Resolution of Chiralic Triarylphosphines [1]

By *G. Wittig, H. J. Cristau,* and *H. Braun* [*]

Unsymmetrical tetraaryl phosphonium salts have been prepared several times [2], yet hitherto these compounds could not be resolved into enantiomers. We have now succeeded in separating a triarylphosphine into its optical antipodes. In order to accomplish this we made use of the fact that phosphines in the presence of acid and paraformaldehyde react to give α-hydroxymethylphosphonium salts [3]. The "method of half quantities" [4] proved especially well suited in our work for the resolution of these optical isomers. This procedure may be illustrated by the case of the resolution of *p*-biphenylyl-α-naphthylphenylphosphine *(1)* [5] (racemate m.p. 192–193 °C).

11 mmole of paraformaldehyde was suspended in a benzene solution of 20 mmole of the phosphine *(1)*, and a solution of 10 mmole of (+)-camphor-10-sulfonic acid *(2)* added. The mixture was stirred for 1h and then allowed to stand overnight, during which time the salt *(3)* crystallized out (yield 92%). The supernatant liquor was decanted off, the solvent was removed under vacuum, and the residue was chromatographed on Al_2O_3 (Brockmann) (eluent benzene).

The phosphine (–)-*(1)* (8.6 mmoles or 86%; m.p. 194 to 195 °C; $[\alpha]_{578}^{24} = -5.2°$; c = 3.38 in methylene chloride) was thus obtained. The camphor sulfonate *(3)* remaining behind after decantation (9.2 mmole; m.p. 111–112 °C) exhibited, after a triple recrystallization, a rotation value of $[\alpha]_{578}^{25.4} = +19.0°$ (*c* = 3.86 in methylene chloride). Cleavage of *(3)* to the phosphine (+)-*(1)* was accomplished with triethylamine in benzene (yield 93%; m.p. 195–196 °C; $[\alpha]_{578}^{25.4} = +8.7°$; *c* = 3.11 in methylene chloride) [6].

If a molecular ratio of 1:1:1 of the components was used, the separation of the diastereoisomers was unsuccessful. It was impossible to apply the above technique to aliphatic or aliphatic-aromatic phosphines, possibly because of the greater basicity of these compounds.

Tricarbonyl(organometalophosphine)nickel(0)

By *H. Schumann* and *O. Stelzer* [*]

The stability of organometalophosphines of type $(R_3M)_nPR_{3-n}$ (M = Si, Ge, Sn, or Pb) is ascribed to participation of the "free" electron pair on the phosphorus in the covalent M–P bond [1]. All previous attempts to prepare organometalophosphines with tetra- or quinque-valent phosphorus have been unsuccessful. Fission of the metal-phosphorus bond occurs on utilization of the "free" electron pair, for instance, by quaternization of the phosphorus or by oxidation.

By treatment of tetracarbonylnickel with tris(trimethylsilyl)-, tris(trimethylgermanyl)-, tris(trimethylstannyl)-, or tris(trimethylplumbyl)-phosphine in tetrahydrofuran at room temperature, it has now been possible to synthesize carbonylnickel(0) complexes *(1)* which represent the first stable organometal-substituted phosphines with tetravalent phosphorus.

The compounds, which are formed in quantitative yield as colorless crystals after four hours' stirring under a nitrogen atmosphere, can be isolated in high purity on distilling off the solvent. In contrast to the starting phosphines they are astonishingly stable to air; but they decompose, in some cases at very low temperatures, with separation of metal.

(1), M	Decomp. temp. (°C)	$J[^1HCM^{31}P]$ (Hz)	ν CO (cm^{-1})	ν PM_3 (cm^{-1})	ν NiP (cm^{-1})
Si	30	5.2	2074 1995	363	478
Ge	100	4.65	2070 1996	362	454
Sn	90	3.35	2057 1968	345	448
Pb	85	2.9	2049 1960	321	446

The considerable increase in the coupling constants $J[^1HCM^{31}P]$ of the complexes in comparison with those of the free organometalophosphines (Si, 4.62 Hz; Ge, 4.00 Hz; Sn, 1.95 Hz; Pb, 0 Hz) confirms the increase in s-character of the P–M bonds on going from the p^3 hybridized phosphorus atom of the free phosphines to the sp^3 hybridized phosphorus in the complexes. The IR spectrum shows the two CO stretching vibrations required by the C_{3v} symmetry [2]; these bands being shifted, as expected, to longer wavelengths with increase in the size of the phosphine ligands. In addition to the internal vibrations of the trimethylmetal groups there are two bands between 4000 and 280 cm^{-1} which we ascribe to $\nu_{as}PM_3$ (E) and νPNi (A_1) of the atomic grouping M_3PNi (C_{3v}). The small long-wave shift of $\nu_{as}PM_3$, compared with the tris(organometalo)phosphines, shows that the M–P bond is only slightly weakened by complex formation. The stability of the new compounds towards oxygen confirms the hypothesis that on oxidation of organometalophosphines the oxygen attacks the "free" electron pair of the phosphorus [3]. In the complexes *(1)*, this electron pair is no longer open to electrophilic attack, owing to coordination to the nickel.

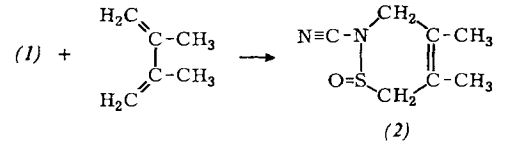
Thionylcyanamide

By *O. J. Scherer* and *R. Schmitt* [*]

Silicon-nitrogen compounds are extremely useful for the preparation of new types of thionyl imide [1] and fluorosulfur imide derivatives [2].

On treatment of bis(trimethylsilyl)carbodiimide with thionyl chloride at −70 °C (molar ratio 1:1, no solvent) and removal of the chlorotrimethylsilane in a water-pump vacuum, one obtains as residue a liquid that decomposes explosively with



the greatest ease (storage in a refrigerator or distillation under reduced pressure leads to explosions). However, if the reaction mixture is worked up in an oil-pump vacuum, thionylcyanamide *(1)* is obtained as a yellow liquid (b.p. 23–24 °C/4 mm, m.p. −37 °C) in 60 % yield.

The product *(1)* is moderately soluble in CCl_4, readily so in $CHCl_3$, CH_2Cl_2, ether, or benzene, but insoluble in petroleum ether. Traces of water or alcohol lead to explosive decomposition. Although compound *(1)* can be kept for several days in the refrigerator (closed vessels) without decomposi-

tion, polymerization with simultaneous loss of sulfur dioxide occurs within a few hours under the influence of daylight at room temperature; the same occurs when the substance is warmed to 90–100 °C. IR spectrum: ν(CN)2190, ν_{as} (NSO) 1260, ν_s (NSO) 1170, δ(NSO) 620 cm^{-1}.

Compound *(1)* reacts exothermally with an ethereal solution of 2,3-dimethylbutadiene to give the cyclic product *(2)*.

(2)

The thiazine derivative *(2)* forms colorless crystals (m.p. 97–98 °C, yield 90 %).

Treating *(1)* with bis(trimethylsilyl)methylamine in ether at −70 °C gives bis(trimethylsilyl)carbodiimide (yield *ca.* 80 %), as well as *N*-methylthionylimide (which forms polymers).

(1) + $[(CH_3)_3Si]_2NCH_3$

→ $(CH_3)_3Si{-}N{=}C{=}N{-}Si(CH_3)_3 + CH_3NSO$

Thionylcyanamide (Caution during the preparation – explosive decomposition possible – use a protective shield!):

7.15 g (61 mmoles) of thionyl chloride is added dropwise to 11.2 g (60 mmoles) of bis(trimethylsilyl)carbodiimide[3] at −70 °C, with stirring, over a period of 5–10 min. The reaction mixture is then allowed to warm to 0 °C within about 45 min. The chlorotrimethylsilane is at once distilled off under oil-pump vacuum and the residue is fractionally distilled. Yield 3.2 g (60 %); b.p. 23–24 °C/4 mm; m.p. −37 °. A brown polymeric solid remains as distillation residue. If bis(trimethylsilyl)carbodiimide is added dropwise to a large excess of thionyl chloride, again only thionylcyanamide is formed.

C-C Condensations with the Uracilylmethyl Cation [1]

By *R. Brossmer* [*]

5-Arylmethyl derivatives of uracil can be simply prepared: *In statu nascendi*, the cation that is readily formed from 5-(hydroxymethyl)uracil[2] by catalytic amounts of acid reacts smoothly (forming a C–C bond) with phenols and naphthols and their derivatives and with compounds that can be substituted electrophilically. 5-Benzyl- and 5-(naphthylmethyl)-uracils *(1)* result. The condensation is not hindered by fairly large substituents R′, *e.g.* phenyl, on C–4 of uracil. Analogous reactions occur with free nucleosides or those protected in the sugar portion.

(1)

R	R′	Yield (%)[3]	M.p. (°C)
4-Hydroxyphenyl	H	95	330
3-Chloro-4-hydroxyphenyl	H	88	295–296
3-Chloro-6-hydroxyphenyl	H	90	340 (decomp.)
2-Hydroxy-3,5-dimethylphenyl	H	86	300–303
2-Hydroxy-5-formylphenyl	H	75	295–297
4-Hydroxyphenyl	CH_3	95	310
4-Hydroxyphenyl	C_6H_5	78	150 (decomp.)
4-Hydroxynaphthyl	H	91	298

These products have hitherto been accessible, if at all, only by total synthesis involving several steps[4].

5-(4-Hydroxybenzyl)uracil: 5-Hydroxymethyluracil (1 g) and then concentrated hydrochloric acid or trifluoroacetic acid (0.3 ml) are added to molten phenol (15 g). The mixture is stirred for 0.5 to 1 h at 80 to 100 °C. Dissolution occurs after a few minutes, then a thick precipitate separates. After the mixture has been cooled, precipitation is completed by addition of ether. Yield 1.45 g (95 %); recrystallized from 70 % ethanol or water, the product has m.p. 330 °C.

5-(4-Hydroxybenzyl)-3-(2,3,5-tri-O-benzoyl-β-D-ribofuranosyl)uracil: 5-(Hydroxymethyl)-3-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)uracil (0.5 g) and concentrated hydrochloric or trifluoroacetic acid (0.2ml) are added to molten phenol (20 g). The mixture is kept for 1 h at 80 to 100 °C, then treated with water (1 liter) and decanted; the precipitate is dissolved in a little methanol and the solution is allowed to flow into water (*ca.* 800 ml). Yield, 0.40 g (71 %). Recrystallized from methanol, the product has m.p. 155 °C (decomp.).

Dicyclopropyldiazomethane

By *H. M. Ensslin* and *M. Hanack* [*]

There have been two recent reports[1,2] on the preparation of cyclopropyldiazomethane. Dicyclopropyldiazomethane can also be obtained; its preparation is indeed simpler than that of cyclopropyldiazomethane. A solution of freshly distilled dicyclopropyl ketone hydrazone *(1)* (24 g; readily accessible[3] from dicyclopropyl ketone and 80 % hydrazine hydrate in presence of barium oxide) in anhydrous ether is cooled to 0 °C and added rapidly, with stirring at 0 °C, to a suspension of yellow mercuric oxide (56.2 g, 1.33 equivalents) in ether (20 ml) containing 3 M ethanolic sodium hydroxide (10 drops). The solution becomes deep red instantaneously; after 5 min it is filtered and dried over KOH at −40 °C. The IR spectrum of the etheral solution shows a weak band at

(1) *(2)* *(3)*

2260 cm^{-1}, which is characteristic of a diazo group[1,4]. The cyclopropane rings are indicated by a band at 3090 cm^{-1}. If the ether is pumped off at −20 °C, the product *(2)* remains as a brick-red oily liquid with an odor of decay. The IR spectrum of *(2)* in $CDCl_3$ at −20 °C shows an intense diazo band at 2225 cm^{-1}. Compound *(2)* begins to decompose even while the spectrum is being measured; at −15 °C decomposition sets in with violent evolution of nitrogen. However, it can be kept for several days in ether at −50 °C.

