.07% in $CaCl_2$ at 1000 °C [58]), while that of Fe_2O_3 in potassium fluoride at 1100 °C is 24% by weight [59]. An important point in electrometallurgical processes is the solubility of titanium, zirconium, and hafnium oxides in alkali metal fluorides [60], which is about 0.1% by weight. Qualitative investigations on the solubilities of oxides in a LiCl/KCl melt at 500 °C have led to a series in which almost all the important oxides are classified according to solubility [61].

A similar classification has been carried out for the sulfides [62]: the highest solubilities are shown by the alkali metal and alkaline earth sulfides, while the sulfides of most of the sub-group elements are insoluble in melts of this type. More detailed experiments were carried out to find the solubility of zinc sulfide; zinc chloride and the eutectics of zinc chloride with sodium chloride and with potassium chloride are particularly good solvents (solubility 0.3 to 0.5 mole/kg of melt at 700 °C) [63]. Almost

[**] A comparison of the solubility of helium in fused lithium silicate, *e.g.* at 1400 °C, with that in ionic melts [52] should be regarded with caution, since the polymeric anion structure gives rise to cavities which have nothing in common with the empty volume of ionic melts.

[52] *H. Scholze* and *H. O. Mulfinger,* Angew. Chem. *74,* 75 (1962); Angew. Chem. internat. Edit. *1,* 52 (1962). Owing to the highly covalent character of the bonds in the silicate skeleton, many silicates contain empty spaces (in the crystallographic sense) even in the solid state, in which smaller ions such as Li^+ and Be^{2+}, as well as He and H_2, can be embedded. It is therefore obvious that the solvent capacity for helium must decrease on addition of lithium oxide. This also applies to silicate melts.

the same solubility was found for calcium sulfide in lithium chloride [64].

Nitrides are insoluble in all common solvents, but dissolve in fused salts, particularly those of lithium. The solubility of calcium nitride is 0.07 mole/mole of LiCl at 650 °C, and that of lithium nitride is 0.15 mole/mole of LiCl. The solubility decreases on addition of potassium chloride [64]. The same is true of carbides, for which lithium halides have the best solvent properties of all the alkali metal halides. The other alkali metal halides react to a slight extent with formation of the alkali metal [65]. Whereas 20% by weight of lithium carbide or 17% of calcium carbide are soluble in lithium chloride at 820 °C, only 5.7% of calcium carbide can be dissolved in calcium chloride [65, 66].

It is generally known that the hydrides of the alkali and alkaline earth metals are soluble in fused salts and (as is also assumed for the oxides, sulfides, nitrides, and carbides) are dissociated into ions [67]. Nevertheless, hardly any quantitative data are available.

For lithium hydride in a LiCl/KCl melt at 400 °C a solubility of only 1–2 by weight was reported [68], while an eutectic was found for the system LiH/LiCl at 486 °C and a lithium hydride concentration of about 37 mole-% [65]. Sodium and calcium hydrides are also sufficiently soluble in alkali metal halides and hydroxides to take part in chemical reactions [43] (*e.g.* the solubility of sodium hydride in sodium hydroxide at 375 °C is 20% by weight).

C. Metals

The metal/fused salt systems are particularly interesting, not only because of their preparative applications, but also in view of their structural characteristics, which have not yet been fully elucidated. While metals are mostly insoluble in solid salts, an appreciable solubility is observed in the melts of their halides (cf. Table 2). Above

Table 2. Solubility (S) of metals in fused salts.

Metal	Melt	Temp. [°C]	S [mole-%]
Na	NaCl	895	4.3
K	KCl	770	16
Mg	$MgCl_2$	800	1.1
Ca	$CaCl_2$	1000	16
Sr	$SrCl_2$	1000	24.6
Ba	$BaCl_2$	1000	30
La	$LaCl_3$	826	9
Ce	$CeCl_3$	800	33
Pr	$PrCl_3$	659	18.5
Nd	$NdCl_3$	841	30.5
Cd	$CdCl_2$	650	16
Hg	$HgCl_2$	350	50
Bi	$BiCl_3$	320	45

a characteristic temperature, the metal and the melt are completely miscible and form a homogeneous liquid. Below this temperature progressive separation into two phases occurs.

The alkali metal systems have been investigated in detail: with a given anion, the miscibility appears to be the better, the larger the cation [69–71]. The alkaline earth metals are also readily soluble or even completely miscible with their halides, depending on the temperature [72–74]; for example, this makes the isolation of barium by melt electrolysis extremely difficult. The electrical conductivity of such systems is considerably greater, even at low metal concentrations, than that of the pure fused salts [75]. This suggests that the dissolved metal contributes an electronic conductivity component to the ionic conductivity already present. In particular the solubilities of rare earth metals in their halides promise a deeper insight into the structural relationships in metal/fused salt systems.

The discovery of very small metal droplets in rapidly cooled metal/melt systems led to the assumption that these systems were colloidal solutions referred to as "pyrosols" [76]. This is contradicted, however, by the depression of the melting point at low concentrations of the metal. More likely, at least in the case of the more electropositive elements, is a combination of the lattice of the salt with a hypothetical lattice of the metal, consisting of cations and F centers [77], *i.e.* the metal dissolves in the ionic form; the cation belongs to the quasi-lattice structure of the melt and the electron – although localized – can no longer be assigned to any one definite cation. This view is supported by the particularly high solubilities of metals in melts of their own salts. As the concentration of the metal increases, a quasi-periodic arrangement of the F centers seems to be formed, which ultimately leads to overlapping of the valence electron levels and hence to electronic conduction similar to that in the metal. The conductivity in the system LaI_3/La is even higher than that of the metal; formation of the "diiodide" is therefore proposed, in which the metal is present in the oxidized form [78]:

$$La + 2\ La^{3+}(I^-)_3 \rightarrow 3\ La^{3+}(I^-)_2e^- \quad (1)$$

Whereas the solubility of lanthanum [79] and cerium [80] in melts of their chlorides is normal, and the conductivity of the system $Ce/CeCl_3$ [81,82] also indicates the presence of relatively mobile electrons, a continuous transition from electronic to purely electrolytic conduction and to stable

compounds in lower oxidation states can be observed for the lighter rare earth metals. In the case of neodymium, for example, the following equation can be written [83]:

$$Nd + 2\ Nd^{3+}(I^-)_3 \rightarrow 3\ Nd^{2+}(I^-)_2 \quad (2)$$

Praseodymium occupies an intermediate position [84]. The greater the tendency to accommodate one or more valence electrons in the shell of the cation and not in zones of energy states of the whole system, the more probable is the formation of a "sub-compound". The anions are of decisive importance in this connection, since these must be compatible with the high concentration of F centers. There appears to be a relation between the reducing power (the "aggressiveness") of the dissolved metal and the "mobility" of its electrons. The more firmly the electrons are bound, the lower will be the reducing power of the system, since the electrons are used for the formation of compounds in low oxidation states.

Subhalides, which have also been discussed in the case of the alkali and alkaline earth metals (*e.g.* CaCl or Na_2Cl) [75], are clearly evident from the phase diagrams of $HgCl_2$/Hg [85], $CdCl_2$/Cd [86], and $BiCl_3$/Bi [87]. These systems exhibit no electronic conduction, and the specific conductivity decreases on addition of the metal. Mercury dissolves in molten mercury(II) chloride to form $Hg^{2+}(e^-)_2\ Hg^{2+}$. Similar species, presumably trimeric and tetrameric Bi_3^{3+} and Bi_4^{4+}, are formed by bismuth in bismuth trichloride.

Investigations on quenched melts can only rarely yield informations about the conditions in the liquid phase [88]. In the case of cadmium, it was assumed that the metal forms solvated complexes such as $Cd{\cdot}nCdCl_2$ with adjacent cadmium chloride molecules [89]; however, it is impossible to differentiate between these complexes and subhalides. Since the solutions are diamagnetic, the existence of Cd^+ ions (or CdCl) can be ruled out [90]. More recent investigations have shown that dimers such as Cd_2^{2+} are also present in the system $Cd/CdCl_2$. By the use of suitable anions, it was possible to stabilize the cadmium(I) oxidation state, and to isolate $Cd_2(AlCl_4)_2$ as a stable compound [91].

The solubilities of metals in their salts are in some cases greatly reduced by the addition of salts of other metals. This is of advantage in the technical use of molten salts as extractants and in the electrolytic production of metals. Table 3 shows the effects of monovalent, divalent, and trivalent foreign cations on the solubility of bismuth [92] and cadmium [93]. The decrease in the solubility of the metal is inversely proportional to the ratio of the number of anions to the number of cations of the foreign salt and directly proportional to the electropositive

Table 3. The decrease in the solubilities of bismuth and cadmium in melts of their salts, on addition of foreign ions.

Melt	Bi Solubility [mole-%]	Melt	Cd Solubility [mole-%]
$BiCl_3$	45	$CdCl_2$	15
$BiCl_3{\cdot}NaCl$	10	$CdCl_2{\cdot}KCl$	1
$BiCl_3{\cdot}CaCl_2$	30	$CdCl_2{\cdot}CaCl_2$	4
$BiCl_3{\cdot}CuCl$	33	$CdCl_2{\cdot}CeCl_3$	10
$BiCl_3{\cdot}ZnCl_2$	34	$CdCl_2{\cdot}ZnCl_2$	6
		$CdCl_2{\cdot}MgCl_2$	10
		$CdCl_2{\cdot}MnCl_2$	12

character of the foreign cation. It is assumed that the energy levels of the quasi-lattice of the melt are raised by the foreign cation, so that the metal to be dissolved can no longer give up its valence electrons so easily to the energy bands of the whole system, *i.e.* i.s solubility is reduced [93].

IV. Electrochemical Preparation of Compounds [*]

For a long time electrochemistry in fused salts referred exclusively to the electrometallurgical production of the elements. Although development in this field is by no means complete (cf. for example, the electrolytic production of titanium and other metals, *e.g.* niobium, tantalum, uranium, thorium, zirconium, beryllium, and boron, which are used in the construction of reactors and rockets) we shall be more concerned in the present paper with the preparation of compounds by the reaction of electrolytic products (for example with the electrode material).

The cathodic formation of calcium carbide in fused salts is achieved by the reaction of calcium with a porous carbon electrode or by electrolysis of dissolved calcium carbonate as a source of carbon [94]. Sodium carbide can be prepared in a similar manner at 450 to 800 °C in the presence of active charcoal [95]:

$$2\ NaCl + 2\ C \rightarrow Na_2C_2 + Cl_2 \quad (3)$$

The carbides dissolve readily in fused salts [65] and can react further in these media (cf. Section V).

Fluorocarbons, in particular CF_4, C_2F_6, and small quantities of higher homologues [96], can be prepared on an industrial scale by electrolysis of oxide-free mixtures of alkali metal fluorides, alkaline earth fluorides, or aluminum fluoride at about 600 to 1000 °C, using an anode consisting of fine carbon particles bonded with pitch. The proportion of hexafluoroethane in the product can be increased to 70% if the current density at the anode is not too high and the electrolysis is carried out at 750 to 850 °C [97]; at about 1200 °C only tetrafluoromethane

is formed [98]. Chlorofluorocarbons or bromofluorocarbons are obtained if chlorides or bromides are added to the melt [99], or if the anode is flushed with chlorine or bromine during electrolysis [100]. The reaction is very unspecific, however, and leads to a large number of perhalogenofluorocarbons. Partially fluorinated products are obtained, on the other hand, if hydrocarbons (acetylene) or halogenocarbons [101], possibly mixed with an inert gas, are blown through the porous anode. Alkali metals simultaneously separate out at solid cathodes (Ni). When lead, tin, aluminum, or calcium are used as liquid cathodes, the corresponding alloys with the alkali or alkaline earth metals are formed in yields of up to 96%, calculated on the cathode current [102].

If alkali metal pseudo-halides, in particular cyanides or thiocyanates, are added to the molten fluorides, nitriles of fluorocarbons, *e.g.* CF_3CN, are obtained together with perfluorocarbons [103]. Similar products are formed if gaseous cyano compounds, *e.g.* cyanogen, cyanogen chloride, hydrogen cyanide, *etc.*, are passed into molten fluorides with simultaneous electrolysis [104]. This process may be referred to as high-temperature electrofluorination.

When inert electrodes are used, the electrolytic products can be reacted with substances which are introduced into the melt. For example, when sodium is deposited electrolytically from a sodium hydroxide/potassium hydroxide melt, and the cathode is simultaneously flushed with ammonia, sodamide forms instantaneously at the cathode. The NH_2^- ions migrate to the anode, where they are probably discharged to form hydrazine, which immediately decomposes into ammonia and nitrogen. No hydrogen can be detected [43]. Traces of hydrazine were detected and the decomposition reaction was confirmed by electrolysis experiments using high-purity graphite electrodes and high-purity alkali metal amides [105]. Elements which form nitrides can react at a cathode flushed with nitrogen. Lithium nitride thus formed during the electrolysis of a mixture of lithium chloride and potassium chloride goes into solution (cf. Section III) and leaves the surface of the lithium free to react further. In general, reactions in fused salts proceed more rapidly and more completely than the reactions of the elements alone.

The importance of a clean metal surface becomes clear in the formation of hydrides from alkali metals and hydrogen. The reaction proceeds to completion only in the presence of a fused salt as the solvent, *e.g.* in the electrolysis of NaOH/KOH using an iron cathode flushed with hydrogen [43]. Instead of the usual graphite or metal anodes, liquid sodium amalgam anodes can also be used as a source of the sodium [106]. Solutions of alkali metal or alkaline earth hydrides in fused salts can be used for hydrogenations (cf. Section V), and it was by electrolysis of these systems and of pure fused lithium hydride, that the complete dissociation of the salt-like hydrides and the anodic liberation of hydrogen in quantitative current yield was proved [107]. Here a liquid aluminum cathode was used to intercept the lithium, after earlier attempts had failed owing to the high solubility of lithium in lithium hydride and owing to the recombination of the metal with the hydrogen.

An example of an electrochemical process in which the product separates at the anode is the electrolysis of alkali metal borohydrides, in particular $NaBH_4$, in fused salts. The alkali metal is removed as an amalgam, and diborane is obtained in good yield, together with a little pentaborane, at the inert anode [108].

Electrochemical reactions can also be used as stages in continuous or discontinuous cyclic preparative processes, generally to regenerate the initial state.

V. Chemical Reactions in Fused Salts

Chemical reactions in fused salts can be divided into three types:

1. Reactions involving participation of the melt and consumption of one or more of its components, with no simple means of regenerating the latter.

2. Reactions in which the melt simply acts as a solvent for the reactants, or in which the components of the melt are formed as by-products, or in which the by-products can be chemically or electrochemically reconverted into the starting compounds.

3. Reactions in which the melt acts as a catalyst (cf. Section VI).

In all these reactions it is naturally desirable to remove the products from the melt by evaporation, to decant them in the liquid form from two-phase systems, or to deposit them electrochemically. Products which remain suspended in the melt can if necessary be isolated with the aid of a high-temperature centrifuge [109], otherwise they can only be isolated by extraction from the cooled melt.

A. Digestion

Reactions in fused salts are familiar even to the chemistry student. Thus basic oxides such as Fe_2O_3, Al_2O_3, TiO_2, and $FeO{\cdot}Cr_2O_3$ are digested with acidic melts such as pyrosulfates or borates. Similarly, acidic oxides, such as SiO_2, and silicates dissolve readily in strongly basic melts such as sodium and potassium carbonates, sodium hydroxide or oxide, and mixtures of these. Samples containing elements which can form thio-salts can be digested with sodium polysulfide, which is also formed in

[108] *W. H. Schlechter*, U.S.-Pat. 3033766 (May 8th, 1962).

[109] *L. J. Wittenberg*, J. Amer. ceram. Soc. *42*, 209 (1959).

melts of sodium carbonate with sulfur (Freiberg digestion).

In alkali metal hydroxide melts, the presence of oxygen and water vapor leads to the formation of peroxides [110], towards which neither the noble metals nor most ceramic materials (with the exception of thorium oxide) are resistant [111]. Melts of this type have long been known as oxygen carriers. They make possible oxidations using air, *e.g.* the oxidation of dissolved manganese oxides [112] which leads to potassium manganate(V) at 240 to 300 °C, or to potassium manganate(VI) which precipitates out and can be filtered off [113].

$$2\ MnO_2 + 6\ KOH + {}^1/_2\ O_2 \rightarrow 2\ K_3MnO_4 + 3\ H_2O \quad (4)$$

$$2\ K_3MnO_4 + {}^1/_2\ O_2 + H_2O \rightarrow 2\ K_2MnO_4 + 2\ KOH \quad (5)$$

From investigations on the oxidation states of manganese in fused alkali metal nitrates it was found that the addition of hydroxide promotes the formation of manganate(V), whereas only manganate(VI) is formed in the presence of peroxide [114].

If, instead of oxygen, ozone is used as the oxidizing agent in an alkali metal nitrate melt containing Np salts at 150 °C, hexavalent neptunium is formed (detected by spectroscopy) [115], and neptunium(VI) oxide can be isolated [116].

Typical reactions involving participation of the melt are the preparations of alkali metal and alkaline earth titanates from hydroxides or carbonates and titanium dioxide [116a], and of chloro- and bromoapatites from alkaline earth phosphates, arsenates, and vanadates in fused alkali metal halides [117]. While metaphosphates react with fluoride ions with cleavage of the P–O–P chain

$$(PO_3^-)_n + n\ F^- \rightarrow n\ PO_3F^{2-} \quad (6)$$

and with hexafluorophosphates to form difluorophosphates

$$2\ (PO_3^-)_n + n\ PF_6^- \rightarrow 3\ n\ PO_2F_2^- \quad (7)$$

the analogous reaction with chloride ions cannot be carried out [118]. Finally, various silver silicates can be prepared in molten silver nitrate by cation exchange

$$3\ \beta\text{-}Na_2Si_2O_5 + 6\ AgNO_3 \rightarrow Ag_4SiO_4 + Ag_2SiO_3 + 4\ SiO_2 + 6\ NaNO_3 \quad (8)$$

With the exception of α-$Na_2Si_2O_5$, all silicates with layer structures undergo this reaction [119].

B. Acid-Base Reactions

The study of acid-base reactions and their kinetics in fused nitrates is of particular interest. The nitrate ion is slightly dissociated:

$$NO_3^- \rightleftharpoons NO_2^+ + O^{2-} \quad (9)$$

A relatively high concentration of nitryl ions is obtained by interception of the oxide with salts of strong acids, *e.g.* the readily soluble dichromates [120] or pyrosulfates [121]:

$$S_2O_7^{2-} + NO_3^- \rightleftharpoons NO_2^+ + 2\ SO_4^{2-} \quad (10)$$
$$Cr_2O_7^{2-} + NO_3^- \rightleftharpoons NO_2^+ + 2\ CrO_4^{2-}$$

The nitryl ions react further with nitrate ions or with added bromide ions:

$$NO_2^+ + NO_3^- \rightarrow 2\ NO_2 + {}^1/_2\ O_2 \quad (11)$$
$$NO_2^+ + Br^- \rightarrow NO_2 + {}^1/_2\ Br_2$$

Investigations have also been carried out on the reaction of bromates in the presence of divalent cobalt, copper, nickel, and zinc cations to form the corresponding metal oxides [122]:

$$6\ M^{2+} + 12\ BrO_3^- \rightarrow 6\ Br_2 + 15\ O_2 + 6\ MO \quad (12)$$

Bromates decompose in the presence of bromide ions [123]:

$$BrO_3^- + Br^- \rightarrow BrO_2^- + BrO^- \text{ (slow)}$$
$$BrO^- + BrO_3^- \rightarrow 2\ BrO_2^- \text{ (fast)} \quad (13)$$
$$BrO_2^- \rightarrow Br^- + O_2 \text{ (fast)}$$

Perchlorates decompose in a similar manner in fused sodium hydroxide; this reaction is accelerated by binding the oxygen as peroxide [124].

C. Halogenations

Molten salts are in many respects particularly suitable as solvents for halogenations. Apart from their stability towards hydrogen halides or halogens, they dissolve these substances as well as the reaction products which otherwise cover the surface. Thus the reaction of spent uranium-zirconium fuel elements with hydrogen fluoride to form the tetrafluorides of the two metals proceeds satisfactorily only in fluoride melts [9, 125]. If fluorine or chlorine trifluoride is passed into the melt, the UF_4 reacts further to form UF_6, which separates from the melt and, after repeated adsorption and desorption on sodium fluoride, can be led directly to the isotope separator. Zirconium and more than 99% of the fission products remain in the melt.

[121] *F. R. Duke* and *S. Yamamoto,* J. Amer. chem. Soc. *81,* 6378 (1959).

[122] *F. R. Duke* and *W. W. Lawrence,* J. Amer. chem. Soc. *83,* 1269 (1961).

[123] *F. R. Duke* and *E. A. Shute,* J. physic. Chem. *66,* 2114 (1962).

[124] *R. P. Seward* and *H. W. Otto,* J. physic. Chem. *65,* 2078 (1961).

[125] *R. P. Milford,* Ind. Engng. Chem. *50,* 187 (1957).

To avoid corrosion, chlorine was used in the lower-melting chloride systems. Here, uranium trichloride and zirconium tetrachloride are formed; the latter is evaporated, while all of the uranium remains in the melt and is extracted by electrolysis. Its separation from fission products is more difficult in this case (cf. Section IV), since *e.g.* plutonium is also present in the melt as K_2PuCl_6, *i.e.* in the less common tetravalent state [126].

Valence states which are otherwise difficult to obtain, *e.g.* of titanium and other transition elements, can be stabilized in a melt. In a solution of titanium metal in molten titanium halides more than 90% of the titanium is present in the divalent state, as the complex K_2TiCl_4 [127]. A particularly elegant method of preparing halides of divalent titanium [128], iron, and chromium [129] makes use of the fact that the products of chlorination are obtained in the molten state and that compounds of higher valence states are reduced by excess metal.

As in the case of uranium, the use of fused salts is advantageous when, in the chlorination of an alloy, large quantities of other volatile chlorination products are formed, which would otherwise block the reaction vessel. For example, in the preparation of silicon tetrachloride from ferrosilicon or from the silicon/copper mixture remaining from the Rochow synthesis of organochlorosilanes, a smooth and complete reaction is inhibited by the iron and copper chlorides formed. Addition of alkali metal chlorides gives a melt of non-volatile complexes in which the reaction proceeds to completion, the heavy metal chlorides formed in various valence states acting as chlorine carriers [43]. The resulting silicon tetrachloride is very pure. Fused salts can also be used as washing liquids for the separation of volatile halides which differ in their tendencies towards complex formation, *e.g.* for the absorption of iron or aluminum chloride from niobium pentachloride [130] or zirconium tetrachloride [131] vapors.

Volatile chlorides can be prepared directly from oxides by chlorination under reducing conditions. The oxides are generally dissolved or suspended in the presence of finely divided carbon, or carbon monoxide is simultaneously led into the melt to act as a reducing agent. Boron trichloride is prepared in a eutectic mixture of sodium, calcium, and barium chlorides in which 10 to 15% by weight of boron trioxide are dissolved [132]:

$$B_2O_3 + 3\,C + 3\,Cl_2 \rightarrow 2\,BCl_3 + 3\,CO \qquad (14)$$

The best yields are obtained at 800 °C. Carbon tetrachloride can also be used for this reaction [43]. Silicon tetrachloride is prepared directly from silicon dioxide by a similar method, while beryllium and thorium oxides react with carbon and chlorine to form complex chlorides which are soluble in the melt. The metals are then extracted by electrolysis [134].

It is also possible to obtain 97% of the titanium from ilmenite in the form of the volatile titanium tetrachloride by reductive chlorination in the melt at 500 °C, while the greater part of the iron remains bound as $NaFeCl_4$. With columbite the result is similar: iron and all of the uranium remain in the melt, while 90% of the niobium and tantalum are obtained as the volatile chlorides [135]. Elegant reductive chlorinations are achieved in fused alkali metal or alkaline earth chlorides by the use of anodes of the appropriate oxides and carbon [136].

Halogenations in fused salts can also be carried out by halogen transfer, *e.g.* between a halide and an element. Thus, halides of boron, aluminum, and silicon are produced by reaction of the element with silver or copper halides [137, 138]:

$$\begin{aligned} B(Al) + 3\,AgX &\rightarrow BX_3\,(AlX_3) + 3\,Ag \\ Si + 4\,CuX &\rightarrow SiX_4 + 4\,Cu \qquad X = Cl, Br, I \end{aligned} \qquad (15)$$

This procedure is particularly useful for the preparation of radioactive compounds. Although the reaction begins when the solid components are heated, the conversion in many cases becomes appreciable only when the temperature reaches the melting point of the halide. An example is the formation of boron trichloride using CuCl.

For compounds which are thermally stable, halogen exchange reactions in molten fluorides [139] offer advantages over the conventional methods of fluorination using fluorides of the transition elements (Ag, Hg, Cd, Co), which are difficult to obtain, or suspensions of solid fluorides. Chlorine compounds of sulfur, carbon, silicon, and phosphorus react between 300 and 550 °C in a LiF/NaF/KF melt or in the $ZnCl_2$/KCl eutectic containing potassium or calcium fluoride to give the fluorides, sometimes in good yields, *e.g.*

$$\begin{aligned} SO_2Cl_2(SOCl_2, COCl_2) + 2\,NaF &\rightarrow \\ SO_2F_2(SOF_2, COF_2) + 2\,NaCl & \\ CCl_4 + x\,NaF &\rightarrow CF_xCl_{4-x} + x\,NaCl \end{aligned} \qquad (16)$$

Carbonyl fluoride and sulfuryl fluoride (the latter free from thionyl fluoride) can be readily prepared by this method, without the use of elementary fluorine which is otherwise necessary. The alkali metal chlorides formed as by-products depress the melting point of the reaction medium. This halogen exchange was also used to prepare thiocarbonyl fluoride [140] in such quantities that it was possible to determine the physical properties of the colorless gas, record its spectra, determine its structure by

electron diffraction [141], and to study its chemical behavior.

$$CSCl_2 + 2\,NaF \rightarrow CSF_2 + 2\,NaCl \quad (17)$$

Attention should be drawn to the reactions with chlorine and bromine yielding the difluorohalogenomethanesulfenyl halides, $F_2XC-S-X$, and to the possible industrial importance of the polymerization of CSF_2 to elastomeric products.

D. Halogen-Pseudohalogen Exchange

Exchange of halogen for pseudohalogen in solutions of alkali metal pseudohalides in fused salts leads to cyanides, cyanates, and thiocyanates of silicon and carbon [*] [142].

$$\begin{aligned} (CH_3)_3SiCl + KCN &\rightarrow (CH_3)_3SiCN + KCl \\ (CH_3)_2SiCl_2 + 2\,KOCN &\rightarrow (CH_3)_2Si(NCO)_2 + 2\,KCl \\ SiCl_4 + 4\,KSCN &\rightarrow Si(NCS)_4 + 4\,KCl \end{aligned} \quad (18)$$

The entire series of cyanates and thiocyanates $(CH_3)_xSiX_{4-x}$ (X = NCO, NCS) have been obtained, in some cases in very good yield. Advantages of this method are: (a) the starting materials are the more readily available alkali metal pseudohalides instead of the silver salts used in other methods; (b) the alkali metal pseudohalides are more readily soluble in melts than the potassium or silver salts are in organic solvents, and hence the reaction proceeds in the homogeneous phase. The corresponding reactions with halogenated hydrocarbons yield acetonitrile and ethyl thiocyanate:

$$\begin{aligned} CH_3Cl + KCN &\rightarrow CH_3CN + KCl \\ C_2H_5Cl + KSCN &\rightarrow C_2H_5SCN + KCl \end{aligned} \quad (19)$$

This is in contrast to the reaction with silver or copper cyanide, in which methyl isonitrile (CH_3CN) is formed. It was therefore assumed that the silicon pseudohalides of Equation (18), which were formerly regarded as isocompounds, contain the same anion as the alkali metal pseudohalides from which they are formed. This assumption has been confirmed in the case of trimethylcyanosilane [143]. The same method was used for the preparation of methylazidosilanes by reacting the corresponding methylchlorosilanes with a 1.0 to 20% suspension (or to some extent solution) of sodium azide in a $ZnCl_2$/KCl melt at 250 °C [144]:

$$(CH_3)_xSiCl_{4-x} + x\,NaN_3 \rightarrow (CH_3)_xSi(N_3)_{4-x} + x\,NaCl \quad (20)$$
$$x = 1, 2, 3$$

Phenylazidosilanes and (for the first time) mixed halogenated-pseudohalogenated silanes have also become available *via* trimethylazidosilane by exchange reactions.

Metal pseudohalides are obtainable in valence states which are difficult to achieve by other methods. Thus potassium tetracyanonickelate(0) can be prepared in accordance with Equation (21) in fused cyanide, as can

$$K_2Ni(CN)_4 + 2\,KCN \rightarrow K_4Ni(CN)_4 + (CN)_2 \quad (21)$$

potassium tetracyanonickelate(I) by reduction of tetracyanonickelate(II) with metallic nickel in the melt [145]. Similarly, cyanomanganates, cyanomolybdates, and cyanopalladates in various oxidation states are obtainable in fused salts by reduction with cyanide ions [146].

The industrial preparation of sodium cyanide illustrates how important the fused state can be for a good conversion. The reaction of sodium with ammonia in the presence of wood charcoal at 700 to 900 °C proceeds particularly smoothly if sodium cyanide has already been formed or has been added in advance. Sodium cyanide is a good solvent or suspending medium for all intermediates of the reaction which presumably proceeds in the following steps:

$$\begin{aligned} 2\,NH_3 + 2\,Na &\rightarrow 2\,NaNH_2 + H_2 \\ 2\,NaNH_2 + C &\rightarrow Na_2N_2C + 2\,H_2 \\ Na_2N_2C + C &\rightarrow 2\,NaCN \end{aligned} \quad (22)$$

A similar method is used for the preparation of calcium cyanide from calcium cyanamide, and of potassium cyanide by anion exchange between sodium cyanide and potassium chloride in the melt [147]. Alkali metal cyanates are prepared analogously. For example, sodium cyanate is obtained in 71 % yield at 530 °C by the reaction

$$CaCN_2 + Na_2CO_3 + CO_2 \rightarrow 2\,NaOCN + CaCO_3 \quad (23)$$

Potassium cyanide, either fused or dissolved in molten alkali metal halides, reacts quantitatively with oxygen at 400 °C to give potassium cyanate [43], while the reaction with chlorine yields cyanogen:

$$2\,KCN + Cl_2 \rightarrow (CN)_2 + 2\,KCl \quad (24)$$

Owing to the high temperature, however, the latter is 40% polymerized to paracyanogen. The assumption that cyanogen chloride occurs as an intermediate in Reaction (24) has been confirmed both by the reaction of cyanogen chloride with potassium cyanide in the melt

$$KCN + CNCl \rightarrow (CN)_2 + KCl \quad (25)$$

and by the almost exclusive formation of cyanogen chloride in the reaction of the cyanide with excess chlorine [43].

$$KCN + Cl_2 \rightarrow CNCl_2 + KCl \quad (26)$$

E. Preparation of Amides, Nitrides, Carbides, and Sulfides

The melt appears to have a catalytic effect in the preparation of alkali metal and alkaline earth amides from the metals and ammonia in molten alkali metal hydroxides

[141] This work was kindly carried out by Prof. *E. Rogowski*, Physikalisch-Technische Bundesanstalt Braunschweig (Germany).

[*] Unconvincing structural investigations of the silicon compounds of Eq. (18) were interpreted to indicate that these are isocyanates and isothiocyanates.

[142] *W. Sundermeyer*, Z. anorg. allg. Chem. *313*, 290 (1961).

[144] *W. Sundermeyer*, Chem. Ber. *96*, 1293 (1963).

[145] *S. von Winbush, E. Griswold*, and *J. Kleinberg*, J. Amer. chem. Soc. *83*, 3197 (1961).

[146] *W. L. Magnuson, E. Griswold*, and *J. Kleinberg*, Inorg. Chem. *3*, 88 (1964).

[147] Ullmanns Encyklopädie der technischen Chemie. 3rd.Edit., Urban & Schwarzenberg, München 1954, Vol. 5, p. 648.

at 300 to 400 °C. In the industrial preparation of sodamide, the product serves as the solvent (as in the production of sodium cyanide) [148]. Boron nitride, which is stable at high temperatures, can be synthesized in an almost eutectic melt of sodium hydroxide and sodamide [149]:

$$B_2O_3 + 3\ NaNH_2 \rightarrow 2\ BN + NH_3 + 3\ NaOH \quad (27)$$

When prepared from boron trioxide and ammonia in the NaCl/KCl eutectic at 850 to 950 °C, the boron nitride floats on the surface of the melt, and can be isolated without wasting the melt by dissolving it in water [150]. As for nitrides, fused salts appear to be the only solvents suitable for the production of carbides. Reaction

$$MgCl_2 + CaC_2 \rightarrow MgC_2 + CaCl_2 \quad (28)$$

(28) again proceeds only upon liquefaction of the powdered mixture. The MgC_2 decomposes further into carbon and Mg_2C_3, which is only stable below 600 °C [151]. Thus, to obtain Mg_2C_3, hydrolysis of which yields mainly propyne [152], sodium chloride is added to the melt. Solutions of calcium carbide in alkali metal and alkaline earth halides can be used for the synthesis of titanium

$$TiO_2 + CaC_2 \rightarrow TiC + CaO + CO \quad (29)$$

carbide [153] and for the reduction of oxides and sulfides of high-melting metals (Cr, Ti, Zr) [154]. An interesting reaction takes place between calcium or aluminum carbide and alkali metal or alkaline earth fluorides in the presence of chlorine [155]:

$$CaC_2 + 2\ x\ NaF + 5\ Cl_2 \rightarrow 2\ F_xCCl_{4-x} + CaCl_2 + 2\ x\ NaCl \quad (30)$$

It appears to offer a new route to the perhalogenated fluorochloromethanes.

The high solubility of the alkali metal and alkaline earth sulfides in fused salts permits the preparation of many sulfides of transition elements, which are generally sparingly soluble and separate out in a highly crystalline form. Sulfide ions are oxidized to elementary sulfur by oxidizing agents such as Cu^{2+}, Fe^{3+}, Hg^{2+}, and iodine [62]:

$$4\ S^{2-} + 4\ Cu^{2+} \rightarrow 2\ Cu_2S + S_2 \quad (31)$$

In the resulting blue solution the sulfur is probably present in the diatomic form, and can be titrated to decolorization with a solution of potassium cyanide in the same

$$S + KCN \rightarrow KSCN \quad (32)$$

melt, as has been demonstrated for solutions of polysulfides in potassium thiocyanate [156]. Solutions containing sulfides can be used *e.g.* for the preparation of carbon oxide sulfide from phosgene

$$COCl_2 + K_2S \rightarrow COS + 2\ KCl \quad (33)$$

and for the preparation of bis(trimethylsilyl) sulfide from trimethylchlorosilane [157]:

$$2\ (CH_3)_3SiCl + K_2S \rightarrow (CH_3)_3Si{-}S{-}Si(CH_3)_3 + 2\ KCl \quad (34)$$

F. Hydrogenations

An example which illustrates the advantages of chemical reactions in ionic liquids is the synthesis of silicon- and boron hydrides [158]. It had formerly been necessary to use the expensive complex hydrides of aluminum and boron, since no solvents could be found for the reaction of the salt-like hydrides of the alkali metals and of the alkaline earths. However, these dissolve in fused salts, *e.g.* in a LiCl/KCl melt at 400 °C (cf. Section III). If silicon- or boron halides are passed through such a melt containing an alkali metal hydride, halogen-hydrogen interchange takes place:

$$4\ LiH + SiCl_4 \rightarrow SiH_4 + 4\ LiCl \quad (35)$$

If an electrolysis is carried out in the same melt using a cathode flushed with hydrogen, new lithium hydride is continuously formed. The overall equation of the reaction sequence (which would proceed explosively in the reverse direction) then is:

$$SiCl_4 + 2\ H_2 \rightarrow SiH_4 + 2\ Cl_2 \quad (36)$$

The chlorine which is produced electrolytically can be used again for the preparation of silicon tetrachloride. The suggestion [159] to carry out the reaction with a silicon or boron anode appears to be impracticable, since very pure anode materials would be needed. A similar process described can be used for the preparation of diborane and for the hydrogenation of partially alkylated silanes. Thus dimethylsilane, an important starting material for the preparation of dimethylchlorosilane, can be obtained from dimethyldichlorosilane.

It proved impossible to carry out the reaction continuously or discontinuously in one reaction vessel on the industrial scale [158, 160]; however, an apparatus consisting essentially of a three-branched tube [158] could be developed into an industrial plant which is used today [161] (see Fig. 2).

The lithium, which is electrolysed in a conventional cell at 400 °C, flows into the hydrogenation unit, which operates at about 600 °C to obtain a faster reaction. To suppress the thermal decomposition of the silicon- or boron hydride, the

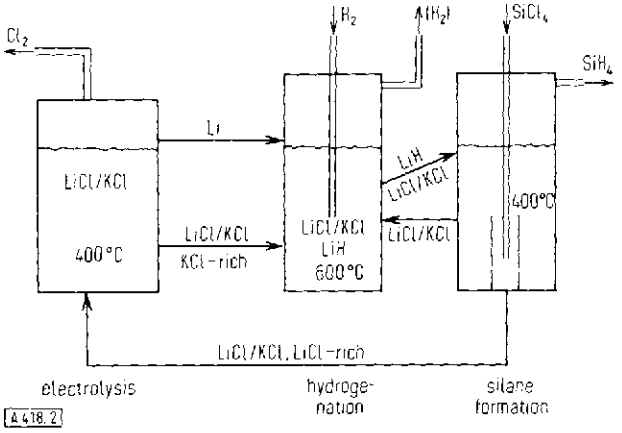

Fig. 2. Schematic representation of the silane synthesis of *Sundermeyer*.

third unit, *i.e.* the silane unit, again operates only at 400 °C. This has the further advantage that the solution containing the alkali metal hydride can be transported to the third stage simply by convection. The melt in which the lithium chloride has accumulated is recycled to the electrolysis unit. The process has been in use for several years in an unattended experimental plant [161], with more than 90 per cent conversion and almost quantitative yield [162]. Since the decomposition of trichlorosilane reaches an equilibrium and since monosilane can be easily purified and decomposed to yield silicon, this method is advantageous for the preparation of very pure silicon.

By a coincidence, the new process originated in the same laboratory from which *Friedrich Wöhler* reported the first preparation of monosilane exactly 100 years earlier [158, 163]. *Wöhler* also decomposed the silane by heat to obtain silicon, a sample of which is still held in the institute's collection in a tube labeled in *Wöhler*'s own handwriting (see Fig. 3).

Owing to the technical importance of the silanes and boranes, other methods are available for their preparation in fused salts. Whereas only traces of monosilane are obtained when silicon tetrachloride is reduced with hydrogen in the presence of aluminum in a $NaCl/AlCl_3$ melt at normal pressure [43], a conversion of 84% is

$$3\ SiCl_4 + 4\ Al + 6\ H_2 \rightarrow 3\ SiH_4 + 4\ AlCl_3 \quad (37)$$

achieved at 750 atm. Silicon dioxide can also be reduced in a vibrating autoclave at high pressures [164]:

$$3\ SiO_2 + 4\ Al + 2\ AlCl_3 + 6\ H_2 \rightarrow 3\ SiH_4 + 6\ (AlOCl) \quad (38)$$

Boron trioxide or borates undergo a similar reaction to yield diborane [165], which can also be prepared by the reaction of alkali metal borohydrides with Lewis acids, *e.g.* with hydrogen chloride, or better, boron halides in alkali metal chloride/aluminum chloride or alkali metal chloride/zinc chloride systems [166]:

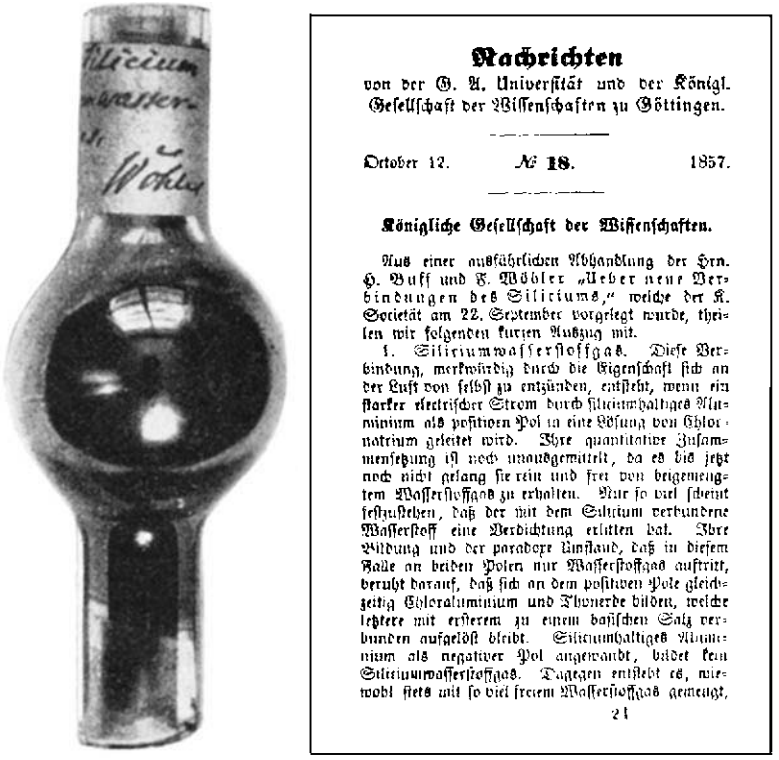
$$3\ NaBH_4 + BCl_3 \rightarrow 2\ B_2H_6 + 3\ NaCl \quad (39)$$

In another reaction the starting materials are the alkali metal borohydride and tin(II) chloride [167]. While diborane and hydrogen escape the melt without decomposing, the tin separates as a liquid:

$$2\ NaBH_4 + SnCl_2 \rightarrow Sn + 2\ NaCl + B_2H_6 + H_2 \quad (40)$$

Finally, some methods should be mentioned which proceed satisfactorily only in the melt and in which the end-product itself provides the melt. Lithium perchlorate, which is used as an oxidizing agent in rocket technology, is prepared according to Equation (41) and is then decanted in the

$$Li_2CO_3 + 2\ NH_4ClO_4 \rightarrow 2\ LiClO_4 + 2\ NH_3 + CO_2 + H_2O \quad (41)$$



Nachrichten

von der G. A. Universität und der Königl. Gesellschaft der Wissenschaften zu Göttingen.

October 12. № 18. 1857.

Königliche Gesellschaft der Wissenschaften.

Aus einer ausführlichen Abhandlung der Hrn. H. Buff und F. Wöhler „Ueber neue Verbindungen des Siliciums," welche der K. Societät am 22. September vorgelegt wurde, theilen wir folgenden kurzen Auszug mit.

1. Siliciumwasserstoffgas. Diese Verbindung, merkwürdig durch die Eigenschaft sich an der Luft von selbst zu entzünden, entsteht, wenn ein starker electrischer Strom durch siliciumhaltiges Aluminium als positiven Pol in eine Lösung von Chlornatrium geleitet wird. Ihre quantitative Zusammensetzung ist noch unausgemittelt, da es bis jetzt noch nicht gelang sie rein und frei von beigemengtem Wasserstoffgas zu erhalten. Nur so viel scheint festzustehen, daß der mit dem Silicium verbundene Wasserstoff eine Verdichtung erlitten hat. Ihre Bildung und der paradoxe Umstand, daß in diesem Falle an beiden Polen nur Wasserstoffgas auftritt, beruht darauf, daß sich an dem positiven Pole gleichzeitig Chloraluminium und Thonerde bilden, welche letztere mit ersterem zu einem basischen Salz verbunden aufgelöst bleibt. Siliciumhaltiges Aluminium als negativer Pol angewandt, bildet kein Siliciumwasserstoffgas. Dagegen entsteht es, mögleich stets mit so viel freiem Wasserstoffgas gemengt,

21

Fig. 3. Silicon obtained by *Wöhler* in 1857 by thermal decomposition of silane.

[162] Monosilane can now be produced at one third of the former cost. The present experimental plant could supply the entire U.S. market for high-purity silicon.

molten state [168]. Lithium nitrate can be prepared in a similar manner from ammonium nitrate [169]. Ammonium beryllium fluoride is decomposed to form beryllium fluoride by introducing it into molten beryllium fluoride at 900 °C [170]:

$$(NH_4)_2BeF_4 \rightarrow BeF_2 + 2\ NH_4F \quad (42)$$

G. Reactions in Suspensions of Metals

Relatively little is known about reactions with suspensions or solutions of metals in fused salts. A number of quaternary systems, consisting of two metals and their halides, and their equilibria in alkali metal chloride melts have been investigated. These equilibria are often strongly displaced towards the "right", *e.g.* in the violent reaction (43) of zinc with various metal chlorides. Spectroscopically pure lead or cadmium separate out [171]. Lead is also displaced from lead chloride by cadmium.

$$PbCl_2 + Zn \rightarrow Pb + ZnCl_2 \quad (43)$$
$$CdCl_2 + Zn \rightarrow Cd + ZnCl_2$$

The reaction of mercury(II) chloride with zinc begins with a spontaneous rise in temperature of the powder and becomes explosive at the melting point. The same is reported for the reaction of aluminum with zinc chloride [172]. The reactions of tin(II) chloride with zinc [173] and of tin(IV) chloride with aluminum [43] also proceed vigorously in fused salts, with separation of metallic tin.

The fact that the reactions often proceed to completion is generally due to the removal of one component as a separate liquid phase or as a vapor. For example, when calcium is added to a lithium chloride/potassium chloride melt, alkali metals distil off [43]. These can also be liberated from alkali metal fluorides by magnesium and calcium [174], and by uranium, zirconium, and yttrium.

The reduction with metals is used industrially in the production of titanium. Titanium tetrachloride is blown into melts of alkali metal chlorides or alkaline earth chlorides containing sodium [175] or lithium [176]. The titanium is obtained as a fine powder or as a sponge. If the reaction is carried out with magnesium, the product is a magnesium-titanium alloy, which is subsequently separated into its components above 750 °C [177]. Niobium and tantalum are obtained in a similar manner from the double fluorides, using sodium [178].

$$K_2TaF_7 + 5\ Na \rightarrow 2\ KF + 5\ NaF + Ta \quad (44)$$

Uranium [179] and zirconium are displaced from their chlorides by aluminum. If the zirconium is only partially reduced, it can be separated from the unreacted hafnium tetrachloride [180].

The "subchloride process" for the electrothermal production of aluminum is likely to achieve great technical importance [181]. It involves the endothermic reaction of aluminum with gaseous aluminum chloride, or a sodium chloride/aluminum chloride melt, to form aluminum subchloride. At 1200 °C, the equilibrium lies 98 % to the right [182].

$$2\ Al + AlCl_3 \rightleftharpoons 3\ AlCl \quad (45)$$

If the subchloride vapor is brought into contact with liquid aluminum or with the above melt in a separate reaction vessel at 700 °C, the reaction is reversed and pure aluminum separates out. A particular advantage of this process is that the subchloride can also be produced from compounds with a high aluminum content or from alloys formed *e.g.* by reduction of bauxite with coke [183] or by direct electrolysis of bauxite in a cryolite melt, thus avoiding the Bayer digestion process. A very large quantity of the aluminum can be extracted from an alloy in this manner, before appreciable quantities of other metals are entrained, since AlCl reacts with foreign metal chlorides as shown in Equation (46) [184].

$$MnCl_2 + AlCl \rightarrow Mn + AlCl_3 \quad (46)$$

Whereas the reaction (47) of aluminum oxide with carbon and aluminum chloride in a sodium chloride/aluminum

$$Al_2O_3 + AlCl_3 + 3\ C \rightarrow 3\ AlCl + 3\ CO \quad (47)$$

chloride melt, with subsequent separation of aluminum is difficult to carry out, aluminum oxide can be reacted with phosgene in an alkali metal chloride/aluminum chloride melt at lower temperatures (550 to 900 °C):

$$Al_2O_3 + 3\ COCl_2 \rightarrow 2\ AlCl_3 + 3\ CO_2 \quad (48)$$

The aluminum chloride formed sublimes out of the melt. This reaction is best carried out in a fluidized bed [185] and is a first example of a reaction catalysed by fused salts.

VI. Fused Salts as Catalysts

In many respects, fused electrolytes are particularly suitable media also for organic reactions. Owing to the high thermal conductivity, the heat of reaction is rapidly dissipated, whereas local overheating and consequent autocatalytic decomposition is often unavoidable on solid supports. Moreover, catalytically active material remains permanently active and is not removed with the reaction products. Finally, the melt is generally immiscible with decomposition products, which are therefore easily removed, whereas the large surface of solid sup-

ports may become blocked and ineffective. Frequently, reactions in ionic melts yield products which are different from those obtained on solid catalysts, owing to the polarizing forces of the melt.

It is thought that the mechanism of the catalytic action of ionic melts is similar to that of the corresponding metals [186]. In the metals, we have a lattice of positively charged atoms with freely moving electrons, whereas an ionic melt contains cations "diluted" with anions. A similar "dilution" is observed in many activated solid catalysts. Owing to the varying distances between the cations in the melt, however, more products are likely to be formed here than on solid catalysts with fixed lattice distances.

The melting point of the catalytically active salt must be as low as possible, and in any case lower than 500 °C. High catalytic activities are shown by the purely ionic salts, which have high melting points even in binary or ternary systems, and in particular by salts whose cations occur in two or more valence states; these are generally salts of the transition metals. Since some of these are strongly covalent, *i.e.* form "molecular melts", they are mixed with alkali metal or alkaline earth halides; the original molecular structures then dissolve to form complex ions (solvation). The salt must also be able to form an intermediate or addition compound with the reactants.

A. Catalytic Chlorination

The chlorination of hydrocarbons is generally accompanied by the evolution of considerable heat, which can lead to local overheating and hence to unsuccessful reactions. Advantages of using a melt are the high solubility of chlorine, and a close control of the reaction temperature. Controlled partial chlorinations can therefore be carried out with no danger of explosion, owing to the high dilution.

The reaction of acetylene with chlorine (1:1), using carbon tetrachloride as a diluent, at 175 to 250 °C in an $NaCl/AlCl_3$ melt containing iron(III) chloride yields a mixture of ethylene chloride, tetrachloroethylene, and carbon tetrachloride [187], while ethylene chloride reacts at 400 to 480 °C to form 1,1-dichloroethylene (20 %), 1,2-dichloroethylene (22 %), trichloroethylene (29 %), and other chlorinated products. If the ratio of ethylene chloride to chlorine is reduced to between 0.55:1 and 0.75:1, the principal product at about 350 °C is 1,1,2-trichloroethane (about 50 %) [188]. Ethane and chlorine (1:3) react at 400 °C in a sodium chloride/aluminum chloride melt containing $CuCl_2$ to give ethyl chloride (46 %), vinyl chloride (22 %) (by elimination of HCl from 1,1- or 1,2-dichloroethane), and methyl chloride (4 %) [189]. The chlorination of benzene at 200 to 250 °C in an $NaCl/AlCl_3/FeCl_3$ melt is more specific. Monochlorobenzene is formed with an 88 % conversion and an equally high yield when gaseous benzene and chlorine are introduced into the melt. Only about 10 % of more highly chlorinated products, mainly dichlorobenzene, are formed. The lower the temperature and the shorter the contact time, the higher is the ratio of monosubstituted to polysubstituted products [190, 191].

Since the vapor-phase chlorination of methane to form methyl chloride is difficult to control, the reaction was tried in fused salts (potassium hydrogen sulfate, zinc chloride, and alkali metal and alkaline earth chlorides with relatively large quantities of iron(III) chloride or copper(II) chloride).

At 320 °C and a molar ratio $CH_4:Cl_2 = 2:1$, methyl chloride is obtained in 50 % yield, together with very small quantities of methylene chloride and chloroform [192]. The chlorination can also be carried out in potassium chloride/copper chloride (70 mole-% of CuCl) if up to 48 % of the copper(I) chloride is chlorinated to copper(II) chloride; this then acts as a mild chlorinating agent [193]:

$$CH_4 + 2\ CuCl_2 \rightarrow CH_3Cl + Cu_2Cl_2 + HCl \quad (49)$$

The bath can be regenerated by bubbling in chlorine or hydrogen chloride and oxygen. With less than 20 mole-% of copper(II) chloride, the conversion remains small; this is explained by the fact that, in a melt containing 30 mole-% of potassium chloride, up to 21.4 mole-% of the copper(II) chloride are bound as K_2CuCl_4 (very low partial pressure of chlorine over melts containing less than 20 mole-% of $CuCl_2$). Investigations on the ternary system $KCl/CuCl/CuCl_2$ and the partial pressure of chlorine over the melt have led to the conclusion that the chlorine is made available by Reaction (50) [194].

$$Cu^{2+} + CuCl_4^{2-} \rightarrow Cu_2Cl_2 + Cl_2 \quad (50)$$

An unsatisfactory feature of all chlorinations of organic substances is that half of the chlorine used is lost as hydrogen chloride. This can be avoided, particularly in the reactions in alkali metal chloride/copper chloride or alkali metal chloride/ferric chloride systems, by mixing oxygen with the chlorine during the reaction [Equation (51)] or by using hydrogen chloride and oxygen right from the beginning [Reaction (52)].

$$CH_4 + x/2\ Cl_2 + x/4\ O_2 \rightarrow CH_{4-x}Cl_x + x/2\ H_2O \quad (51)$$

$$CH_4 + x\ HCl + x/2\ O_2 \rightarrow CH_{4-x}Cl_x + x\ H_2O \quad (52)$$

However, this direct oxidative chlorination at 400 to 550 °C yields 40 % of carbon tetrachloride, 40 % of chloroform, 15 % of methylene chloride, and only 5 % of methyl chloride. The two-step process, involving chlorination with copper(II) chloride and regeneration of the melt with hydrogen chloride and oxygen, is therefore more favorable [195, 196]. Another example of oxidative chlorination, this time with a copper chloride/potassium chloride melt on a solid support in a fluidized bed, is the reaction of ethylene at 300 to 500 °C, which yields 53 % of tetrachloroethylene, 23 % of trichloroethylene, 9 % of pentachloroethane, and 5 % of dichloroethylene [197]. If ethylene, hydrogen chloride, and oxygen are used in the ratio of 2:2:1, a 61 % yield of vinyl chloride is obtained [198]:

$$H_2C{=}CH_2 + HCl + {}^1/_2\ O_2 \rightarrow H_2C{=}CHCl + H_2O \quad (53)$$

Vinyl chloride is also obtained on oxidative chlorination of ethane [199]:

$$C_2H_6 + HCl + O_2 \rightarrow H_2C{=}CHCl + 2\ H_2O \quad (54)$$

The addition of alkali metal chlorides as "activators" to copper or zinc chlorides on a support was frequently described. Here a molten phase is formed in which the reaction proceeds with a good conversion; also, the vapor pressure of the catalytically active salt is reduced.

The mechanism of the oxidative chlorination has been investigated in detail. When air is led through a potassium chloride/copper(I) chloride melt, up to 75 % of the oxygen is absorbed [200] and Cu_2OCl_2 is formed at 350 to 400 °C:

$$2\ CuCl + {}^1/_2\ O_2 \rightarrow CuO{\cdot}CuCl_2 \qquad (55)$$

This compound, which can be isolated, is partly dissolved in the melt. If the temperature of the melt is raised to 450 to 525 °C, chlorine-free oxygen is liberated; this provides a method of extracting oxygen from the air [201]. On reaction with hydrogen chloride $CuO{\cdot}CuCl_2$ forms water and copper(II) chloride:

$$CuO{\cdot}CuCl_2 + 2\ HCl \rightarrow 2\ CuCl_2 + H_2O \qquad (56)$$

Summation of the two Equations (55) and (56) gives Equation (57) for the Deacon process:

$$2\ HCl + {}^1/_2\ O_2 \rightleftharpoons H_2O + Cl_2 \qquad (57)$$

The Deacon process using copper salts as catalysts is particularly susceptible to exhaustion of the catalyst owing to migration of the salt from the support (which can be compensated by continuous evaporation of a copper(II) chloride melt). It is therefore not surprising that the possibility of using fused salts as catalysts has been intensely investigated [203].

The problem here (as in experiments with solid catalysts and with fused salts on solid supports) is that the reaction is an equilibrium which permits a conversion of only 65 to 75 % at the required temperatures of 350 to 400 °C. This conversion is only achieved in a few cases, mainly when alkali metal chloride/copper(II) chloride, alkali metal chloride/iron(III) chloride, or chromium-, manganese- or rare earth chloride melts are used as catalysts. A property common to chromium, manganese, and the rare earths is their ability to form stable oxide chlorides. Optimum conversion is readily achieved in fused salts by good contact between the gases and the liquid phase (use of an aerating stirrer) [43, 142]. However, the residual gas always contains 20 to 25 % of hydrogen chloride and oxygen, and this makes isolation of the chlorine difficult.

These difficulties are avoided if the Deacon process is carried out in two steps [204]. Oxygen (air) and hydrogen chloride are bubbled into a copper chloride/potassium chloride melt at 350 to 425 °C. Water and copper(II) chloride are formed via $CuO{\cdot}CuCl_2$. When the $CuCl_2$ concentration in the melt reaches 45 to 75 %, the melt is heated at 500 to 800 °C in a separate chamber, whereupon pure chlorine is liberated, with regeneration of copper(I) chloride. The ratio of hydrogen chloride to absorbed oxygen should be as close as possible to 4:1, since the oxide chloride separates out, if the concentration of this intermediate exceeds 30 mole-%. The potassium chloride content should also be maintained at or below 30 mole-%. Otherwise too much copper(II) chloride is bound as a complex and is not available for decomposition in the second step.

Instead of isolating chlorine by raising the temperature, hydrocarbons can also be introduced in the second step of the Deacon process, or phosgene can be produced from carbon monoxide [205]:

$$CO + 2\ HCl + {}^1/_2\ O_2 \rightarrow COCl_2 + H_2O \qquad (58)$$

Recent investigations have shown that the oxidation potential of iron(III) ions in the melt (in contrast to aqueous solutions) is practically the same as that of copper(II) ions [206]. This explains the use of iron(III) ions as catalysts in the Deacon process. The optimum conversion of 70 % is achieved in an iron(III) chloride/potassium chloride melt at 430 °C [207].

Catalytically active fused salts can be used as solvents for esterification and ether cleavage reactions [208]. Methanol is quantitatively converted to methyl chloride by hydrogen chloride, without the need for other substances to remove the water. Only traces of dimethyl ether are formed during the reaction. Dimethyl ether which is formed in the industrial methanol synthesis, and for which uses are difficult to find, can be cleaved to methyl chloride by hydrogen chloride in a zinc chloride/potassium chloride melt. The conversion is 90 %.

$$H_3C{-}O{-}CH_3 + 2\ HCl \rightarrow 2\ CH_3Cl + H_2O \qquad (59)$$

The reaction of diethyl ether with hydrogen chloride in an $AlCl_3$/KCl/NaCl melt to form ethyl chloride has been reported [209]. However, it was found that it is the reaction with aluminum chloride which leads to ethyl chloride [208]:

$$3\ H_5C_2{-}O{-}C_2H_5 + 2\ AlCl_3 \rightarrow Al_2O_3 + 6\ C_2H_5Cl \qquad (60)$$

The hydrolysis of methylchlorosilanes to produce methylpolysiloxanes gives rise to the formation of large quantities of hydrochloric acid. On the other hand, if *e.g.* dimethylchlorosilane is reacted with methanol in a melt containing zinc chloride, the desired dimethylcyclosiloxane is obtained in 80 % yield, in addition to methyl chloride which is required for the Rochow synthesis of methylchlorosilanes [208]:

$$(CH_3)_2SiCl_2 + 2\ CH_3OH \rightarrow [(CH_3)_2SiO] + 2\ CH_3Cl + H_2O \qquad (61)$$

The reaction of dimethyldichlorosilane with dimethyl ether is less satisfactory.

The Rochow synthesis, which is generally carried out in fluidized beds nowadays, has also been investigated in various fused salts, in the hope of obtaining a more favorable ratio of dimethyldichlorosilane to other methylchlorosilanes. Silicon powder was reacted with methyl chloride in a $ZnCl_2$/KCl/NaCl melt at 290 °C, using 10 % of copper powder and 0.5 % of zinc powder as catalysts [43, 210]. The yields of dimethyldichlorosilane did not come up to expectations, in spite of the quantitative consumption of silicon. The attempt

to methylate silicon by reaction of the Si–H bond with methyl chloride was unsuccessful. Instead, chlorosilane and methane were formed in the copper chloride/potassium chloride melt [43]:

$$SiH_4 + CH_3Cl \begin{cases} \xrightarrow{\Delta} CH_3SiH_2Cl + H_2 \\ \rightarrow SiH_3Cl + CH_4 \end{cases} \quad (62)$$

Chlorosilanes were formerly prepared in sealed tubes at high pressures because of the volatility of the aluminum chloride catalyst. They can now be produced continuously and at normal pressure by two methods, in a $NaCl/AlCl_3$ melt. If a mixture of monosilane and hydrogen chloride (1:1) is led into the melt at 120 °C, 80% of monochlorosilane is obtained together with other chlorosilanes [211]:

$$SiH_4 + HCl \rightarrow SiH_3Cl + H_2 \quad (63)$$

To avoid evolution of hydrogen from the valuable Si–H compounds, the commutation under otherwise identical conditions is preferable:

$$SiH_4 + SiCl_4 \rightarrow 2\ SiH_2Cl_2 \quad (64)$$

Alkylated silanes can also be reacted in this way. This provides a simple and extremely favorable method of preparing dimethylchlorosilane, which is used for the synthesis of α,ω-hydridopolysiloxanes [43, 212]:

$$(CH_3)_2SiH_2 + (CH_3)_2SiCl_2 \rightarrow 2\ (CH_3)_2SiHCl \quad (65)$$

The Friedel-Crafts hydrocarbon synthesis can also be carried out in melts containing aluminum chloride, *e.g.* the reaction of benzene with ethyl chloride or ethyl bromide at 150–170 °C to yield ethylbenzene; however, large amounts of tarry products are formed [191, 213].

B. Catalytic Eliminations and Additions

Elimination and addition reactions generally proceed satisfactorily in a zinc chloride/potassium chloride melt. The preparation of vinyl chloride by thermal dehydrohalogenation of 1,1- and 1,2-dichloroethanes has recently attracted attention at the expense of the hydrohalogenation of acetylene on activated charcoal loaded with mercury salts. Heating difficulties are avoided when fused salts are used. A further advantage of fused salts is the stabilization of the catalyst.

If 1,1-dichloroethane is passed through a $ZnCl_2/KCl$ or $ZnCl_2/CnCl$ melt at 330 °C, vinyl chloride is obtained in 97% yield and 77% conversion [214]. The conversion obtained with 1,2-dichloroethane is lower (about 50%). To avoid formation of acetylene compounds, 5% by weight of mercury(II) chloride must be added. The addition of hydrogen chloride to acetylene also proceeds in 89% yield in this melt. By a combination of both steps 2 moles of vinyl chloride can be obtained from one mole of acetylene and one mole of 1,1-dichloroethane:

$$HC{\equiv}CH + Cl_2HC{-}CH_3 \rightarrow 2\ H_2C{=}CHCl \quad (66)$$

Moreover, butene can be produced with a 77% conversion by elimination of hydrogen chloride from n-butyl chloride in a zinc chloride/copper(I) chloride melt at 400 °C [191]. Examples of the hydrochlorination of olefins are also known, such as the addition of HCl onto ethylene, which gives an 82% yield of ethyl chloride in a $NaCl/KCl/AlCl_3$ melt at 100 °C. The remainder of the ethylene polymerizes.

Olefins can be prepared by elimination of water from alcohols; the reaction proceeds most readily with tertiary alcohols. Ethanol reacts at 350 °C in molten copper(I) chloride to form ethylene [186], while the same reaction in molten $NaCl/ZnCl_2$ is more specific, giving a yield of 98% [191]. Propylene and butene have also been prepared in this way.

Perchloroethylene is obtained by dehydrogenation of symmetrical tetrachloroethane at 300 to 500 °C in a copper chloride/zinc chloride melt [215]:

$$Cl_2HC{-}CHCl_2 + {}^1/_2\ O_2 \rightarrow Cl_2C{=}CCl_2 + H_2O \quad (67)$$

If the oxygen supply is insufficient, trichloroethylene is also formed by elimination of hydrogen chloride [216]. Another way to prepare trichloroethylene is the reaction of tetrachloroethylene with hydrogen at 300 °C [217]:

$$Cl_2C{=}CCl_2 + H_2 \rightarrow Cl_2C{=}CHCl + HCl \quad (68)$$

C. Miscellaneous Reactions

About 25 patents have been granted for methods of isomerizing n-paraffins to branched-chain compounds. Melts are used in which compounds of the type of Friedel-Crafts catalysts are dissolved, *e.g.* an alkali metal chloride/aluminum chloride melt with an excess of aluminum chloride [218]. Additions of antimony chloride [219], zinc chloride [220], or nickel and cobalt chlorides, as well as other chlorides of subgroup VIII elements also serve their purpose [221]. The reaction is generally carried out below 200 °C. The longer the carbon chain of the n-paraffin, the lower is the temperature chosen, since otherwise undesirable cracking occurs. In the case of hydrocarbons with more than five C-atoms, the reaction is carried out below 80 °C. It has been found particularly useful to add a small quantity of hydrogen chloride [222]; for example, the isomerization of n-butane to isobutane then proceeds at 141 °C with a 50% conversion. This process is of interest for increasing the octane rating of petroleum fractions.

The nitration of paraffins proceeds more readily in fused nitrates than in the vapor phase. Propane and nitric acid react at 372–444 °C to give nitropropane with an 11% conversion; this is due to both the efficient temperature control and to the catalytic effect of the melt [223]. However, the reaction of organic substances in fused nitrates always leads to fairly large quantities of various oxidation products [43].

Finally, fused salts have also been used for reactions with acetylene. Here again the rapid dissipation of the heat of reaction, which would otherwise cause decomposition to carbon and hydrogen, is of advantage. Acyclic oligomers, such as monovinylacetylene (80%), and higher-boiling products (15%), are formed from acetylene in a copper(I) chloride/amine hydrochloride melt [224]. Benzene (40%), toluene (10%), xylene (10%), and naphthalene (20%), are obtained, together with 30% of tars and carbon, at 500 to 600 °C in melts containing zinc chloride (and only in these) [225]. Acetylene has been reacted with ammonia at 440 to 550 °C, again in an alkali metal chloride/zinc chloride melt, in an attempt to synthesize pyridine derivatives; however, acetonitrile was obtained in 60% yield [226].

VII. Conclusion

In view of the large number of publications on fused salts [10], and particularly on their physicochemical properties, the present paper can only be almost complete in the intended field, *i.e.* the use of ionic liquids in preparative chemistry. Very informative papers have been published on the manipulation of melts [227], corrosion problems, isotope separation, electrophoresis, polarography, Raman and infrared recording techniques, chromatography, gas chromatography (with a melt as the stationary phase), and analyses using fused salts as solvents [228, 229].

Ionic liquids, which still represent a wide and new scientific territory, will take their place alongside nonpolar and water-like solvents, and, like these, will frequently be the best solvents for given preparations.

I am sincerely grateful to the Director of the Anorganisch-Chemisches Institut, Prof. O. Glemser, and to Farbenfabriken Bayer in Leverkusen (Germany) for their generous support of my work, and particularly to Dr. F. Freund, Göttingen, for valuable and critical discussions.

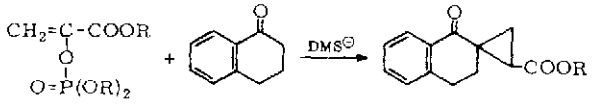
Synthesis of Cyclopropane Compounds from Triethyl Phosphoenolpyruvate or α-Halogenoacrylic Esters

By Prof. Dr. Ulrich Schmidt

Chemisches Laboratorium der Universität Freiburg/Brsg. (Germany)

Triethyl phosphoenolpyruvate *(1)* is obtained by a Perkow reaction [1] between ethyl bromopyruvate and triethyl phosphite (85% yield, b.p. 95–100 °C/0.1 mm, $n_D^{20} = 1.4342$). It reacts in the presence of one mole of base (the dimethylsulfinyl carbanion [2] or t-butoxide) with methylene compounds to give cyclopropane derivatives. With tetralone, for example, an 80% yield of spiro-[2-ethoxycarbonylcyclopropane-1,2'-tetralone] *(2)*, m.p. 86.5–87.5 °C, is obtained.



(1), R = C_2H_5 *(2)*

Reaction between *(1)* and acetophenone or acetoacetic ester yields 60% ethyl 2-benzoylcyclopropanecarboxylate *(3)* [b.p. 110 °C/0.1 mm, $n_D^{20} = 1.5242$, m.p. of dinitrophenylhydrazone 173–174 °C] or 40% diethyl 2-acetylcyclopropane-1,2-dicarboxylate [b.p. 82–87 °C/0.1 mm, $n_D^{20} = 1.4668$].

Procedure: A solution of 2.5 g of sodium hydride in 50 ml of dimethylsulfoxide [2] is added dropwise under nitrogen to a mixture of 25 g of triethyl phosphoenolpyruvate and 15 g of α-tetralone, keeping the temperature of the reaction mixture at 45 °C. After 30 min, the mixture is poured into 500 ml of water. Extraction with chloroform and processing of the chloroform extract affords 80% *(2)*, which is purified by recrystallization from ethanol or by vacuum distillation (0.01 mm) in a sausage flask at a bath temperature of 180 °C.

This new cyclopropane sythesis probably proceeds by a Michael addition followed by a 1,3-elimination and is stereospecific as regards the formation of *(2)* and *(3)*. Only one isomer of *(2)* is formed (homogeneous on thin-layer chromatograms) which on saponification produces only one isomer of the carboxylic acid *(2)*, R = H, m.p. 117 °C. The carbonyl and ethoxycarbonyl groups in *(2)* are probably in *trans*-relationship, since no intramolecular hydrogen bond can be detected by infrared spectroscopy in the free acid. Compound *(3)* is also homogeneous in gas chromatograms. Hydrolysis affords the low-melting isomer of 2-benzoylcyclopropanecarboxylic acid [3]. Gas chromatography of *(4)* yields two isomers in a ratio of 2:1.

Analogous cyclopropane syntheses can be carried out with α-halogenoacrylic esters. Thus, for example, *(2)* is formed in 30% yield from ethyl α-chloroacrylate and tetralone.

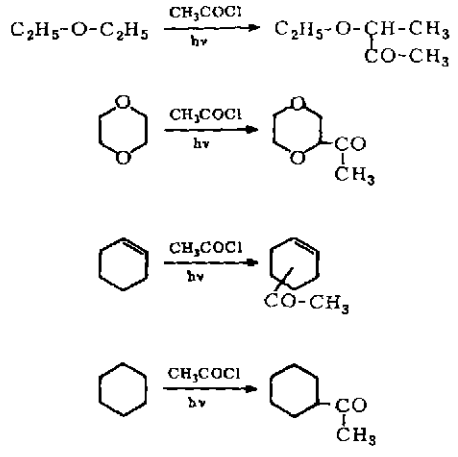
Substitution Reactions with Photochemically Produced Acyl Radicals [1]

By Prof. Dr. Ulrich Schmidt

Chemisches Laboratorium
der Universität Freiburg/Brsg. (Germany)

Acyl chlorides are split into acyl and chlorine radicals by light of wavelength 254 mμ. Since the dissociation energy of the chlorine-hydrogen bond is considerably larger than that of the acyl-hydrogen bond, substitution of the substrate by acyl radicals is observed on irradiation of acid chlorides. On irradiation of acetyl chloride the following reactions take place:



A few percent of aldehyde and diacetyl are always found, the latter being formed by combination of acetyl radicals. After irradiation of acetyl chloride in cyclohexane free chlorine was present in the reaction mixture. Ethers are substituted with particular ease.

With a large (five- to ten-fold) excess of substrate the yields are 10–20 %. Recovery of the starting material increases the yield to 30–50 %.

Example: Acetylchloride (30 g) in 170 ml ether was irradiated for 24 hours with a low-pressure mercury lamp (10 watts at 254 mμ). Distillation produced 9 g of 3-ethoxybutan-2-one (b.p. 62–64 °C/80 mm, n_D^{20} = 1.3970; dinitrophenylhydrazone: m.p. 86–87 °C).

Synthesis of 3-Phenyl-, 3,4-Diphenyl-, and 3-(β-Naphthyl)-1,2,5-thiadiazole

By Dr. V. Bertini and Prof. Dr. P. Pino

Istituto di Chimica Organica, Facoltà di Scienze, Università di Pisa (Italy)

None of the methods known for preparing 1,2,5-thiadiazoles [1] is suitable for obtaining their aryl derivatives.

We have found that 3-phenyl-1,2,5-thiadiazole *(1)*, m.p. 43 to 44 °C is formed on refluxing S_4N_4 with ethylbenzene for 6 h in a molar ratio of 1:5. The product is purified by distillation at 90 °C/0.9 mm and recrystallization from petroleum ether. The yield is 12.6% based on the S_4N_4 consumed. 3,4-Diphenyl-1,2,5-thiadiazole *(2)*, m.p. 85–86 °C, is obtained analogously in 6.5% yield from dibenzyl and S_4N_4. Similarly, 3-(β-naphthyl)-1,2,5-thiadiazole *(3)*, m.p. 84–85 °C, is formed in 9% yield from β-ethylnaphthalene and S_4N_4. The product *(3)* is isolated by chromatography on a column of Al_2O_3 (40 cm long and 1.15 cm diameter for a charge prepared from 6 g of S_4N_4) with petroleum ether (b.p. 45–60 °C) as eluent; *(3)* occurs in the 14–47th of 25 ml fractions taken from the column and is purified by recrystallization from petroleum ether. Compound *(2)* is purified analogously.

Ultraviolet spectra of the products in iso-octane show the following maxima:

(1): λ_{max} = 228 mμ (ε = 9800); 280 (13500) [2]

(2): λ_{max} = 214 mμ (ε = 23800); 250 (10600); 295 (13100)

(3): λ_{max} = 212 mμ (ε = 24300); 236 (38300); 257 (13000); 269 (16100); 278 (19300); 293 (19000); 304 (21100); 324 (5160); 340 (2070).

Oxidation of *(1)* with hot alkaline permanganate affords over 80% benzoic acid. Reduction of *(1)* with sodium in alcohol yields α,β-diaminoethylbenzene. The NMR spectrum of *(1)* has signals at 7.25–7.45 and 7.80–8.00 ppm (phenyl protons) and at 8.77 ppm (proton on C-4) relative to tetramethylsilane as internal standard. Reduction of *(2)* with sodium in ethanol gives rise to *meso*-α,α'-diphenylethylenediamine, m. p. 120 to 121 °C.

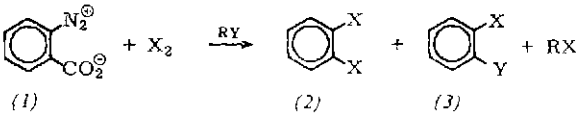
Synthesis of o-Dihalogenobenzenes from Benzenediazonium-2-carboxylate

By Dr. L. Friedman and F. M. Logullo

Case Institute of Technology, Cleveland, Ohio (U.S.A.)