The ethereal solution of *(2)* was added dropwise to a solution of acetic acid in ether at −20 °C. The course of the reaction could be followed by the evolution of nitrogen; it yielded dicyclopropylmethyl acetate *(3)*, whose IR spectrum and retention time in the gas chromatograph agreed with those of an authentic specimen[5].

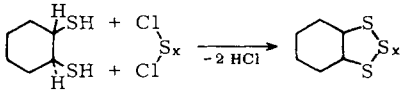
New Sulfur-containing Cyclic Compounds

By *F. Fehér* and *B. Degen*[*]

trans-1,2-Cyclohexanedithiol *(1)*[1] reacts with dichloromonosulfane or iodine with ring formation, if the dilution method is used.

(1) *(2)*



(3)

	M.p. (°C)	Yield (%)	λ_{max} (mμ) in cyclohexane	log ε
(2)	216–218	5.9	274	3.36
(3)	191.5–192	52	242	2.95

It yields perhydrodibenzo-1,2,3,6,7,8-hexathiecin *(2)* and perhydrodibenzo-1,2,5,6-tetrathiocin *(3)*, respectively, which are stable, colorless substances that can be recrystallized from chlorobenzene. They can also be obtained by reaction of bis(2-chlorocyclohexyl)-trisulfane or -disulfane with sodium trisulfide or disulfide, respectively[2], but then only in poor yield.

Reaction of the dithiol *(1)* with chlorosulfanes S_xCl_2 ($x \geq 2$)[3] in very dilute solution gives bicyclic sulfur compounds *(4)*.

(4)

	(4), M.p. (°C)	*(4)*, Yield (%)	*(4)*, λ_{max}(mμ) in cyclohexane	log ε
$x = 2$	88.5–89	74	232; 277	3.65; 3.24
$x = 3$	66.5–67	75	231; 278	3.92; 3.48
$x = 4$	81–82	9	232; 279	3.70; 3.26
$x = 5$	128–129	7.5	288	3.75

In the mass spectra, fragments appear at mass numbers that correspond to compounds *(2)*, *(3)*, and *(4)*; in addition, key fragments are found that are formed by successive loss of one sulfur atom at a time. From compounds *(4)* with $x = 3$, 4, or 5, a metastable fragment with mass number 131 is found. In the 400 to 500 cm^{-1} region of the IR spectrum the bands due to S–S stretching vibrations are well developed. The ^1H–NMR spectra of *(4)* are appreciably more complicated than that of cyclohexane.

1-Substituted 1,2-cyclohexanedithiols do not give cyclic compounds on reaction with S_xCl_2; nor does *o*-benzenedithiol.

Preparation of (4):

0.2 mole of 1,2-cyclohexanedithiol and 0.2 mole of S_xCl_2 are dissolved separately, each in 100 ml of an anhydrous ether/carbon disulfide mixture (3:1). The solutions are added simultaneously from two dropping funnels, during a period of 12 h at room temperature and with stirring, to 3.5 liters of anhydrous ether. Finally, the HCl is removed in a stream of nitrogen, insoluble polymeric products are filtered off, and the solution is concentrated to 100 ml. The stable crystals that separate are recrystallized from ether. — Compounds *(2)* and *(3)* are obtained similarly.

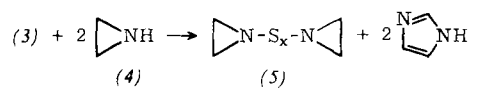
Preparation of Diimidazolylsulfanes and Di(aziridinyl)sulfanes

By *F. Fehér* and *B. Degen*[*]

Silylation of imidazole by hexamethyldisilazane affords *N*-(trimethylsilyl)imidazole *(1)*[1]. The silylated heterocycle *(1)* is suitable for reaction with chlorosulfanes *(2)*[2], since the chlorotrimethylsilane formed thereby is readily removed from the reaction mixture; furthermore, no side reactions occur. The diimidazol-1-ylsulfanes *(3)* are precipitated in analytically pure form.



(1) *(2)* *(3)*

$x =$	1	2	3	4	5
(3), m.p. (°C)	111	91–92	88	75	73–74 (decomp.)
(3), yield (%)	92	90	82	77	70

If stoichiometric amounts of compounds *(1)* and *(2)* in anhydrous benzene are used under a nitrogen atmosphere with exclusion of moisture, higher chlorosulfanes ($x \geq 3$) being dissolved in a little anhydrous carbon disulfide, then the sulfanes separate at once in pure crystalline form.

The silyl derivative of ethyleneimine *(4)* is obtained pure only with difficulty. So it is interesting that use of the products *(3)* make it possible to transfer the sulfur chain to *(4)*.

(4) *(5)*

$x =$	1	2	3	4	5
(5), n_D^{20}	1.4892	1.5794	1.6550	1.7170	1.7720
(5), λmax (mμ) in cyclohexane	212; 275	258	225; 290	230; 298	232; 305
(5), log ε	3.41; 2.51	3.41	3.88; 3.41	4.00; 3.51	4,79 3.78

The ring bonds in compound *(5)* can conjugate with the sulfur chain, as is shown by the bathochromic shift of the absorption maxima of *(5)* in comparison with those of dipiperidinosulfanes[3]. Attempts to distil compound *(5)* often led to violent explosions.

Di(aziridin-1-yl)sulfanes (5):

Diimidazol-1-ylsulfane *(3)* (0.02 mole) was suspended in anhydrous n-pentane (50 ml) and treated with *(4)* (0.04 mole) at 5 to 10 °C. After storage at −20 °C for 5 h the crystalline imidazole was filtered off and the solvent was removed from the filtrate by distillation in a vacuum. The pure compound *(5)* remained as residue.

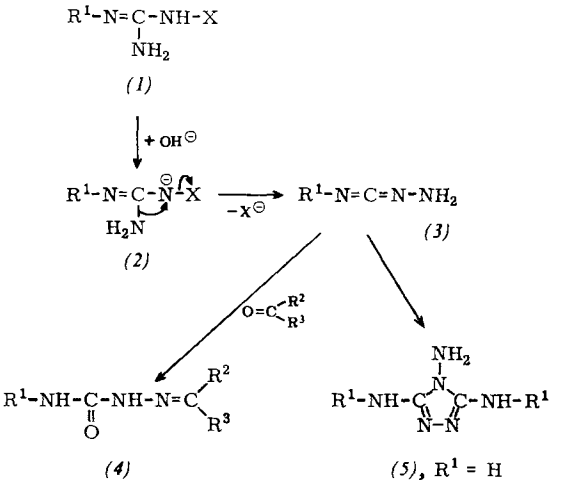
Rearrangement of Electronegatively Substituted Guanidines to Semicarbazones



By *A. Heesing* and *H. Schulze* [*] [1]

Hydroxylamine-*O*-sulfonic acids and *N*-chloroamines react with ketones in alkaline solution, yielding oxaziridines[2]. On the other hand, diaziridones are formed from *N*-chloroureas in strongly basic media[3].

Nevertheless, we have found that with the guanidine derivatives *(1a)*–*(1d)* the guanidine system rearranges to the semicarbazone system *(4)*. Hydroxyguanidine-*O*-sulfonic acids *(1a)* and *(1b)* and the *N*-chloroguanidines *(1c)* and *(1d)* react with aldehydes and ketones in aqueous alkaline solution, forming the semicarbazones *(4)*.

Semicarbazone formation occurs only if the carbonyl compound and the base are both present. With sodium hydroxide alone, the guanidine derivative does not give a semicarbazide, so that the latter does not come into question as an intermediate. Instead, decomposition of *(1a)* by alkali gives a high yield of guanazine (3,4,5-triamino-1,2,4-triazole) *(5)* [4].

The reaction mechanism is thus as follows: An anion *(2)* is first formed, which, however, is not stabilized by migration of a hydrocarbon group (as in the Hoffmann degradation of *N*-chloroamides or in the rearrangement of *N*-chloroamidines[5]) but rather an amino group migrates with simultaneous elimination of a sulfate or chloride ion. The intermediate product, an aminocarbodiimide *(3)*, dimerizes in absence of a reaction partner to give guanazine *(5)*, but in presence of carbonyl compounds it is trapped, the semicarbazone *(4)* being formed.

(1) *(2)* *(3)* *(4)* *(5)*, R^1 = H

	R^1	X	R^2	R^3	*(4)*, Yield (%)
(1a) [6]	H	O–SO_3H	C_6H_5	H	74
(1a)	H	O–SO_3H	$-(CH_2)_5-$		61
(1a)	H	O–SO_3H	C_6H_5	CH_3	68
(1b) [6]	C_4H_9	O–SO_3H	C_6H_5	H	62
(1c) [7]	$H_5C_6-CH_2$	Cl	CH_3	CH_3	15
(1d) [7]	n-C_4H_9	Cl	C_6H_5	H	43

Benzylidenesemicarbazone:

1.0 ml (10 mmoles) of benzaldehyde and 15 ml of 2 N NaOH are added to a solution of 1.55 g of hydroxyguanidine-*O*-sulfonic acid *(1a)* in 15 ml of water. The mixture is shaken vigorously and, after about 10 minutes, the semicarbazone crystallizes in almost pure form. – When working with *N*-chloroguanidines *(1c)* and *(1d)* it is advisable to add a little methanol to aid dissolution.

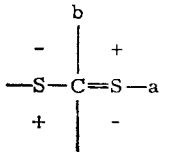
Quadrant Rule for the n → π* Cotton Effect of Dithiourethanes from Optically Active Amines

By *H. Ripperger* [*]

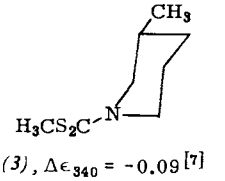


Relations between spatial structure and optical activity of chiral amine derivatives are still largely unknown. The dithiourethane chromophore is coplanar because of mesomerism[2–4]. Dipole moments indicate that we are concerned chiefly with the conformation *(1)* [5]. The geometry of the chromophore and of the n- and π*-orbitals[2] lead one to

(1)

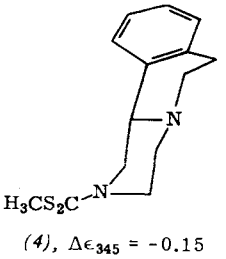
expect that the contributions of individual atoms to the n → π* Cotton effect at about 340 nm will change sign on the planes a and b. It is possible also that importance attaches to the nodal surfaces of the n-orbital on the side of the chromophore remote from the nitrogen, but this can be neglected when the group R is symmetrical.

According to the experimental results, the signs are as given in *(2)*[**]. The same signs have been found for lactones[6].



(2)

The inequality of the formal double and single C–S bonds has been neglected in the present discussion of the quadrant rule for dithiourethanes, as it was for lactones; this simplification seems permissible since both C–S bonds have partial double bond character, although to unequal extents. With this assumption, it becomes immaterial which of the two conformations that differ by rotation of 180° around the N–CS_2 bond is considered.



The Cotton effects for compounds *(3)* to *(6)* can be estimated by means of the quadrant rule displayed in *(2)*. This leads to a negative effect for *(3)* because of the methyl group, and for *(4)* because of the benzene ring in a negative quadrant, but to a positive effect for *(5)* and *(6)* because of the methyl group in the β-position and the 18-methyl and 12-methylene groups in a positive quadrant. Here it is to be noted that atoms in plane a or b make no contribution to the Cotton effect, that atoms in mirror-image positions relative to these planes cancel their effects, and that the effect of an atom decreases with increase in its distance from the chromophore.

The quadrant rule can also be applied to pyrrolidines and open-chain compounds. Dioxane was used as solvent in the measurements of the circular dichroism of each of the compounds except *(4)*; in the case of *(4)* methanol was used as solvent.

(Halogenocarbonyl)sulfur Pseudohalides

By *A. Haas* and *H. Reinke*[*]

We have been able to obtain the hitherto unknown (halogenocarbonyl)sulfur pseudohalides by treating (halogenocarbonyl)sulfur halides with silver pseudohalides. The synthesis of these compounds was of interest because they can be used for the preparation of further (halogenocarbonyl)sulfur compounds.

We first obtained (fluorocarbonyl)sulfur chloride *(2)*, in 70 % yield, by fluorinating the chlorine compound *(1)*[11] with antimony trifluoride in tetrahydrothiophene dioxide at 85 to 90 °C. The product was isolated by fractional distillation.

$$\underset{(1)}{Cl\text{–}CO\text{–}SCl} \xrightarrow{SbF_3} \underset{(2)}{F\text{–}CO\text{–}SCl}$$

Compounds *(1)* and *(2)* react with silver cyanate, in absence of a solvent, at 20 °C to give 60 % yields of the isocyanates *(3)*, X = Cl or F, which are then distilled off from the solids in a vacuum and are purified by fractional distillation. The isocyanates are hydrolysed completely in moist air to the *N,N'*-bis(halogenocarbonylthio)ureas *(4)*, X = Cl or F. Methanolysis of these ureas gives the methoxy derivative *(4)*, X = CH_3O, quantitatively.

X–CO–S–NCO *(3)* X–CO–S–NH–CO–NH–S–CO–X *(4)*

Compounds *(1)* and *(2)* react completely with silver isothiocyanate at room temperature. However, only (fluorocarbonyl)-sulfur thiocyanate *(5)* could be isolated – in 80 % yield by fractional condensation at −40 °C. It decomposes slowly at room temperature in accordance with:

$$\underset{(5)}{F\text{–}CO\text{–}S\text{–}SCN} \rightarrow COF_2 + COS + S + (SCN)_x$$

	^{19}F-NMR δ (ppm)[a]	B.p. (°C/mm)	M.p. (°C)	IR-absorption bands (cm^{-1}) [b]

[a] Referred to CCl_3F as internal standard. [b] br = broad, m = medium, s = strong, vs = very strong, w = weak.

COS and $(SCN)_x$, together with small amounts of phosgene and S_2Cl_2 are found after reaction of *(1)* with AgSCN. We assume that both chlorine atoms in *(1)* react with AgSCN. Reaction of *(1)* with silver cyanide is explosive; Cl–CO–S–CN could not be isolated. Reaction of *(2)* with AgCN is also very violent but, when less than 5 g of *(2)* is used, $S(CN)_2$, COS, COF_2, and F–CO–NCS are obtained. We postulate the following reactions:

$$(2) + AgCN \longrightarrow F\text{-}CO\text{-}S\text{-}CN \xrightarrow{80\text{–}90\%} S(CN)_2 + COS + COF_2$$

$$F\text{-}CO\text{-}S\text{-}CN \xrightarrow{10\text{–}20\%} F\text{-}CO\text{-}NCS$$

The Table lists the physical properties of the new compounds. The vapor pressure of F–CO–SCl is reproduced by the following equation:

$$\log p = 7.316 - 1426/T$$

Thence b.p. 48.5 °C/760 mm can be calculated, in agreement with the experimental value. The heat of vaporization of this compound is calculated to be 6521 kcal $mole^{-1}$. The Trouton constant is 20.3 cal $degree^{-1}$ $mole^{-1}$.

A Halogen-deficient Phase in the System Tellurium-Iodine

By *A. Rabenau, H. Rau,* and *P. Eckerlin*[*]

Dedicated to Professor F. Asinger on his 60th Birthday

The halides of sulfur, selenium, and tellurium constitute an interesting group of compounds because of their structural and bonding relations[1]. Their systematics are, however, not yet firmly founded. Only monohalides and compounds of high halogen content have been described.

During hydrothermal synthesis of tellurium crystals in concentrated hydriodic acid[2], we observed the occurrence of needle-shaped crystals with a metallic sheen. Their structure did not agree with that of any of the compounds described for the tellurium-iodine system[3]. Analysis showed a tellurium: iodine ratio greater than one.

Larger amounts of the crystals are formed regularly when tellurium-iodine mixtures containing less than 40 wt-% of iodine are heated with concentrated hydriodic acid in a temperature gradient. Reaction occurs in sealed quartz ampoules; the temperature must be below 210 °C. Crystals obtained under various conditions contain between 35 and 48% of iodine, which indicates a considerable phase width. The crystals are insoluble in non-oxidizing acids, in alkali hydroxide solutions, and in organic solvents, but dissolve in hot concentrated sulfuric or nitric acid.

Single-crystal studies show a monoclinic structure with a = 15.44 Å, b = 4.17 Å, and c = 12.05 Å, β = 128.1 °. D_{calc} = 5.55 g/cm^3; $D_{obs.}$ = 5.57 g/cm^3.

It has so far not been possible to obtain this phase by solid-state reactions of tellurium with iodine, which indicates strong kinetic hindrance. However, crystals of this phase have also been observed on forced sublimation with very pure argon as carrier gas[4].

Isomeric Chlorides and Fluorides of Sulfenic Acids

By *F. Seel, W. Gombler,* and *R. Budenz*[*]

We have proved that substitution of chlorine bonded to carbon in perchloromethane sulfenyl chloride, CCl_3SCl *(1)*, and in the chlorofluoromethane sulfenyl chlorides, $CFCl_2SCl$ *(2)*, and CF_2ClSCl *(3)* by fluorine proceeds *via* previously

unknown sulfenyl fluorides. The intermediate products are sufficiently stable to permit a study of their NMR and IR spectra at −50 °C (as liquids) and at room temperature (as gases at low pressure (≈10 mm)). The fluorination of *(1)*, *(2)*, and *(3)* has been effected in the gas phase at 150 °C with active potassium fluoride[1]. The ^{19}F–NMR spectra of the condensed products thus obtained exhibit the unusually high positive shifts characteristic of sulfenyl fluorides[2], as well as the multiplet structure expected for the CF–SF and F_2–SF groupings (Table 1). It is evident from the IR spectra that the carbon atoms of the C–SF, CF–SF, and CF_2–SF groupings are converted by chlorine into perhalomethyl groups. IR spectra of the sulfenyl fluorides show a band of type C in a constant position at 790 cm^{-1} which is assigned to S–F stretching.

At room temperature, rapid rearrangement of the liquid sulfenyl fluorides, $CF_nCl_{3-n}SF$ to the isomeric sulfenyl chlorides, $CF_{n+1}Cl_{2-n}SCl$ (n = 0,1,2) takes place.

Finally, our experiments demonstrate a decrease in the rate of substitution of chlorine by fluorine at the sulfur atom as the number of fluorine atoms on the carbon atom increases. We were also able to prepare the concluding member of the series, trifluoromethanesulfenyl fluoride.

Table 1. Chemical shifts (δ ppm.) and coupling constants (J Hz) for the ^{19}F–NMR spectra of perhalomethane sulfenyl halides (based on $CFCl_3$ as external reference).

Anomalous Course of the Neutralization of Periodic Acid by Sodium Hydroxide

By *K. F. Jahr* and *E. Gegner*[*]

Recently we showed[1] that the volume-contraction or -dilatation of a solution that occurs during a titration can be measured directly and used for indication of the end point. In neutralization of acids that proceeds normally one always observes a dilatation that has the same value for almost all strong acids. However, on neutralisation of free periodic acid H_5IO_6, we observed an anomalous course: a very strong dilatation up to the first equivalence point (consumption of 1 $OH^{\ominus}$) is followed by a strong contraction up to the second equivalence point (consumption of 2 $OH^{\ominus}$) (see Fig. 1).

We interpret the shape of this titration curve as due to the peculiarity of I(VII), which can adopt various coordination numbers towards oxygen, and we assume that the neutralization to the first equivalence point:

$$H_5IO_6 + OH^{\ominus} = H_4IO_6^{\ominus} + H_2O$$

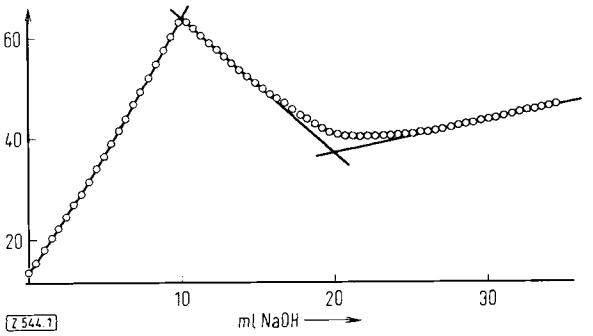

Fig. 1. Dilatometric titration of 100 ml of 0.1 M H_5IO_6 with 1 N NaOH.

Ordinate: Position of meniscus (cm).

is superposed by a change in coordination and thus by a dehydration that also occurs with dilatation:

$$H_4IO_6^{\ominus} = IO_4^{\ominus} + 2\,H_2O$$

The considerable volume contraction between the first and the second equivalence points can then be explained by resolvation, which occurs with a further change in coordination:

$$H_2O + IO_4^{\ominus} + OH^{\ominus} = H_3IO_6^{2\ominus}\ [**]$$

The slow further rise in the titration curve after the second equivalence point indicates further, incomplete neutralization of a weak acid. There are no other inflections.

That iodine can occur with various coordination numbers (4, 5, and 6) in periodates is proved by preparation of neutral anhydrous salts and by evaluation of their IR spectra[2]. Further, the central iodine atom does not retain its original coordination number during dissociation of periodic acid H_5IO_6 in aqueous solution; *Crouthamel et al.*[3], by pH measurements and spectrophotometric studies, and *Siebert*[4], by measurement of Raman spectra, have demonstrated the decomposition of $H_4IO_6^{\ominus}$ and the presence of the anion $IO_4^{\ominus}$; *Kustin* and *Lieberman*[5] have studied the kinetics of the decomposition $H_4IO_6^{\ominus} = IO_4^{\ominus} + 2\,H_2O$ in detail by the temperature-jump method and have found that on addition of alkali the anion $IO_4^{\ominus}$ is converted into the anion $H_3IO_6^{2\ominus}$ with addition of water. In agreement with these findings, crystalline salts are known that contain this anion, *e.g.* $Na_2H_3IO_6$, whereas salts of the type $M^IH_4IO_6$ have not hitherto been prepared.

In favorable circumstances the dilatometric indicator method thus makes it possible to observe addition or loss of water directly in aqueous solutions.

Dimethylfluorophosphine

By *F. Seel, K. Rudolph*, and *W. Gombler* [*]

Dimethylfluorophosphine, $(CH_3)_2PF$ *(1)*, could be obtained in the low pressure (<10 mm) reaction of gaseous dimethylchlorophosphine *(2)* [1] with active potassium fluoride [2] at 140 °C, thus closing the gap in the series PF_3, CH_3PF_2 [3], and $(CH_3)_3P$. Compound *(1)* melts at −109 °C, its boiling point is 26 °C/760 mm, and its vapor pressure is given by the equation $\log p$ (mm) = 7.46−1370/T (°K). The Trouton constant of *(1)* is 21.0 cal deg^{-1} mole^{-1}.

The most abundant fragments in the mass spectrum of *(1)* are CH_3PF^+ and $(CH_3)_2PF^+$. The IR spectrum of the vapor exhibits bands characteristic of a methyl compound which is closely related to the starting material (ν_{CH} = 2980, 2910 cm^{-1}; δ_{CH} = 1415, 1290 cm^{-1}; ρ_{CH} = 940, 875 cm^{-1}). The stretching frequencies of the C_2PF skeleton are found at 835, 760, and 690 cm^{-1}. In the ^{31}P–NMR spectrum the expected 1–1 doublet is observed, each component being split into a septet due to spin-spin coupling between ^{31}P and the protons of the two methyl groups. Likewise, the septets to be expected on account of F–P and F–H coupling are observed in the ^{19}F spectrum. The proton resonance in the methyl region consists of a doublet of doublets, due to H–F and H–P coupling. Chemical shifts and coupling constants are listed in Table 1.