Benzenediazonium-2-carboxylate *(1)* [1,2] and an equimolar quantity of halogen in a solvent (see Table) were refluxed with stirring until gas evolution ceased. Most of the reactions were complete in less than 30 minutes. *o*-Dihalgenobenzenes were identified by gas chromatography and infrared spectroscopy. Yields were determined by quantitative gas chromatography.



(1) *(2)* *(3)*

RY = solvent

X_2	RY	Yield [%]		
		(2), X=Br	*(2)*, X=I	*(3)*, X=I, Y=Cl
Br_2	CCl_4	29		
Br_2	$CHCl_3$	26		
Br_2	CH_2Cl_2	55		
Br_2	$Cl(CH_2)_2Cl$	59 [a]		
ICl	$CHCl_3$			15
ICl	$Cl(CH_2)_2Cl$			32
I_2	CCl_4		28	0.1
I_2	$CHCl_3$		67	2
I_2	CH_2Cl_2		41	8
I_2	$Cl(CH_2)_2Cl$		50	22

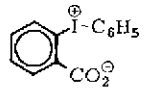
[a] *o*-C_6H_4BrCl (6 %) was also formed.

In addition to *o*-dihalogenobenzenes acidic products were obtained. Formation of monohalogenobenzenes was not observed.

Compound *(1)* and iodine in 1,2-dimethoxyethane gave *o*-iodoanisole (2 %), *o*-diiodobenzene (36 %), 1-(*o*-iodophenyl)-2-methoxyethane (40 %), and methyl iodide.

Reaction of 4-iodo-, 4-chloro-, and 4-nitrobenzenediazonium-2-carboxylate [2] with iodine in chloroform gave 1,2,4-triiodobenzene (69 %), 3,4-diiodochlorobenzene (76 %), and 3,4-diiodonitrobenzene (27 %).

Diphenyliodonium-2-carboxylate *(4)* [3] and iodine in *o*-dichlorobenzene reacted to give *o*-diiodobenzene (60 %).



(4)

Aprotic diazotization [4] of anthranilic acid and its 5- and 3-methyl derivatives in the presence of iodine gave *o*-diiodobenzene (53 %), 3,4-diiodotoluene (30 %), and 2,3-diiodotoluene (55 %), respectively.

The intermediacy of dehydrobenzene in these reactions is indicated by the fact that 4- and 5-chlorobenzenediazonium-2-carboxylate [2] with iodine monochloride forms the same mixture (37:63) of 2,4- and 2,5-dichloroiodobenzene (76 and 40 % yields, respectively).

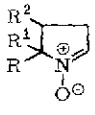
Oxidative Phosphorylation Following Addition of Inorganic Phosphate onto Compounds with a C=N$^{\oplus}$ Double Bond

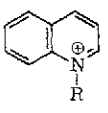
By Professor Dr. V. M. Clark [*],
Dr. D. W. Hutchinson, and D. E. Wilson

University Chemical Laboratory, Cambridge (England)

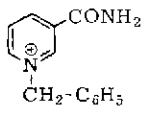
Compounds of the type *(1)–(3)* containing an sp^2 hybridized carbon atom bonded to a planar nitrogen atom bearing a formal positive charge react with tris(tetra-n-butylammonium) or tris(trimethylsulfoxonium) orthophosphate at room temperature in anhydrous solvents to form adducts, which can be detected by ultraviolet spectroscopy (see Table).



(1)



(2)



(3)

Starting material	λmax [mμ]	Solvent	λmax of adduct [mμ] after 24 h
(1a), R=R^2=H, R^1=C$_2$H$_5$ [1]	245	Dioxane	[a]
(1b), R=R^1=CH$_3$, R^2=H [1]	244	Dioxane	[a]
(1c), R=R^1=R^2=CH$_3$ [1]	247	Dioxane	[a]
(2a), R=O$^{\ominus}$ [2]	248, 347	Dioxane	[a]
(2b), R=CH$_3$	317	Acetonitrile	331, 538, 584
(3)	263	Ethanol	290–300

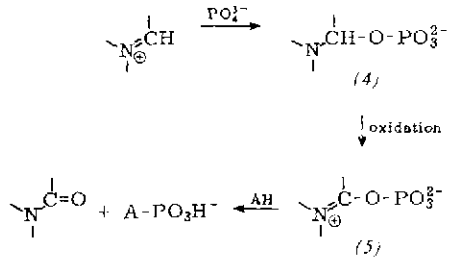
[a] The solution absorbs at the same wavelength as the initial solution but with less than 10 % of the original intensity.

Some of the changes in absorption are complete within one hour. Adducts with similar spectroscopic characteristics are formed from *(1)–(3)* with other inorganic anions [1, 3].

The phosphate adducts have not yet been isolated. It appears that adduct formation with the Δ^1-pyrroline *N*-oxides *(1)* is reversible, since dilution of the solutions with anhydrous solvent or with water restores the original ultraviolet absorption.

If a twofold excess of orthophosphate is used during adduct formation and if the solution is subsequently oxidized, *e.g.* with bromine or permanganate at room temperature, pyrophosphate can be detected in 25 % yield (estimated by the method of [4]). If only one equivalent of orthophosphate is used for adduct formation, other substrates can be phosphorylated by oxidation of the adducts. For example, bis-(tetra-n-butylammonium)phenyl phosphate is phosphorylated by the orthophosphate adduct of *(1b)* with $KMnO_4$ as oxidizing agent to give a 25 % yield of phenyl pyrophosphate. Similarly, addition of bromine to a solution of the orthophosphate adduct of *(3)* in ethanol afforded a 10 % yield of ethyl phosphate.

These phosphorylation reactions can be formulated as follows (cf. [5]):



(4) *(5)*

Imidoyl phosphates analogous to *(5)* are known as phosphorylating agents [6]. A nicotine-adenine-dinucleotide derivative corresponding to *(4)* has been isolated from mitochondria [7].

^{17}O-Hyperfine Structure in the ESR Spectrum of [^{17}O]-2,4,6-Triphenylphenoxyl

By Prof. Dr. K. Dimroth, Dr. F. Bär, and
Dipl.-Chem. A. Berndt

Chemisches Institut der Universität Marburg/Lahn (Germany)

In connection with investigations of deuterated and ^{13}C-labelled 2,4,6-triphenylphenoxyls [1] aimed at determining the distribution of the unpaired electron throughout the molecule, we have prepared [^{17}O]-2,4,6-triphenylphenoxyl as the first ^{17}O-labelled free radical with a C–O bond [2].

2,4,6-Triphenylbenzenediazonium fluoroborate was treated with $H_2{}^{17}O$ containing about 13 atom-% ^{17}O [3] in a little methanol (to enhance solubility). The [^{17}O]-2,4,6-triphenylphenol obtained was then dehydrogenated to the phenoxyl radical. The ratio of the intensities of the ^{17}O-HFS lines in the

ESR spectrum of the labelled radical to that of the main signal obtained from the unlabelled compound indicates a degree of enrichment of 13 atom-% ^{17}O in the labelled phenoxyl. Thus, no isotope dilution has occurred during its synthesis.

In the ESR spectrum, four of the six HFS lines expected [I(^{17}O) = 5/2] are readily differentiated; the remaining two are masked by the main signal from the unlabelled radical. The ^{17}O-splitting constant is a(^{17}O) = 9.7 gauss, a value which indicates a considerable spin density ρ on the oxygen atom. A simple HMO calculation gave $\rho_O = 0.174$ [4].

In order to be able to calculate the spin density on the oxygen from the splitting constant, more data on ^{17}O-labelled C–O radicals are required, particularly because the influence of the spin density at the neighboring atom [5] upon the coupling constant of the oxygen cannot be estimated at present.

Preparation of 1-Bromo-2-chloroethane and 1-Chloro-2-iodoethane

By Dr.-Ing. J. Lorenz and J. Auer

Forschungslaboratorium der Deutschen Advance Produktion GmbH., Marienberg bei Bensheim/Bergstrasse (Germany)

Tris-(β-chloroethyl) phosphite, which is readily prepared from ethylene oxide and PCl_3 [1], undergoes a smooth Arbusow reaction with benzyl bromide to give 1-bromo-2-chloroethane. An equimolar mixture of benzyl bromide and tris-(β-chloroethyl) phosphite is warmed slowly with stirring to 120 °C, when an exothermal reaction commences. The reaction mixture is then heated for 3 h at 140 °C. The product is distilled off at 150 mm and separated by fractional distillation from traces of 1,2-dichloroethane; 83–85% yields of 1-bromo-2-chloroethane, b.p. 106 °C, are obtained.

With methyl iodide instead of benzyl bromide, the exothermal reaction begins at 70 °C, and after heating the mixture for 1 h at 80–90 °C, an 85% yield of 1-chloro-2-iodoethane, b.p. 140 °C, is obtained.

These procedures are less laborious and give better yields than those used to date [2]. No reaction takes place with potassium fluoride instead of benzyl bromide.

N-Substituted 4H-1,3-Oxazinium Salts

By Dr. Richard R. Schmidt

Institut für Organische Chemie der Technischen Hochschule Stuttgart (Germany)

The surprising ease with which bis-(2,6-diphenyl-4*H*-1,3-oxazinium) hexachlorostannate is formed from *N*-chloromethylbenzamide, phenylacetylene, and stannic chloride [1] encouraged us to synthesize the corresponding *N*-substituted compounds *(3)* from *N*-methylbenzylideneimine, acyl halides, phenylacetylene, and stannic chloride.

The components were dissolved in anhydrous chloroform or ethylene dichloride and were mixed at room temperature in the above order. The mixture was boiled for 2 hours. On cooling, the *N*-methyl-4*H*-1,3-oxazinium salts *(3)* crystallized out and were filtered off. The structures of the products were proved by their reaction with ammonia: treatment of *(3d)* with concentrated ammonia produces *(4)* and *(5)*, whereas with dilute ammonia, only *(5)* is formed.

The formation of pyrylium salts from acyl halides, phenylacetylene, and stannic chloride [2] or of *N*-substituted phthalimidines from *N*-methylbenzylideneimine and acyl halides [3] was not observed. The reaction proceedes *via* the *N*-acyl-*N*-(α-halogenoalkyl)methylamines *(1)* [4] and the *N*-methyl-*N*-acyl-*N*-benzylideneiminium salts *(2)* formed from *(1)* and stannic chloride. 1,4-Addition of phenylacetylene onto *(2)* then affords *(3)*.

Synthesis and Properties of Red Tantalum Nitride Ta_3N_5

By Prof. Dr. G. Brauer and Dr. J. R. Weidlein

Chemisches Laboratorium der Universität Freiburg/Brsg. (Germany)

We have produced Ta_3N_5 [1] from pure tanatalum pentoxide and extremely pure ammonia (2–4 l/h) at 860–920 °C. The reaction of 1–2 g of oxide is complete only after 36–120 h and

only if titanium turnings are present to act as getter for the oxygen. The titanium metal probably also catalyses the decomposition of ammonia in the immediate vicinity of the reacting oxide. As the oxygen in the pentoxide is replaced by nitrogen, the color changes *via* dark green, bright green, yellow-brown, and red-brown to the red color of the oxygen-free nitride Ta_3N_5.

Ta_3N_5 is stable up to about 950 °C under NH_3 at normal pressure. On heating *in vacuo*, it starts to lose nitrogen at about 500 °C and decomposes into black tantalum nitride TaN [2].

Ta_3N_5 has a tetragonal crystal lattice with the lattice constants a = 10.265 Å and c = 3,898 Å; its density measured pyknometrically is 9.85 g/cm³; the unit cell contains four Ta_3N_5 formula units.

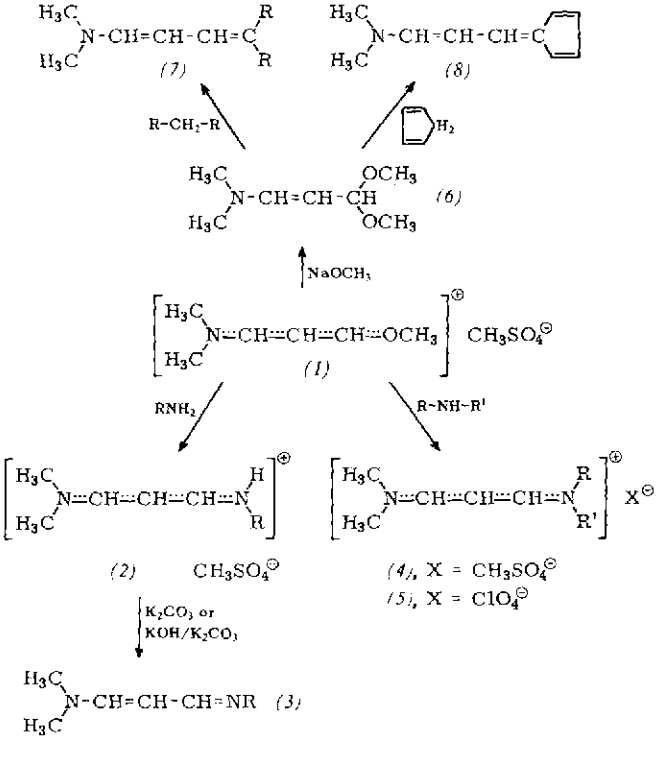
Synthesis and Reactions of Vinylogous Amide Acetals and Vinylogous Amidines

By Prof. Dr. H. Bredereck, Dr. F. Effenberger, and Dipl.-Chem. D. Zeyfang

Institut für Organische Chemie der Technischen Hochschule Stuttgart (Germany)

Dimethyl sulfate reacts smoothly, sometimes exothermally, with β-(*N*,*N*-dimethylamino)acrolein to give the adduct *(1)* [1–3], which smoothly reacts with nucleophilic reagents, even at room temperature.

With primary amines, the salts *(2)* [R = CH_3: m.p. 78–80 °C, 46% yield; R = C_6H_5: m.p. 138–140 °C, 53% yield; R = α-pyridyl: oil, n_D^{20} = 1.6330] are formed. Treatment of *(2)* with a solution of potassium carbonate or of potassium hydroxide/potassium carbonate liberates the vinylogous amidines *(3)* [R = CH_3: b.p. 90–96 °C/13 mm, picrate: m.p. 140–142 °C; 29% yield; R = C_6H_5: m.p. 62–65 °C, 43% yield; R = α-pyridyl: m.p. 113–115 °C, 48% yield].



The reaction of *(1)* with secondary amines leads to the methyl sulfates *(4)*, which do not crystallize well. However, treatment of *(4)* with a concentrated solution of sodium perchlorate [3,4] produces analytically pure perchlorates *(5)* [R = R' = CH_3: m.p. 119 °C, 68% yield; R = C_6H_5, R' = CH_3: m.p. 143–146 °C, 62% yield].

The reaction of *(1)* with sodium methoxide gives rise to β-(*N*,*N*-dimethylamino)acrolein dimethylacetal *(6)* [b.p. 78 °C/15 mm, n_D^{20} = 1.4521, 62% yield], which condenses readily with compounds containing an activated methylene group (*e.g.* malonodinitrile or diethyl malonate) to give butadiene derivatives *(7)* [R = CN: m.p. 130–134 °C, 53% yield; R = $COOC_2H_5$: m.p. 100–102 °C, 38% yield] or with cyclopentadiene to give 60% (β-dimethylaminovinyl)fulvene *(8)*, m.p. 70–72 °C [5].

5,6-Dimethylbenzo[a]calicene

By Doz. Dr. H. Prinzbach, Dipl.-Chem. D. Seip, and Dipl.-Chem. Ulf Fischer

Chemisches Laboratorium der Universität Freiburg/Brsg. (Germany)

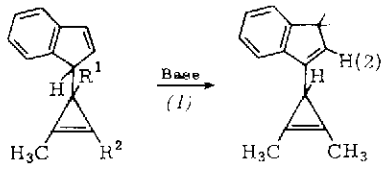
In the series of hydrocarbons with a cyclic, cross-conjugated π-bond system, so far cyclopropenylidenecyclopentadiene (calicene) could not be synthesized. We have prepared a monobenzo derivative *(5)* of this system by the following route [1].

Treatment of 30 mmoles of indenylmagnesium bromide with 20 mmoles of dimethylcyclopropenylium fluoroborate in tetrahydrofuran at 20 °C leads to a 5:1 mixture of *(1)* and *(2)*, b.p. 68–70 °C/0.01 mm, in 35% yield. The structure of *(1)* was proved *inter alia* by its infrared spectrum (C=C absorption at 1850 cm^{-1}) and NMR spectrum [2.81 τ (4 H, M); 3.33; 3.63 (AB quartet, J = 5.5 cps); 6.84 (1 H, M); 8.61 (1 H, D, J = 5.5 cps); and 8.02 (6 H, S)], by its isomerization to *(3)* [NMR: 2.80 τ (4 H, M); 4.10 (1 H, D, J = 2.1 cps); 6.83 (2 H, D, J = 2.1 cps); 7.58 (1 H, S); and 7.93 (6 H, S)], and by the formation of its crystalline derivatives *(6)*.

The dehydrogenation of *(1)* to *(4)* is effected with triphenylmethyl fluoroborate in chloroform at 0 °C for 30 min in 50 to 55% yield. Compound *(4)* forms colorless crystals, m.p. 98 to 99 °C, with λ_{max} in 70% $HClO_4$ at 309 mμ (ε = 2450) and 230 (17800). Its NMR in CF_3COOD has signals at 1.68 τ (T, J = 1.8 cps); 2.10–2.70 (M); 6.02 (broad singlet); and 6.86 (S) in area ratios of 1:4:2:6. In accordance with the coupling expected of *(4)*, the H(2) triplet converges to a sharp singlet, and the half-width of the methylene signal is reduced by half [2], when *(4)* is irradiated with the methylene or H(2) resonance frequency, respectively.

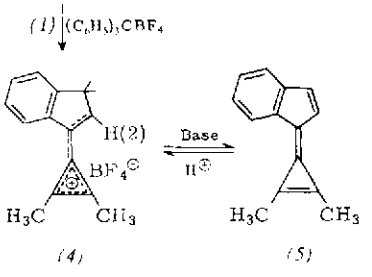
Compound *(4)* is a very weak acid; no isotopic exchange of the methylene protons can be detected when *(4)* is left for several days in CF_3COOD. Accordingly, *(4)* is stable for a few hours in 2% $HClO_4$. Treatment of *(4)* with a five- to ten-fold excess of trimethylamine or pyridine at 10 °C converts it in 95% yield into 5,6-dimethylbenzo[*a*]calicene *(5)*, which exists only in dilute solution but which can be characterized by reconverting it into *(4)* by protonation. Hydrocarbon *(5)*

has λ_{max} in ether at 336 mμ (ε approx. 4400) and 267 (ε approx. 8300), in chloroform at 343 (ε approx. 5000), and in n-hexane at 335 mμ (ε approx. 4100). In accordance with the



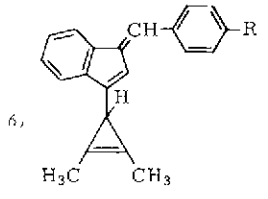
(3)

(1), R^1 = H, R^2 = CH_3
(2), R^1 = CH_3, R^2 = H



(4) (5)

weak acidity of *(4)*, compound *(5)* is a strong base: it is extracted in the form of *(4)* from its solution in chloroform by only 15% $HClO_4$.



(6)

The 6-phenyl-4-cyclopropenylbenzo[*b*]fulvenes *(6)* obtained from *(2)* by condensation with 4-substituted benzaldehydes (R = Cl, CH_3O) are not isomerized to the corresponding benzocalicene derivatives [1] under conditions which allowed the prototropic conversion of the analogous cycloheptatrienylbenzofulvenes into the benzosesquifulvalenes [3]. Since no hydrogen-deuterium exchange was observed in the three-membered ring of *(6)* in CH_3OD/CH_3ONa, it need not be thermodynamic reasons that are responsible for the lack of reaction.

Synthesis of 1-Dicyanomethylenephenalene and 1-(Ethoxycarbonylcyanomethylene)phenalene

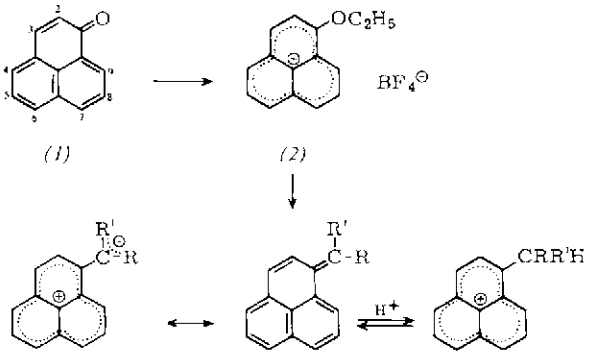
By Doz. Dr. H. Prinzbach and Dipl.-Chem. V. Freudenberger

Chemisches Laboratorium der Universität Freiburg/Brsg. (Germany)

For methylenephenalene *(3)*, R = R' = H ("phenafulvene"), as for its vinylogues heptafulvene and triafulvene, a dipolar resonance structure *(4)* is included in the quantum-mechanical description of the ground state. We have prepared the first stable derivatives of *(3)* by two routes.

1. Phenalen-1-one *(1)* [1] is alkylated in CH_2Cl_2 at 40 °C with an equimolar amount of triethyloxonium fluoroborate, giving 80–90% of the ethyloxonium fluoroborate *(2)*, m.p. 170 to 171 °C (decomp.), λ_{max} in acetonitrile = 408 mμ (ε = 14400), NMR spectrum in nitromethane: 8.18 τ [T, CH_3]; 5.0 [Q, CH_2]; 2.30 [H(2), D, J_{2-3} = 9.3 cps]; 2.1–1.0 [H(3)-H(8), M]; and 0.96 [H(9), Q, J_{9-8} = 7.5 cps]; its ultraviolet and NMR spectra correspond largely to those of protonated *(1)* in CF_3COOH.

The salt *(2)* reacts with either sodiomalonodinitrile or sodiocyanoacetic ester in tetrahydrofuran at 20 °C to form *(3a)* or *(3b)* by elimination of ethanol.



(1) (2)

(4) (3a), R = R' = CN (5)
(3b), R(R') = CN, R'(R) = $CO_2C_2H_5$

1-Dicyanomethylenephenalene *(3a)* forms violet-red needles, m.p. 236 °C; its infrared spectrum has C = C absorptions at 1577 and 1626 cm^{-1} and $\nu_{C\equiv N}$ at 2208 cm^{-1}; its NMR spectrum in [$^2H_6$]-dimethyl sulfoxide has signals at 2.64 τ [H(2), D, J_{2-3} = 9.0 cps]; 2.3–1.5 [H(3)-H(8), M]; and 0.78 [H(9), Q, J_{9-8} = 7.5 cps]; it has λ_{max} in iso-octane at 451 mμ, in acetonitrile at 472 (ε = 18800), and in ethanol at 476 (19000). The NMR and ultraviolet spectra reveal that, like 8,8-dicyanoheptafulvene [2] and the 4,4-dicyanotriafulvenes [3], *(3a)* is not detectably protonated in CF_3COOH.

1-(Ethoxycarbonylcyanomethylene)phenalene *(3b)* is an approximately 1:1 mixture of the *cis*- and *trans*-isomers and forms dark red needles, m.p. 135–137 °C; the infrared spectrum has C=C absorptions at 1570 and 1626 cm^{-1}, $\nu_{C=O}$ at 1695 cm^{-1}, and $\nu_{C\equiv N}$ at 2193 cm^{-1}; NMR signals are observed in $CDCl_3$ at 8.59/8.53 τ [T, CH_3]; 5.89/5.65 [Q, CH_2]; 2.9–1.9 [H(2)-H(8), M]; and 0.76 [H(9), D, J_{9-8} = 7.5 cps]; λ_{max} in iso-octane is at 463 mμ, in acetonitrile at 482 (ε = 11900), and in ethanol at 492 (11400). Compound *(3b)* is a stronger base than *(3a)*, and in CF_3COOH the equilibrium *(3)* ⇌ *(5)* lies largely on the side of the conjugate acid *(5)*, judging from ultraviolet spectra.

2. Low yields of *(3a)* and *(3b)* are also obtained by direct condensation of *(1)* in acetic anhydride at 100 °C, with malonodinitrile and ethyl cyanoacetate, respectively.

The distribution of the π-electrons in *(3a)* and *(3b)* estimated from the NMR data imply polarization of the molecules as indicated in *(4)*.

ESR-Spectroscopic Detection of a [^{33}S]-Sulfur Radical

By Dr. W. Rundel and Dr. K. Scheffler

Chemisches Institut der Universität Tübingen (Germany)

Free radicals can be detected by electron spin resonance spectroscopy in solutions of 2,4,6-tri-t-butylthiophenol *(1)* after irradiation with ultraviolet light; the radicals are stable

for some time at room temperature ($t^1/_2$ *ca.* 30 min). The g factor of 2.0104 and the absence of any hyperfine structure in the ESR spectrum indicate that the unpaired electron is located largely on the sulfur atom [1]. Participation of the sulfur in the free radical state should be recognizable from the hyperfine structure in the ESR-spectrum of the radical labelled with ^{33}S [2].

Using a sample of *(1)* containing 11.5 % ^{33}S, we found in addition to the main ESR signal (g = 2.0103 ± 0.0001) a symmetrically distributed weaker quartet due to the interaction of the unpaired electron with the nuclear magnetic ^{33}S isotope. The intensity ratio of the signals was 100:12, corresponding to the ratio $^{33}S/^{32}+^{34}S$ (value calculated from the isotope ratio:100:13). The quartet had a splitting constant a(^{33}S) of 14.75 gauss at a line width of 2.8 gauss. This proves that *(1)* is a genuine sulfur radical, most probably the tri-t-butylphenyl sulfide radical [3].

To measure the ESR spectrum exactly, a solution in benzene of labelled *(1)* and dibenzoyl peroxide was heated to 80 °C. Under these conditions, a relatively large stationary concentration of the radicals is available for a long time [4].

Received: January 15th, 1965 [Z 896/722 IE]
German version: Angew. Chem. 77, 220 (1965)

[1] *W. Rundel* and *K. Scheffler*, Z. Naturforsch. *18b*, 984 (1963).

[2] Funds for purchasing the sulfur isotope were provided by the Deutsche Forschungsgemeinschaft.

[3] Further experiments with a ^{13}C-labelled benzene ring are in progress to prove that the radicals are not formed from liberated sulfur.

[4] Subsequent processing of the mixture yielded some unchanged *(1)* plus bis(tri-t-butylphenyl) disulfide and benzoic acid.

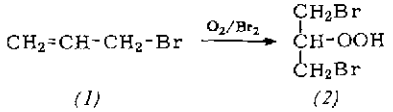
Synthesis of Halogenoalkyl Hydroperoxides by "Bromine-Induced Autoxidation" of Allyl Halides

By Prof. Dr. A. Rieche, Dr. Manfred Schulz, and Dipl.-Chem. K. Kirschke

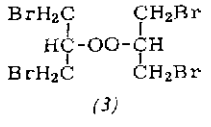
Institut für Organische Chemie der Deutschen Akademie der Wissenschaften zu Berlin, Berlin-Adlershof (Germany)

According to *Bockemüller* and *Pfeuffer* [1], the simultaneous action of oxygen and bromine on a solution in benzene of allyl bromide *(1)* at room temperature in diffuse daylight produces the tetrabromodialkyl peroxide *(3)*.

However, we have found that the reaction does not really lead to *(3)*, but to 1,3-dibromo-2-propyl hydroperoxide *(2)*, b.p. 66 °C/0.1 mm, n_D^{25} = 1.5493 [2]. Apart from *(2)*, no other peroxide could be detected either by paper- or thin-layer chromatography.

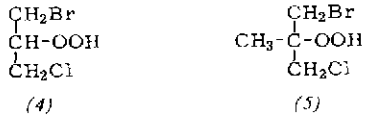


(1) *(2)*



(3)

Conversion of *(2)* into *(3)* could not be accomplished. Both the reaction of *(2)* with acids and thermolysis of *(2)* yielded 1,3-dibromoacetone. Reduction of *(2)* with KI/acetic acid or $LiAlH_4$ afforded 1,3-dibromopropan-2-ol.



(4) *(5)*

Oxidation of allyl chloride under analogous conditions led to 1-bromo-3-chloro-2-propyl hydroperoxide *(4)*, b.p. 61 °C/0.1 mm.

Similarly, methallyl chloride gave rise to α-bromomethyl-α-chloromethylethyl hydroperoxide *(5)*, b.p. 56 °C/0.25 mm.

Received: January 18th, 1965 [Z 897/723 IE]
German version: Angew. Chem. 77, 219 (1965)

[1] *W. Bockemüller* and *L. Pfeuffer*, Liebigs Ann. Chem. *537*, 178 (1939).

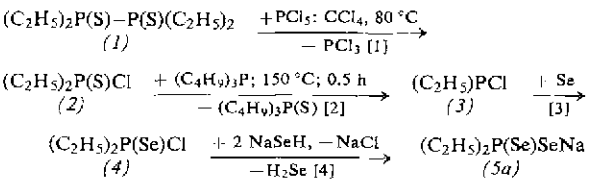
[2] Use of moist oxygen promotes the reaction leading to *(2)*. 1,2,3-Tribromopropane is formed in addition to *(2)*.

Synthesis of Diethyldiselenophosphinic Acid and Its Salts and Esters

By Prof. Dr. W. Kuchen and Dipl.-Chem. B. Knop

Institut für Anorganische und Elektrochemie der Technischen Hochschule Aachen (Germany)

Sodium diethyldiselenophosphinate *(5a)* has been prepared in 80 % yield [based on *(4)*] by the following route.



In order to obtain *(5a)* from *(4)*, a stoichiometric amount of hydrogen selenide was passed into a solution of sodium ethoxide in alcohol, which was then cooled in ice, *(4)* being added dropwise afterwards.

Dissolution of *(5a)* in acetone/H_2O (95:5 v/v) and reprecipitation with ligroin yielded the hydrate $(C_2H_5)_2P(Se)SeNa \cdot 2H_2O$ *(5b)* in the form of stable colorless needles, m.p. 129–130 °C.

When *(5b)* was passed over a stronly acidic cation exchanger [Ionenaustauscher I from E. Merck, Darmstadt (Germany)], aqueous solutions of diethyldiselenophosphinic acid $(C_2H_5)_2P(Se)SeH$ *(5)* were obtained which could be kept for about 24 h at room temperature in the dark, but which decomposed rapidly in diffuse daylight with precipitation of elemental selenium.

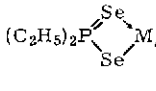
Treatment of *(5b)* with HCl gas in benzene at 0 °C also produced the free acid *(5)* in the form of a yellow oil; however, because of the lability of *(5)*, this preparation is not pure. It decomposes rapidly to bis(diethylselenophosphoryl) selenide *(6)*, colorless platelets, m.p. 65 °C, and orange-red bis(diethylselenophosphoryl) triselenide *(7)*, m.p. 135–137 °C [5]. Compound *(6)* was also made by heating *(4)* with *(5a)* in benzene.

$(C_2H_5)_2P(Se)-(Se)_n-P(Se)(C_2H_5)_2$

(6), n = 1; *(7)*, n = 3

When *(5b)* is refluxed with alkyl bromides, alkyl diethyldiselenophosphinates are produced, *e.g.* the ethyl ester, b.p. 105 °C/0.13 mm, n_D^{20} = 1.6193, and the n-propyl ester, b.p. 98 °C/0.1 mm, n_D^{20} = 1.6037.

Intramolecular coordination compounds of formula *(8)* are precipitated from aqueous solutions of various metal salts by addition of *(5b)*.



(8)

Complexes of this type include the zinc(II) salt, m.p. 151 °C, the cadmium(II) salt, m.p. 158 °C, the lemon-yellow lead(II) salt, m.p. 157–158 °C, the brown-red palladium(II) salt, m.p.

197 °C, the vermilion-red bismuth(III) salt, m.p. 132 °C, the bright yellow indium(III) salt, m.p. 146 °C, and the pale yellow thallium(I) salt, m.p. 129 °C.

Potentiometric determination [6] of the apparent dissociation constants in 80 % aqueous isopropanol at 20 °C gave the following sequence for the strengths of the various phosphinic acids:

$(C_2H_5)_2P(S)OH$ [pK 4.98] ≪ $(C_2H_5)_2P(S)SH$ [pK 2.60]

$(C_2H_5)_2P(S)SeH$ [pK 2.29] ≈ $(C_2H_5)_2P(Se)SeH$ [pK 2.18]

Received: January 19th, 1965 [Z 899/725 IE]
German version: Angew. Chem. 77, 259 (1965)

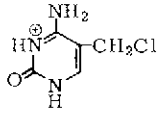
Synthesis and Properties of 5-Chloromethylcytosine

By Priv.-Doz. Dr. Dr. R. Brossmer and E. Röhm

Max-Planck-Institut für Medizinische Forschung, Institut für Chemie, Heidelberg (Germany)

Up to the present, reactive chloromethyl derivatives of naturally occurring pyrimidine bases were known only in the uracil series.

When 5-hydroxymethylcytosine or its hydrochloride is heated with thionyl chloride in tetrahydrothiophene 1,1-dioxide [1], the hydrochloride of 5-chloromethylcytosine *(1)* is obtained in 95 % yield as slightly grey crystals, m.p. above 300 °C.



$Cl^{\ominus}$ *(1)*

For reasons of analogy and on the basis of the infrared spectra, we assume that the basic nitrogen atom of the ring is protonated. On account of its high reactivity, the free base of *(1)* is rather difficult to isolate. Proof of structure *(1)* is supplied by the elemental analysis, by its chemical reactions, and by its infrared spectrum [the 7 strongest bands in order of decreasing intensity occur at 1665, 1725, 2855 (part of a group of bands at 3280–2740), 1215, 1235, 1600, and 760 cm^{-1}; the band at 1025 cm^{-1} typical of the alcohol is not observed].

Under mild conditions the allylic chlorine atom can be displaced with compounds containing a nucleophilic group. Ethers, thioethers, amines, or esters are formed in mostly good yields [2]. Ethers, for example, are produced by heating *(1)* in an alcohol or phenol or by treating *(1)* with alkali metal alkoxides or phenoxides. Many amines react with *(1)* even at room temperature in acetone. In this manner, many substances can be linked *via* the methylene bridge to the cytosine nucleus, wich can act as a low molecular-weight mobile carrier.

Received: January 20th, 1965; supplemented: February 1st, 1965
German version: Angew. Chem. 77, 260 (1965) [Z 911/735 IE]

[1] This solvent (Sulfonal from Shell) has proved to be extremely valuable for other reactions as well. Its properties (strongly polar, chemically inert, heat-stable, miscible with water and organic solvents) make it appear suitable for use in various fields of nucleic acid chemistry.

[2] Reported at the Fall Meeting of the Deutsche Gesellschaft für Physiologische Chemie in Köln (Germany), October 22nd to 24th, 1964.

Crystal Structure of Strontium Disilicide

By Dipl. Chem. K. Janzon, Dr. H. Schäfer, and Prof. Dr. Armin Weiss

Anorganisch-Chemisches Institut der Universität Heidelberg (Germany)

In calcium disilicide $CaSi_2$, the silicon atoms are linked together in a two-dimensionally infinite, corrugated net of hexagons [1]. In contrast, in barium disilicide $BaSi_2$ [2], sodium silicide NaSi [3], and potassium silicide KSi [4], isolated Si_4 tetrahedra occur.

In strontium disilicide $SrSi_2$, the silicon atoms form a three-dimensional framework. The shortest Si–Si distances are 2.41 Å and thus comparable with those in elemental silicon (2.34 Å). The Si–Si–Si angles are 113° 2′ each, *i.e.* very close to the angles in a regular tetrahedron. As the electronegativity of the Group II elements decreases, the shortest Si–Si distance falls off from 2.48 Å in $CaSi_2$ via 2.41 Å in $SrSi_2$ to 2.34–2.37 Å in $BaSi_2$. Despite the differences in the structural framework of the silicon in these three compounds, each silicon atom is linked directly to three neighboring silicons. Each strontium atom in $SrSi_2$ is surrounded by six silicon neighbors at distances of 3.21 Å and two further silicons at 3.43 Å.

Crystallographic data for $SrSi_2$:

Cubic pentagonal-icositetrahedral, space group O^6–$P4_232$, a = 6.540 ± 0.002 Å; d_m = 3.40 ± 0.05 g/cm³; d_x = 3.42 g/cm³.

The unit cell contains four Sr atoms, which occupy the 4a positions, and eight silicon atoms in the 8c positions of the space group with x = 0.428. The minimum for the discrepancy index R is very unsharp as a function of x_{Si}.

x_{Si}	0.420	0.422	0.424	0.426	0.428	0.430	0.434
R	0.14_3	0.12_8	0.11_4	0.10_9	0.10_8	0.11_4	0.16_5

Hence the parameter x cannot be given with very great accuracy. When x = 0.428, R for the series (hk0) becomes 0.10_8, for the series (hk1) 0.09_2, and for the series (hk2) 0.11_4. In work with the $Cu_{K\alpha}$ radiation, "Umweganregung" is observed.

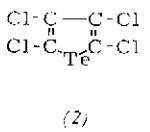
Preparation of Tetrachlorotellurophene and Tetrachloroselenophene

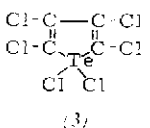
By Dr. W. Mack

Consortium für elektrochemische Industrie GmbH., München (Germany)

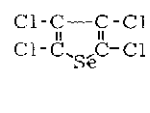
The ring system of tellurophene was so far known only from the synthesis of its tetraphenyl derivative [1]. We have now prepared tetrachlorotellurophene *(2)* by the reaction of hexachloro-1,3-butadiene *(1)* with tellurium.



(2)



(3)



(5)

Finely pulverized tellurium (0.3 mole) is shaken for 40 h at 250 °C with 0.1 mole of *(1)*. The tellurium tetrachloride formed

is removed with concentrated hydrochloric acid. Distillation of the organic phase affords 13.1 g (14%) of *(2)*, b.p. 31 °C/0.02 mm, yellow needles, m.p. 49 °C from methanol. It has λ_{max} = 295 mμ, log ε = 4.05 in cyclohexane, and infrared absorptions at 695 (m), 805 (s), 1000 (m), 1230 (s), and 1490 (m) cm^{-1} [2].

The new compound readily absorbs 1 mole of chlorine, being converted quantitatively into hexachlorotellurophene *(3)*, bright yellow crystals, m.p. 200 °C. When a suspension of *(3)* in benzene is shaken with aqueous sodium hydrogen sulfite, it is reconverted quantitatively into *(2)*.

In contrast to *(2)*, the hexachloro derivative *(3)* is decomposed rapidly by aqueous alkali to 1,2,3,4-tetrachloro-1,3-butadiene *(4)*, tellurous acid, and alkali chloride. This ring cleavage and the elemental analyses prove the structures of *(2)* and *(3)*. In view of its formation from *(3)*, it appears that *(4)*, m.p. 51 °C, n_D^{60} = 1.5438 [3], has the *cis,cis*-configuration [4].

The hitherto unknown tetrachloroselenophene *(5)* can be prepared by a synthesis analogous to that of *(2)* [5]. Selenium (0.3 mole) is shaken for 20 h at 250 °C with 0.3 mole of *(1)*. The reaction mixture is poured into acetone to reduce the Se_2Cl_2 formed. Distillation then affords 25.8 g (32%) of *(5)*, b.p. 127 °C/15 mm, colorless needles, m.p. 35 °C from ethanol. Compound *(5)* has λ_{max} = 266 mμ, log ε = 3.97 in cyclohexane, and infrared absorptions at 740 (s), 843 (s), 1033 (m), 1270 (m), and 1510 (m) cm^{-1} [2].

Isonitrilocyclopentadienyl Complexes of Lanthanides

By Prof. Dr. E. O. Fischer and Dipl.-Chem. Hartmut Fischer

Anorganisch-Chemisches Laboratorium der Technischen Hochschule München (Germany)

The reaction of tricyclopentadienyl compounds of lanthanides with cyclohexyl isonitrile at 20 °C in benzene leads to novel complexes of formula $M(C_5H_5)_3CNC_6H_{11}$. These are the first compounds in which isonitriles are linked to rare-earth metals and in which a stable metal-carbon σ-bond is formed with such metals.

So far we have isolated green $Yb(C_5H_5)_3CNC_6H_{11}$, m.p. 167 °C *(1)*, yellow $Ho(C_5H_5)_3CNC_6H_{11}$, m.p. 165 °C *(2)*, and colorless $Tb(C_5H_5)_3CNC_6H_{11}$, m.p. 162 °C *(3)* in analytical purity. The crystalline substances can be sublimed *in vacuo* and dissolve well in benzene and ethers, but are only slightly soluble in pentane and hexane. They are thermally stable and decompose only above 240 °C. The action of oxygen and water results in rapid decomposition.

The infrared spectra (recorded in Nujol/Hostaflon mulls) of the three compounds are very similar, and show, as expected, one sharp ν_{CN} band at 2205 cm^{-1} (the ν_{CN} band of the free ligand lies at 2130 cm^{-1}). Further bands occur at 3077, 1449, 1014, and 787/759 cm^{-1}, and have been assigned to ν_{CH}, ω_{CC}, δ_{CH}, and γ_{CH} vibrations of the symmetrical five-membered ring.

All three compounds are paramagnetic; their magnetic moments were measured by the susceptibility method in benzene using NMR methods [1,2]. The values obtained for μ_{eff} were 4.5 B.M. for *(1)*, 10.6 B.M. for *(2)*, and 10.1 B.M. for *(3)*.

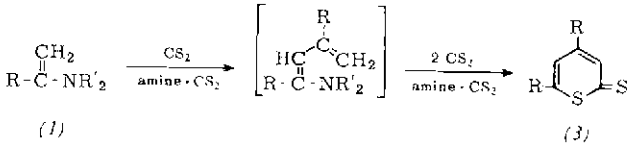
α-Dithiopyrones from Enamines and Carbon Disulfide [1]

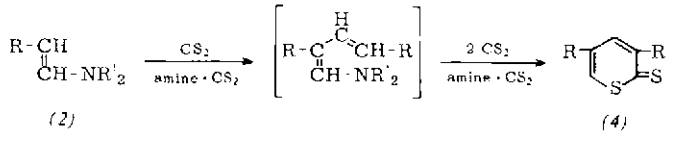
By Prof. Dr. Roland Mayer and Dipl.-Chem. J. Wehl

Institut für Organische Chemie der Technischen Universität Dresden (Germany)

Carbon disulfide reacts with enamines of type *(1)* or *(2)* at room temperature and atmospheric pressure to give α-dithiopyrones. 2-Aminoalkenes *(1)* generally yield 4,6-disubstituted derivatives *(3)*, while 1-aminoalkenes yield 3,5-disubstituted products *(4)*. The yields vary widely but are usually over 50%.



(1) *(3)*



(2) *(4)*

The dienamines indicated as intermediates react analogously if their steric configuration is correct. Thus, the parent compound α-dithiopyrone [2] can be prepared from 1-amino-1,3-butadiene [3].

Example: In order to prepare 4,6-diphenyl-α-dithiopyrone *(3)*, R = C_6H_5, 100 g of 1-pyrrolidinyl-1-phenylethylene *(1)*, R = C_6H_5, NR'_2 = pyrrolidinyl, are dissolved in 200 ml of anhydrous dioxane, and 200 ml of carbon disulfide are added with stirring over 10 min, initially at a temperature of 60 °C. The mixture is stirred for 1 h, the excess CS_2 is distilled off, and 200 ml of a 1:4 mixture of methanol and water are stirred in. The product *(3)* is then extracted from the dark red mass with chloroform. The yield is 60–68 g or 74–84% of shiny red needles, m.p. 113 °C from dioxane/methanol, λ_{max} in ethanol at 245 mμ (log ε = 4.16), 308 (4.17), 477 (3.64).

Synthesis of Cyclopropanols from β-Chloroethyl Cyclopropyl Ethers

By Dr. J. Paust and Prof. Dr. U. Schöllkopf

Organisch-Chemisches Institut der Universität Göttingen (Germany)

If β-chloroethyl dichloromethyl ether [1] is treated with methyl-lithium/lithium iodide [2] in the presence of olefins [3], β-chloroethyl cyclopropyl ethers are obtained. These ethers can be readily converted into cyclopropanols by two routes [4]: a) by dehydrochlorination with base and

subsequent acidic hydrolysis of the resulting cyclopropyl vinyl ethers, or b) by cleavage with butyl-lithium and hydrolysis of the resulting lithium cyclopropoxides.

Olefin	Cyclopropanol	B.p. [°C/mm]	Yield [%] [a]
Isobutene	2,2-Dimethyl-	65–70/80	a) 71 b) 92
Tetramethyl-ethylene	2,2,3,3-Tetramethyl-	54–56/13	a) 61 b) 90
Cyclohexene	*exo/endo*-7-hydroxy-bicyclo[4,1,0]heptane	83–86/13	a) 57 b) 94
Cyclooctene	*exo/endo*-9-Hydroxy-bicyclo[6,1,0]nonane	75–79/0.6	b) 91

[a] Based on β-chloroethyl cyclopropyl ether.

7-Hydroxybicyclo[4,1,0]heptane

By Method a): Potassium hydroxide (80 g) is melted on an oil bath at 250 °C, and 20 g of *exo/endo*-7-bicyclo[4,1,0]-heptyl β-chloroethyl ether are added dropwise with stirring over 45 min. The resultant vinyl ether is distilled off over a fractionating column 15 cm long (63 % yield, b.p. 56–59 °C/13 mm). This product is added dropwise over 10 min to a mixture of 150 ml of glycol dimethyl ether and 150 ml of 0.3 N sulfuric acid at 50 °C. The solution is neutralized with sodium hydrogen carbonate and extracted with ether.

By Method b): 130 ml of a 1 N solution of butyl-lithium in ether are added dropwise at room temperature to a solution of 10 g of *exo/endo*-7-bicyclo[4,1,0]heptyl β-chloroethyl ether in 50 ml of ether until the Gilman test [5] becomes positive. The reaction mixture is poured into 400 ml of a saturated solution of sodium hydrogen carbonate, and the product is extracted with ether.

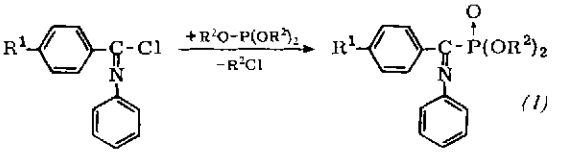
Synthesis of N-Phenyliminobenzylphosphonates and Benzoylphosphonates by Michaelis-Arbusow Reaction of Aromatic Imidoyl Chlorides

By Prof. Dr. G. Hilgetag, Dipl.-Chem. K. Zieloff, and Dr. H. Paul

II. Chemisches Institut der Humboldt Universität zu Berlin (Germany)

The reaction of *N*-phenylbenzimidoyl chlorides with trialkyl phosphites produces good yields of dialkyl phenyliminobenzylphosphonates *(1)*.

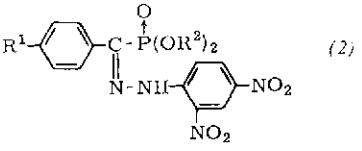
Triethyl-, tri-n-propyl-, tri-isopropyl-, and tri-n-butyl phosphites react with *N*-phenylbenzimidoyl chloride or its *p*-chloro, *p*-bromo, *p*-methoxy, and *p*-nitro derivatives at 130–160 °C. A temperature of 110–130 °C suffices for the reaction with trimethyl phosphite. The azomethines *(1)* are yellow oils, but only compounds *(1a)–(1e)* could be obtained analytically pure by vacuum distillation.



(1)

	R^1	R^2	M.p. [°C/mm]	n_D^{20}	Yield [%]
(1a)	H	C_2H_5	151–152/0.1	1.5626	75
(1b)	H	C_3H_7	157.5–158/0.03	1.5558	65
(1c)	H	C_4H_9	170–171/0.04	1.5460	74
(1d)	CH_3	C_2H_5	159/0.03	1.5661	63
(1e)	Cl	C_2H_5	155/0.005	1.5742	74

Without exception, the phenyliminobenzylphosphonates *(1)* could be hydrolysed with dilute sulfuric acid at 50 °C to give aniline and the corresponding benzoylphosphonates, which were isolated as their 2,4-dinitrophenylhydrazones *(2)*.



(2)

R^2	M.p. [°C]	R^2	M.p. [°C]

C_4H_9	116.5–118	C_4H_9	127.5–129

N-Methylbenzimidoyl chloride reacts analogously with trialkyl phosphites to give pale greenish-yellow azomethines, from which 2,4-dinitrophenylhydrazones *(2)*, R^1 = H, can be obtained in a one-stage reaction by hydrolysis and condensation with 2,4-dinitrophenylhydrazine in aqueous ethanol containing sulfuric acid.

These investigations show that the Michaelis-Arbusow reaction can be applied to any *N*-substituted aromatic benzimidoyl chloride. To our knowledge only one example [1] of this type of reaction has so far been published.

Coordination Chemistry

The 8th International Conference on Coordination Chemistry was organized by the Verein Österreichischer Chemiker (*A. Maschka*) and was held in Vienna (Austria) from September 7th to 11th, 1964 under the chairmanship of *V. Gutmann*. There were 850 participants from 34 countries, and the 155 lectures and discussions were dedicated to three major problems: the nature of the chemical bond in coordination compounds, novel coordination compounds, and new results and methods in coordination chemistry in solution [1].

Plenary Lectures [2]:

New Approaches to the Theory of Complex Ions and Their Physical Foundations

H. Hartmann, Frankfurt/Main (Germany)

A "united atom model" for complex compounds has been developed which affords information beyond the limitations of the ligand field theory (crystal field theory) with reasonable calculatory effort, provided the mathematical operations are carried out precisely, and which is still applicable even when MO–LCAO calculations fail owing to non-orthogonality of the functions belonging to the various centers involved. In this model, use is made of hydrogen-like single-center functions which correspond in their symmetry and in the nature and number of their nodal surfaces to MO–LCAO multicenter functions. In the Hamiltonian operator, a term c/r_2 is included for correction; the only parameters used are a variation parameter ($Z_{effective}$) and a free parameter (c in the term c/r_2). This model gives very close agreement with experimental data for Ti(III) and V(III) complexes.

Metal-Metal Interactions in Coordination Compounds

L. Lewis, Manchester (England)

Compounds with metal-metal bonds between the same elements have so far been found for all transition elements with the exceptions of zinc and metals of the scandium group. Here the elements occur in any oxidation state from +5 to −1 and with electronic configurations (of the electrons not bonded to ligands or anions) d^1–d^1 to d^9–d^9 and s^1–s^1; d^6–d^6 is never observed. They also occur in the most diversified structural arrangements, *e.g.* Mo in $[\overset{+5}{Mo}(OC_6H_5)_3Cl_2]_2$ (d^1–d^1), $[\overset{+4}{Mo}O_2]_x$ (d^2–d^2), $[\overset{+3}{Mo}_2Cl_9]^{3-}$ (d^3–d^3), $[\overset{+2}{Mo}Cl_2]_x$ (d^4–d^4), $[\overset{+1}{Mo}(\pi\text{–}C_5H_5)(CO)_3]_2$ (d^5–d^5), and $[\overset{-1}{Mo}_2(CO)_{10}]^{2-}$ (d^7–d^7). The tendency for M–M bonds to be formed is greater in the second and third periods of transition elements as well as in higher groups of transition elements and at lower states of oxidation of the elements. Frequently there are ligand bridges in addition to the M–M bonds. Occasionally structural units are observed where 3, 4, 5, or 6 metal atoms are intercombined and remain together even in solution. Thus, for example, there are always 3 atoms of rhenium at the corners of the equilateral triangle in the entities $[ReCl_3]_n$, $[(R_3P)_3Re_3Cl_9]$, $[Re_3Cl_{11}]^{3-}$, and $[Re_3Cl_{12}]^{3-}$. A M≡M triple bond is postulated in the diamagnetic ion $[W_2Cl_9]^{3-}$ since the W–W distance (2.40 Å) here is much shorter than in tungsten metal (2.74 Å). M–M quadruple bonds even occur in $[Cr(CH_3COO)_2]_2$ and in the diagmagnetic ion $[Re_2Cl_8]^{2-}$, where the Re–Re distance (2.27 Å) is extremely short and overlap of d_{z^2} (= σ), d_{xz} and d_{yz} (= π), and d_{xy} (= δ) orbitals occurs.

The number of compounds with σ-M–M bonds between two different metals is still relatively small. The combinations observed are V–Au, W–Mo, W–Au, Mo–Fe, Mn–Re, Mn–Fe, Mn–Co, Mn–Cu, Mn–Au, Fe–Co, Fe–Ni, Fe–Cu, Fe–Ag, Fe–Au, Fe–Hg, Co–Cu, Co–Ag, Co–Au, Rh–Hg, Ir–Hg, Pd–Pt, and Pt–Cu. Atoms with a $d^{10}s^1$ configuration form particularly strong bonds. Thus, the bond energy for Au–Au is 51.5 kcal/mole, for Cu–Au 54.5, for Ag–Au 47.6, for Cr–Au 50.4, and for Sn–Au 57.5 kcal/mole. σ-Metal-metal bonds can be strongly influenced by back-donation from the metals to ligands and from ligands to the metals, by π-M–M bonds, by repulsion effects from non-bonding orbitals, and by steric requirements. Metal-metal bonds are best recognized by combination of Raman and infrared spectroscopy (M–M frequencies lie below 200 cm^{-1}), X-ray structural analysis, and magnetic measurements. There is considerable variance in the lengths of the bonds observed to date for individual elements depending on the strengths of the bonds in question.

Tetrahedral and Octahedral Cationic Chelates of Main Group Elements

E. L. Muetterties, Wilmington, Del. (U.S.A.)

Salts such as $[L_2BH_2]^{\oplus}X^{\ominus}$ with ligands L = R_2S, R_3N, R_3P, and R_3As can be prepared according to Equations (a) and (b)

$$LBH_3 + LH^{\oplus}X^{\ominus} \rightarrow H_2 + [L_2BH_2]^{\oplus}X^{\ominus} \quad (a)$$

$$[L_2BH_2]^{\oplus} + 2\,L' \rightarrow 2\,L + [L'_2BH_2]^{\oplus} \quad (b)$$

as well as by the reaction of LBH_3 with B_2H_6, which leads with evolution of hydrogen to $[L_2BH_2]^{\oplus}$ $[B_{12}H_{11}L]^{\ominus}$. Compounds of the type $[L_2BH_2]^{\oplus}OH^{\ominus}$ are strong bases, $[L_2BH_2]^{\oplus}Cl^{\ominus}$ are strong electrolytes. The cation $[(R_3N)_2BH_2]^{\oplus}$ is remarkably stable. It is not attacked by concentrated sulfuric, hydrochloric, or nitric acid, alkalies, $Au^{3\oplus}$, 30 % H_2O_2 up to 100 °C, I_2, or Friedel-Crafts reagents. When heated at 100 °C with *aqua regia*, the complex is converted without decomposition into $[(R_3N)_2BHCl]^{\oplus}$. Its salts decompose according to Equation (c) below 180 °C in the presence of small, compact anions (X = Cl, Br, or N_3).

$$[(R_3N)_2BH_2]^{\oplus}X^{\ominus} \rightarrow R_3NBXH_2 + NR_3 \quad (c)$$

Amine exchange occurs above 150 °C, *e.g.* according to Equation (d).

$$[(R_3N)_2BH_2]^{\oplus} + R_2NC_2H_4NR_2 \rightarrow [(R_2NC_2H_4NR_2)BH_2]^{\oplus} + 2\,NR_3 \quad (d)$$

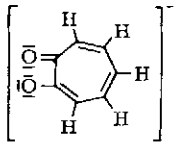
For theoretical reasons, this can be preceded only by a dissociation equilibrium [Equation (e)].

$$[(R_3N)_2BH_2]^{\oplus} \rightleftharpoons [H_2BNR_3]^{\oplus} + NR_3 \quad (e)$$

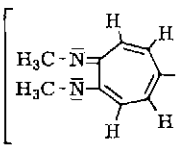
Substitution of the hydrogen atoms can be achieved only by means of radical reactions. Thus, $[(R_3N)_2BH_2]^{\oplus}$ reacts with fluorine in aqueous solution to give $[(R_3N)_2BF_2]^{\ominus}$, with FSO_2OOSO_2F to give $[(R_3N)_2B(OSO_2F)_2]^{\oplus}$, and with ICl to give $[(R_3N)_2BCl_2]^{\oplus}$. The stability of the other complexes decreases in the series $R_3N > R_3P > R_3As > R_2S$.

[1] Abbreviations used in this report are: El = atom of an element, L = ligand, M = metal, R = organic ligand, THF = tetrahydrofuran, s* = s/p hybrid orbitals.

[2] Complete and partially extended versions of the plenary lectures will be published in the Journal of Pure and Applied Chemistry.



(1)



(2)

The anions $(C_7H_5O_2)^{\ominus}$ *(1)* and $(C_9H_{11}N_2)^{\ominus}$ *(2)* derived from tropolone and its methylaminomethylimino derivative, respectively, give rise to pseudotetrahedral (D_{2d}) cations $(C_7H_5O_2)_2B^{\oplus}$ and $(C_9H_{11}N_2)_2B^{\oplus}$. The salt $(C_7H_5O_2)_2B^{\oplus}Br^{\ominus}$ is a strong 1:1 electrolyte, $(C_9H_{11}N_2)_2B^{\ominus}OH^{\ominus}$ is a strong base. Salts of the pseudo-octahedral ions $(C_9H_{11}N_2)_3El^{\oplus}$ with El = Si, Ge, or Sn are also strong electrolytes. On the other hand, $(C_7H_5O_2)_3SnCl$ and $(C_7H_5O_2)_3SnC_6H_5$ – which can be sublimed – are non-electrolytes with seven-coordinated tin. Experiments with ^{18}OH have revealed that hydrolysis of $(C_7H_5O_2)_3El^{\oplus}$ proceeds primarily by substitution on the ligands and not by attack of the central atom. Other ions produced included $(C_7H_5O_2)_3P^{2\oplus}$ (from PCl_5 and 3 $C_7H_6O_2$), $(C_7H_5O_2)_2As(OH)_2^{\oplus}$ and the eightfold coordinated compounds $(C_7H_5O_2)_4Nb^{\oplus}Cl^{\ominus}$ and $(C_7H_5O_2)_4Ta^{\oplus}Cl^{\ominus}$. Hydrolysis of $(C_7H_5O_2)_4Nb^{\oplus}$ yields $(C_7H_5O_2)_3NbO$, but $(C_7H_5O_2)_4Ta^{\oplus}$ is not markedly hydrolysed even at 140 °C.

The Role of Organometallic Compounds in the Development of Coordination Chemistry

F. G. A. Stone, Bristol (England)

Starting from π-$C_5H_5V(CO)_4$, $Fe(CO)_5$, $HMn(CO)_5$, and $NaMn(CO)_5$, complex compounds containing metal-carbon bonds were prepared whose investigation led to the discovery of novel classes of compounds and which have brought decisive advances in the development of coordination chemistry and organometallic chemistry. Thus, $C_5H_5V(CO)_4$ reacts with cycloheptatriene to give a π-aromatic complex $(C_7H_7)V(C_5H_5)$ in which V has the oxidation state zero. The weakly paramagnetic compound $[\pi$-$C_5H_5V(SCH_3)_2]_2$, which is also prepared via $C_5H_5V(CO)_4$, is a binuclear complex with four $S(CH_3)$ bridges and strong V–V bonds. Paramagnetism occurs within the thermic range. Iron pentacarbonyl is substituted even at room temperature according to Equation (f) to give σ-perfluoroalkyliron complexes (n = 1, 2, or 3).

$$Fe(CO)_5 + C_nF_{2n+1}I \rightarrow CO + C_nF_{2n+1}Fe(CO)_4 \qquad (f)$$

π-$C_5H_5Co(CO)$ $(C_nF_{2n+1})I$ or π-$C_5H_5Ni(CO)$ (C_nF_{2n+1}), for example, can be prepared analogously. $Fe(CO)_5$ reacts with dibutyldivinyltin to give $[(C_4H_9)_2SnFe(CO)_4]_2$. $Mn(CO)_4NO$ is a compound that is isosteric with $Fe(CO)_5$ and has a trigonal bipyramidal structure; it is a deep red diamagnetic liquid which decomposes on exposure to air and whose vapors are similar to those of bromine. It is formed from $HMn(CO)_5$ and p-CH_3–$C_6H_4SO_2$–NCH_3–NO in ether at 25 °C in the dark. Tetrafluoroethylene adds onto $HMn(CO)_5$ in pentane at 20 °C and 2 atm to give $H(CF_2)_2Mn(CO)_5$. Analogous reactions were achieved with the carbonyl hydrides of W, Re, and Fe and with $RMn(CO)_5$ (R = CH_3 or C_6H_5) on the one hand and with $ClFC{=}CF_2$, $Cl_2C{=}CF_2$, and $F_3C{-}C{\equiv}C{-}CF_3$ on the other. $NaMn(CO)_5$ reacts with π-$C_5H_5Fe(CO)_2I$ or $Re(CO)_5Cl$ to give π-$C_5H_5(CO)_2Fe$–$Mn(CO)_5$ or $(CO)_5Re$–$Mn(CO)_5$, *i.e.* carbonyl complexes with a covalent hetero-metal-metal bond. With perfluoroalkylcarbonyl chlorides it reacts to give compounds of the type $C_nF_{2n+1}COMn(CO)_5$, which on heating decompose into CO and $C_nF_{2n+1}Mn(CO)_5$. An analogous reaction takes place according to Equation (g).

$$2\ C_3F_7COCl + Na_2Fe(CO)_4 \rightarrow 2\ NaCl + 2\ CO + (C_3F_7)_2Fe(CO)_4 \qquad (g)$$

σ-Perfluoroalkylmetal complexes are generally very stable and have confirmed the theoretical predictions by *Orgel* that additional CO valence frequencies should appear in the infrared spectra of carbonyl complexes with distorted symmetry owing to splitting of the E bands and appearance of an additional B_1 band.

Intermediates in the Electrode Reactions of Coordination Compounds

A. A. Vlček, Prague (Czechoslovakia)

Redox processes at inert polarized electrodes differ from those occurring with redox reagents in homogenous solution. They sometimes take a different course, and in the case of complex ions, often proceed via a number of chemical transformations not occasioned by redox processes, *e.g.* alterations of the type or number of ligands attached to the complex.

$$D_1 \rightleftharpoons D_2 \rightleftharpoons \ldots D_n \xrightarrow{+e^-} D_n^- \rightleftharpoons \ldots D_z^-$$

Only the particle with the greatest redox activity (D_n) reacts at the electrode. If the rates of the subsequent chemical transformations $D_n^- \rightarrow D_z^-$ are slow, it is possible to detect otherwise unrecognizable intermediates by polarography at a dropping mercury electrode and even occasionally to prepare the species by electrolysis. Thus, $[Mn(dipy)_3]^{2\oplus}$ is reduced at −1.5 volt in 1 M alcoholic LiCl to stable $[Mn(dipy)_3]^{\oplus}$, which had hitherto never been isolated in the form of salts; beyond −1.6 volt reduction of the dipyridyl ligands begins. On homogeneous reduction in aqueous systems, $[Ni(CN)_4]^{2\ominus}$ leads to $[Ni_2(CN)_6]^{4\ominus}$, and in liquid ammonia to $[Ni(CN)_4]^{4\ominus}$. It can be concluded from electrode processes that it is always the complex of nickel with the oxidation state zero that is formed first and that this is rapidly oxidized by water to give $[Ni_2(CN)_6]^{4\ominus}$. The primary product of electrode reduction of $[Cr(CN)_5NO]^{3\ominus}$ is $[Cr(CN)_5NO]^{4\ominus}$, which can be isolated as such by electrolysis in 0.1 M NaOH; however, below pH 9.5 the species is decomposed by addition of two protons or because further reduction occurs. Rapid oxidation of $[Co(dipy)_3]^{\oplus}$ in the presence of catalytic amounts of $[Cr(CN)_5NO]^{3\ominus}$ in homogeneous solution proceeds via the steps shown in Equations (h) and (i).

$$[Co(dipy)_3]^{\oplus} + [Cr(CN)_5NO]^{3\ominus} \rightarrow [Co(dipy)_3]^{2\ominus} + [Cr(CN)_5NO]^{4\ominus} \qquad (h)$$

$$[Cr(CN)_5NO]^{4\ominus} + H^{\oplus} \rightarrow [Cr(CN)_5NO]^{3\ominus} + H \qquad (i)$$

From the Research Reports [3]:

The major accent of preparative and synthetic coordination chemistry still lies on the field of carbonyl, π-aromatic, and π-olefin complexes, although increasing attention is being paid to the corresponding σ-compounds. New aspects worthy of inclusion in textbooks have appeared in the preparation of σ-metal-metal compounds and also in the detection of multiple bonds in oxo complexes of transition metals (*e.g.* in $\rangle VO$ or $\rangle CrO_2$), whose structures (*e.g.* $\rangle \overset{\oplus}{V}{\equiv}\overset{\oplus}{O}$ analogous to $\overset{\ominus}{C}{\equiv}\overset{\oplus}{O}$) explains their stability even towards protons. X-ray structural analysis and magnetic measurements (together with ESR and NMR spectroscopy) are still the most important aids for elucidating the details of the structures of coordination compounds; novel possibilities are offered by application of the Mössbauer effect [*E. Fluck*, Heidelberg (Germany); *I. Danon*, Rio de Janeiro (Brazil)]. In the following, a short review will be given of the most important results of preparative and synthetic coordination chemistry reported.

[3] Cf. *V. Gutmann*: Proceedings of the 8th International Conference on Coordination Chemistry. Springer, Vienna-New York 1964.

Metal-Metal Compounds

Metal-metal bonds occur in pure metals (Cu), metallic alloys (Cu/Zn), and salt-like alloys ($Cs^{\oplus}Au^{\ominus}$), as well as in compounds of transition metals with low states of oxidation ("$MoCl_2$" ~ $[Mo_6Cl_{12}]$; Ta_6Cl_{14}), in s*-donor compounds ($[Pt(SnCl_3)_4]^{2\ominus}$) and d-donor compounds (Ni-diacetyldioxime), and finally in distinctly covalent σ-bonding species such as s*/s* (Hg_2Cl_2), s*/d ($[(C_6H_5)_3PAuMn(CO)_5]$), and d/d ($[Mn_2(CO)_{10}]$). Classes of compounds prepared for the first time were $L{\cdot}M{-}M'(CO)_n$, pale yellow to clear brown solids with melting points between 80 and 200 °C (L = $(C_6H_5)_3P\rightarrow$, $H_3C{-}C[CH_2As(CH_3)_2]_3\rightrightarrows$, $H_3C{-}As[C_6H_4{-}O{-}As(CH_3)_2]_2\rightrightarrows$; M = Cu, Ag, or Au; M' = V, W, Mn, Fe, or Co; and n = 4,5, or 6) [*R. S. Nyholm*, London (England)], and $L_3X_2M{-}HgX'$ and $L_2X_3M'{-}HgX'$ (L = $(C_6H_5)_2AsCH_3$ or $(C_6H_5)_3P$; M = Rh or Os; M' = Ir; X = Cl, Br, or CO; and X' = F, Cl, Br, I, CN, or SCN) [*K. Vrieze*, London (England)].

Crystallographic analysis of $(C_6H_5)_3P\rightarrow Au{\cdot}Mn(CO)_5$ indicated a linear P–Au–Mn arrangement with an Au–Mn distance of 2.47 Å (r_{Au} = 1.2 and r_{Mn} = 1.27 Å), whereas the bonding radius of the Mn in $Mn_2(CO)_{10}$ is 1.46 Å and in $(C_6H_5)_2Sn[Mn(CO)_5]_2$ is 1,31 Å; here the two Sn–Mn distances are both 2.70 Å [*H. M. Powell*, Oxford (England)]. In the violet crystals of composition $K_{1,6}Pt(C_2O_4)_2{\cdot}2.5\ H_2O$ (Pt–Pt = 2.76 Å) and $K_2Pt(CN)_4Cl_{0,2}$ (Pt–Pt = 2.83 Å), the Pt–Pt distances are unusually short [*K. Krogmann*, Stuttgart (Germany)]. Investigations of the structures of the cations $[M_6X_{12}]^{2\ominus}$, where M = Nb or Ta and X = Cl or Br, revealed an octahedral arrangement of the equivalent metal atoms – formally 2 $M^{3\oplus}$ and 4 $M^{2\ominus}$ is expected – with strong M–M bonds [*M. B. Robin*, Murray Hill, N.J. (U.S.A.)]. Molybdenum(II) chloride reacts with pyridine or $(C_6H_5)_3P$ to give the non - electrolytes $(Mo_6Cl_8)Cl_4L_2$ and the electrolytes $[(Mo_6Cl_8)Cl_3L_3]Cl$ and $[(Mo_6Cl_8)Cl_2L_2(ROH)_2]Cl_2$ [*C. J. Wilkins*, Christchurch (New Zealand)].

Carbonyl Compounds

Vanadium hexacarbonyl reacts with benzene with liberation of 2 moles of CO to form $[V(CO)_4C_6H_6][V(CO)_6]$, which can be converted into the compounds $[V(CO)C_6H_6]PF_6$ and $[V(CO)_4C_6H_6][B(C_6H_5)_4]$ [*E. Calderazzo*, Geneva (Switzerland)]. Trimeric $[Mn(CO)_4]_3$ and polynuclear derivatives $[M(CO)_4]_x$ where M = Mn, Tc, or Re were formed during attempts to prepare $M(CO)_5H$ [*H. Kaesz*, Los Angeles, Calif. (U.S.A.)]. New hydrides and carbonyl hydrides of iridium were obtained by *L. Malatesta*, Milan (Italy): H_3IrL_2 (m.p. 145°C), H_3IrL_2py (m.p. 134°C), $HIr(CO)L_2$, and $H_3Ir(CO)L_2$ with the isomers *cis,cis-*, and *trans*-H, and *cis*-L, where L = $(C_6H_5)_3P$. Carbonyl acetylene complexes of tungsten such as $(RC{\equiv}CR')_3W(CO)$ with R and R' = CH_3, C_2H_5, and C_6H_5 [*D. Tate*, Akron, Ohio (U.S.A.)], of iron such as $(RC{\equiv}CR')Fe(CO)_4$ (yellow), $(RC{\equiv}CR)_2Fe_2(CO)_6$, $(RC{\equiv}CR)_3Fe_2(CO)_6$, $(RC{\equiv}CR)_2COFe_2(CO)_6$, $(RC{\equiv}CR')Fe_2(CO)_7$ (dark-green), and $(RC{\equiv}CR')Fe_3(CO)_9$ [*C. Hoogzand*, Brussels (Belgium)], and of cobalt such as $[(CH_3)_3C{-}C{\equiv}CH]$, $(HC{\equiv}CH)Co_2(CO)_4$, and $(HC{\equiv}CH)Co_2(CO)_9$ [*O. S. Mills*, Manchester (England)] were prepared and their occasionally unusual constitutions elucidated. *M. Tsutsui*, New York, N.Y. (U.S.A.) treated estrone with $Cr(CO)_6$ and acetylergosterol as well as vitamin A acetate with $Fe_3(CO)_{12}$ and succeeded in isolating the derivatives estrone-$Cr(CO)_3$, acetylergosterol-$Fe(CO)_3$, and vitamin A acetate-$Fe(CO)_3$. The reaction of $Co_2(CO)_8$ with S_8 led depending on the Co : S ratio to $Co_3(CO)_9S$, $Co_3(CO)_7S_2$, or $[Co_2(CO)_5S]_n$ [*L. Marko*, Veszprem (Hungary)]. $(CO)_5Mn{-}SCN$ can be prepared from $(CO)_5MnNa$ with ClSCN and rearranges within 5 min at 25 °C in acetonitrile to its bond isomer $(CO)_5Mn{-}NCS$, but is reformed from the latter in suspension in Nujol within 5 h at 25 °C [*A. Wojcicki*, Columbus, Ohio (U.S.A.)]. $NaMo(CO)_3(C_5H_5)$ reacts with CH_3SCH_2Cl in THF at 25 °C to form $CH_3SCH_2Mo(CO)_3(C_5H_5)$ which on irradiation with ultraviolet light is transformed into $CH_3SCH_2Mo(CO)_3(C_5H_5)$; both compounds are yellow and melt at 66–67 °C, and both are supposed to involve π-bonds over the $CH_2{=}S{-}CH_3$ moieties. $(CH_3S)Fe(CO)_2(C_5H_5)$, m.p. 67–69 °C, is a monomer without sulfur bridges [*R. B. King*, Pittsburgh, Pa. (U.S.A.)]. *J. A. Ibers*, Upton, N.Y. (U.S.A.) succeeded *in elucidating the details* of the structures of the crystalline carrier of molecular oxygen $(O_2)IrCl(CO)[(P(C_6H_5)_3]_2$, which can be prepared from its components and is comparable with the O_2/oxyhemoglobin complex, and of the analogous complex $(SO_2)IrCl(CO)[P(C_6H_5)_3]_2$.

π- and σ-Complexes with Aromatics and Olefins

The reaction of triphenylcyclopropenyl bromide with $Ni(CO)_4$ in methanol leads to red crystals of the bromine-bridged binuclear complex $\{[\pi{-}(C_6H_5)_3C_3]Ni(CO)Br\}_2$ [*S. F. A. Kettle*, Sheffield (England)]. π-Tetraphenylcyclobutadienepalladium dibromide is obtained via diphenylacetylene and is substituted by triphenylphosphine to form octaphenylcubane according to Equation (k).

$$2\ [\pi{-}(C_6H_5)_4C_4]PdBr_2 + 4\ (C_6H_5)_3P \rightarrow 2\ [(C_6H_5)_3P]_2PdBr_2 + (C_6H_5)_8C_8 \quad (k)$$

Ligand exchange occurs with $[(C_6H_5)_3P]_2NiBr_2$ to form $[(C_6H_5)_3P]_2PdBr_2$ and $[(C_6H_5)_4C_4]NiBr_2$, and it reacts with $Fe(CO)_5$ to form $[(C_6H_5)_4C_4]Fe(CO)_3$ and with $(C_5H_5)Fe(CO)_2Br$ by transfer of the cyclopentadienyl group to yield $\{[(C_6H_5)_4C_4]Pd(C_5H_5)\}^{\oplus}FeBr_4^{\ominus}$ [*P. M. Maitlis*, Hamilton, Ont. (Canada)].