Table 1. ^{31}P-, ^{19}F-, and H^1-NMR data for dimethylfluorophosphine

^{31}P (ext. H_3PO_4)			^{19}F (ext. $CFCl_3$)			^{1}H (ext. TMS)		
δ_P (ppm)	J_{P-F} (Hz)	J_{P-H} (Hz)	δ_F (ppm)	J_{F-P} (Hz)	J_{F-H} (Hz)	δ_H (ppm)	J_{H-P} (Hz)	J_{H-F} (Hz)
−187	820	6.0	+195.5	823	18.5	−1.45	5.9	18.5

Dimethylfluorophosphine is an extremely reactive compound which ignites spontaneously in air. It disproportionates cleanly at room temperature in accordance with the equation

$$3\,(CH_3)_2PF \rightarrow \underset{(3)}{(CH_3)_2PF_3} + \underset{(4)}{(CH_3)_2P{-}P(CH_3)_2}$$

to give dimethyltrifluorophosphorane *(3)* and tetramethylbiphosphine *(4)*. The identity of *(3)* was established from its ^{19}F–NMR spectrum [4], whereas *(4)* was identified by its ^{1}H- and ^{31}P–NMR spectra [5]. Hydrolysis of *(1)*, as well as of *(2)*, leads to formation of dimethylphosphine oxide, $(CH_3)_2P(O)H$.

In a manner analogous to methyldifluorophosphine [6], *(1)* combines with hydrogen fluoride in a 1:1 molar ratio to give a product containing a P–H bond, which is characterized by a proton NMR signal at −7.45 ppm. (J_{H-P} = 733 Hz), and by an IR band at 2435 cm^{-1}. *(1)* and *(2)* react with transition metals, even at low temperature, to form colored coordination compounds which are currently being investigated.

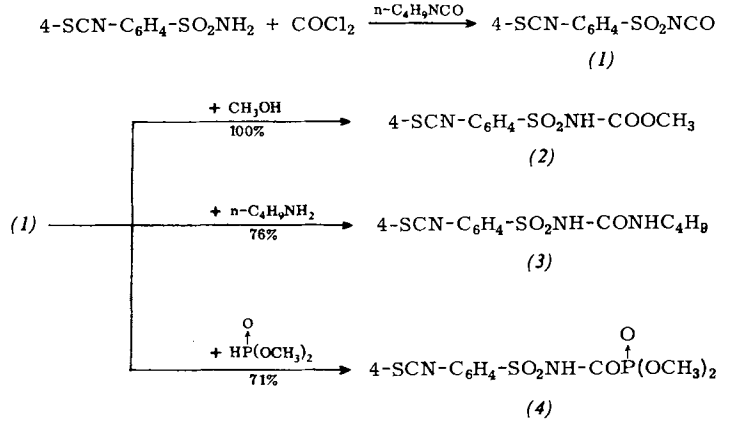
p-Isothiocyanatobenzenesulfonyl Isocyanate: a Bifunctional Compound with Selective Reactivity



By *H. Ulrich, B. Tucker*, and *A. A. R. Sayigh* [*]

Few compounds are known containing two cumulene functions in which the reactivity of the two double-bond systems is so different that selective reaction can be achieved at only one of the two groups. We recently reported the synthesis of isocyanatobenzenesulfonyl isocyanates in which the reactivity of the sulfonyl isocyanate function was appreciably greater than that of the isocyanate group [1]. The difference between the two groups should be considerably larger in isothiocyanatobenzenesulfonyl isocyanates.

p-Isothiocyanatobenzenesulfonyl isocyanate *(1)* can be obtained by direct phosgenation of *p*-isothiocyanatobenzenesulfonamide in the presence of n-butyl isocyanate as catalyst. On treatment of *(1)* with alcohols, amines, or dialkyl phosphites at room temperature, reaction occurs at the sulfonyl isocyanate group with formation of the 1:1 adducts *(2)*, m.p. 150–153 °C, *(3)*, m.p. 152–156 °C, and *(4)*, m.p. 152 to 153 °C.

When the urethane *(2)* is heated with methanol in the presence of triethylenediamine (DABCO) as catalyst, the 1:2 adduct, m.p. 168–170 °C, is obtained in 47.5% yield. Under similar conditions, the urea *(3)* reacts with methanol with formation of the mixed 1:2 adduct, m.p. 75 °C (yield 92.5%); and the mixed 1:2 adduct, m.p. 140–142 °C (yield 56%), results from *(3)* and isopropylamine.

Reagents can be chosen that permit synthesis of a series of mixed 1:2 adducts, which are only very difficulty accessible by other routes.

p-Isothiocyanatobenzenesulfonyl isocyanate (1):

Phosgene is passed (1 g/min; 90 min) into a boiling solution of *p*-isothiocyanatobenzenesulfonamide[2] (21.4 g, 0.1 mole) and *n*-butyl isocyanate (8.56 g) in *o*-dichlorobenzene (500 ml). Nitrogen is passed through the mixture, and then the solvent and catalyst are removed in a vacuum. Vacuum-distillation of the residue gives 19 g (79 %) of *p*-isothiocyanatobenzenesulfonyl isocyanate, b.p. 140 °C/0.2 mm, m.p. 64–67 °C; IR, $\lambda_{max}^{CHCl_3}$ = 2232 cm^{-1} (NCO) and 2128–2041 cm^{-1} (NCS).

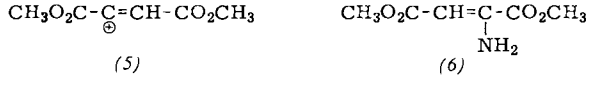
Cycloaddition of Ketoximes

By *E. Winterfeldt* and *W. Krohn*[*]

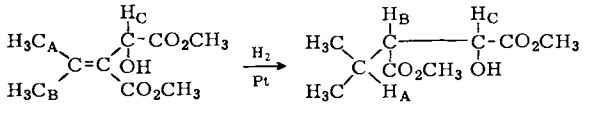
We have treated the oximes of cyclohexanone and acetone with dimethyl acetylenedicarboxylate in dimethylformamide or dimethyl sulfoxide at room temperature for 15 h. Pouring the mixtures into water gives in each case a 75 % yield of a product that, on the basis of analysis and mass spectra, is to be regarded as a 2:1 adduct.



Basically, there are two ways for formation of such an adduct: (i) Formation of the 1:1 adduct *(1)* and subsequent cycloaddition to give *(2)*; and (ii) proton shift to give *(3)* with subsequent cycloaddition resulting in the formation of *(4)*.

(4a), $R^1 = R^2 = CH_3$
(4b), $R^1 + R^2 = -(CH_2)_5-$

Whilst the analytical data ($C_{15}H_{19}NO_9$ for the product from acetoxime)[1] are in agreement with either possible mechanism, the spectral data indicate structure *(4a)*.



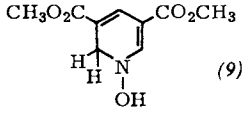
The intense peak (base peak) in the mass spectrum occurs at *m/e* = 143 and corresponds to fragment *(5)*; further important peaks lie at *m/e* = 342 (M − CH_3) and 298 (M − CO_2CH_3). The UV spectrum (in metnanol) with a maximum at 280 nm is not compatible with structure *(2)*.

(5) *(6)*

The IR spectrum shows bands at 1620, 1675, 1730, and 1750 cm^{-1} (no OH band) and thus accords well with structure *(4)*, as does also the NMR spectrum [τ = 8.44 (6), 6.37 (3), 6.28 (3), 6.18 (3), 6.15 (3), 4.51 and 3.89 (together 1)]. The NMR spectrum also indicates that *(4a)* is a mixture of *cis*- and *trans*-compounds in which the maleic ester configuration (the product of *cis*-addition) largely predominates (85 %). The failure of the protons with τ = 4.51 and 3.89 to undergo exchange with deuterated methanol excludes the presence of an OH group.

The following degradation reactions prove structure *(4a)*: Hydrogenation affords *(6)* (reductive N–O fission and allyl-hydrogenolysis), which proved to be identical with authentic material. Reduction with zinc in 10 % methanolic sulfuric acid at room temperature (30 min) yields *(7)* (reductive ring fission and Hofmann degradation), which gives *(8)* on hydrogenation.

(7) *(8)*



(7), IR: 3530, 1750, 1640 cm^{-1}.

NMR: H_3C_A τ = 8.03 (3); H_3C_B τ = 7.92 (3); CO_2CH_3 τ = 6.35 (3), 6.27 (3); H_C τ = 5.12 (1); OH τ = 7.0 (1).

(8), IR: 3550, 1750 cm^{-1}.

NMR: CH_3 τ = 9.0 (3), d*J* = 6.5, 9.06 (3), d*J* = 6.5; H_A τ = 7.78 (1); H_B τ = 7.52 (1), tr. *J* = 7; H_C τ = 5.71 (1), d*J* = 7; CO_2CH_3 τ = 6.25 (3), 6.38 (3); OH τ = 7.12 (1).

The structure *(4a)* is thus established for the adduct of acetoxime. Analogous spectral data for the adduct of cyclohexanone oxime permit it to be allotted structure *(4b)*. This

(9)

finding is remarkable because the investigations of *Ochiai et al.*[2] suggested that compound *(9)* of dihydropyridine type occurs as intermediate in the reaction of propiolic ester with formaldehyde oxime, and this product can be envisaged as formed by 1,4-addition.

N-(Cyano)phenylphosphonimidic Difluoride and *N*-(Cyano)diphenylphosphinimidic Fluoride

By *O. Glemser*, *E. Niecke*, and *J. Stenzel*[*]

2,4-Difluoro-1,3,2,4-diazadiphosphetidines are formed on treatment of bis(trialkylsilyl)-nitrogen compounds with Lewis-acid phosphorus fluorides[1]. The stability of the four-membered ring apparently prevents formation of a compound with a phosphorus-nitrogen double bond, so that

hitherto only one representative of the phosphorus fluorides, namely *N*-methyldiphenylphosphinimidic fluoride, has been known [2]. By treatment of bis(trimethylsilyl)carbodiimide [3] with tetrafluoro(phenyl)phosphorane [4] and diphenylphosphinic trifluoride, we have now synthesized the two phosphorus fluoride imides *(1)* and *(2)*.

$$(CH_3)_3Si{-}NCN{-}Si(CH_3)_3 + H_5C_6{-}PF_4 \rightarrow 2\,(CH_3)_3SiF + H_5C_6{-}PF_2{=}NCN \quad (1)$$

$$(CH_3)_3Si{-}NCN{-}Si(CH_3)_3 + (C_6H_5)_2PF_3 \rightarrow 2\,(CH_3)_3SiF + (C_6H_5)_2PF{=}NCN \quad (2)$$

The compounds *(1)* and *(2)* are formed quantitatively when carbodiimide is added dropwise to the phosphorus fluoride (molar ratio 1:1 [5]) with stirring and warming [*(1)* at 30 °C, *(2)* at 70 °C]. A large part of the trimethylsilyl fluoride escapes from the mixture during the reaction, and the remainder is pumped off under vacuum (1 mm).

The composition of compounds *(1)* and *(2)* is proved by the results of elemental analyses and by determination of the molecular weight [mass spectroscopic: for *(1)*, *m/e* = 186; for *(2)*, *m/e* = 244] [6].

The phosphorus fluoride imides *(1)* and *(2)* are viscous, high-boiling liquids that fume in air and undergo considerable decomposition on distillation in a vacuum – their separation by distillation was therefore not attempted.

The IR spectra (capillary film) of *(1)* and *(2)* in the NaCl region showed the following bands, as well as those of the phenyl group:

$H_5C_6{-}PF_2NCN$: 2230 ν(NC≡N); 937, 908, 814 ν_{as},ν_{sym}(PF), ν(N–CN)

$(C_6H_5)_2{-}PFNCN$: 2210 ν(NC≡N); 885, 815 ν(N–CN), ν(PF)

The ^{31}P–NMR spectrum [6] of *(1)* contains a triplet, and that of *(2)* a doublet. As expected, the ^{19}F–NMR signal is a doublet for both compounds. Coupling of the *ortho*-protons on the phenyl group with the fluorine was not observed, nor was P–H coupling over two carbon atoms.

	$\delta^{31}P$(ppm)[a]	J_{PF}(Hz)	$\delta^{19}F$(ppm)[a]	J_{FP}(Hz)
$H_5C_6{-}PF_2NCN$	−15.3	1140	66.5	1132
$(C_6H_5)_2PFNCN$	−50.3	1074	82.1	1064

[a] 85 % H_3PO_4 and $CFCl_3$, respectively, were used as external standard.

The center of the signal for the *para*-proton on the phenyl ring of *(1)* is at −7.41 ppm, and of *(2)* is at −7.18 ppm, referred to $(CH_3)_4Si$ as external standard.

Comparison of the $\delta^{31}P$ values of difluorodiazadiphosphetidines (of the order of 45–70 ppm) with those of the phosphorus fluoride imides shows that the phosphorus nucleus is more strongly shielded in the cyclic compounds.

Thus the difference in the coordination number of the phosphorus in the difluorodiazadiphosphetidines (v) and in the phosphorus fluoride imides (iv) has its effect on the PF coupling constants. Whereas J_{PF} for the former is at 900 Hz, for the latter one obtains values some 200 Hz greater.

Synthesis of Sulfur Difluoride (Difluorophosphinyl)-imide and Sulfur Oxide Difluoride (Fluorosulfonyl)imide

By *O. Glemser*, *H. W. Roesky*, and *P. R. Heinze* [*]

Phosphorodifluoridamide *(1)*, prepared by ammonolysis of pyrophosphoryl tetrafluoride [1], reacts with sulfur tetrafluoride at 40 °C to give a 55 % yield of sulfur difluoride (difluorophosphinyl)imide *(2)*, which decomposes even at room temperature to phosphoryl fluoride and thiazyl fluoride.

$$\underset{(1)}{OPF_2NH_2} + SF_4 \rightarrow \underset{(2)}{OPF_2N{=}SF_2} + 2\,HF$$

$$(2) \rightarrow POF_3 + NSF$$

Fluorosulfonyl amide *(3)* reacts with sulfinyl tetrafluoride at 130 °C in presence of sodium fluoride as HF trap, to give a 30 % yield of sulfur oxide difluoride (fluorosulfonyl)imide *(4)* [2].

$$\underset{(3)}{FSO_2NH_2} + SOF_4 \rightarrow \underset{(4)}{FSO_2N{=}SOF_2} + 2\,HF$$

Compound *(2)* is a clear liquid with a pungent odor and has b.p. 45 °C/80 mm and m.p. −41 °C. Even in absence of moisture it decomposes within a few hours, becoming deep red. The vapor pressure accords with

$$\log p_{mm} = -(1904/T) + 7.887$$

with a heat of vaporization of 8.7 kcal mole^{-1} and a Trouton constant of 22.9 cal deg^{-1} mole^{-1}; b.p. (extrap.) = 108 °C. The composition of the compound is proved by the results of elemental analysis and by the mass spectrum. The ^{19}F–NMR spectrum of *(2)* shows four triplets of equal intensity.

Signal	Position (Hz)	Chem. shift [a]	Coupling constant
A	+3207	δ_{SF} = −57.1 ppm	$J_{P\text{-}F(S)}$ = 28 Hz
B	+3235		
C	−4457	δ_{PF} = +69.9 ppm	J_{PF} = 1026 Hz
D	−3431		J_{FF} = 4.5 Hz

[a] Referred to CCl_3F as external standard at 30 °C.

The IR spectrum (recorded in the gas phase) showed the following bands: 1392 vs ν(PO), 1352 vs ν(SN), 957 s ν_{as}(PF), 920 s ν_s(PF), 798 s ν_{as}(SF), 731 s ν_s(SF), 696 m ν(PN) cm^{-1} [3]; weak bands at 630, 566, 529, and 488 cm^{-1} are ascribed to deformation vibrations.

Because of the dependence of the strength of P–O and P–F bonds on the sum of the electronegativities of the halogens in phosphoryl halides, the IR data can be used to afford the electronegativity of the NSF_2 group. From the equation [4]

$\nu(PO) = 31.3\ \Sigma x_i + 1039$

one obtains the electronegativity $x_{NSF_2} = 3.3$. If one plots the mean PF frequency of the phosphoryl halides against the sum of the electronegativities, one obtains a linear dependence, whence the electronegativity of the NSF_2 group again appears as 3.3.

Compound *(4)* is a clear liquid of b.p. 72 °C and m.p. −70 °C and, as expected, is more stable than sulfur difluoride (fluorosulfonyl)imide. The compound was characterized by elemental analysis and by its IR, ^{19}F–NMR, and mass spectra.

The mass spectrum shows, besides the molecular ion at m/e = 183, the typical fragments M − F (164), FSO_2N (97), SOF_2 (86), FSO_2 (83), FSO (67), SF (51), and SO (48).

The ^{19}F–NMR spectrum shows a doublet at −45.4 and a triplet at −60.1 referred to CCl_3F as external standard; the coupling constant is J_{FF} = 8 Hz.

The IR spectrum (gas) in the NaCl region shows strong bands at 1475, 1450, 1245, 888, 821, 740, and 716 cm^{-1}, which are to be ascribed to stretching virations.

Preparation of Sulfur Oxide (Fluorosulfonyl)imide and Sulfur Dichloride (Fluorosulfonyl)imide [1]

By *H. W. Roesky* [*]

Fluorosulfonamide *(1)*, which can be prepared by hydrolysis of fluorosulfonyl isocyanate [2] by concentrated formic acid, reacts with thionyl chloride *(2)* to give sulfur oxide (fluorosulfonyl)imide *(3)*.

$$\underset{(1)}{FSO_2NH_2} + \underset{(2)}{SOCl_2} \rightarrow \underset{(3)}{FSO_2{-}N{=}S{=}O} + 2\,HCl$$

Thionyl chloride (0.75 mole) is added to the amide *(1)* (0.5 mole), and the whole is heated under reflux, with stirring, for 48 h, then distilled under vacuum (oil-pump). The product *(3)* is collected in a cold trap (−10 °C; ice/salt) and distilled [yield, 42 g (57 %); b.p. 20 °C/0.3 mm, 32 °C/15 mm]. Partial decomposition sets in at higher pressures.

Compound *(3)* is a yellow liquid that reacts explosively with water at room temperature. At −20 °C its reaction with water regenerates the amide and sulfur dioxide. The mass spectrum of *(3)* contains the molecular ion peak at m/e = 145 and peaks for the fragments FSO_2 (83), SO_2 (64), SO (48), and NS (46). The IR spectrum (capillary film) in the NaCl and KBr region shows bands at 1435, 1260, 1210, 1125, 830, 700, 628, 615, 595, 538, 482, and 460 cm^{-1}; these are provisionally allotted to the following vibrations: $\nu_{as}(SO)$ 1435, $\nu_s(SO)$, $\nu(SO)$, $\nu(N{=}S)$ 1260, 1210, 1125, $\nu(SF)$ 830, $\nu(SN)$ 700, and deformation vibrations.

Reaction of the imide *(3)* with phosphorus pentachloride gives sulfur dichloride (fluorosulfonyl)imide *(4)*.

$$\underset{(3)}{} + PCl_5 \rightarrow \underset{(4)}{FSO_2{-}N{=}SCl_2} + OPCl_3$$

Compound *(3)* is added dropwise to an excess of PCl_5 with stirring and with passage of dry nitrogen (molar ratio 1:1.2) at such a rate that the temperature does not rise above 50 °C. The mixture is then filtered under nitrogen from the excess of PCl_5 and fractionated in a vacuum (yield 70 %; b.p. 45 °C/0.4 mm).

Compound *(4)* can also be prepared, in an impure form, from *(1)* and sulfur dichloride.

The IR spectrum of *(4)* contains bands at 1425, 1210, 1125, 805, 712, 582, 537, 480, and 442 cm^{-1}, which are provisionally allotted to the following vibrations: $\nu_{as}(SO)$ 1425, $\nu_s(SO)$, $\nu(N{=}S)$ 1210, 1125, $\nu(SF)$ 805, $\nu(SN)$ 712, and $\nu(SCl)$ and deformation vibrations. The mass spectrum shows many fragments as well as the molecular ion at m/e = 199 and 201 (isotopic ratio).

Sulfur dichloride (fluorosulfonyl)imide *(4)* is a colorless liquid, that is hydrolysed immediately by water. It reacts with V2A steel at room temperature with decomposition.

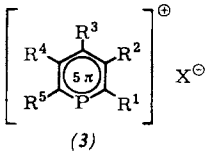
Determination, by ESR Spectroscopy, of the Constitution of the Phosphorus Radicals formed on Oxidation of Phosphorins

By *K. Dimroth, N. Greif, W. Städe*, and *F. W. Steuber* [*]



As part of a study of the radicals formed on oxidation of 2,4,6-triarylphosphorins [1] we have prepared the new phosphorins *(2)* listed in the table. These compounds, which were prepared by *Märkl*'s method [2] from the corresponding pyrylium salts *(1)*, were oxidized by 2,4,6-triarylphenoxyls, lead(IV) acetate or benzoate, mercury(II) acetate, or other oxidizing agents to the phosphorus radical cations *(3)*, which are very stable in solution.

[a] These phosphorin derivatives were recently prepared by *G. Märkl et al.* [3] by another method. Material discrepancies in melting point occur only for *(2c)* and *(2d)*. These may be due, as for tetra- and penta-phenylbenzene derivatives, to formation of different crystal modifications.

[b] From 2, 4, 6-tri-t-butylpyrylium tetrafluoroborate, m. p. 216°C (*K. Dimroth* and *W. Mack*, unpublished).

The ESR spectra of all these radicals are very similar in type: They contain a doublet that is due to interaction of the free electron with the phosphorus. The phosphorus coupling constant a_P lies between 21.5 and 27 gauss (see table) according to the nature of the substituents. The doublet has hyperfine structure owing to coupling with the protons.

There are about 70 lines in the spectrum of the 2,4,6-triphenylphosphorin radical. However, if the three phenyl groups in 2-, 4-, and 6-position are replaced by pentadeuteriophenyl, then, exactly as with 2,4,6-tri(pentadeuteriophenyl)phenoxyl[4], the spectrum is greatly simplified by the small magnetic moment and the larger nuclear spin of the deuterium. Only the two protons in the central nucleus lead to resolution to hyperfine structure. One obtains a triplet 1:2:1, which, by phosphorus coupling ($|a_P|$=23.2 gauss) appears twice, (Fig. 1a). The hyperfine structure coupling constant $|a_H|$ amounts to about 2.4 gauss. In the NMR spectrum tris-(pentadeuteriophenyl)phosphorin *(2a)* gives signals only for the two protons in the central ring (doublet at $\delta = -8.12$ ppm, $J = 6$Hz).

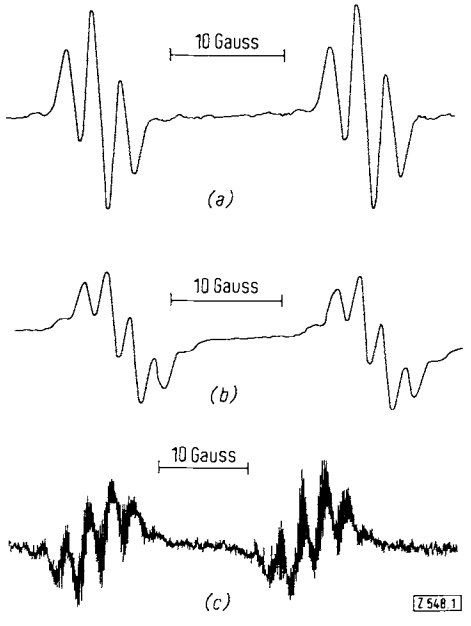

Fig. 1. ESR spectra of the cation radicals from (a) 2,4,6-tris(pentadeuteriophenyl)phosphorin *(2a)*, (b) 2,6-bis(pentadeuteriophenyl)-4-phenylphosphorin *(2b)*, and (c) 2,6-di-t-butyl-4-phenylphosphorin *(2p)*.

Every group of lines in the ESR spectrum of the oxidation product of 2,6-bis(pentadeuteriophenyl)-4-phenylphosphorin *(2b)* consists of a sextet with approximate intensities 1:5:10:10:5:1 (Fig. 1b), analogously to the spectrum of the correspondingly substituted phenoxyl[4]. The coupling constants of the protons in positions 3 and 5 of the central ring, and of the two *ortho*-protons and the *para*-proton of the phenyl group, are about equal in size (2.4 gauss), but the *meta*-protons on this phenyl ring have significantly lower coupling constants, so that no further resolution is observed. The spectrum can be unequivocally reconstructed.