The complex $C_{13}H_{17}Ni(C_5H_5)$ formed from NaC_5H_5 and $[(CH_3)_4C_4]NiCl_2$ was recognized by X-ray structural analysis to be π-cyclopentadienyl-1,2,3,4-tetramethyl-1-cyclopenta-1',3'-dienocyclobutenylnickel(II), a representative of a completely new type of compound [*L. Dahl*, Madison, Wisc. (U.S.A.)]. The reaction of $ZrCl_3$ with cyclopentadiene at 200 °C leads to $(\pi{-}C_5H_5)ZrCl_3$. $ZrCl_4$ reacts with NaC_5H_5 to form yellow $(\pi{-}C_5H_5)_4Zr$. The $[(\pi{-}C_5H_5)_2ZrCl]_2$ formed from "$(C_5H_5)_2ZrCl_2$" and aniline reforms the "$(C_5H_5)_2ZrCl_2$" with HCl without liberation of hydrogen, hence there must be a hidden proton somewhere in this compound [*A. F. Reid*, Melbourne (Australia)]. *F. Jellinek*, Groningen (Holland) succeeded in preparing purple colored $(C_5H_5)_2Ti(C_3H_5)$, m.p. 118 °C, and a similar complex $(C_5H_5)_2Ti(CH_2C_6H_5)$. *M. Cais*, Haifa (Israel) reported on some metal complexes of the pentalene system, *e.g.* $[(C_8H_6)Mn(CO)_3]^{\oplus}X^{\ominus}$. Crystalline olefin complexes of silver of general formula $[Ag(RR'C{=}CR'R)]^{\oplus}BF_4^{\ominus}$ have π-bond character [*H. W. Quinn*, Sarna (Canada)]. The chlorine-bridged complex $[Cl_2Pd_2(\pi{-}C_4H_6Cl)_2]$ obtained from $PdCl_2(C_6H_5CN)_2$ and butadiene reacts rapidly with alcohols to yield $[Cl_2Pd_2(\pi{-}C_4H_6OR)_2]$. The complex $[Cl_2Pd_2(C_3H_4Cl)_2]$ can be prepared analogously with allene. Na_2PdCl_4 and allene form the π-complex $[Cl_2Pd_2(C_6H_8Cl)_2]$ [*S. Robinson*, Leeds (England)]. *Dahl* found that $[(\pi{-}C_3H_5)PdCl]_2$ crystallizes in the space group $C_{2h}{-}2/m$. The reactions with hydrogen and with sodium acetate of the [(diolefin) (ROH)PdCl] complexes which have a π-allyl structure were described by *E. J. Smutny*, Emeryville, Calif. (U.S.A.). Unstable complexes of allene and transition metals are highly active and selective catalysts for converting butadiene into cyclodecatriene, 4-methyl-1,3,6-heptatriene, or 1,2-polybutadiene, and for polymerizing ethylene in solution [*G. Wilke*, Mülheim/Ruhr (Germany)]. *S. F. Mason*, Exeter (England) reported on some σ-π-complexes of cobalt and iron, *e.g.* tricarbonyloctafluoro-1,3-cyclohexadienyliron, and *E. Kurras*, Jena (Germany) described σ-π-allylchromium complexes and the dark violet compound $Li_4[V(\sigma{-}C_6H_5)_6]$.

Complex and Addition Compounds of Main Group Elements

The methylammonium *N*-methylboranocarbamate formed according to Equation (I) from methylamine and borane carbonyl is converted by 2 moles of KOH in refluxing alcohol

$$2\,CH_3NH_2 + H_3BCO \rightarrow [CH_3NH_3]\,[CH_3NH{-}CO{-}BH_3] \quad (I)$$

via elimination of 2 moles of methylamine and 1 mole of water into fine crystals of dipotassium boranocarbonate $K^{\oplus}[^{\ominus}O{-}CO{-}\overset{\ominus}{B}H_3]K^{\oplus}$ which decomposes only on heating above 400 °C, which is converted into the hydrogen carbonate $K^{\oplus}[HO{-}CO{-}\overset{\ominus}{B}H_3]$ by titration with acids, and which forms coordination compounds with transition metals [*R. W. Parry*, Ann Arbor, Mich. (U.S.A.)]. The preparation of a yellow crystalline sublimable borazole addition compound $[-(CH_3)BN(CH_3)-]_3TiCl_4$ which dissolves readily in benzene was achieved by *H. Nöth*, Munich (Germany). Aminoborane forms soluble 1:1 complexes with iodine in inert solvents [*J. J. Lagowski*, Austin, Tex. (U.S.A.)]. Acetonitrile and tetramethyldiborane $[R_2BH]_2$ combine to form two isomers of the type $[H_3C{-}CH{=}N{-}B(CH_3)_2]_2$ of m.p. 76 and ca. −5 °C. Analogously, compounds of general formula $[RR'C{-}NAlR'_2]_2$ are formed from RCN and AlR'_3 at 150–250 °C [*K. Wade*, Durham (England).

B. J. Aylett, London (England) reported on silyl iodide addition products, *e.g.* $H_3SiI(py)_2$ and $H_3SiI(dipy)$, and their reactions. Novel complexes of aluminum and gallium with coordination number 4 were isolated by *H. Schmidbaur*, Marburg/Lahn (Germany) in compounds of the types $[-(R_3Si)O\text{-}AlR'_2-]_2$, $Na[R'_2Al(OSiR_3)_2]$, and $K[Ga(OSiR_3)_4]$; he also succeeded in preparing complexes of lithium with the coordination number 2 in the form of the compounds $M[Li(OSiR_3)_2]$, where M = Na (m.p. 233–235 °C) and K (m.p. 258–262 °C). *H. Bürger*, Graz (Austria) investigated transition metal bistrimethylsilylamides $M[N(SiR_3)_2]_n$, where M = Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, or Hg, which are mostly intensely colored liquids or crystals and are distillable or sublimate. From their infrared spectra and behavior toward Lewis bases it can be seen when and whether the lone pair of electrons on the nitrogen form π-bonds with the silicon or with the metal atom. Tetra- and pentafluoroorganylsilicates such as $[(C_2H_5)_4N]\,[CH_3SiF_4]$, $K_2[CH_3SiF_5]$, and $(NH_4)_4[F_5Si{-}CHCl{-}SiF_5]$ were prepared for the first time by *R. Müller*, Dresden-Radebeul (Germany) and are suitable as intermediates for separating methylchlorosilanes produced by direct synthesis, as carburating agents, or for the production of organomercury compounds. *M. Onyszchuk*, Montreal (Canada) managed to add two oxa rings $[-O(CH_2)_n-]_{ring}$ with n = 2, 3, 4, or 5 each onto SiF_4 and GeF_4, and simultaneously obtained $SiF_4[O(CH_3)_2]_2$, $GeF_4(CH_3OH)_2$, $GeF_4[OC(CH_3)_2]_2$, and $GeF_4O(CH_2)_4O$. The GeF_4 adducts are considerably more stable than the SiF_4 adducts. Some specially substituted phosphines and phosphites were examined in their capacity as complex-forming ligands, and compounds such as $(CO)_3Ni \leftarrow PR_2{-}B(NR'_2)_2$ or the cyclic derivative $[\rightarrow Ni(CO)_2 \leftarrow PR_2{-}B(NR_2){-}B(NR_2){-}R_2P \rightarrow]_{ring}$ (*Nöth*), octahedral complexes of Re(0), Re(II), Re(III), and Re(V), *e.g.* $[(R_2PCH_2CH_2PR_2)_2ReX_2]^{\oplus}X^{\ominus}$ [*E. S. Stern*, Runcorn (England)] or $Ni[\leftarrow P(OCH_2)_3C{-}CH_3]_4$ [*J. G. Verkade*, Ames, Iowa (U.S.A.)] were obtained. *K. Issleib*, Halle/Saale (Germany) synthesized such unusual compounds as $P[FeP(C_6H_5)_2]_3$, $P[Ti(PR_2)_2]_3$, or the cyclic complex $[-Fe{-}PR{-}PR{-}PR{-}PR-]_{ring}$. X-ray structural analysis of $K_4[As_2O_2F_8]$ indicated the space group $P2_1/n{-}C5_{2h}$ and the presence of a four-membered AsO ring [*W. Haase*, Jena (Germany)]. XeF_6 can be made to form complexes with Lewis acids; the colorless solids F_6XeBF_3, m.p. 90 °C, F_6XeAsF_5, and $F_6Xe(SbF_5)_2$ were isolated. They are extremely hygroscopic and react with moisture to form highly explosive XeO_3. Structures such as $F_6Xe \cdot BF_3$, $F_5Xe^{\oplus}AsF_6^{\ominus}$, and $F_4Xe(F_2SbF_4)_2$ came up for consideration [*H. Selig*, Argonne Ill. (U.S.A.)].

Miscellaneous

W. Beck, Munich (Germany) prepared some new fulminato complexes $M(CNO)_x$ (with M–C bonds), *e.g.* $HPt(CNO)(PR_3)_2$, $Ni(CNO)_2(PR_3)_2$, $Hg(CNO)_2(PR_3)_2$, the extremely stable category of compounds $(C_6H_5)_3El(CNO)$, where El = C, Si, Ge, Sn, or Pb, and the explosive complexes $(CH_3)_2Tl(CNO)$ and $(C_3H_7)_3Pb(CNO)$. *G. W. A. Fowles*, Southampton (England) reported on addition compounds of the type X_4TiL_2, X_3TiL_2, and Cl_3VL_2 in which X = Cl or Br, L = SR_2, and R = CH_3, C_2H_5, or $(CH_3)_2CH-$. *J. C. Carter*, Pittsburgh, Pa. (U.S.A.) obtained a labile complex $(C_5H_5)_2Ti(B_{10}H_{13})_2$ from $(C_5H_5)_2TiCl_2$ and $NaB_{10}H_{13}$. Dipole measurements on the compounds $[Cl_3ReNC_6H_5(PR_3)_3]$ and $[Cl_3ReO(PR_3)_3]$ suggested strong $\pi\text{-}\overset{\ominus}{R}e\equiv\overset{\oplus}{O}|$ and $\pi\text{-}\overset{\ominus}{R}e\equiv\overset{\oplus}{N}$ bonds, comparable with $\overset{\ominus}{C}\equiv\overset{\oplus}{O}$ or $\overset{\ominus}{C}\equiv\overset{\oplus}{N}{-}C_6H_5$ [*J. Chatt*, Welwyn (England)]. $Fe(dipy)_3$ has formally iron of zero valence and is obtained as deep green to black crystals from the reaction of $[Fe(dipy)_3]I_2$ and $Li_2(dipy)$ in THF or of $FeCl_3$ with dipyridyl and $Li_2(dipy)$; it dissolves in benzene to give a violet solution and is very sensitive to air and moisture [*S. Herzog*, Greifswald (Germany)].

[VB 874/178 IE]

German version: Angew. Chem. 77, 263 (1965)

Symposium on Macromolecular Compounds

The 3rd Symposium on Macromolecular Compounds took place at Zurich (Switzerland) on October 16th and 17th, 1964, the main subject of this year's discussion being additives to synthetic polymers.

From the lectures:

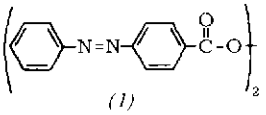
L. Dulog (Mainz, Germany) reported on the primary step in autoxidation. As ageing of synthetic polymers is mainly due to autoxidation, the initiation of this process is of interest. The primary step consists of a direct reaction of molecular oxygen with the organic compound. It precedes any autocatalytic oxidation which is initiated by peroxides present in the substrate. The primary reaction could be observed by analysing very small conversions in the autoxidation of n-butyl methacrylate and of tetralin. Some deviations from the usual kinetic relations were found. The mechanism could be derived from the kinetics of the autoxidation of styrene, indene, deuterated indene, and 1,1-dimethylindene. The primary step of the autoxidation was found to be a dehydrogenation of the organic compound by molecular oxygen, yielding free radicals.

H. Hartel (Troisdorf, Germany) dealt with inhibitors of the styrene polymerization. More than 100 inhibitors (quinones and their derivatives, nitroso compounds, phenols, amines, and hydrazines) were tested in concentrations of 10^{-2} mole-%. At 90 °C, the time of induction, *i.e.* the time elapsing before polymerization starts, was measured in relation to the inhibitor concentration. The results allowed some conclusions

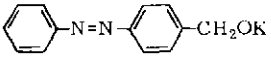
regarding the connection between inhibiting effect and chemical structure: The inhibiting effect of quinones decreases from *o*- to *p*-quinones, with the number of alkyl or halogen substituents, with the chain length of the alkyl groups, and with the number of rings. Introduction of hydroxy groups causes an increase of the inhibiting effect, provided that at least one position of the quinone ring is not substituted. The introduction of nitro groups into phenols (particularly at position 2), of nitroso groups, and of additional hydroxy groups increases the inhibiting effect, whereas aldehyde, keto, and halogen substituents have the opposite effect. Amino groups prolong the induction time only slightly less than hydroxy groups in the same position. Nitroso compounds inhibit more strongly than analogous phenols.

H. W. Schnecko (Mainz, Germany) reported on the polymerization of acrylonitrile with small amounts of silver nitrate in the solid state or in solution. The reaction which was examined in a homogeneous system (dimethylformamide as solvent) seems to involve a radical mechanism. An investigation into the part which the solvent plays, showed that the combination of amines with silver nitrate gives rise to very active catalysts which are far more active than pure $AgNO_3$ and approximately as active as redox catalysts. A stable complex between the monomer and silver nitrate has, so far, not been found. The action of silver nitrate on polyacrylonitrile causes considerable changes of properties which particularly affect the rate of ageing at higher temperatures.

H. Kämmerer (Mainz, Germany) discussed the introduction into polymers of unusual groups and in particular groups which can be determined colorimetrically in order to allow the elucidation of the polymer structure or of the mechanism of polymerization. The quantitative determination of such groups is carried out by extinction measurements. The groups should, therefore, possess strong absorptions which obey the Lambert-Beer law and are different from those of the polymer. Thus azo groups, which were introduced during the radical polymerization of styrene *via* the peroxide *(1)* or during polymerisation of ethylene oxide *via* the alcoholate *(2)*, could be analysed with at least the same degree of accuracy as radioactive groups.



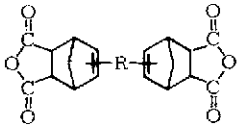
(1)



(2)

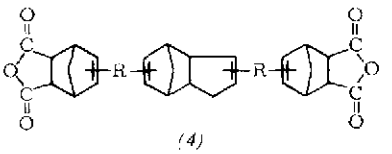
From a colorimetric determination of end groups in polystyrene, the minimum molecular weight, or in some cases the average molecular weight can be calculated with certain assumptions. According to present results, it should be possible to determine molecular weights up to 10^7. Copolymerizations, as well as transfer and cross-linking reactions can also be detected using this method.

A. Renner (Basel, Switzerland) gave a report on new bis-diene addition products as hardening agents for epoxide resins. For example, the reaction of bis-cyclopentadienyl com-



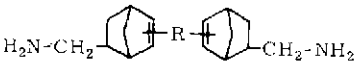
(3)

pounds with maleic anhydride yields dianhydrides *(3)* of tetracarboxylic acids. At a molar ratio of 1:1, tetracarboxylic acid dianhydrides *(4)* are formed possessing a dicyclopentadienylene group which can be opened.



(4)

These dianhydrides react with epoxide resins and polyvalent dienophiles, *e. g.* unsaturated polyesters, to form crosslinked products which can be used as metal binders.



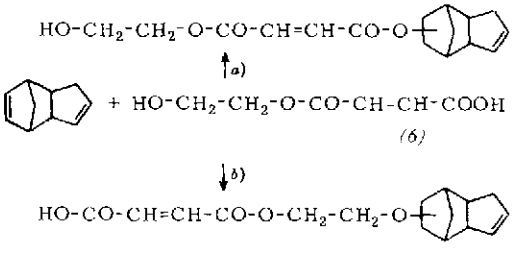
(5)

Amine hardeners of formula *(5)* are obtained from dienes and acrylonitrile by diene synthesis, followed by catalytic hydrogenation of the dinitriles. These hardeners, when used as additives to liquid epoxide resins of the bisphenol type, yield solid products of good mechanical properties.

R. Zimmermann and *F. Reiners*, Wiesbaden-Biebrich (Germany) discussed the structure and properties of polyesters modified with dicyclopentadiene. After graft polymerization with styrene, these polymers exhibit some remarkable properties compared with normal unsaturated polyesters: for example, they can be used to prepare coatings which do not stick and are absolutely dry after a short time without the addition of wax, and which can be wet-ground after a few hours. The hydroxy and color numbers and the reactivity of these unsaturated polyester resins depend on the esterification temperature and the time at which the dicyclopentadiene is added. It was shown by quantitative analysis of the products obtained by alkaline hydrolysis of the polyesters that the dicyclopentadiene reacts mainly as follows:

1) The cyclopentadiene formed by cleavage of the dicyclopentadiene during esterification adds onto the double of the maleic anhydride to give *endo*-methylenetetrahydrophthalic acid.

2) The mono-ester *(6)* formed in the first stage of the polycondensation from ethylene glycol and maleic anhydride adds on dicyclopentadiene at both the carboxyl and terminal hydroxyl functions.

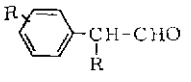


(6)

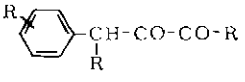
Whether the dicyclopentadiene is condensed into the polyester according to 1) or 2) depends on the temperature conditions during the reaction. Temperatures of 100–120 °C during the initial phase of the condensation and addition of the dicyclopentadiene to the preformed mono-ester *(6)* promotes condensation by Mechanism 2). At 180 °C, Reaction 1) is predominant. The reactivity and mechanical properties of the resins are optimum when the incorporation of dicyclopentadiene occurs mainly by Reaction 2).

H. Hopff and *E. K. Kleiner* (Zurich, Switzerland) reported on keto-enol tautomers as polymerization initiators. α-Phenylcarbonyl compounds having at least one hydrogen atom on the α-carbon or α-nitrogen, are effective initiators for the polymerization of vinyl compounds. They were extensively investigated in the polymerization of methacrylic esters and in the copolymerization of unsaturated esters with vinyl monomers. The activity of these initiators decreases in the sequence *(7)* > *(8)* > *(9)* > *(10)* > *(11)*.

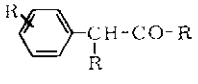
The most effective compounds are: phenylformylacetonitrile, hydratropa-aldehyde, phenylacetaldehyde, methyl- and ethyl phenylformylacetate, phenylpyruvic acid and its esters, and benzylmethylglyoxal. The ketones *(9)*, *e. g.* deoxybenzoine,



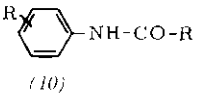
(7)



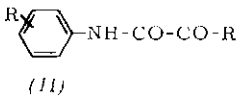
(8)



(9)



(10)



(11)

benzyl methyl ketone, and benzyl ethyl ketone, are much weaker. Among α-phenylcarbonyl compounds of which tautomers can be isolated, *trans*-enols show higher activity than *cis*-enols. Keto-isomers are much weaker initiators than *cis*- and *trans*-enols. The polymerizations were carried out, using 0.1 to 2% by weight of initiators at temperatures above 60 °C. Quinone, diphenylpicrylhydrazyl and nitro compounds are strong inhibitors, whereas hydroquinone has hardly any inhibiting effect. Traces of oxygen activate and so does ultraviolet irradiation. The hardening of polyester monomer solutions proceeds more equally with α-phenylcarbonyl initiators than with peroxides, and lower maximum temperatures are possible at similar gelling and hardening times. The polymers sometimes possess improved mechanical properties, *e. g.* impact hardness, but they need longer after-hardening for optimal hardness.

H. D. Hermann (Frankfurt/Main, Germany) reported on the influence of regulators for the trioxane polymerization. The stability to alkali of the end groups depends upon the nature of the regulators which was used for polymerization. Water, carboxylic acids and acid anhydrides yield alkali-labile end groups, whereas alcohols and carboxylic esters yield one stable and one labile end group. Acetals and ethers yield

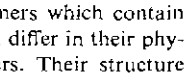
two stable end groups. The molecular weights are much smaller than theoretical. These observations and some experiments directed towards regulation of the trioxane polymerization by various chain transmitters led to the assumption that a hydride shift takes place as a side reaction: Boric esters and alkyl-substituted aromatic compounds were mentioned as new regulators.

H. G. J. Overmars and *G. M. van der Want* (Utrecht, Holland) reported on organolead compounds as catalysts in the formation of polyurethane foams. Polyether-urethane foams are usually prepared by reacting a polyether (mol. wt. 2000 to 3000) possessing hydroxyl end groups, with a diisocyanate, and using as foaming agent a volatile substance, such as Freon or carbon dioxide. The latter is formed by the reaction of water with an isocyanate group. As the addition of the isocyanate onto the polyol and onto water are slow reactions, both are accelerated by specific catalysts. The isocyanate-polyol reaction is usually accelerated by organotin compounds, among which compounds of the type R_2SnX_2 are particularly active and are used technically in foam processes. Among lead compounds only products of the type $RPbX_3$ possess catalytic activity. They catalyse both addition reactions to about the same degree. Organolead compounds are advantageous for the production of urethane foams, because there is no need for a tertiary amine as cocatalyst.

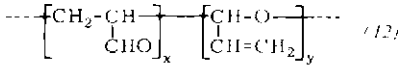
A. Krieger (Emmenbrücke, Switzerland) discussed the reactions of copper compounds in polyamide 6. The poor light- and heat-fastness of polycaprolactam or Nylon-6,6 fibres can be improved by the addition of stabilizing systems during the manufacture. The best-known group of stabilizers are copper compounds which may, however, cause precipitations in the polymer melt and discoloration of the polymer. As potential differences of up to 0.5 V can occur between different metals in technical plants and as the conductivity of the polyamide at 260 °C in the presence of electrolytes can reach 10^3 $ohm^{-1}cm^{-1}$, metallic copper can be deposited electrolytically under the conditions of polymerization. Secondary reactions of the copper sol lead to discoloration of the polymer. This can be prevented by complexing the copper before the start of the reaction, *e. g.* with salicylic or thioglycolic acids. Another way of improving the color fastness and the stability of the polymer consists in the addition of redox systems, *e. g.* potassium iodide, to the copper acetate.

K. Elbel (Wesseling, Germany) reported on the use of polymers as protection against ionizing radiation. The protecting effect can be improved by the addition of fillers. Heavy metals (lead, tungsten, and enriched uranium) or their compounds are suitable as fillers for polymers which are to absorb γ-rays. The absorption of γ-rays of different energies by lead-filled sheets of epoxide resin was discussed. Lithium-, boron-, cadmium-, and gadolinium compounds are suitable for the capture of thermal neutrons. Thus boron carbide and cadmium oxide are used as fillers for epoxide resins. Fast neutrons must be slowed down to thermal energy before they can be absorbed. Compounds of high hydrogen content (water, polyethylene) serve this purpose. Finally, possibilities for improving the stability of polymers to irradiation were discussed. Aromatic rings improve the stability, aliphatic ether groups and aliphatic double bonds have the opposite effect.

R. C. Schulz (Mainz, Germany) reported on the ionic polymerization of acrolein. As monomeric acrolein contains two groups capable of polymerization (vinyl and aldehyde group) which are conjugated, chemically and physically different polymers can be obtained, according to the nature of the catalysts and the reaction conditions. Radical catalysts cause only polymerization of the vinyl group, yielding polymers which possess very reactive aldehyde groups in the side chains



The use of ionic catalysts leads to polymers which contain both carbonyl and vinyl groups and which differ in their physical properties from the radical polymers. Their structure can be represented by formula *(12)*.



(12)

The ratio x:y can be varied widely by altering the catalyst and the conditions of polymerization. Solvents exert a considerable influence on the chemical structure of the polymers. The copolymerization of acrolein with vinyl compounds can be carried out with radical and with ionic catalysts. A new method was developed by which cross-linked polymers are obtained in two consecutive stages. The method is called two-stage copolymerization and is carried out as follows: a mixture of acroleine and styrene, for example, is converted into an unsaturated polymer of the type *(12)* by an ionic catalyst (*e.g.* sodium methoxide) acting selectively on acroleine; the styrene serves only as solvent. On addition of a radical catalyst, the styrene is copolymerized with the polyacroleine in a second step. The dimer of acroleine, 2-formyldihydropyrane, can be polymerized by ionic catalysts at the vinyl ether group and at the aldehyde group.

Symposium on Radiochemical Methods of Analysis

The "Symposium on Radiochemical Methods of Analysis" of the International Atomic Energy Agency (IAEA) was held in Salzburg (Austria) from October 19th to 23rd, 1964 and was attended by more than 300 participants from 25 countries in Europe and overseas. About sixty papers [*] covering the potentialities, importance, and fields of application of radiochemical methods of analysis were red.

H. Spenke, Vienna (Austria) reported on a method for the non-destructive determination of boron in steel from measurements of ^{59}Fe activation, which is inversely proportional to the boron content of the steel, owing to the high neutron capture cross-section of ^{10}B. A boron content of 0.1 % diminishes the activation of ^{59}Fe by 10 %. The limit of detection is 0.008 % B. The distribution of the boron can be determined by autoradiography.

The use of activation analysis in deciding the age of paintings by determining the trace elements in white lead pigments was described by *J. P. W. Houtman*, Delft (Holland). The nature of the impurities in white lead varies with the method used for purification of the lead. These methods were changed in the middle of the 19th century, so that the contents of Ag, Hg, Zn, and Cu can show whether a given sample of white lead was produced before or after 1850. Even if very small quantities are used, activation analysis can also give some indication of the Co, Cr, Ba, and Sb contents. Precipitation and extraction methods were used in the separation procedures required.

H. Stärk, Munich (Germany) dealt with the determination of Ta and W in niobium by activation analysis. Neutron activation leads to the short-lived isotope ^{94}Nb. After this has disappeared, the desired nuclides ^{182}Ta and ^{187}W can be readily determined without chemical separation by γ-spectroscopy, even in niobium of high purity.

The numerous difficulties encountered in the determination by activation analysis of traces of Cu, Zn, As, Sb, and Au in high-purity indium for semiconductor junctions were described by *J. V. Jakovlev* (USSR). Separation from the high-activity matrix is achieved quickly and readily by continuous extraction with isopropyl ether of a solution of the activated sample in 4.5 N HBr. The individual impurities were separated by distillation, extraction, or precipitation. After activation of a 100 mg sample for 12 h at a flux of 8.7×10^{12} neutrons/cm², the five trace elements could be determined to levels as low as 10^{-6}–10^{-8} %. Difficulties resulted mainly from the high activity and the marked self-shielding effect of the matrix.

Ch. Engelmann, Saclay (France) described the determination of oxygen, carbon, nitrogen, and other impurities in beryllium, calcium, sodium, and boron by means of γ-activation with a linear accelerator (28 MeV electrons). Extensive automation of the counting setup resulted in non-destructive analyses with sensitivity limits of 1–100 ppm. For the determination of very small amounts of oxygen, carbon, fluorine, and other light elements, particularly in materials of high purity (for semiconductors), use was made of (p,n), (p,α), and (p,pn) reactions in the cyclotron. Sensitivities were then increased to a lower detection limit of 0.001 ppm.

Sources of error in both quantitative and qualitative γ-spectroscopy were pointed out by *W. S. Lyon*, Oak Ridge (U.S.A.). Because of the number and complexity of effects which may distort the spectra, automatic analyses depending solely on γ-spectroscopy are highly liable to disturbances. Topics of discussion were: the dependence of the spectra on the geometrical arrangement of the detector and source, possible influences on spectra from Bremsstrahlung, reactions of high-energy γ-quanta with the shielding walls, and possibilities for the recognition and elimination of sources of error.

[*] The papers and verbatim reports of the discussions will be published by the IAEA.

The analytical scope of polydimensional γ-spectroscopy was investigated by *R. W. Perkins*, Richland (U.S.A.). The measuring device (impulse height analyser with 4096 channels) consisted of an anticoincidence screen and large detectors in order to maintain a low background radiation and to obtain maximum gain. The wide applicability of the method was illustrated by examples of the direct determination of radionuclides in mixtures: these included the direct determination of ^{22}Na, ^{60}Co, ^{88}Y, and ^{134}Cs in fall-out samples and the quantitative estimation of ^{64}Cu, ^{72}Ga, ^{76}As, ^{140}La, ^{140}Ba, ^{124}Sb, and ^{60}Co in reactor water.

S. Amiel, Yavne (Israel), showed how non-destructive determination of small quantities of a radionuclide in other high-activity material can be carried out if the nuclide in question emits high-energy γ-quanta. The method is based on the expulsion of photoneutrons from beryllium and deuterium by energies of 1.67 and 2.23 MeV, respectively. Since relatively few radionuclides have sufficiently high γ-energies, the method has a high inherent selectivity, even when only a determination of the half-life is used for the identification of an isotope. The measuring arrangement consists of a beryllium chamber or a D_2O container to hold the material under investigation, which is surrounded by a circular array of $^{10}BF_3$ neutron counting tubes. The error of the method is about ± 2 %; the detection limit is 1–100 μg.

New techniques of radiometric titration were reported by *E. Körös*, Budapest (Hungary). In radiocoulometric titration, the titrant is not added from a burette but is produced by electrolysis in solution. Here the analytical solution or the electrodes or both can be labelled. The course of radiometric titrations can be followed either by conventional procedures or by observations of β-absorption or reflective scattering. Both procedures have the advantage that it is possible to use an enclosed radiation source and thus to minimize sources of danger and to reduce licensing difficulties.

The technique of determining elements by addition of sub-stoichiometric quantities of reagent was described by *J. Ružicka*, Prague (ČSR) using iron as an example. The sample for analysis and an Fe standard are irradiated simultaneously and then the same quantity of iron carrier is added to both, followed by equal sub-stoichiometric quantities of cupferron to convert part of the iron into the Fe(III)-cupferron complex, which is extracted with chloroform; in this way it is unnecessary to determine the chemical yield. The iron content (Y) of the sample is calculated from the equation $Y = Y_S \cdot a/a_S$, where Y_S is the iron content of the standard and a and a_S are the activities of the chloroform extracts from the solutions of the sample and standard, respectively. For theoretical reasons, this method of analysis should have a much higher selectivity than the conventional method where excess reagent is added.

T. Florkowski, Cracow (Poland) described the determination of Fe, Zn, and Cu in ores by X-ray fluorescence analysis. He used Bremsstrahlung from a $^{3}H/Zr$ source and either a proportional counter with a Be window or a Geiger-Müller counter depending on whether measurements were to be made in the laboratory or at the mine. Sources of error such as the moisture content and the particle size and hardness of the sample were investigated, and the results of the method were compared with those of classical analytical techniques. The error in determinations of the Fe in iron ores with Fe contents of 0–40 % was from ± 0.2 to ± 0.5 %; the time required for completion of an analysis was 1–5 minutes. Important advantages of the method are rapidity and simplicity, and low investment and working costs for the measuring apparatus.

German version: Angew. Chem. 77, 220 (1965)

The Analytical Chemistry Division of the Gesellschaft Deutscher Chemiker together with the Chemistry Committees of the Gesellschaft Deutscher Metallhütten- und Bergleute, of the Steinkohlenbergbauverein, and of the Verein Deutscher Eisenhüttenleute, the Deutsche Arbeitskreis für Spectroskopie, and the Mass-Spectrometry Division of the Deutsche Physikalische Gesellschaft organized a lecture conference in Düsseldorf (Germany) from October 5th to 7th, 1964.

From the lectures:

The Detection and Analysis of Minute Amounts of Gas in Metals Using the Mass Filter

K. G. Günther, Nürnberg (Germany)

The accepted method for determining minute residual contents of gas in metals is that involving the hot extraction procedure. The sample of metal is heated in a graphite crucible *in vacuo* to expel any occluded gases. The most sensitive analytical instruments applying this principle can detect gas contents of down to about 0.1 ppm. Attempts to increase this sensitivity have so far failed because some of the gas is adsorbed in the apparatus or because the desorption of foreign gas layers is superimposed.

In order to lower the residual gas level and to avoid interfering adsorption phenomena, the entire analytical and extraction equipment was enclosed in an ultrahigh-vacuum container and put into operation only after a preliminary hot degassing cycle. The metal samples are heated by bombardment with electrons. A Bayard-Alpert vacuum gauge is used to measure the total pressure, and an electrical mass-filter is used to measure the partial pressure; the ion source required for the mass filter is placed in the immediate vicinity of the sample crucible. This instrument can be used to detect residual gas contents down to roughly 10^{-3} ppm at partial pressures in the range of 10^{-10} mm. A built-in chamber for holding samples permits the analysis of ten individual specimens in a single run. The gaseous fractions are estimated and analysed during their release from each sample. Changes in the individual partial pressures with time can be used to determine the composition of the gas and detect its supposed source (from regions in the vicinity of the surface, trapped gas-bubbles, or uniformly dissolved gases). By coupling the instrument with an oscillograph, short-lived eruptions of gas can also be detected and analysed. Examination of sample surfaces subjected to various different treatments showed that below 0.1 ppm the amount of gas adsorbed onto the surface can be much higher than that dissolved in the bulk of the material.

Detection of Non-Metals in Metals by Mass Spectroscopy

H. Hintenberger, Mainz (Germany)

There are two main techniques used in this procedure: hot extraction coupled with detection of the extracted substances by mass spectroscopy, and solid-sample mass spectroscopy using a spark-ion source.

Mass-spectroscopic analysis during hot extraction greatly increases the sensitivity of this method and enables the course of the degassing processes to be followed in detail. However, the isotope-dilution technique is even better for quantitative analysis of hot-extracted gases; this adaptation was tested particularly for the estimation by mass spectroscopy of oxygen in metals. The sensitivity of the detection of the inert gases is comparable to that of radioactive scaling methods.

Solid-sample mass-spectroscopy can be used to detect most elements in amounts between 10^{-3} and 1 ppm. In principle, it can be used to detect non-metals in metals as well as for the detection of metallic impurities. The detection limits for the various elements depend on the nature of the spectrum in the neighborhood of the lines to be examined. In general, with hydrogen, carbon, nitrogen, and oxygen, a decrease in the sensitivity of detection is to be expected owing to the background of fragmentation ions from impurities. Moreover, with these elements, interferences are caused relatively frequently by overlap of lines due to multicharged ions from the main elements in the samples. However, with elements of higher atomic weights, limits of detection in the region of 10^{-3} to 1 ppm can generally be achieved for non-metals as well, although errors of a factor of 2–3 are still unavoidable. At present, solid-sample mass spectroscopy using spark-ion sources can be regarded as a semi-quantitative analytical procedure of extremely high sensitivity which with a single measurement gives a good survey over all the impurities present in a metal.

The Estimation of Metallic Nickel and Nickel Oxide in Metallurgical Products

G. Kraft, Frankfurt/Main (Germany)

Halogen/methanol mixtures were found to be unsuitable, of metallic nickel and NiO were examined: the Cl_2/CH_3OH method, the Br_2/CH_3OH method, the chlorine-gas method, and the $Ag/CNS^{\ominus}$ method.

Halogen/methanol mixtures were found to be unsuitable, because they dissolve not only metallic Ni, but also some NiO; although both are dissolved at different rates, the amount of oxide dissolved was never below tolerable limits. The chlorine-gas procedure was also rejected because neither Ni nor NiO was converted into the chloride.

Completely satisfactory results were achieved with the $Ag/CNS^{\ominus}$ procedure; here a solution of AgCNS buffered at pH 5.0 with sodium acetate and containing excess NH_4CNS was used. However, the analytical sample must be pulverized to a grain size of less than 0.06 mm. Nickel is completely dissolved out of such powdered samples within 2 h at 36 °C; NiO is not attacked. After separation in this way, the components can be estimated by known procedures. The accuracy of the estimation is about ± 2% for both phases in 50 mg samples. Metallic iron, Fe_2O_3, and Fe_3O_4 do not interfere.

Advances in the Determination of Oxygen, Hydrogen, and Nitrogen in Metals

T. Kraus, Balzers (Liechtenstein)

In order to secure as rapid an analysis as possible of the carbon monoxide/nitrogen/hydrogen mixtures released on melting metallic samples in a graphite crucible *in vacuo*, a detector/recorder system is required which responds with practically no time lag and which delivers specific measurements directly from the gaseous phase without separation of the component gases. The most suitable solution to this problem incorporates measurement of the total pressure in a given volume in combination with heat conductivity and infrared absorption measurements [1].

The gas released in the vacuum melting furnace is pumped off very quickly under high vacuum (the final pressure being very low) and is collected in a pre-evacuated measuring cell; the total pressure is recorded continuously. When it is evident from the curve that the sample has been completely degassed, the analysis system is switched on and the analysis

[1] These three parameters are measured in the "Exhalograph" instrument manufactured by Balzers AG., Balzers (Liechtenstein).

proceeds automatically. To simplify interpretation of the results and to improve the sensitivity of the measurements, hydrogen is admitted into the measuring cell until a preselected total pressure has been attained. Since the previous measurements of the total pressure have already given the total amount of $H_2 + N_2 + CO$, heat conductance is now used to determine the partial amount of $N_2 + CO$ and the infrared absorbance to estimate the CO content; the amounts of hydrogen and nitrogen present are then calculated by difference. The accuracy of the hydrogen analysis can be increased even further by waiving an accurate nitrogen determination and using nitrogen instead of hydrogen to fill up the measuring cell. The heat conductance measurement then gives the amount of hydrogen alone.

Investigations by *A. Gerhardt* have shown that in the method described above, the error in the estimation of the three gases increases approximately linearly with the amount of gas released. The lower limits of detection are about 0.4 mm^3 (S.T.P.) for CO, about 1.3 mm^3 for N_2, and about 0.5 mm^3 for H_2. For 1 cm^3 of gas, the relative mean error for a single measurement is about $\pm$ 0.6 % for CO, about $\pm$ 0.2 % for N_2, and about $\pm$ 0.25 % for H_2. Hence this method provides a means of carrying out measurements not only very rapidly, but also with great accuracy.

Radioactive Nuclides for Investigating Physicochemical Processes in Graphite Electrodes during Excitation in an Electric Arc

H. Nickel, Jülich (Germany)

The combustion of graphite electrodes containing boron in a d. c. arc leads to the formation of boron carbide in the anode, independent of the working gas and of the nature of the boron compound in the graphite. The evaporation behavior, the losses resulting from fractionated evaporation and diffusion, and the distribution of material in the anode pellet after the electrodes were burned out were studied. For lack of a suitable radioactive boron isotope, ^{59}Fe was used as tracer. It could be shown that the boron is transported towards the burning surface of the anode, *i.e.* into the hot zone, during the electric discharge. Graphite electrodes doped with ^{59}Fe were used to study the influence of various parameters, *e.g.* the form of the counter-electrode or the dynamics of the working gas, on the evaporation properties of the iron. It was found that considerable amounts of the iron leaving the anode were deposited on the counter-electrode and that some of this material returned to the excitation zone via cathodic evaporation.

Estimation of the Oxygen in Uranium Carbides by Hot Extraction

H. Nickel and *J. Rottmann*, Jülich (Germany)

Nuclear fuels based on uranium carbide are of great interest for high-temperature reactors. The utility of these ceramic materials as nuclear fuels depends *inter alia* on their oxygen content, which influences their compatability with the coating of the fuel elements and their phase diagram. Comparative experiments on the estimation of oxygen in uranium carbides using the hot extraction method were carried out applying both the vacuum and carrier-gas techniques. It was found that the vacuum extraction is better than the carrier-gas method. Of the bath metals examined (iron, cobalt, nickel), cobalt used at 1900–2000 °C proved to be most suitable. The samples to be analysed were added in small pieces to the bath; powders were unsuitable because of the segregation of graphite in the baths.

Structures and Chemical Properties of Nitrides in Ternary Iron Alloys

K.-H. Sauer, Düsseldorf (Germany)

In order to estimate the nitrogen in metals after dissolution of the sample with acid, it is important to know which compounds of nitrogen occur in steels and how they react with non-oxidizing acids. For this reason, pure binary alloys of iron were produced and annealed in a stream of ammonia at 1000–1200 °C. The ammonia decomposes largely into its elements at this temperature and the nitrogen formed diffuses rapidly into the alloy. The nitrides formed in this process were separated from the nitrated layers by electrolytic isolation, and their structures and chemical properties were examined. Pure nitrides of chromium, aluminum, titanium, vanadium, zirconium, niobium, tantalum, and boron – silicon nitrides form exceptions – are dissolved by acid or by sulfuric acid plus bisulfate, and the nitrogen transformed quantitatively into the ammonium salt. The bromine-ester procedure makes it possible to distinguish between the nitrogen dissolved in the metal lattice, that originating from iron nitride, and that originating from alloying elements.

Determination of Traces of Impurities in Highly Purified Germanium(IV) Chloride and Germanium(IV) Oxide

E. Wunderlich and *E. Göring*, Goslar (Germany)

In analyses of the impurities in germanium, to date it has been common practice to remove the germanium from its compounds by volatilizing it off as $GeCl_4$ by evaporating a sample with hydrochloric acid in the presence of nitric acid, and then to determine the impurities in the residue, taking a separate portion for every trace element. The concentrations of the impurities generally lie below 0.5 ppm. The most important elements are As, Fe, Cu, and Ni. They can be determined in one sample (with extensive recovery of the Ge contained in the sample) in the following manner: A 50 ml sample of $GeCl_4$ is shaken with 10 ml of 6 N HCl containing bromine. The As, Fe, Cu, and Ni are taken up quantitatively into the hydrochloric acid phase. Alternatively, 50 g of GeO_2 are decomposed with pure hydrochloric acid in the presence of nitric acid in a closed apparatus. The $GeCl_4$ is distilled off and the residual germanium-free solution evaporated to dryness. Separations: The As is extracted from the brominated hydrochloric acid solution (d = 1.19) with benzene; the iron is extracted from 6–7 N HCl solution with isobutyl methyl ketone; the copper is extracted from 0.5 N HCl solution with dithizone in CCl_4; the nickel remains in the aqueous phase. About 0.05–0.1 ppm of these impurities can be determined. About 98 % of the germanium can be recovered from the $GeCl_4$, and about 90 % from the GeO_2.

German version: Angew. Chem. 77, 267 (1965)

Symposium on Magnetic Nuclear and Electron Resonance

This symposium was held at Freiburg/Brsg. (Germany) from October 22nd to 23rd, 1964. It was arranged by the Chemische Institut der Universität Tübingen and by the Institut für Elektrowerkstoffe der Universität Freiburg, with the support of the Wirtschaftsministerium of Baden-Württemberg.

A. Mannschreck, Heidelberg (Germany), spoke on the determination of the structure of organic compounds in solution using proton resonance spectroscopy. Caused by fine-structure effects, extreme chemical shifts can occur, *e.g.* in the methyl protons of 15,16-dimethyl-15,16-dihydropyrene (τ = 14.2 ppm), in the methylene protons of 1,6-methanocyclodecapentaene (τ = 10.5 ppm), in the β-proton of dimethyl *trans,trans*-muconate (τ = 1.8 ppm) or in the methyl proton of diphenylmethyl hexafluoroantimonate (τ = 0.3

ppm). Splitting by spin coupling was illustrated for the spin systems AB (AX), AB_2 (AX_2), A_2B_2 (A_2X_2) and A_2X_3.

The structure determination by proton resonance was discussed on selected examples: *e.g. N*-methylisoindole is protonated and deuterated in 2-position by sulfuric acid. The *cis-trans* equilibrium of *N*-methyl-*N*-benzylmesitylcarboxamide in CCl_4 was derived from the PMR spectrum. Finally, structure determinations of isothiazoles and the deuteration of thiamine were discussed.

According to *H. Kessler*, Tübingen (Germany), proton resonance allows the investigation of reversible intramolecular isomerizations. The rate constants and the energies of activation were determined in proton exchange reactions. Isomerizations by internal rotation were discussed on the example of acid amides possessing partial double bond character; polar solvents increase the participation of polar structures and thereby the energy of activation of the inversion. For acid amides the energies of activation are 10 kcal/mole and for their *O*-protonated modifications 13 kcal/mole. Examples were given of *cis-trans*-isomeric rotamers in the classes of nitrosamines, nitrites and methyl diazotate. Ring inversions were demonstrated on cycloheptatriene (energy of activation 6.3 to 9.2 kcal/mole, depending on the substituent). Valence-bond tautomerizations were described for benzonorcaradiene and homocycloheptatriene.

N. C. Franklin, Tübingen (Germany), dealt with the conformations of substituted cyclohexanes. Caused by the difference of energy between chair and boat forms of cyclohexane, separate PMR signals appear at low temperatures for the equatorial (e) and axial (a) protons of the chair form. Splitting of the signals by spin coupling depends upon the conformation ($J_{a,a} \approx 11.5$ cps; $J_{a,e} \approx 4$ cps; $J_{e,e} \approx 3$ cps). Conformational equilibria can be determined from the band widths (ω):

$$K = \frac{\omega_a - \omega}{\omega - \omega_e}; \quad \omega_a = 2(J_{a,a} + J_{a,e}); \quad \omega_e = 2(J_{e,a} + J_{e,e})$$

Nitrocyclohexane, 2-methylcyclohexylamine and di-t-butylcyclohexanoles were investigated.

B. Dischler, Freiburg (Germany), discussed the principles and methods of analysis of NMR spectra. Spectra of the types AB (AX, A_2), AB_2 (ABX, AX_2, A_3) and A_2B_2 which can be evaluated without any or with very simple calculations were treated systematically (equations for their evaluation were given). The analysis of spectra from more complicated spin systems (A_2BX, ABC, A_2B_2C) was then discussed. The analysis of the A_2B_2X spectrum of *p*-fluoronitrobenzene was achieved by dividing it into two A_2B_2 spectra. In the case of the ABC spectrum of 1,2,4-trichlorobenzene and of the AB_2C_2 spectrum of pyridine, the measured and calculated spectra were compared. The method of iteration was explained for the calculation of A_2B_2C systems. The sign of the coupling constant of α,β-dibromopropionic acid (ABC type) was determined by experiments using double resonance and from the doubly-quantized spectrum.

H. Dreeskamp, Stuttgart (Germany), spoke on the magnitude and sign of indirect nuclear spin interaction and its dependence on angles and substituents. The coupling constant J was defined and the normalized coupling constant J' was introduced.

The coupling constants of the hydrides of Group IV elements, XH_4, were measured. Here, all coupling constants J'_{X-H} are positive. The relation between J_{CH} and $E_X \cdot R_{CX}$ (E_X = electronegativity of X; R_{CX} = distance CX) in compounds CH_3X with different substituents X gives: $J_{C-H} > 0$. The silanes $^{29}SiH_x(CH_3)$ from x = 4, y = 0 to x = 0, y = 4 and the stannanes $^{117/119}SnH_x(CH_3)_y$ were investigated. It was found that $J_{Si-C-H} < 0$ and $J_{Sn-C-H} < 0$. When $K = J_{X-C-H}/J_{X-H}$ is introduced, a correlation between K and J_{C-H} can be found from which the sign of the coupling constant can be derived.

A. Saupe, Freiburg (Germany), discussed NMR spectra of orientated molecules. Molecules can be orientated in an electrical field, in clathrates and on expanding surfaces, and particularly in crystalline liquids (*e.g.* nematic *p*-azoxyanisol) at higher temperatures. The following spectra were measured: 1,2,3,5-tetrachlorobenzene in di-*p*-heptoxyazoxybenzene at 82 °C, 1,3,5-trichlorobenzene in di-*p*-hexoxyazoxybenzene at 80 °C and 170 °C, [*carboxyl*-D]-*p*-chlorobenzoic acid in [*carboxyl*-D]-*p*-butoxybenzoic acid at 144 °C, and 1-methoxy-2,3,4,6-tetrachlorobenzene in di-*p*-heptoxyazoxybenzene at 92 °C. The PMR spectrum of benzene in di-*p*-hexoxyazoxybenzene was particularly impressive. Here, due to direct dipole-dipole interactions, 50 lines of the benzene spectrum (which theoretically has 78 lines) can be observed. With growing number of protons the spectra of orientated molecules soon become very complicated even if the protons are structurally equivalent.

Compared with the ^1H–NMR spectra, the NMR spectra of heavier nuclei are often simple (*e.g.* due to the large chemical shifts; $\tau_F \approx 700$ ppm), as *E. Fluck*, Heidelberg (Germany), pointed out. However, complications can arise with quadrupolar nuclei. NMR spectroscopy of the ^{11}B, ^{19}F, and ^{31}P nuclei is of particular importance in inorganic compounds.

Examples of ^{19}F resonance: The AB_2 spectrum of ClF_3 at 10 Mc at different temperatures proves an exchange of F atoms. In the case of the cyclic compound $(SONF)_3$, two stereoisomers are possible. The ^{19}F spectra of JF_5, SF_4, and R_3PF_2 at 30 Mc were discussed. The application of ^{19}F resonance to problems of bonding was shown: differences in electronegativity are related to chemical shifts. The ionic character of the Xe–F bonds in xenon fluorides was discussed.

Examples of ^{31}P resonance: The state of oxidation and the coordination number of phosphorus can often be determined from the chemical shift of the ^{31}P resonance (*e.g.* identification of $PCl_6^{\ominus}$ in solution). The chemical shifts in spectra of phosphorus compounds can be calculated from increments, provided that no fluorine is bound to phosphorus. The products formed in the reaction of $(C_6H_5)PCl_2$ with S_4N_4 were identified with the help of the ^{31}P spectrum. The spectrum of $(C_6H_5)_4P_4K_2$ was discussed and the reaction of $[(C_6H_5)_2P]_3N$ with $(C_6H_5)_2PCl$ was described. The $^{203(205)}Tl$ resonance spectrum of thallium ethoxide proves the molecule to be tetrameric.

Nuclear quadrupole resonance spectroscopy allows the determination of polarity, ionic character and double bond character of a bond from the nuclear quadrupole resonance coupling constant eQq [*W. Zeil*, Kiel (Germany)]:

$$(eQq)_{mole} = (1 - s + d - I - \pi/2) - (eQq)_{atom}$$

(s = % s-character; d = % d-character; π = % double bond character; I = % ionic character of the bond; Q = nuclear quadrupole moment; q = field gradient.)

The ^{35}Cl resonance spectrum of crystalline CCl_4 at about −180 °C shows 15 lines, because all Cl atoms in the crystal (Z = 4) are different. The eQq values of several alkyl halides were reported and the ionic character of the bonds was compared with values for the splitting of the hyperfine structure in microwave spectra in gases. The ionic character increased in the series R–I < R–Br < R–Cl (*e.g.* $CHCl_3$: eQq = 68.4 cps, 26.6 % ionic character. C_2H_5Cl: eQq = 66.0 cps, 28.2 % ionic character). Only the electron which is available for a covalent bond determines the quadrupole coupling constant, *e.g.* Cl_2: eQq = 108.95 cps, Cl: eQq = 109.74 cps, Cl^-: eQq = 0. It was shown that the CCl-, CBr- and CI-bonds in the acetylenes $(CH_3)_3X-C\equiv C-Cl$ (X = C, Si, Ge, Sn) and $H_3C\equiv C-Y$ (Y = Cl, Br, I) have strong double bond character (more than 50 %). In alkyltellurium halides and tellurium halides the Te-valence bipyramid has different electronegativities at the top and at the base.

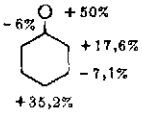
F. Gerson, Zurich (Switzerland), discussed simple ESR spectra of radical anions of benzene, naphthalene and

pyrazole, and the influence of molecular symmetry on the spectra of the radical anions of naphthalene and quinoline. The spin densities ρ_μ at the carbon atoms (μ) of aromatic radical anions are derived from the coupling constants a_μ for the proton attached to the C_μ atom, according to: $a_\mu = Q \cdot \rho_\mu$ ($Q \approx 23$ Gauss). Hückel's theory, *i.e.* the equation

$$\Psi^2 = \sum_\mu c_\mu^2 \Phi_\mu^2$$

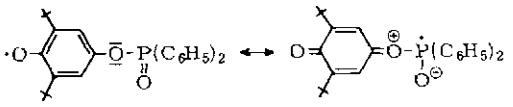
yields reliable results for the real spin densities, as shown for some radical anions of benzene and the acenes (relation between a_μ and $\rho_\mu = c_\mu^2$). The following ESR spectra were described: radical anion and radical cation of 1,3,6,8-tetraazapyrene, several dimethylnaphthalene anions, radical anions of 1,6-methanocyclodecapentaene and pyrrolo [2,1,5-*cd*]-indolizine, radical anion and radical cation of 15,16-dimethyl-15,16-dihydropyrene. The spectra allow the calculation of the electron densities in the molecules and thereby the direct measurement of the wave functions (*e.g.* position of orbitals in bridged perimeters). If the binding and anti-binding orbitals are symmetrical to the non-binding state, then the ESR spectra of radical cations and radical anions are equal (*e.g.* in phenanthrene).

According to ESR investigations on aroxyls by *A. Rieker*, Tübingen (Germany), splitting of the hyperfine structure (coupling with the nuclear momentum of the protons) allows one to decide whether or not the radical electron is located at the oxygen. The ESR spectra of pentachlorophenoxyl, 2,3,4,6-tetrachlorophenoxyl, 2,4,6-trichlorophenoxyl, 2,4,6-tris(diphenylmethyl)phenoxyl *(1)* and [1-^{13}C]-2,6-di-t-bu-



(1), $-CH(C_6H_5)_2$ at positions 2, 4, and 6

tyl-4-butoxyphenoxyl are characteristic. In the first example, the carbon atoms 1, 3 and 5 show negative spin densities; the spin density on the O atom is +50 %. Spin densities in positions 3 and 5 were determined for 2,6-di-t-butylaroxyls with 23 different substituents in position 4. Interestingly there is a linear correlation between the coupling constants a_H [cps] and the absorption maximum $\tilde{\nu}$ [cm^{-1}] of longest wavelength. Examples were given of comparative measurements on deuterated *p*-phenylphenoxyls, with the aim of clarifying more complicated spectra. Hetero-atoms between aromatic rings in aroxyls influence the ESR spectra, *i.e.* they carry finite spin densities [*e.g. (2)*].



(2)

Irradiation of organic single crystals (amino acids) often gives rise to long-lived radicals (years!) which, according to *G. Schoffa*, Karlsruhe (Germany), can be investigated by ESR spectroscopy. The anisotropy of the g-factor can be determined (*e.g.* in hematin). An irradiated monocrystal of betaine $[(CH_3)_3\overset{\oplus}{N}-CH_2-CO_2^{\ominus}]$ yields a 30-line spectrum, corresponding to the location of the unpaired electron in the trimethylammonium group (no further splitting by the methylene group). Analogously the fine structure of the ESR spectrum of *N*-acetylvaline showed the electron to be located in the isobutylidene group. Difficulties in these investigations often arise from the fact that several radicals are formed simultaneously in the irradiation of crystals.

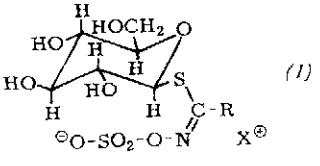
J. Schneider, Freiburg (Germany), reviewed the importance of electron spin resonance for investigations of the solid state. ESR of free conducting electrons in metals and semiconductors, of color centers in crystals, of donators and acceptors in semiconductors, of ions with 3d- and 4f-shells and of centers of luminescence was described. The F-centers, V_F-centers, V_K-centers and M-centers of alkali halides were discussed. The M-centers can be paramagnetic in the excited state. In silicon which possesses P, As, or Sb as donator, the donator level lies about 0.05 eV below the conductivity level, and at sufficiently low temperatures the interaction of the electron with the donator can be derived from the ESR spectra. Cr^{3+} in Al_2O_3, Nd^{3+} in CaF_2, Eu^{2+} in NaCl were mentioned as examples for the application of ESR spectroscopy to 3d- and 4f-ions. The spectra are influenced by the symmetry of the neighborhood of the ions. Centers of luminescence (acceptors in ZnS, CdS, or ZnO) are paramagnetic in the excited state and can, therefore, be examined by ESR spectroscopy, in particular when a high concentration of excited states can be achieved by excitation with a laser. [VB 877/183 1E]

German version: Angew. Chem. 77, 269 (1965)

Symposium on Isothiocyanates

The Chemical Society and the Biological Institutes of the Czechoslovakian Academy of Sciences, in conjunction with the Faculty of Chemistry of the Slovakian Technical University, Bratislava, organized a symposium on isothiocyanates from October 15th to 17th, 1964 in Smolenice Castle (ČSR). Over thirty lectures were given on syntheses, reactions, physicochemical properties, biological effects, and medical applications of isothiocyanates and of mustard oil glucosides (as the precursors of native isothiocyanates).

Mustard oil glucosides, *e.g. (1)*, form an interesting class of organic natural products; their structures were long the



(1)

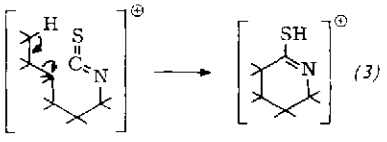
subject of much controversy, but they are now known with certainty to be substituted imino thioesters.

The formation of isothiocyanates from the glucosides is explained by an intramolecular rearrangement following enzymatic hydrolysis of the glucosidic linkage. Up to the present, about fifty glucosides with the same basic structure *(1)* but with different R groups are known; R can he a saturated or unsaturated aliphatic group, an unbranched chain with a hydroxyl or carbonyl funtion in the β- or γ-position and with methylmercapto, methylsulfoxy, or methylsulfonyl groups, and it can be aromatic, cycloaliphatic, or heterocyclic groups.

A. Kjaer, Copenhagen (Denmark) reported on the elucidation of the structures of isothiocyanates R'NCS of natural origin. Because of the extremely minute amount of material available combination of gas chromatography and mass spectrometry proved particularly useful. Isothiocyanates with unbranched R' chains had lines of mass number 72, which can be ascribed

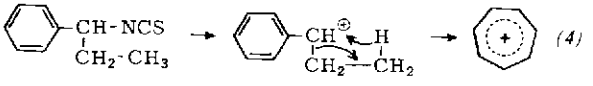
(2)

to the mesomerically stabilized ion *(2)*. All R′ groups with six or more carbon atoms can be recognized by lines originating from an ion *(3)* of mass number 115 formed by β-fragmentation and subsequent cyclization.



(3)

Araikyl isothiocyanates, *e.g. (4a)*, have a maximum at mass number 91, which is characteristic of the tropylium cation *(4)*. If the aromatic nucleus is substituted, then the fragment

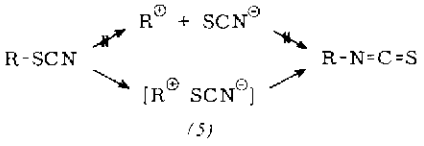


(4a) (4)

obtained is a benzylium cation. The ion $CH_3-S-CH_2^{\oplus}$ of mass number 61 is formed from all ω-methylthioalkyl isothiocyanates.

One particularly interesting mustard oil glucoside, which presumably occurs in all species of *Brassica* and *Raphanus*, is glucobrassicin investigated by *N. Kutáček* et al., Prague (ČSR); it is *(1)* with R = 3-indolylmethyl. It is thought to be the factor in cabbage species which gives rise to strumitis, for on enzymatic hydrolysis at pH 7, this glucoside yields to 3-indolylmethyl isothiocyanate, which immediately decomposes and releases the strumigenic thiocyanate ion. The 3-indolylmethylene cation formed at the same time is transformed by ascorbic acid in the cabbage into ascorbigen. The biosynthesis of glucobrassicin proceeds via tryptophan; the tryptophan content of plants – particularly barley – was found to be augmented by the presence of Zn^{2+} but reduced by irradiation. When young cauliflower plants were grown in an atmosphere containing $^{35}SO_2$ (1.7 mC/l) while being irradiated with a 500 watt lamp, labelled glucobrassicin was later detected by paper chromatography, and $^{35}SCN^{\ominus}$ was found after enzymatic hydrolysis with myrosinase. These results deserve particular consideration in view of the high SO_2 concentrations in the atmosphere around industrial areas.

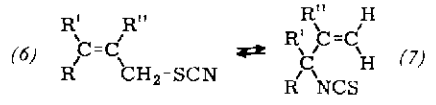
The mechanism of the isomerization of thiocyanates to isothiocyanates was discussed by *A. Fava*, Perugia (Italy). From the results of labelling experiments, it appears that the rearrangement of saturated aliphatic thiocyanates cannot be regarded as being due to a dissociation; instead, it proceeds via an internal ion pair *(5)*.



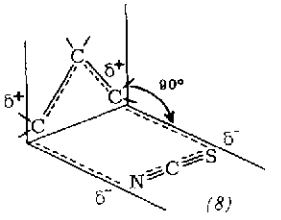
(5)

The effects of substituents and solvents on the kinetically controlled isomerization of allyl thiocyanates *(6)* are so slight that an intramolecular non-ionic transition state *(8)* seems to be involved.

If the carbon skeleton formed by the isomerization is less stable than that of the original thiocyanate, then the reaction yields only an equilibrium concentration of the isothiocyanate. This situation occurs for example in the transformation of γ-methylallyl thiocyanate [*(6)* with R = CH_3 and R′ = R″ = H] into α-methylallyl isothiocyanate [*(7)* with R = CH_3 and R′ = R″ = H], where a loss of hyperconjugative energy occurs when the methyl group becomes isolated from the double bond. Isomerization via

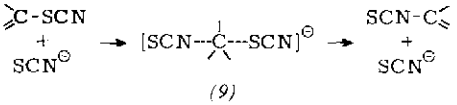


(6) (7)



(8)

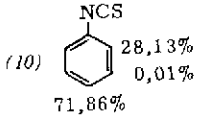
the ambident thiocyanate ion *(9)* by direct nucleophilic exchange occurs with primary thiocyanates (*e.g.* benzyl and benzhydryl isothiocyanates) which exhibit no tendency to ionize.



(9)

K. Antoš, Bratislava (ČSR) found that the reaction of thiophosgene with amines to give isothiocyanates does not occur when the amino group, like that in 9-aminoacridine, can participate in amino-imino tautomerism. Amino groups that are strongly hydrogen-bonded are also unable to react with thiophosgene. Thus, 2-aminoazobenzene reacts with thiophosgene only when an additional methyl group is introduced at position 3 in order to force the molecule into a conformation which is unfavorable for the participation of the amino group in hydrogen bonding.

A number of reports dealt with the structure and reactivity of the isothiocyanate group. Because of the values found for the dipole moments of *m*- and *p*-substituted phenyl isothiocyanates, especially the value for *p*-phenylene diisothiocyanate, which is very close to zero (0.009 D), *K. Antoš*, *A. Martvoň*, and *P. Kristián*, Bratislava (ČSR) assumed an approximately linear arrangement of the aromatic residue with the NCS group. An angle of 162°44′ was calculated for *p*-chlorophenyl isothiocyanate. The theoretical yields for the nitration of phenyl isothiocyanate *(10)* were calculated from the dipole moments of phenyl isothiocyanate (2.9 D) and of t-butyl isothiocyanate (3.73 D). Electrophilic substitution of aromatic isothiocyanates has not yet been achieved. It can bee seen from *(10)* that the isothiocyanate group exerts a −I effect comparable with that of halogeno substituents.



(10)

A. M. Kardos, Prague (ČSR) investigated the polarographic reduction of *m*-substituted phenyl isothiocyanates and found a linear correlation of the half-wave potentials and the σ_m constants of polar substituents with a slope of $\rho = 0.22$. Polarographic measurement of the kinetics of the addition of hydroxyl anion onto isothiocyanates in a water/methanol/dioxane system also gave a linear Hammett relationship between the logarithms of the rate constants and the σ_m constants with a slope of $\rho = 1.57$. *Š. Kováč*, Bratislava (ČSR) reported on the infrared spectra of a series of *m*- and *p*-substituted phenyl isothiocyanates in solvents of differing polarity. The vibrational frequencies of the NCS group and the integrated intensities of the absorption bands at 2100 cm^{-1}

gave a linear correlation with the Hammett σ constants. Accordingly, isothiocyanates containing electron-attracting substituents are supposed to have preferably the mesomeric structure *(11)* while those with electron-donating groups are given the structure *(12)*. The NCS group hardly participates in the mesomerism of the aromatic ring.

(11) *(12)*

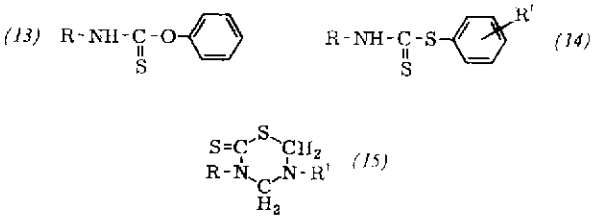
The Raman spectra of *p*-substituted phenyl isothiocyanates were discussed by *M. Pisárčik*, Bratislava (ČSR). All the spectra contain a broad absorption band at about 2100 cm^{-1}, a strong absorption at 1250 cm^{-1}, and a weak absorption at 927 cm^{-1}; the appearance of the first band is influenced by the nature of the substituents. The position of the maximum near 2100 cm^{-1} exhibits a linear dependence upon the Hammett σ_p constants with a negative tangential gradient. The value for the NCS group was found by extrapolation to be $\sigma_{p_{NCS}} = 0.34 \pm 0.09$.

Contributions to the relationships between the structure and the biological activity of isothiocyanates and to the mode of action of isothiocyanates upon cellular metabolism were made by *P. Kristián, Ľ. Drobnica*, and *P. Nemec*, Bratislava (ČSR). A linear correlation was observed between the biological activity (log ED_{50}; log ID_{50}) [*] of *m*- and *p*-substituted phenyl isothiocyanates and the values which characterize the reactivity of the NCS group (log k; σ) or a physical property of the complete molecule (logarithm of the molar solubility or of the partition coefficient). For example the bacteriostatic activity of isothiocyanates is determined by their reactivity. This can be described by a modified Hammett equation (a) in which τ_i and τ_r are measures of the biological activity of substituted isothiocyanates and of phenyl isothiocyanate, respectively, α is the tangential gradient, and β expresses the physical properties of the substituent [1]. The rate constants for the reaction of the isothiocyanates with glycine are taken as a measure of β.

$$\log (\tau_i/\tau_r) = \alpha \beta \qquad (a)$$

A case, in which the solubility determines the activity of the isothiocyanates, is the inhibition of the growth of yeasts. This can be explained by the difference in the structure of bacterial and yeast cells: in bacteria, the isothiocyanates react with the proteins and enzymes located in the cell walls, hence their antimicrobial activity is determined by their chemical reactivity. Their effect on the growth of yeast cells, on the other hand, requires that they first penetrate into the interior of the cell, so that their biological activity depends primarily upon their lipid solubility. *Ľ. Drobnica*, Bratislava (ČSR) and *T. Zsolnai*, Debrecen (Hungary) consider the antimicrobial activity of isothiocyanates to be due to their interference in protein and ribonucleic acid metabolism and their blockage of enzymes containing mercapto groups. It is assumed that the essential groups are blocked by isothiocyanates in the series $SH > NH_2 > OH$.

The occasionally high toxicity and pungency of isothiocyanates allow only limited medical application, *e.g.* as anthelminthics or for expelling trichophytosis. In this connection, the proposition of *A. Rieche* and *D. Martin*, Berlin (Germany) to synthesize simple compounds which liberate isothiocyanates under physiological conditions deserves consideration. Thus, synthetic isothiocyanate precursors modelled on the mustard oil glucosides were prepared; these have a broader range of application because they can be obtained in greater purity and can be dosed with precision; in addition, unlike the plant extracts containing mustard oil glucosides, these preparations contain no ballast materials. Suitable compounds for this purpose include *N*-monosubstituted thiocarbamidic esters *(13)*, dithiocarbamidic esters *(14)*, and 2-thionotetrahydro-1,3,5-thiadiazines *(15)*.



(13) *(14)*

(15)

Compounds such as *(13)*, *(14)*, and *(15)* are practically non-toxic (LD_{50} = 2000 mg/kg in mice) and exhibit bacteriostatic, fungistatic, and virostatic activity in concentrations as low as 0.5–1.0 γ/ml. Optimum activity is obtained with *(13)* when R = phenethyl, with *(14)* when R = benzyl and R′ = *p*-chloro, and with *(15)* when R = benzyl and R′ = carboxymethyl. Compounds of type *(15)* have an aureomycin-like growth-promoting effect on young animals, according to investigations by *H. Haenel*, Berlin (Germany) and have a broad spectrum of application for fungal infections. According to *R. Narasimha*, Bangelore (India), the toxicity of isothiocyanates is strongly reduced in their bisulfite adducts without deterioration of their antimicrobial efficiency.

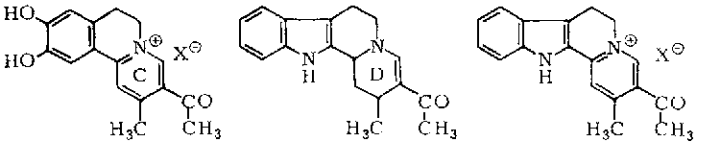
Synthesis of Heterocyclic Compounds and Model Reactions of Alkaloid Biogenesis

H.-J. Teuber, Frankfurt/Main (Germany)

Dihydroxyphenylalanine hydrochloride reacts in water with acetoacetaldehyde dimethylacetal or 1-methoxy-1-buten-3-one to give the quaternary ammonium salt *(1)*; analogously, tryptamine hydrochloride yields a mixture of *(2)* and *(3)* [1].



(1) *(2)* *(3)*

X = Cl

These reactions proceed at almost neutral pH and are therefore in accordance with the hypothesis that acetic acid residues are used instead of aromatic amino acids of the phenylalanine type in the biosynthesis of indole alkaloids of the α-series [2]. Since ring D in *(2)* [or *(3)*] is built up

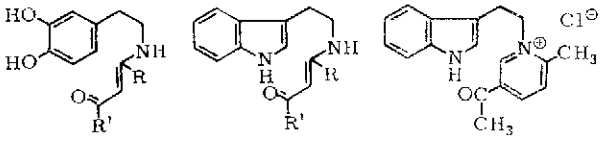
[*] ED_{50} = concentration (moles/l) which inhibits growth of microorganisms by 50 %; ID_{50} = concentration (moles/l) which inhibits metabolic processes by 50 %.

[1] See also *R. Zahradník* and *M. Chvapil*, Experientia *16*, 511 (1960).

[1] *H.-J. Teuber* and *U. Hochmuth*, Tetrahedron Letters *1964*, 325; *H.-J. Teuber* and *D. Laudien*, Angew. Chem. *76*, 534 (1964); Angew. Chem. internat. Edit. *3*, 507 (1964); *H.-J. Teuber*, *O. Glosauer*, and *U. Hochmuth*, Chem. Ber. *97*, 557 (1964).

[2] Review: *R. Robinson*, Pure appl. Chem. *6*, 601 (1963).

from acetate residues exclusively, it may be considered that the C_1 unit (formaldehyde equivalent) in indole alkaloids of the α-type is located in ring E and not in ring D [corresponding to a bridge between the CH_3-groups of *(2)* or *(3)*]. Preliminary tracer experiments seem not to preclude this possibility [3].



(4) *(5)* *(6)*

During attempts to convert acylalkenylamines of type *(4)* and *(5)* [R = H or alkyl, R′ = alkyl or aryl] into their hydrochlorides, they cyclized in a Pictet-Spengler-type reaction to yield derivatives of tetrahydroisoquinoline or tetrahydro-3-carboline with one or two substituents in the 1-position. These compounds can in turn be converted into heterocycles of the type *(1)–(3)* [*D. Laudien, Th. Raabe*]. Dihydroresorcinol condenses with tryptamine hydrochloride to give an acylalkenylamine analogous to *(5)*. Tryptaminobutenone *(5)*, R = H, R′ = CH_3, reacts with acids to form the pyridinium salt *(6)*.

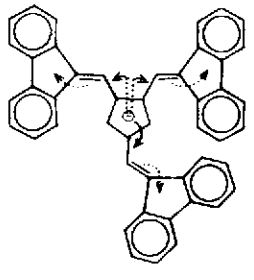
New Results in the Chemistry of Quasi-Aromatic Compounds

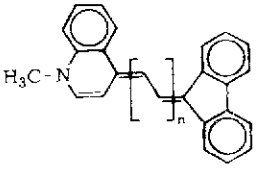
Ch. Jutz, München (Germany)

3,4-Bis-(9′-fluorenylidenemethyl)-6-(9′-fluorenyl)fulvene was prepared as red needles, m.p. 234.5 °C, *via* its anion *(1)*, λ_{max} = 588 mμ, log ε = 4.87, from 3,4-bis-(9′-fluorenylideneprethyl)-6-dimethylaminofulvene and fluorenyl-lithium. It moved to be the most acidic hydrocarbon known to date. In the anion *(1)*, the negative charge can be distributed over four cyclic π-sextets.



(1)

Related to the 9-aminofulvenes are the deep-colored heterologues of sesquifulvapolyene. Vinylogous 1-methyl-4(2)-fluorenylidene-1,4(1,2)-dihydroquinolines, *e.g. (2)*, were made by treating the corresponding polymethine salts with fluorene and sodium methoxide. Protonation of the 9-position of the fluorenyl residue with mineral acids gives rise to quinolinium salts.



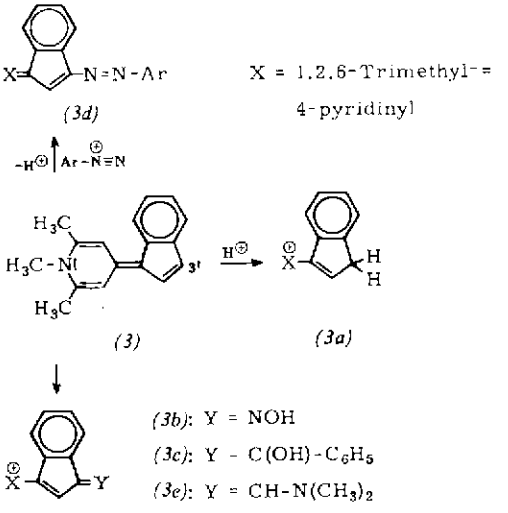
(2)

n = 0, 1, 2, 3

[3] Cf. the contradictory results obtained by *E. Leete* and *S. Ghosal*, Tetrahedron Letters *1962*, 1179, and by *A. R. Battersby, R. Binks, W. Lawrie, G. V. Parry*, and *B. R. Webster*, Proc. chem. Soc. (London) *1963*, 369.

A vinylogue of 1-methyl-4-cyclopentadienylidene-1,4-dihydropyridine with n = 3 was obtained similarly. It is a strongly basic, labile, blue compound.

1,2,6-Trimethyl-4-cyclopentadienylidene-(or-4-indenylidene-)1,4-dihydropyridine is a particularly good model for studying electrophilic substitutions in quasi-aromatic systems. The indenylidene compound *(3)* undergoes reactions at the 3′-position: protonation gives *(3a)*, nitrosation yields *(3b)*, benzoylation leads to *(3c)*, coupling with aromatic diazonium salts gives *(3d)*, and on substitution with dimethylformamide/phosphorus oxychloride one obtains *(3e)*; substitution with azastreptocyanin cations also occurs at the 3′-position.



(3d) X = 1,2,6-Trimethyl-4-pyridinyl

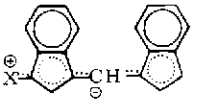
(3) *(3a)*

(3b): Y = NOH

(3c): Y = C(OH)-C_6H_5

(3e): Y = CH-$N(CH_3)_2$

Cyclopentadienylsodium or indenylsodium displace the secondary amino group in salts of type *(3e)* to form intensely colored merocyanins with a latent carbanionomethine structure *(4)*.



(4)

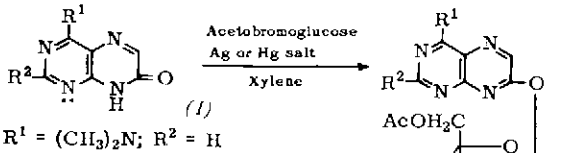
[VB 887/196 IE]

German version: Angew. Chem. 77, 224 (1965)

Syntheses of Heterocyclic O- and N-Glycosides

W. Pfleiderer, Stuttgart (Germany)

2-Amino-4-alkoxy-7-oxodihydropteridines are converted, on direct glycosidation under the conditions described by *Fischer* and *Helferich*, into 2-amino-4-alkoxy-7-glycosyloxypteridines [1]. Pteridine *N*(8)-glycosides were not obtained, even after varying the substituent on the pyrimidine moiety of the 7-hydroxypteridine skeleton. 4-Dimethylamino- *(1a)* [2], 2-amino- *(1b)*, and 2-dimethylamino-7-oxodihydropteridine *(1c)* in the form of their heavy-metal salts react uniformly with α-acetobromoglucose to yield the *O*-glycosides *(2a)–(2c)*.