It is thus proved that the new radicals retain the intact phosphorin ring. The same conclusion is reached on comproportionation of one molecule of the radical formed on oxidation and one of that formed on reduction of 2,4,6-triphenylphosphorin[5], which regenerates 2,4,6-triphenylphosphorin.

The phosphorins *(2o)* to *(2r)* are the first compounds of this type containing aliphatic groups. They too give very simple ESR spectra because the coupling constants of the t-butyl groups are small. Figure 1c shows the spectrum of 2,6-di-t-butyl-4-phenylphosphorin cation radical ($|a_P| = 23.7$ gauss, $|a_H| = 2.5$ gauss). For 2,6-di-t-butyl-4-(*p*-methoxyphenyl)-phosphorin cation radical the sextet of lines becomes a quintet, since here the coupling with the *para*-proton on the phenyl ring at C-4 is absent.

Mechanism of the Gomberg Reaction and of Phenylation by *N*-Nitrosoacetanilide

By *Ch. Rüchardt* [*]

Phenylation of aromatic compounds by the Gomberg reaction and by *N*-nitrosoacetanilide can both be interpreted as formation and homolysis of diazoanhydrides *(1)* [1].

(1) *(2)*

The key hypothesis for understanding these reactions, namely, formation of relatively stable diazotate radicals *(2)*, is supported by chemical and physical evidence.

Polymerisation of styrene initiated by *N*-nitrosoacetanilide gives only a small amount of polymer (1 to 2 wt-%) containing nitrogen. The inhibiting action of stable diazotate radicals, which trap the growing chains, can explain this result. During the whole period of decomposition of *N*-nitrosoacetanilide in benzene an ESR spectrum is observable (g = 2.0055) that contains three groups of lines whose fine structure agrees with the structure of the diazotate radicals. By using ^{15}N-labeling the N coupling constant a_N = 11.61 gauss was assigned to the "outer" nitrogen atom and a_N = 1.67 gauss to the nitrogen attached to the aromatic group. The spectra of *p*-deuterio- and *p*-t-butyl-diazotate radicals can be best reproduced by assuming differing *ortho*-couplings, according to which diazotate radicals have a non-linear structure, as has been assumed also for diazotate anions.

The Viscosity of Liquid Aluminum Halides

By *K. H. Grothe* and *P. Kleinschmit* [*]

It is difficult to determine the viscosity of molten salts by the usual methods [1] if the substances are sensitive to air or have a high vapor pressure. Such substances include aluminum tribromide and triiodide. A method was therefore chosen in which a vessel suspended from a wire was made to execute torsional oscillations, the damping of the oscillations being measured and used to determine the viscosity. The salts were distilled into a cylindrical glass vessel of about 3 cm diameter and 4 cm height and the vessel was subsequently sealed in a vacuum. The vessel was hung on a torsion wire and made to oscillate about its vertical axis. The friction between the layer of liquid adhering to the inner wall and the liquid near the wall leads to damping of the oscillations.

$AlBr_3$					
T (°C)	100	150	200	250	
η (cP)	2.37	1.42	0.96	0.71	
AlI_3					
T (°C)	200	240	300	340	400
η (cP)	2.62	1.90	1.32	1.10	0.86

The values in the Table were found for the viscosity of $AlBr_3$ (m.p. 97.5 °C; b.p. 255 °C) and AlI_3 (m.p. 192 °C; b.p. 386 °C).

In both cases the exponential function $\eta = A \exp (E_\eta/RT)$ proposed by *Andrade* [2] was followed. For $AlBr_3$, $A = 34.5\times10^{-3}$ cP and E_η = 3.13 kcal mole^{-1}; for AlI_3, $A = 64.0\times10^{-3}$ cP and E_η = 3.46 kcal mole^{-1}.

The viscosities found also follow the equation given by *Batschinski* [3]: $v = B\varphi + b$, where v is the specific volume, $\varphi = 1/\eta$ the fluidity, b is the specific volume at zero fluidity, and B is a constant. The values of b extrapolated from this equation do not agree with the specific volumes of the solid aluminum halides at the melting point but are about 10 % greater.

Measurement of Vapor-pressure Differences for Isotopic Compounds

By *H. Wolff* and *A. Höpfner* [*]

Replacement of H by D either decreases (normal effect) or increases (inverse effect) the vapor pressure (p) of a substance. Hydrocarbons show the inverse effect; alcohols and amines (including H_2O and NH_3) show a normal effect insofar as replacement is at the hydroxyl or amino group, but otherwise an inverse effect.

Study of the vapor-pressure isotope effect for the methylamines CH_3NH_2 *(1)*, CH_3ND_2 *(2)*, CD_3NH_2 *(3)*, and CD_3ND_2 *(4)* in relation to temperature and concentration (in mixtures with n-hexane) showed strong, temperature-dependent normal effects for the pairs *(1)/(2)* and *(3)/(4)*, that change to inverse effects at high dilution (molar fraction < 0.1). The inverse effects observed for *(1)/(3)* and *(2)/(4)* are only slightly dependent on temperature and independent of concentration.

It is concluded from the experimental results that appearance of the normal vapor-pressure isotope effect for the substances named is connected with the occurrence of association by hydrogen bonding. Quantitative interpretation seems to be possible by means of the hydrogen-bond vibrations to which the translational and rotational degrees of freedom of the free molecule correspond, though these vibrations are not readily accessible spectroscopically. For the ideal case of wholly independent harmonic vibrations the isotope effect of one degree of freedom is given by

$$\frac{p_D}{p_H} = \frac{\theta_H \sin \frac{\theta_D}{2T}}{\theta_D \sin \frac{\theta_H}{2T}}$$

This formula also explains why all substances show a normal effect at very low temperatures (< 70 °K), since, under these conditions, the lattice vibrations (whose characteristic temperatures mostly lie below 100 °K) may contribute to the

vapor pressure isotope effect whereas they are fully excited at room temperature and thus do not contribute.

Developments of Fuel Cells

By *W. Vielstich* [*]

General Motors recently exhibited a bus (Electrovan) driven by a 32 kW H_2/O_2 battery (Union Carbide Inc.) operating an alternating current motor. Disadvantages of this experimental model are the tanks containing liquid hydrogen and liquid oxygen (danger of explosion) and the high cost of the noble metals in the hydrogen electrode. A 200 kW battery constructed by Firma ASEA, Sweden, for propulsion of a submarine, utilizes ammonia and liquid air; the ammonia is first cracked in a reformer and the hydrogen obtained is fed to skeleton nickel electrodes.

The triangular potential scan method is useful for study of the fundamental principles. In the region between initial H_2- and O_2-evolution, the electrode potential varies linearly with time in a periodic manner. In this way, the experimental electrode is reproducibly reactivated during measurement.

The nature of the intermediate product in the oxidation of formic acid is of particular interest. By comparing the charge needed for oxidation of the adsorbed intermediate with the amount of carbonate formed (determined by titration) it was shown that one electron is consumed per carbon atom. This result suggests that COOH radicals are the intermediates, rather than CO.

The composition and structure of the catalyst have a great effect on the dehydrogenation of methanol and formate in alkaline electrolytes. At the same electrode potential the anodic current densities for methanol (uncharged particles) and formate (charged particles) on various catalysts (*e.g.* Pt, Pd, and Pt/Pd alloys) differ by more than one order of magnitude.

Fuel cell batteries based on methanol/air and formate/air and incorporating these catalysts have already been tested as energy sources in signal installations and TV relay stations. Fuel monocells are superior to the usual dry batteries in respect of greater capacity, constant discharge potential, ease of recharging, and better storage life. Monocells are constructed on the following principles: The lid of the monocell is fitted with a cylindrical carbon diffusion electrode with an air inlet and a metal terminal. The cell also contains a cylindrical fuel electrode and fuel electrolyte (20 ml 4 M CH_3OH + 9 N KOH). After discharge (*e.g.* 50 mA, 0.6 V, 240 h, 12 Ah), the element can be regenerated simply by renewal of the electrolyte.

Intramolecular Hydrogen Bridges in Nitrosophenols

By *H. Uffmann* [*]

Tautomeric equilibria of the type *p*-nitrosophenol $\rightleftarrows$ 1,4-benzoquinone 4-monoxime are established *via* an intermediate mesomeric ion which can itself play a considerable part in the equilibrium [1]. Formation of the ion and achievement of the equilibrium are suppressed by internal hydrogen bridges. For instance, the 2-methoxycarbonyl compound *(1)* is a true nitrosophenol both in the solid state and in benzene or dioxane.

(1)

(2)

On the other hand, in the solid state the 3-methoxycarbonyl compound *(2)* is a quinone oxime with intermolecular hydrogen bridges. The oxime group is in the *anti*-position to the methoxycarbonyl group, as it is also in other quinone 4-oximes having a substituent on C-3 [2].

5-Methoxy-2-nitrosophenol exists in a brownish-green and in an orange form. *Burawoy* [3] concluded from the electronic spectra of this compound in various solvents that an equilibrium exists between the nitrosophenol with an internal bridge and a quinone oxime with an internal bridge. *Bartindale* [4] proved that the orange form in the solid state is a quinone oxime with intramolecular bridges and *anti*-relation of the oxime group to the quinone oxygen atom, which is in agreement with the behavior of 1,4-quinone oximes [2]. By means of IR and electron band spectra of the two solid forms and in various solvents, aided by the dependence of the spectra on the hydrogen ion concentration and on temperature, it has been found that, in carbon tetrachloride, there is an *o*-nitrosophenol with an internal bridge but that in polar solvents there is an equilibrium between the nitrosophenol with an internal bridge, the mesomeric ion, and the quinone oxime with intermolecular bridges (cf., however [5]).

A 1,2-quinone oxime with internal bridge is to be expected if a substituent in the second neighboring position to the oxime group prevents the movement of that group from the *syn*-position to the quinone oxygen, even though this type of substitution favors the quinone oxime structure. Such a case exists in 1,2-naphthoquinone 1-oxime; here also polar solvents lead to partial fission of the internal hydrogen bridge, so that the naphthoquinone with internal bridge is in equilibrium with the mesomeric ion and 1-nitroso-2-naphthol.

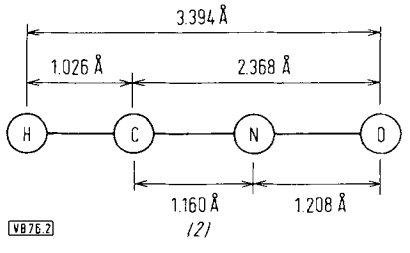
Investigation of Unstable Molecules and Free Radicals by Rotational Spectroscopy

By *M. Winnewisser* [*]

The millimeter and submillimeter region of the electromagnetic spectrum is a field of molecular spectroscopy that is rich but almost undeveloped. Because of their short wavelength [10 mm (30000 MHz) to 1 mm (300000 MHz) these waves can be collimated and focused by a combination of waveguides, horns, and Teflon lenses, which permits the use of large glass or quartz absorption cells for spectroscopy of unstable molecules and gaseous radicals [1]. The gases to be studied are contained in a cylindrical glass cell (diameter 10 cm, length 100 cm), which is placed in the path of the millimeter radiation. A system of gas discharge



tubes, connected directly to the cell, serves for production of free radicals.

Using such a spectrometer, *Winnewisser, Sastry*, and *Gordy*[2] first obtained the millemeter spectrum of sulfur monoxide (electron ground state $^3\Sigma$) in the gas discharge products of SO_2 and studied the magnetic properties of the radical[3]. In the gas discharge product of H_2S the relatively unstable H_2S_2 is formed from the SH radical by secondary reactions[4], similarly to the production of H_2O_2 from OH radicals. Formation of disulfane was proved by the rotational spectrum in the millimeter region. The disulfane rotational spectrum is the first $\perp$-type spectrum of an almost symmetrical top with $\varkappa = -0.999985$. This shows that the dipole moment is perpendicular to the symmetry axis of the inertia tensor and parallel to the twofold symmetry axis, thus proving the chain structure of HSSH with C_2 symmetry. Analysis of the millimeter spectrum[5] and electron-diffraction measurements[6] yielded the preliminary structure *(1)* for disulfane.

(1) VB75.1

Fulminic acid is another unstable molecule whose structure in the free gaseous state was hitherto unknown. *Beck* and *Feldl*[7] proved that it has the nitrile oxide form by means of its IR spectrum. The microwave spectrum between 10000 and 50000 MHz indicates a linear molecule[8]. Measurement of the various isotope combinations showed the atomic bonding HCNO and the preliminary structural parameters indicated in formula *(2)*.

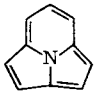
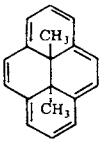
Electron Spin Resonance Studies of Bridged Annulenes

By *F. Gerson*[*]



A model of a ten- or fourteen-membered π-electron perimeter can be used for interpretation of the ESR spectra of radical ions of the bridged annulenes *(1)* to *(4)*[1].



(1)
X = CH_2, O, NH

(2)

(3)

(4)

The lowest antibonding (ψ_a) and the highest bonding orbita (ψ_b) of the two perimeters are twofold degenerate. They can be classified as ψ_{a+} and ψ_{a-}, and as ψ_{b+} and ψ_{b-}, respectively. Here plus denotes symmetrical and minus antisymmetrical with respect to a plane that passes through two opposed centres in the perimeter and is perpendicular to the plane of the perimeter. Bridging of the system results in lifting of the degeneracy of ψ_{a+} and ψ_{a-} on the one hand and of ψ_{b+} and ψ_{b-} on the other.

In the radical anions of the bridged [10]annulenes *(1)* and *(3)* the unpaired electron occupies the antisymmetrical orbital ψ_{a-}, which thus lies lower than ψ_{a+}. However, in the radical anions of the bridged [14]annulenes *(2)* and *(4)* the unpaired electron is in the symmetrical orbital ψ_{a+}, which is here more stable than ψ_{a-}.

In the radical cation, which can also be prepared from compound *(4)*, there is an unpaired electron in the symmetrical ψ_{b+} orbital, which thus has a higher energy than ψ_{b-}.

These results permit conclusions to be drawn about the nature and direction of the effect exerted by the bridges on the π-electron systems in compounds *(1)* to *(4)*. Considered in conjunction with the geometry of the compounds, they lead to the following conclusions: In *(1)* and *(2)* the effect of CH_2, O, and N bridges is mainly inductive and electron-repelling. In *(4)*, however, this effect may perhaps be accompanied by hyperconjugation between the σ-electrons of the butane bridges and the π-electrons of the perimeter. Finally, in *(3)* the mesomeric and electron-donating effect of the central nitrogen atom plays the most important part.

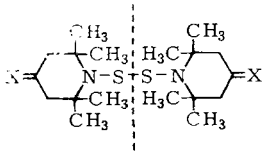
Fixation of molecular nitrogen in a tris(triphenylphosphine)-cobalt complex *(1)* has been observed by *Y. Yamamoto, S. Kitazume, L. S. Pu,* and *S. Ikeda.* The complex was prepared under nitrogen as follows:

$$Co(acac)_3 + 3\ Al(C_2H_5)_2OC_2H_5 + 3\ P(C_6H_5)_3 + N_2 \rightarrow [\{(C_6H_5)_3P\}_3Co{\cdot}N_2]$$
(1)



(1) forms yellow crystals, which can be recrystallized from toluene at low temperature, and is moderately stable under nitrogen. The nitrogen is released quantitatively at 80 °C. The IR spectrum of *(1)* contains a sharp band at 2088 cm^{-1}. / Chem. Commun. *1967*, 79 / –Kr. [Rd 656 IE]

Pahutoxin, the poison of the blue boxfish *(Ostracion lentiginosus)*, has been isolated in the crystalline form by *D. B. Boylan* and *P. J. Scheur.* The structure was established by alkaline and acidic hydrolysis and by synthesis. Approximately 60 mg of pahutoxin *(1)*, m.p. 74–75 °C, $[\alpha]_D^{22} = +3.05°$, was isolated per adult boxfish.

$$CH_3\text{-}(CH_2)_{12}\text{-}\underset{\underset{OCOCH_3}{|}}{CH}\text{-}CH_2\text{-}COO\text{-}(CH_2)_2\overset{\oplus}{N}(CH_3)_3Cl^{\ominus} \quad (1)$$

The fish emit *(1)*, together with mucus, on hard rubbing. Fish of other species are killed rapidly by the poison. / Science (Washington) *155*, 52 (1967) / –De. [Rd 655 IE]

New stable sulfur radicals, according to *J. E. Bennett, H. Sieper* and *P. Tavs*, are formed reversibly from the bis-(2,2,6,6-tetramethylpiperidino)disulfides *(1a)* and *(1b)* when they are heated to 90–150 °C and 140–200 °C respectively.

(1a), X = H_2
(1b), X = O

The three-line ESR spectrum shows a hyperfine splitting of about 11 oersted and a *g* factor of 2.0172. (Values for the corresponding nitroxyl radicals: about 15 oersted and *g* = 2.0061). *(1a)* (m.p. 84–85 °C; yield 66%) and *(1b)* (m.p. 145–147 °C; yield 81%) were prepared by treatment of the appropriately substituted pyridines with SCl_2 in dimethylformamide; S_2Cl_2 gives a chromatographically separable mixture of the di- and trisulfides. Tri-, tetra-, and pentasulfides are formed in nonpolar solvents (hexane, ether). / Tetrahedron *23*, 1697 (1967) / –Bu. [Rd 678 IE]

Thiolates of cobalt, nickel, copper, and zinc have been described by *D. C. Bradley* and *C. H. Marsh.* The cobalt and nickel thiolates are obtained by the addition of thiol (RSH) to $CoCl_2{\cdot}6H_2O$ and to $NiCl_2{\cdot}6H_2O$ or $Ni(NO_3)_2{\cdot}6H_2O$ in C_2H_5OH/NH_3 solution (molar ratio of reactants approx. 2:1) (R = C_2H_5, C_3H_7, i-C_3H_7, t-C_4H_9, C_5H_{11}, C_6H_5). Thiols with R = n-alkyl give mainly cobalt(III) thiolates (magnetic susceptibility!), while those with R = iso- or t-alkyl and phenyl give cobalt(II) thiolates. The brown to black nickel(II) thiolates mainly have degrees of polymerization of 4 to 6 in the primary stage, are stable up to about 180 °C, and undergo exchange with higher thiols.

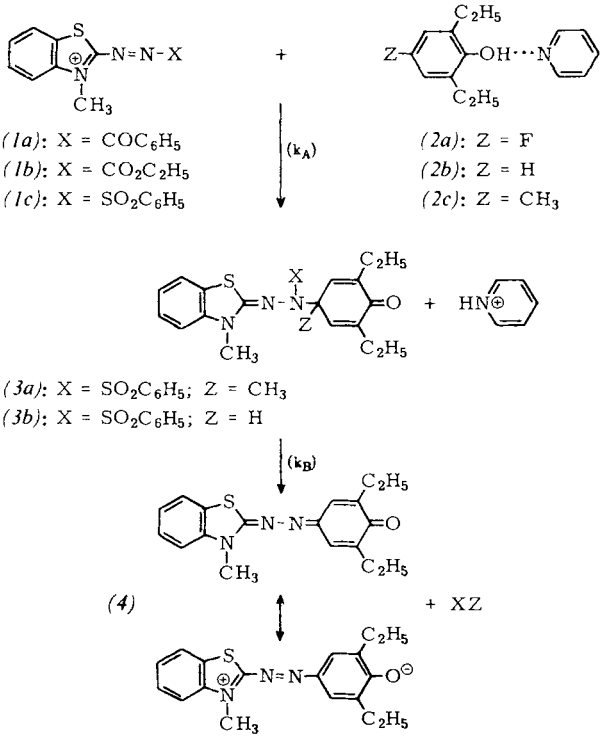
The copper(I) thiolates, *e.g.* CuS-i-C_3H_7, CuS–C_5H_{11}, are pale yellow, diamagnetic solids, and are stable up to about 200 °C/0.1 mm Hg. The zinc thiolates, $Zn(S\text{-i-}C_3H_7)_2$, $Zn(SC_6H_5)_2{\cdot}2NH_3$, $Zn(SC_5H_{11})_2$, form white precipitates, and are stable up to about 190 °C/0.1 mm Hg. Coordination polymers occur in every case. It should be noted that these thiolates can be obtained in the presence of water, *i.e.* thiolates of $3d^6$ to $3d^{10}$ transition metal ions are resistant to hydrolysis. / Chem. and Ind. *1967*, 361 / –Jg. [Rd 692 IE]

The first carbonylmetal complexes of hydrogen isocyanide (HNC) have been obtained by *R. B. King* in the reaction of $Na[M(CO)_5CN]$ *(1)* with 4 N HCl.

$$Na[M(CO)_5CN] + HCl \rightarrow (HNC)M(CO)_5 + NaCl$$
(1) *(2)*

(2a), M = Cr; decomp. point 114–116 °C; the crystals are purified by sublimation at 60–90 °C/0.1 mm; yield 41%. *(2b)*, M = Mo; no decomposition point; sublimation at 70–80 °C/0.1 mm; yield 13%. *(2c)*, M = W; decomp. point > 105 °C; sublimation at 70–90 °C/0.1 mm; yield 32%. *(2b)* is very unstable; it turns brown within a few hours at room temperature. *(2c)* and *(2a)* are generally much more stable, but occasionally turn blue *(2c)* or yellow *(2a)*. The salts *(1)* are readily obtained from sodium bis(trimethylsilyl)amide and hexacarbonylmetal in benzene.

Their reaction with trimethylchlorostannane yields the colorless, crystalline trimethyltin isocyanide complexes $(CH_3)_3SnNCM(CO)_5$ (M = Cr, Mo, W). Spectroscopic investigations (IR and ^1H–NMR) clearly show that *(2)* contains an HNC ligand, which, in contrast to free HNC (rearrangement into HCN), is stabilized in this case by complex formation. / Inorg. Chem. *6*, 25 (1967) / –Sch. [Rd 661 IE]



The mechanism of the Guerbet reaction was studied in the reaction of benzyl alcohol with potassium lactate to give α-hydroxy-γ-phenylbutyric acid (together with hydrogen and benzoic acid). According to *S. Veibel* and *J. I. Nielsen*, the reaction proceeds as follows: (a) Both hydroxy compounds are dehydrogenated to the carbonyl compounds, which (b) undergo aldol condensation followed by elimination of water. (c) Hydrogen is transferred to the resulting α,β-unsaturated ketones from the starting compounds, which are themselves reduced in this way (see step (a)) to carbonyl compounds. This leads to a chain reaction. The chain is terminated (d) by a Cannizzarro disproportionation of the benzaldehyde. The ratio of the rates of steps (a) to (c) to the rate of step (d) therefore determines the yield of α-hydroxy-γ-phenylbutyric acid. Raney nickel and Pd are effective catalysts for the dehydrogenation-hydrogenation reaction, though the reaction also takes place in their absence. If potassium benzylidenepyruvate is present at the beginning of the reaction, the latter can be carried out at 130 °C instead of at 160 °C (reaction (a), which is otherwise rate-determining, is thus avoided) and the liberation of hydrogen is greatly reduced. / Tetrahedron *23*, 1723 (1967) / –Bu. [Rd 675 IE]

Inactivation repression is the name given by *J. J. Ferguson, M. Boll,* and *H. Holzer* to a regulation phenomenon of yeast malate dehydrogenase (MDH, E.C. 1.1.1.37). When washed yeast cells grown on glucose are suspended in a nutrient medium that is 4×10^{-2} molar in acetate, a rapid increase in the MDH activity (doubled in about 30 min) takes place over 6 hours after an induction period of about 20 min. The num-

ber of cells increases by only about 10% during this time. The increase in the MDH activity is stopped by cooling and by the addition of cycloheximide ("Actidione" 1.78×10^{-5} M) and glucose (5.5×10^{-2} M). A rapid decrease in the MDH activity occurs some 5 min after the addition of glucose, and after about 60 min the MDH level has returned to its value before induction by acetate. It is interesting to note that this "repression" of MDH by glucose is prevented by cycloheximide (an inhibitor of protein biosynthesis) when this is added together with the glucose, but not when it is added 12 min later. Attempts to demonstrate the existence of an MDH inhibitor or of an MDH-inactivating protein or enzyme, *e.g.* by mixing extracts from acetate-induced and glucose-repressed cells, were unsuccessful. In the inactivation by glucose, no MDH is given up to the medium. MDH from induced cells is kinetically and physically (chromatography on DEAE cellulose) distinguishable from that from "repressed" cells. / Europ. J. Biochem. *1*, 21 (1967) / –Hö.