(1)

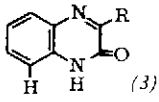
(a): R^1 = $(CH_3)_2N$; R^2 = H

(b): R^1 = H; R^2 = NH_2

(c): R^1 = H; R^2 = $(CH_3)_2N$

(2)

Similarly, 2-oxodihydroquinoxalines *(3)*, R = H, CH_3, C_6H_5, or $CO_2C_2H_5$, yield 2-glycosyloxyquinoxalines exclusively and in excellent yields on glycosidation by the silver- or mercury salt method.

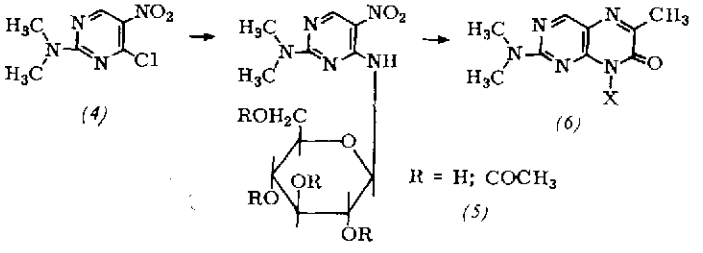


(3)

The selective *O*-glycosidation is explained by a steric inhibition of the *N*-glycosidation by the hydrogen atom on C-8 in *(3)*, and by the lone electron pair in *(1)*. This interpretation is supported by the facts that *O*-glycosides are not rearranged to *N*-glycosides by $HgBr_2$ [3] and that *O*- and *N*-trimethylsilyl derivatives of 2-oxoquinoxalines fail to react with halogeno sugars [4].

Pteridine *N*(8)-glycosides *(6)* may be obtained from 4-aminopyrimidine derivatives [2], or more advantageously by way of a novel route [5] from 4-chloro-5-nitropyrimidines and 1-amino sugars. In 4-chloro-5-nitro-2-dimethylaminopyrimidine *(4)*, the chlorine is readily substituted nucleophilically by 1-amino-β-D-glucose or its 2,3,4,6-tetraacetyl derivative in aprotic solvents.

Catalytic reduction of the 5-nitro group of *(5)* yields 5-amino derivatives, which are key compounds for condensations to pteridine *N*(8)-glycosides *(6)* (using C_2-units), to purine



(4) *(6)*

R = H; $COCH_3$

(5)

(7) *(8)*

N(9)-glycosides *(7)* (using C_1-units), and to triazolo[4,5-*d*]-pyrimidine *N*(3)-glycosides *(8)* (using nitrous acid).

Starting from 1,3-dimethyl-4-chloro-5-nitrouracil, we succeeded in synthesizing, by an analogous route, the first theophylline *N*(9)-glycoside [6]. In this case, steric factors again exert a decisive influence on the course of the reaction.

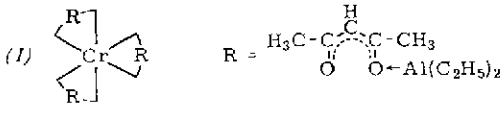
SELECTED ABSTRACTS

Monomeric FCN was obtained in over 50 % yield by *F. S. Fawcett* and *R. D. Lipscomb* by pyrolysis of $(FCN)_3$ at 1300 °C/50 mm. The trimer is passed through an electric arc, the reaction products are immediately quenched and trapped at the temperature of liquid nitrogen. Apart from FCN (m.p. −82 °C, b.p. −46.2 °C), F_3CCN, CF_4, C_2F_4, and other products are also formed. Liquid FCN polymerizes rapidly at room temperature to give $(FCN)_3$ and a high-melting substance that decomposes in water. In the gaseous phase at 1 atm and room temperature, some FCN is still present after a few weeks. FCN can be caused to explode. / J. Amer. chem. Soc. *86*, 2576 (1964) / −Kr. [Rd 124/311 IE]

Mainly 1,2-polybutadiene is formed from butadiene using the soluble complex catalyst *(1)* prepared from chromium acetylacetonate and triethylaluminum according to *C. E. H. Bawn*, *A. M. North*, and *J. S. Walker*. By varying the ratio of the



(1)

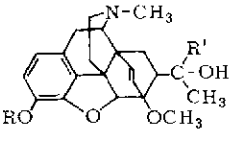
components and the ageing time of the catalyst, either syndiotactic or isotactic 1,2-polybutadiene or a mixture of both can be obtained. For example, with a molar ratio of triethylaluminum to chromium acetylacetonate of 11.6:1, a polymer was obtained at 30 °C, whose analysis by infrared spectroscopy indiciated it to contain 12 % *cis*-1,4- (15.8 μ), 18 % *trans*-1,4- (10.3 μ), and 70 % 1,2-linkages (11.0 μ). Freshly prepared catalyst yields exclusively syndiotactic 1,2-polybutadiene. The growth process is of the first order based on monomer. The number of active sites remains constant throughout the polymerization. / Polymer *5*, 419 (1964) / −Hl. [Rd 184/393 IE]

A simple method for the synthesis of chromium oxide trichloride, $CrOCl_3$, was discovered by *R. B. Johannesen* and *H.-L. Krauss*. It is formed by the reaction

$$6\,CrO_2Cl_2 + 4\,BCl_3 \rightarrow 6\,CrOCl_3 + 3\,Cl_2 + 2\,B_2O_3$$

in refluxing boron trichloride (−13 °C), nitrogen being passed through to carry off the chlorine produced. Excess BCl_3 and unreacted CrO_2Cl_2 are removed from the reaction mixture by vacuum distillation, and the remaining $CrOCl_3$ is then sublimed onto a cold finger at −30 °C. This is the first time that a homopolar Cr(V) compound has been obtained in good yield (50 %). / Chem. Ber. *97*, 2094 (1964) / −Gn. [Rd 165/352 IE]

Alcoholic derivatives of tetrahydro-6,14-endoethenothebaine have a high analgetic effect, according *R. E. Lister*. Although the parent opium alkaloid thebaine has no therapeutic action, some of its tetrahydro-6.14-endoetheno derivatives have activities which are far beyond that of morphium; compounds of type *(1)* have the best analgetic effects.

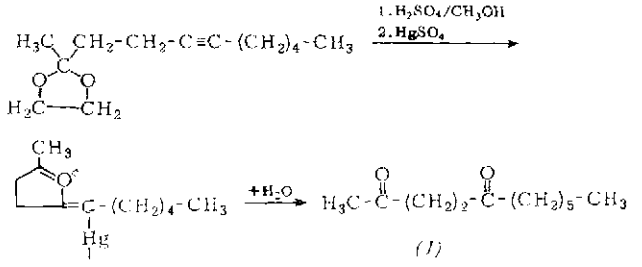


(1a), R = H, R′ = n-propyl
(1b), R = $COCH_3$, R′ = n-propyl
(1c), R = H, R′ = $(CH_2)_2$–$CH(CH_3)_2$

Their relative activities (morphium = 1) are 2060 for *(1a)*, 5330 for *(1b)*, and 7800 for *(1c)*, while their relative toxicities in rats are increased only by factors of 10.8, 16.7, and 27.5, respectively. These compounds therefore possess significantly better therapeutic indices than morphium. / J. Pharmacy Pharmacol. *16*, 364 (1964) / −De. [Rd 68/355 IE]

Complete separation of nucleoside monophosphates has been achieved by *K. Randerath* using two-dimensional thin-layer chromatography on cellulose impregnated with poly(ethyleneimine) which acts as an ion exchanger. Development with 1 N HCOOH in one direction and with 60 % ammonium sulfate in the other not only permits differentiation of AMP, GMP, CMP, UMP (TMP), and their deoxy derivatives, but also effects separation of isomeric purine 2'- and 3'-nucleotides. The separations require only 2 h. / Experientia (Basel) *20*, 406 (1964) / –Re. [Rd 132/319 IE]

1,4- and 1,5-diketones can be prepared from unsymmetrically substituted acetylenes containing a carbonyl group in the γ- or δ-position, according to *G. Stork* and *R. Borch*. The hydration of the triple bond catalysed by H_2SO_4 is directed by a neighboring group effect of the carbonyl group so that 1,4- or 1,5-diketones are produced. Undecane-2,5-dione *(1)*



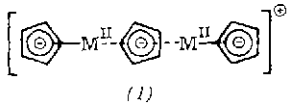
(1)

was obtained in an overall yield of 40 %. The hydration of undec-6-yn-2-one proceeds via a quasi-six-membered ring and yields exclusively undecane-2,6-dione. The formation of 1,5-diones proceeds much slower than that of 1,4-diketones. / J. Amer. chem. Soc. *86*, 935 (1964) / –Re. [Rd 90/360 IE]

Triple decker sandwich complexes derived from ferrocene and nickelocene were found by *E. Schumacher* and *R. Taubenest* during mass-spectrometric investigations of these compounds. The new complexes are presumably formed by ion-molecule association:

$$MCp^{\oplus} + MCp_2 \rightarrow [M_2Cp_3]^{\oplus} \quad (1),$$

where M = Fe or Ni, and Cp = C_5H_5, in the ion source of the mass spectrometer. Peaks with mass numbers which can be



(1)

assigned to mixed triple deckers, $[FeNiCp_3]^{\oplus}$, were also found. / Helv. chim. Acta *47*, 1525 (1964) / –Hz. [Rd 169/378 IE]

N,N-Dialkylhydroxylamines are formed by Michael addition of hydroxylamines onto activated C=C double bonds. *A. A. R. Sayigh, H. Ulrich*, and *M. Green* thus used Reactions (a) and (b) to improve the hitherto unsatisfactory methods of preparing *N,N*-dialkylhydroxylamines. The hydroxylamine hydrochlorides are dissolved in water or methanol with sodium carbonate and the solution of the vinyl component is added dropwise at room temperature over 30 min.

$$RCH{=}CH_2 + H_3CNOH \rightarrow RCH_2{-}CH_2{-}N(CH_3)OH \qquad (a)$$

$$2\,RCH{=}CH_2 + NH_2OH \rightarrow (RCH_2{-}CH_2)_2NOH \qquad (b)$$

Examples: Reaction (a): R = 2-pyridyl, 79 % yield; R = $SO_2C_2H_5$, 49 % yield; Reaction (b): R = 2-pyridyl, 61.5 % yield; R = $SO_2C_2H_5$, 88.5 % yield. With divinyl sulfone, Reaction (a) gives bis-2-(*N*-methylhydroxylamino)ethyl sulfone, m.p. 166–167 °C (74 % yield), and Reaction (b) gives 4-hydroxytetrahydro-1,4-thiazine-1,1-dioxide, m.p. 192–193 °C (85.5 % yield). / J. org. Chemistry *29*, 2042 (1964) / –Jg. [Rd 116/303 IE]

Emission-spectrometric analysis using intermittent beams from a laser for excitation of the samples was described by *E. F. Runge, R. W. Minck*, and *F. R. Bryan*. Here the laser beam is used instead of the conventional discharge or flame to evaporate and photoexcite the material for analysis. Each flash from the laser supplies an energy of 50–75 MJoules in 15–20 nanosec. The photocurrent intensity in the neighborhood of an optical image lies above 10^{13} Watts/cm². This technique brings the significant advantage that even non-conductors can be analysed; furthermore, the analytical sample can be enclosed in a vacuum or under an inert atmosphere. The reproducibility attained so far for quantitative analysis is about 95 %. / Spectrochim. Acta *20*, 733 (1964) / – Hz. [Rd 58/364 IE]

[14]-Annulene occurs as two conformers *(1a)* and *(1b)*; this is the conclusion drawn by *Y. Gaonis* and *F. Sondheimer* from its two sharp NMR signals at τ = 4.42 p.p.m. *(1a)* and τ = 3.92 p.p.m. *(1b)*. The conformers can even be separated by

(1a)   *(1b)*

thin-layer chromatography on silica gel impregnated with $AgNO_3$ and give ultraviolet absorption spectra with slightly different intensities (maxima and shoulders at 317 and 378–380 mμ, respectively). The equilibrium *(1a)* ⇌ *(1b)* depends on the temperature: 5.6:1 at 30 °C, 4.6:1 at 80 °C. X-ray analysis of the crystals at 20 °C indicates only a single molecular form, probably the centrosymmetrical conformer *(1a)*. The attainment of the equilibrium can be followed in freshly prepared solutions, *e.g.* by ultraviolet spectroscopy. / Proc. chem. Soc. (London) *1964*, 299 / –Jg. [Rd 161/348 IE]

Free-radical intermediates of Grignard reactions have been detected by *K. Maruyama*. When nitrobenzene or *p*-nitrosotoluene was mixed in a 1:1 to 1:5 proportion with phenyl- or *p*-toluylmagnesium bromide at –78 °C, the reaction solution

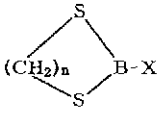
$$C_6H_5NO + C_6H_5MgBr \rightarrow C_6H_5{-}\underset{\displaystyle O^{\bullet}}{N}{-}C_6H_5 \quad (1)$$

$$C_6H_5NO + p\text{-}CH_3{-}C_6H_4MgBr \rightarrow p\text{-}CH_3{-}C_6H_4{-}\underset{\displaystyle O^{\bullet}}{N}{-}C_6H_5 \quad (2)$$

$$p\text{-}CH_3{-}C_6H_4NO + C_6H_5{-}MgBr \rightarrow p\text{-}CH_3{-}C_6H_4{-}\underset{\displaystyle O^{\bullet}}{N}{-}C_6H_5 \quad (2)$$

suddenly turned brown, and strong electron-spin resonance signals due to the free radicals *(1)* and *(2)* could be observed. / Bull. chem. Soc. Japan *37*, 1013 (1964) / –Kr. [Rd 123/310 IE]

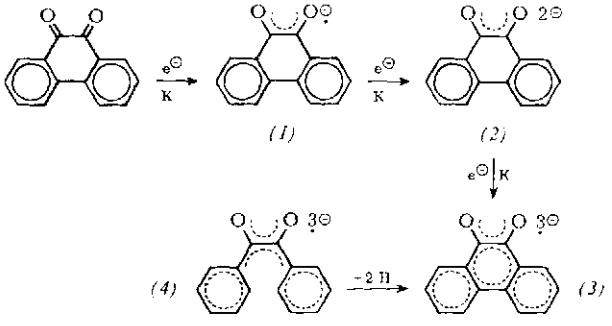
The production and properties of boron heterocycles containing sulfur are described by *A. Finch* and *J. Pearn*. Compounds of type *(1)* were prepared by adding suitable dithiols to BCl_3 or phenylboron dichloride in CH_2Cl_2 at –80 °C and allowing the mixture to warm up to room temperature. The heterocyclic products *(1)* are readily hydrolysed, and though sensitive to oxygen are stable at room temperature and resist heating at



(1) X = Cl, C_6H_5

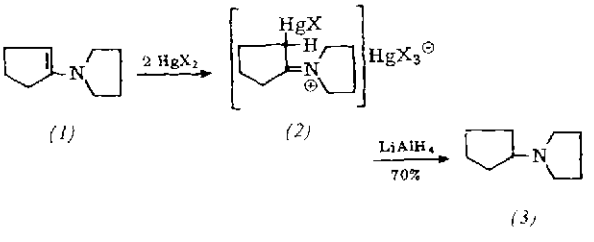
100 °C for several hours. Examples of *(1)* are 2-chloro-1,3,2-dithiaborolane (n = 2), b.p. 24–25 °C/0.1 mm (obtained in 88 % yield), 2-chloro-1,3,2-dithiaborinane (n = 3), b.p. 56–58 °C/0.2 mm (80 % yield), 2-phenyl-1,3,2-dithiaborolane (n = 2), b.p. 97–98 °C/0.1 mm (92 % yield), and 2-phenyl-1,3,2-dithiaborinane (n = 3), b.p. 109–110 °C (90 % yield). / Tetrahedron *20*, 173 (1964) / –Ma. [Rd 128/315 IE]

A novel radical trianion was obtained by *N. L. Bauld* on treatment of phenanthroquinone with potassium metal. The free-radical monoanion *(1)* formed first is transformed into the dianion *(2)* and finally into the free-radical trianion *(3)* by progressive addition of electrons. The product *(3)* is purple with λ_{max} = 555 and 410 mμ and behaves like a triacidic base on titration with acid. Its ESR spectrum shows a signal for the unpaired electron. The third electron is released very readily to reducible materials, with reconversion of *(3)* to the dianion *(2)*, which can be trapped in 70 % yield with benzoyl chloride in the form of 9,10-di-(benzoyloxy)phenanthrene. The trianion *(3)* is also obtained from the radical trianion *(4)* of benzil, which loses two of its *ortho*-hydrogens spontaneously from a *cis*-configuration.



Molecular-orbital calculations suggest that the two extra electrons in *(2)* are located in a non-bonding orbital of its 1,2-dioxo grouping. On the other hand, the third electron in *(3)* is supposed to be distributed in an orbital spread out over the aromatic rings with high spin density in the four positions *ortho* and *para* to the keto groups. The resolution of the ESR signals into 5 lines confirmed this hypothesis. / J. Amer. chem. Soc. *86*, 3894 (1964) / –Eb. [Rd 194/403 IE]

***C*-Mercuration of an alkenylamine** has been observed for the first time by *K. Broderson, G. Opitz*, and *D. Breitinger*. The tertiary alkenylamine pyrrolidinocyclopentene *(1)* was known from earlier studies by these authors to be highly reactive. When treated with HgX_2 in ether, it gives an amorpbous precipitate $C_9H_{15}N \cdot nHgX_2$, where n = 1.9 (X = Cl) or 2.0 (X = Br). The



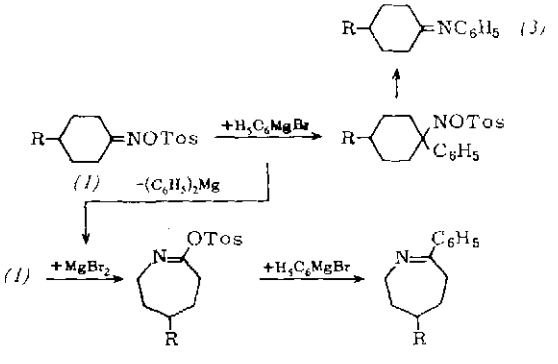
hypsochromic shift of the double-bond absorption from 1630 cm^{-1} in the alkenylamine to 1657 cm^{-1} in the adducts supports their formulation as *(2)*; confirmatory evidence is obtained from the reduction of the adducts, which affords *(3)*. Moreover, cyclopentanone should have been obtained by degradation of the product if it had been an *N*-mercurated compound, but no cyclopentanone could be detected. / Chem. Ber. *97*, 2046 (1964) / –Gn. [Rd 163/350 IE]

A synthesis of nitriles from α-chloro ethers and NaCN is reported by *P. A. Argabright* and *D. W. Hall*. Although α-chloro ethers do not react with NaCN or KCN in hydrocarbons or ethers, they react vigorously in other non-protonated solvents such as dimethylformamide or dimethylsulfoxide. Thus, for example, methoxyacetonitrile, b.p. 111 °C/624 mm, was obtained in 62 % yield from H_3COCH_2Cl and biscyanomethyl ether, m.p. 38–39 °C, in 30 % yield from bischloromethyl ether (crude yield 90 %) in this way. / Chem. and Ind. *1964*, 1365 / –Ma. [Rd 126/313 IE]

The mechanism of the end-product inhibition of aspartate transcarbamylase (ACTase) is described by *J. C. Gerhart* and *A. B. Pardee*. The enzyme from *Escherichia coli* is tetrameric (molecular weight = 250000) and consists of subunits with a molecular weight of 65000. The feedback inhibitor cytidine triphosphate (CTP) acts by strengthening the bonding between the subunits, thus decreasing the affinity of the enzyme for its substrate aspartic acid. The enzyme can be broken down into its subunits without loss of activity; the subunits cannot be inactivated with CTP. Adenosine triphosphate is a competitive antagonist of CTP. This mechanism is an example of the allosteric inhibition described by *Monod* [1], whereby the inhibitor becomes attached to a site on the enzyme which is remote from the site of attachment of the substrate. The inhibitor alters the conformation of the enzyme and thus decreases the affinity for the substrate. / Federat. Proc. *23*, 727 (1964) / –Hö. [Rd 190/399 IE]

An unusually high H/D isotope effect of 24.2 was discovered by *L. Funderburk* and *E. S. Lewis* for the proton transfer from 2-deuterio-2-nitropropane to 2,4,6-collidine as acceptor during iodination of the compound. This is a sterically hindered and therefore slow acid-base reaction which can be followed conveniently at room temperature by measuring (by spectrophotometry in butanol/water at 24.88 °C) the decrease in the concentration of the iodine, which is used up in a rapid reaction following the rate-determining anionization. This isotope effect lies above the highest observed to date (k_H/k_D = 16) and above the maximum permissible by the classical theory of absolute reaction rates ($k/_Hk_D$ = 17); the authors consider that it can be explained only by quantum mechanical tunnelling. It is known that compressional energies are strongly dependent upon alterations in the interatomic distances. Since the reaction investigated has a transition state which is essentially characterized by compressional energies, the energy profile must be narrow and very high. This is the ideal prerequisite for the occurrence of a tunnel effect. / J. Amer. chem. Soc. *86*, 2531 (1964) / –Eb. [Rd 191/400 IE]

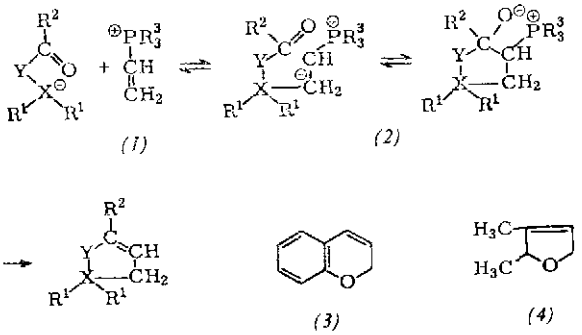
The reaction of oxime tosylates with phenylmagnesium bromide was investigated by *R. E. Lyle* and *St. S. Palosi*. Since the tosyl group – in contrast to the *O*-hydrogen on oxime groups – is stable towards the Grignard reagent, side reactions are avoided. Rearrangement occurs and the Schiff bases are formed in yields of about 80 %. – The formation of 60 % 5-t-butyl-2-phenyl-1-azacycloheptene *(2)* and 20 % 4-t-butylcyclohexanone anil *(3)* from 4-t-butylcyclohexanone oxime *O*-tosylate *(1)* and phenylmagnesium bromide can be explained as follows:



It was shown that the Lewis base $MgBr_2$ catalyses the rearrangement of the oxime by rearranging pure benzophenone oxime *O*-tosylates with $MgBr_2$ in ether. / Chem. Engng. News *42*, No. 16, p. 45 (1964) / –Re. [Rd 91/361 IE]

[1] *J. Monod, J.-P. Changeux*, and *F. Jakob*, J. molecular Biol. *6*, 306 (1963).

A novel general synthesis of heterocyclic and carbocyclic compounds is described by *E. E. Schweizer*. Anions formed from ROH, R_2NH, RSH, R_3CH, or R_2PH add onto triphenylvinylphosphonium bromide *(1)* to form phosphorylides *(2)* which in turn attack functional groups. For example, *(1)* reacts with the sodium salt of salicylaldehyde at 110 °C to give 3,4-chromene *(3)*, b.p. 91–93 °C/13 mm, in 62 % yield together with triphenylphosphine oxide; in acetonitrile the yield rises to 71 %. Acetoin and NaH react in ether with *(1)* when dimethylformamide is subsequently added to give 2,5-dihydro-2,3-dimethylfuran *(4)*, b.p. 104 °C, in 39 % yield within 48 h at room temperature, together with 49 % triphenylphosphine oxide.



(1) *(2)* *(3)* *(4)*

Y is any bivalent aliphatic or aromatic group, X may be O, N, or C; R^1 is an aliphatic, aromatic, or electron-attracting group, or can be omitted (*e.g.* when X = O); R^2 is an aliphatic or aromatic group or hydrogen, and R^3 is C_6H_5. / J. Amer. chem. Soc. *86*, 2744 (1964) / –Ma. [Rd 131/318 IE]

BOOK REVIEWS

Thermodynamik der irreversiblen Prozesse (Thermodynamics of Irreversible Processes). By *R. Haase*. Fortschritte der Physikalischen Chemie (Advances in Physical Chemistry) Vol. 8. Edited by *W. Jost*. Dr. Dietrich Steinkopff Verlag, Darmstadt 1963. 1st Edit., XII + 552 pp., 40 figs., 23 tables, hard covers DM 90.– (about $ 22.50), linen DM 95.– (about $ 24.00).

The discussion in this book is limited to the macroscopic-phenomenological theory of the thermodynamics of irreversible processes; the problems concerned with statistical or kinetic confirmation of the postulates used are left untouched.

In the first chapter, a summary is given of thermodynamic fundamentals, equilibrium criteria, and stability conditions, and the entropy balance for homogeneous systems is derived; next the linear equations for the connections between generalized currents and forces are introduced, and the Onsager-Casimir reciprocity relationships are postulated. A final section on the transformation of currents and forces completes the principles of the theory, which is then developed further in the next chapters.

The second chapter deals with processes in homogeneous systems (chemical reactions, relaxation phenomena, the speed of sound in liquid phases), while the third chapter is devoted to processes occurring in discontinuous heterogeneous systems (electrokinetic effects, membrane processes, and thermomechanical effects).

In the fourth chapter, processes in continuous systems are discussed. During the development of the formulae for the entropy balance in Part A, the reduced thermal current is used throughout, and thus the local production of entropy and the total entropy current remain independent of the reference speed in many practically important cases. Part B deals with isothermal and Part C with non-isothermal processes, separate sections (*e. g.* on thermodiffusion, concentration cells, centrifugal cells, thermo-cells, electrolytic thermoelements, *etc.)* being devoted to electrolyte solutions. Part D gives a discussion on processes with internal friction, in magnetic fields, and in anisotropic media. – The fifth chapter gives a discourse on stationary states and closes with an outlook towards biological systems.

The book is characterized by the ease with which it can be read, owing to the combination of scientific exactness with a broad presentation of topics and to the effort to give each symbol a characteristic individual meaning by purposeful use of sub- and superscripts. The frequent comparisons of theory with experimental results should arouse considerable interest, for this conveys some impression of the order of magnitude or importance of the coefficients which crop up.

The unfortunately high price of the volume evokes the question whether scientific monographs should not be regarded as being worthy of subvention. *M. Becker* [NB 330/188 IE]

Die chemische Bindung. Drei Vorlesungen für Chemiker (The Chemical Bond – Three Lectures for Chemists). By *H. Hartmann*. Springer-Verlag, Berlin-Göttingen-Heidelberg 1964. 2nd Revised edit., vi + 109 pp., 61 figs., linen DM 9.80 (about $ 2.50).

In his three lectures *H. Hartmann* develops the theory of the chemical bond on the basis of the field theory of matter. The book has been developed from lecture manuscripts and is intended primarily for the use of chemistry students.

In the first lecture, the fundamentals of the field theory of the "cathode substance" (*i.e.* the electron), the electronic theory of the atom, and the periodic system of the elements are discussed. The second lecture deals with problems relating to the chemical bond. Examples are used to illustrate the hydrogen-molecule ion, directed valences, hybridization of the carbon atom, and simple and multiple bonds. The third lecture is confined to the discussion of a few special problems of bonding. The basic principles of the ligand field theory are derived, starting from a consideration of ion lattices and ion complexes. The bond order in complicated molecules, the theory of π-electron systems, and finally the energy bands in metal lattices form the subjects for discussion. The lecture closes with a brief interpretation of the transition states of chemical reactions.

The book does not demand a knowledge of mathematics, but still does not make easy reading, for not only does it convey information about the chemical bond, but strives to impart a complete understanding of the phenomenon. Hence it can definitely be recommended to every student of chemistry who is seeking a firmer foundation for his knowledge. In addition, on account of its original approach and unusual presentation of ideas, the book will certainly be of interest to all associated with didactic problems in chemical education.

H. Zimmermann [NB 269/126 IE]

Lehrbuch der anorganischen Chemie (Textbook of Inorganic Chemistry). By *A. F. Holleman* and *E. Wiberg*. Verlag Walter de Gruyter & Co., Berlin 1964. 57th–70th Edits., xxi + 766 pp., 177 figs., one table, linen DM 32.– (about $ 8.00).

The popularity of "Holleman-Wiberg" has been maintained for decades by its readers and is shown in the rapid sequence of new editions. This is due principally to the success with which the authors have constantly revised and modernized their textbook. Here only the most important of the numerous additions and improvements included in this printing (which corresponds to a total of 14 editions) can be recorded.

The chapter on the chemical bond has been significantly extended and modernized. The wave-mechanical concepts of s-,

p-, and d-orbitals, the explanation of the formation of σ- and π-bonds according to the valence bond theory, and the stereochemical consequences of hybridization are discussed in a new eleven-page section illustrated with numerous figures. Brief reference is also made to the ligand field theory and its more quantitative aspects. Considerable extensions have been made to the chapters on metal carbonyls and aromatic complexes, molecular spectroscopy (including nuclear magnetic resonance), and the lattice structures of elements and compounds – a field that was hitherto only incompletely considered. One valuable didactic improvement in the textbook is the enclosure of "three-dimensional" illustrations, which when viewed through red/blue spectacles reproduce the stereoscopic images of the most important molecular and lattice structures; this innovation will be especially welcomed by younger students who are not yet accustomed to picturing such structures in three dimensions. The atomic weights of the elements are all referred to the new basis $^{12}C = 12.000$. The historical and biographical appendices have been augmented, and both author index and subject index are included. Another welcome feature is the inclusion for the first time of numerous references to review articles and monographs in order to facilitate further reading by those interested in specialized topics of inorganic chemistry.

This new presentation of "Holleman-Wiberg" fulfills all the requirements of a modern textbook on inorganic chemistry, and its clarity and topicality leaves nothing to be desired.

R. Nast [NB 262/120 IE]

Fortschritte der Chemie organischer Naturstoffe (Advances in the Chemistry of Organic Natural Products). Vol. XXI. Edited by *L. Zechmeister*. Springer-Verlag, Vienna 1963. 1st Edit., VII + 362 pp., 14 figs., linen DM 76.– (about $19.50).

The high quality of previous contributions to this series has been maintained in the present volume. *W. Oroshnik* and *A. D. Mebane* discuss the chemistry of "Polyene Antifungal Antibiotics". Since all of these compounds are macrolides and cannot be distinguished from other macrolides biogenetically, it would be better to designate them as polyene macrolides and thus avoid confusing them with acetylene antibiotics such as mycomycin. The elucidation of the structures and the chemical properties of tetracyclines are described by *H. Muxfeldt* and *R. Bangert* in a detailed review. Attempts at their synthesis are mentioned only briefly here as they are to be discussed in detail in a later contribution. Derivatives of 7,8,9,10-tetrahydro-5,12-tetracenoquinone are termed anthracyclinones by *H. Brockmann* who gives the first comprehensive survey of this antibiotic natural pigment. *L. Crombie* reviews recent developments in the field of rotenoids, particularly the clarification of the absolute configurations of these compounds. The chapters by *J. Bonner* on the biosynthesis of rubber and by *L. Jaenicke* and *C. Kurtzbach* on folic acid and folate enzymes go beyond the conventional limits of this series, for here it is mainly enzymatic reactions that are discussed. Although the interest of natural-product chemists in biochemistry is increasing constantly, the reviewer doubts that extension of the coverage of the series in this direction in future volumes would be advantageous.

A study of Vol. 21 will also be most profitable even to those whose interests are only remotely connected to the chemistry of natural products. It would be good if the publishers decided to designate the formulae with Arabic numerals.

H. Grisebach [NB 246/104 IE]

Allgemeine Biochemie. By *J. Kostir*. VEB Gustav Fischer Verlag, Jena 1963. 1st Edit., xiv + 509 pp., 24 figs., 3 tables, linen DM 64.70 (about $16.50).

Textbooks on biochemistry tend to emphasize either the biological aspects or the chemical aspects of the subject. In his "General Biochemistry" *J. Kostir* attempts to present both points of view in a manner advantageous to the student. The chemical portion is placed in the foreground; its content is more than sufficient to satisfy the needs of the medical student. On the other hand, the presentation of the functional topics is less gratifying. Even though some new results have been considered, the outlay and description of functional processes are not in keeping with a modern short presentation of the field of biochemistry. This already becomes apparent from the arrangement of the material, where, for example, the concept of "biocatalysis" is prominently displayed; although this may have been a valuable approach at one time, it is didactically erroneous nowadays. The book is valuable as a supplementary textbook, since it attempts to reproduce a condensed but comprehensive coverage of the whole field. However, it is not to be recommended as sole textbook for an introduction to biochemistry. *M. Klingenberg* [NB 247/105 IE]

The Chemistry of Nucleosides and Nucleotides. By *A. M. Michelson*. Academic Press, Inc., London-New York 1963. 1st Edit., ix + 622 pp., several figs. and tables, linen £6.6.0 (about $17.50).

Following a short historical introduction, the first two chapters describe the isolation, structure, chemical properties, and chemical syntheses of nucleosides and nucleotides, their intramolecular anhydrides, and cyclonucleosides and cyclic nucleotides. In Chapter 4 mixed anhydrides of nucleoside phosphates with other acids are discussed, according to the same pattern. This group includes nucleoside diphosphates and triphosphates and their compounds with sugars and peptides, diphosphopyridine nucleotide and triphosphopyridine nucleotide, nicotinamide adenine dinucleotide, and mixed anhydrides with sulfuric acid, carbonic acid, and organic acids. After the section on the chemical syntheses of these compounds, the next chapter deals with their biosynthesis. Chapters 6–9 are devoted to high molecular-weight nucleic acids. The organic chemistry of nucleic acids is dealt with first, emphasis being on the purification, isolation, and identification of these substances and on their chemical and enzymatic reactions. In the next chapter, the various possibilities for synthesizing oligonucleotides are described. This is followed by discussion of the physical chemistry of nucleic acids: this section includes, for example, the investigations on their hypochroism and other optical properties, their hydrogen-bond formation, the formation of double helices, the determination of their charge, their viscosities, their flow birefringence, and the processes occurring during their denaturation and renaturation. In the concluding chapter a short survey is given of the biological functions of nucleic acids, including a discussion of transformation and transduction and of their importance for protein synthesis. As already indicated by the title of the book, it is the chemistry of the nucleic acids that is emphasised, in accordance with the field of research of the author who is himself a prominent nucleic-acid chemist. The individual sections have been worked out with great care and criticism and are amply illustrated by numerous formulae. The volume contains over 2000 references divided into groups at the end of each chapter.

Factual information in this field is increasing so rapidly that it is hardly longer surveyable without the aid of this excellent book. Despite its shortness, the immensity of its content makes it more a work of reference than a textbook.

The reviewer himself has often consulted the book as regards his own work for some time now, and can therefore say from his own experience that it will be needed by everyone wanting to work in the field of nucleic acids.

G. Schramm [NB 281/139 IE]

Methods in Carbohydrate Chemistry. Edited by *R. L. Whistler, R. J. Smith, J. N. BeMiller*, and *M. L. Wolfrom*. Vol. IV: Starch. Academic Press, New York-London 1964. 1st Edit., xvi + 335 pp., numerous illustrations and tables, linen $13.50.

The chemistry of starch is complicated by differences in its composition depending on its source, by its formation from

two different polysaccharides, and by the numerous products which contaminate it. It is therefore to be welcomed that a volume on starch has been published in the series on "Methods in Carbohydrate Chemistry". Sixty-one authors combine to discuss the entire field in six chapters: 1. Production of starch and its fractions; 2. Chemical analysis; 3. Physical analysis; 4. Microscopy; 5. Degradation reactions; and 6. Derivatives and modifications (oxidation products).

A great advantage of the book is that the individual sections have been written by acknowledged experts and that the practical procedures given can be repeated without reference to further literature. However, the divison into very short contributions has also some disadvantages which cannot be overlooked. For example, there is unavoidably a lack of objectivity, since understandably, every contributor places his method in the forefront. One result of this is that, as in the volume on cellulose, German publications are hardly mentioned, although this would in fact be highly justified. The uniformity also suffers as a result of the book having so many authors; thus, sometimes only starch is discussed, and at other times only amylose and amylopectin are considered, without any recognizable organizing principle. This finds its expression in the highly differentiated and frequently inadequate characterizations given; data on the degree of degradation effected by the individual reactions or on the characterization by viscosity measurements throughout would greatly simplify use of the volume.

The treatment of the physical methods does not appear to be very fortunate; the basic priniples of diffusion, light scattering, and ultracentrifugation are described, topics which can be read up in many monographs, but practically no examples are given. It would be more important for the reader if tables of substances that have been investigated by these methods were compiled.

The book is suitable as a guidebook for introductory preparative work in the field of starch. For more intensive work on the subject, other monographs or original publications must be consulted.

E. Husemann [NB 282/140 IE]

Complexation in Analytical Chemistry. A Guide to the Critical Selection of Analytical Methods Based on Complex Formation Reactions. By *A. Ringbom*. Chemical Analysis: A Series of Monographs on Analytical Chemistry and its Applications, Vol. XVI. Edited by *P. J. Elving* and *I. M. Kolthoff*. Interscience Publishers, a Division of John Wiley & Sons, New York - London 1963. 1st Edit., x + 395 pp., numerous illustrations and tables, linen $15.00.

This excellent book by the well-known Finnish analyst deals with complex formation in aqueous solution using a theoretical approximation which permits simple prediction of important quantitative data with sufficient accuracy to satisfy the practitioner, *e.g.* on the most favorable experimental conditions, on the effect of interfering side-reactions in conventional analytical procedures, or on suitable methods for solving a particular analytical problem. Here the concept of "complex" is used in a rather broad sense and encompasses *inter alia* acids and bases as well. Complex formation is discussed with regard to masking, complexometric titrations, acid-base titrations, ion exchange, extraction, and electrochemical and photometric analysis. In these sections the theoretical basis of each method is discussed without giving comprehensive literature surveys or special working procedures. The application of the approximation method is illustrated by numerical examples. An appendix comprising eighty pages contains stability constants *etc.*

For the analyst who has a good knowledge of the theory of aqueous electrolyte solutions, this very valuable book will help him to avoid much experimental groundwork in appraising any specific analytical procedure. For those who are less familiar with the field, especially students, it will serve as an easily intelligible introduction to the subject, since the text is lucid and readily comprehensible.

Werner Fischer [NB 243/101 IE]

Interfacial Phenomena. By *J.T. Davies* and *E. K. Rideal*. Academic Press, New York-London 1963. 2nd Edit., viii + 480 pp., numerous illustrations and tables, linen $15.00.

This book deals with the phenomena associated with the interfaces between non-miscible liquids, between liquids and gases, and between solids. The treatment is intelligible even to those who are not experts in this field, and the text is supplemented by abundant references; it is directed mainly at chemists and biologists. The principal theme is about the fundamental problems of interfacial phenomena; the more technical aspects of the subject fade somewhat into the background. Theory and experimental methods are discussed in detail. Separate chapters are devoted to electrostatic and electrokinetic phenomena, adsorption at interfaces, the properties of monomolecular layers (including the damping of waves), reactions at interfaces, and diffusion through interfaces. The final chapter deals with the most important properties of disperse systems and with adhesion insofar as they are related to the fundamentals disclosed earlier in the book. This chapter includes a discussion of aerosols, emulsions and suspensions, and phenomena such as foaming and lubrication, and also wetting problems are analysed.

A. Saupe [NB 272/129 IE]

Interpretation of Mass Spectra of Organic Compounds. By *H. Budzikiewicz, C. Djerassi*, and *D. H. Williams*. Holden-Day, Inc., San Francisco 1964. 1st Edit., xiii + 271 pp., numerous illustrations, linen $8.75.

The impetus for the publication of this book came from the papers (over fifty in number) which appeared over somewhat less than three years. In these papers *Djerassi* and *Budzikiewicz* have discussed their work on mass spectrometric investigations of organic compounds. The book is directed exclusively towards the organic chemists, and typical mass spectrometric fragmentations, *e.g.* of alcohols, ethers, thiols, carbonyl compounds, amines, amides, halides, and nitriles, are described in detail with recourse to the complete literature. The sections on heterocyclic and aromatic compounds are particularly good.

The only departure from the general approach adopted in the book is the too detailed discussion of a few highly specialized classes of compounds (cyclic ketones and amides). The sections on tobacco alkaloids and steroids are superfluous, since the same authors have announced their intention to publish separate books on these subjects. However, it might have been expected that the pioneer work by *Stenhagen* and *Ryhage* would have been discussed more thoroughly.

In order to give as uniform a presentation of fragmentation reactions as possible, the concept is adopted at the outset that in compounds containing a hetero-atom, the electron which is split off during ionization is removed only from the hetero-atom. Although this is usually true for simple molecules, the validity of this assumption cannot be generalized, particularly for larger molecules. The attempt to explain all fragmentations using this scheme leads to reaction mechanisms such as that given on page 5 where an electron pair and a single electron inexplicably migrate in the same direction, or to the postulation of degradation reactions (p. 90, decomposition of compound LI) for which simpler explanations are at hand (cf. *H. Audier, M. Fetizon*, and *W. Vetter*, Bull. Soc. chim. France *1963*, 1971).

The arguments presented in the text are supplemented by a wide selection of mass spectra. A short subject index provides an aid to rapid reference.

G. Spiteller [NB 252/110 IE]

Chemical Kinetics of Gas Reactions. By *V. N. Kondrat'ev*, translated from the Russian by *J. M. Crabtree* and *S. N. Carruthers*, edited by *N. B. Slater*. Pergamon Press, Oxford-London-New York-Paris 1964. 1st Edit., xi + 812 pp., 200 figs., 62 tables, linen £5.5.0 (about $15.00).

The kinetics of chemical reactions in the gas phase has made tremendous theoretical advances and has been applied to various new fields within recent years. Theoretical treatment

by numerous authors of elementary chemical processes has met with a large measure of success. Such processes include the use of transition-state methods or quantum-mechanical methods, of unimolecular reactions by *Slater*, and of the transfer of translatory, vibrational, and rotational energy. From the experimental standpoint, the classic thermal reactions have been supplemented by many new ones, *e.g.* reactions occurring in the upper terrestial atmosphere, reactions occurring in electrical discharges, radiochemical reactions, and novel flame reactions.

In his book which appeared in Russian in 1958, *Kondrat'ev* gave an excellent survey of these developments; the same can be said of the present English translation edited by *Slater*, which also provides extensive coverage of work meanwhile reported. The topics dealt with include the general laws of chemical reactions and their mechanisms, the theory of elementary processes, unimolecular, bimolecular, and termolecular reactions, energy conversions during molecular collisions, photochemical reactions causing fluorescence or quenching of fluorescence, reactions initiated by electrical discharges, bombardments with fast ions and atoms, the effects of penetrating radiation, chain reactions, and combustion reactions.

An enormous number of theoretical and experimental results have been evaluated with great care; *Kondrat'ev* has classified these and called attention to many imperfections and disparities requiring further theoretical and experimental investigations.

The book should prove to be of value to all chemists; it can even be considered indispensible to all working on reaction kinetics in the widest sense. It can be recommended to students on account of its lucid and simple presentation of the theoretical side of the subject.

W. Groth [NB 259/117 IE]

Tables of Experimental Dipole Moments. By *A. L. McClellan*. W. H. Freeman and Co., San Francisco-London 1963. 1st Edit., 713 pp., linen £5.0.0 (about $ 16.00).

Every chemist who sometimes wants to know the dipole moment of a certain compound is familiar with the difficulties involved in finding the desired value because only older incomplete tables are available so that he must look for the dipole moment in general abstract journals or in the original literature. For this reason the author of this book has undertaken the commendable task of collecting all the dipole-moment values published up to the end of 1961 and arranging them into three tables. Table I contains the dipole-moments for about 250 compounds containing no carbon atoms, Table II summarizes those for about 4500 compounds containing one or more carbon atoms, and Table III lists the values for about 100 compounds whose formulae are not exactly known. The method of tabulation corresponds to that of the formula indexes of Chemical Abstracts, so that all the compounds listed can be found rapidly. Each entry in the tables gives the molecular formula, the dipole moment (with limits of error), and reference to the source of the measurement, together with the name of the appropriate compound, its state of aggregation or solvent used, the temperature, measuring procedure, and the atomic polarization used for evaluation. The only worthwhile data missing are particulars of the methods used to calculate the values from the dielectric constants.

The quality of the tables can be appreciated from their completeness, the correctness of the data, and the orderliness of arrangement. Numerous references selected at random proved that 90–95 % of the entries taken from the literature are correctly listed. The layout of the tables is very orderly. A few small errors are naturally unavoidable within the confines of such an extensive work; *e.g.* all the dipole-moments given that were allegedly determined by the "fluorescence" method were actually found from the dependence of the dielectric constants of solutions on the concentration, and the dipole moment of *p*-dimethylamino-ω-nitrostyrene is given on page 495 under the formula and name of the corresponding stilbene.

The book can be recommended to every chemical library, and it will soon be a familiar work of reference for every chemist who has to search frequently for dipole moments. It is only to be hoped that supplements will appear at short intervals.

W. Liptay [NB 263/121 IE]

Advances in Chemical Physics. Edited by *I. Prigogine*. Vol. VI. Interscience Publishers, a Division of John Wiley & Sons, London-New York-Sidney 1964. 1st Edit., ix + 506 pp., several illustrs. and tables, linen £6.0.0 (about $ 17.00).

Most of the contributions in this volume attempt at as stringent a discussion of the theory of the respective topic as possible: thus, for example, in the first article "Towards an analytic theory of chemical reactions", *H. Aroeste* states prefatorily: "The main purpose of an analytic approach to the theory of chemical reactions is to furnish a detailed understanding of the elements involved rather than to provide a quick comparison with experimentally determined macroscopic rates".

Similar remarks apply to the contribution of *A. Bellemans* and *M. de Leener* on the "Electron gas in a lattice of positive charges". *M. Fixman*'s treatment of „The critical region", although fundamentally theoretical, lies closer to experimentation. This chapter can be recommended to all interested in this field, which is still far from stagnating. The same can be said of the following chapter by *H. L. Frisch* on "The equation of state of the classical hard-sphere fluid". This is a strongly idealized model of a liquid, but it can be carried through up to comparison with experiment. The next chapter too, "Studies in the kinematics of isothermal diffusion. A macrodynamical theory of multicomponent fluid diffusion" by *O. Lamm*, concerns the experimentor. The next contribution, on the "Many-electron theory of atoms, molecules, and their interaction", by *O. Sinanoglu* conveys an impressive view of the high level of theoretical chemical research in the U.S.A., but is only accessible to the theorist. The same might hold for the article by *J. Stecki* on "Ionic solvation". Another theoretical article by *J. Chr. Erikson* attempts to improve the unsatisfactory situation in the thermodynamics of surface systems. The final chapter by *A. R. J. P. Ubbelohde* on the "Melting mechanisms of crystals" is again of a more experimental orientation.

The volume is of high quality throughout and ought to provide a good work of reference for all specialists in these fields, but is probably much too specialized for the average pure chemist.

W. Jost [NB 267/138 IE]

Analytical Chemistry of the Actinide Elements. By *A. J. Moses*. Vol. 9 of the International Series of Monographs on Analytical Chemistry edited by *R. Belcher* and *L. Gordon*. Pergamon Press, Oxford-London-New York-Paris 1963. 1st Edit., 137 pp., numerous illustrations and tables, linen £2.5.0 (about $6.25).

In view of the increasing scientific and technical importance of the actinides, the appearance of this monograph is to be welcomed. The scope of the book is limited in so far as the analytical chemistry of the transamericium elements is still relatively unknown, although some known procedures might be applicable to them. The presentation of the material is terse and clear, especially due to numerous tables. Appropriate space has been devoted to the description of the nuclear properties and the analytical applications of the radioactivity of the nuclides; several pictures of radiation detection and irradiation facilities covering full pages are however more of an illustrative nature than of utility. The importance of chromatographic separation procedures should have been accounted for to a greater extent. The numerous methods of detection and determination described will be especially appreciated. Although detailed analytical procedures are given only occasionally, the book provides useful hints and suggestions for the analyst in helping him to solve even special problems of actinide analysis.

K. Schwochau [NB 274/131 IE]

The Theory of the Electronic Spectra of Organic Molecules. By *J. N. Murrell*. Methuen & Co., Ltd. London; John Wiley & Sons, Inc., New York 1963. 1st Edit., xiv + 328 pp., numerous illustrations and a few tables, linen £2.15.0 (about $8.00).

J. N. Murrell, University of Sheffield (England), presents the subject here so that it will appeal to those interested in either the practical or theoretical aspects of electronic spectra. In the first three chapters, the quantum-mechanical fundamentals and theories of electronic spectra are discussed, particular attention being paid to the valence bond theory and the molecular orbital theory, the latter with emphasis on the treatment of the free electron and the LCAO approximation. The author describes this introduction as being intended merely as a resumé and as a recapitulation for readers who already have some knowledge of quantum mechanics. Chapters 4–6 are devoted to the absorption spectra of ethylene, acetylene, conjugated open-chain unsaturated hydrocarbons, and benzenoid hydrocarbons. Here the experimental findings are taken as the starting point for a discussion of the theoretical aspects of the spectra, their mathematical evaluation, and of the resulting information about the structures of the molecules concerned. Somewhat surprisingly, but perhaps justifiably on account of its non-stereotypical spectrum, benzene itself is discussed after the other benzenoids. The remaining eight chapters deal with more specific problems: chromophores with weak interactions, transitions of non-bonding electrons, inductive, mesomeric, and steric effects, radicals and ions, molecular complexes, and fluorescence and phosphorescence. Some mathematical theorems and calculation procedures are discussed in an appendix separated from the main body of the text. Every chapter is embellished with references (as footnotes) including sources of more detailed information for further study. The book closes with a rather inadequate subject index, but its lay-out and print are excellent. The reviewer considers the book unsuitable for occasional cursory reference, but whoever takes the trouble to work through it methodically will be amply rewarded and will find it an excellent guidebook.

The Chemistry of Diimine

BY PROF. DR. S. HÜNIG [1], DR. H. R. MÜLLER, AND DR. W. THIER

CHEMISCHES INSTITUT DER UNIVERSITÄT MARBURG/LAHN, INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT MÜNCHEN, AND CHEMISCHES INSTITUT DER UNIVERSITÄT WÜRZBURG (GERMANY)

The presence of diimine in solution can be shown conclusively by the stereospecific cis-hydrogenation of symmetrical multiple bonds. Apart from reactions which have hitherto been attributed to hydrazine, this review deals primarily with the various sources and secondary reactions of diimine.

I. Early History of Diimine

In spite of the highly developed state of azo-chemistry, the question of the existence of the parent compound, "azohydrogen", *i.e.* diimine [2], remained unanswered until a few years ago, although the first attempts to detect it date back to the last century.

The smooth decarboxylation of the potassium salt of azodicarboxylic acid *(1)* on hydrolysis at room temperature led *Thiele* [3] (1892) to believe that he had evidence for the existence of diimine. However, the hydrolysis products consist of equivalent quantities of nitrogen and hydrazine [Reaction (a)], and *Thiele*, therefore, interpreted this reaction as the disproportionation (b) of diimine. By subsequent investigations on the kinetics of

$$\underset{(1)}{HO_2C\text{-}N{=}N\text{-}CO_2H} \xrightarrow[\sim 20^\circ C]{H_2O} {}^1/_2\,N_2 + {}^1/_2\,N_2H_4 + 2\,CO_2 \quad (a)$$

$$2\,N_2H_2 \rightarrow N_2 + N_2H_4 \quad (b)$$

the decarboxylation of *(1)*, the reaction was shown to be vigorously catalysed by protons, but there was no further evidence for the participation of diimine itself [4].

According to *Raschig* [5a, 5b], diimine occurs as an intermediate in the cleavage of the benzenesulfonyl hydrazide *(2)* with hot alkali. *Raschig* found equivalent quantities of nitrogen and hydrogen, which he assumed to result from the decomposition (d) of the intermediate diimine. According to *Raschig* [5a, 5b], *Thiele*'s results

$$\underset{(2)}{C_6H_5\text{-}SO_2\text{-}NH\text{-}NH_2} + OH^\ominus \xrightarrow{100^\circ C} C_6H_5\text{-}SO_2^\ominus + N_2 + H_2 + H_2O \quad (c)$$

$$N_2H_2 \rightarrow N_2 + H_2 \quad (d)$$

were due to attack of the decomposing diimine on azodicarboxylic acid. Thus it appeared to him that the disproportionation of diimine was simply simulated according to Reaction (e); a similar interpretation of this finding was given by *H. Wieland* [6].

$$^\ominus O_2C\text{-}N{=}N\text{-}CO_2^\ominus + N_2H_2 \rightarrow N_2 + {}^\ominus O_2C\text{-}\underset{H}{N}\text{-}\underset{H}{N}\text{-}CO_2^\ominus \quad (e)$$

$$2\,CO_2 + 2\,OH^\ominus + N_2H_4 \xleftarrow{+2\,H_2O}$$

Although these contradictory results are consistent with the occurrence of diimine as an intermediate, they do not prove its existence. Moreover, the secondary reaction still remains unexplained: does the diimine disppor-

[1] Address: Chemisches Institut der Universität Würzburg (Germany).

[2] The nomenclature here is just as confused as in the case of the species NH. Diimine appears less ambiguous than diimide and maintains association with the older literature. The systematic name "diazene", suggested by *W. R. McBride* and *E. M. Bens* [J. Amer. chem. Soc. *81*, 5546 (1959); c.f. *H. Bock* and *G. Rudolph*, Chem. Ber. *94*, 1457 (1961)] would be appropriate if NH was analogously named "azene".

tionate, does it decompose into its elements, or does the reaction follow both paths, depending on the temperature, solvent, and basicity of the medium? These questions have been answered in the last few years.

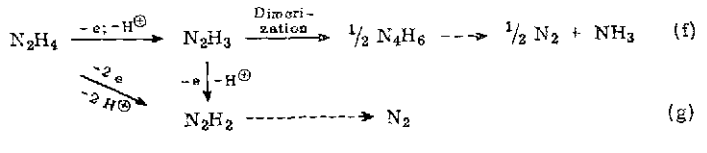
II. Properties of Diimine

A. Diimine in the Gas Phase

Diimine was first detected by mass spectrometry [7] during the decomposition of hydrazoic acid or hydrazine in an electric discharge under reduced pressure. The decomposition products, which can be isolated as a yellow coating at −180 °C, still contain particles having the required mass number of 30. Anthracene-9,10-bisimine *(5)* loses diimine at about 100 °C in the mass spectrometer, showing that diimine has a relatively high thermal stability [8]. On the other hand, diimine cannot be detected mass-spectrometrically during the thermal decomposition of hydrazine in argon at 1470 to 2770 °C [9].

B. Diimine in Solution

The somewhat contradictory results obtained on oxidation of hydrazine [10a–10f] were traced back to the competition between two reactions by *Higginson* [10d]. According to this author, the formation of ammonia is always associated with a one-electron oxidation [10d], which is brought about especially by Ce(IV) and Fe(III) in acidic solution [Equation (f)]. On the other hand, two-electron acceptors [10c, 10d], such as Tl(III), Cr(VI),



(f)

(g)

and V(V) in acidic solution, and the one-electron oxidant $Fe(CN)_6^{3\ominus}$ in alkaline solution, give only nitrogen [Equation(g)]. In agreement with this view, labelling with isotopes [10e, 10f] shows that nitrogen obtained according to Equation (f) is formed from two molecules of hydrazine, while that obtained according to Equation (g) is formed from one molecule of hydrazine. Thus, diimine, N_2H_2, is probably an intermediate in Equation (g). The polarographic two-electron oxidation of alkaline hydrazine solutions also requires the occurrence of diimine as an intermediate [11].

The existence of diimine has now been confirmed chemically: In the Wolff-Kishner reduction of long-chain ketocarboxylic acids having a double bond in the ω-position, a more or less marked hydrogenation of the double bond is observed as soon as the hydrazone is formed. This side reaction can be completely suppressed by exclusion of atmospheric oxygen, showing that hydrogenation of the double bond is not caused by hydrazine itself, but by a dehydrogenation product of hydrazine [12]. The stoichiometry of this redox reaction, the stereochemistry of the hydrogenation, and the discovery that the olefinic double bond is also hydrogenated by decomposing benzenesulfonyl hydrazide or azodicarboxylate, lead to the conclusion that the hydrogenating agent is diimine [13–15].

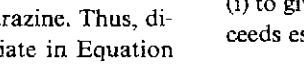
The same conclusion was reached almost simultaneously by *Corey* [16], *van Tamelen* [17], and *Aylward* [18], evidently as a result of similar observations. Since then, as the following survey shows, the chemistry of diimine has become well-known.

It should be stressed here that the only evidence for the existence of diimine in solution is the hydrogenation of multiple bonds. Attempts to isolate diimine by a Diels-Alder reaction have so far been unsuccessful [13, 14, 16].

III. Sources of Diimine

The numerous sources of diimine mentioned below were discovered through the uncatalysed hydrogenation of olefins.

1. Hydrazine yields diimine in accordance with Equation (h) in the presence of oxidizing agents such as atmospheric oxygen [15, 16, 18], peroxides (especially with traces of Cu^{2+}) [16], mercuric oxide [15], *N,N*-dichlorotoluenesulfonamide [14], and particularly Chloramine T [14] and hexacyanoferrate(III) [15].



(h)

2. Azodicarboxylate [15–17] decomposes in agreement with *Thiele*'s view [3], and in accordance with Reaction (i) to give diimine and carbon dioxide; this reaction proceeds especially readily in the presence of acid [4, 17].

[18] *F. Aylward* and *M. Sawistowska*, Chem. and Ind. *1962*, 484.

3. Arenesulfonyl hydrazides [15,19–21] undergo thermal cleavage, primarily in accordance with Equation (j). This is similar to *Raschig*'s scheme (c) [5a, 5b], but the

$$ArSO_2\text{-}NH\text{-}NH_2 \xrightarrow{100\text{-}150^\circ C} ArSO_2H + HN{=}NH \qquad (j)$$

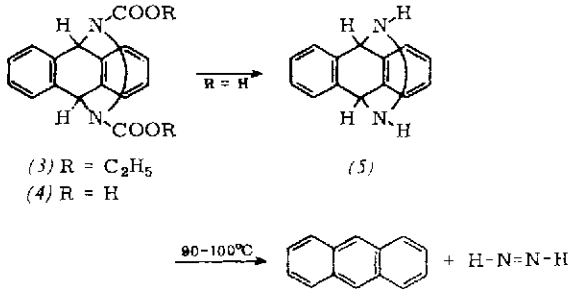
yield of hydrogenated olefin is reduced by strong alkali [20,21]. Diimine can be obtained from *m*-, *p*-, and *o*-nitrobenzenesulfonyl hydrazide, at a rate suitable for preparative use, at about 75, 50, and 25 °C, respectively [21].

4. The hydrochloride of chloroacetyl hydrazide decomposes in alkaline medium even at 0 °C according to Equation (k).

$$ClCH_2\text{-}CO\text{-}NH\text{-}NH_2\cdot HCl + 2\,NaOH \longrightarrow 2\,NaCl + 2\,H_2O + H_2C{=}C{=}O + HN{=}NH \qquad (k)$$

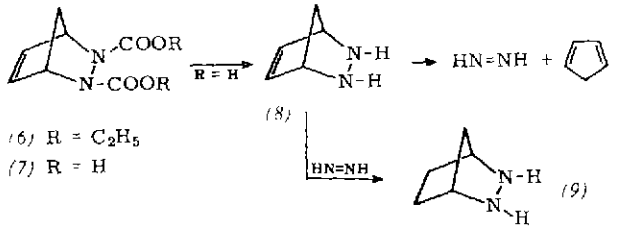
Ketene is formed as a second energy-rich intermediate which adds on water or acylates hydrazine resulting from disproportionation of diimine [21a].

5. Mild hydrolysis of the diene adduct *(3)* [22] yields the dicarboxylic acid *(4)*, controlled decarboxylation of which leads to the formation of anthracene-9,10-bisimine *(5)* [8]. This undergoes thermal decomposition to yield anthracene and diimine.



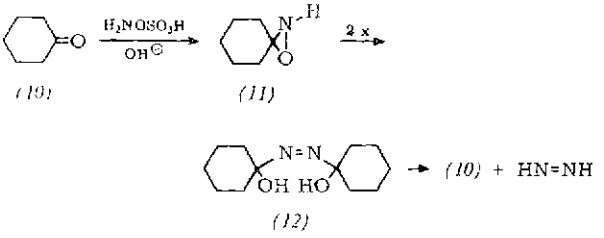
(3) R = C_2H_5
(4) R = H
(5)

6. When the diene adduct *(6)* [23] undergoes the series of reactions mentioned in Paragraph 5, the free carboxylic acid *(7)* cannot be isolated. The expected decarboxylation product *(8)* spontaneously undergoes a retrodiene reaction. The resulting diimine is consumed in a hydrogenation reaction, *e.g.* with formation of *(9)* [24].



(6) R = C_2H_5
(7) R = H
(8)
(9)

7. Cyclohexanone *(10)* and hydroxylamine-*O*-sulfonic acid react at 10 °C, *via (11)*, to form the crystalline 1,1′-dihydroxyazocyclohexane *(12)* which liberates diimine even at room temperature [25,26].



(10)
(11)
(12)

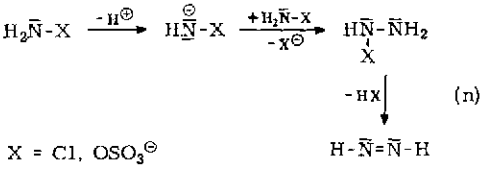
8. Diimine is also formed on decomposition [see Equation (1)] of hydroxylamine-*O*-sulfonic acid [27,28].

$$2\,H_2N\text{-}O\text{-}SO_3^\ominus \xrightarrow{-2\,H^\oplus} HN{=}NH + 2\,SO_4^{2\ominus} \qquad (l)$$

9. The alkaline cleavage of chloramine [28] follows a course similar to that described in Paragraph 7 [27,28].

$$2\,H_2NCl \xrightarrow{-2\,H^\oplus} HN{=}NH + 2\,Cl^\ominus \qquad (m)$$

In cases 8 and 9, the mechanism is probably as shown in Equation (n) [26].



Raschig [5b] had already pointed out that the overall Reaction (o) must proceed in several steps, but the intermediate formation of diimine only became obvious when olefin was present.

$$3\,NH_2Cl + 3\,NaOH \rightarrow N_2 + NH_3 + 3\,NaCl + 3\,H_2O \qquad (o)$$

IV. Detection of Diimine

A. Stoichiometry of the Hydrogenation of Olefins by Oxidation of Hydrazine

If the hydrogenation of olefins in the presence of hydrazine is due to the oxidation stage of diimine, this must be apparent in the stoichiometry of the redox reaction. This can be tested using hexacyanoferrate(III) as

[19] *E. E. van Tamelen* and *R. S. Dewey*, J. Amer. chem. Soc. *83* 3729 (1961).

[27] *R. Appel* and *W. Büchner*, Angew. Chem. *73*, 807 (1961); Liebigs Ann. Chem. *654*, 1 (1962).

[28] *E. Schmitz* and *R. Ohme*, Angew. Chem. *73*, 807 (1961).

the oxidizing agent for hydrazine in the presence of an olefin, since the oxidation of hydrazine by path (p) requires exactly four oxidation equivalents [29, 30], whereas that by path (q) should require only two equivalents.

$$4\ [Fe(CN)_6]^{3\ominus} + N_2H_4 \longrightarrow N_2 + 4\ H^{\oplus} + 4\ [Fe(CN)_6]^{4\ominus} \quad (p)$$

$$2\ [Fe(CN)_6]^{3\ominus} + N_2H_4 + >C{=}C< \longrightarrow N_2 + 2\ H^{\oplus} + 2\ [Fe(CN)_6]^{4\ominus} + >\underset{H}{C}\text{-}\underset{H}{C}< \quad (q)$$

The stoichiometry of Reaction (q) can be observed together with the oxidation which always proceeds by path (p), if the oxidizing agent consumed and the volume of nitrogen formed are determined simultaneously. If the sum of the oxidation equivalents consumed by paths (p) and (q) is denoted by $Ox = Ox_p + Ox_q$ and the number of moles of nitrogen liberated by $B = N_{2p} + N_{2q}$, the number of moles of hydrogenated olefin (C) at any time during the reaction (slow addition of the $[Fe(CN)_6]^{3\ominus}$ solution to the alkaline solution of olefin and hydrazine) can be easily determined [13, 15] from

$$C = Ox_p/2 = 2\ B - Ox/2.$$

The values calculated in this way agree to within ± 4 % with those obtained by bromometric titration of the unreacted olefin.

A plot of the yield of hydrogenated olefin against the number of oxidation equivalents per mole of olefin initially present gives the curves of Figure 1. Exclusive hydrogenation of the olefin according to Equation (q) would be expected to give the straight line.

In fact, however, oxidation of the hydrazine to nitrogen according to Equation (p) competes with Reaction (q). The extent of competition depends on the ease of hydrogenation of the olefins (see Section IV.C) [14, 15].

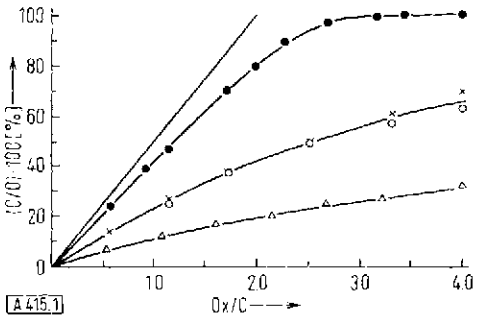

Fig. 1. Hydrogenation curves for fumaric acid (●), *trans*-cinnamic acid (x and o), and *cis*-cinnamic acid (Δ) [6 mmoles of acid, 36 mmoles of hydrazine hydrate, and 100 mmoles of ethanolamine were made up to 100 ml with water; 40 ml of 0.6 N $K_3[Fe(CN)_6]$ solution were added over about 60 min; pH 10–11; 25.0 °C].

Abscissa: Ox/C = oxidation equivalents consumed per mole of olefin initially present.

Ordinate: (C/O)·100 = percentage of hydrogenated olefin.

Since the stoichiometry of the hydrogenation is always found to follow Equation (q) [31], it is certain that the hydrogenating agent has an oxidation stage corresponding to that of diimine, although the structure of the hydrogenating agent is not thereby established.

B. Stereochemistry of the Hydrogenation

As Table 1 shows, it has been determined by infrared analysis [13–15, 32] and by gas chromatography [13, 14] that hydrogenation of the carbon-carbon multiple bonds proceeds at least 97–98 % stereospecifically *via cis*-addition [32]. Deuterium is likewise introduced by N_2D_2 unambiguously *via cis*-addition onto the olefin, whereas catalytic deuteration involves subsequent exchange reactions on the catalyst.

Table 1. Stereochemistry of the hydrogenation of olefins with diimine.

Source of diimine	Substrate	Product	Ref.
$N_2H_4/[Fe(CN)_6]^{3\ominus}$	phenylpropiolic acid [*]	*cis*-cionamic acid	[13, 15]
$H_2N{-}OSO_3^{\ominus}/OH^{\ominus}$	phenylpropiolic acid [*]	*cis*-cinnamic acid	[27]
N_2H_4/H_2O_2	diphenylacetylene [*]	*cis*-stilbene	[32]
$C_6H_5{-}SO_2{-}NH{-}NH_2$	diphenylacetylene [*]	*cis*-stilbene	[21]
N_2H_4/H_2O_2	dimethylmaleic acid	*meso*-2,3-dimethyl-succinic acid	[32]
N_2D_4/oxidizing agent	maleic acid	*meso*-[2,3-D_2]-succinic acid	[32]
or	fumaric acid	(±)-[2,3-D_2]-succinic acid	[32]
$KO_2C{-}N{=}N{-}CO_2K/D_2O$	*cis*-2-butene-1,4-diol	*meso*-[2,3-D_2]-butane-1,4-diol	[32]
	trans-2-butene-1,4-diol	(±)-[2,3-D_2]-butane-1,4-diol	[32]
	cis-stilbene	*meso*-[1,2-D_2]-1,2-diphenylethane	[32]
	trans-stilbene	(±)-[1,2-D_2]-1,2-diphenylethane	[32]

[*] Perhydrogenation of acetylene derivatives also occurs, even when the system is deficient in diimine.

Since the stereospecificity is the same for various olefins as well as for various "sources of hydrogen",

1. the hydrogenation must be effected by the same reagent in every case, and

2. the two hydrogen atoms must be transferred simultaneously.

[29] *P. R. Ray* and *H. K. Sen*, Z. anorg. allg. Chem. *76*, 380 (1912).

[30] *C. J. Dernbach* and *J. P. Mehlig*, Ind. Engng. Chem., analyt. Edit. *14*, 58 (1942).

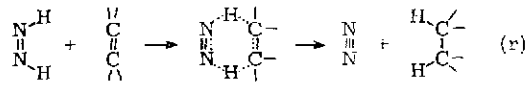
[31] The stoichiometry suggested by *F. Aylward* and *M. Sawistowska*, Chem. and Ind. *1961*, 433, and J. chem. Soc. (London) *1964*, 1435:

$$2\ N_2H_4 + 3/2\ O_2 + >C{=}C< \rightarrow >CH{-}HC< + 2\ N_2 + 3\ H_2O$$

is certainly incorrect. Difficulties were probably encountered in the evaluation, owing to the gaseous oxidizing agent.

[32] *E. J. Corey*, *W. L. Mock*, and *D. J. Pasto*, J. Amer. chem. Soc. *83*, 2957 (1961).

This, together with the stoichiometry, is accepted as proving the existence of diimine. The hydrogenation may be formulated as a concerted reaction (r) [13–15, 32].



(13)

Stepwise hydrogen-transfer, *e.g. via* $H-\ddot{N}-\ddot{N}:^{\ominus}$ can be ruled out. On the other hand, *cis*-hydrogen transfer by the unsymmetrical isomer of diimine, $H_2\overset{\oplus}{N}=\ddot{N}:^{\ominus}$, is not impossible. However, the fact that various sources of diimine have the same effect favors the symmetrical uncharged diimine, and the cyclic transition state requires the *cis*-form of diimine. While the infrared spectrum of solid diimine seems to indicate the exclusive occurrence of the *cis*-form, the configuration of gaseous diimine could so far not be determined unequivocally [32a].

If, as in the case of difluorodiimine, the energy of the *cis*-form is about 27 kcal/mole greater than that of the *trans*-form [33], *cis*-diimine must be formed from its precursors in a kinetically controlled reaction [14]. If the energy difference is less, it must be assumed that an equilibrium is rapidly reached between the isomers.

C. Substrate-Specificity of the Hydrogenation

In agreement with the symmetrical transition state *(13)*, the hydrogenation with diimine has a high substrate specificity. Unsymmetrical multiple bonds such as

$$C\equiv N,\ -NO_2,\ -N=C\langle,\ \rangle S=O$$

are not attacked [13, 14, 34], and no hydrogenolysis of the bonds

Ar–I, Ar–Br, R–Br, R–SH, R–S–S–R, R–S–C–S–R

can be observed [13, 14, 34]. Instead, hydrogen is generally transferred to symmetrical multiple bonds of the type

$$C=C,\ \rangle C=C\langle,\ N=N-,\ O-O$$ [34].

This pronounced difference permits selective hydrogenations. Since even the labile disulfide bond remains intact, diallyl sulfide can be smoothly hydrogenated to give dipropyl sulfide in 93 to 100% yield. This reaction cannot be accomplished by any other route [34].

The N=N double bond of azobenzene takes up hydrogen smoothly from various sources of diimine [8, 14, 16, 17, 25, 26]. Azodicarboxamide is a very active hydrogen acceptor. This compound, which is almost insoluble in water, not only reacts in suspension with diimine, but is even hydrogenated by hydrazine itself [14]. This shows that *Thiele*'s experiment [Equations (a) and (b)] gives no information about the disproportionation of diimine, and that *Raschig*'s interpretation [5a, 5b] is probably correct (see Section 1). The nature of the olefin has a strong influence on the relative rates of hydrogenation, as can be seen from Figure 1. The deviation of the hydrogenation curves from the theoretical straight line results from competition between the hydrogenation of the olefin and the secondary reactions of the diimine. Since only the olefin is varied under the standardized conditions, it is possible to calculate the relative rates of hydrogenation [14, 35]. Table 2 shows the values obtained for a number of olefinic carboxylic acids, based on a value of 100 for fumaric acid [14]. The table also shows the degree of hydrogenation after the liberation of one equivalent of diimine. The differences in the relative rates of hydrogenation exhibit the following regularities which also confirm the cyclic transition state *(13)*:

Table 2. Yield (C/O) on hydrogenation of olefinic carboxylic acids, and relative rates of hydrogenation v_r (cf. Fig. 1).

	Olefinic carboxylic acid	C/O·100 [%]	v_r
1	fumaric acid	80	100
2	acrylic acid [36]	ca. 74	ca. 52
3	undecenoic acid	69	40
4	maleic acid	41	10
5	maleamic acid [36]	38	8
6	crotonic acid [36]	22	5
7	methylfumaric acid	18	3
8	methylmaleic acid	4	0.7
9	ethylenetetracarboxylic acid [36]	2.9	0.3
10	β,β-dimethylacrylic acid	2.6	0.3
11	dimethylfumaric acid	≈0	0.0
12	dimethylmaleic acid	≈0	0.0
13	*trans*-cinnamic acid	41	10
14	*p*-dimethylaminocinnamic acid	32	8
15	*p*-methoxycinnamic acid	37	8
16	*p*-chlorocinnamic acid	37–39	8–9
17	*p*-nitrocinnamic acid	35–44	7–11
18	*o*-chlorocinnamic acid	44	11
19	*cis*-cinnamic acid	20	3
20	α-methylcinnamic acid	5	1.4
21	β-methylcinnamic acid	5	1.4

1. *trans*-olefins are hydrogenated 3–10 times faster than *cis*-olefins (cf. compounds nos. 1 and 4; 7 and 8; 13 and 19 in Table 2);

2. the rate of hydrogenation decreases rapidly with increasing number of substituents on the double bond (one substituent: nos. 2, 3; two substituents: nos. 1, 4, 5, 6, 13, 19; three substituents: nos. 7, 8, 10, 20, 21; four substituents: nos. 9, 11, 12 in Table 2).

The relative ease of hydrogenation by diimine of all positional and stereoisomeric n-undecanes confirms these results [37].

Points 1 and 2 are to be expected in general for cyclic transition states in additions to double bonds [38], as was shown by systematic investigations of the 1,3-dipolar addition [38] and the diene addition [39]. Since, in the transition state, the bond angles of the olefin are compressed from 120° to about

[38] *R. Huisgen, H. J. Sturm*, and *H. Wagenhofer*, Z. Naturforsch. *17b*, 202 (1962); *R. Huisgen*, Angew. Chem. *75*, 742 (1963); Angew. Chem. internat. Edit. *2*, 633 (1963).

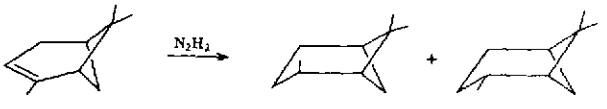
[39] *J. Sauer, H. Wiest*, and *A. Mielert*, Z. Naturforsch. *17b*, 203 (1962); *J. Sauer, D. Lang*, and *H. Wiest*, ibid. *17b*, 206 (1962). Chem. Ber. *97*, 3208 (1964).

109°, substituents on the double bond increase the activation energy. *Cis*-substituents are more strongly affected by this change in bond angle than *trans*-substituents, so that *cis*-olefins react more slowly than their *trans*-isomers. Moreover, there are specific substituent effects, since deactivation increases in the order $-CO_2^{\ominus} < -C_6H_5 < -CH_3$, *i.e.* the bulk of the substituents is not the only determining factor. It is not yet known whether this is due mainly to a difference in the electron density of the double bond or to specific solvation (aqueous medium) [40]. A strong effect due to the π-electron density is inconsistent with point 3, which is compatible with a cyclic intermediate.

3. *p*-Substituents in the phenyl nucleus have almost no effect on the hydrogenation rate. Their effect is even less than in the case of 1,3-dipolar additions [38]. Since 70 kcal/mole are liberated during hydrogenation [7, 16], the position of the equilibrium, according to the Hammond principle [41], must be assumed to lie well on the side of the substrate. The slight electronic substituent effect fits into this picture.

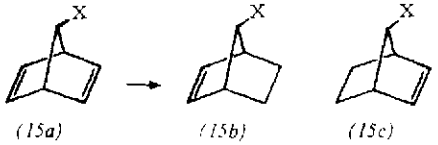
It is remarkable that dimethylmaleic acid is hydrogenated with hydrazine/H_2O_2 in methanol [32], while neither this compound nor the more reactive dimethylfumaric acid are appreciably hydrogenated under our conditions, even when nine equivalents of diimine are used [14]. This agrees with the fact that Δ^9-octalin is not attacked by decomposing benzenesulfonyl hydrazide in boiling glycol monomethyl ether [21].

As a result of the high stereoselectivity and the steric relationships in the transition state *(13)*, diimine always attacks the olefin from the least hindered side, even if this gives rise to the thermodynamically labile hydrogenation product [42]. This stereokinetic control is shown especially in the case of α-pinene *(14)* which reacts with diimine to give a 99% yield of *cis*-pinane *(15)* (having the methyl group in the less favorable position) [42].



(14) *(15)*, 99% 1%

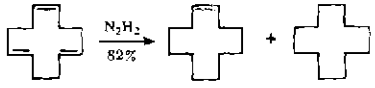
Norbornadienes *(15a)* substituted at the 7-position are hydrogenated at the *syn*-double bond and yield *(15b)* instead of *(15c)* as expected. Deuterium atoms are introduced in *exo*-positions, using N_2D_2 as reagent [42a].



(15a) *(15b)* *(15c)*

X = OH, $OCO\text{-}CH_3$, $OC(CH_3)_3$

The rigidity of the ring of *cis*, *trans*, *trans*-1,5,9-cyclododecatriene *(15d)* produces large differences in the conformations of the possible transition states for the diimine reaction, so that specific hydrogenation of the *trans*-double bonds is possible. Such a marked selectivity is not observed with acyclic olefins.



(15d) 95 : 5

V. Hydrogenations with "Hydrazine"

The discovery that double bonds are not hydrogenated by hydrazine itself, but by diimine formed by oxidation, provides the key to many hydrogenations which were formerly attributed to hydrazine [43].

As early as 1914, *Falciola* and *Mannino* isolated the hydrazide of stearic acid from a mixture of oleic esters and hydrazine hydrate which had been allowed to stand at room temperature [44]. This surprisingly mild, and at the same time unexpected, hydrogenation of an isolated olefinic double bond has since then been repeatedly observed, both with the esters [44–46] and with the unsaturated fatty acids themselves [47, 48]. This reaction is even recommended in one patent for the hardening and refining of oils [49].

If, in the last step of the synthesis of dioleyl cephalins, the phthaloyl residue is eliminated as usual [50] using hydrazine, hydrogenation occurs [51].

Systematic investigations of the hydrogenation of unsaturated fatty acids by "hydrazine" suffer from poor reproducibility [52–57]. Nevertheless, it has been possible to show that the double bond does not migrate during the hydrogenation [53, 55, 58], nor does it isomerize to the *trans*-form [58]. Thus, the positions of the double bond in the chain can be unambiguously marked by N_2D_4, whereas catalytic deuteration may be accompa-

[40] The polarizability of the substituents may play some part; cf. [38].

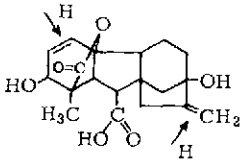
nied by migration of the double bond [57]. Competitive experiments show that terminal double bonds are more rapidly hydrogenated than non-terminal ones, and are conjugated more rapidly than isolated double bonds [55]. However, the differences are too small to be of preparative use (cf. Table 2) [13,14]. Hydrogenation with "hydrazine" has scarcely found any application outside fatty-acid chemistry, with the exception of *Hans Fischer*'s hydrogenation of vinyl groups in porphyrins [59] and, more recently, *Cross*' hydrogenation of gibberellic acid *(16)* [60] which has also been reduced with diimine [16].



(16)

In all these reactions the significance of atmospheric oxygen remained hidden, and was ultimately recognized by *Hünig* [13-15], *Corey* [16], and *Aylward* [18,61]. The hydrogenation of aromatic azocompounds by hydrazine [62,63] also requires air [14,36].

VI. Secondary Reactions of Diimine

Let us now consider how diimine reacts when there is no foreign acceptor for the labile hydrogen, *i.e.* whether the diimine is disproportionated into hydrogen and hydrazine, as suggested by *Thiele* [3], or whether it decomposes into its elements, in agreement with *Raschig*'s hypothesis [5a, 5b] [cf. Section I].

A. Competition between Disproportionation and Decomposition

The answer was first found with benzenesulfonyl hydrazide as the source of diimine, since in this case nitrogen and hydrogen can be quantitatively determined without interference by the oxidizing agent or the source of diimine [21,64].

As is shown in Figure 2, the decomposition of benzenesulfonyl hydrazide follows *Raschig*'s scheme [5a, 5b] [Equation (c); Section I] quantitatively only in strongly alkaline solution. As the concentration of alkali decreases, the volume of gas also decreases, although all the sulfonyl hydrazide is consumed. Gas analysis shows that the hydrogen component decreases twice as rapidly

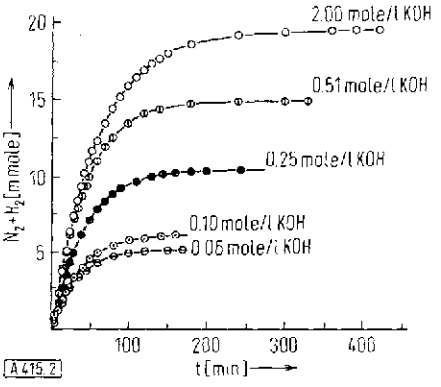


Fig. 2. Gas yield ($N_2 + H_2$) during the decomposition of 10.0 mmoles of benzenesulfonyl hydrazide in 165 ml of glycol monomethyl ether at 99 °C, as a function of the KOH concentration and of time.

in volume as the nitrogen component, until finally, in a weakly alkaline medium, the gas liberated consists only of nitrogen (Table 3). It can be seen from Table 3 that the quantity of gas ($N_2 + 2\ H_2$) required to make up the amount expected from *Raschig*'s scheme [Equation (c)] appears quantitatively as hydrazine, since it is found that, within the limit of error,

$$[N_2 + H_2] + 3\ [N_2H_4] = 200\,\%.$$

Table 3. Total quantity of gas and quantities of hydrazine, hydrogen, and nitrogen obtained on cleavage of 10 mmoles of benzenesulfonyl hydrazide in 165 ml of glycol monomethyl ether at 99 °C.

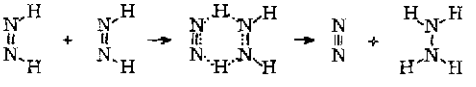
[a] Initial KOH concentration.

[b] 2 moles per mole of benzenesulfonyl hydrazide ≡ 200 %.

[c] 1 mole per mole of benzenesulfonyl hydrazide ≡ 100 %.

The decomposition of diimine gives rise to products of composition ($2\ N_2 + 2\ H_2$), while the disproportionation gives products of composition ($N_2 + N_2H_4$). The disproportionation products therefore lack gas of composition ($N_2 + 2\ H_2$) as compared to the decomposition products. *Thus the disproportionation and decomposition of diimine are competitive reactions.*

The disproportionation can be formulated as the hydrogenation of a second molecule of diimine, in which, by



(17)

analogy with the hydrogenation of olefins [cf. *(13)*], a cyclic transition state *(17)* is likely. The liberated energy of 75 kcal/mole [7,16] corresponds to that of the hydrogenation of olefins. The decomposition of diimine is base-catalysed, and so presumably proceeds according to Equation (s) *via* the anion of diimine, from which a hy-

dride ion, and hence ultimately hydrogen, is liberated [Equation (t)]. The possibility that the decomposition

$$HN{=}N{-}H + :B^{\ominus} \rightleftarrows HN{=}N{:}^{\ominus} + HB \qquad (s)$$

$$HN{=}N{:}^{\ominus} \rightarrow N_2 + H^{\ominus} \qquad (t)$$

$$H^{\ominus} + HB \rightarrow :B^{\ominus} + H_2$$

proposed by *Raschig* does not proceed from the diimine stage, but directly from the sulfonyl hydrazide anion

$$R{-}SO_2{-}\overset{\ominus}{\underset{(18)}{N}}{-}NH_2 \rightarrow RSO_2^{\ominus} + N_2 + H_2$$

(18), can be ruled out, owing to the similar behavior of other sources of diimine.

If *N,N'*-bis(methoxycarbonyl)anthracene-9,10-bisimine *(3)* is hydrolysed in boiling glycol monomethyl ether at *e.g.* 125 °C, *i.e.* under conditions in which the expected bisimine *(5)* immediately loses diimine, the quantity of gas liberated again increases with increasing KOH concentration. The decomposition of the diimine liberated in this way therefore shows the same dependence on the concentration of the base (see Fig. 3) [36].

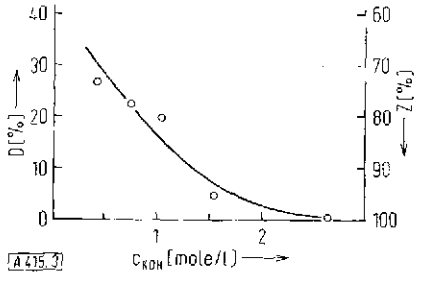

Fig. 3. Disproportionation (D [%]) and decomposition (Z [%]) of the diimine liberated from 1.4 mmole of *N,N'*-bis(methoxycarbonyl)-anthracene-9,10-bisimine *(3)* in 25 ml of boiling glycol monomethyl ether, as a function of the KOH concentration (c_{KOH}).

B. Competition between Decomposition and Hydrogenation of Olefins

Since the hydrogenation of olefins proceeds *via* neutral diimine, the deprotonation and subsequent decomposition of the latter in strongly alkaline solution greatly reduces the yield of hydrogenation product. Thus, tolane is no longer attacked by decomposing benzenesulfonyl hydrazide in 2.5 N KOH/glycol monomethyl ether; the more reactive styrene, on the other hand, is hydrogenated to 77% under the same conditions [21]. It can, therefore, be concluded that either the deprotonation rate of diimine is similar to the hydrogenation rate of the olefin, or, as shown in Equation (s), deprotonation leads to rapid establishment of an equilibrium, and the decomposition rate of the anion is of the same order of magnitude as the hydrogenation rate of the olefin. The second interpretation would explain a rapid *cis-trans* isomerization of the diimine.

Competition by Raschig decomposition of the diimine is also responsible for reducing the yield of hydrogenation product as the alkali concentration in the system hydrazine/hexacyanoferrate(III)/undecenoic acid [13,14] is increased.

Where sulfonyl hydrazides are used as sources of diimine, it has been possible in every case investigated to eliminate this undesirable side-reaction completely by using ethanolamine as the base. The diimine formed exclusively undergoes disproportionation [see Reaction (u)]. These are also the best conditions for hydrogenating

$$R{-}SO_2{-}NH{-}NH_2 \xrightarrow[-\,BH^{\oplus}]{+:B} RSO_2^{\ominus} + N_2H_2 \rightarrow \underbrace{{}^1/_2\,N_2 + {}^1/_2\,N_2H_4} \qquad (u)$$

olefins; no by-products containing sulfur are formed [21]. (Cf. thermal cleavage of sulfonyl hydrazides, Section VIII).

C. Competition between Disproportionation and Hydrogenation of Olefins

Since the disproportionation of diimine can be regarded as an autohydrogenation, it competes with the hydrogenation of olefins, as indicated in Scheme (v).

$$HN{=}NH \begin{cases} \xrightarrow{HN=NH} N_2 + H_2N{-}NH_2 \\ \xrightarrow{>C{=}C<} N_2 + >\underset{H}{C}{-}\underset{H}{C}< \end{cases} \qquad (v)$$

Thus, at a given diimine concentration, the disproportionation is suppressed by a higher olefin concentration, as can be seen from Figure 4 [21]. The ratio of the rates of the two

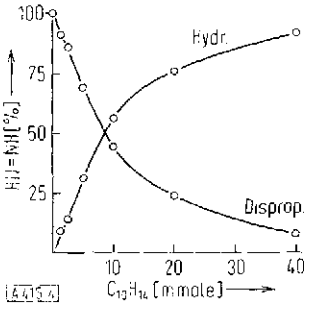

Fig. 4. Disproportionation and hydrogenation of olefins during the reaction of 10 mmoles of benzenesulfonyl hydrazide with dihydrodicyclopentadiene ($C_{10}H_{14}$) in 150 ml of glycol monomethyl ether/ethanolamine at 78.8 °C.

reactions naturally also depends on the ease of hydrogenation of the olefin (see Section IV, B and C). Moreover, the temperature coefficients of the two competing reactions are very different. Thus, if diimine is liberated from various substituted benzenesulfonyl hydrazides at temperatures of equal decomposition rates, the same stationary diimine concentration leads to widely different yields of hydrogenation product (Table 4) [21]. Owing to the higher activation energy

Table 4. Reaction of sulfonyl hydrazides (5m moles) with dihydrodicyclopentadiene (5 mmoles) in glycol monomethyl ether/ethanolamine (60 ml).

Hydrazide	Temp. [°C]	Disprop. of N_2H_2	N_2H_2 effecting hydrogenation
$C_6H_5{-}SO_2N_2H_3$	104.9	55 ± 2	45 ± 2
m-NO_2-$C_6H_4{-}SO_2N_2H_3$	78.8	69	31
o-$NO_2{-}C_6H_4{-}SO_2N_2H_3$	39.1	97	3

for the hydrogenation of olefins as compared to their disproportionation, high yields of hydrogenation product are to be expected at high temperatures.

Consideration of Table 4, together with the data for *p*-nitrobenzenesulfonyl hydrazide [21], shows that the rate of cleavage increases in the following order:

$$H \ll p\text{-}NO_2 < m\text{-}NO_2 \ll o\text{-}NO_2 \text{ [65]}$$

In fact, the only secondary reaction of diimine in weakly basic media is hydrogen transfer to a symmetrical double bond, even in the presence of hexacyanoferrate(III). Thus, if a solution of hydrazine is added to the undecenoic acid/hexacyanoferrate(III) solution, the olefin will be extensively hydrogenated, in spite of the permanent excess of oxidizing agent. This result of reversing the reaction procedure was completely unexpected and provides strong evidence that the further oxidation of diimine is of no importance in the hydrogenation of olefins.

The stoichiometric conversion (w) [10, 29]

$$N_2H_4 + 4\ [Fe(CN)_6]^{3\ominus} + 4\ OH^{\ominus} \rightarrow N_2 + 4\ [Fe(CN)_6]^{4\ominus} + 4\ H_2O \quad (w)$$

therefore corresponds only to the diimine stage of a direct oxidation (x).

$$N_2H_4 + 2\ [Fe(CN)_6]^{3\ominus} + 2\ OH^{\ominus} \rightarrow N_2H_2 + 2\ [Fe(CN)_6]^{4\ominus} + 2\ H_2O \quad (x)$$

The subsequent disproportionation (y)

$$2\ N_2H_2 \longrightarrow N_2 + N_2H_4 \quad (y)$$

yields hydrazine, which is again oxidized to the diimine. The anodic oxidation of hydrazine can be similarly interpreted [11].

As regards the rates of the two competing reactions, only that of the disproportionation increases with the square of the intermediate diimine concentration (the rate of the hydrogenation of olefins increases with the first power of the diimine concentration). The yield of hydrogenation product is therefore reduced, *e.g.* in the system $N_2H_4/[Fe(CN)_6^{3\ominus}]$/undecenoic acid, under all conditions leading to an increase in the diimine concentration [13, 14, 36]:

a) increased rate of addition of the $[Fe(CN)_6]^{3\ominus}$ solution to N_2H_4/undecenoic acid,

b) increased rate of addition of N_2H_4 to $[Fe(CN)_6]^{3\ominus}$/undecenoic acid,

c) increased N_2H_4 concentration in the N_2H_4/undecenoic acid mixture, and

d) increased $[Fe(CN)_6]^{3\ominus}$ concentration in the $[Fe(CN)_6]^{3\ominus}$/undecenoic acid mixture.

VII. Reduction of Nitrobenzenesulfonyl Chlorides with Hydrazine

If nitrobenzenesulfonyl chlorides in benzene are added dropwise to excess hydrazine in alcohol at 30 to 60 °C, a high yield of sulfinic acid is formed, together with the calculated quantity of nitrogen, corresponding to Equation (z) [65]. The reaction can be used both for the preparation of sulfinic acids and (by variation of the temperature) for the separation of isomeric nitrobenzenesulfonyl chlorides [65]. According to the results available

$$2\ ArSO_2Cl + 2\ N_2H_4 \rightarrow 2\ ArSO_2H + N_2 + N_2H_4 \cdot 2\ HCl \quad (z)$$

at present, the initially formed sulfonyl hydrazide (cf. Table 4) undergoes cleavage according to Equation (α).

$$2\ ArSO_2\text{–}NH\text{–}NH_2 \rightarrow 2\ ArSO_2H + 2\ N_2H_2 \rightarrow N_2 + N_2H_4 \quad (\alpha)$$

The sulfonyl chloride is therefore not directly reduced either by hydrazine or by diimine [21].

VIII. Thermal Cleavage of Benzenesulfonyl Hydrazide

The cleavage of benzenesulfonyl hydrazide described in Section VII is apparently in contradiction to the technically used thermal decomposition [66] which corresponds to the overall Equation (β). The products are *S*-phenyl

$$4\ C_6H_5\text{-}SO_2\text{-}NH\text{-}NH_2 \xrightarrow{100\text{–}140^{\circ}C} C_6H_5\text{-}SO_2\text{-}S\text{-}C_6H_5 + C_6H_5\text{-}S\text{-}S\text{-}C_6H_5 + 4\ N_2 + 6\ H_2O \quad (\beta)$$

(19)

benzenethiosulfonate *(19)* [67] and diphenyl disulfide [68], while all the nitrogen is liberated as gas [68]. Reaction (β) proceeds in stages, as is shown by the rate of evolution of nitrogen in solution (Fig. 5) [21].

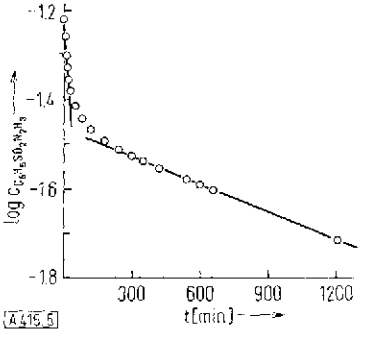

Fig. 5. Course of the thermal cleavage of benzenesulfonyl hydrazide (10 mmoles) in glycol monomethyl ether (165 ml) at 119.2 °C

Only the initial reaction corresponds to the cleavage of the sulfonyl hydrazide in accordance with Equation (γ).

[66] *F. Lober*, Angew. Chem. *64*, 71 (1952); *F. Muth* in *Houben-Weyl*: Methoden der organischen Chemie. 2nd Edit., Thieme-Verlag, Stuttgart 1955, Vol. 9, p. 650.

[67] *J. Cymerman* and *J. B. Willis*, J. chem. Soc. (London) *1951*, 1332.

[68] *Th. Curtius* and *F. Lorenzen*, J. prakt. Chem. *58*, 160 (1898).

This is shown by the preparative hydrogenation of olefins [15, 19–21]. If the disproportionation is suppressed

$$Ar\text{-}SO_2\text{-}NH\text{-}NH_2 \xrightarrow{k_1} ArSO_2H + N_2H_2 \quad (\gamma)$$

$$N_2H_2 \xrightarrow{fast} {}^1/_2\,N_2 + {}^1/_2\,N_2H_4$$

by an excess of styrene, the yield of gas is doubled, while the cleavage proceeds at almost the same rate ($k_1 = 8.2 \times 10^{-2}$ min^{-1}).

As a result of the initial cleavage, sulfinic acid and hydrazine are formed in the ratio 2:1. The reaction stops at this stage if the sulfinic acid is neutralized by a base (see Section VI, B and Figure 2). If the corresponding quantity of hydrazinium dibenzenesulfinate $[(C_6H_5SO_2H)_2 N_2H_4]$ [68] is decomposed under the conditions of Figure 5, nitrogen is liberated at the rate ($k_2 = 1.5 \times 10^{-3}$ min^{-1}) which characterizes the second stage of the cleavage. Again, diimine is formed initially, as can be shown by the hydrogenation of allylbenzene. Thus, it must be assumed that benzenesulfonyl hydrazide is regenerated

$$2\ ArSO_2H \xrightarrow{fast} Ar\text{-}SO_2\text{-}SO\text{-}Ar + H_2O$$

$$Ar\text{-}SO_2\text{-}SO\text{-}Ar \xrightarrow{slow} (Ar\text{-}SO_2\text{-}O\text{-}S\text{-}Ar) \quad (\delta)$$

in the second stage, although it is still unknown whether this is preceded by the reaction sequence (δ) [69] which could be followed by formation of the hydrazide as follows:

$$(ArSO_2\text{--}O\text{--}S\text{-}Ar) + H_2N\text{-}NH_2 \rightarrow ArSO_2\text{-}NH\text{--}NH_2 + (ArSOH). \quad (20)$$

The expected sulfenic acid *(20)* is known to disproportionate in accordance with Scheme (ε) to form the products observed in the cleavage of benzenesulfonyl hydrazide [70].

$$4\ (C_6H_5\text{-}SOH) \rightarrow 2\ (C_6H_5\text{--}SO\text{--}S\text{--}C_6H_5) + 2\ H_2O \quad (\varepsilon)$$

(20)

$$2\ (C_6H_5\text{-}SO\text{-}S\text{-}C_6H_5) \rightarrow C_6H_5\text{-}S\text{-}S\text{-}C_6H_5 + C_6H_5\text{--}SO_2\text{-}S\text{-}C_6H_5$$

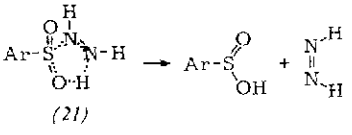
This Scheme (ε), which has yet to be confirmed in detail, satisfies the stoichiometry of the overall reaction. Thus the quantitative liberation of nitrogen in the thermolysis of benzenesulfonyl hydrazide requires formation of free sulfinic acid. It should also be mentioned that the initial thermal cleavage of benzenesulfonyl hydrazide requires a much higher ordering in the transition state than does the cleavage in the presence of ethanolamine (Table 5) [21].

Table 5. Thermal cleavage of benzenesulfonyl hydrazide (10 mmoles) in glycol monomethyl ether (165 ml).

Base	Temp. [°K]	$k_1 \times 10^2$ [min^{-1}] [a]	E_A [kcal/mol] [b]	$\Delta H^{\neq}$ [kcal/mol] [b]	$\Delta G^{\neq}$	$\Delta S^{\neq}$ [cal/deg./mole] [c]
0.91 M ethanolamine	352.0	0.71	23.5	22.8	27.0	−12.0
	372.3	4.4			27.3	−12.2
none	372.3	1.94	20.9	20.1	27.9	−21.0
	392.4	8.26			28.3	−20.9

[a] Mean relative error: ± 2 %.
[b] Mean relative error: ± 3 %.
[c] Margin of error: ± 6 %.

For the same free energy of activation, $\Delta G^{\neq}$, of 27 to 28 kcal/mole, the entropy loss associated with the transition state in the thermal cleavage of benzenesulfonyl hydrazide is almost twice as large as when a proton acceptor is present; therefore, a transition state *(21)* is likely.



(21)

IX. Outlook

During the last decade, the use of unstable neutral organic substances has led to many novel reactions. An excellent example of this is carbene chemistry [71]. Similarly, the field of organic syntheses should profit from the use of labile neutral inorganic substances [19]. Here the chemistry of the imenes [72] and of diimine are the first results.

We are sincerely grateful to the Fonds der Chemischen Industrie as well as to Badische Anilin- & Soda-Fabrik AG., Ludwigshafen/Rhein, for their support of this work.

Exchange Rates of Ligands in Complex Ions

BY PROF. R. G. PEARSON

DEPARTMENT OF CHEMISTRY, NORTHWESTERN UNIVERSITY, EVANSTON, ILLINOIS (U.S.A.)

AND DR. MARY M. ANDERSON

RESEARCH DEPARTMENT, HERCULES POWDER COMPANY, WILMINGTON, DELAWARE (U.S.A.)

It is possible to study the very rapid exchange rates between molecules or ions, L, coordinated to paramagnetic ions and the free molecules or ions, L, in the body of the solution by measuring the line width of the NMR signal of L*.*

$$ML_n + L^* \rightleftharpoons ML_n^* + L$$

Lifetimes of coordinated ligands that can be measured fall into the range of milliseconds to microseconds. The lifetime, or an upper limit to the lifetime, can be measured directly.

1. Introduction

The effect of rapid chemical exchange in an equilibrium situation on nuclear magnetic resonance spectra has given us the rates of many types of exchange that have not been accessible by other methods. As examples, these types of reactions have included: exchange of hydroxylic protons in alcohols, alcohol-water mixtures, hydrogen peroxide solutions, and of amine protons in aqueous amine solutions; rates of rotation about chemical bonds as in ring inversion in cyclohexane derivatives and rates of rotation about the OC–N bond in amides; rates of ligand exchange in transition metal complexes [1].

The determination of rates of exchange in paramagnetic complexes depends upon the fact that the coordinated species has a much shorter nuclear spin lifetime (larger line width of the NMR signal) than the uncoordinated species in the bulk solution.

The nuclear spin lifetime is short in a paramagnetic environment because the nucleus is subjected to strong, fluctuating magnetic fields from the unpaired electrons which are responsible for the paramagnetism. These magnetic fields act on the small magnetic dipole of the nucleus and cause it to "flip over", or change its direction. Thus, the lifetime of a given spin state (*i.e.* the orientation of the magnetic dipole) is shortened.

2. Mathematical Principles

The shape of NMR signals in the absence of chemical exchange can be predicted from the Bloch equations [2]. *Gutowsky*, *McCall*, and *Slichter* [3] first published a solution of the Bloch equations corrected to account for the effects of chemical exchange of the nucleus between sites that are not equivalent in nuclear magnetic resonance. Later, *McConnell* published a mathematically simpler approach [4]. *Swift* and *Connick* [5] have published the most rigorous derivation of the equations relating NMR line shapes and lifetimes of ligands in paramagnetic environments for use where only the solvent resonance is observed. Their derivation proceeds after the method of *McConnell* in the following manner:

The first step is the addition of terms to the differential Bloch equations to include transfer of magnetization among three magnetically unequivalent species present in the solution. These species are the uncoordinated potential ligand present in the bulk solution (subscript a) and two possible types of coordinated ligands (subscripts b and c). The original Bloch equation for the rate of change of the magnetization of the uncoordinated species, G_a, is [2]:

$$\frac{dG_a}{dt} = -\frac{G_a}{T_{2a}} + iG_a\Delta\omega_a - i\gamma H_1 Mo_a \qquad (1)$$

In this equation $\Delta\omega_a = (\omega - \omega_a)$, where ω is the applied radiofrequency (customarily 40–60 Mc), and ω_a is the resonance frequency for species a. Mo_a is the maximum magnetization of species a in the direction of the high external magnetic field, γ is the gyromagnetic ratio of the proton, and H_1 is the low magnetic field strength of the applied radiofrequency. Also, T_{2a} is the transverse relaxation time for the species a. It may be regarded theoretically as being the mean lifetime of a spin state in the environment of a. Experimentally, T_{2a} is related to the line width ν_a at half peak height of the resonance signal for species a only:

$$\pi\nu_a = 1/T_{2a} \qquad (2)$$

The differential equation for the rate of change of G_a, corrected to account for chemical exchange is

$$\frac{dG_a}{dt} = i\gamma H_1 Mo_a + iG_a\Delta\omega_a - \frac{G_a}{T_{2a}} - \frac{G_a}{\tau_{ab}} - \frac{G_a}{\tau_{ac}} + \frac{G_b}{\tau_{ba}} + \frac{G_c}{\tau_{ca}} \qquad (3)$$

[1] A recent review article has covered the use of NMR spectroscopy in studying the kinetics of some of these reactions: *A. Loewenstein* and *T. M. Connor*, Ber. Bunsenges. physik. Chem. *67*, 280 (1963).

[2] A general discussion of the Bloch equations and the effects of chemical exchange is contained in *J. A. Pople*, *W. G. Schneider*, and *H. J. Bernstein*: High-resolution Nuclear Magnetic Resonance. McGraw-Hill, New York 1959, Chapter 10.

[3] *H. S. Gutowsky*, *D. W. McCall*, and *C. P. Slichter*, J. chem. Physics *21*, 279 (1953).

[4] *H. M. McConnell*, J. chem. Physics *28*, 430 (1958).

[5] *T. J. Swift* and *R. E. Connick*, J. chem. Physics *37*, 307 (1962).

where τ_{ab} is the lifetime for chemical exchange of "a" magnetization to b, τ_{ac} the lifetime for chemical exchange of "a" magnetization to c, τ_{ba} the lifetime for chemical exchange of "b" magnetization to a, and τ_{ca} the lifetime for chemical exchange of "c" magnetization to a.

There are two completely analogous equations for the rates of change of G_b and G_c.

The second step is the solution of the differential equations for the magnetization of the ligand free in solution. Chemical equilibrium and slow passage through resonance (slow variation of the high magnetic field) are assumed so that dG_a/dt, dG_b/dt, and $dG_c/dt = 0$. The assumption is also made that the uncoordinated species is present in large excess so that the total magnetization is essentially only that of the uncoordinated species. In such a dilute solution, the direct exchange of ligands between complexes would be rare and terms involving the lifetimes of such exchanges are dropped.

Finally, the complex equation for the magnetization of the uncoordinated species is solved for the imaginary component, which is proportional to the height of the NMR signal. The result is further simplified by the assumption that the resonance signal is being observed near the frequency of its maximum such that $\Delta\omega_a$ is nearly zero. The final equation for the NMR line shape is Lorentzian in form and may be solved for the line width at half height which is

$$\frac{1}{T_2} = \frac{1}{T_{2a}} + \sum_{j=b}^{c} \tau_{aj} \left[\frac{\frac{1}{(T_{2j})^2} + \frac{1}{T_{2j}\tau_{ja}} + \Delta\omega^2{}_j}{\left(\frac{1}{T_{2j}} + \frac{1}{\tau_{ja}}\right)^2 + \Delta\omega^2{}_j} \right] \quad (4)$$

In this equation, $1/T_{2_a}$ is the line width at half height in the absence of paramagnetic exchange, $1/T_{2j}$ is the much larger line width of the coordinated species b and c, τ_{ja} is the lifetime for chemical exchange of the coordinated ligand back into the solution, and $\Delta\omega_j$ is the chemical shift of species b or c from that of a. This equation is applicable to any number of paramagnetic components in the solution which may be included in the summation. The physical significance of the resultant equation is perhaps more easily seen from the simplified derivation by *Pearson* et al. [6]. This simplified equation assumes that only one paramagnetic environment is present in solution in small amount, and that $\Delta\omega_b$ as well as $\Delta\omega_a$ are small.

$$\frac{1}{T_2} = \frac{1}{T_{2a}} + \frac{P_b}{P_a}\left[\frac{1}{T_{2b} + \tau_{ba}}\right] \quad (5)$$

Here again $1/T_{2_a}$ is the line width of the signal of the uncoordinated ligand in the absence of chemical exchange, $1/T_{2_b}$ is the line width for the coordinated species, and P_b/P_a is the ratio of the molar concentration of the coordinated ligand to that of the uncoordinated ligand. It is seen that the line broadening produced by the paramagnetic species can be controlled by either the nuclear relaxation produced by the paramagnetism, if T_{2b} is greater than τ_{ba}, or by the length of time that the ligand spends in contact with the paramagnetism, if τ_{ba} is greater than T_{2b}. If the paramagnetism is relatively inefficient in producing line broadening (large T_{2b}), the line width will depend upon three laxation produced during the time of contact. If the paramagnetic relaxation is very efficient (small T_{2b}), the line width will depend upon the rate at which the paramagnetically relaxed nuclei are released into the bulk of the solution.

The NMR signal of the released ligand will be averaged with that of the uncomplexed and more abundant species. Measurement of the line broadening in solutions containing paramagnetic ions will, therefore, give at least the lower limit of the exchange rate.

It is possible to decide whether the observed line width is controlled by relaxation (T_{2b}) or chemical exchange (τ_{ba}) by temperature variation studies [6]. At a given concentration, $1/\tau_{ba}$ will behave as a (pseudo) first order rate constant and have a normal Arrhenius type temperature dependence. Hence, the line broadening (when dependent on τ_{ba}) will increase with increasing temperature. From the temperature variation, the value of the

$$1/\tau_{ba} = k = A\exp(-E_a/RT) \quad (6)$$

activation energy, E_a, can be found. A is a frequency factor which may be dependent on concentration.

The factor $1/T_{2b}$ will usually have a small temperature dependence, the correlation time being slightly dependent on temperature [*] [7]. However, $1/T_{2b}$ will be independent of changing concentrations since it is not a chemical rate constant.

3. Examples

a) Solvent as Ligand

The simplest chemical system to which the line broadening method can be applied is a solution of a paramagnetic salt in water. *Swift* and *Connick* [5] have applied the results of their derivation in detail to the ^{17}O line widths in aqueous solutions of manganous, cupric, nickel, cobaltous, and ferrous salts to determine the rates of solvation exchange in $M(H_2O)_6^{2+}$ ions as well as $\Delta H^{\neq}$ and $\Delta S^{\neq}$ of the exchange. The process involved is

$$M(H_2O)_6^{2+} + H_2O^* \rightleftharpoons M(H_2O^*)_6^{2+} + H_2O \quad (7)$$

Here, H_2O^* is a water molecule from the bulk of the solvent, M is a metal ion.

Since only two environments are considered [*i.e.* solvent (subscript H_2O) and complex (subscript M)] Equation (4) becomes:

$$\frac{1}{T_2} = \frac{1}{\tau_{H_2O}}\left[\frac{\frac{1}{(T_{2M})^2} + \frac{1}{T_{2M}\tau_M} + \Delta\omega_M^2}{\left(\frac{1}{T_{2M}} + \frac{1}{\tau_M}\right)^2 + \Delta\omega_M^2}\right] \quad (8)$$

[*] The correlation time is the average time that a molecule has before its position or condition with respect to the applied magnetic field changes. It may be the time of rotation of the molecule, the lifetime of a spin state of the unpaired electrons, or even the chemical exchange time. In general, whichever of these times is the shortest will be the correlation time. The relaxation time T_{2b} will be inversely proportional to the correlation time since the mechanisms for nuclear relaxation have a greater chance to operate during longer correlation times.

[6] *R. G. Pearson, J. Palmer, M. M. Anderson,* and *A. L. Allred,* Z. Elektrochem., Ber. Bunsenges. physik. Chem. *64,* 110 (1960).

[7] *R. A. Bernheim, T. H. Brown, H. S. Gutowsky,* and *P. E. Woessner,* J. chem. Physics *30,* 950 (1959).

Where τ_{ab} has been replaced by τ_{H_2O}, τ_{ba} by τ_M, T_{2b} by T_{2M}, and $\Delta\omega_b$ by $\Delta\omega_M$. Four possible cases arise for controlling factors in the line broadening:

1. $\Delta\omega_M^2 \gg 1/(T_{2M})^2 + 1/(\tau_M)^2$; $\quad 1/T_2 = 1/\tau_{H_2O}$

The relaxation of nuclear spins is caused by the large difference between the resonance frequencies in the coordinated state and in the bulk of the solution and is very rapid. In this case, the line broadening is controlled by the rate of exchange [$\tau_{ba} \gg T_{2b}$ in Equation (5)].

2. $1/(\tau_M)^2 \gg \Delta\omega_M^2 \gg 1/T_{2M}\tau_M$; $\quad 1/T_2 = P_M\tau_M\Delta\omega_M^2$

$P_M = \tau_M/\tau_{H_2O}$ proton fraction coordinated

The line broadening is controlled by the rate of relaxation through the change of resonance frequency, and the chemical exchange is rapid. This intermediate case is not covered by Equation (5).

3. $1/(T_{2M})^2 \gg \Delta\omega_M^2$ and $1/(\tau_M^2)$; $\quad 1/T_2 = 1/\tau_{H_2O}$

The relaxation is comparatively rapid and is controlled by the lifetime of the nuclear spin state. Therefore, the measured line width is controlled by the rate of chemical exchange [$\tau_{ab} \gg T_{2b}$ in Equation (5)].

4. $1/T_{2M}\tau_M \gg 1/(T_{2M})^2$ and $\Delta\omega_M^2$; $\quad 1/T_2 = P_M/T_{2M}$

The chemical exchange is comparatively rapid, $\Delta\omega_M$ is small and the line width is controlled by the nuclear spin relaxation in the complex [$T_{2b} \gg \tau_{ba}$ in Equation (5)].

Connick and *Swift* used the temperature dependence of the line width to determine which factors were controlling. Their results are shown in Table 1. *Pearson* et al. [6] utilized the fact that in ligands containing more than one kind of proton, the paramagnetic relaxation rate is inversely dependent upon the distance of the proton from the paramagnetic center. Therefore, if the line broadening is the same for two types of protons, it must be controlled by the exchange rate of the ligand.

Theoretical equations for the transverse relaxation rate, $1/T_{2M}$, have been given by *Solomon* [8] and *Bloembergen* [9]. There are two mechanisms, a dipole-dipole interaction and an isotropic contact interaction. The dipole-dipole interaction between an unpaired electron and a proton can operate over a certain distance. The contact interaction, on the other hand, depends upon coupling of the electron spin with the nuclear spin by the actual presence of the electron at the proton. It therefore requires close contact of the paramagnetic ion and the molecule containing the protons being studied. As a result some broadening of the NMR signal can occur due to dipole-dipole relaxation even for a molecule which is not directly coordinated to a paramagnetic ion. However, the effect does fall off with distance and is only significant when the molecule is in the layer right next to the coordinated layer. This line broadening is called "outer-sphere relaxation" and can be corrected for.

Table 1 gives some data for the rate of exchange of coordinated methanol [6] and ethylene glycol [10]. In these cases signals for CH and OH protons can be observed. Only for Ni^{2+} is the line broadening the same for both kinds of protons. In this case the rate of exchange is being measured. For the other metal ions the OH line broadening is greater than the CH line broadening. Hence, only a lower limit to the rate of exchange can be given using the OH data.

Table 1. Rate constants $1/\tau_M = k_{exchange}$ [sec^{-1}] for the exchange of water, methanol, and ethylene glycol coordinated to metal ions at 25 °C.

Metal ion	Water [a]	Methanol	Glycol[e]
Mn^{2+}	3×10^7	$>2.5\times10^5$ [c]	$>1.5\times10^6$
Fe^{2+}	3×10^6	—	$>2.5\times10^3$
Co^{2+}	1×10^6	1.8×10^4 [d]	$>3.4\times10^3$
Ni^{2+}	3×10^4	1.0×10^3 [d]	4.4×10^3
Cu^{2+}	2×10^8 [b]	1.0×10^4 [c]	$>1.5\times10^5$

[a] Data from reference [5].

[b] Some evidence for a second, slower reaction.

[c] From reference [6].

[d] From reference [12].

[e] From reference [10], temperature 27 °C.

The coordinated ligand can also give an NMR spectrum which can be seen in special cases. For example ethylenediamine coordinated to nickel(II) or cobalt(II) shows an NH_2 peak about 200 p.p.m. on the high-field side and a CH_2 peak about 100 p.p.m. on the low-field side with respect to water [11]. At 60 Mc for the resonance frequency these shifts, $\Delta\omega_M$, are of the order of 10^3 to 10^4 cps. Similar shifts can be found for coordinated OH protons.

Luz and *Meiboom* [12] have observed the resonance lines for the methyl and hydroxy groups of bound methanol separate from those of bulk solvent methanol in solutions containing $Ni(ClO_4)_2$ and $Co(ClO_4)_2$. Below −40 °C the exchange was sufficiently slow, so that the line width observed was completely caused by the coordinated ligand. Above −40 °C additional line broadening occurred due to chemical exchange. The rate of exchange could be calculated from the line width in the usual way.

When coordination of a paramagnetic ion to nitrogen occurs, the values of T_{2M} for the protons on the nitrogen atom are very small, about 10^{-5} to 10^{-7} seconds [10]. Coordination to oxygen produces values of T_{2M} which are much greater for bound protons, about 10^{-3} to 10^{-4} seconds [6, 12]. This difference is due to the greater polarizability of nitrogen compared to oxygen. Thus, a higher unpaired spin density due to the isotropic contact interaction will be found on nitrogen. By polarization this spin density will be transmitted to the proton bound to nitrogen and produce relaxation [13]. Since, moreover, τ_M is greater for nitrogen ligands than for oxygen ligands, this means that rates of exchange will be commonly measured for nitrogen-containing ligands, but not so often for oxygen ligands.

b) Solvent and Ligand Different

The results of Table 1 refer to cases in which the solvent is also the coordinated ligand. It is also possible to study the exchange of ligands, L, present in smaller amounts in a solvent such as water.

$$ML_n + L^* \underset{\tau_{ba}}{\overset{\tau_{ab}}{\rightleftharpoons}} ML_n^* + L \qquad (9)$$

[8] *J. Solomon*, Physical Rev. *99*, 559 (1955).

[9] *N. Bloembergen*, J. chem. Physics *27*, 572 (1957).

[10] *R. G. Pearson* and *R. D. Lanier*, J. Amer. chem. Soc. *86*, 765 (1964).

[11] *R. S. Milner* and *L. Pratt*, Discuss. Faraday Soc. *34*, 88 (1962).

[12] *Z. Luz* and *S. Meiboom*, J. chem. Physics *40*, 1058 (1964).

[13] *R. E. Benson*, *D. R. Eaton*, *A. D. Josey*, and *W. D. Phillips*, J. Amer. chem. Soc. *83*, 3714 (1961).

The NMR spectrum for free L will show the usual line broadening due to exchange. If the protons of L are being observed, as is usually the case, then it must be remembered that NH and OH protons of free L will very rapidly average with the solvent. Thus, if L is glycine ($gly^{\oplus} = NH_2CH_2COO^{\ominus}$), the NMR spectrum in water will show a CH_2 peak and a H_2O/NH_2 averaged peak. The glycine must be about 1 molar for easy observation, but a large portion of this can be in the form of $LH^{\oplus}$, or $^{\oplus}NH_3CH_2COO^{\ominus}$, since $NH_3^{\oplus}$ will also exchange rapidly with the solvent.

The experiments are done at a constant value of P_M (or P_b). This means a constant concentration of metal ion and a constant amount of $[L] + [LH^{\oplus}]$. The line broadening, $\Delta\nu$, is plotted as a function of [L], the concentration of free ligand, which is varied by changing the pH. Four kinds of results can be found as shown in Figure 1.

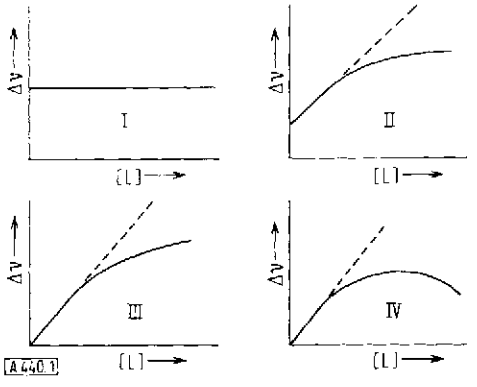

Fig. 1. Experimental results for plots of line broadening $\Delta\nu$ *vs.* concentration of free ligand [L].

For case I, there is no dependence of $\Delta\nu$ on [L]. Such results were found for some nickel complexes, where the rate of exchange is so slow that only a small broadening due to "outer-sphere relaxation" [6] was observed.

Case II has ligand dependence and a nonzero intercept. Thus, there is a line broadening process which is independent of the concentration of free ligand, L, and one which is directly proportional to the concentration of L. This suggests that there is a kinetically first-order exchange mechanism (independent of [L]) and a second-order exchange mechanism with a rate directly dependent on [L]. A positive temperature coefficient and near equality of the OH and CH line broadenings would be needed to confirm that exchange rates are controlling. Rate constants k_1 and k_2 would govern the first order and second order processes, respectively. The dashed line is for the case where T_{2M} remains small compared to τ_M at all concentrations of L used. Eventually, of course, τ_M must become smaller than T_{2M} with increasing [L] because of the relation

$$1/\tau_M = k_1 + k_2\,[L] \qquad (10)$$

Hence, at large [L], the curve must flatten out and reach a constant slope. It is possible, in principle, to obtain k_1, k_2, and T_{2M} in such cases.

The third case, III, involves dependence on [L] and a zero intercept. This indicates that only a second order exchange reaction is occurring, k_1 in Equation (10) being zero. Curvature will occur when [L] becomes large enough so that T_{2M} is greater than τ_M. Equation (10), with $k_1 = 0$, Equation (2), and Equation (5) can be combined to give

$$\pi\nu = \pi\nu_a + \frac{P_b}{P_a}\left[\frac{1}{T_{2b} + 1/k_2\,[L]}\right] \qquad (11)$$

Accordingly, a plot of the reciprocal of the line broadening, $\Delta\nu$, against the reciprocal of the concentration, [L], gives a straight line from which T_{2b} and k_2 can be found.

The plot for case IV shows a maximum. This is due to a change in the concentration of species contributing differently to the line broadening. Some copper(II) systems show this behavior. For example, Cu^{2+}/NH_3 gave such a result because $Cu(NH_3)_5^{2+}$ formed at high concentration of NH_3 is inefficient at line broadening.

Table 2 shows some data obtained for metal ion/ligand systems in aqueous solution. The results can be confirmed by information from other sources in several instances. For example, data on the rate of dissociation of $Ni(en)_3^{2+}$ ($k_1 = 3\ sec^{-1}$) and of $Ni(gly)_3^-$ ($k_1 = 10\ sec^{-1}$) [14] show that the rates are too small to be measured by NMR line broadening methods. They can be measured by flow methods however [14]. Thus, the rate of acid catalysed dissociation was found to be some 20–30 times faster than ligand exchange since only one end of the chelate needs to be free for acid dissociation, but both ends must be free for ligand exchange.

It will be noted that rates of exchange in Table 2 calculated from the averaged OH/NH signals are usually

Table 2. Rate limits for the ligand exchange in complexes at 27 °C. en = ethylenediamine, gly = glycine, sarc = N-methylglycine (sarcosine), dmg = *N,N*-dimethylglycine.

Complex	k_1 [sec^{-1}] or k_2 [M^{-1} sec^{-1}]	Temperature dependence
$Cu(en)_2^{2+}$	$kOH = 2.6\times10^6\ M^{-1}\ sec^{-1}$	$E_a = 7$ kcal/mole
	$kCH_2 = 1.8\times10^6\ M^{-1}\ sec^{-1}$	$E_a = 7$ kcal/mole
$Ni(en)_3^{2+}$	$kOH < 1\times10^3\ sec^{-1}$	None
	$kCH_2 < 2\times10^2\ sec^{-1}$	Small
$Co(en)_3^{2+}$	$kOH = 4.8\times10^3\ sec^{-1} + 3.3\times10^3\ M^{-1}\ sec^{-1}$	$E_a = 10.5$ kcal/mole
	$kCH_2 = 2.5\times10^3\ M^{-1}\ sec^{-1}$	$E_a = 10.5$ kcal/mole
$Cu(gly)_2$	$kOH = 8.2\times10^6\ M^{-1}\ sec^{-1}$	$E_a = 6$ kcal/mole
	$kCH_2 = 2.6\times10^6\ M^{-1}\ sec^{-1}$	$E_a = 6$ kcal/mole
$Ni(gly)_3^-$	$kOH < 1\times10^3\ sec^{-1}$	Negative
	$kCH_2 < 3\times10^2\ sec^{-1}$	Positive
$Co(gly)_3^-$	$kOH = 5.7\times10^3\ sec^{-1} + 4.8\times10^3\ M^{-1}\ sec^{-1}$	$E_a = 10$ kcal/mole
	$kCH_2 = 5.7\times10^3\ sec^{-1} + 3.8\times10^3\ M^{-1}\ sec^{-1}$	$E_a = 10$ kcal/mole
$Mn(gly)_2$	$kOH > 1\times10^3\ sec^{-1}$	Negative
	$kCH_2 > 1\times10^4\ sec^{-1}$	Negative
$Fe(gly)_2$	$kOH = 2.2\times10^4\ sec^{-1} + 5\times10^4\ M^{-1}\ sec^{-1}$	$E_a = 9.5$ kcal/mole
	$kCH_2 = 2.2\times10^4\ sec^{-1} + 3.2\times10^4\ M^{-1}\ sec^{-1}$	$E_a = 9.5$ kcal/mole
$Cu(sarc)_2$	$kOH = 6\times10^5\ M^{-1}\ sec^{-1}$	$E_a = 7$ kcal/mole
$Ni(sarc)_3^-$	$kCH_2 = 60\ sec^{-1} + 1\times10^2\ M^{-1}\ sec^{-1}$ [a]	Positive
$Co(sarc)_3^-$	$kOH = 6.7\times10^2\ sec^{-1} + 3.3\times10^3\ M^{-1}\ sec^{-1}$	$E_a = 13$ kcal/mole
	$kCH_2 = 4.2\times10^2\ sec^{-1} + 2.1\times10^3\ M^{-1}\ sec^{-1}$	$E_a = 13$ kcal/mole
$Cu(dmg)_2$	$kCH_2 = 1.3\times10^4\ M^{-1}\ sec^{-1}$	$E_a = 9.5$ kcal/mole
$Ni(dmg)_3^-$	$kCH_2 = 70\ sec^{-1} + 4.7\times10^2\ M^{-1}\ sec^{-1}$	$E_a = 17$ kcal/mole
$Co(dmg)_3^-$	$kCH_2 = 3.2\times10^3\ sec^{-1} + 7.3\times10^3\ M^{-1}\ sec^{-1}$	Positive

[a] Rate constant at 54 °C.

[14] *R. G. Wilkins* and *A. K. Shamsuddin-Ahmed*, J. chem. Soc. (London) *1959*, 3700; *1960*, 2901; *P. Ellis* and *R. G. Wilkins*, ibid. *1959*, 299.

somewhat larger than those from the CH signals. This is expected because release of the NH end of the chelate will lead to an acid-base proton exchange which will broaden the OH peak only. The extreme case is $Co(en)_3^{2+}$ where the OH peak gives a k_1 of 3.3×10^3 sec^{-1} and the CH peak shows $k_1 = 0$. If k_1 is entirely due to one end only being released and if *Wilkins'* factor [14] of 30 is valid, then the contribution of a first-order process for the complete dissociation of the group en would be too small to be measured from the CH signal.

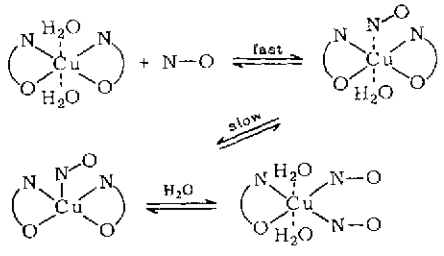
The difference between the rate constants derived from the OH and CH signals is small for glycine and sarcosine. In these cases it is probably the carboxylate end which is released first. This does not lead to proton exchange and hence k_1 and k_2 calculated from the CH and OH signals should be the same. Copper gives the largest difference in k_2 values between the two signals for glycine. This may be due to an additional exchange of a glycine ion coordinated through the amine group only to one of the axial positions above and below the plane of $Cu(gly)_2$ [15]. It is known [5] that groups held in the axial position are very labile. Hence, τ_{ba} in Equation (5) is very small compared to T_{2b}. Since the coordinated NH_2 group is closer to the copper ion than the CH_2 group, its signal would be broadened more.

Copper, manganese, and iron(II) have two water molecules still coordinated in most of the complexes studied. Presumably these molecules are labile and could cause OH line broadening. However, a consideration of the high rates of exchange of such water molecules and the low rates of relaxation of protons bonded to oxygen [16] suggests that the contribution of such a process to the overall line broadening would be small. Manganese(II) would possibly be an exception, since it gives higher rates of relaxation, and part of the difference between the OH and CH signals for this ion in Table 2 could be due to water exchange. Otherwise, it should be noted that the approximate activation energies listed in Table 2 are the same for both OH and CH signals. This suggests that the same process is rate determining for both.

In all cases the order of exchange reactivity found, $Mn(II) > Fe(II) > Co(II) > Ni(II) \ll Cu(II)$, agrees with previous observations for the same series [17]. An explanation has been given in terms of crystal field theory, in which the important factor is the different loss of crystal field stabilization energy in going from the ground state to the transition state for each metal ion. To use such a theory, it is necessary to assume a mechanism and a structure for the transition state as well as for the ground state.

The data are in agreement with a number of possible mechanisms. They are best considered in combination with available information on substitution reactions of other complex ions. It is safe to assume that the complexes of Mn(II), Fe(II), Co(II), and Ni(II) are octahedral, or slightly distorted octahedral, structures. Cu(II) complexes have such a serious tetragonal distortion that they may be considered essentially as planar. It has been found that octahedral complexes react by mechanisms which are, or strongly resemble, S_N1 or dissociation mechanisms [17]. Planar complexes, however, have always been found to react by S_N2 or displacement mechanisms in their substitution reactions [17, 18].

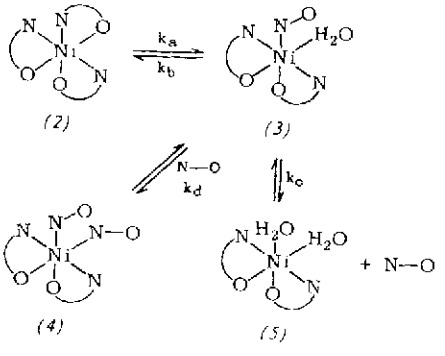
It is significant that in Table 2 copper always reacts by a totally second-order process, where exchange rates are being measured. This suggests an S_N2 mechanism for copper(II) complexes in agreement with their structures. By analogy with complexes of platinum(II) and palladium(II) [18], the first step in the reaction would be the facile replacement of an axial water molecule by the substituting ligand. This would be followed, probably, by rearrangement to a trigonal bipyramid structure, expulsion of one end of the coordinated ligand, and return to a planar structure *(1)* containing two unidentate ligands. (In the formulae N–O is a glycinate anion.) At



(1)

this point exchange has been assured since the ligand originally in solution has taken up a position identical with that of the ligand originally present in the complex. The rate of exchange would be equal to the rate of formation of *(1)*, *i.e.* it would be second order, depending on the concentrations of the complex and of the free ligand. A corresponding first-order reaction in which water is the nucleophilic reagent would be too slow to be detectable because planar complexes are very sensitive to the reactivity of the nucleophile [18].

Octahedral complexes with three bidentate ligands are not as easily accessible for an incoming ligand molecule. Instead, by a mechanism which may be described as a dissociation assisted by water (see below), one end of a bound chelate is replaced by a water molecule in a readily reversible process. After releasing one end of the chelate, the intermediate *(3)* could reclose the chelate, could



(2) *(3)* *(4)* *(5)*

[15] The third en group of $Cu(en)_3^{2+}$ is attached as a unidentate ligand: *J. Bjerrum*, Acta chem. scand. *2*, 297 (1948).

react by the same dissociation mechanism to release both ends of the chelate, or could have the coordinated water replaced by an external ligand molecule. Either of the last two events would lead to exchange. The rate of exchange would be given by

$$\text{rate} = \{k_c + k_d [L]\} [(3)] \qquad (12)$$

Applying the steady-state treatment to *(3)* and assuming the concentrations of *(4)* and *(5)* to be very small, gives for the rate of exchange

$$\text{rate} = \frac{\{k_c + k_d [L]\} k_a [NiL_2]}{k_b + k_c + k_d [L]} \qquad (13)$$

If $k_d[L]$ is small compared to $(k_b + k_c)$, then the observed rate constant for exchange will be the sum of a first-order term and a second-order term, in agreement with the experimental results.

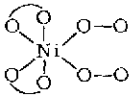
This mechanism can be tested because, first of all, it should be true that k_b is 20–30 times as large as k_c, as mentioned above for $Ni(en)_3^{2+}$ and $Ni(gly)_3^-$. Secondly, let us assume that $(k_b + k_c)$ is large compared to $k_d[L]$. The denominator of Equation (13) is then simply a constant since $k_d[L]$ can be ignored. This means the equation is of the same form as Equation (10), found experimentally. We can now identify k_1 as $k_a k_c/(k_b + k_c)$ or $k_a k_c/k_b$, since $k_b \gg k_c$. In the same way k_2 becomes $k_a k_d/k_b$. An examination of Table 2 shows that in no case does $k_2[L]$ become as much as ten times k_1 for the highest [L] used. This means that $(k_b + k_c)$ will indeed be large compared to $k_d[L]$, as assumed. Some leveling of the rate with increasing [L] may occur but would ordinarily be obscured by the normal curvature of plots of line broadening *vs.* [L] due to relaxation control superseding exchange control. A similar mechanism can be written for octahedral chelates containing two bidentate ligands and, in addition, a second-order path in which the reverse process *(5)* → *(3)* occurs can be visualized.

There is no absolute reason why a mechanism involving an S_N2 attack on the metal by the incoming ligand should not account for the second-order rateconstants for exchange in the octahedral systems. The chief evidence against such a process is the general failure to detect nucleophilic displacement reactions with octahedral complexes of transition metals [19]. It is significant that it is the "special mechanism for chelate compounds" [17] which causes second-order kinetics without a true bimolecular reaction. In the dissociation of any chelate ligand (bidentate or polydentate), it is necessary that one point of attachment be broken at a time. Almost invariably a water molecule will replace the released part of the ligand. Since other ligands can replace water, it is now possible for the rates of ligand substitution or exchange to depend on the concentration of the new ligand. When unidentate ligands such as NH_3 or CNS^- are exchanging, only first-order exchange is observed [20].

The rate sequence glycine > sarcosine > dimethylglycine observed for copper(II) complexes is expected for an S_N2 mechanism and may be attributed to steric hindrance to the approach of the nucleophile. Similar cases are known for platinum(II) complexes [18]. For octahedral cobalt(II) and nickel(II) complexes the opposite order is found: dimethylglycine > sarcosine > glycine. This is readily explained as steric acceleration of the dissociation mechanism and has been observed for other octahedral systems, too [17]. *Wilkins* [21] has found the same order for the rate of dissociation of *N*-methylethylenediamine complexes of nickel(II).

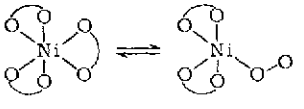
The water-assisted dissociations, *i.e.* the steps with rate constants k_a and k_c, are visualized as requiring a critical extension of the metal-ligand bond and the partial coordination of a water molecule before the bond is completely broken. This follows from the improbability for energetic reasons of a five-coordinated intermediate with a square pyramid structure [22]. Rearrangement to a trigonal bipyramid structure might occur instead in certain cases, for example, where there is no crystal field stabilization energy or where π-bonding is important. If a water molecule is required, then the transition state will be seven-coordinated, with five groups in the original octahedral positions and two groups, water and the leaving group, adjacent to each other and somewhat further away [23].

The results for glycol exchange given in Table 1 call for some special comment. First of all, the rates of exchange of this chelate ligand are about the same as those for the unidentate methanol. This is understandable in terms of the mechanism of a solvent-assisted dissociation. The intermediate *(6)* guarantees exchange after only one end



(6)

of the chelate has dissociated. A five-coordinated intermediate, *(7)*, would lead to a greatly reduced exchange rate for glycol compared to methanol because of rapid reclosing of the chelate ring.



(7)

4. Other Methods

Another NMR line broadening method not using paramagnetic metal ions has been developed chiefly by *Hertz* [24]. Here, advantage is taken of the fact that a halide ion coordinated to any metal ion has a high rate of magnetic relaxation, due to coupling of the nuclear quadrupole moment of the halide ion with the asym-

metric electric field produced at the halide nucleus by the metal ion. Rates of reactions such as

$$Cd(H_2O)_6^{2+} + Br^- \rightleftharpoons Cd(H_2O)_5Br^+ + H_2O$$

can be evaluated.

Finally, it is of interest to mention that rates of rapid exchange reactions can also be measured by using the line broadening in EPR or ESR spectra [25]. Since the time scale of EPR is some 10^3 times larger than that of NMR (the frequency used is of the order 10^{10} cps rather than 10^7 cps) only very rapid reactions can be studied. Half-lives of 10^{-6}–10^{-9} seconds are most convenient.

It has been possible to study rates of outer-sphere complex formation between paramagnetic cations and a paramagnetic anion, the nitrosyldisulfonate ion. Such outer-sphere reactions are very rapid, being diffusion controlled [26]. It is also possible to study rates of inner-sphere complex conversions by selecting a cation the complexes of which are very labile, for example Mn(II), and going to high temperatures where the rates become sufficiently rapid [27].

We are indebted to Prof. A. L. Allred for much help in the theory and practice of nuclear magnetic resonance spectroscopy.

Formation and Reactivity of Phosphonium Salts in the Vitamin A Series

BY DR. H. FREYSCHLAG, DR. H. GRASSNER, DR. A. NÜRRENBACH, DR. H. POMMER, DR. W. REIF, AND DR. W. SARNECKI

HAUPTLABORATORIUM DER BADISCHEN ANILIN- & SODA-FABRIK AG., LUDWIGSHAFEN/RHEIN (GERMANY)

Published on the occasion of the 100th anniversary of the establishment of Badische Anilin- & Soda-Fabrik AG., on April 6th, 1965.

For syntheses in the carotenoid field using the Wittig reaction, particularly on the technical scale, it was necessary to carry out extensive studies on the preparation and properties of the intermediates. Here the part of this work is discussed which dealt with quaternary phosphonium compounds of trimethylcyclohexene derivatives.

1. Formation of Phosphonium Salts

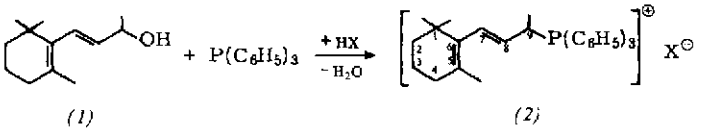
The well-known reaction of tertiary phosphines with organic halides to form quaternary phosphonium compounds [1] is unsatisfactory in the vitamin A series, since here the halogen compounds are extremely unstable. However, this difficulty has been overcome by a new method for the preparation of quaternary phosphonium salts [2].

When alcohols are treated simultaneously with tertiary phosphines and acids, they give high yields of quaternary phosphonium salts [3]:

$$R\text{-}OH + PR'_3 + HX \rightarrow [R\text{-}PR'_3]^{\oplus}\,X^{\ominus} + H_2O \qquad (a)$$

Suitable starting materials include primary and secondary alcohols; substituted allyl alcohols react particularly smoothly.

Thus, β-ionol *(1)* reacts with triphenylphosphine [*] and an acid HX to give the β-ionyltriphenylphosphonium salt *(2)*; similarly β-ionylidene-ethanol *(3)* gives the β-ionylidene-ethyltriphenylphosphonium salt *(6)*.



(1) *(2)*

We assume an ionic mechanism for the formation of the quaternary phosphonium salt from alcohol, phosphine, and acid. Under the action of the proton, the alcohol R–OH forms the carbonium ion $R^{\oplus}$, which then alkylates the tertiary phosphine to yield the quaternary salt. In support of this mechanism, replacement of β-ionylidene-ethanol *(3)* by its isomer 9-vinyl-β-ionol *(4)* leads to the same β-ionylidene-ethyltriphenylphosphonium salt *(6)* [4].

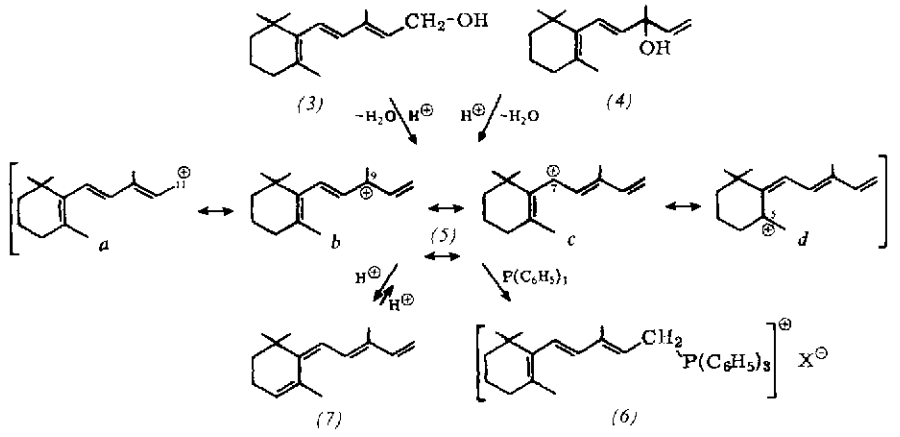
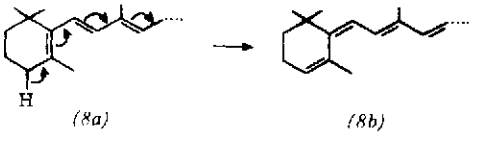
[*] The tertiary phosphine used here and throughout this work is triphenylphosphine, the preferred reagent for the Wittig olefination. The components $(C_6H_5)_3P$ and HX can be replaced by the quaternary phosphonium salt $[(C_6H_5)_3PH]^{\oplus}X^{\ominus}$.

[4] German Patent 1060386 (Sept. 3rd, 1957), BASF; inventors: *W. Sarnecki* and *H. Pommer*; Chem. Zbl. *1960*, 13777.

Compounds *(3)* and *(4)* apparently react with the acid to give the same carbonium ion *(5)*, which has a number of resonance structures *(5a)–(5d)*. This carbonium ion is normally stabilized by loss of a proton with formation



of the hydrocarbon *(7)*, which exists in the so-called retro-configuration. The "retro-ionylidene rearrangement", which was first described by *Oroshnik* et al. [5] and by *Huisman* et al. [6], always takes place when a carbonium ion is formed in the α-position relative to a ring double bond or in a position vinylogous thereto. However, if a tertiary phosphine is present, the cation *(5)* reacts preferentially with this nucleophile, instead of assuming the retro-configuration.



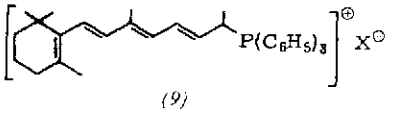
The retro-configuration *(8b)* is energetically more favorable than the trimethylcyclohexene configuration *(8a)*. With a few exceptions, the retro-ionylidene rearrangement is irreversible. Thus, one of the major tasks in carotenoid chemistry is the search for synthetic routes and reaction conditions under which the retro-ionylidene rearrangement either does not take place at all, or can be suppressed.

2. Reconversion of the Retro-Form into the Trimethylcyclohexane Configuration

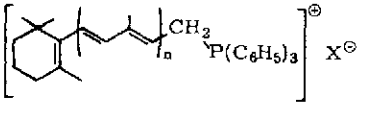
We found that the "rcto-hydrocarbon" *(7)* could be transformed to the trimethylcyclohexene configuration by the combined action of phosphines and acids. For example, a proton from the acid and the phosphorus atom of the phosphine yield the phosphonium salt *(6)* by 1,8-addition to the conjugated system of the retro-hydrocarbon *(7)* [7]. First, the proton adds onto the retro-hydrocarbon *(7)* to reform the carbonium ion *(5)*, which then reacts with the triphenylphosphine to give the β-ionylidene-ethyltriphenylphosphonium salt *(6)*. This reaction occurs with all retro-hydrocarbons in the carotenoid series.

In the vitamin A series, this method is an excellent alternative to the formation of phosphonium salts from alcohols. It proceeds more slowly than the formation of phosphonium salts by direct alkylation of the tertiary phosphine; consequently, the phosphonium salt is always accompanied by a small quantity of retro-hydrocarbon, which disappears only after very long reaction times.

The reaction mechanism discussed above can be applied to the formation of the vinylogous salts *(9)*, *(10)*, and



(9)

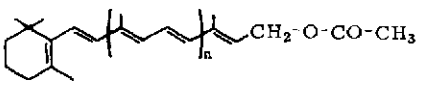


(6a): n = 0 *(10)*: n = 2
(6): n = 1 *(11)*: n = 3

(11) from the corresponding alcohols; competing reactions again lead to the formation of small amounts of the retro-hydrocarbon.

3. Other Syntheses of Phosphonium Salts

Quaternary phosphonium salts can also be synthesized by the combined action of triphenylphosphine and an acid on esters of alcohols in the vitamin A series. Thus, the β-ionylidene-ethyltriphenylphosphonium salt *(6)* can be obtained from β-ionylidene-ethyl acetate *(12)*, and the axerophthyltriphenylphosphonium salt *(10)* from vitamin A acetate *(13)* [8]. The ester can be replaced by



(12): n = 0
(13): n = 1

$\xrightarrow[-CH_3COOH]{P(C_6H_5)_3,\ HX}$

(6): n = 0
(10): n = 1

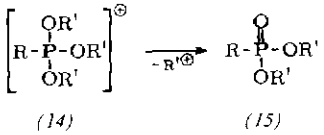
the ether with equal success. These results are again explained by the formation of a carbonium ion by the action of a proton on the ester or ether.

The main product in all our experiments was the terminal phosphonium salt. Salts derived from the resonance structures *(5b)*–*(5d)*, *i.e.* with the phosphorus attached to non-terminal carbon atoms, could be detected either only in traces or not at all. It is obvious that salts derived from structures *(5b)* or *(5c)*, in which the conjugation is interrupted, are energetically less favored than the terminal phosphonium salt *(6)*. On the other hand, energy considerations suggest that *(5d)* should take part in the reaction as well as *(5a)*, since the resulting systems have an equal number of conjugated double bonds. Thus, the nucleophilic reagent must be partly responsible for the fact that only *(6)* is formed. It can be shown with Stuart models that *(6)* is the only isomer with an unstrained structure. The molecule becomes strained, if the triphenylphosphine is attached to carbons 9, 7, or 5.

4. Quasi-Phosphonium Salts and Phosphonates

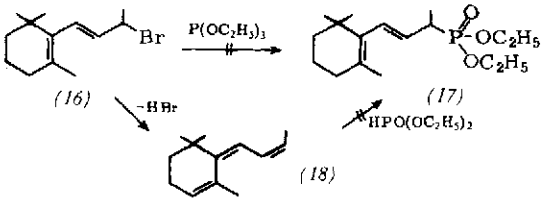
During attempts to synthesize phosphonates *(15)* instead of the quaternary phosphonium salts of type *(6)*, we found that the resonance forms *(5a)* and *(5b)* of the carbonium ion intermediate react with the nucleophile. Like the Michaelis-Arbusow reaction [2,9], the synthesis proceeds *via* a quasi-phosphonium salt *(14)*, which differs from the "normal" phosphonium salts in that three alkyl or aryl residues have been replaced by RO groups.



(14) *(15)*

Despite their low stability – they readily lose a cation $R'^{\oplus}$ with formation of the phosphonate grouping *(15)* [10] – the quasi-phosphonium salts are formed by the same mechanism as normal phosphonium salts.

We then attempted to synthesize the phosphonates, in which we were interested, using the Michaelis-Arbusow reaction. However, the reaction of β-ionyl bromide *(16)* with triethyl phosphite did not yield the desired product *(17)*. Instead, the retro-hydrocarbon *(18)* was formed



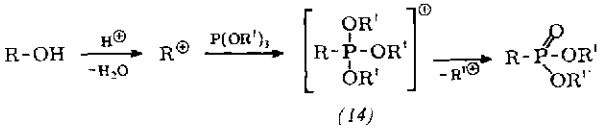
(16) *(17)* *(18)*

[9] Cf. *H. Freyschlag, W. Reif,* and *H. Pommer,* Communication to the IUPAC Symposium on Organic Phosphorus Compounds, Heidelberg (Germany), May 20th, 1964.

[10] *K. Dimroth* and *A. Nürrenbach,* Chem. Ber. *93*, 1649 (1960).

by elimination of HBr, even at temperatures much lower than those required for the Michaelis-Arbusow reaction, *i.e.* a quasi-phosphonium salt is not formed. Addition of hydrogen phosphites onto retro-hydrocarbons was also unsuccessful.

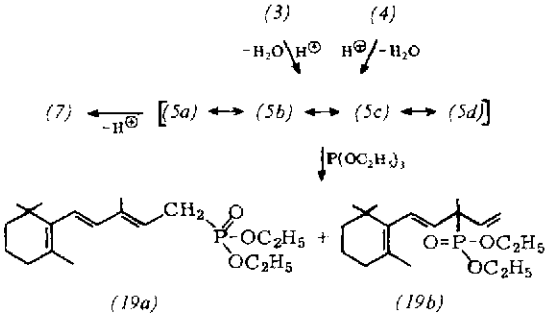
In contrast to tertiary phosphines, tertiary phosphites are not stable toward acids, being rapidly decomposed, even in the absence of water. We were therefore surprised to find that the desired phosphonates could be prepared from alcohols and a phosphite in the presence of proton donors; we assume the mechanism to be as follows: The phosphite reacts with carbonium ion $R^{\oplus}$ formed first to yield the quasi-phosphonium salt *(14)*,



(14)

which is stabilized by elimination of a carbonium ion $R'^{\ominus}$ and formation of the phosphonate grouping. The yield of phosphonate is high only when the phosphite is used in an excess of at least one mole. Diethyl β-ionylphosphonate *(17)* could be obtained in this way from β-ionol *(1)* and triethyl phosphite.

For the preparation of the vinylogous phosphonate by the same method, it should be immaterial wheter the starting material is β-ionylidene-ethanol *(3)* or 9-vinyl-β-ionol *(4)*. With either compound, the first step leads to the cation *(5)*, which can react further either by elimination of a proton to form the retro-hydrocarbon *(7)*, or by alkylation of the phosphorus atom.



(19a) *(19b)*

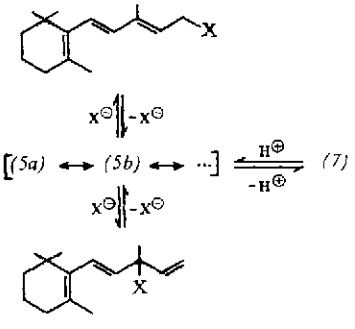
In contrast to the reaction leading to the phosphonium salts *(6)*, however, the formation of the retro-hydrocarbon during the preparation of the phosphonate is irreversible. Probably reformation of the carbonium ion *(5)* from the retro-hydrocarbon *(7)* is relatively slow in comparison with the decomposition of the phosphite by acid. The competing reaction leading to the retro-hydrocarbon must therefore be suppressed here by the use of excess phosphite. In this way, the carbonium ion *(5)* formed as the first intermediate is intercepted as the quasi-phosphonium salt.

Another difference between this reaction and the formation of phosphonium salts is the occurrence of two isomers: a primary phosphonate *(19a)* formed by reaction of the carbonium ion *(5a)* with the phosphite, and a tertiary phosphonate *(19b)* derived from the reso-

nance structure *(5b)*. Phosphonates derived from resonance structures *(5c)* and *(5d)* could not be detected. It can be shown with Stuart models that triethyl phosphite, unlike triphenylphosphine, can be attached to carbon 9 without steric hindrance, but not to carbons 7 or 5.

5. Rearrangement Mechanisms

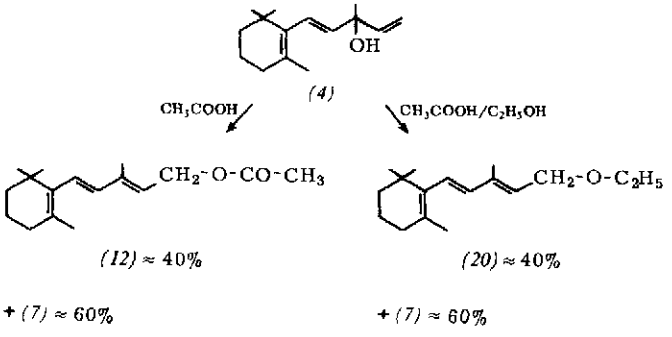
The mechanism proposed for the formation of the retro-hydrocarbon by elimination of a proton from a carbonium ion intermediate also explains why attempts to rearrange 9-vinyl-β-ionol *(4)* to β-ionylidene-ethanol *(3)* have so far met with failure [5,6,11,12]. Evidently, the rearranged compound is converted into the cationic intermediate as easily as the starting material, under the reaction conditions used. Since the conversion of the cation into the retro-compound is the only reaction involved which is almost irreversible [*], the most stable product is the retro-compound. During the formation of phosphonium salts, on the other hand, an allylic rearrangement becomes possible (see Scheme 1) because of the stability of the new P–C bond.



Scheme 1.

Thus, the normal allylic rearrangement should always take place when the reaction of the carbonium ion intermediate with the nucleophile is favored over the reverse reaction. The retro-hydrocarbon can be formed if the carbonium ion intermediate arises equally readily from both allylic isomers. However, if none of these steps is particularly favored, the reaction should lead to a mixture of the products of the allylic rearrangement and of the retro-rearrangement.

Thus, if 9-vinyl-β-ionol *(4)* is treated with glacial acetic acid, the product contains β-ionylidene-ethyl acetate *(12)*, together with the retro-hydrocarbon *(7)*. If the reaction is carried out in an acetic acid/ethanol mixture, on the other hand, it is ethyl β-ionylidene-ethyl ether *(20)* that is formed together with the retro-compound *(7)*, although traces of the acetate *(12)* are also found. These results disagree with the findings of earlier workers [5,6,11,12] but can be readily explained by assuming that the hydroxy group is removed from 9-vinyl-β-ionol and β-ionylidene-ethanol derivatives after protonation more easily than acetoxy or alkoxy groups. This also explains the lability of the halogen derivatives in this series, and the difficulty encountered in preparing them from the alcohols.

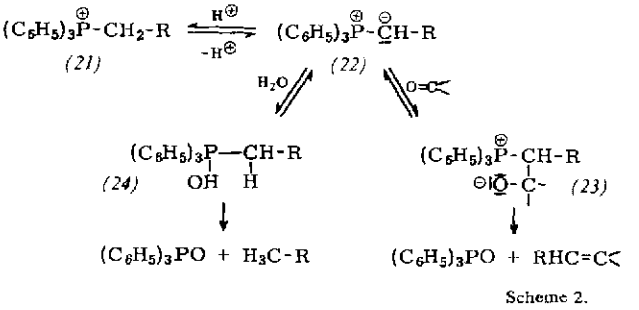


(12) ≈ 40% + *(7)* ≈ 60%

(20) ≈ 40% + *(7)* ≈ 60%

6. Reactivity of the Phosphonium Salts

After we had succeeded in synthesizing all the desired phosphonium salts of the vitamin A series, using the methods described above, we proceeded to study their stability and reactivity [13]. Among the isoprenologous phosphonium salts [cyclogeranyl- *(6a)*, β-ionylidene-ethyl- *(6)*, axerophthyl- *(10)*, and homoisoprenoaxerophthyl-triphenylphosphonium salts *(11)*], *(6a)* reacts only sluggishly with carbonyl compounds when an alkali metal hydroxide is used for ylide formation or when water is present. Elevated temperatures are required for carbonyl olefination, even in absolutely anhydrous solvents and when sodium methoxide is used. On the other hand, the isoprenologous salts *(6)*, *(10)*, and *(11)* react with carbonyl groups even in aqueous solution and with only alkali metal hydroxide as proton acceptor. It was surprising to find that these salts react in aqueous solution, since the Wittig reaction generally proceeds only in the absence of water. The phosphonium ion *(21)* gives up a proton to the base, in accordance with a reaction scheme formulated by *Wittig* (Scheme 2). The resulting ylide *(22)* readily adds on polar substances: addition of carbonyl compounds leads to the betaine *(23)* by the normal olefination reaction, while addition of water leads to the phosphonium hydroxide *(24)* as a hydrolysis intermediate [14,15].



Scheme 2.

[12] *P. Karrer* and *J. Kebrle*, Helv. chim. Acta *35*, 2570 (1952).

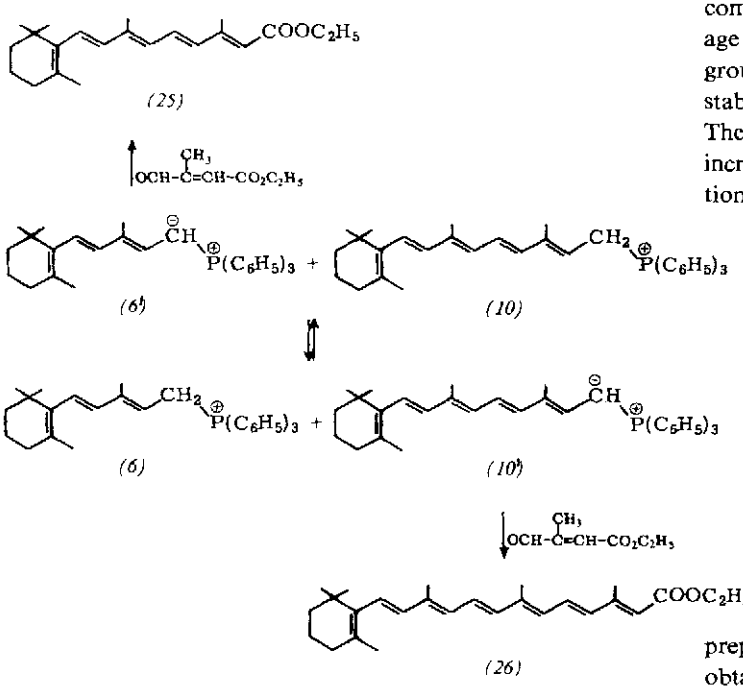
[*] The reverse reaction, *i.e.* the addition of a proton onto the retro-hydrocarbon, is so slow that the formation of the retro-configuration can be regarded as being "almost irreversible" in this case.

[13] Cf. *W. Sarnecki* and *A. Nürrenbach*, Communication to the IUPAC Symposium on Organic Phosphorus Compounds, Heidelberg (Germany), May 20th, 1964.

[14] *D. D. Coffmann* and *C. S. Marvel*, J. Amer. chem. Soc. *51*, 3496 (1929).

[15] *G. W. Fenton* and *C. K. Ingold*, J. chem. Soc. (London) *1929*, 2342.

Addition of water onto, and hence hydrolysis of, the isoprenologous salts should be more difficult owing to the increased stabilization by resonance of the corresponding ylides; this enhancement of the ylide stability can be detected experimentally. If the phosphonium ion *(21)* and its ylide *(22)* are regarded as a conjugate acid-base pair, the equilibrium established between an ylide and the phosphonium ion of a second compound will always be displaced towards the weaker acid and the weaker base [16]. Thus, a mixture of the ylide *(6')* and a stoichiometric quantity of phosphonium salt *(10)* react with ethyl β-formylcrotonate to form only the ethyl heptaenoate *(26)*; no ester of vitamin A acid *(25)* is formed. It follows, therefore, that the ylide *(10')* must be a weaker base than the ylide *(6')*, *i.e.* the phosphonium ion *(6)* is a weaker acid than the phosphonium ion *(10)*. Thus, any increase in the number of double bonds is accompanied by an increase in the acidity of the phosphonium ions, and a decrease in the basicity of the ylides. However, measurement of the rates of hydrolysis of the



ylides [*] showed that hydrolysis is by no means retarded by the increasing resonance stabilization. Contrary to our original assumption, the rate of hydrolysis actually increases with the number of conjugated double bonds. The cyclogeranyltriphenylphosphonium salt *(6a)* undergoes practically no hydrolysis at room temperature, whereas the salt *(11)* is hydrolysed fairly rapidly. The hydrolysis is strongly dependent on temperature; with the β-ionylidene-ethyltriphenylphosphonium salt *(6)*, for example, it ceases at about 0 °C (cf. Fig. 1).

Thus, olefination in the presence of water can proceed in high yield only when the reaction is carried out below the temperature at which hydrolysis ceases.

[16] *H. Bestmann*, Chem. Ber. *95*, 58 (1962).

[*] The hydrolysis to $(C_6H_5)_3PO$ is accompanied by a corresponding consumption of base. Thus, after reaction of the phosphonium salts with sodium methoxide in methanol to form the ylides, followed by addition of water, determination of the sodium methoxide consumption provides a simple titrimetric method of determining the rate of hydrolysis (Fig. 1).

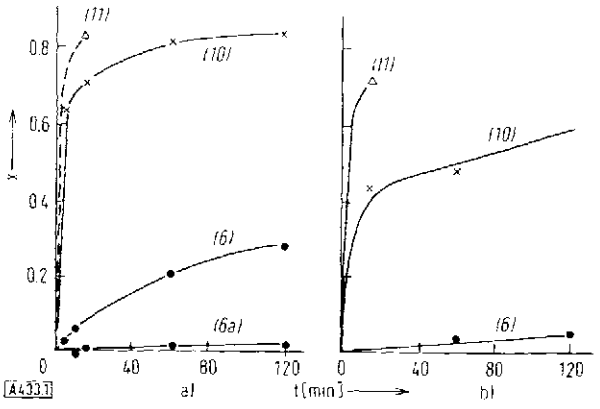


Fig. 1. Hydrolysis of C_{10}, C_{15}, C_{20}, and C_{25} ylides ($c = 275 \times 10^{-3}$ mole/l) in a 4:5 methanol/water mixture at a) 26 °C; b) 4 °C.
Ordinate: Moles of base consumed per mole of phosphonium salt.
Abscissa: Hydrolysis time [min].

No decomposition of phosphonium salts in anhydrous alcohols in the presence of alkoxides was observed in the vitamin A series. This is in contrast to the thermal decomposition of phosphonium alkoxides [17,18]. Cleavage occurred only on addition of water, and the leaving group was always that which was able to form the most stable anion, *i.e.* the trimethylcyclohexene group [*]. The attachment of these groups becomes less firm with increasing chain length, owing to resonance stabilization. The ease of cleavage can be used to advantage in preparative work. For example, axerophthene *(27)* is obtained in a smooth reaction from the axerophthyltriphenylphosphonium salt *(10)*. Other carotenoid hydrocarbons can also be obtained in good yields by a similar method.

New Methods in the Chemistry of Pyridazones

BY (THE LATE) DR. K. DURY

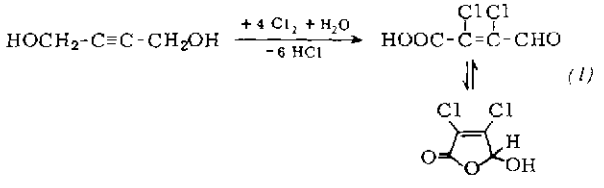
HAUPTLABORATORIUM DER BADISCHEN ANILIN- & SODA-FABRIK AG., LUDWIGSHAFEN/RHEIN (GERMANY)

Published on the occasion of the 100th anniversary of the establishment of Badische Anilin- & Soda-Fabrik AG., on April 6th, 1965.

A new synthesis of mucochloric acid by chlorination of butynediol has facilitated the preparation of a series of 4,5-dichloropyridazones. The high reactivity of these compounds has been investigated and applied in several ways. New classes of compounds, some with biological activity, were obtained by displacement of the chlorine atoms. New heterocyclic systems were prepared by condensation and rearrangement reactions.

1. Introduction

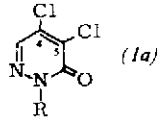
Mucochloric acid *(1)* has recently become readily available by chlorination of 2-butyne-1,4-diol, which is produced in large quantities by Reppe reactions [1].



(1)

This polyfunctional γ-aldehydo-acid is extremely reactive. The most interesting of its many reactions are those which lead to cyclic compounds. In particular, its reaction with hydrazine or hydrazine derivatives to form pyridazones might lead to physiologically active substances analogous to the pyrazolones [2]. A number of pyridazones possessing interesting phytophysiological properties have, in fact, been discovered and reported elsewhere [3].

Only a few derivatives of the parent 4,5-dichloropyridazone *(1a)* [4] were previously known. At the turn of the century, *Bistrycki* et al. [5] achieved the first synthesis of 4,5-dihalogenopyridazones, *i.e.* of 4,5-dibromopyridazone and its 1-phenyl derivative, by treating mucobromic acid with hydrazine hydrate or phenylhydrazine, respectively. Ring closure with elimination of two molecules of water to form the pyridazone derivative proceeded so readily that the open-chain phenylhydrazone initially formed could be isolated only with difficulty. The semicarbazone of mucobromic acid also reacts readily on heating in glacial acetic acid, with loss of the amido group to give a quantitative yield of the pyridazone with no substituent in the 1-position. The analogous 4,5-dichloropyridazone and its 1-phenyl derivative were discovered much later [6, 7], as was the corresponding 1-methyl derivative [8].



(1a)

2. Synthesis of Dichloropyridazones

4,5-Dichloropyridazones are prepared by the reaction of mucochloric acid with hydrazine or its monoalkyl or monoaryl derivatives.

The condensation generally proceeds smoothly with elimination of two molecules of water. The latter may be distilled off azeotropically with a solvent [9], or the mixture can be heated in an organic acid. An elegant variant of the synthesis of 4,5-dichloropyridazones discovered by *Hensel* and *Baumann* [10] entails condensation of the reactants in dilute mineral acid. The hydrazine salts resulting from reduction of the corresponding diazonium salts are used directly in this procedure. The yields of 4,5-dichloropyridazones obtained are generally excellent. The intermediate hydrazones of mucochloric acid can be isolated only under mild conditions, *e.g.* in alcohol at room temperature; even on only slight warming, they readily lose a second molecule of water to form the pyridazones.

The phenylhydrazone of mucochloric acid *(2)* is formed from *(1)* and phenylhydrazine in alcohol at room temperature. It is a bright yellow compound, m. p. 126 °C, which even on gentle heating, neat or in solution, loses water to form colorless 4,5-dichloro-1-phenylpyridazone *(3)*, m. p. 162 °C.

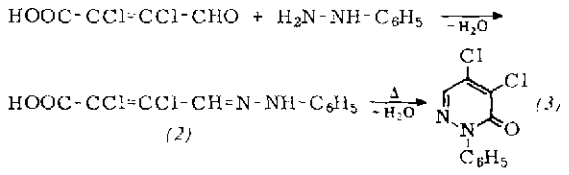
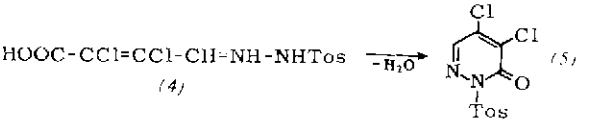
[10] U.S. Patent 3045014 (June 20th, 1960; German priority June 23rd, 1959), BASF, inventors: *H. R. Hensel* and *H. Baumann;* Chem. Zbl. *1964*, 32–2063.

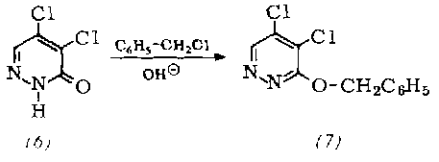


The reaction of acylhydrazines with mucochloric acid generally leads to open-chain hydrazones [11,12], whereas sulfonylhydrazones readily undergo cyclization. Thus, tosylhydrazine is converted, *via* the hydrazone *(4)*, into the cyclic compound *(5)*.

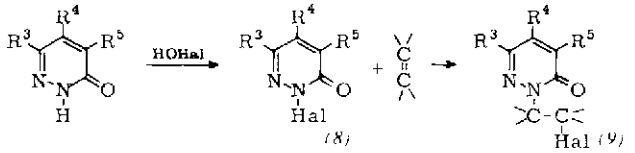


A number of 1-arylsulfonyl-4,5-dichloro-6-pyridazones have been prepared in this way; some of these exhibit strong fungicidal properties.

The synthesis of 4,5-dichloropyridazones has been extended by 1-alkylation of unsubstituted 4,5-dichloropyridazone *(6)* with dialkyl sulfates or reactive halogeno compounds [14–17]. It has frequently been possible by comparison of the product of alkylation of *(6)* with the product obtained from the corresponding alkylhydrazine and mucochloric acid to prove that alkylation had in fact taken place on the 1-nitrogen of the pyridazone ring. Occasionally the isomeric 6-alkoxypyridazone [*e.g.* *(7)*, m.p. 197–198 °C] formed by *O*-alkylation has been isolated as a by-product.



A new method of preparing 1-substituted pyridazones is the addition of 1-halogenopyridazones *(8)* onto olefinic double bonds [18], *e.g.* in cyclohexene, with formation of *(9)*. The *N*-halogenopyridazones are readily formed by treating pyridazones containing a hydrogen atom on the 1-nitrogen with hypohalites [19]. These products were previously unkown but are surprisingly stable, especially in the pure form.



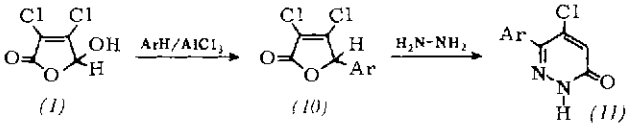
R^3 = H, O-Alk, C_6H_5; R^4 = Halogen; R^5 = OR, H; Hal = Cl, Br

Whereas normally the first step in pyridazone chemistry is the preparation of the halogen-free parent compound, which then has to be halogenated (usually with phosphorus pentachloride) before further reaction [20], halogenated pyridazones are obtained directly by the new method.

A list of 4,5-dichloropyridazones prepared by the various methods is given in Table 1.

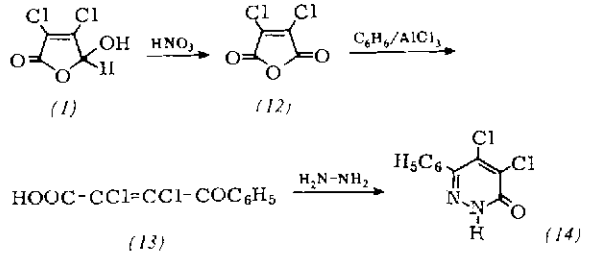
Other halogenated pyridazones can be obtained indirectly from mucochloric acid:

a) Friedel-Crafts alkylation of aromatic compounds with mucochloric acid *(1)* leads to γ-aryldichlorocrotonolactones *(10)* [21]. These compounds react in a complex manner with hydrazine hydrate, with elimination of one atom of chlorine, to afford high yields of 3-aryl-4-chloropyridazones *(11)* [22].



These compounds can be alkylated or tosylated in the 1-position. Since the chlorine in the 4-position is easily replaceable, a series of further derivatives can be prepared.

b) Friedel-Crafts acylation of benzene with dichloromaleic acid or its anhydride *(12)* (obtained by oxidation of mucochloric acid with nitric acid [23]) yields phenylmucochloric acid *(13)*, which reacts with hydrazine hydrate to give 4,5-dichloro-3-phenyl-6-pyridazone *(14)*. This compound exhibits the same reactivity as the pyridazone with no substituent in the 3-position.



[11] Cf. however *A. Bystrycki* and *C. Herbst* [5].

[12] This behavior finds a certain parallel in the chemistry of pyrazolones, where the preparation of 1-benzoyl-3-methylpyrazolone by direct reaction of benzoylhydrazine with acetoacetic ester has also been unsuccessful [13].

3. Reactions of 4,5-Dichloropyridazones

4,5-Dichloropyridazones contain the characteristic –CO–C(Cl)=C(Cl)–Cl grouping of β-chlorovinyl ketones. They are cyclic vinylogous acid chlorides, and have a *trans*-configuration [26]; consequently, the chlorine in the 4-position readily undergoes nucleophilic substitution. Owing to the high reactivity of this chlorine atom, the 4,5-dichloropyridazone residue can be used as the reactive component in novel reactive dyes [27,28].

We have prepared a series of aminochloropyridazones (see Table 2) by the reaction of 4,5-dichloropyridazones with ammonia or primary or secondary amines.

These amino compounds are only very weakly basic. Although they react with concentrated acids to form salts, the latter are more like addition compounds, and readily dissociate to reform the starting materials. Thus, the hydrochloride of *(18)* can be prepared in concentrated hydrochloric acid, but attempts to isolate the salt result in elimination of HCl and regeneration of the free base.

On synthesis of aminochloro-1-phenylpyridazone from 4,5-dichloro-1-phenylpyridazone, two isomeric products are obtained: 4-amino-5-chloro- and 5-amino-4-chloro-1-phenylpyridazone. Reductive dehalogenation by the method of *Grundmann* [29] converts the predominant isomer, which melts at 205–206 °C, into 4-amino-1-phenyl-6-pyridazone *(19)*, which is also the product of dehalogenation of 4-amino-3-chloro-1-phenyl-6-pyridazone *(20)* [30]. The structure of the main isomer was thus established as *(18)*. Morover, this

(18) (19) (20)

The amine *(18)* and a number of other aminochloropyridazones exhibit phytophysiological activity [3, 31]. This fact induced us to investigate some modifications of the active molecule, *e.g.* several acyl derivatives [32]. These can be prepared from the aminopyridazones with acid chlorides or anhydrides, despite the rather weak basicity of the amino group.

Finally, a series of amidines was prepared by condensation of the aminopyridazones with amides in the presence of phosphorus oxide chloride [33].

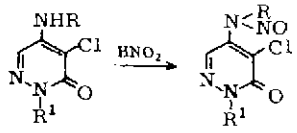
[31] German Patent 1105232 (Nov. 21st, 1958), BASF, inventors: *F. Reicheneder, K. Dury*, and *A. Fischer*; Chem. Zbl. *1961*, 14805.

[32] German Patent 1107998 (March 19th, 1960), BASF, inventors: *F. Reicheneder, K. Dury, H. Stummeyer*, and *A. Fischer*; Chem. Zbl. *1961*, 16982.

[33] Belgian Patent 615519 (Sept. 24th, 1962; German Priority March 25th, 1961 and Nov. 17th, 1961), BASF, inventors: *F. Reicheneder, K. Dury, H. Stummeyer*, and *A. Fischer*. – With regard to the method, cf. *H. Bredereck, R. Gompper, K. Klemm*, and *H. Rempfer*, Chem. Ber. *92*, 837 (1959).

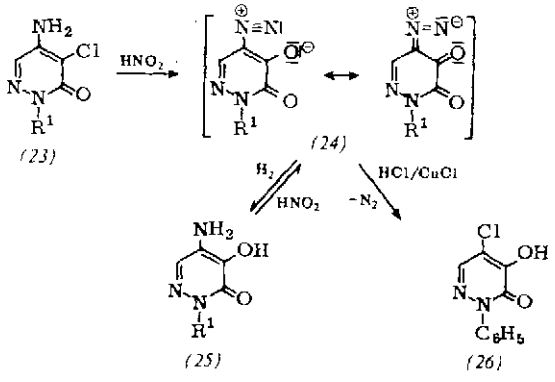
4. Diazoniumpyridazones

Although 4-monoalkylaminopyridazones *(21)* react smoothly with nitrous acid to form the *N*-nitroso derivatives *(22)*, the product obtained from unsubstituted 4-amino-5-pyridazones *(23)*, with HNO_2 is completely different. As a result of a reaction which was formerly known only with aromatic compounds, the amines *(23)*



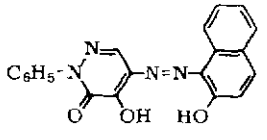
(21) (22)

lose the chlorine adjacent to the amino group (by analogy to the formation of hydrazonoquinones) to yield yellow 4-diazonium-5,6-dioxo compounds *(24)* [34]. The analogy with the formation of hydrazonoquinones extends further in that adjacent groups other than halogen, *e.g. O*-alkyl residues, are also eliminated during this diazotization [35]. Similarly, the 5-amino compounds give the isomeric diazonium enolbetaines which, like *(24)*, crystallize well and are surprisingly stable.



(23) (24) (25) (26)

Reduction of the diazonium compounds *(24)* yields 4-amino-5-hydroxypyridazones *(25)*, which can be reconverted into the 4-diazoniumpyridazones by reaction with nitrous acid. The Sandmeyer reaction leads to 4-halogeno-5-hydroxypyridazones, *e.g.* the 4-chloro-5-hydroxy-1-phenylpyridazone *(26)* obtained from *(24)* with R = C_6H_5. Like aromatic diazonium salts, the diazonium compounds *(24)* couple with phenols, to form a new type of *o*-hydroxyazo dyes. Coupling of *(24)*, R = C_6H_5, and β-naphthol, for example, gives the purple dye *(27)*, which can be converted into a light-fast dye by subsequent metallation [36].



(27)

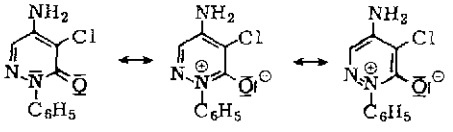
[34] German Patent 1102162 (April 28th, 1959), BASF, inventors: *F. Reicheneder* and *K. Dury*; Chem. Zbl. *1961*, 11903.

[35] Cf. *K. Holzach*: Die aromatischen Diazoverbindungen. Enke, Stuttgart 1947, p. 84.

[36] French Patent 1352341 (Feb. 22nd, 1963; German priority Feb. 24th, 1962), BASF, inventors: *O. Kaufmann* and *K. Dury*.

Diazotization and coupling of the 4-amino-5-halogeno-pyridazones can be used as a sensitive color reaction for detecting them, even in biological material [37].

In order to form stable diazonium compounds which are capable of coupling, the aminohalogenopyridazones must possess a certain degree of aromaticity. This concurs with *Arndt's* theory of the aromaticity of "carboxamide-containing six-membered rings" [38]. 4-Amino-5-chloro-1-phenyl-6-pyridazone may be assumed to have the polar resonance structures *(28)–(30)*.

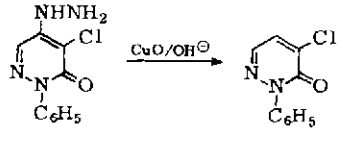


(28) *(29)* *(30)*

5. Hydrazino and Azido Derivatives

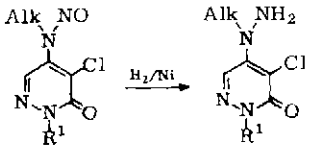
Gentle heating of 4,5-dichloropyridazones in the presence of hydrazine hydrate leads to the formation of 5-chloro-4-hydrazino-6-pyridazones, which react with aldehydes or ketones to form crystalline hydrazones. As expected, the hydrazino group is introduced at the 4-position. The 4-hydrazinopyridazones react smoothly with nitrous acid to form the corresponding 4-azido-5-chloropyridazones, which are pale yellow photosensitive substances. The same compounds can be obtained directly from the dichloropyridazones with sodium azide in either acetone/water or dimethylformamide/water. The constitution of the azides is established by the fact that careful hydrogenation of the azido group leads to the well known 4-amino-5-chloropyridazones *(23)*.

Whereas 2,3-dichloronaphthoquinone readily exchanges both of its chlorine atoms for azide groups when treated with sodium azide [39], it has not been possible to replace the second chlorine atom (in the 5-position) of the 4,5-dichloropyridazones by the azido residue. If 5-chloro-4-hydrazino-pyridazones are gently heated with cupric oxide in sodium carbonate solution [40], nitrogen is eliminated and the hydrazino group is replaced by hydrogen. 5-Chloro-1-phenyl-6-pyridazone *(32)* is readily formed in this manner from 5-chloro-4-hydrazino-1-phenyl-6-pyridazone *(31)*.



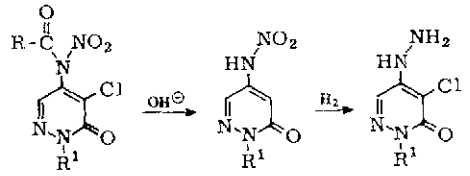
(31) *(32)*

N-Alkylhydrazino derivatives of the pyridazones *(34)* can be prepared from the 4-monoalkylaminopyridazones by reduction of their *N*-nitroso derivatives *(33)*.



(33) *(34)*

Finally, 4-hydrazinopyridazones are also obtained by the reaction of 4-acylaminopyridazones with strong nitric acid to form the corresponding acylnitramines *(35)* followed by reduction of the free nitraminopyridazones *(36)* resulting from hydrolysis of *(35)*.

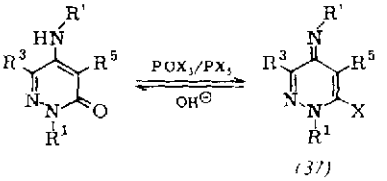


(35) *(36)*

The 5-chloro-4-hydrazinopyridazones exhibit remarkable plant-physiological properties [41], especially when they contain a phenyl or cycloalkyl residue at the 1-position. *Castle* et al. [42] recently examined a number of 4-hydrazinopyridazones and the products of their reactions with aldehydes and ketones, in order to check their activity against tumors.

6. Iminopyridazones

Just as 4-halogeno-6-pyridazones may be regarded as either cyclic β-chlorovinyl ketones or cyclic vinylogous acid chlorides, 4-aminopyridazones may be regarded as cyclic vinylogous amides. Corresponding to the formation of imido chlorides from amides, cyclic vinylogous imido chlorides *(37)*, *i.e.* 4-imino-6-halogenopyridazones are formed from 4-amino-6-pyridazones by the action of phosphorus pentahalides or oxide halides [43]. The halogen atom in position 6, which is the last to enter, is



(37)

extremely reactive in these 6-halogeno-4-imino- and 5,6-dihalogeno-4-iminopyridazones. The chemical behavior of these new compounds is very similar to that of imido chlorides. Hydrolysis leads to regeneration of the starting pyridazone. The halogen readily undergoes nucleophilic substitution with ammonia, primary and secondary amines, hydrazines, alcohols, and thiols. The 6-halogen can also be replaced by a nitro group on reaction with nitrites. Another remarkable feature of the

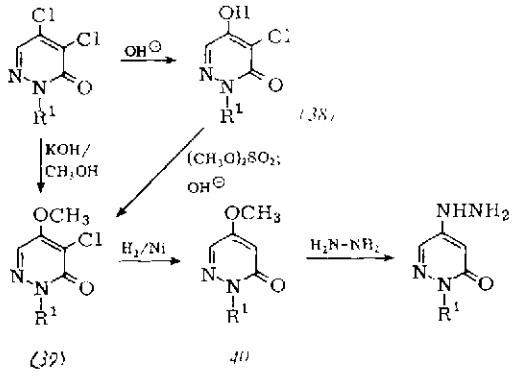
6-halogeno-4-iminopyridazones is their stronger basicity compared with the parent aminopyridazones, by virtue of which they are able to form well defined salts.

7. Introduction of Other Groups

As in the reaction with ammonia and amines, the chlorine in the 4-position of the pyridazone ring is very readily replaced by hydroxy *(38)* or alkoxy groups *(39)* on treatment with aqueous bases or alcohols. We have prepared a large number of such derivatives with a view to investigating their phytophysiological action [44]. Reductive dehalogenation yields halogen-free 4-hydroxy- and 4-alkoxypyridazones *(40)*, which are completely free from phytotoxic activity.

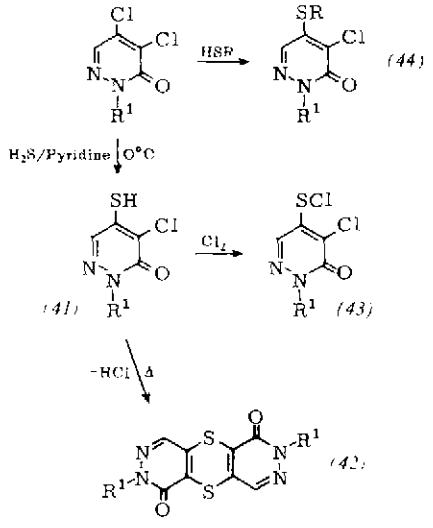


(38) *(39)* *(40)*

Nucleophilic substitution of the chlorine proceeds even more readily with hydrogen sulfide or thiols [45]. For example, 4,5-dichloro-1-phenyl-6-pyridazone and sodium sulfide react smoothly in pyridine/water with cooling to give a high yield of 5-chloro-4-mercapto-1-phenyl-6-pyridazone *(41)*. Under more vigorous conditions, however, further substitution takes place in the 5-position as well. This readily leads (as does the reaction with sodium thiocyanate, sodium thiosulfate, or thiourea) to interlinkage of two pyridazone rings by sulfur bridges to form a dipyridazo[4,5-*b*:4,5-*e*]-1,4-dithiine-1,6-dione *(42)*. Such "dithiine pyridazones" have recently also been prepared by *Castle* et al. [46,47] by the reaction of dichloropyridazones with sodium sulfide. The mercaptopyridazone *(41)* forms stable heavy metal salts.

Compound *(41)* is converted by chlorine into the 4-sulfenylchloride *(43)*.

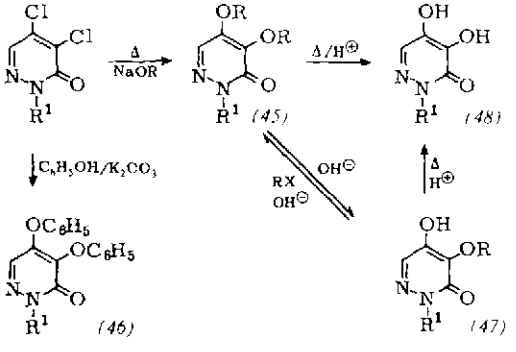
Similarly, careful reaction of thiols and thiophenols with dichloropyridazones yields 4-alkylthio-5-chloropyridazones and the 4-phenylthio-5-chloropyridazones *(44)*, R = alkyl and aryl, respectively. Under more vigorous conditions, both chlorine atoms are readily eliminated from 4,5-dichloro-6-pyridazones to form the 4,5-bisalkylthio or 4,5-bisarylthio compounds.



(44) *(41)* *(43)* *(42)*

In a similar manner, but under much more vigorous conditions, 4,5-dichloropyridazones react with excess alkoxide or phenoxide to form the 4,5-dialkoxy *(45)* or 4,5-diphenoxy compounds *(46)*. The formation of the 4,5-dialkoxypyridazones is often accompanied by that of 5-alkoxy-4-hydroxypyridazones *(47)*.

Alkylation of 5-alkoxy-4-hydroxypyridazones also yields 4,5-dialkoxypyridazones *(45)*. Compounds with different alkoxy residues in the 4- and 5-positions can also be



(45) *(48)* *(46)* *(47)*

prepared in this manner. Examination of the phytotoxicity of these gives insight into the relationship between structure and activity.

4,5-Dialkoxypyridazones *(45)* can be hydrolysed to form 4,5-dihydroxypyridazones *(48)* which may be regarded as reductones of the pyridazone series. This viewpoint is strongly supported by their properties, particularly their pronounced reactivity.

4,5-Dichloropyridazones react even more readily with phenols than with alcohols, both halogen atoms being eliminated. Thus, 4,5-dichloro-1-phenylpyridazone is readily diphenoxylated on heating in excess phenol containing potassium carbonate, the product being 4,5-diphenoxy-1-phenyl-6-pyridazone *(46)*.

Replacement of both halogen atoms by primary or secondary amines to give 4,5-diaminopyridazones *(49)* is more difficult and requires very high temperatures and

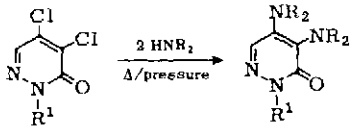
[44] Belgian Patent 607934 (Sept. 7th, 1961; German priority Sept. 9th, 1960), BASF, inventors: *F. Reicheneder, K. Dury, A. Fischer*, and *H. Stummeyer*.

[45] We believe that this enhanced reactivity towards thiols is a possible cause of the bactericidal and fungicidal action of 4,5-dichloropyridazones; these compounds probably block thiol groups of microbial or fungal enzymes [6].

[46] *R. N. Castle* and *K. Kaji*, Naturwissenschaften *51*, 38 (1964).

[47] Cf. *R. N. Castle* and *K. Kaji*, Tetrahedron Letters *1962*, 393.

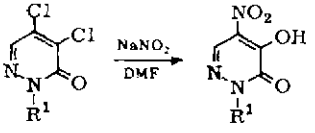
pressures. However, the parent compound of this class, 4,5-diaminopyridazone, cannot be obtained in this way [48]. It is prepared by another method.



(49)

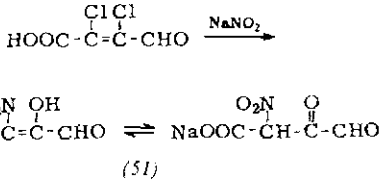
8. Hydroxynitropyridazones

The reaction of 4,5-dichloropyridazones with sodium nitrate in dimethylformamide (DMF) proceeds extremely readily with elimination of both chlorine atoms to yield 5-hydroxy-4-nitropyridazones *(50)*.



(50)

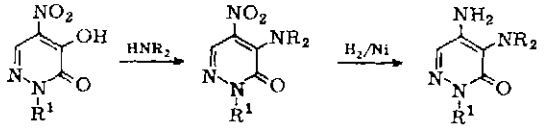
There is clearly some analogy with mucochloric acid, which reacts with sodium nitrite to give sodium 3-formyl-2-nitro-3-oxopropionate *(51)* [49].



(51)

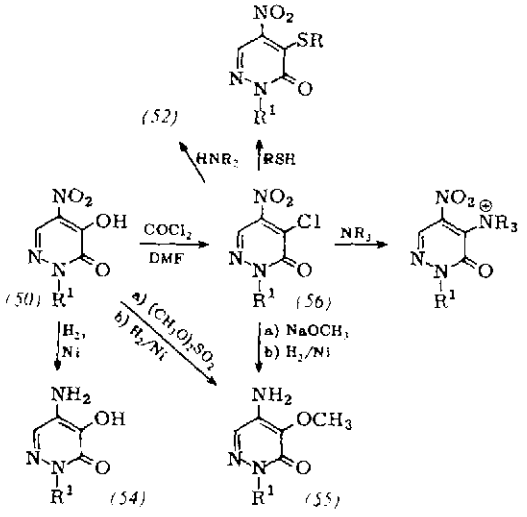
In the halogenoquinone series, chloranil, for example, also reacts with sodium nitrite to form so-called "nitranilic acid", *i.e.* 3,6-dihydroxy-2,5-dinitro-1,4-benzoquinone [50].

5-Hydroxy-4-nitropyridazones *(50)* are strongly acidic enols and readily form salts. The salts formed with ammonia and some amines are converted on heating into 5-amino-4-nitro compounds *(52)*, which can then be reduced, either catalytically or with zinc dust, to 4,5-diamino-6-pyridazones *(53)*. We have obtained a series of diaminopyridazones in this way.



(50) *(52)* *(53)*

4-Amino-5-hydroxypyridazones *(54)* and 4-amino-5-methoxypyridazones *(55)* can be easily prepared by the reduction of 5-hydroxy-4-nitropyridazones. Replacement of the hydroxy group by chlorine then leads to the 5-chloro-4-nitro compounds *(56)*. Owing to the reactivity of the strongly activated halogen atom, these compounds can undergo further reactions.



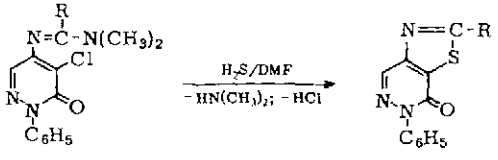
(50) *(52)* *(54)* *(55)* *(56)*

It is interesting that chlorination of 5-hydroxy-4-nitro-1-phenylpyridazone *(50)*, R = C_6H_5, followed by reduction of the resulting chloronitropyridazone *(56)* and reaction of the product with sodium methoxide, leads to two isomeric aminomethoxypyridazones which on diazotization yield a 4-diazoniumpyridazone and a 5-diazoniumpyridazone, respectively. These can also be obtained from 4-amino-5-chloro-1-phenylpyridazone and 1-phenyl-5-amino-4-chloro-1-phenylpyridazone, respectively. This indicates that the starting material *(50)* itself must contain a small quantity of the isomeric 4-hydroxy-5-nitro compound.

9. Heterocyclic Systems

By treating acyl derivatives of 4-amino-5-chloropyridazones with hydrogen sulfide, we obtained a new heterocyclic system, namely the pyridazothiazole system.

Amidines react readily with hydrogen sulfide to form thiocarboxamides [51]. Reaction of an amidine of 4-amino-5-chloro-1-phenyl-6-pyridazone, *e.g.* 5-Chloro-4-(dimethylaminomethyleneamino)-1-phenyl-6-pyridazone *(57)*, R = H, with hydrogen sulfide in dimethylformamide (DMF) leads by thiolysis and simultaneous elimination of hydrogen chloride to the thiazolo derivative *(58)*.



(57) R = H, CH_3, C_6H_5 *(58)*

The thiazolopyridazone isomeric with *(58)* can be prepared from 5-amino-4-chloropyridazone, again by thiolysis of an amidine. The action of hydrogen sulfide on the corresponding amidrazone *(59)*, on the other hand,

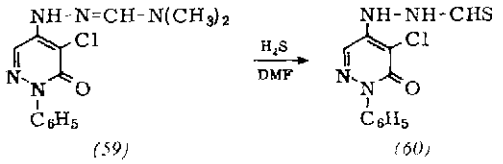
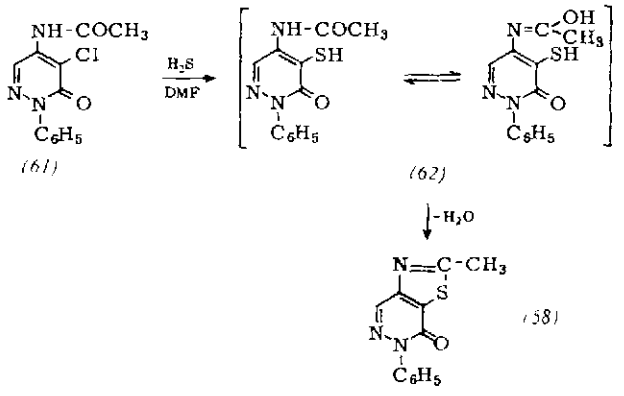
yields only the open-chain *N'*-thioformylhydrazino derivative *(60)*.



(59) *(60)*

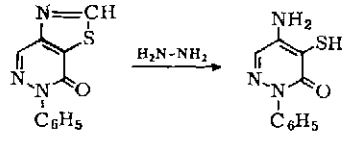
The thiazolo derivatives can also be obtained directly from the *N*-acylaminopyridazones, *e.g.* the *N*-acetyl derivative *(61)*, by treatment with hydrogen sulfide in dimethylformamide. The intermediate *(62)* immediately loses one molecule of water under the reaction conditions. This suggests that the halogen atom in the 4-amino-5-chloropyridazones, which is otherwise rather



(61) *(62)* *(58)*

inert, is activated by acylation. It is possible that, with the amidine derivatives, thiolysis is again preceded by replacement of the halogen atom by hydrogen sulfide.

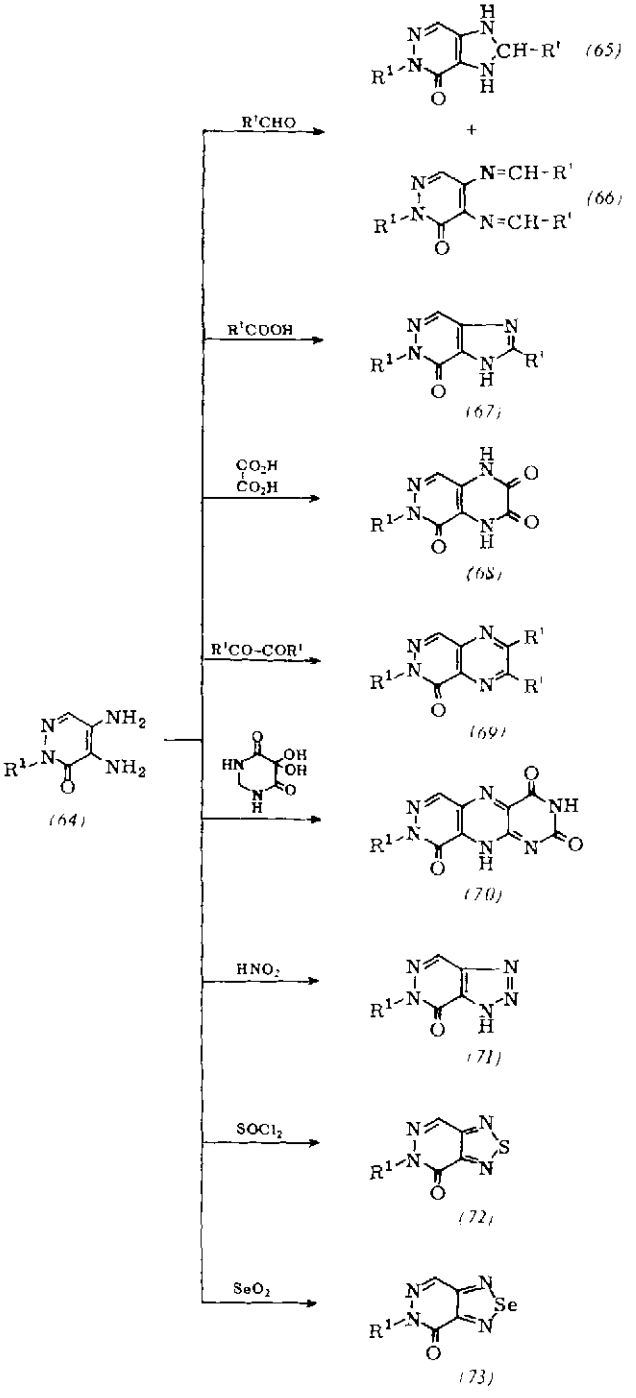
4-Amino-5-mercaptopyridazone *(63)* is formed by cleavage of the thiazole ring on hydrazinolysis of pyridazothiazoles such as *(58)*.



(58) *(63)*

Another convenient route to diheterocyclic systems of the pyridazone series has now been provided by the availability of 4-amino-5-hydroxypyridazones and 4,5-diaminopyridazones *(64)*, particularly the latter. Although aldehydes react with 4,5-diaminopyridazones *(64)* to form only the condensation products *(65)* and *(66)*, reaction of *(64)* with organic acids leads to pyridazo[4,5-*d*]imidazoles *(67)*, which are of interest on account of their relationship with naturally occuring purines.

Oxalic acid, α-diketones, and chloral (which is used in *F. Bergmann*'s method [52] for the preparation of 6-hydroxypteridines) yield pterin-like derivatives *(68)* and *(69)* from *(64)*. An "alloxazine" *(70)* is obtained from *(64)* and alloxan. The action of nitrous acid on *(64)* leads to a triazolo[*d*]pyridazone *(71)*, while thionyl chloride and selenium dioxide form a thiadiazolo *(72)* and a selenadiazolo derivative *(73)*, respectively.



(64) *(65)* *(66)* *(67)* *(68)* *(69)* *(70)* *(71)* *(72)* *(73)*

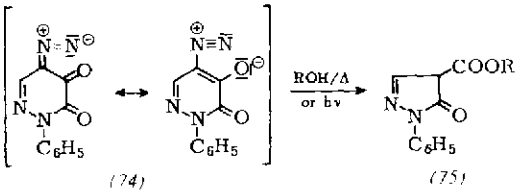
10. Ring Contraction

We shall conclude this paper with a description of some new transitions from the pyridazone series to the pyrazolone series. The 4-diazonium-5,6-dioxopyridazones *(74)* readily undergo a Wolff rearrangement of the type investigated by *Süs* [53] with hydrazonoquinones to form the corresponding pyrazolone-4-carboxylic acids *(75)*. The reactivity of the diazoniumpyridazones is higher than that of the purely aromatic hydrazonoquinones,

[52] *F. Bergmann, M. Tamari*, and *H. Ungar-Waron*, J. chem. Soc. (London) *1964*, 565.

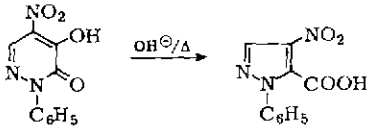
[53] References given in *H. Zollinger*: Chemie der Azofarbstoffe. Birkhäuser, Basel 1958, pp. 90ff.

as shown by the fact that this rearrangement takes place without photocatalysis on heating gently in a suitable medium, *e.g.* an alcohol [54].



(74) (75)

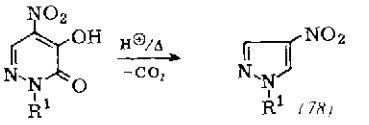
Another reaction leading from pyridazones to pyrazoles occurs when 5-hydroxy-4-nitropyridazones are warmed in an acidic or alkaline medium: the compounds undergo ring contraction to form derivatives of 4-nitropyrazole. This rearrangement can be effected with 1-aryl-5-hydroxy-4-nitropyridazone *(50)*, $R^1 = C_6H_5$, in alkaline medium; the reaction proceeds smoothly to yield 4-nitro-1-phenylpyrazole-5-carboxylic acid *(76)*.



(50) (76)

[54] Cf. *P. Yates* and *E. Robb*, J.Amer.chem.Soc. *79*, 5760 (1957).

5-Hydroxy-4-nitropyridazones which are unsubstituted or alkyl-substituted in the 1-position *(77)*, on the other hand, react only in acidic media, and the 4-nitropyrazole-5-carboxylic acid formed decarboxylates spontaneously to the correspondingly substituted 4-nitropyrazole *(78)*.



(77) (78)

R^1 = H, Alkyl

This ring concentration shows an interesting similarity to the rearrangement of 5-hydroxypyridazone described by *Ach* [55], and to the recently discovered rearrangement of 1-aryl-3,5-dihalogenopyridazones [56].

The Chemistry of Vinylsulfonic Acid [1]

BY DR. H. DISTLER

BADISCHE ANILIN- & SODA-FABRIK AG., LUDWIGSHAFEN/RHEIN (GERMANY)

Published on the occasion of the 100th anniversary of the establishment of Badische Anilin- & Soda-Fabrik AG., on April 6th, 1965

Vinylsulfonic acid and its derivatives can be prepared from β-chloroethanesulfonyl chloride or carbyl sulfate (β-hydroxysulfonyloxyethanesulfonic anhydride). The chemistry of vinylsulfonic acid has assumed industrial importance since the discovery of a simple synthesis of β-chloroethanesulfonyl chloride from chloroethane or ethane, sulfur dioxide, and chlorine by the Reed process. Carbyl sulfate is as important a starting material as β-chloroethanesulfonyl chloride, and surpasses the latter in some respects, e.g. on account of the low price of its components ethylene and sulfur trioxide. Vinylsulfonates undergo addition reactions with alcohols, phenols, thiols, sulfinic acids, carboxylic acids, amides, imides, and hydrazides, as well as with amines, ureas, diazonium salts, and nitroparaffins. Furthermore, they undergo halogenation, nitration, olefination, and the Diels-Adler reaction. — Methods for the preparation of the free vinylsulfonic acid are described. Alkyl vinylsulfonates are excellent alkylating agents. The derivatives of vinylsulfonic acid are used e.g. as plasticizers, emulsifiers, and fungicides.

I. Synthesis of Vinylsulfonates

A. Alkyl Vinylsulfonates

Alkyl vinylsulfonates are obtained by the reaction [3] of alkoxides with β-chloroethanesulfonyl chloride [2]:

$$ClCH_2\text{-}CH_2\text{-}SO_2Cl \xrightarrow[\text{in ROH}]{2\ RONa} CH_2{=}CH\text{-}SO_2\text{-}OR + 2\ NaCl \quad \text{(a)}$$

The reaction proceeds most smoothly and gives the highest yield when a 30% methanolic solution of sodium methoxide is added to the β-chloroethane-

[1] Delivered in part as a lecture at the 19th International Congress for Pure and Applied Chemistry in London, July 1963.

[2] The preparation of β-chloroethanesulfonyl chloride on a technical scale: unpublished work (1955–1956) of *K. Küspert*; see also *Ch. Walling* and *W. F. Pease*, J. org. Chemistry *23*, 478 (1958); German Pat. 1152687 (Oct. 28th, 1961) BASF, inventors: *H. Schlecht* and *H. Götz*.

sulfonyl chloride solution until the end-point is reached. An excess of the base is to be avoided, as otherwise the alcohol adds onto the double bond. Higher esters are prepared in a similar manner. The vinylsulfonates of aliphatic alcohols hydrolyse easily to yield vinylsulfonic acid and the alcohol, methyl vinylsulfonate being the easiest to cleave. When the hydrolysis is carried out with steam, using methanol as solvent, very pure vinylsulfonic acid is obtained even on a technical scale [4]:

$$CH_2=CH-SO_2-OCH_3 \xrightarrow{H_2O} CH_2=CH-SO_3H + CH_3OH \quad (b)$$

In a different preparation, β-chloroethanesulfonyl chloride is esterified with an alcohol in the presence of pyridine [5]. Vinylsulfonyl chloride can similarly be used for the synthesis of esters in the presence of alkali [6].

B. Aryl and Polyfluoroalkyl Vinylsulfonates

Unlike the alkyl vinylsulfonates, the aryl esters are remarkably stable towards hydrolysis, and can therefore be prepared by reacting a phenol with β-chloroethanesulfonyl chloride in an aqueous alkaline medium:

$$ClCH_2-CH_2-SO_2Cl + C_6H_5-OH + 2\ NaOH \quad (c)$$

$$\xrightarrow[-2\ NaCl]{H_2O} CH_2=CH-SO_2-OC_6H_5$$

It is advisable to carry out the acylation at pH 8–9 and a temperature of 0 to 5 °C. At higher temperatures and at pH > 9, the phenol adds onto the α,β-unsaturated sulfonate [7]. In the presence of a base acting as HCl-acceptor, acylation and dehydrochlorination take place with great ease. Aryl vinylsulfonates are formed with good, occasionally with quantitative yields, even under technical conditions.

Polyfluorinated alcohols can be similarly esterified [8]:

$$HCF_2-(CF_2)_2-CH_2OH + ClCH_2-CH_2-SO_2Cl \quad (d)$$

$$\xrightarrow[-H_2O;-2\ NaCl]{2\ NaOH} HCF_2-(CF_2)_2-CH_2-O-SO_2-CH=CH_2$$

Similar to aryl vinylsulfonates, the resulting esters are relatively stable to hydrolysis and have no alkylating effect. Fluorinated alcohols containing 5 to 11 carbon atoms give the highest yields, and it is immaterial whether they are fully or only partially fluorinated.

Table 1. Aryl vinylsulfonates $CH_2=CH-SO_2-OR$ prepared from β-chloroethanesulfonyl chloride and various phenols.

R	B.p. [°C/mm]	M.p. [°C]	Yield [%]

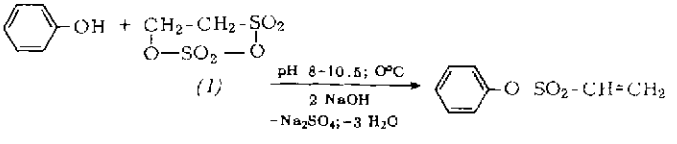
2-Methoxyphenyl	135–140/0.2		66
4-Methoxycarbonylphenyl	156–161/0.2		64
4-Ethoxycarbonylphenyl	142–148/0.2		64
2-Methoxycarbonylphenyl	133–138/0.2		62
2-Phenoxycarbonylphenyl	182–187/0.2		65
α-Naphthyl		51–53	84
o-Biphenylyl	132–136/0.2		82
2-Acetylphenyl	64–66/0.3		80
2-Fluorophenyl	118–121/0.3		86
4-Fluorophenyl	124–126/0.2		84
2,4,6-Triiodophenyl		112–114	45
1,3-Phenylene		54–56	92

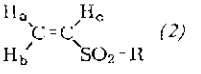
Aryl vinylsulfonates can also be prepared from phenols and carbyl sulfate *(1)* in an aqueous alkaline medium at about 0 °C [9].



(1)

The yields are sometimes lower than in the case of β-chloroethanesulfonyl chloride, possibly because of the easy conversion of carbyl sulfate into the sulfate of β-hydroxyethanesulfonic acid, *i.e.* ethionic acid, which no longer shows any acylating action.

Table 2. ^{1}H-NMR data (chemical shifts τ and coupling constants J) of vinylsulfonyl derivatives *(2)*.



(2)

R	τ_a [ppm]	τ_b [ppm]	τ_c [ppm]	J_{ab} [cps]	J_{ac} [cps]	J_{bc} [cps]

II. Reactions of Vinylsulfonates

A. Reactions with Compounds Containing Active Hydrogen

Most reactions with compounds (HA) containing active hydrogen proceed very smoothly, giving rise to β-substituted ethanesulfonates:

$$HA + H_2C{=}CH{-}SO_3R \rightarrow A{-}CH_2{-}CH_2{-}SO_3R \qquad (e)$$

Since vinylsulfones react in a similar manner, we propose to use the term "sulfonethylation", introduced by *Truce* and *Wellisch* [11], also to describe additions to vinylsulfonates.

1. Addition of Alcohols and Phenols [7]

In the presence of catalytic quantities of a base, primary, secondary, and tertiary alcohols add onto vinylsulfonates with great ease:

$$ROH + CH_2{=}CH{-}SO_2{-}OR' \xrightarrow[0\text{–}10^{\circ}C]{\text{Base}} \underset{(3)}{RO{-}CH_2{-}CH_2{-}SO_2{-}OR'} \qquad (f)$$

The hydroxides, carbonates, or alkoxides of the alkali metals and the alkaline earth metals are used as bases, in quantities of up to 2 % of the sulfonate. Quaternary ammonium hydroxides such as trimethylbenzylammonium hydroxide (Triton B®) are also suitable.

Adducts formed from long-chain primary alcohols and aryl vinylsulfonates are very good plasticizers for PVC [7]: they are distinguished by their compatibility, low volatility, and low solidification point.

The addition of long-chain alcohols to alkyl vinylsulfonates at a low temperature leads to alkyl β-alkoxyethanesulfonates *(3)*, which can be saponified to metal β-alkoxyethanesulfonates. These are suitable as emulsifiers in the preparation of stable polymer dispersions [12].

$$(3) \xrightarrow{NaOH} RO{-}CH_2{-}CH_2{-}SO_3Na + R'OH$$

The reaction of alkyl β-alkoxyethanesulfonates *(3)* with tertiary amines results in ammonium salts, which are useful in the production of low-foaming polymer dispersions [13].

$$\underset{(3)}{RO{-}CH_2{-}CH_2{-}SO_3R'} + NR_3 \rightarrow RO{-}CH_2{-}CH_2{-}SO_3^{\ominus} + R_3R'N^{\oplus}$$

Phenols can also add onto vinylsulfonates, giving very stable alkyl β-aroxyethanesulfonates which crystallize easily in most cases. Esters with more than one vinylsulfonic acid group, *e.g.* resorcinyl divinylsulfonate, are cross-linking agents used in the chemistry of paints [14].

2. Addition of Sulfur Compounds

In the presence of tertiary amines, vinylsulfonates give symmetrical thioethers *(4)* with H_2S.

$$H_2S + CH_2{=}CH{-}SO_2{-}OR \xrightarrow{\text{Base}} \underset{(4)}{S(CH_2{-}CH_2{-}SO_2{-}OR)_2}$$

Unsymmetrical thioethers *(5)* are formed with thiols or thiophenols.

$$R{-}SH + CH_2{=}CH{-}SO_2{-}OR' \xrightarrow{\text{Base}} \underset{(5)}{RS{-}CH_2{-}CH_2{-}SO_2{-}OR'}$$

Thus the addition of long-chain alkanethiols to alkyl vinylsulfonates leads to alkyl β-alkylthioethanesulfonates. The reactions proceed smoothly, and the yields are quantitative. The products [15] can be saponified to metal sulfonates which crystallize easily.

$$\underset{(6)}{RS{-}CH_2{-}CH_2{-}SO_2{-}OR'} \xrightarrow{NaOH} RS{-}CH_2{-}CH_2{-}SO_3Na + R'OH$$

These metal sulfonates *(6)* serve, *inter alia*, as emulsifiers in the production of stable polymer dispersions [12]. The easy addition of thiols is utilized for the quantitative determination of vinylsulfonates (cf. Section "Experimental"). The thiophenol adducts crystallize very easily. They can be converted into the β-sulfonylethanesulfonate derivatives by oxidation with potassium permanganate or H_2O_2.

3. Addition of Sulfinic Acids [16]

Sulfinic acids *(7)* react almost quantitatively with α,β-unsaturated sulfonates. The immiscible components can be reacted in an aqueous medium at 50–80 °C, an acid being added to adjust the pH to 4–6. The resulting sulfones *(8)* are obtained in high purity and crystallize with remarkable ease. Sulfones such as *(10)* and formaldehyde are formed on the addition of hydroxymethanesulfinic acid *(9)* (formaldehyde sulfoxylate).

$$\underset{(7)}{R'{-}SO_2H} + CH_2{=}CH{-}SO_2{-}OR \xrightarrow[\text{pH 4–6}]{} \underset{(8)}{R'{-}SO_2{-}CH_2{\cdot}CH_2{-}SO_2{-}OR}$$

$$2\,CH_2{=}CH{-}SO_2{-}OR + HO{-}CH_2{-}SO_2H \xrightarrow[\text{pH 4–6}]{} \underset{(10)}{O_2S(CH_2{-}CH_2{-}SO_2{-}OR)_2} + HCHO$$

$$(9)$$

If *(9)* is reacted with a bifunctional compound, such as *e.g.* resorcinyl divinylsulfonate, a linear high-melting polymer is obtained [17].

[14] French Pat. 1321629 (1961) BASF, inventors: *D. Ludsteck, G. Lützel, W. Rohland*, and *H. Distler*.

[15] German Published Patent Application 1108210 (Jan. 2nd, 1960) BASF, inventor: *H. Distler*.

[16] German Pat. applied for.

[17] The K-value [as defined by *H. Fikentscher*, Cellulosechemie *13*, 58 (1932)] is 20–25.

4. Addition of Sodium Hydrogen Sulfite [18]

The addition of sodium hydrogen sulfite to vinylsulfonates is similar to its addition to derivatives of maleic and acrylic acids and results in practically quantitative yields of sodium β-(alkoxysulfonyl)ethanesulfonates:

$$NaHSO_3 + CH_2{=}CH{-}SO_2{-}OR \longrightarrow NaSO_3{-}CH_2{-}CH_2{-}SO_2{-}OR \qquad (g)$$

The immiscible components are reacted in an aqueous medium either at or slightly above room temperature. The sulfonates formed are generally crystalline and water-soluble. When R is sufficiently long, the sulfonates will exhibit good surface-active properties.

5. Addition of Amines

Nucleophilic agents such as primary and secondary amines react vigorously and quantitatively with vinylsulfonates to give substituted taurine esters *(11a)* and *(11b)*, which are characterized by very good fungicidal activities [19].

$$2\ CH_2{=}CH{-}SO_2{-}OR + R'{-}NH_2 \longrightarrow R'{-}N(CH_2{-}CH_2{-}SO_2{-}OR)_2 \qquad (11a)$$

$$CH_2{=}CH{-}SO_2{-}OR + R'_2NH \longrightarrow R'_2N{-}CH_2{-}CH_2{-}SO_2{-}OR \qquad (11b)$$

The "sulfonethylation" of long-chain amines with methyl vinylsulfonate leads to methyl β-alkylaminoethanesulfonates, which give surface-active metal sulfonates on alkaline hydrolysis [20]. Polyadducts are formed when polyamines are reacted with di- or polyfunctional vinylsulfonates [21].

Taurine esters can be quaternized with the usual alkylating agents to give water-soluble products, *e.g. (12)*, which have a strong microcidal action and are used in combating algal growth [22]. They undergo a Hofmann elimination [Reaction (h)] under very mild conditions. Since the low concentration of OH^- ions in water is sufficient for this elimination to occur, the vinylsulfonate separates out when an aqueous solution of the taurine ester is simply allowed to stand for a fairly long time. Heating increases the OH^- concentration, and therefore promotes the elimination, which occurs instantaneously in the presence of NaOH or sodium carbonate.

$$[C_6H_5{-}O{-}SO_2{-}CH_2{-}CH_2{-}N^{\oplus}R^1R^2R^3]\ X^{\ominus} \qquad (12) \qquad (h)$$

$$\longrightarrow C_6H_5{-}O{-}SO_2{-}CH{=}CH_2 + [HNR^1R^2R^3]^{\oplus}X^{\ominus}$$

This easy elimination can be utilized in the synthesis of tertiary amines which are otherwise difficult to prepare. The vinylsulfonate is recovered quantitatively, and the tertiary amine can be isolated from the aqueous solution.

6. Addition of Nitroparaffins [23]

Nitroparaffins can be "sulfonethylated" using NaOH, KOH, quaternary ammonium hydroxides, or tertiary amines as catalysts, the use of *N,N*-dimethylcyclohexylamine at 70 to 90 °C being particularly convenient.

$$3\ CH_2{=}CH{-}SO_2{-}OR + O_2N{-}CH_3 \xrightarrow{Base} O_2N{-}C(CH_2{-}CH_2{-}SO_2{-}OR)_3 \qquad (i)$$

$$CH_2{=}CH{-}SO_2{-}OR + \text{C}_6\text{H}_4(NO_2)H \xrightarrow{Base} \text{C}_6\text{H}_4(NO_2)(CH_2{-}CH_2{-}SO_2{-}OR) \qquad (k)$$

Higbly satisfactory results are obtained when the reaction is carried out with primary and secondary nitroparaffins.

Nitrocycloalkanes, *e.g.* nitrocyclooctane or nitrocyclododecane, also give good yields. The resulting nitroalkanesulfonates crystallize very easily, and exhibit remarkable fungistatic actions.

7. Addition of Phosphorus Compounds

Derivatives of thiophosphoric acid are easily "sulfonethylated" in the presence of a catalysing base.

$$(R'O)_2P(S)(O){-}SH + CH_2{=}CH{-}SO_2{-}OR \xrightarrow{Base} (R'O)_2P(S)(O){-}S{-}CH_2{-}CH_2{-}SO_2{-}OR \qquad (13)$$

The products *(13)* do not however show the expected insecticidal action.

8. Addition of Compounds Containing Dichloromethyl Groups

Compounds containing active hydrogen atoms, for example the derivatives of dichloroacetic acid, can be "sulfonethylated" in the presence of a base catalyst [24].

---

[18] German Pat. 1124032 (June 25th, 1960) BASF, inventors: *H. Distler* and *H. J. Krause*.

[19] German Pat. 1151149 (May 20th, 1961) BASF, inventors: *H. Distler, G. Leibner, K. J. Fust, E. Pommer*, and *H. Stummeyer*.

[20] German Pat. 1129284 (May 4th, 1960) BASF, inventors: *H. Fikentscher, H. Willersinn, E. Penning*, and *H. Distler*.

[21] German Pat. 1116405 (Jan. 29th, 1960) BASF, inventors: *K. Demmler, H. Distler, F. F. Miller*, and *L. Würtele*.

[22] German Published Patent Application 1174454 (Sept. 5th, 1961) BASF, inventors: *H. Distler, W. Müller, H. Stummeyer*, and *E. Pommer*.

[23] German Pat. 1157217 (March 24th, 1961) BASF, inventor: *H. Distler*.

[24] German Published Patent Application 1134070 (Dec. 23rd, 1960) Farbenfabriken Bayer, inventors: *H. Timmler* and *R. Wegler*.

Aryl esters are cleaved less easily when the reaction is catalysed by alkoxides.

$$Cl_2CH\text{-}COOR' + CH_2{=}CH\text{-}SO_2\text{-}OR \quad (CN) \quad (l)$$
$$\xrightarrow{Base} Cl_2C(COOR')(CN)\text{-}CH_2\text{-}CH_2\text{-}SO_2\text{-}OR$$

9. Michael Condensation

Similarly to the nitroalkanes and dichloroacetic acid derivatives, other compounds containing active methylene groups, *e.g.* esters, nitriles, and ketones, can also be "sulfonethylated". Ethyl acetoacetate, derivatives of malonic acid, ethyl cyanoacetate, and benzyl cyanide undergo the reaction with good yields.

$$CH_2{=}CH\text{-}SO_2\text{-}OR + CH_3\text{-}CO\text{-}CH_2\text{-}CO\text{-}OC_2H_5 \quad (m)$$
$$\xrightarrow{Base} RO\text{-}SO_2\text{-}CH_2\text{-}CH_2\text{-}CH(CO\text{-}OC_2H_5)\text{-}CO\text{-}CH_3$$

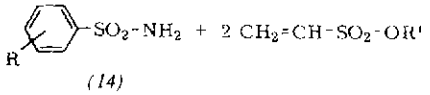
Double addition [25] may sometimes occur, provided that an excess of vinylsulfonate is employed, in which case both active hydrogens participate in the reaction.

$$CH_2{=}CH\text{-}SO_2\text{-}OR + H_2C(COOR')_2 \quad (n)$$
$$\xrightarrow{Base} CH(COOR')_2\text{-}CH_2\text{-}CH_2\text{-}SO_2\text{-}OR$$

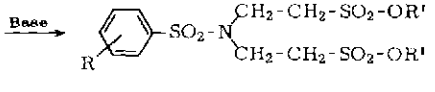
The catalyst, generally *N,N*-dimethylcyclohexylamine, is always added in such a quantity that a spot-test just gives an alkaline reaction.

10. Addition of Sulfonamides, Amides, Imides, and Hydrazides of Carboxylic Acids, and of Ureas, Thioureas, and Oximes

Sulfonamides possessing replaceable hydrogen can be "sulfonethylated" at higher temperatures, the reaction being catalysed by the hydroxides of the alkali and alkaline earth metals [26]. Sulfonamides with unsubstituted nitrogen atoms *(14)* undergo double addition:



(14)



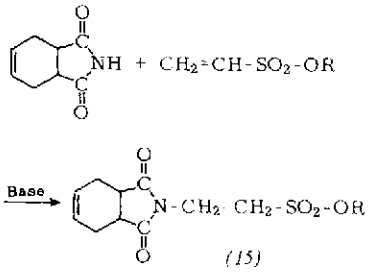
Carboxamides react less readily than sulfonamides, undergoing only monosubstitution:

$$R\text{-}CO\text{-}NH_2 + CH_2{=}CH\text{-}SO_2\text{-}OR' \quad (o)$$
$$\xrightarrow{Base} R\text{-}CO\text{-}NH\text{-}CH_2\text{-}CH_2\text{-}SO_2\text{-}OR'$$

[25] Unpublished work together with *W. Müller*.

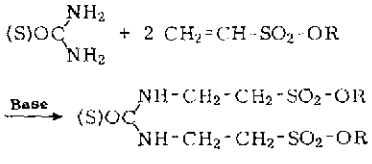
[26] German Published Patent Application 1155118 (Dec. 30th, 1961) BASF, inventor: *H. Distler*.

Carboxylic imides, on the other hand, are very reactive, giving crystalline products in high yields, *e.g. (15)*. *N,N*-Dimethylcyclohexylamine is generally used as the catalyst.



(15)

Urea and thiourea give the disubstituted products *(16)* in moderate yields.

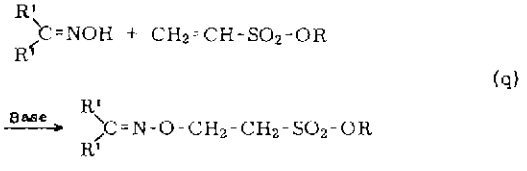


(16)

By comparison, carboxylic hydrazides react much more readily to give monosubstituted products:

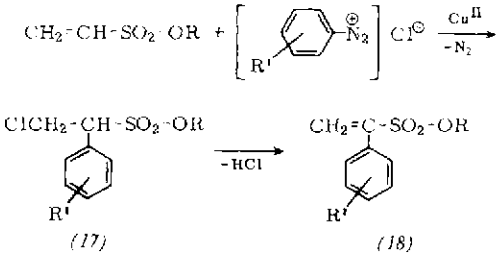
$$R'\text{-}CO\text{-}NH\text{-}NH_2 + CH_2{=}CH\text{-}SO_2\text{-}OR \quad (p)$$
$$\xrightarrow{Base} R'\text{-}CO\text{-}NH\text{-}NH\text{-}CH_2\text{-}CH_2\text{-}SO_2\text{-}OR$$

Oximes react at higher temperatures in the presence of bases, the reaction being sometimes very vigorous.



11. Addition of Diazonium Salts

In the presence of Cu(II) salts, diazonium chlorides react with vinylsulfonates at room temperature to give crystalline products *(17)*.



(17) *(18)*

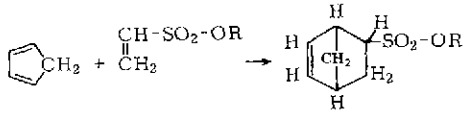
The synthesis is a form of the Meerwein reaction [27]. The easy elimination of HCl in the presence of a base leads to substituted vinylsulfonates *(18)*. Vinylsulfones react in a similar manner [28].

[27] *H. Meerwein, E. Buchner,* and *K. v. Emster,* J. prakt. Chem. *152,* 237 (1939).

[28] *E. Siegel* and *S. Petersen,* Angew. Chem. *74,* 873 (1962); Angew. Chem. internat. Edit. *1,* 593 (1962).

1. Diels-Alder Reaction

Heating of a vinylsulfonate with a diene, such as cyclopentadiene or hexachlorocyclopentadiene results in a substituted sulfonate, *e.g. (19)*, in very good yields.



(19)

2. Reaction with Olefins [29]

Olefins, *e.g.* propylene, butylene, propylene oligomers, and higher α-olefins, react with α,β-unsaturated sulfonates giving highly satisfactory yields of terminally unsaturated alkenesulfonates:

$$(CH_3)_2C{=}CH_2 + H_2C{=}CH{-}SO_3R \rightarrow H_2C{=}C(CH_3){-}(CH_2)_3{-}SO_3R \quad (r)$$

The reactants are heated at 100 °C or above, using a sealed tube for the low-boiling olefins. The products are suitable as plasticizers for PVC.

3. Reaction with Halogens

Cl_2, Br_2, and I_2 are practically inert toward vinylsulfonates, even in the warm. On irradiation or addition of compounds (*e.g.* azodiisobutyronitrile) capable of forming free radicals, however, rapid bromination or chlorination will occur. The addition of bromine is almost quantitative under these conditions:

$$CH_2{=}CH{-}SO_2{-}OR + Br_2 \rightarrow Br{-}CH_2{-}CHBr{-}SO_2{-}OR \xrightarrow{-HBr} CH_2{=}CBr{-}SO_2{-}OR \xrightarrow{Br_2} Br{-}CH_2{-}CBr_2{-}SO_2{-}OR \quad (s)$$

The α,β-dibromo derivatives lose HBr on treatment with a dilute solution of sodium carbonate or aqueous NaOH. The resulting α-bromovinylsulfonates can be rebrominated to give tribromo derivatives. The mono-, di-, and tribromo derivatives are distinguished by their unusually strong microcidal action, which is comparable to that of the organic compounds of mercury [30].

4. Nitration [31]

Below 30 °C, nitrating acid or sodium nitrate in conc. sulfuric acid react with aryl vinylsulfonates to give exclusively mononitrated products. Above 30 °C, however, hydrolysis occurs to form nitrophenols. Owing to ester cleavage, attempts aimed at the preparation of more highly nitrated derivatives under more vigorous conditions, were unsuccessful. It may be noted that the analogous phenyl acrylate and phenyl crotonate are split immediately under the same conditions, and cannot be nitrated.

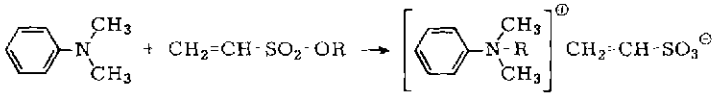
[29] German Pat. 1126860 (Dec. 9th, 1960) BASF, inventors: *W. Friedrichsen* and *H. Distler*.

[30] German Pat. applied for.

[31] German Pat. applied for.

5. Alkylation [32]

Alkyl vinylsulfonates are among the most effective alkylating agents. Unlike dimethyl sulfate or methyl *p*-toluenesulfonate, they are capable of converting *e.g.* phenol into anisole in a smooth reaction at room temperature. The reactions proceed under very mild conditions, and are usually quantitative. Primary, secondary, and tertiary alcohols undergo similar reactions. Sulfhydryl and primary or secondary amino groups linked to aromatic residues can be alkylated as well. Tertiary amines are converted into the quaternary ammonium salts *(20)* under very mild conditions.



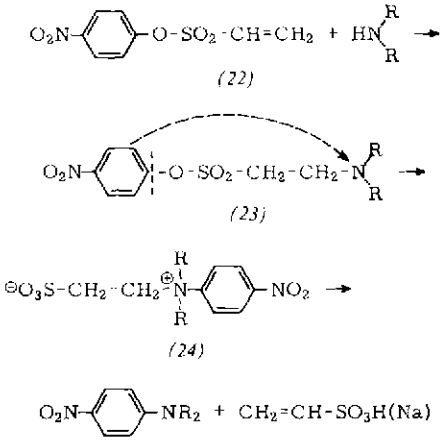
(20)

These products *(20)* are particularly useful as catalysts in emulsion polymerizations without emulsifiers [33].

Liquid methyl vinylsulfonate and ammonium chloride react vigorously in the absence of water, giving ammonium vinylsulfonate *(21)* and gaseous methyl chloride.

$$NH_4Cl + H_2C{=}CH{-}SO_3CH_3 \rightarrow ClCH_3 + H_2C{=}CH{-}SO_3^{\ominus}\ NH_4^{\oplus} \quad (21)$$

All attempts to use aryl vinylsulfonates for the arylation of amines in a similar way have been unsuccessful. If the aryl vinylsulfonate carries one or more electron-attracting substituents, *e.g.* nitro groups, on the nucleus, intramolecular arylation takes place to a small extent. For example, dimethylamine adds onto 4-nitrophenyl vinylsulfonate *(22)* in the cold, to give an unstable taurine ester *(23)*. The electrophilic character of the nitro group clearly weakens the ester bond,



(22)

(23)

(24)

and thereby favors intramolecular alkylation. An internal salt *(24)* is finally obtained, which in an aqueous alkaline medium undergoes a Hofmann degradation resulting in *N,N*-dialkylnitroaniline and a metal vinylsulfonate.

[32] German Pat. 1122064 (Jan. 9th, 1960) BASF, inventors: *H. Distler, W. Müller*, and *H. Werner*.

[33] German Pat. 1114320 (April 28th, 1960) BASF, inventors: *E. Penning, H. Reinhard*, and *H. Distler*.

6. Polymerization

Alkyl and aryl vinylsulfonates polymerize very sluggishly. On the other hand, the copolymerization with other vinyl monomers proceeds easily [34], and a number of such copolymers have been described [35,36]. Aryl vinylsulfonates can moreover be incorporated into polyester resins [37].

III. Synthesis of Other Derivatives of Vinylsulfonic Acid

A. Vinylsulfonamides

1. Syntheses

The synthesis of vinylsulfonamide has frequently been attempted, but only *Matlack* [38] succeeded in giving the first unambiguous description of this compound: m.p. 24 °C; $n_D^{20} = 1.4880$ [39]; b.p.143 °C/2 mm. He prepared vinylsulfonamide by the thermal degradation of β-alkylaminosulfonamide or β-methoxyethanesulfonamide, using alumina, calcium oxide, or phosphoric acid as catalyst.

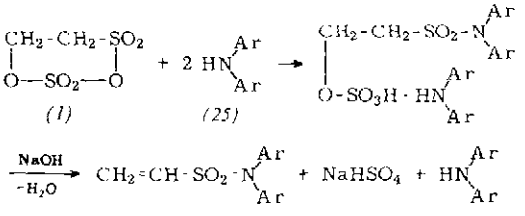
Vinylsulfonamide can also be prepared by the dehydration of ammonium vinylsulfonate between −40 and +40 °C with phosphorus pentoxide or magnesium perchlorate in the presence of small amounts of sulfur or phenols [40], as well as by the thermal cleavage of 2-aminoethanesulfonic anhydride (taurine anhydride) at 300 to 500 °C under reduced pressure [41]. The method suggested in another patent [42], whereby an aqueous solution (pH 6.5 to 7.5) of vinylsulfonyl chloride is treated with ammonium chloride at 15 to 30 °C in the presence of an alkaline buffer, does not seem to give vinylsulfonamide, as the product is not identical with the material described by *Matlack*.

A simple and elegant route to vinylsulfonamide [43] is provided by the reaction of vinylsulfonyl chloride or β-chloroethanesulfonyl chloride with ammonia in an inert solvent. Side reactions, such as the addition of ammonia to the vinylsulfonamide already formed, and the formation of tris-(2-sulfamoylethyl)amine, $N(CH_2-CH_2-SO_2-NH_2)_3$, are extensively suppressed under these conditions. If β-chloroethanesulfonyl chloride is used, 3 moles of ammonia are required for the reaction to take place.

$$ClH_2C-CH_2-SO_2Cl + 3\ NH_3 \rightarrow H_2C=CH-SO_2NH_2 + 2\ NH_4Cl \quad (t)$$
$$40\text{–}50\,\%$$

The use of vinylsulfonyl chloride instead of β-chloroethanesulfonyl chloride offers no advantage as far as the yield of vinylsulfonamide is concerned. The yield can however be considerably improved by using a primary or secondary aliphatic amine instead of ammonia [42,44]. With diethylamine for example, under otherwise identical conditions, *N,N*-diethylvinylsulfonamide (b.p. 80–84 °C/1 mm Hg; 78 °C/0.5 mm Hg [*]; m.p. −1.3 to −0.4 °C; $n_D^{25} = 1.4602$; $n_D^{20} = 1.4622$ [*]) can be prepared in a yield of about 70 % [45]. Addition reactions take place if an excess of the aliphatic dialkylamine is used [46].

Vinylsulfonamides derived from aromatic amines are prepared by an older method [47,58], *e.g.* by the reaction of aniline with ethane-1,2-disulfonyl chloride giving vinylsulfanilide (m.p. 68 °C), or by *Ebel*'s method [48] of treating primary or secondary *(25)* aromatic amines with carbyl sulfate *(1)* followed by treatment with alkali:



(u)

Carbyl sulfate *(1)* is prepared by treating 1 mole of ethylene with 2 moles of SO_3. Aromatic amines react with carbyl sulfate at room temperature without complications, but it is advisable to dilute the reaction mixture with an inert solvent. The sulfuric ester is cleaved by aqueous NaOH even at room temperature or slightly above. The yields obtained with this method are usually 80 % or more.

N-Arylvinylsulfonamides are soluble in strong alkalis, as are all compounds of this type, the dissolution being accompanied by the formation of salts. They are noted for their action as herbicides and are used in weed control [49].

Unfortunately, Reaction (u) is inapplicable to aliphatic amines, which form amides of ethionic acid with carbyl sulfate [50]. The potassium salts *(26)* of these products crystallize with particular ease. Vinylsulfonamides are said to be formed on the hydrolysis of the amide *(26)*, possibly as in Equation (v).

$$R_2N-SO_2-CH_2-CH_2-OSO_3K + KOH \xrightarrow[-K_2SO_4]{-H_2O} R_2N-SO_2-CH=CH_2 \quad (v)$$
(26)

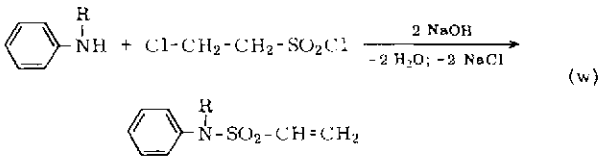
The vinylsulfonamides of primary or secondary aromatic amines may also be prepared very simply by Reaction (w).

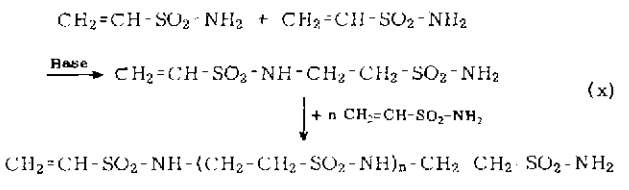


(w)

The amine is treated with β-chloroethanesulfonyl chloride in an aqueous alkaline medium (pH 9 to 10) at 0 to 5 °C. The addition of dichloroethane is advantageous, since it results in a better distribution and therefore in higher conversions. The yields are over 70 %, especially when secondary aromatic amines such as *N*-methylaniline or *N*-methyltoluidine are used. Surprisingly, the aromatic amine does not add onto the double bond of the vinylsulfonamide under these conditions, as do primary and secondary aliphatic amines. A similar but very complicated method also leads to *N*-arylvinylsulfonamides in the absence of water. Owing to the presence of by-products, however, the isolation is very difficult [51].

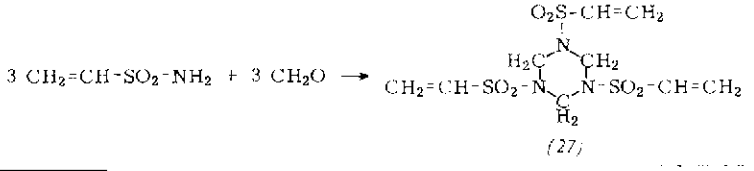
2. Chemical Properties

The reactions described for vinylsulfonates (cf. Section II) can be easily applied to vinylsulfonamides. The strong tendency of vinylsulfonamide to undergo polymerization at the C–C double bond is particularly interesting [52]. Both *N*-alkyl- and *N*-aryl-vinylsulfonamides are less susceptible to polymerization. However, they can copolymerize with other vinyl monomers [53, 54]. Furthermore, unsubstituted vinylsulfonamide tends to polymerize in the presence of basic catalysts and at elevated temperatures, presumably by head-to-tail addition:



(x)

With formaldehyde in the presence of catalytic amounts of conc. sulfuric acid, vinylsulfonamide undergoes cyclization to give a triazine derivative *(27)* [55]. This is used as a cross-linking agent in the paint industry [56].



(27)

B. Vinylsulfonyl Halides

1. Vinylsulfonyl Chloride

Sodium vinylsulfonate reacts with phosphorus pentachloride between 30 and 40 °C to give vinylsulfonyl chloride [57], which is a colorless, lachrimatory liquid (b.p. 42–44 °C/5 mm Hg; n_D^{20} = 1.4686; d_4^{20} = 1.393). A simpler method, giving a higher yield, is the dehydrochlorination of β-chloroethanesulfonyl chloride with lutidine at −50 °C [58].

Lutidine may be replaced by other tertiary amines, *e.g.* dimethylaniline or diethylaniline, the latter being particularly convenient because it forms an easily crystallizable hydrochloride. Side reactions will occur unless very low temperatures are used, and above +50 °C β-chloroethanesulfonyl chloride will decompose completely into 1,2-dichloroethane and SO_2.

Attempts have failed to dehydrochlorinate β-chloroethanesulfonyl chloride with catalysts such as active carbon, $Al_2O_3/ZnCl_2$, silica gel/$ZnCl_2$, or silica gel/$MgCl_2$. 1,2-Dichloroethane and SO_2 were formed instead at temperatures above 180 °C. This result is in good agreement with that of *Rieche*'s pyrolytic experiments [59] showing that alkanesulfonyl chlorides liberate SO_2 and form alkyl chlorides.

2. Vinylsulfonyl Fluoride

β-Chloroethanesulfonyl chloride can be converted with potassium fluoride into vinylsulfonyl fluoride [60]:

$$ClH_2C{-}CH_2{-}SO_2Cl + 3\ KF \rightarrow H_2C{=}CH{-}SO_2F + KHF_2 + 2\ KCl \qquad (y)$$

On dehydrochlorination with weak bases, such as $NaHCO_3$, MgO, or $CaCO_3$, β-chloroethanesulfonyl fluoride leads to vinylsulfonyl fluoride, a colorless liquid which strongly irritates the mucous membranes (b.p. 119 °C; n_D^{25} = 1.3797 [61]). It is very suitable as starting material for the preparation of vinylsulfonamides. The vinyl group generally behaves as described for vinylsulfonates.

The polymerization of vinylsulfonyl fluoride and its copolymerization with other vinyl monomers, *e.g.* vinyl acetate and styrene, were described by *Kern* and *Schulz* [62].

3. Reduction of Sulfonyl Halides – a New Olefin Synthesis

According to *Otto* [63], and *Pauly* and *Bazlen* [64], sulfonyl chlorides can be reduced to sulfinic acids with zinc and HCl. Simpler and more elegant is *Bredereck*'s method [65], which uses sodium hydrogen sulfite and leads directly to the sodium sulfinates. The application of this method to β-chloroethanesulfonyl chloride and to vinylsulfonyl chloride slightly above room temperature results in a vigorous reaction yielding ethylene instead of β-chloroethanesulfinic acid and vinylsulfinic acid, respectively [66].

This smooth formation of olefins is not restricted to β-chloroethanesulfonyl chloride and vinylsulfonyl chloride but proceeds with all β-halogenoalkylsulfonyl chlorides. When 2-chloropropane-1-sulfonyl chloride is used, propylene is eliminated quantitatively even at 10 to 20 °C. Temperatures of 50 to 60 °C are required in other cases. The reduction can also be carried out with sodium dithionite or with zinc dust and HCl, in which case the pH is adjusted to 5–6. The unstable intermediate, *e.g.* vinylsulfinic acid *(28)*, loses SO_2 to give ethylene.

$$\begin{matrix} Cl\text{-}CH_2\text{-}CH_2\text{-}SO_2Cl \xrightarrow{pH\ 5\text{-}6} \\ CH_2{=}CH\text{-}SO_2Cl \xrightarrow{H_2} \end{matrix} [CH_2{=}CH\text{-}SO_2H] \longrightarrow \underset{+\ SO_2}{CH_2{=}CH_2}$$

(28)

The rate of formation of the olefin increases with increasing alkalinity of the reaction medium and with the temperature. If a temperature of about 10 °C is used, the sulfinic acid, *e.g.* chloroethanesulfinic acid, can be extracted with ether after acidification with H_2SO_4. We obtained free chloroethanesulfinic acid containing about 20 % water in the form of a yellowish oily liquid which decomposed slowly at 0 °C. Attempts to increase the stability by salt formation with bases had an adverse effect: ethylene was formed as soon as NaOH was introduced. It appears that free β-chloroethanesulfinic acid and vinylsulfinic acid can exist only for a short time. Nevertheless, they undergo all reactions characteristic for sulfinic acids, *e.g.* precipitation with iron(III) chloride, addition to acrylamide, acrylic esters, vinylsulfonamide, vinylsulfonates, and other α,β-unsaturated systems.

C. New Synthesis of Vinyl Sulfones [67]

The reactions between β-halogenoalkanesulfonyl chlorides and sodium hydrogen sulfite, dithionite, or zinc dust at low temperatures result in the formation of unstable β-chloroalkanesulfinic acids, which can be stabilized by adding them onto the following conjugated systems: acrylic acid, acrylamide, acrylic esters, acrylonitrile, methacrylic acid, crotonic acid, maleic acid, acrolein, methacrolein, methyl vinyl ketone, vinylsulfonic acid and its derivatives, vinyl sulfones, *etc.* The reaction is assumed to take the following course:

$$\begin{matrix} ClCH_2\text{-}CH_2\text{-}SO_2Cl \xrightarrow[0\text{-}10^{\circ}C]{H_2} [ClCH_2\text{-}CH_2\text{-}SO_2H] \\ \xrightarrow{+\ CH_2{=}CHY} ClCH_2\text{-}CH_2\text{-}SO_2\text{-}CH_2\text{-}CH_2\ Y \\ \text{(29)} \\ \xrightarrow{-\ HCl} CH_2{=}CH\text{-}SO_2\text{-}CH_2\text{-}CH_2\text{-}Y \\ \text{(30)} \end{matrix} \qquad (\gamma)$$

Y = COOH, CHO, COR, $SO_3H(R)$, SO_2R, $CH{=}CH_2$

Since the β-chloroalkanesulfinic acids are very unstable at room temperature, the addition must be carried out at 0 to 10 °C. Furthermore, the reaction is advantageously carried out in a strongly acid medium since the sulfinic acids must be present in the free form and not as salts. The β-chloroalkylsulfones *(29)*, produced in a very pure form, can generally be converted to vinyl sulfones *(30)* under very mild conditions, using the alkali metal or alkaline earth carbonates or hydroxides as dehydrochlorinating agents.

Vinyl sulfones *(30)* are sometimes very sensitive to aqueous alkalis since the latter catalyse the hydration of the vinylsulfonyl group. It is therefore advisable not to exceed the stoichiometric amount of the base. The pH must not be over 6.5 in the dehydrochlorination of the particularly sensitive 3-(β-chloroethanesulfonyl)propionamide. Boiling with water, possibly in the presence of catalytic amounts of a base, promotes the hydration of the vinylsulfonyl group.

D. Preparation of Vinylsulfonic Acid and Its Salts

Several methods have been suggested for the preparation of vinylsulfonic acid and its salts, but only a few are really applicable. Irrespective of this fact, all practicable methods will be discussed in this Section.

1. Metal Vinylsulfonates

a) The removal of hydrogen chloride from sodium β-chloroethanesulfonate with aqueous alkali [68] has long been carried out on a technical scale. This method has recently become of interest after it was found possible to add sodium hydrogen sulfite onto vinyl chloride [69] in the presence of ultraviolet light or radical-formers

$$ClCH_2\text{-}CH_2\text{-}SO_3Na \xrightarrow[-\ NaCl]{NaOH} CH_2{=}CH\text{-}SO_3Na \qquad (\alpha)$$

such as azodiisobutyronitrile, thus making sodium β-chloroethanesulfonate accessible *via* a simple route. It is equally advantageous to prepare this compound from an NaCl melt with carbyl sulfate [70].

[63] *Otto* and *Schiller*, Ber. dtsch. chem. Ges. *9*, 1584 (1876); *Otto* and *Lüders*, ibid. *13*, 1283 (1880).

[64] *C. Pauly*, Ber. dtsch. chem. Ges. *10*, 941 (1877); *M. Bazlen*, ibid. *60*, 1470, 1479 (1927).

[65] *H. Bredereck*, Chem. Ber. *87*, 136 (1954).

[66] Belg. Pat. 595105 (Sept. 15th, 1960) BASF, inventors: *H. Distler* and *H. A. Brauns*.

[67] Belg. Pat. 635013 (July 17th, 1963) and French Pat. 1363046 (July 16th, 1963) BASF, inventors: *H. Distler* and *H. A. Brauns*.

[68] German Pat. 836491 (May 20th, 1941) Farbwerke Hoechst, inventor: *W. Schmidt*; Chem. Zbl. *1952*, 5975; German Pat. 678730 (Febr. 23rd, 1936) IG.-Farbenindustrie, inventors: *O. Nicodemus* and *W. Schmidt*; *W. Kern*, *V. V. Kale*, and *B. Scherhag*, Makromolekulare Chem. *32*, 37, 43 (1959).

[69] Belg. Pat. 593513 (July 28th, 1960) Colgate Palmolive Co.

[70] German Pat. 1059443 (Dec. 20th, 1957) DuPont, inventors: *W. E. Catlin* and *A. M. Jenkins*.

Sodium β-bromoethanesulfonate loses hydrogen bromide with even greater ease [71], forming vinylsulfonate in very good yields [72]. Sodium vinylsulfonate can be separated from NaBr or NaCl by recrystallization from 96 % ethanol.

b) The hydrolysis of ethane-1,2-disulfonyl chloride in an aqueous ammoniacal solution leads to ammonium vinylsulfonate [5, 73]:

$$ClSO_2\text{-}CH_2\text{-}CH_2\text{-}SO_2Cl \xrightarrow[NH_3]{H_2O} CH_2{=}CH\text{-}SO_3^{\ominus}\overset{\oplus}{N}H_4 \qquad (\beta)$$

c) An elegant route to vinylsulfonate is *via* the hydrolysis of the easily available carbyl sulfate *(I)* [74], which first undergoes ring-cleavage with aqueous alkali to give the salt of ethionic acid *(Ia)*, followed by cleavage of the ester bond leading to vinylsulfonate.

$$\begin{matrix} CH_2\text{-}CH_2\text{-}SO_2 \\ | \quad\quad | \\ O\text{—}SO_2\text{—}O \end{matrix} \xrightarrow[-2\,H_2O,\,Na_2SO_4]{3\,NaOH} CH_2{=}CH\text{-}SO_3Na$$

(I)

The formation of a small amount of the sodium salt of isethionic acid (β-hydroxyethanesulfonic acid) is a disadvantage in the alkaline hydrolysis. Sodium sulfate, an interfering substance in several cases, *e.g.* in the polymerization, can be removed almost entirely at 0 °C as the decahydrate.

Similarly to carbyl sulfate, ethionic acid [75] can be hydrolysed to give vinylsulfonate [76]:

$$\underset{(Ia)}{HO_3S\text{-}O\text{-}CH_2\text{-}CH_2\text{-}SO_3H} \xrightarrow[-Na_2SO_4]{3\,NaOH} CH_2{=}CH\text{-}SO_3Na \qquad (\gamma)$$

d) β-Chloroethanesulfonyl chloride, easily obtainable by the chlorosulfonation of chloroethane [2], can be hydrolysed to form a very pure vinylsulfonate containing only NaCl [77]:

$$ClCH_2\text{-}CH_2\text{-}SO_2Cl \xrightarrow[-2\,H_2O]{3\,NaOH} CH_2{=}CH\text{-}SO_3Na + 2\,NaCl \qquad (\delta)$$

Sodium hydroxide can be replaced by hydroxides or carbonates of the alkali or the alkaline earth metals. The use of tertiary amines or ammonia leads to ammonium salts on hydrolysis. Oxides of heavy metals such as Cu, Hg, Zn, Sn, or Pb react with β-chloroethanesulfonyl chloride in an aqueous suspension, and form very soluble, colorless metal vinylsulfonates.

The common feature of all these methods is that the vinylsulfonate is coprecipitated with a neutral salt such as sodium sulfate. After removal of the inorganic salt, the vinylsulfonate can be directly polymerized. To avoid spontaneous polymerization (which is particularly probable at about pH 7), stabilizers known in the chemistry of acrylates are used. These are hydroquinone, sodium nitrite, or nitroso compounds. Vinylsulfonate solutions above pH 9, on the other hand, are usually stable.

2. Free Vinylsulfonic Acid

a) In order to prepare free vinylsulfonic acid, a concentrated aqueous solution of the metal vinylsulfonate is saturated with HCl at about 0 °C [78]. An aqueous solution of vinylsulfonic acid is obtained from a dilute solution of vinylsulfonate with the aid of strongly acidic ion exchangers. The hydrolysis of ethane-1,2-disulfonyl chloride [5, 6, 79] also leads to vinylsulfonic acid.

b) A very simple preparation of vinylsulfonic acid, and one that is also practicable on the technical scale, utilizes the fact that methyl vinylsulfonate can be easily saponified. The latter is obtained in practically quantitative yield from β-chloroethanesulfonyl chloride and sodium methoxide in a methanolic solution [3], and is hydrolysed by a countercurrent of steam in a column packed with Raschig rings [4]. The methanol simultaneously distills off:

$$CH_2{=}CH\text{-}SO_2\text{-}OCH_3 \xrightarrow[100°C]{H_2O} CH_2{=}CH\text{-}SO_3H + CH_3OH \qquad (\varepsilon)$$

The resulting 40 to 45 % aqueous solution of vinylsulfonic acid is free from foreign salts, and can be concentrated to 55 % in a thin-layer evaporator made of Hastelloy®. Vinylsulfonic acid can be isolated in small quantities from its aqueous solution by distillation under a high vacuum. The product is a colorless, oily liquid, soluble in water and most organic solvents.

Potassium permanganate is reduced instantaneously to the Mn(II) state by vinylsulfonic acid, which resembles conc. H_2SO_4 in its dehydrating action: a pine shaving dipped into vinylsulfonic acid turns dark immediately. Vinylsulfonic acid remains unchanged for a fairly long time when stored in a closed container at about 0 °C. The polymerization of vinylsulfonic acid and its salts is the subject of numerous patents and publications [80].

IV. Experimental

A. Detection of Vinylsulfonates

1. Determination of Aryl Vinylsulfonates (Thiol Addition)

Aryl vinylsulfonates (also vinylsulfonamides and vinyl sulfones) can be determined by a method used for acrylic compounds, *i.e.* by the addition of thiols to the vinyl group:

$$RSH + CH_2{=}CH\text{-}SO_2\text{-}OC_6H_5 \xrightarrow{Base} RS\,CH_2\text{-}CH_2\text{-}SO_2\text{-}OC_6H_5$$

[80] *W. Kern* and *R. C. Schulz* in *Houben-Weyl*: Methoden der organischen Chemie. 4th Edit., Thieme Verlag, Stuttgart 1961, Vol. 14/1, p. 1099.

About 0.3 to 0.7 g of a sample (quantity E) are dissolved in 100 ml of 95% alcohol (or alcohol/toluene, acetone, or methanol). A 5% alcoholic solution of n-dodecanethiol (20 ml) and 1 ml of a 5% solution of KOH in ethanol are then added at 20 to 25 °C. The mixture is allowed to stand for 2 to 3 minutes, is shaken a few times, and acidified with glacial acetic acid. The sample is then titrated against 0.1 *N* iodine to a yellow end-point (the yellow color should persist for at least 2 minutes). Titer: a ml of 0.1 *N* iodine solution. The blank test is carried out under the same conditions. Titer: b ml of 0.1 *N* iodine solution.

$$\text{Iodine value} = \frac{(b-a) \times 2.538}{E}$$

The method fails with vinylsulfonic acid and its salts.

2. Determination of Alkyl Vinylsulfonates

The method of thiol addition cannot be applied to metal and alkyl vinylsulfonates, since these convert the thiols into thioethers. Hydrogenation on Pd is therefore recommended. The analytical results obtained in this way are fairly satisfactory. Owing to the fact that substitution takes place, conventional methods of determining iodine values lead to erroneous results.

3. Physiological Effects

All alkyl vinylsulfonates are very toxic, methyl vinylsulfonate being particularly so; being a powerful alkylating agent, its toxicity resembles that of dimethyl sulfate. It also has a strong lachrimatory action, and causes inflammation of the skin leaving behind deep, slow-healing ulcers. Esters with fluorinated alcohols (with 3 to 6 carbon atoms) are chemical warfare agents. Aryl vinylsulfonates are less toxic, but can sometimes irritate the skin. Their strong fungicidal action, comparable to that of the organomercury derivatives, is particularly striking. Aryl vinylsulfonates are used as microcides and in combating the South American leaf-cutting ant [81].

B. Syntheses

1. Methyl Vinylsulfonate

β-Chloroethanesulfonyl chloride (326 g, 2 moles) is placed in a container fitted with a stirrer, and cooled to 0 °C. An approximately 30% methanolic solution of 710 g of sodium methoxide is then added dropwise over a period of 2 hours, the mixture being maintained at about 0 °C. The addition is stopped when the pH reaches a value of 5. (The solution must not under any circumstances be allowed to become alkaline.) After warming for 1 hour to about 30 °C, NaCl is filtered off and the solvent is distilled off *in vacuo*. The gel-like residue is washed with about 100 ml of ice-cold water. After drying, the methyl vinylsulfonate is distilled under vacuum (< 1 mm), giving 210 g of a colorless liquid, b.p. 54–60 °C/0.2–0.4 mm; $n_D^{20} = 1.4310$; 86% yield.

Warning: Care should be taken in all work with methyl vinylsulfonate. Contact with skin must be avoided, and the operator should wear rubber gloves, and work in a fume-cupboard!

2. Pentachlorophenyl Vinylsulfonate

Pentachlorophenol (800 g, 3 moles) and 1500 ml of cyclohexanone are suspended in 500 ml of water. β-Chloroethanesulfonyl chloride (570 g, 3.5 moles) and about 1150 g of 25% NaOH are then added, simultaneously and dropwise, over a period of about 1.5 hours, the mixture (pH 7 to 8) being stirred and cooled to 0–5 °C. Stirring is continued for another 30 minutes, and the reaction mixture is then adjusted to pH 4–5 with about 5 g of conc. HCl. Cyclohexanone is distilled off by steam, the ester is separated from the warm solution and added immediately to 750 ml of alcohol with constant stirring. Pentachlorophenyl vinylsulfonate crystallizes out on cooling to 15 °C. The crystals are filtered with suction and washed with a little alcohol. After drying, 1000 g of the ester are obtained in the form of colorless crystals, m.p. 82 to 86 °C (yield 93%, calculated on pentachlorophenol). After recrystallization from alcohol the substance melts at 93 °C.

3. 2-Chlorophenyl Vinylsulfonate

2-Chlorophenol (257 g, 2 moles), 500 ml of 1,2-dichloroethane, and 1000 ml of water are placed in a vessel fitted with a stirrer. Crude (ca. 85%) carbyl sulfate (704 g, 3.2 moles) is then added in several portions, with vigorous stirring, over a period of about 2 hours at 0 to 5 °C, the mixture being adjusted to pH 10–10.5 by the simultaneous dropwise introduction of 1370 g of 25% NaOH. Stirring is continued for another ½ hour and the reaction mixture is then made weakly acidic by the addition of 5 g of conc. HCl and separated in a separating funnel. This last operation is facilitated by warming to 30–35 °C. The organic phase is steam-distilled, removing the solvent and unaltered 2-chlorophenol. Separation of the product from water in the warm yields 430 g (96.5% calculated on 2-chlorophenol) of ca. 98% pure 2-chlorophenyl vinylsulfonate. The ester is distilled under vacuum; b.p. 110–115 °C/0.2 mm; $n_D^{20} = 1.5212$.

4. Phenyl Vinylsulfonate

Phenol (188 g, 2 moles), 400 ml of water, and 400 ml of 1,2-dichloroethane are placed in a 4 l three-necked flask. β-Chloroethanesulfonyl chloride (375 g, 2.3 moles) and about 700 g of 25% NaOH are then added, simultaneously and dropwise, from two inlet tubes, over a period of 2 to 3 hours, the mixture (pH 8.5–9.5) being stirred and cooled to 0–5 °C. Stirring is continued for another hour, and the reaction mixture is then made weakly acidic with conc. HCl. The organic mixture is then separated (separation being facilitated by warming to 30–40 °C), dried over sodium sulfate, filtered, and distilled under vacuum. Phenyl vinylsulfonate distills over at 90 to 91 °C/0.1 mm. It is a colorless, oily liquid solidifying at 40 to 42 °C; $n_D^{40} = 1.5171$; yield: 313 g (85% calculated on phenol).

5. Cresyl β-Allyloxyethanesulfonate

A suspension of 2.5 g of dry finely powdered NaOH in 500 g of allyl alcohol is treated with 198 g of cresyl vinylsulfonate over a period of 3 hours. The reaction mixture is maintained at 40 °C for 4 hours and then at 50 °C for 1 hour. The solution is filtered and the filtrate distilled under vacuum, giving 214 g (84%) of cresyl β-allyloxyethanesulfonate, b.p. 135 to 142 °C/0.1 mm.

6. β,β′-Sulfonyl-bis-(2-chlorophenyl ethanesulfonate)

Sodium hydroxymethanesulfinate dihydrate (85 g) is added to 218.5 g of 2-chlorophenyl vinylsulfonate and 500 ml of water. The reaction mixture is heated to 80–85 °C, with constant stirring. The pH of the solution is adjusted to 4.5 to 6.5 by the slow addition of 25 g of 50% H_2SO_4. The reaction reaches completion in about 1 hour, after which the product is filtered off with suction and dried. Sulfonylbis-(2-chlorophenyl ethanesulfonate) is thus obtained as white crystals, m.p. 150 °C (from alcohol). The yield is 210 g (83.5 %).

[81] German Published Patent Application 1173720 (March 24th 1961) BASF, inventors: *H. Distler* and *E. Pommer*.

7. Monophenyl Ethane-1,2-disulfonate

Phenyl vinylsulfonate (92 g), 100 ml of ethanol, 250 ml of water, and 150 g of a 40% solution of sodium hydrogen sulfite are placed in a flask fitted with a stirrer. The reaction is allowed to proceed at about 50 to 60 °C until a clear solution is obtained. The mixture is then cooled to about 5 °C, reduced to $^2/_3$ of the original volume under vacuum, and the product is filtered off with suction. A yield of 135 g (about 93%) of sodium phenyl ethane-1,2-disulfonate is thus obtained.

8. Phenyl β-(1-Nitrocyclohexyl)ethanesulfonate

N,N-Dimethylcyclohexylamine (26 g) is added dropwise over a period of about 2 hours to 200 g of nitrocyclohexane and 184 g of phenyl vinylsulfonate at 70 to 90 °C. The reaction mixture is kept slightly alkaline at all times. After stirring for a further 2–3 hours, the excess nitrocyclohexane is removed with steam. The organic phase of the residue is separated and diluted with 200 ml of ethanol, yielding 244 g (78%) of phenyl β-(1-nitrocyclohexyl)ethanesulfonate, m.p. 72–73 °C.

9. *N,N*-Bis-(1-phenoxysulfonyl-2-ethyl)-*p*-toluenesulfonamide

Phenyl vinylsulfonate (92 g, 0.5 mole) and 43 g (0.25 mole) of *p*-toluenesulfonamide are heated to 110 °C for 3–4 hours with constant stirring, in the presence of 2 g of powdered NaOH, and the mixture is then boiled with water. The water-insoluble residue is recrystallized from about 300 ml of alcohol giving 108 g of *N,N*-bis-(1-phenoxysulfonyl-2-ethyl)-*p*-toluenesulfonamide in the form of white crystals, m.p. 117 °C.

10. 2,4,6-Trichloro-3-nitrophenyl Vinylsulfonate

2,4,6-Trichlorophenyl vinylsulfonate (720 g) is dissolved in 3000 g of conc. sulfuric acid in a flask fitted with a stirrer, the reactants being cooled to about 10 °C. At this temperature, 171 g of 98% HNO_3 are added, dropwise, over a period of 1 hour. After stirring for a further hour at the same temperature, the reaction mixture is poured into about 10 l of ice-cold water, precipitating the 2,4,6-trichloro-3-nitrophenyl vinylsulfonate as yellow crystals. After filtration and drying, 786 g of the product are obtained (94.3% yield). After recrystallization from alcohol, the m.p. is 108–109 °C.

11. 3-(β-Chloroethanesulfonyl)propionamide

β-Chloroethanesulfonyl chloride (489 g, 3 moles) is added dropwise, over a period of 1.5 hours, to a solution of 312 g (3 moles) of $NaHSO_3$ in 1500 ml of water, with stirring and cooling to 5–10 °C. The pH is adjusted to 5–5.5 by the simultaneous addition of 1326 g of about 25% NaOH. After stirring for a further 15 minutes, 300 g of a 49% solution of H_2SO_4 (1.5 moles) are added dropwise, at the same temperature. The mixture is then stirred for another hour and cooled to 0–5 °C. Sodium sulfate decahydrate is filtered off with suction and washed with about 1000 ml of ice-cold water. The filtrate is treated with 1200 g of a 15% aqueous solution of acrylamide (3 moles) at 5 to 10 °C, with constant stirring. Crystals begin to separate in about 20 minutes. The stirring is continued for about another hour and the solution is allowed to stand for 2 to 3 days at 5 to 10 °C to complete the crystallization. The crystalline product is filtered with suction, washed free from acid with ice-cold water, and dried in an air cupboard, yielding 391 g (65.6%) of β-chlorocthanesulfonylpropionamide as a white powder, m.p. 138–140 °C.

12. 3-Vinylsulfonylpropionamide

To a suspension of 200 g (1 mole) of 3-(β-chloroethanesulfonyl)-propionamide in 600 ml of water, stirred and maintained at 20 to 25 °C, 156 g of a 25% solution of NaOH is added dropwise over a period of 2 hours, with constant stirring, in such a manner that the pH does not exceed 7. A clear, colorless solution is obtained. Pure vinylsulfonylpropionamide is isolated by extraction with four portions (200 ml each) of ethyl acetate. The product is a white crystalline solid, m.p. 74 °C (from alcohol/benzene).

13. Preparation of Ethylene

Water (500 ml) and 260 g of an approximately 40% aqueous solution of $NaHSO_3$ are mixed in a flask fitted with a stirrer, the solution is adjusted to pH 5–6 and maintained at 50 to 60 °C. β-Chloroethanesulfonyl chloride (163 g, 1 mole) and 630 g of a 25% aqueous solution of NaOH are then added, dropwise and simultaneously, from two inlet tubes. This procedure yielded 21.8 l (N.T.P.) of ethylene in a vigorous reaction.

New Cotton Dyes

BY DR. H. R. HENSEL AND DR. G. LÜTZEL

FARBENFORSCHUNGSLABORATORIUM, BADISCHE ANILIN- & SODA-FABRIK AG., LUDWIGSHAFEN/RHEIN (GERMANY)

Published on the occasion of the 100th anniversary of the establishment of Badische Anilin- & Soda-Fabrik AG., on April 6th, 1965.

The present paper deals with new cotton dyes, approaching the subject from two directions. In the first section the synthesis of a new type of reactive dye from products of Reppe acetylene chemistry is reported. The second part describes a dyeing process which does not start with reactive dyes. Instead, the homopolar bonding between dye and cotton is formed by linking the dye to the substrate via polyfunctional bridges. These two programs have led to the development of the ®Primazin P and ®Basazol dyes.

In his review of the century which had passed since the discovery of the first synthetic dye, *Zollinger* [1] referred to the reactive dyes as "the most important technical discovery of the last two decades in the field of dye chemistry". After decades of dyeing cotton with vat dyes and direct dyes, reactive dyes now presented the possibility of using brilliant dyes with relatively simple structures. Stimulated by this new development, fashion turned to brighter hues. The problems solved by the dye manufacturers in this connection are reflected in the many types of reactive dyes which have since been produced.

I. Reactive Dyes Containing Dichloropyridazone Residues [*]

The reactive dyes which have become commercially available can be grouped into a few types. They contain either activated vinyl [*(a)* and *(b)*] or alkyl hydrogen sulfate groups *(c)*, or they are imide chlorides containing the characteristic grouping *(d)*, with a halogen atom attached to the imide carbon atom. This last structural unit in particular has been frequently varied as part of heterocyclic rings. The first reactive dyes were members of the triazine series. These were followed by dyes based on chlorinated pyrimidines, quinoxalines [2], and phthalazines. The ®Remazol dyes [3] are vinyl sulfones *(a)* or compounds which are converted to vinyl sulfones when

$-SO_2-CH=CH_2$ *(a)* $-NH-CO-CH=CH_2$ *(b)*

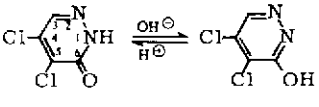
$-SO_2-NH-CH_2-CH_2-O-SO_3H$ *(c)* $-N=\underset{|}{C}-Cl$ *(d)*

fixed to the fiber by treatment with alkali. The dyes containing acrylamide groups *(b)* have similar structures.

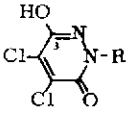
The reactive dyes described below are 1-substituted 4,5-dichloro-6-pyridazones. The negative leaving group (on reaction with the fiber) is again a halogen atom, and the reactive group forms part of a heterocycle; however, these compounds are not imide chlorides.

1. The 4,5-Dichloro-6-pyridazone System

The reactivity of halogen atoms on the pyridazone ring depends on several factors. 4,5-Dichloro-6-pyridazone, which is prepared from hydrazine and mucochloric acid (α,β-dichloro-β-formylacrylic acid) can be heated in strong sodium hydroxide solution and recovered unchanged on acidification. Provided that the nitrogen



(1a) *(1b)*



(2)

atom 1 is unsubstituted, the equilibrium between the "lactam form" *(1a)* and the "lactim form" *(1b)* in NaOH solution lies in favor of the aromatic "lactim form". In the 4,5-dichloro-3-hydroxypyridazones *(2)*, which are prepared from dichloromaleic acid and hydrazine derivatives, the two halogen atoms again lack the reactivity required of reactive dye components.

Only the 1-substituted 4,5-dichloro-6-pyridazones *(3a)* show sufficient activation of the 4-chlorine atom. The fact that it is the 4-halogen atom which is particularly readily replaced by nucleophilic reagents was first recognized by *Sonn* [4] who studied 4,5-dibromo-1-

[1] *H. Zollinger*, Angew. Chem. *73*, 125 (1961).

[*] By *H. R. Hensel*.

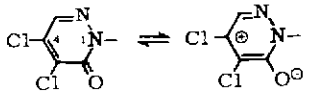
[2] *K. G. Kleb, E. Siegel*, and *K. Sasse*, Angew. Chem. *76*, 423 (1964); Angew. Chem. internat. Edit. *3*, 408 (1964).

[3] *J. Heyna*, Angew. Chem. *74*, 966 (1962); Angew. Chem. internat. Edit. *2*, 20 (1964).

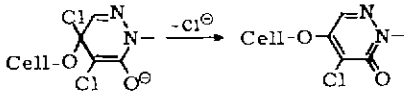
[4] *A. Sonn*, Liebigs Ann. Chem. *518*, 290 (1935).

phenyl-6-pyridazone [5]. Swiss workers [6] later investigated the substitution with primary amines, and *Dury* [7], in a comprehensive study of the chemistry of pyridazones, synthesized a large number of 4,5-disubstituted derivatives.

Owing to the presence of the 1-substituent in *(3a)*, enolization of the carbonyl group is no longer possible. However, its polarization *(3b)* leads to an electron deficiency at C–4, which is required for a nucleophilic reaction. Attack by the cellulose anion Cell–$O^{\ominus}$ results



(3a) *(3b)*



(4a) *(4b)*

in the formation of the intermediate *(4a)* with a tetrahedral C–4. This loses the chlorine atom with reformation of the carbonyl group *(4b)*. Thus the oxygen atom serves as an electron acceptor. If the system is regarded as a vinylogous acyl chloride, it becomes clear why only the β-chlorine atom (*i.e.* that on C–4) is activated.

2. Synthesis of Dyestuff Intermediates

Druey [8] has attempted to use 3,4,5-trichloropyridazine, which can be obtained from the "lactim" *(1b)*, in the same way as substituted s-triazines. However, stepwise substitution of the chlorine atoms does not proceed as smoothly here as in the case of the technically important cyanuric chloride. The hopes which had initially been aroused by these products were thus partly disappointed.

Instead of selectively removing one of the chlorine atoms from 3,4,5-trichloropyridazines, we synthesized 4,5-dichloro-6-pyridazones from mucochloric acid and hydrazine derivatives. The pyridazone ring can often be closed simply by heating the components in aqueous solution [9].

Mucochloric acid itself is technically readily available by a new process developed by *Dury* and *Reicheneder*, involving oxidative chlorination of 2-butyne-1,4-diol, which can be obtained from acetylene [10, 11]. Thus our first aim was to prepare unsymmetrically substituted hydrazine derivatives and to investigate their ring closure to form the corresponding pyridazones.

a) The Hydrazone-Pyridazone Ring Closure

Whereas aliphatic hydrazine derivatives can generally be smoothly cyclized with mucohalic acids, the tendency of aromatic hydrazine derivatives to close the ring strongly depends on the substituents on the aryl group (cf. Table 1). Phenylhydrazine combines with mucochloric acid in aqueous solution at 50–60 °C to form 4,5-dichloro-1-phenyl-6-pyridazone, passing rapidly through the hydrazone stage, which can be recognized by its deep yellow color. *p*-Nitrophenylhydrazine and 2,4-dinitrophenylhydrazine, on the other hand, initially form only the open-chain hydrazones *(5)*, even if the reaction is carried out in glacial acetic acid containing acetic anhydride [12]. In order to complete the ring closure, it is necessary to heat at 50–60 °C in concentrated sulfuric acid. 4,5-Dichloro-1-(*p*-nitrophenyl)-6-pyridazone, which is colorless in the pure form, can also be obtained by nitration of 4,5-dichloro-1-phenyl-6-pyridazone.

Table 1. Reaction of arylhydrazines with mucochloric acid.

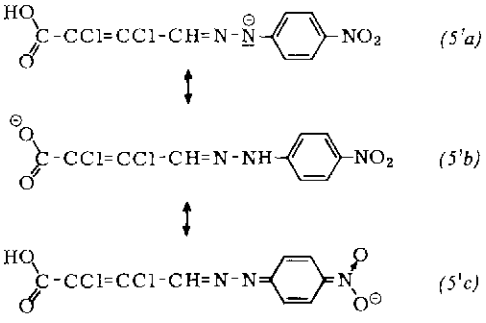
[11] *K. Dury*, Angew. Chem. *72*, 864 (1960).

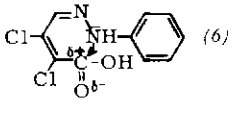
[12] According to our results, the 2,4-dinitrophenyl derivative, m.p. 221 °C, described by *A. N. Kosst, A. A. Shumakova, J. I. Koslova*, and *I. I. Grandberg*, Vestnik Moskovskogo Univ., Ser. Mat., Mech., Astr., Fiz., Khim. *14*, 205 (1959); Chem. Zbl. *1961*, 13597, is the open-chain hydrazone.

The open-chain *p*-nitrophenylhydrazone *(5')* [*i.e. (5)* with R = *p*-NO_2–C_6H_4] can be esterified and is characterized by the deep red-violet color which develops on reaction with aqueous alkali. The color is due to the anion, which may be represented by the three resonance structures *(5'a)*, *(5'b)*, and *(5'c)*.



When ether/diazomethane vapors are passed over the yellow solution of the nitrophenylhydrazone *(5')* in dimethylformamide, the surface of the solution turns deep violet, which is again the color of the anion *(5'a)* ↔ *(5'c)*. The color disappears on shaking, or when the diazomethane solution is run in. Only then is nitrogen evolved, and the methyl ester is obtained by working up the resulting yellow solution. The color reaction impressively demonstrates the high proton affinity of diazomethane and the enhanced mobility of the proton in *(5')*. It also confirms the mechanism suggested by *E. Müller* [12a] for methylation with diazomethane, in which the first step is the uptake of a proton to form a methyldiazonium cation.

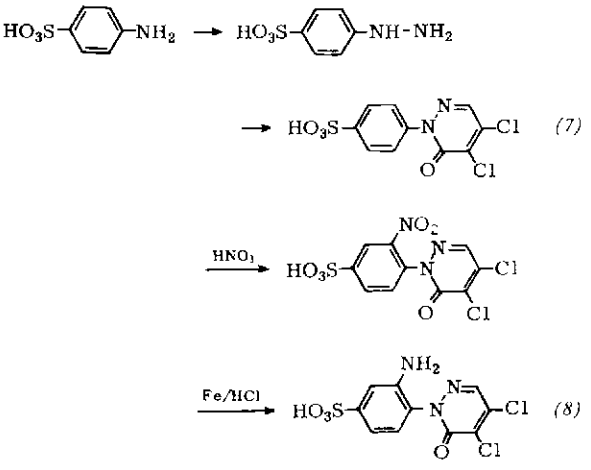
2,6-Dimethylphenylhydrazine, which is obtained from *vic*-xylidine, reacts with mucochloric acid to form the pale yellow 4,5-dichloro-1-(2',6'-dimethylphenyl)-6-pyridazone on short heating in glacial acetic acid. Even a sulfo group in the *o*-position with respect to the hydrazine group does not prevent formation of the pyridazone. This shows that *steric factors* do not have a decisive influence on the ring closure reaction. It can be seen from Stuart models of 4,5-dichloro-1-(*p*-tolyl)-6-pyridazone and its 2'-nitro derivative that an *ortho*-substituted aryl residue is compatible with pyridazone formation. It is not necessary for the two rings to be coplanar. Instead, they are probably rotated out of the common plane to a certain extent, depending on the nature and position of the substituents on the aryl ring; this phenomenon is also found in the pyrazolone series [13]. Thus the principal factors governing the ring closure are *substituent effects*. They increase or decrease the electron density at N–1 and effect the attack of this center on the carboxyl carbon atom C–6 which carries a partial positive charge [cf. *(6)*].



(6)

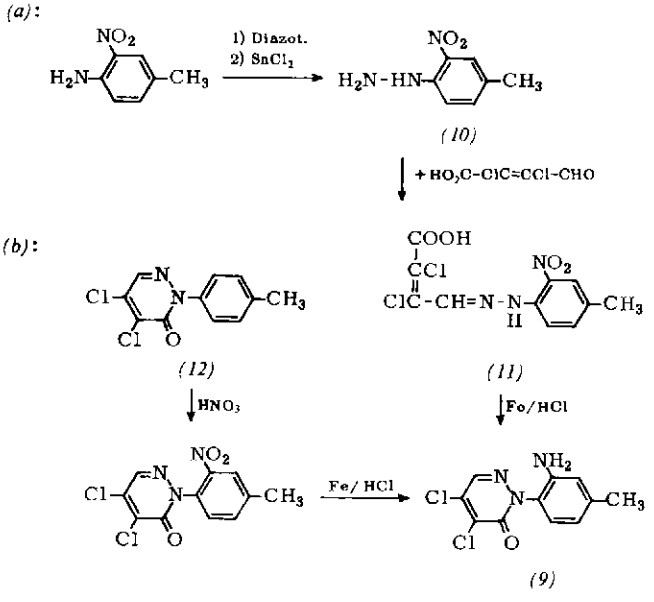
b) 1-Aryl-4,5-dichloro-6-pyridazones in Diazo and Coupling Components

1-Phenylpyridazones containing amino groups can be obtained *via* the corresponding nitro or acetamino compounds. Another route starts from sulfanilic acid, which is diazotized and reduced with sodium sulfite to form 4-sulfophenylhydrazine; this is not isolated, but is reacted directly with mucochloric acid. In this way, the intermediate *(7)* can be obtained in 88% yield by a single pass in an acidic aqueous solution. The amine *(8)* is obtained by nitration and subsequent Béchamp reduction.



(7) *(8)*

It was found that the 4,5-dichloro-6-pyridazonyl group is a first-order substituent, *i.e.* it is *ortho*- and *para*-directing with respect to the 1-phenyl residue. Thus 1-(2'-amino-4'-tolyl)-4,5-dichloro-6-pyridazone *(9)* can be prepared by two routes: (a) 3-Nitro-*p*-toluidine is converted to the hydrazine derivative *(10)*, which is then reacted with mucochloric acid. The hydrazone *(11)* is

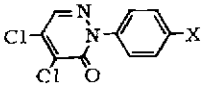


unaffected by boiling glacial acetic acid, and undergoes ring closure to form the pyridazone only after the nitro group has been reduced to the amino group. The same amine *(9)* (identified by melting point and infrared spectrum) can be obtained [Route (b)] from the *p*-tolylpyridazone *(12)* by nitration and reduction. Thus the nitro group enters the *o*-position with respect to the dichloropyridazonyl residue.

Components which contain reactive dichloropyridazonyl residues and are suitable for azo coupling have been prepared by acylation with acyl chlorides. 4,5-Dichloro-

[12a] *E. Müller*: Neuere Anschauungen der organischen Chemie. 2nd Edit., Springer, Berlin-Göttingen-Heidelberg 1957, p. 444.
[13] *H. Hopff*, Chimia *15*, 193 (1961).

1-phenyl-6-pyridazone reacts with chlorosulfonic acid to form the sulfochloride *(13)* (m.p. 141 °C), and with phosgene in molten urea/$AlCl_3$ [14] to form the carboxylic acid corresponding to *(14)*; this acid can also be obtained from *p*-aminobenzoic acid *via p*-hydrazinobenzoic acid by reaction with mucochloric acid.

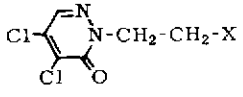


(13): X = SO_2Cl

(14): X = COCl

Dyes or dye intermediates containing amino groups can be acylated in the usual manner with the acyl chlorides *(13)* and *(14)* [m.p. of *(14)*: 153 °C]. However, the resulting dyes are only moderately soluble. We therefore turned our attention to the synthesis of intermediates containing aliphatic bridges.

β-Hydrazinopropionitrile is readily obtainable from hydrazine and acrylonitrile. It reacts with mucochloric acid to give the pyridazone derivative *(15)* (yield > 90%),



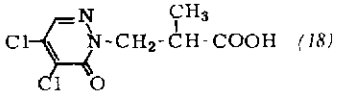
(15): X = CN

(16): X = COOH

(17): X = COCl

which forms the β-substituted propionic acid *(16)* on hydrolysis with sulfuric acid (70%) or hydrochloric acid. Intermediates obtained by reaction with the acyl chloride *(17)* can be converted to azo dyes which are completely satisfactory with regard to solubility and affinity.

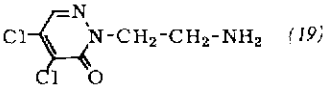
The bridge between the reactive 4,5-dichloro-6-pyridazonyl residue and the chromophore system has some effect on the affinity of the dye. For this reason, intermediates with a branched aliphatic chain were also prepared. The isobutyric acid dervative *(18)*, m.p. 135 °C, is obtained from hydrazine and methacrylonitrile by reaction with mucochloric acid and subsequent hydrolysis.



(18)

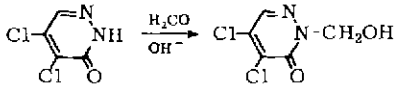
c) Aminoalkyl and Hydroxymethyl Derivatives of 4,5-Dichloro-6-pyridazone

β-Aminoethylhydrazine, which is prepared from hydrazine and ethylene imine, can be reacted with mucochloric acid to form the pyridazone derivative *(19)*, which is isolated from its solution in hydrochloric acid as the hydrochloride (m.p. 265 °C). The corresponding γ-aminopropyl derivative is obtained by catalytic hydrogenation of the nitrile [15]. Aliphatic amines of this type are particularly suitable for reaction with anthraquinone- and phthalocyanine dyes which contain acyl chloride groups.

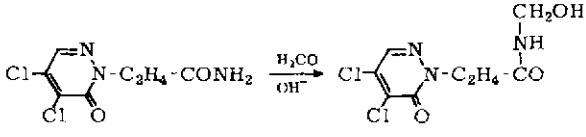


(19)

4,5-Dichloro-6-pyridazone *(1a)*, m.p. 205 °C, reacts with formaldehyde in alkaline solution to form the 1-hydroxymethyl compound *(20)*, m.p. 104 °C. In a similar reaction the hydroxymethylamide *(22)*, m.p. 136 °C, is obtained from the propionamide *(21)*, m.p. 173 °C, and formaldehyde. Hydroxymethyl compounds of this type can be combined with dyes or dye intermediates containing activated methylene groups by condensation in concentrated sulfuric acid [15,16].



(1a) *(20)*



(21) *(22)*

3. Dyes

a) Synthesis of Dyes

The high stability of the dichloropyridazonyl group is of advantage in the synthesis of dyes. This group remains intact below pH 8.5 even at 100 °C. It survives sulfonations, nitrations, and reductions. The preparation of metal complexes, chroming and cobalting at 100 °C, and oxidative coppering or coupling down to pH 10 are also possible without special precautions.

The reader is referred to the patent literature [17–24] for details of the preparation of the azo-, anthraquinone-, and phthalocyanine dyes.

Mucochloric acid is used as a starting material in all the syntheses mentioned so far. Mucobromic acid has been used

in a similar manner. Although dyes containing the 4,5-dibromo-6-pyridazonyl group can be combined with the fibers under milder conditions (lower temperature), the advantages do not compensate for the higher costs.

b) Affinity of Dyes

The dyeing of cellulose fibers always begins with the penetration of the dye molecule, which is dissolved in water, into the cellulose micelles, where they can become fixed in various ways. In the case of substantive dyes, the latest views [25] are in favor of an aggregation of the dye molecules, with no true adhesion between the dye and the cellulose. The situation is different in the case of reactive dyes. Here the dye is finally attached to the substrate by a covalent bond, and this step is preceded by a phase in which the dye molecules are adsorbed on the surface of the fibers. The fact that they react preferentially with the cellulose anions is explained by an increase in the concentration of the dye at the cellulose surface, just as is assumed to be the case in reactions on catalyst surfaces [25a].

The adsorption process, in which the distribution equilibrium between the dye bath and the fiber is displaced in favor of the fiber, is affected by two factors: molecular structure and solubility. Of these, the solubility can be varied only within narrow limits. It is normally determined by the number of sulfo groups in the dye molecule; in addition there is a solvation effect in the case of metal complexes.

The molecular structure, on the other hand, offers many possibilities of modification. Assuming that the chromogenic portion [F] of the dye molecule is given, the structure can be modified not only by altering the reactive residue [R], but also by altering the bridge between [F] and [R]. In the case of the reactive dyes of the triazine and pyrimidine series, which are synthesized from imide chlorides, the bridge is an imino group. It affects the resistance to hydrolysis and the reactivity of the dye through the reactivity of its hydrogen atom [26]. Aliphatic bridges, on the other hand, favor the adsorption on the surface of the substrate owing to their flexibility [26a].

The reactive dyes of the 4,5-dichloro-6-pyridazone series can be classified according to the nature of the bridges. In the azo dyes of Type I, which are prepared from the amines in Table 1, the chromophore [F] is linked to the 4,5-dichloro-6-pyridazonyl ring by a phenylene group. The dyes obtained by acylation with the acyl chlorides

I: 
II: 
III: 
(13), *(14)*, and *(17)*, on the other hand, contain a carboxamide or sulfonamide bridge linked to the pyridazone ring [R] by an aromatic (Type II) or aliphatic (Type III) group.

Thus these dyes are similar to the dichloroquinoxaline dyes of the ®Levafix-E series, which also contain a carboxamide bridge. However, *Rattee*'s view [25a] that the high color yield [*] of the dichloroquinoxaline dyes is partly due to their pronounced planar-angular structure, is not applicable to the 4,5-dichloro-6-pyridazone dyes. Here, the best coloristic properties are shown by the dyes of Type III, in which the residue [R] can move freely. This favors the adsorption process and the subsequent nucleophilic substitution of the reactive chlorine atom. The number of collisions appears to be higher for this type than for the more rigid dye molecules of Types I and II. Another advantage is that the conjugation is interrupted by the non-planarity of the molecule; consequently the chromogenic part and the reactive part of the dye do not affect each other, so that the dye exhibits good light-fastness.

c) Stability and Fixation of the Dyes

It was explained in Section I that the chlorine atom on C-4 of the pyridazone residue is responsible for the reactivity of the dyes discussed here.

The kinetics of the nucleophilic substitution are directly related to a number of questions concerning the application and synthesis of these dyes. Using the propionic acid derivative *(16)* as a model, the elimination of chloride ions was measured in 4% aqueous solution (*i.e.* roughly under the conditions prevailing in the dye bath) at various reaction times, temperatures, and pH values.

It can he seen from Figure 1 that, at pH 9, hydrolysis is observed only at elevated temperatures. In similar experiments with sodium hydrogen phosphate as a buffer (pH 8.5), no chloride ions were detected even after boiling (100 °C) for 20 hours. The same result is obtained on keeping the compound for 20 hours at 20–40 °C in Na_2CO_3 solution; under these conditions, chloride ions are formed only in the presence of stronger bases (above pH 10). Thus compound *(16)* is stable at 35 °C in sodium carbonate solution, but half of the chlorine is removed from C-4 after 3.5 hours in NaOH solution at 35 °C, and after 5 minutes at 60–65 °C.

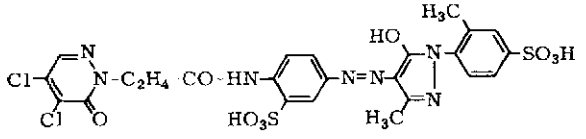
[26a] *H. Zollinger,* Chimia *15*, 186 (1961).

[*] The term color yield, or more accurately dyeing yield, denotes the proportion of a dye which remains on the fiber and cannot be washed off. In the case of the dyes discussed in the present paper, the dyeing yield is identical with the degree of fixation, *i.e.* the proportion of the dye which is attached to the fiber by homopolar bonds.

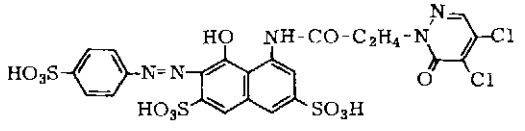
The half-reaction times for the hydrolysis of dyes (*i.e.* the time in which 50 % of the dye is hydrolysed) in various pH ranges have been determined by *Baumgarte* and *Feichtmayr* [27]. They concluded that the reaction proceeds by an S_N2 mechanism.

The fact that 4,5-dichloro-6-pyridazone dyes become attached to cotton and artificial wool very rapidly from alkaline printing pastes without special additives is of importance for their technical use.

Baumgarte and *Meyer* [27a] carried out a colorimetric determination of the color yield for a series of dichloropyridazone dyes, including the yellow dye *(23)* and the red dye *(24)*. The maximum yield was generally obtained after steaming for 3 minutes at 100 °C, or after 1 minute at 110 °C. Hot-air fixing at 150 °C gave yields of 50–60 % after 30 sec, and up to 75 % after 1 minute.



(23)



(24)

The storage life of the printing pastes is practically unlimited. Since the substantivity of the dyes is low, no difficulties are encountered in washing out unfixed dye.

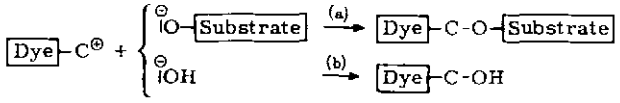
The dichloropyridazone dyes can also be used for dyeing cellulose fibers in a dye bath. However, their fixing power is not always sufficient for a number of new dyeing processes, in which reactive dyes are used under strongly alkaline conditions at room temperature.

These new reactive dyes are marketed as ®Primazin-P dyes. The letter "P" indicates that the dyes are pyridazone derivatives. They can be combined with all other reactive dyes.

II. Bonding of Dyes to Cellulose via Polyfunctional Bridges [*]

In order to produce homopolar bonds between dyes and high molecular-weight substrates (cellulose in particular) attempts were made to provide dyes with reactive groups which could assume a positive charge, *i.e.* form a carbonium ion, and which would thus be accessible to nucleophilic attack by the substrate. The reactive dye systems mentioned on page 312 have found wide application [1,2].

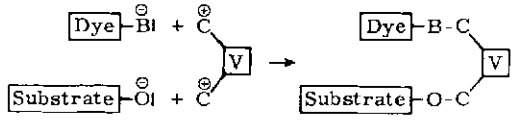
Besides the substrate, however, nucleophilic $OH^{\ominus}$ ions are also present during the dyeing process (Reaction a). Consequently, part of the reactive dye is always lost in hydrolytic side reactions (b) (see Scheme 1).



Scheme 1. Dyeing process (a) and hydrolytic side reaction (b) of the dye.

The color yield is therefore generally only 60–85 % [1]. Where hydrolysis of the reactive dye leads to water-insoluble products [2], the color yield is increased by the hydrolysis product deposited on the substrate. Reactive dyes which have been deactivated by hydrolysis are often substantively incorporated into the substrate, *i.e.* in the form of high molecular-weight aggregates [25]. This portion of the dye which is not fixed to the substrate by homopolar bonds reduces the fastness to wet processing and must be removed by thorough washing [1].

We therefore looked for reactions whereby dyes not containing reactive groups of this type could be attached by homopolar bonds to nucleophilic substrates in high yields. We found that even under the conditions used for dyeing and printing, color yields of up to about 90 % could be obtained by linking the dyes to the substrates *via* multifunctional, non-coloring bridges [V] (Scheme 2) [28]. In this process, dyes containing a *nucleophilic* group $-B:^{\ominus}$ and nucleophilic substrates such as the cellulose anion are reacted with bridge molecules containing several positively charged carbon atoms, to form mixed adducts. As can be seen from Scheme 2, the positively charged carbon atom is

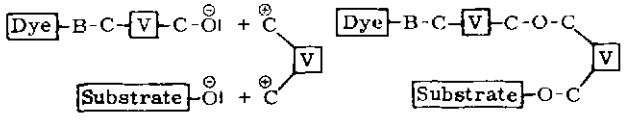


Scheme 2. Homopolar bonding between dye and substrate produced by a polyfunctional bridge molecule.

no longer supplied by the dye, but by the bridge. Consequently, any material lost by hydrolysis will be the bridge compound, and not the dye.

Since the dye and the component containing the positively charged carbon atoms can be used separately and in various proportions, the reaction of Scheme 2 can be made to yield higher degrees of fixation (cf. footnote on page 316 and Figure 2).

Even if some of the reactive groups of the polyfunctional bridge molecules have been deactivated by hydrolysis, the molecules can still take part in the reaction provided that two or more reactive groups are still available. Furthermore, hydrolysis of the bridge material yields compounds containing nucleophilic groups, which can themselves react with bridge molecules. One of the many conceivable combinations is shown in Scheme 3.



Scheme 3. Possible combinations of dye, substrate and bridge molecules.

[*] By *G. Lützel.*

[28] *G. Lützel, W. Rohland, A. Tartter, G. Barts, W. Dietrich, R. Müller*, and *W. Federkiel*, German Published Patent Application 1155088 (Nov. 2nd, 1960), BASF.

Imide chlorides such as cyanuric chloride and its reaction products with amines or phenols [29–31], as well as a number of compounds containing epoxide [32,33], sulfate, or halogenoalkyl groups [33] have previously been described as bridging compounds. However, yields were unsatisfactory with compounds of these types.

Several experimental results support the assumption that new homopolar bonds are formed in reactions according to Schemes 2 or 3. Thus the cotton dyes obtained with 1,3,5-tris-(β-chloropropionyl)hexahydro-s-triazine *(34c)*, 2,4,6-trisethylenimino-s-triazine *(29)* (triethylenemelmine), or bis(acryloylamino)methane *(25)* (methylenebisacrylamide) as the bridge compound are extremely fast to wet processing; the dye cannot be removed even by boiling dimethylformamide. Cellulose which has been treated in this way, in contrast to the untreated fabric, is extremely difficult to dissolve in cuprammonium solution. On the other hand, non-substantive dyes, which were applied to cotton under similar conditions but do not form bridges, can be completely removed by washing with water. Moreover, we were able to detect homopolar linkages between water-soluble cellulose models (β-dextrins) and dyes by chromatography [34].

1. Bridge Compounds

Compounds suitable as bridges must be able to form at least two positively charged carbon atoms which are accessible to nucleophilic attack. Multifunctional compounds of this type [*(25)–(33)*, *(34a)–(34m)*] contain, for example, polarized C=C double bonds, three-membered heterocyclic rings which are capable of undergoing addition, or reactive halogen atoms. We have synthesized such compounds [*(26)*, *(30)–(33)*, *(34e)*, *(34h)*] and compared their reactivities using the color yields on cotton as a basis.

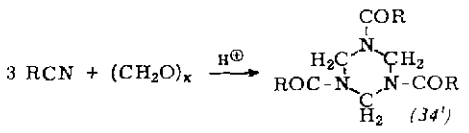
a) Preparation

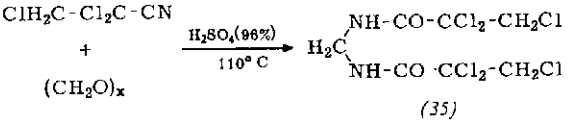
The 1,3,5-triacylhexahydro-s-triazines *(34)* were prepared by the method decribed by *Wegler* and *Ballauf* [46–48], from nitriles and paraformaldehyde or trioxane in anhydrous media and in the presence of strongly



(34')

acidic condensing agents, or [*e.g. (34f)* and *(34l)*] by nucleophilic addition to *(34a)*. The sulfur analogue *(34e)* is formed by the proton-catalysed condensation of vinylsulfonamide with paraformaldehyde [53].

The reaction of nitriles with paraformaldehyde in the presence of water leads to bis(acylamino)methanes [48]. However, some of these compounds can also be obtained in yields of up to 85% from nitriles in anhydrous media. For example, the cyclization of α,β-dichloropropionitrile leads to 1,3,5-tris-(α,β-dichloropropionyl)-hexahydro-s-triazine *(34d)*, which had previously been obtainable only by addition of halogen onto the α,β-unsaturated precursor *(34a)* [49], while the same reaction of α,α,β-trichloropropionitrile [61] yields bis-(α,α,β-trichloropropionylamino)methane *(35)*, m.p. 161 °C; NH bands at 1520 and 3340 cm^{-1}.



(35)

b) Reactions

In general compounds such as *(25)–(34')* react with groups which can be cyanoethylated. These include NH, SH, OH, or activated CH_2 groups. However, only a limited comparison can be drawn between cyanoethylation and the formation of homopolar bonds during the dyeing process, owing to the presence of water in the latter.

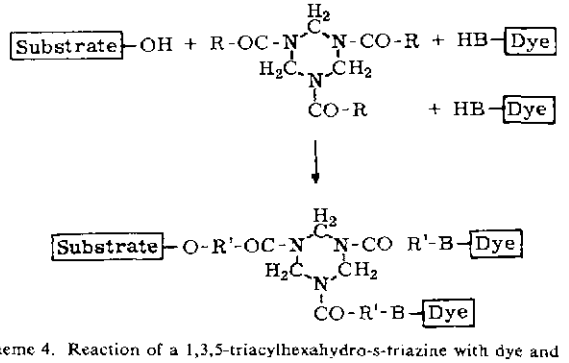
The best color yields were obtained with 1,3,5-triacylhexahydro-s-triazines *(34)*. These compounds are particularly effective as bridging groups for the following reasons:

1. The three substituents are very mobile, as can be seen from Stuart models.

2. The carbonyl groups have a strong polarizing effect.

3. If a halogen atom of the aromatic 2,4,6-trichloro-s-triazine is replaced by another substituent, the reactivities of the remaining halogen atoms decreases. On the other hand, the reactivity of the substituents on the non-aromatic hexahydro-s-triazine skeleton is not appreciably altered when some of these substituents react with other groups [62].

The reaction of a 1,3,5-triacylhexahydro-s-triazine *(34')* with nucleophilic dyes and substrates is shown in a simplified form in Scheme 4.



Scheme 4. Reaction of a 1,3,5-triacylhexahydro-s-triazine with dye and substrate molecules.

If we assume that each of the three reactive groups can react with equal probability with each of three partners (substrate, dye, water), then there are $3^3 = 27$ possible adducts, only 12 (= 44.5%) of which correspond to a dye-substrate compound. However, the color yields [27a] as found by spectrophotometry of dye cellulose compounds in concentrated phosphoric acid [63] are much higher than would be expected from this figure, values of about 90% being obtained with many dyes under optimum conditions. Thus hydrolysis is largely suppressed.

[63] *E. Rexroth,* BASF, personal communication.

Bifunctional bis(acylamino)alkanes such as *(25)–(27)* generally give lower color yields than the 1,3,5-triacylhexahydro-s-triazines *(34a)–(34d)*. α-Methyl-substituted analogues such as bis(methacryloylamino)methane [59] or 1,3,5-tris(methacryloyl)hexahydro-s-triazine, in contrast to *e.g.* the α-halogen compound *(34b)*, form practically no covalent bonds with dyes containing nucleophilic groups under the conditions used in dyeing (cf. Section II.4).

The color yield is also much lower in the case of 1,3,5-tris-(vinylacetyl)hexahydro-s-triazine [60], where the conjugation between the carbonyl group and the double bond is interrupted by a methylene group, than with the α,β-unsaturated or β-halogenated 1,3,5-triacylhexahydro-s-triazines, *e.g.(34a)* and *(34c)*.

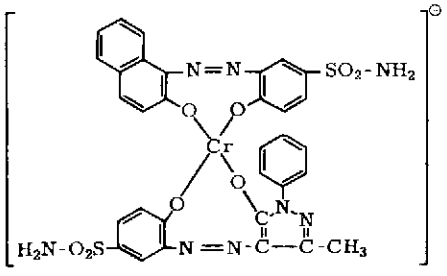
The color yield obtained with halogenomethylbenzoyl derivatives falls off rapidly with increasing halogenation. 1,3,5-Tris-(*p*-trichloromethylbenzoyl)hexahydro-s-triazine, m.p. 220–221 °C, unlike the *p*-chloromethylbenzoyl compound *(34i)*, gave practically no dyeing effect. Similar behavior is observed with bis-(α,α,β-trichloropropionylamino)methane *(35)*, as compared with *(25)*.

2. Dyes

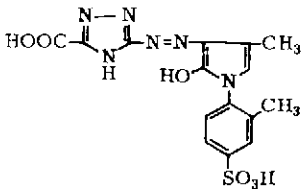
Dyes or substances which are to be reacted in accordance with Scheme 4 must contain nucleophilic groups, such as primary or secondary amino groups, sulfonamido or *N*-monosubstituted sulfonamido groups, hydroxy or mercapto groups, acetoacetyl groups, or heterocyclic systems with NH groups in the ring.

However, it is impossible to predict the color yield. The nucleophilic character of the groups containing active protons cannot be used as a basis for estimations, since the yield also depends on the number and position of the nucleophilic groups in the dye and substrate, on adjacent substituents, the diffusibility of the dye, and the spatial orientation of the dye with respect to the substrate (cf. also Section II 4). Dyes containing sulfonamido [*(36)*, brown] [64,65], aminoalkylsulfonamido [66], acetoacetyl [*(37)*, red] [67], or OH groups [*(38)*, red], heterocyclic compounds with NH groups [*(39a)*, yellow] [35], as well as dyes which are derivatives of triazole, pyrazole [*(39b)*, red] [35], indole, or imidazole, generally give good color yields.

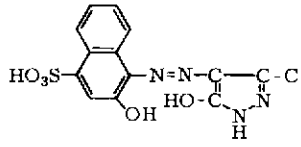
To obtain homopolar bonding of the dyes *(36)–(39)* with cellulose, cotton fabrics are impregnated with an aqueous solution containing *e.g.* 20 g/l of dye, 10–20 g/l of bis(acryloylamino)methane *(25)*, and 10 g/l of sodium carbonate or 10 g/l of a 32 % sodium hydroxide solution; the impregnated fiber is then dried, steamed for 5 min, and washed in boiling soap solution.



(36) [64]

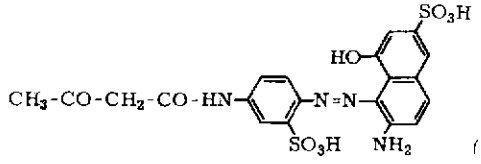


(39a) [35]

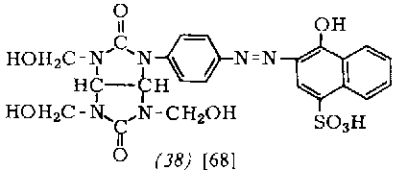


(1:2 Cr-complex)

(39b) [35]



(37) [67]



(38) [68]

3. Substrates

The substrates must also contain or form groupings capable of nucleophilic attack at the positively charged carbon atoms of the bridge molecule. Examples are the hydroxy groups of polysaccharides and the amino or mercapto groups of natural polyamides, as well as their ions.

We have used the reaction (Scheme 4) mainly for the dyeing of cellulose. However, the results are applicable to other substrates containing hydroxy groups, such as paper, ®Cellophane film, wheat starch, or β-dextrin [34] (a cyclic compound consisting of seven glucose units). High molecular-weight polyamides such as wool or silk often give somewhat lower color yields than cellulose.

4. Dyeing of Cellulose

Hexahydro-s-triazine derivatives possess no appreciable substantivity. For this reason, bridges of this type are mainly used in impregnating processes (printing, pad dyeing), in which substantivity is undesirable. The substrate is impregnated with aqueous solutions or printing pastes containing the dye, the bridge compound, and an alkaline catalyst. In the first step the catalyst removes protons from the dye and the substrate, thus forming the nucleophilic centers:

[64] *H. Pfitzner*, German Pat. 742939 (Dec. 28th, 1938), BASF; Chem. Zbl. *44*, I, 1331.

[65] *F. Graser, D. Weiser, G. Lützel*, and *W. Rohland*, Belg. Pat. 631584 (Apr. 26th, 1963), BASF.

[66] *A. Tartter, G. Lützel*, and *W. Rohland*, French Pat. 1336945 (Aug. 30th, 1962), BASF.

[67] *H. Baumann* and *G. Lützel*, BASF, unpublished work.

Basic compounds which are themselves strongly nucleophilic, *e.g.* ethylenediamine or hexamethylenediamine, displace other reactants (*e.g.* cellulose) from the reaction. Consequently, the most suitable catalysts are those which do not form groupings more nucleophilic than hydroxide ions under the reaction conditions. The most important of such compounds are inorganic bases and their alkaline salts such as Na_2CO_3, $NaHCO_3$ *etc.*, as well as pyridine or ®Triton B (benzyltrimethylammonium hydroxide).

If one of the components is insoluble in water, it is used in a water-miscible solvent, *e.g.* dimethylformamide. In the case of moderately soluble compounds, it is often sufficient to deposit these on the substrate in a finely divided form; they dissolve on steaming for a few minutes.

The dye and the bridge component can also be applied in succession from different solvents. After drying, the reaction is started by raising the temperature. This is followed by washing in order to remove additives, alkalis, and unbonded dye from the substrate.

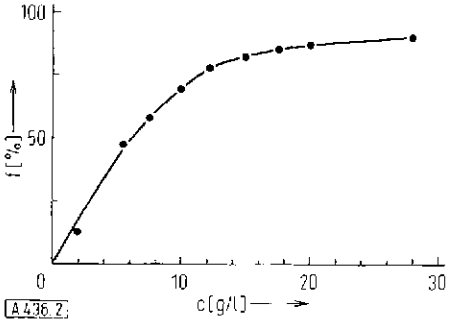


Fig. 2. Color yield (f) for printing of cotton with the 1:2 chromium complex of dye *(39b)* and the bridge component *(34a)* [27a]. (Dye concentration: 30 g/kg of printing paste.)

Abscissa: Concentration of bridge component *(34a)* [g/l].

Ordinate: Color yield f [%].

The color yield for a given dye depends on the nature and quantity of the bridge component used. 1,3,5-Triacylhexahydro-s-triazines *(34)* with the dyes *(36)–(39)* give maximum yields at dye/bridge component ratios as low as about 2:1 to 3:2 (cf. Figure 2). It is therefore possible in practice to work with a constant dye/bridge component ratio of about 2:1.

In the case of very dilute dye solutions (less than about 10 g/l), the concentration of bridge component should not be less than 6–10 g/l, to compensate for hydrolysis. The color yields then are unusually high.

The reaction time required for maximum yield depends, as with reactive dyes, on the application method (printing, dyeing), the nature of the heat supply (steaming, dry heat, contact heating [*]), the temperature, and the presence of additives (*e.g.* urea) (cf. Table 2). Many dyes

Table 2. Approximate reaction times for the linkage of bridge component, substrate, and dye.

Steaming at:		Dry heat at:	
102 °C	110 °C	150 °C	190 °C
3 min	45 sec	3 min	1 min

and bridge components give high color yields after steaming at 100 to 110 °C for only 30 to 60 sec. Such dyes can be applied by the technically important shortfixing process, in which the textile is passed through special steaming equipment (*e.g.* arch steamers) with residence times of only about 60 sec.

The reaction can even be carried out at room temperature, *e.g.* with the dye *(39a)*, by impregnating the substrate (*e.g.* cotton) with an alkaline solution of the dye, bridge component, and neutral salts, and by storing it in the wet state for 15 hours.

Thus it is possible, with the aid of the bridge components described, to form very fast homopolar bonds between cellulose and dyes containing nucleophilic groups. Good results have already been obtained using the new series of ®Basazol dyes [69]. The separate handling of the dye and the bridge component offers advantages over the use of reactive dyes, particularly in printing and impregnating processes.

Metal Chelates as Polymerization Initiators

BY DR. E.-G. KASTNING, DR. H. NAARMANN, DR. H. REIS, AND DR. C. BERDING

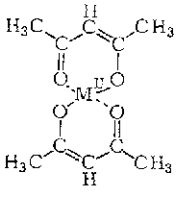
BADISCHE ANILIN- & SODA-FABRIK AG., LUDWIGSHAFEN/RHEIN (GERMANY)

Published on the occasion of the 100th anniversary of the establishment of Badische Anilin- & Soda-Fabrik AG., on April 6th, 1965.

Metal chelates can be used as initiators in the polymerization of vinyl compounds. Their action, as shown here for the polymerization of styrene, is determined by both the central atom and the ligand. Chelates of manganese(III) and cobalt(III) with 1,3-dicarbonyl compounds are most effective. The metal chelate initiators can be activated by γ- or ultraviolet irradiation, or else by combination with cocatalysts such as organic halogen compounds or unsaturated hydrocarbons which are typical π-complex formers. There is some evidence indicating that the polymerization takes place via a free-radical mechanism. The central metal atom affects the steric configuration of the polymer chain.

Metal chelates have long been known and are relatively easy to prepare [1]. As far as polymers are concerned, some metal chelates, *e.g.* those of cobalt, manganese, and copper, have been known to promote the air-hardening of lacquers and varnish resins (siccatives). When combined with metal alkyls, the acetylacetonates of titanium, vanadium, or cobalt form Ziegler-Natta catalysts for the polymerization of olefins. Moreover, metal chelates promote the polyaddition of organic isocyanates [2]. Their solubility in organic liquids makes them particularly useful.

Polyethylene was unexpectedly obtained by using acetylacetonates *(1)* of Group VIII metals as catalysts in the cyclooligomerization of ethylene. This result gave the impetus for an investigation of the initiation of vinyl



(1)

polymerization by metal chelates. Since both the central atom and the ligand may be varied, the number of metal chelates available is almost unlimited.

1. Efficiency of Metal Chelates as Polymerization Initiators

The initiating efficiency as a function of the central atom and of the ligand was investigated in the case of the polymerization of styrene. Unstabilized styrene was heated for 1 hour with 0.5 % by weight of the metal chelate in an atmosphere of nitrogen, and the conversion into polystyrene was determined.

a) Effect of the Central Atom

As shown by Fig. 1 and Table 1, of all the metal acetylacetonates examined, those containing metals of Groups VII and VIII gave the highest yields of polystyrene, the complexes of manganese(III) and cobalt(III) being particularly effective. The rate of polymerization with manganese(III) acetylacetonate is comparable to that obtained by using di-t-butyl peroxide as an initiator (cf. Fig. 1). In the case of metals which can exist in more than one valence state, the chelate containing the metal in the higher valence state is always more active. Among the less active metal acetylacetonates, which are listed in

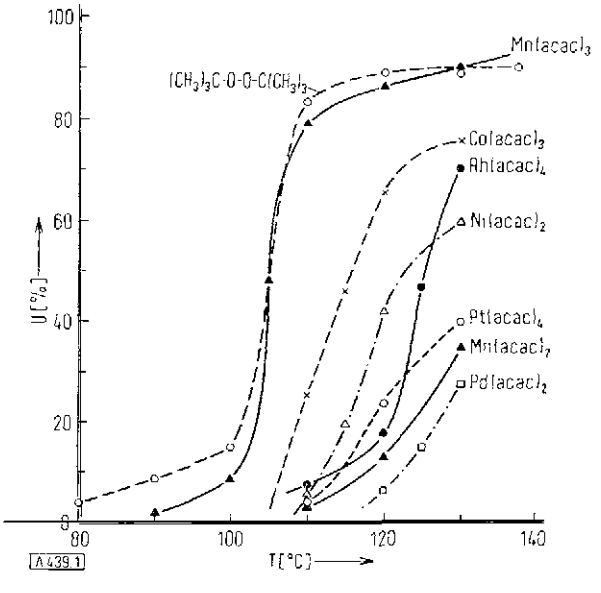


Fig. 1. Polymerization of styrene using metal acetylacetonates as initiators. The percentage of conversion U as a function of the temperature T. acac = Acetylacetonyl. (Duration of polymerization 1 hour, initiator concentration 0.5 % by weight.)

[1] *F. Gach*, Mh. Chem. *21*, 89 (1900).

[2] Brit. Pat. 886636 (Sept. 2nd, 1959), inventors: *D. M. O'Mant* and *H. J. Twitcheff*, Imperial Chemical Industries.

Table 1, only those containing ruthenium(III) and iron(III) still exhibit considerable catalytic activity. The conversions effected by the other metal acetylacetonates lie within the limits of error of the thermally initiated polymerization of styrene.

Table 1. Polymerization of styrene using metal acetylacetonates. (Duration of polymerization 1 hour, initiator concentration 0.5 % by weight.)

Polymerization with	Conversion [%]

[*] acac = Acetylacetonyl.

b) Effect of the Ligands

Figure 2 shows that the chelates of manganese(III) with 1,3-dicarbonyl and aminocarboxylic compounds are the most effective. Even the manganese(III) complexes that are not chelates have a slight initiating effect. Under the same conditions, the polymerization of styrene by thermal initiation alone proceeds at a rate several times slower (cf. the last line in Table 1).

The initiator activity of the metal chelates of 1,3-dicarbonyl compounds steadily increases from the dibenzoylmethane complex to the ethyl acetoacetate complex

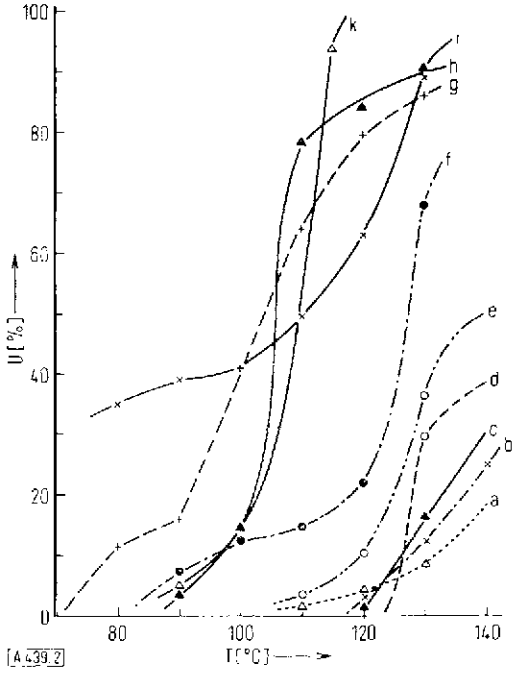

Fig. 2. Polymerization of styrene using manganese chelates as initiators. The percentage of conversion U as a function of the temperature T. (Duration of polymerization 1 hour, initiator concentration 0.5 % by weight.)

a: K_2MnCl_5; b: $K_3Mn(CN)_6$; c: Mn(III) oxalate; d: Mn(II) oxinate; e: Mn(II) acetylacetonate; f: Mn(III) *N*-hydroxymethylcaprolactam; g: Mn(III) anthranilate; h: Mn(III) acetylacetonate; i: Mn(III) 3-methylbut-1-en-3-yl acetoacetate enoxide; k: Mn(III) glycinate.

(Fig. 3). However, the stability constants of the complexes decrease in the same order, as shown by *Calvin* and *Wilson* [3,4] for copper(II) chelates. Obviously there is a connection between the stability of the complexes and their initiating action. A similar connection has been found in the case of the 1,3-dicarbonyl chelates of cobalt(III) and copper(II).

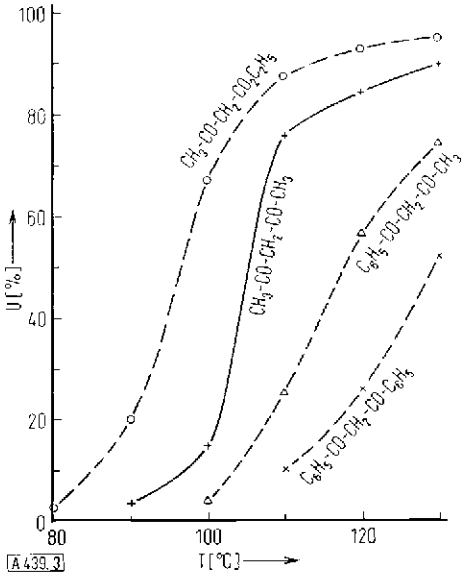

Fig. 3. Polymerization of styrene initiated by the manganese(III) chelates of various 1,3-dicarbonyl compounds. (Duration of polymerization 1 hour, initiator concentration 0.5 % by weight.)

Metal chelates of 3-methylbut-1-en-3-yl acetoacetate are even more active than those of ethyl acetoacetate; manganese(III) chelates of 3-methylbut-1-en-3-yl acetoacetate, for example, give a conversion of about 30% at 70–80 °C (Fig. 2).

When the ethyl residue in ethyl acetoacetate is replaced by the 3-methylbut-1-en-3-yl residue, the contribution of the carbonyl group to the resonance of the ester group increases, while the resonance in the chelate ring decreases. This leads to a further destabilization of these chelates, but stability constants are still unknown.

2. Activation of the Metal Chelate Initiators

A disadvantage of polymerization by metal chelates is that relatively high temperatures must be employed. We have therefore tried to activate the metal chelate initiators by irradiation and by additives.

a) Activation by Irradiation

The crystalline metal chelates were exposed to ultraviolet light or to γ-rays in the absence of air, and were then used immediately to initiate the polymerization of styrene. For the ultraviolet irradiation (60 minutes) a mercury vapor quartz lamp (Quarzlampen-Gesellschaft, Hanau, Model S 80) was used and for the γ-irradiation a ^{60}Co

[3] *M. Calvin* and *K. W. Wilson*, J. Amer. chem. Soc. *67*, 2003 (1945).

[4] *A. E. Martell* and *M. Calvin*: Die Chemie der Metallchelat-Verbindungen. Verlag Chemie, Weinheim/Bergstr. 1958, pp. 140, 150.

source (doses 10^2 to 10^6 r). On γ-irradiation the activity of the initiator increased as the doses were raised to about 10^3 r, after which it remained practically constant up to doses of 10^6 r. Figure 4 shows the activation obtained by irradiation of manganese(III) acetylacetonate. In the polymerization of styrene, the temperature at which the reaction begins is appreciably reduced (by about 20 °C) only by γ-irradiation of the initiator. Ultraviolet irradiation results in only very slight activation.

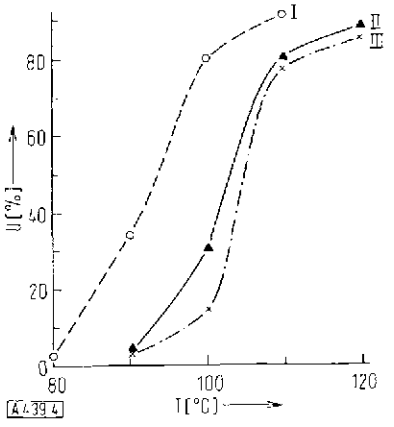

Fig. 4. Polymerization of styrene initiated by irradiated manganese(III) acetylacetonate. (Duration of polymerization 1 hour, initiator concentration 0.5 % by weight.)

Curve I: activation with γ-rays of 10^3 r.
Curve II: activation with ultraviolet light (Hg vapor lamp, 60 minutes).
Curve III: unirradiated reference sample.

b) Chemical Activation

The greatest increase in activity is reached by the addition of organic balogen compounds, such as hexachloroethane, carbon tetrachloride, chloroform, n-butyl chloride, or n-amyl chloride (see Tables 2 and 3), or of unsaturated hydrocarbons, *e.g.* 1,5-cyclooctadiene, 1,3-cyclooctadiene, 1,5,9-cyclododecatriene, or cycloheptatriene, which are typical π-complex formers [5]. *Teyssié* and *Dauby* [6] have recently shown that the emulsion polymerization of butadiene, initiated by rhodium(III) chloride, is also accelerated by the addition of 1,3-cyclobexadiene. A smaller increase in activity results from the use of the halides of aluminum, magnesium, and zinc, as well as from the addition of ketones, amines, phosphites, or carbon disulfide (see Table 3).

Table 2. Activation of manganese(III) acetylacetonate for the polymerization of styrene at 100 °C. (Duration of polymerization 1 hour, initiator concentration 0.5 % by weight, activator concentration 0.5 % by weight.)

γ-Irradiation	80
1,3-Cyclooctadiene	63
Triphenylphosphine	60
Triphenylphosphite	40
Sodium hypophosphite	30
Benzil	20
No activator	9

The best activation is achieved with an approximately equimolar mixture of the metal chelate and the activator. The effects of various methods of activation on the rate of polymerization are compared in Table 3, the data being based on the polymerization of styrene with manganese(III) acetylacetonate.

Both in the presence and in the absence of an activator, the rate of polymerization is proportional to the square root of the initiator concentration (Fig. 5).

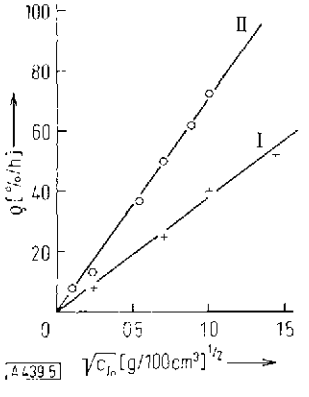

Fig. 5. Rate of the polymerization (ρ) of styrene at 110 °C as a function of the concentration of the metal chelate (c_{In}).

Curve I: non-activated cobalt(III) acetylacetonate as the initiator;
Curve II: cobalt(III) acetylacetonate activated by carbon tetrachloride, the ratio of initiator: activator being 1:1 by weight.

The polymerizations of acrylic esters, methacrylic esters, vinyl esters, ethylene, and butadiene can also be initiated by metal chelates, the results being similar to those obtained with styrene.

[6] *Ph. Teyssié* and *R. Dauby*, Polymer Letters *2*, 413 (1964).

3. Homo- and Copolymerization of Some Monomers

a) Homopolymerization of Olefins

Ethylene is converted into high-molecular weight polymers, when it is polymerized with metal chelates under a pressure of more than 300 atm and at temperatures above 80 °C. The results obtained with different chelates are reproduced in Table 4. The 1,3-dicarbonyl complexes of trivalent manganese and cobalt are again distinguished by high activity, which is further increased by activating additives. The number of CH_3 groups per 1000 carbon atoms of the polymer (Column 3 of Table 4) lies between 5 and 30, and the density varies between 0.928 and 0.958 g/cm³. Polyethylenes containing 10 to 20 methyl groups per 1000 carbon atoms and having densities between 0.94 and 0.95 g/cm³ can be prepared with particular ease.

Table 4. Polymerization of ethylene with metal chelates (duration 1 hour). The experiments at 1500 atm (upper part of the table) were carried out in a 300-ml autoclave at 145 °C with 0.1 g of initiator in 50 ml of n-hexane, and the experiments at 600 atm (lower part of the table) were carried out in a 50-l container at 125 °C with 4 g of initiator in 20 l petroleum ether.

b) Homopolymerization of Diolefins

The polymerizations of butadiene and isoprene initiated by metal chelates lead to particularly interesting polymers. Soluble, high-molecular polybutadiene is obtained by solution polymerization of butadiene. Depending on the central atom of the chelate, the product has up to 60 % of 1,4-*cis* and about 10 % of 1,2-vinyl configuration. The highest *cis* yield is reached with manganese(III) chelates, while cobalt(III) chelates and copper(II) chelates result in about 50 % and about 30 % of 1,4-*cis* yield, respectively. These polybutadienes differ substantially from those obtained with rhodium(III) salts [8,9], the latter leading to over 90 % of the 1,4-*trans* configuration.

The emulsion polymerization of butadiene proceeds at a considerably higher rate, at a lower temperature, and gives a higher conversion than the solution polymerization. The resulting high-molecular weight polymers are free from gels, and their steric compositition is similar to that of the polymers obtained in solution. In contrast to the solution polymerization which requires a temperature of 80 to 100 °C, the emulsion polymerization is carried out between 30 and 60 °C and in the presence of the usual emulsifiers. Chelates activated by halogen compounds are particularly suitable initiators. Butadiene is polymerized, as in the well-known SBR process [*], with a conversion of about 60 %. The K-values [7] of the products lie between 80 and 100. They increase with the conversion, reaching their final values at a conversion of about 60 %. The use of peroxide initiators in the emulsion polymerization of butadien under similar conditions leads to a polybutadiene with an appreciable gel fraction [9a], the product being sterically completely different (cf. Table 5) and unsuitable for use as raw material in the manufacture of rubber.

Table 5. Emulsion polymerization of butadiene at 50 °C, activated by carbon tetrachloride. The configuration was determined by infrared spectroscopy [9b].

Initiator	K-value (1 % in benzene)	Yield of 1,4-*cis* product [%]	Yield of 1,4-*trans* product [%]	Yield of 1,2-vinyl product [%]
Mn(III) acetylacetonate	91	55	38	7
Co(III) acetylacetonate	89.5	45	41	14
Cu(II) acetylacetonate	80.5	32	52	16
Peroxide	insol.	13	65	22

The technological characteristics of rubber (Mooney plasticity, "defo" value) [9c] can be adjusted within wide limits by varying the conditions of the polymerization (initiator concentration, type and amount of activator, regulator, and the conversion of butadiene). As regards its mechanical properties, polybutadiene rubber prepared with metal chelates is similar to the commercial SBR copolymers made of about 75 % of butadiene and 25 % of styrene. The behavior of the homobutadienes at low temperatures is, however, far superior, because their glass temperature [9d] is lower by about 30 °C than those of the copolymers.

[7] The K-value equals 10^3 k, when k is defined by *Fikentscher*'s viscosity equation:
$\log z = c\,[k + 75\,k^2/(1 + 1.5\,kc)]$
where z = relative viscosity; c = concentration of polymer [g/100 cm³]; k = constant. – *H. Fikentscher*, Cellulosechemie *13*, 58 (1932).

[9a] "Gel fraction" is the polymer fraction which does not dissolve in benzene at 25 °C.

[9b] *H. Günzler* and *G. Schnell*, BASF.

[9c] For an explanation of these parameters, see *S. Boström*: Kautschuk-Handbuch. Berliner Union, Stuttgart 1962, Vol. 5, pp. 84–86.

[9d] The glass temperature is the temperature of transition from the liquid or elastic state to the glass-like state of the polymer.

In conclusion it can be stated that the polybutadienes obtained with metal chelates differ from both the SBR products and the sterically uniform polybutadienes prepared with the aid of organometallic initiators.

c) Copolymerization

Some monomeric vinyl compounds can be copolymerized using metal chelates even when the conventional radical initiators fail or present difficulties. For example, heating (80 °C) of a mixture of equal parts by weight of styrene and vinyl acetate in the presence of manganese(III) acetylacetonate yields a styrene-vinyl acetate copolymer containing 28 % by weight of vinyl acetate. Ethylene and styrene can be copolymerized at a temperature of 100 to 150 °C and an ethylene pressure of 1000 to 1600 atm.

Homogeneous copolymers are obtained when the amount of styrene is between 1.5 and 15 % by weight, or over 90 % by weight. Mixtures of polymers are formed in the intermediate region. The crystallinity of the copolymers with a predominant ethylene fraction depends on their styrene content.

The products whose styrene content predominates are transparent, but have lower softening points than polystyrene. Both the transparency and the temperature dependence of the mechanical shear modulus and of the mechanical loss modulus derived from the former [10] indicate homogeneous copolymers (cf. Figures 6a and 6b).

The presence of ethylene reduces the damping maximum from about 105 to about 80 °C, and correspondingly, the decrease in the shear modulus begins at a temperature about 25 °C lower. Moreover, the maximum which can be attributed to the beginning of rotation of longer CH_2-sequences and which is known from polyethylene occurs at −150 °C.

Vinyl ether, which does not homopolymerize with metal chelates, can be copolymerized with ethylene up to about 30 % by weight (see Table 6).

Table 6. Data relating to the copolymerization of ethylene and vinyl ether. (Duration of polymerization 1 hour, initiator 0.3 % by weight of manganese(III) acetylacetonate + 0.3 % by weight of chloroform.)

	p [atm]	T [°C]	Yield [g of polymer/g of initiator]	Vinyl ether units [%]
15 g Vinyl methyl ether	1570	128	970	1.5
40 g Vinyl ethyl ether	1500	150	400	10

4. Discussion

The mechanism of "vinyl polymerization" initiated by metal chelates has not yet been established beyond doubt. However, numerous observations point to a free-radical mechanism: for example, the copolymerization of equimolecular mixtures of styrene and methyl methacrylate results in copolymers whose composition is the same as that of the monomer mixture. *Walling* [11] believes that this indicates a free-radical mechanism and rules out an ionic one. A purely ionic mechanism is also disproved by the fact that the polymerization proceeds in an aqueous medium at a considerably higher rate, although the initiators dissolve preferentially in the organic phase.

Bamford [12] points out that polar vinyl compounds polymerize *via* a free-radical mechanism when mixed with metal carbonyl compounds containing formally zerovalent metals and with organic polyhalogen compounds. In the course of this polymerization, a halogen atom is cleaved off the halogen compound, accompanied by the oxidation of the metal atom, thus giving rise to an initiating halogenalkyl radical. The liberation of the halogen can also be effected by copper(I) acetylacetonate, or a finely divided metal. No change in the valence state of the central metal atom has however been established in the chelate-initiated vinyl polymerizations described here. Valence change occurs only when the polymerization temperature exceeds the decomposition temperature of the metal chelate, and a lower valence state is then formed, as for example in the case of cobalt(III) chelates at about 150 °C. After the valence state has changed, the rate of polymerization decreases to the value which would be obtained with the chelate containing the metal in the lower valence state.

It has been established by infrared spectroscopy and by labelling the ligands with ^{14}C that the ligand combines with the polymer. Although no statement can be inferred

[11] *C. Walling, E. R. Briggs, W. Cummings*, and *F. R. Mayo*, J. Amer. chem. Soc. *72*, 48 (1950).

[12] *C. H. Bamford, M. S. Blackie*, and *C. A. Finch*, Chem. and Ind. *1962*, 1763.

from this fact as to the mechanism, the observation is nevertheless compatible with the assumption that the polymerization might be initiated by free radicals originating from the ligands.

It must however be mentioned that the polymers prepared with the aid of metal chelates differ sterically in many respects from those obtained by the use of free-radical initiators, such as peroxides and azo compounds (cf. the steric differences in polybutadiene shown in Table 5). Poly(methyl methacrylate) polymerized with metal chelates is substantially isotactic and has a glass temperature of 78 °C. In contrast, poly(methyl methacrylate) prepared by peroxide-initiated polymerization has a predominantly syndiotactic structure and a glass temperature of 98 °C.

The steric structure of the polymers has been shown to be independent of both the ligands and the activating additives, which affect only the rate of the polymerization, *i.e.* the rate of initiation. Only the central metal atom of the chelate can therefore be responsible for the steric structure of the polymers [13]. Similar observations have been reported by *Bamford* [12]. Metal ions were also described by *H. P. Smith* [14] as influencing the steric structure of polybutadiene in peroxide-initiated free-radical polymerizations

Recent Results in the Catalytic Oligomerization and Co-oligomerization of Butadiene

BY DR. HERBERT MÜLLER, DR. D. WITTENBERG, DR. H. SEIBT, AND DR. E. SCHARF

HAUPTLABORATORIUM DER BADISCHEN ANILIN- & SODA-FABRIK AG., LUDWIGSHAFEN/RHEIN (GERMANY)

Published on the occasion of the 100th anniversary of the establishment of Badische Anilin- & Soda-Fabrik AG., on April 6th, 1965.

A number of new catalyst systems based on transition-metal compounds have been developed for the oligomerization and co-oligomerization of butadiene. These catalysts promote dienylations and the formation of other C–C linkages, and make possible the synthesis of new open-chain and cyclic compounds from butadiene.

I. Introduction

As a result of investigations on the thermal oligomerization of butadiene, a number of cyclic hydrocarbons which are difficult to obtain by other methods, such as 1-vinyl-3-cyclohexene, 1,5-cyclooctadiene, and *trans*-1,2-divinylcyclobutane, can now be easily prepared [1]. These products are accompanied, according to *Reed*, by small quantities of n-1,3,7-octatriene, formed by open-chain linkage of two butadiene molecules. Although the cyclic hydrocarbons are formed from butadiene in a remarkably simple manner, the reaction conditions and the yields make the thermal oligomerization unsuitable for large-scale syntheses. However, various groups of workers have recently discovered catalysts which permit the highly selective oligomerization of butadiene under simpler conditions. Our work in this field is reported in the present paper.

II. The Dimerization of Butadiene

a) Cyclodimerization to 1,5-Cyclooctadiene

The dimerization of butadiene to cyclooctadiene in the presence of nickel catalysts was first described briefly by *Foster* [2]. Shortly afterwards, *Reed* [3] dimerized butadiene with the catalysts used by *Reppe* et al. [4] for the cyclization of acetylene. 1,5-Cyclooctadiene was obtained in 30–40 % yields when nickel carbonyl phosphines and nickel carbonyl phosphites were used. *Reed* also found that the activity of the catalysts was increased by addition of acetylene, and

that co-oligomers of butadiene and acetylene were formed as by-products. Investigations described in a series of patents [5] were primarily concerned with the activation of Reppe catalysts by unsaturated hydrocarbons. *Reed* had suspected that the true catalyst was formed by displacement of carbon monoxide from the nickel carbonyl complexes by olefins or acetylene, since his experiments had shown nickel carbonyl itself to be catalytically inactive. *Wilke* [6, 7] finally succeded in showing that nickel catalysts containing no carbonyl groups are indeed the most active, and that the catalysts are poisoned by carbon monoxide. He used complexes of nickel(0), which he obtained by reduction of nickel salts with metal alkyls in the presence of electron donors, and which enabled him to carry out selective syntheses of cyclooctadiene or cyclododecatriene [8].

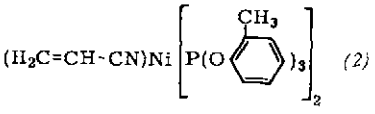
Despite previous failures and assumptions, we attempted to use nickel carbonyl as catalyst. If the displacement of carbon monoxide from nickel carbonyl by butadiene leads to an equilibrium, a sufficiently large excess of olefin and removal of the carbon monoxide formed should displace the equilibrium to such an extent as to lead ultimately to the formation of an active catalyst.

We found that nickel carbonyl dissolved in 1,5-cyclooctadiene rapidly loses up to two molecules of carbon monoxide at 100 °C, presumably with formation of cyclooctadienenickel(0) dicarbonyl. This complex is unstable and is catalytically inactive. Attempts to replace further carbonyl groups with 1,5-cyclooctadiene lead to rapid decomposition of the complex with separation of nickel. However, the complex can react in dilute solutions with excess butadiene if the carbon monoxide liberated is removed from the system. The product of this reaction is a catalyst solution which is suitable for oligomerization of butadiene [9].

During the synthesis of cyclic oligomers of butadiene by a continuous process with nickel carbonyl as catalyst, excess cyclooctadiene and butadiene are present in the reaction vessel. If nickel carbonyl is now introduced continuously, its carbonyl groups are displaced as described above, provided the carbon monoxide liberated is also removed continuously. If the process is discontinuous, it is necessary to generate the catalyst in a separate step. In a continuous synthesis in a pilot-plant, we have succeeded in oligomerizing about 800 kg of butadiene per mole of nickel carbonyl. Here 85–90% of the butadiene was cyclized to 1,5-cyclooctadiene and *trans*, *trans*,*trans*-1,5,9-cyclododecatriene. 1-Vinyl-3-cyclohexene and higher oligomers of butadiene are formed as by-products. The ratio of the two ring systems in the product depends on the conditions of the reaction. The formation of cyclododecatriene is favored by an increase in the butadiene concentration, the formation of cyclooctadiene by an increase in temperature. The product is exclusively the cyclodimer if phosphines or phosphites are introduced into the system as cocatalysts together with the nickel carbonyl [10]. The best results have been achieved with triaryl phosphites containing *o*-substituted rings [11]. These compounds give high reaction rates and result in extremely high selectivity. For example, with a butadiene pressure of 3.5 atm at 100 °C, a catalyst system containing nickel carbonyl and tri-*o*-tolyl phosphite as cocatalyst gives 90% 1,5-cyclooctadiene with a conversion of 1000 kg of butadiene per mole of nickel carbonyl. Another very active cyclodimerization catalyst containing no carbonyl groups can be prepared as follows: Nickel carbonyl is first treated with acrylonitrile to form bisacrylonitrilenickel(0) *(1)* as described by *Schrauzer* [12].

$$Ni(H_2C{=}CH{-}CN)_2 \quad (1)$$

The complex is then allowed to react further with tri-*o*-tolyl phosphite (or another phosphite or phosphine) to form acrylonitrilenickel(0) bis(tri-*o*-tolyl phosphite) *(2)*



(2)

It is immaterial to the dimerization whether the complex *(2)* is prepared in advance, or whether it is formed in a solvent, *e.g.* cyclooctadiene, by mixing the reagents. In pilot-plant experiments, 600 kg of butadiene per mole of the complex were converted into cyclooctadiene in 90% yield.

Catalysts for the synthesis of cyclooctadiene other than highly toxic nickel carbonyl and dangerous aluminum alkyls include complexes obtained by treating soluble nickel chelates with molten or finely divided metals of Groups I–III in the presence of phosphines or phosphites in cyclooctadiene as solvent [13]. This reaction is favored by the presence of tertiary alcohols and butadiene. Catalysts made with one mole of nickel acetylacetonate and containing tri-*o*-tolyl phosphite as complexing ligand converted 200 kg of butadiene per hour at 100–110 °C and a butadiene pressure of 3.5 atm. The yield of cyclooctadiene was 93%, based on the reacted butadiene.

b) Oligomerization to Open-Chain Dimers

As mentioned above, *Reed* believed that one of the fractions isolated from the products of thermal dimerization of butadiene contained 1,3,7-octatriene [14], *i.e.* a product formed by open-chain oligomerization of butadiene. *Wilke* then succeeded in carrying out the first open-chain oligomerization of dimethylbutadiene and isoprene using Ziegler catalysts containing titanium and

chromium [15-17], and later dimerized butadiene to 3-methyl-1,4,6-heptatriene in the presence of cobalt or preferably iron catalysts. The yields obtained were still too low to make the process industrially attractive.

During our work on the dimerization of butadiene, we found two methods of linking two molecules of butadiene together to give good yields of open-chain products at high reaction rates. The principal products are n-octatrienes [18] or 3-methyl-1,4,6-heptatriene [19,19a], depending on the catalyst system used.

The n-octatrienes can be synthesized with the nickel catalysts used for the cyclodimerization, *i.e.* containing nickel(0) and electron donors as ligands. Surprisingly, in the presence of alcohols, these catalysts no longer bring about cyclization but effect open-chain linkage of two butadiene molecules. Examples of suitable dimerization initiators are the nickel carbonyl phosphites, nickel carbonyl phosphines, and above all the nickel complexes, *e.g. (2)*, prepared as described above from bisacrylonitrilenickel(0) and phosphites. For simplicity, the complexes are not used in pure form. Instead, the bisacrylonitrilenickel(0) and the phosphorus compound are introduced together into the alcohol which is to be used as the solvent.

The principal products are isomeric n-octatrienes; of these *trans*-n-1,3,7-octatriene, *cis,trans*-n-1,3,6-octatriene, and *trans,trans,trans*-n-2,4,6-octatriene have been isolated and identified. 3-Methyl-1,4,6-heptatriene and 1,5-cyclooctadiene are also formed in small amounts, together with more or less large quantities (depending on the reaction conditions) of branched and unbranched dodecatetraenes and higher oligomers of butadiene. Preparatively interesting quantities of a new five-membered cyclic dimer of butadiene have also been isolated. Chemical analysis and infrared and nuclear resonance spectra of this compound show that it is 1-vinyl-3-methylcyclopentane *(3)*.

(3)

In total, the yields of distillable oligomers were up to 90%.

Which of the hydrocarbons predominates, depends essentially on the complexing ligand of the catalyst. Thus, when the ligand is triethyl phosphite, tributylphosphine, or phosphorus trimorpholide, the principal products are 1,3,6-octatriene, 1,3,7-octatriene, and 2,4,6-octatriene, respectively.

A mixture of open-chain oligomers of butadiene was also obtained in high yield in a rapid reaction by the action of cobalt(0) catalysts on butadiene at 50–100 °C. Similar results have recently been reported by Japanese authors [20,21].

Our catalysts were obtained by reduction of cobalt salts in organic solvents in the presence of butadiene. Suitable reducing agents include organometallic compounds, metals, and metal hydrides. The reactions yield brown solutions which presumably contain cobalt(0) complexed with butadiene. The action of butadiene on these solutions gives rise to oligomers: dimers, trimers, and tetramers can be separated by fractional distillation. The new oligomers have the composition $(C_4H_6)_n$ and contain n + 1 double bonds. They are therefore open-chain compounds. Two of the double bonds are conjugated. The dimeric fraction consists of about 90% 3-methyl-1,4,6-heptatriene *(4)* and 10% 1,3,6-octatriene *(5)*, which are formed by 1,2- and 1,4-addition, respectively, of two butadiene molecules:

$$\begin{array}{l} H_2C{=}CH{-}CH{=}CH{-}\underset{\displaystyle CH_3}{CH}{-}CH{=}CH_2 \quad (4) \\ \uparrow \\ H_2C{=}CH{-}CH{=}CH_2 + H_2C{=}CH{-}CH{=}CH_2 \\ \downarrow \\ H_2C{=}CH{-}CH{=}CH{-}CH_2{-}CH{=}CH{-}CH_3 \quad (5) \end{array}$$

The dimers have a 1,3-diene structure. It is therefore not surprising that the reaction does not stop at this stage but proceeds further by the scheme indicated to yield trimers, tetramers, and higher oligomers. If a given amount of butadiene is allowed to react with a constant quantity of catalyst for various times, it can be demonstrated that the oligomers are built up in steps. As the conversion increases, the yield of dimers decreases, while the yield of higher oligomers increases (see Table 1).

Table 1. Yields at various conversions during the oligomerization of butadiene with cobalt catalysts.

Butadiene conversion [%]	30	50	60	90
Yield of dimers [%]	90	78	72	16
Yield of trimers and tetramers [%]	8	15	16	45
Yield of higher oligomers [%]	2	7	12	39

The character of the catalysts described above changes completely when phosphorus compounds such as tri-*o*-tolyl phosphite are added as cocatalysts. The principal products are then 1,5-cyclooctadiene and 1-vinyl-3-cyclohexene [22]; open-chain oligomers are formed only in traces.

III. Trimerization of Butadiene

In 1956 *Wilke* [23] discovered that certain Ziegler catalysts containing titanium bring about the ready cyclization of butadiene to give high yields of *trans,trans,*

cis-1,5,9-cyclododecatriene. This synthesis is of great theoretical and practical importance and was subsequently also carried out with catalysts based on chromium and nickel compounds [24]. The products then contained two other isomers of cyclododecatriene, namely the *trans,trans,trans*- and the *trans,cis,cis*-compounds.

Investigations by *Wilke* et al. [24] showed that, with catalysts containing titanium, the cyclotrimerization is effected by the trivalent central metal atom. It is surprising, therefore, that we found a system which apparently contains divalent titanium and which is a very effective catalyst for the cyclotrimerization of butadiene to *trans,trans,cis*-1,5,9-cyclododecatriene [*]. This catalyst is formed by the reaction of titanium halides, particularly titanium tetrachloride, with aluminum and aluminum chloride in aromatic solvents [25]. *Natta* et al. [26] discovered independently that a complex with the composition $TiCl_3 \cdot Cl_2AlC_6H_5 \cdot AlCl_3$ is apparently formed when this reaction is carried out in benzene. Later, *Martin* and *Vohwinkel* [27] produced conclusive proof that this was in fact an aromatic complex with the composition $TiCl_2 \cdot 2\ AlCl_3 \cdot C_6H_6$, in which the titanium is divalent. These authors found that the same complex results from the reaction of titanium(II) chloride with aluminum chloride in benzene. The compound obtained in this manner also catalyses the synthesis of cyclododecatriene [28]. The activity and selectivity of the catalyst are greatly improved when substances are present which form complexes with aluminum chloride [29]. The acidic character of aluminum chloride is then at least partially neutralized, with consequent suppression of side reactions. Examples of suitable complexing agents are ethers, thioethers, amines, and alkali metal halides.

The titanium catalysts are very selective and extremely active. Using the catalyst combination aluminum/aluminum chloride/titanium tetrachloride/sodium chloride/benzene, it was possible to produce 1000 kg of cyclododecatriene per mole of titanium tetrachloride in 90% yield, at a daily output of 10 kg of cyclododecatriene per liter of reaction space. The concentration of titanium in the reaction product is between 0.5×10^{-3} and 1×10^{-3} gram-atom/l. About 1% vinylcyclohexene and cyclooctadiene are formed as by-products. The remainder is a low molecular-weight, waxy polybutadiene with a molecular weight of 1500. Unlike the rubbery polybutadienes which frequently result from the oligomerization of butadiene, this does not hinder the manipulation of the reaction products.

If iron(III) chloride is used instead of the titanium compound, the reaction is less specific and yields a mixture of *trans,trans,trans*- and *trans,trans,cis*-1,5,9-cyclododecatrienes, together with other cyclic and open-chain oligomers of butadiene [30].

We were also able to develop nickel-containing catalysts for the industrial synthesis of *trans,trans,trans*-1,5,9-cyclododecatriene; previously *Reed* [3] had obtained cyclododecatriene as a by-product in the dimerization of butadiene with nickel-based catalysts.

In the simplest case, nickel carbonyl is used as catalyst. The procedure is fundamentally the same as for the synthesis of cyclooctadienes. It is essential to maintain a high concentration of butadiene and to ensure that the temperature is not too high. This catalyst system is particularly suitable for the industrial process, although lower rates of reaction result than with titanium catalysts. The process is technically simpler, however, and the only by-product formed in appreciable quantities is cyclooctadiene, which is not undesired.

Bisacrylonitrilenickel *(1)* reacts with pyridine, quinoline, or quinaldine to form complexes of the composition *(6)*, which are also suitable for the synthesis of cyclododecatriene.

$$Ni(CH_2{=}CH{-}CN)_2 \cdot \text{(pyridine)} \qquad (6)$$

IV. Co-oligomerization of Butadiene with Other Unsaturated Compounds

In the co-oligomerization of butadiene with other unsaturated compounds two types of reaction can be distinguished, according to the manner in which the molecules are linked together.

The first type includes ring-closure reactions in which C–C bonds are formed simply by electron shifts. A classical example is the uncatalyzed Diels-Adler reaction of butadiene. New examples have recently been added by *Wilke* et al. [6,31], *e.g.* the co-oligomerization of two molecules of butadiene with ethylene or dimethylacetylene to form 1,5-cyclodecadiene or 1,2-dimethyl-1,4,8-cyclodecatriene.

The second reaction type gives rise to open-chain co-oligomers, which are formed by C–C linkage and a hydrogen shift, the hydrogen moving either from the butadiene or from the other unsaturated compound. Only in the former case products with conjugated double bonds are obtained. *Wittenberg* has suggested the term "dienylation" for this reaction [19a].

$$H_2C{=}CH{-}CH{=}CH_2 + RCH{=}CHR' \rightarrow H_2C{=}CH{-}CH{=}CH{-}RCH{-}CH_2R'$$

Our investigations have shown that the formation of cyclic and open-chain co-oligomers without conjugated double bonds is favored by nickel(0) catalysts, while cobalt catalysts favor dienylation.

The simplest dienylation reaction is the oligomerization of butadiene with cobalt catalysts to form 3-methyl-1,4,6-heptatriene *(4)* and higher oligomers described above.

$$H_2C{=}CH{-}CH{=}CH_2 + H_2C{=}CH{-}CH{=}CH{-}\overset{CH_3}{\overset{|}{C}}H{-}CH{=}CH_2 \qquad (4)$$

$$\rightarrow H_2C{=}CH{-}CH{=}CH{-}\overset{CH_3}{\overset{|}{C}}H{-}CH{=}CH{-}\overset{CH_3}{\overset{|}{C}}H{-}CH{=}CH_2$$

[29] German Patent 1095819 (1959/61), BASF, inventor: *H. Müller*.

[30] German Patent 1106758 (1960/61), BASF, inventor: *H. Müller*.

[31] Austrian Patent 232495 (1962/64), Studiengesellschaft Kohle mbH., Mülheim/Ruhr.

Using cobalt catalysts at 80 °C, we have obtained very pure *trans*-1,3-hexadiene from ethylene and butadiene under pressure. A side reaction is the formation of 5-methyl-1,3,6-nonatriene *(8)* and 3-methyl-1,4,6-nonatriene *(9)* by reaction of the hexadiene *(7)* with a further molecule of butadiene.

$$H_2C{=}CH{-}CH{=}CH_2 + H_2C{=}CH_2 \rightarrow H_2C{=}CH{-}CH{=}CH{-}CH_2{-}CH_3 \quad (7)$$

$$H_2C{=}CH{-}CH{=}CH{-}\underset{\displaystyle CH_3}{CH}{-}CH{=}CH{-}CH_2{-}CH_3 \quad (8)$$

$$H_2C{=}CH{-}CH{=}CH_2 + H_2C{=}CH{-}CH{=}CH{-}CH_2{-}CH_3 \quad (7)$$

$$H_2C{=}CH{-}\underset{\displaystyle CH_3}{CH}{-}CH{=}CH{-}CH{=}CH{-}CH_2{-}CH_3 \quad (9)$$

Butadiene reacts very readily with acrylic esters, even at 40–60 °C and normal pressure, to form heptadienoic esters as the principal products.

$$H_2C{=}CH{-}CH{=}CH_2 + H_2C{=}CH{-}COOR \rightarrow CH_2{=}CH{-}CH{=}CH{-}CH_2{-}CH_2{-}COOR \quad (10)$$

Butadiene also reacts with phenyacetylene at room temperature. After the reaction has proceeded for a few minutes, yellow crystals of 1,8-diphenyl-1,3,5,7-octatetraene *(11)* formed by dienylation at both ends of the butadiene molecule separate out of the reaction mixture.

$$C_6H_5{-}C{\equiv}CH + H_2C{=}CH{-}CH{=}CH_2 + HC{\equiv}C{-}C_6H_5 \rightarrow C_6H_5{-}HC{=}CH{-}HC{=}CH{-}CH{=}CH{-}HC{=}CH{-}C_6H_5 \quad (11)$$

The dienylation is catalysed by the cobalt complexes described above for the synthesis of methylheptatriene. These are used in solution in ethers or hydrocarbons. Unlike the corresponding nickel complexes, they are relatively stable. Their activity and selectivity are scarcely affected by the addition of amines, ketones, esters, alcohols, or even small quantities of water. The simplest catalyst for the reaction is cobalt carbonyl.

Co-oligomers of butadiene and other unsaturated compounds, resulting from the addition of a C–H bond of the unsaturated compound onto butadiene, have been obtained by *Friedmann* [32], *Alderson* [33], and *Verbanc* [34] using cobalt oxide and rhodium chloride as catalysts. For example, butadiene and ethylene give 1,4-hexadiene:

$$H_2C{=}CH{-}CH{=}CH_2 + H_2C{=}CH_2 \rightarrow H_3C{-}CH{=}CH{-}CH_2{-}CH_2{=}CH_2$$

Wilke [6] used nickel(0) complexes to co-oligomerize butadiene and ethylene. In this reaction, the principal product is 1,5-cyclodecadiene, with n-1,4,9-decatriene as a by-product. We carried out experiments with catalysts formed from nickel chelates, alkali metals, and butadiene in organic solvents and succeeded in co-oligomerizing butadiene and ethylene to obtain a 50% yield of 1,5,9-decatriene. 1,3,8-Decatriene, 1,5,9-cyclodecatriene, 1,5-cyclooctadiene, and 1-vinyl-3-cyclohexene were also isolated from the reaction products.

On studying the behavior of styrenes in this reaction, we found that these react very readily with butadiene [35]. Here the main reaction is the linkage of two molecules of butadiene with one molecule of the styrene to form aryl-n-decatrienes *(12)*.

$$Ar{-}CH{=}CH_2 + 2\ H_2C{=}CH{-}CH{=}CH_2 \rightarrow ArHC{=}CH{-}H_2C{-}CH{=}CH{-}CH_2{-}CH_2{-}CH{=}CH{-}CH_3 \quad (12)$$

The position of the double bond in the product depends to some extent on the catalyst used and on the reaction conditions. A mixture of isomers with the double bond in various positions is generally obtained, 1-aryl-1,4,8-decatrienes predominating. The co-oligomers of styrene and butadiene, *i.e.* the phenyldecatrienes, are particularly interesting from a technical point of view. They can be readily hydrogenated to n-decylbenzene, a convenient starting material for the preparation of soft detergents.

The co-oligomerization proceeds with the evolution of about 410 cal/g and is best carried out at 90–100 °C using nickel catalysts which cyclize pure butadiene to cyclododecatriene or cyclooctadiene.

Consequently, these homo-oligomers occur as by-products. Their formation can be largely suppressed, however, by working in the presence of excess styrene. In a continuous process in a pilot-plant, 75% of the butadiene feed was converted into phenyldecatriene in the presence of a 30% excess of styrene. The yield, based on the styrene, was practically quantitative.

Catalysts with ligands containing phosphorus were found to be less suitable than nickel(0) olefin complexes or nickel carbonyl. The phosphorus-free nickel complexes give the purest phenyldecatriene and are also extremely active. Depending on the contact time, it is possible to obtain 500–1000 kg of phenyldecatriene per mole of nickel compound.

Co-oligomerization to form cyclic products predominates in the reaction with ethylene and leads to the formation of cyclodecadiene, but occurs only to a small extent with styrene. Here cyclization is evidently hindered by the conjugation of the vinyl group with the aromatic nucleus, which still persists in the phenyldecatrienes, so that the reaction leads to the energetically favored open-chain hydrocarbon. This is probably also why vinylcyclohexene reacts much less readily than styrene.

By analogy to the reaction with butadiene, styrene derivatives also react with butadiene or other 1,3-dienes. For example, styrene reacts smoothly with isoprene to form 1-phenyl-4,8-dimethyldecatriene *(13)*, and vinylnaphthalene on reaction with butadiene yields 1-naph-

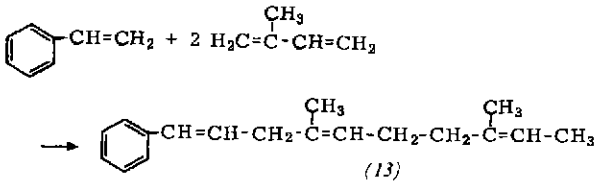
thyldecatriene. With divinylbenzene, both vinyl groups can take part in the reaction, and the products include



(13)

didecatrienylbenzene and vinyldecatrienylbenzene. α-Substituted styrenes such as α-methylstyrene are much less reactive than styrene itself. Consequently, the competing homo-oligomerization of butadiene predominates, and the co-oligomers are obtained in yields of only 5–10%.

The authors are highly indebted to their colleagues in the analytical laboratories of BASF, and particularly to Dr. W. Brügel, Dr. D. Noffz, Dr. K. Müller, Dr. H. Günzler, and Dr. G. Matz for carrying out spectroscopic investigations and structural elucidations.

Formation of Free Radicals in Polyamide Fibers during Drawing

BY DR. P. MATTHIES, DR. J. SCHLAG, AND DR. E. SCHWARTZ

KUNSTSTOFFLABORATORIUM AND HAUPTLABORATORIUM DER BADISCHEN ANILIN- & SODA-FABRIK AG, LUDWIGSHAFEN/RHEIN (GERMANY)

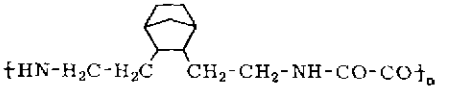
Published on the occasion of the 100th anniversary of the establishment of Badische Anilin- & Soda-Fabrik AG., on April 6th, 1965.

The formation of free radicals during the process of drawing of spun fibers was observed for the first time with two polyoxamides. The fibers turn red, and an ESR signal can be detected. Both, color and ESR absorption are not permanent. The decrease in the intensity of the ESR absorption and the change in the optical reflectance with time, as well as the dependence of the decoloration on temperature were investigated. The action of high-energy radiation on the polyoxamides also leads to a red coloration and gives rise to ESR signals. It is concluded that the red color is due to free radicals associated with the oxamido group.

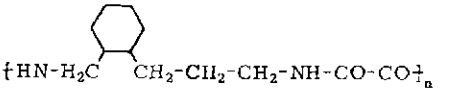
Introduction

Free-radical formation in polymers as a result of mechanical stress has until now been observed only when the stress was very great, *e. g.* during pulverisation in a mill [1–5]. Investigations of this type on polyamides have been described by *Bresler* et al. [3], who observed free-radical formation in polycaprolactam on grinding at −196 °C, although no free radicals were detected after grinding at room temperature.

We have now found that free radicals can be formed in certain polyoxamides as a result of mechanical stress of a different nature, namely during drawing, at room temperature, of fibers spun from the melt. The following polymers were examined:



"Polyoxamide I"



"Polyoxamide II"

If these polyoxamides are spun at a temperature at which the melt is very viscous, *i. e.* between 200 and 230 °C, the fibers assume an intense red coloration on drawing at room temperature (Fig. 1). This phenomenon is not observed if the fibers are spun at higher temperatures. The red color is unstable, particularly in the presence of oxygen, and the rate of decoloration depends on the temperature. Fibers of polyoxamide I which turned red on drawing are no longer soluble in cresol, even after spontaneous decoloration.

1. Electron Spin Resonance

The red drawn fibers of both polyoxamides give electron spin resonance (ESR) signals, which indicate the presence of unpaired electrons. The ESR spectra are shown in Figure 2, the curves recorded being the first derivatives of the absorption spectra. As in the ESR spectra of most solids, the hyperfine structure is poorly resolved. The fact that hyperfine structure is at all present, indicates interaction of the unpaired electron with nitrogen or hydrogen nuclei.

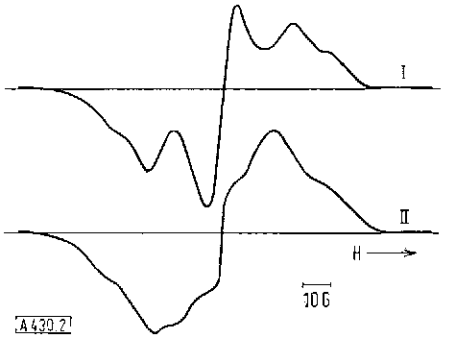

Fig. 2. ESR spectra of drawn fibers of polyoxamides I and II. Ordinate: $d\chi''/dH$.
χ'' = imaginary part of the complex high-frequency susceptibility; H = magnetic field strength.

The form of the spectrum depends slightly on the orientation of the fibers in the magnetic field. The spectra in Figure 2 were obtained from fibers with their axes parallel to the magnetic field; for fibers with their axes perpendicular to the magnetic field, the middle line becomes weaker relative to the outer lines.

The intensity of the ESR signal corresponds to about 10^{16} spins per gram. Thus there is roughly one unpaired electron for every 3×10^5 structural units in the polymer. The intensity of the signal decreases with time, as does the red color. The rate of the decrease of intensity and the form of the spectrum during the return to normal are influenced by the presence of oxygen.

2. Kinetic Measurements

The intensity of the ESR signal of freshly drawn polyoxamide I decreases with time. The results of measurements in air at room temperature (Fig. 3) can be evaluated with the aid of the equation for the kinetics of a first order reaction:

$$2.303 \log I/I_0 = -kt$$

(I = intensity of the ESR signal; I_0 = initial value).

A number of measurements gave values of k between 0.2 and 0.8 h^{-1}. The disappearance of the radicals evidently is a pseudounimolecular reaction, the concentration of oxygen in the fibers being included as a constant factor in k.

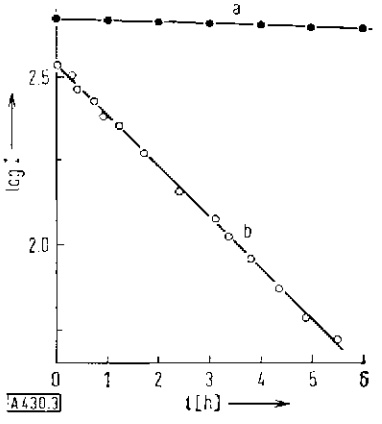

Fig. 3. Decay of the ESR signal of polyoxamide I; a) under nitrogen; b) in air; I = intensity.

On investigating polyoxamide I under nitrogen, it is found that the ESR absorption falls off about one-hundred times more slowly (Fig. 3). Here the decrease in the ESR intensity no longer corresponds to a simple reaction order when the investigation is continued over long periods (400 h). Furthermore, the intensity of the middle line decreases more slowly than that of the outer lines.

Using the method described by *Kubelka* and *Munk* [6, 7], the absorption spectrum was found from the light reflection [7a]. The maximum is located at a wavelength of 505 mμ. The quantity $(1 - R)^2/2R$ (where R = the absolute reflectance of an infinitely thick layer), which is proportional to the concentration of red color centers, also decreases with first order kinetics in the presence of air. The rate constant for the decrease (0.7 h^{-1}) is within the range found from the ESR measurements.

The decrease in the optical extinction also proceeds more slowly under nitrogen than in air. The decrease under nitrogen could not be followed quantitatively with the apparatus available.

[6] *P. Kubelka* and *F. Munk*, Z. techn. Physik *12*, 593 (1931).
[7] *P. Kubelka*, J. opt. Soc. America *38*, 448 (1948).
[7a] It was assumed that the scattering coefficients of colored and decolorized fibers are the same. This is probably correct to a good approximation.

3. Temperature Dependence of the Decoloration

In order to obtain a measure of the influence of temperature and oxygen concentration on the decoloration of the red fibers, the time τ required for loss of visible color was determined at various temperatures under otherwise identical conditions (size of the bundle of fibers, extent of drawing). τ is in fact the time in which the extinction falls to a constant fraction of its initial value.

Figure 4 shows the temperature-dependence of τ for polyoxamide I in air and in the absence of air between 0 and 160 °C. It can be seen that τ decreases with increasing temperature. A plot of log τ against $1/T$ gives a straight line in the absence of oxygen, but in the presence of air the line exhibits a break. The position of this break depends to some extent upon the pretreatment of the fiber. In the experiments on which Figure 4 is based, the break occurred at about 90 °C. Below this temperature, the decoloration times are shorter in the presence of oxygen than in its absence, while above this temperature oxygen has no significant effect. From the fact that the curves are straight it follows that log τ is proportional to the logarithm of the rate constant. The activation energies of the reactions can be calculated from the gradients of the straight lines. The values obtained are 9 kcal/mole for the right-hand branch of Curve (b), and about 30 kcal/mole for the left-hand branch of Curve (b) and for Curve (a). Similar results were obtained with polyoxamide II.

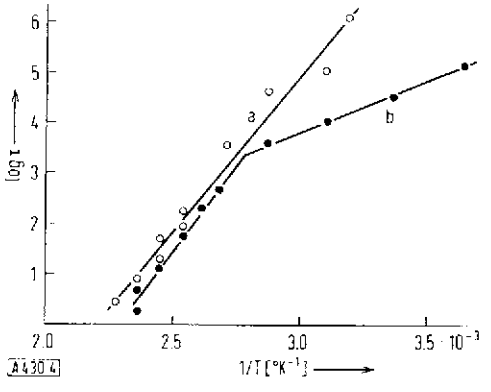

Fig. 4. Temperature-dependence of the decoloration time τ [sec]; a) in the absence of air; b) in air; T = absolute temperature.

4. Irradiation of the Polyoxamides and of Related Monomeric Substances with High-Energy Radiation

The usual method of producing free radicals in solid high polymers is by the action of high-energy radiation. It was desirable, therefore, to find whether irradiation of polyoxamides I and II gives the same red coloration and the same ESR spectra as are observed on drawing. *Zimmerman* [8] has described a red coloration of the polyamide prepared from 2-methylhexamethylenediamine and oxalic acid on irradiation with 2 MeV electrons. No ESR measurements were reported.

Our investigations have shown that polyoxamides I and II, as well as 8,2-polyamide and 12,2-polyamide, assume a red color on irradiation with 2 MeV electrons or with ultraviolet light [8a]. No red coloration is observed with polyamides which do not contain the –COCO– group.

The ESR spectra of the irradiated polyoxamides I and II contain 5 lines each (Fig. 5), exactly as the spectra of the drawn polyoxamides. In some of the irradiation experiments, the spectra of the products had the same form as those of drawn fibers; however, in other cases, the middle line of the quintet was more intense. The reason for this difference is unknown. The ESR spectrum of the irradiated 12,2-polyamide also contains a quintet in which the middle line is more intense than the others.

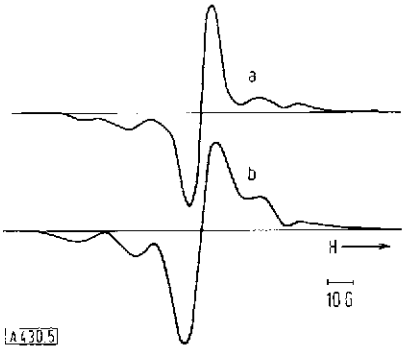

Fig. 5. ESR spectra of polyoxamide I (a) and of oxamide (b) after irradiation.

Ordinate: $d\chi''/dH$.

χ'' = imaginary part of the complex high-frequency susceptibility; H = magnetic field strength.

The extinction and the signal intensity in the ESR spectrum of polyoxamide I increase with the radiation dose over the range investigated (0.5–6.0 Mrad). At low doses, the increase is proportional to the dose, but becomes somewhat slower at higher doses, indicating that the extinction and the signal intensity are approaching a saturation value. Both the intensity of the ESR signal and the extinction of irradiated polyoxamide I decrease in the presence of air. However, the changes did not correspond to a first order reaction.

In an attempt to find the relationship between the red color produced by irradiation and the chemical structure, monomeric derivatives of oxalic acid were irradiated with electrons. It was found that oxamide and *N,N'*-dipropyloxamide also give red colorations. The cyclic oxamide of *N,N'*-dimethyl-1,3-diaminopropane, which contains no hydrogen atoms on the nitrogens, assumes a yellow-orange color. A more or less strong yellow coloration is obtained with oxalic acid, sodium oxalate, dimethyl oxalate, butyl oxamate, and di-t-butyl oxalate.

All the oxalic acid derivatives examined give ESR spectra with hyperfine structure after irradiation. The spectrum of oxamide contains 5 lines (Fig. 5b); those of the other compounds are more complex.

[8] *J. Zimmermann*, J. appl. Polymer Sci. *2*, 181 (1959).

[8a] In order to ensure that the results obtained were as far as possible due to the radicals formed initially, the irradiation was carried out at −78 or −196 °C.

5. Discussion

The ESR absorption of the drawn polyoxamides I and II shows that free radicals are formed during the mechanical deformation. The fact that only fibers which have turned red on drawing become insoluble is also evidence for the formation of free radicals, with subsequent cross-linking of the material.

Under certain conditions, the ESR spectra of drawn fibers and of material which has been irradiated with high-energy electrons are identical. It can therefore be concluded that radicals of the same type are formed under mechanical stress and during irradiation. *Butyagin* [2] has made similar observations on other high polymers. As this author also assumed, the initial products in both cases are excited molecules, which then react further in an identical manner to form relatively stable free radicals. These radicals are detected in the ESR spectrum.

It is striking that the formation of free radicals in fibers during drawing has so far been observed only with the polyoxamides I and II[8b]. Each of these polymers consists of relatively rigid molecular chains with a bulky group projecting laterally. It is conceivable that, during drawing of the fiber, molecular chains that should be slipping past one another occasionally become interlocked, resulting in a local build-up of energy which can lead to excitation of the molecule. This explanation is supported by the fact that the phenomenon is observed only with fibers which are spun at relatively low temperatures. These are already internally strained owing to draw-down during spinning, so that movement of the molecular chains over one another is difficult. Since the second-order transition temperatures T_g [8c] of polyoxamides are appreciably higher than those of normal polyamides (polyoxamide I: T_g = 135 °C, polyoxamide II: T_g = 115 °C), the formation of free radicals should be favored by cold drawing, and their life-time should be prolonged to such an extent as to allow their concentration to exceed the limit of detection.

The excited molecule could conceivably undergo the following reactions:

1. rupture of the main chain;
2. elimination of a hydrogen atom or a side group, possibly followed by addition onto a carbonyl group;
3. removal of an electron which then becomes trapped by the solid high polymer, *e.g.* in the vicinity of a carbonyl group.

No conclusions on the structure of the radicals can be drawn from the investigations carried out so far. The ESR spectra of irradiated polyamides (our own investigations and [9–16]) differ in shape from those of polyoxamides I and II. The structures proposed for the free radicals in polyamides cannot therefore be used to interpret our spectra. Nothing is known of the structure of the free radicals formed on irradiation of monomeric and polymeric oxalic acid derivatives.

The ESR quintet observed with red drawn fibers of polyoxamides I and II is due either to a single type of free radical or to superposition of the spectra of two or more types of free radicals. If the former alternative is correct, the explanation for the differences in the decay of the various lines (in the absence of oxygen) would be that the disappearance of the free radical is accompanied by the formation of another more stable radical. The latter would then be responsible for a singlet occurring at the same position as the middle line of the quintet.

The difference between the spectra of polyoxamides I and II (the middle line of II is much weaker than that of I) can be explained by a larger line-width in the case of polyoxamide II or by a superposition of two signals having different ratios for the polyoxamides I and II.

It seems certain that the red color is associated with the group –NH–COCO–NH–, since even in monomeric oxalic acid derivatives, it occurs only when the oxamide group is present. Since the intensities of the red color and of the ESR signal of polyoxamide I decrease with time in a similar manner, whether the material has been drawn or irradiated, and since both quantities increase at the same rate with the radiation dose, we must conclude that the red color is due to a free radical which is detected by ESR spectroscopy.

The destruction of the free radicals involves various processes, depending on the external conditions. In the presence of air at room temperature, a first order reaction with an activation energy of 9 kcal/mole occurs. This energy can probably be related to the diffusion of oxygen in solid polyoxamide (values of this order of magnitude are given in the literature for the diffusion of oxygen in solid polymers [17]). The reaction of oxygen with the free radical probably proceeds rapidly and with no appreciable activation energy. As the temperature increases (see Fig. 4, Curve b), a competing reaction of unknown order begins to predominate. It seems likely that this is a reaction between two radical sites. The activation energy of about 30 kcal/mole found for Curve (a) and for the left-hand branch of Curve (b) in Figure 4 presumably corresponds to the "diffusion" of free-radical sites. This process may involve both direct diffusion of chain segments and migration of free-radical sites by transfer of hydrogen atoms.

[8b] Note added in proof: Recently similar color changes were observed with a polyamide from hexamethylenediamine and isophthalic acid (Kunststofflaboratorium, BASF). This polyamide turns blue when it is extruded and subsequently subjected to mechanical strain. This is the case, for example, when spun fibers are stretched or when extruded strands are granulated. The same coloration occurs on irradiation. The ESR spectrum of the blue material consitsts of five bands.

[8c] The second-order transition temperature was measured by the penetrometer method, cf. *O. B. Edgar*, J. chem. Soc. (London) *1952*, 2638. In this method the polymer sample is heated in silicone oil at a rate of 1 °C/min. At the same time a cylindrical piston rests on the sample with a load of 1.3 kg/cm². The thickness of the sample and the downward movement of the piston on softening are measured and plotted versus temperature. Below the softening point the slope of the curve depends on the coefficient of expansion, whereas above it depends on the rate of downward movement of the piston. The second-order transition temperature Tg is given by the point of intersection of the tangents at both branches of the curve.

Tetrahydro-1,4-oxazines with large alicyclic or long alkyl groups [*] attached to the nitrogen exhibit good or very good fungicidal activities against fungus diseases of crops, particularly against the true mildew varieties. – By examining several hundred compounds, the relations between chemical constitution and fungicidal action were investigated in an attempt to find the most effective compounds. The factors varied were the nature, chain length, and ring size of the N-substituent, and the nature, number, and positions of the C-substituents on the heterocyclic system. Furthermore, the lone electron pair at the nitrogen atom was incorporated by alkylation, formation of amine oxides or salts, or by complexing with heavy metal salts, and the resulting changes in the fungicidal activity were determined.

I. Introduction

Every year, fungus diseases cause great damage to crops, and thus appreciably lower their yield. Fungal damage in the U. S. A. in 1954 was responsible for a reduction of 7% or 2.8 billion dollars in the agricultural and forestry returns [1]. In Ceylon, the cultivation of coffee beans had to be abandoned owing to the extensive incidence of leaf rust. The cultivation of tobacco in South Africa was severely reduced by a powerful attack of mildew. The fact that practically no winter barley is grown in Denmark and Sweden is due to barley mildew. European viniculture came to the brink of extinction around 1870 following the *Peronospora* epidemic after the disease had found its way here from overseas. It was only thanks to the discovery, or rather the rediscovery, of the Bordeaux spray that the attack was weakened in subsequent years. Great losses were suffered by the tobacco harvest as a result of the blue mold in 1959 and 1960, especially in Germany and the neighboring countries. Practically the entire potato harvest failed in Germany in 1917 because of the fungus *Phytophthora infestans*, and this event was largely responsible for the so-called "turnip winter" in 1917–1918. Fungi can damage fruit even after harvesting, for example in the citrus family, rendering the fruit unpalatable within a few days. The task of developing new fungicides is therefore of great economic importance.

In comparison with the number of herbicides and insecticides, the number of organic compounds possessing fungicidal activity is small. The broadest possible spectrum, good plant tolerance, and a simple and cheap synthesis are the essential criteria of a fungicide.

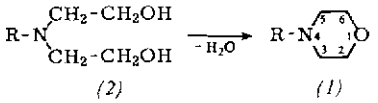
Occasionally nitrogenous compounds with long alkyl chains exhibit considerable biological activity. Thus a herbicidal action is shown by *N*-laurylhexamethyleneimine, while 2-heptadecylimidazoline acetate and laurylguanidine acetate are particularly active against apple scab (*Venturia inaequalis*).

Although easy to prepare by known methods, tetrahydro-1,4-oxazines have not yet been tested for their plant-protecting action. 2-Phenyl-3-methylmorpholine has been the only biologically active oxazine to achieve importance as a drug.

II. The Preparation of Tetrahydro-1,4-oxazines

1. Syntheses of the Ring System

Tetrahydro-1,4-oxazine, *i.e.* morpholine *(1)*, R = H, is obtained in good yield by dehydration and cyclization of bis-(2-hydroxyethyl)amines *(2)*, R = H, by sulfuric acid [2], hydrogen halides, acid halides, or dehydrating catalysts [3] at 160–260 °C. Considerably better yields are



(2) *(1)*

generally obtained and lower temperatures (80–140 °C) are needed when the amino hydrogen of the bis-(2-hydroxyalkyl)amine is replaced by a hydrocarbon group [R ≠ H in *(2)*]. Moreover, ring closure is facilitated when the carbon atoms carrying the OH-groups are tertiary or quaternary [see *(5)* → *(6)*; *(7)* → *(8)*].

[*] Compounds of this type are the subject of German and other patent applications.

Other possibilities are the ring-closure of bis-(2-halogenoethyl) ethers *(3)* [4] or bis-(2-hydroxyethyl) ethers *(4)*, as well as the ring closure of glycols with amines [5].

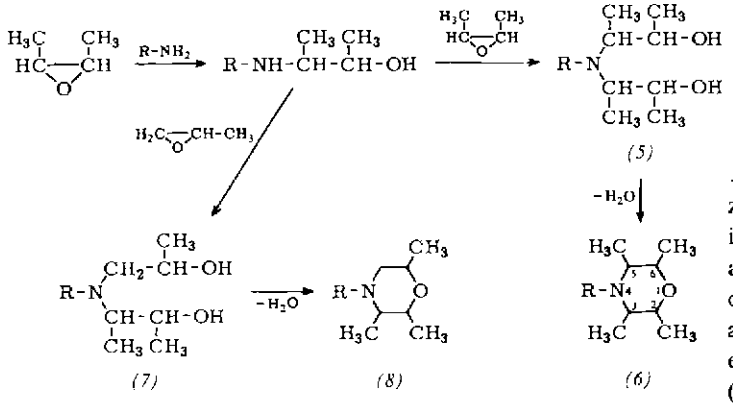
2. Introduction of Substituents at the Carbon Atoms

Bis-(2-hydroxyalkyl)amines can be prepared by adding ammonia or primary amines [2] to 1,2-alkylene oxides, a wide range of the latter being available from petroleum products. If 2 moles of the same epoxide or 1 mole each of two different epoxides (*e.g.* 2,3-butylene oxide and propylene oxide) are reacted with 1 mole of ammonia or a primary amine, then symmetrically *(5)* or unsymmetrically *(7)* substituted bis-(2-hydroxyalkyl)amines are obtained, which on dehydrating cyclization yield symmetric *(6)* or unsymmetric *(8)* tetrahydro-1,4-oxazines.



(5)

(7) *(8)* *(6)*

Substituents can in this way be introduced at positions 2 and/or 6, and, by using a symmetric epoxide, at positions 3 and 5 as well. On adding an unsymmetric 1,2-epoxide to an amine, the epoxide ring will usually be opened in such a way that the OH-group is attached to the carbon atom carrying the least number of hydrogens [6]. Using the same amine, ring opening of the 1,2-alkylene oxides becomes more difficult as the number of substituents in the latter increases (or, in the case of epoxides with the same number of substituents, as the symmetry of the epoxide increases).