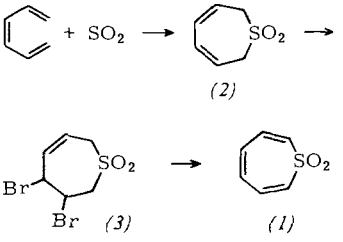
[Rd 679 IE]

The rare case of several possibilities in a two-step reaction ($k_1 \ll k_2$; $k_1 < k_2$; $k_1 \approx k_2$; $k_1 \gg k_2$) has been reported by *S. Hünig* and *G. Kaupp*. The kinetics of the formation of diazamerocyanine *(4)* from the azo-substituted benzothiazolium salts *(1)* and the phenols *(2)* point to the following reaction scheme:

(1a): X = COC_6H_5
(1b): X = $CO_2C_2H_5$
(1c): X = $SO_2C_6H_5$

(2a): Z = F
(2b): Z = H
(2c): Z = CH_3

(3a): X = $SO_2C_6H_5$; Z = CH_3
(3b): X = $SO_2C_6H_5$; Z = H



The rate of the addition step (k_A) remains roughly constant, while the rate of decomposition (k_B) varies over a range of four powers of ten. The marked difference between *(2a)* and

Substrates	k_A/k_B
(1a) + *(2a)*	1:70
(1b) + *(2a)*	1:12
(1c) + *(2a)*	1:1.5
(1c) + *(2b)*	230:1

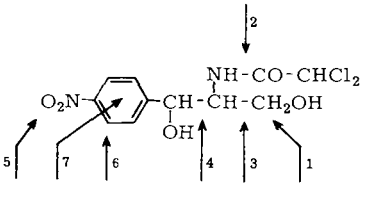
(2b) is probably due to reversal of the electron displacement. Similarly, the reaction of *(1a)* and *(1b)* with *(2b)* could not be evaluated, since the groups X = COC_6H_5, $CO_2C_2H_5$ cannot leave nucleofugally. (However, these combinations give *(4)* in 20–35% yield by another reaction path.) When *(1c)* reacts with *(2c)*, the colorless adduct *(3a)* can be isolated, whereas *(3b)* can be obtained only in the tautomeric (phenolic) form; *(3b)* is the true intermediate since it forms *(4)* as rapidly as when *(1c)* and *(2b)* are chosen as starting materials. / Tetrahedron *23*, 1411 (1967) / –Bu.

[Rd 676 IE]

The synthesis of thiepin 1,1-dioxide *(1)* has been reported by *W. L. Mock*. Hitherto, only benzothiepin 1,1-dioxides have been obtainable. 1,6-Addition of SO_2 to *cis*-hexatriene in ether at room temperature yields 2,7-dihydrothiepin 1,1-dioxide *(2)*, m.p. 107–108 °C, which gives the hexahydro derivative, m.p. 70–71 °C, on hydrogenation. Bromination of *(2)* in chloroform leads to *cis*- or *trans*-3,4-dibromo-2,3,4,7-tetrahydrothiepin 1,1-dioxide *(3)*, m.p. 128–129 °C, which gives thiepin 1,1-dioxide *(1)*, m.p. 117–118 °C, on

(2)

(3) *(1)*

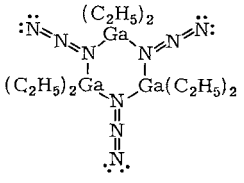


treatment with triethylamine in benzene at 25 °C. *(1)* decomposes at 100 °C into benzene and SO_2, probably *via* an intermediate episulfone. It is evidently nonplanar. / J. Amer. chem. Soc. *89*, 1281 (1967) / –Ma.

[Rd 700 IE]

The β-galactosidase repressor from *Escherichia coli* has been enriched and characterized by *W. Gilbert* and *B. Müller-Hill*. The test used was the bonding of the inductor isopropylthiogalactoside (IPTG, ^{14}C and ^{3}H) to the repressor on equilibrium dialysis. Accumulation from an i^t mutant, which synthesizes a repressor having a particularly high IPTG affinity (K_M approximately 7×10^{-7} as compared with 1.3×10^{-6} M), was achieved by precipitation with spermidine, ammonium sulfate fractionation, and chromatography on DEAE-Sephadex. The IPTG-binding fraction is sensitive to heat and proteinase, but insensitive to DNase and RNase; the molecular weight is 150000–200000 (7.6–8 S). The identity of the protein with the product of the galactosidase regulator gene (i-gene) is indicated by :1. The absence of the protein in i^-, i^s, and i deletion strains (no repressor formation, deficient repressor, and absence of the i-gene); 2. the higher affinity of the repressor from the i^t strain for IPTG than of the repressor from the wild strain, 3. the affinity of the protein for other galactosidase inductors such as thiomethylgalactoside (K_M = 2×10^{-6} M), *o*-nitrophenyl-β-D-galactopyranoside (2×10^{-5}), and galactose (5×10^{-4}, all values for i^t repressor), and 4. the correct correlation of these values with the concentrations of these substances required in the *in-vivo* induction. / Proc. nat. Acad. Sci. USA *56*, 1891 (1966) / –Hö.

[Rd 657 IE]



Chloramphenicol can be used as the only source of carbon and nitrogen by a strain of bacteria isolated from garden soil by *F. Lingens* and *O. Oltmanns*. The antibiotic chloramphenicol is effective against many gram-positive and gram-negative bacteria, as a result of inhibition of protein biosynthesis. The strain of bacteria in question is gram-negative, but despite detailed characterization, it has not yet been classified. Eleven

degradation products of chloramphenicol have been isolated from the culture medium. On the basis of these products, it has been possible to suggest a degradation path, the principal steps of which are indicated by arrows showing the presumed order. The reactions are: 1. oxidation, 2. hydrolysis, 3. decarboxylation and oxidation, 4. decarboxylation, 5. reduction and deamination, 6. hydroxylation, 7. oxidative cleavage. [Rd 658 IE]

Diethylgallium azide *(1)* has been obtained almost quantitatively by *J. Müller* and *K. Dehnicke* from the reaction of triethylgallium *(2)* with chlorine azide in benzene.

$$3\ Ga(C_2H_5)_3 + 3\ ClN_3 \rightarrow$$

(1)  $+ 3\ C_2H_5Cl$

(1) is a colorless, slightly hygroscopic, viscous liquid, which, unlike *(2)*, does not ignite spontaneously, and which distils at 86 °C/0.1 mm without decomposing. Cryoscopic measurement in benzene gives three times the expected molecular weight. In contrast to $(C_2H_5)_2AlN_3$, which decomposes explosively with water, *(1)* is not wetted by water. It is insensitive to mechanical treatment and to fast heating with an open flame. According to its vibration spectra (IR and Raman), diethylgallium azide forms a six-membered Ga–N ring open flame. According to its vibration spectra (IR and Raman), diethylgallium azide forms a six-membered Ga–N ring (D_{3h} symmetry). / J. organometallic Chem. 7, P1 (1967) / –Sch. [Rd 662 IE]

The mass-spectrometric detection of extremely small quantities of alkali metal is reported by *J. Kremer*. A small droplet (about 0.05 ml) of the test solution is placed on a strip of molybdenum and evaporated to dryness in the absence of dust. The strip is heated until thermal emission of alkali metal ions takes place, and the ion current is measured in a mass spectrometer adjusted to the mass of the nuclide to be detected. Measurement is continued until the ion source has given off all the alkali metal. A Geiger counter tube is used as the detector. The total number of pulses counted is then a measure of the quantity of the nuclide in question that was present in the sample. This method is only of theoretical interest for the detection of the lighter alkali metals up to and including Rb, since water cannot be sufficiently freed from alkali metals (the purest water examined contained about 10^{-10} g of K per ml). Only cesium is present in water in such small quantities that test solutions of definite concentration can be prepared. Cesium can be determined in concentrations of 10^{-14} g/ml. / Z. Physik *199*, 94 (1967) / –Hz. [Rd 663 IE]

Carbon trioxide CO_3 has been obtained by *N. G. Moll, D. R. Clutter*, and *W. E. Thompson* in three ways: (i) photolysis of solid CO_2 at 77 °K with vacuum UV from a xenon resonance lamp; (ii) photolysis of ozone in a matrix of solid CO_2 at 50–60 °K with the 2537 Å mercury line; (iii) radio-frequency discharge in gaseous CO_2 and freezing of the products at 50–70 °K. Spectroscopic studies, partly with isotope-enriched CO_2, indicate a planar molecule having symmetry C_{2v}, in which one oxygen is strongly bound to the carbon by a carbonyl-like bond, while the other two oxygen atoms are more weakly bound. There is probably also a covalent bond between the two equivalent oxygen atoms. CO_3 decomposes into CO_2 and atomic oxygen on photolysis with visible and ultraviolet light. / J. chem. Physics *45*, 4469 (1966) / –Hz. [Rd 664 IE]

BOOK REVIEWS

Ullmanns Encyklopädie der technischen Chemie. Band 16: Soja bis Terpentinöl (Ullmann's Encyclopedia of Industrial Chemistry. Vol. 16: Soya to Oil of Turpentine). Chief editor *W. Foerst*. Editor *Hertha Buchholz-Meisenheimer*. Verlag Urban & Schwarzenberg, München-Berlin 1965. 3rd fully revised Edit., 779 pages, 235 figures. Vol. 17: Terpentinöl bis Uran und -verbindungen (Oil of Turpentine to Uranium and its Compounds). 1966, xii, 789 pages, 240 figures, per volume DM 182.–. (obtainable only as the complete work).

With the publication of the present two volumes [*], this huge work draws slowly toward completion. The longer articles in Vol. 16 deal with steels (135 pages), spirits and alcoholic liquors (62 pages), explosives (54 pages), sulfonic acids (53 pages), tar and pitch (45 pages), starch (42 pages), coal (41 pages), synthesis gas (37 pages), sulfonamides (37 pages), and radiochemistry (30 pages). The shorter articles include sorbic acid, ice cream, injection molding masses, strontium and its compounds, sweeteners, superconductivity, tobacco, tall oil, tea, telomerization, and surfactants.

A large part of Vol. 17 deals with textile problems: textile bleaches (18 pages), textile printing (64 pages), textile processing aids (65 pages), and textile technology. Other long articles are concerned with the clay industry (132 pages), oil of turpentine products (64 pages), uranium and its compounds (50 pages), drying oils (44 pages), motor fuels (36 pages), and veterinary remedies (36 pages). This volume again contains a series of shorter articles dealing with, *e.g.* tetrahydrofuran, therapeutic acids, thiourea, toluene, peat, and driers. Not only do these later volumes present new material corresponding to the new entries, but an attempt is also made to include supplementary material on topics discussed earlier, so that the presentation is varied and stimulating. Thus the short article on injection molding masses follows on from Plastic Processing, Vol. 11, 1960, and describes the transition from piston-type injection molding machines to the screw type, as well as the associated material and processing problems. The article on steels follows on from the methods of steel production described under Iron, Vol. 6, 1955, but presents a very informative account of the progress and the present state of steel production. The article on coal is intended to supplement the discussion on coal and the upgrading of coal, which appeared in 1957 and 1958. Many more examples could be quoted. It has been possible in this way to bring the entire work (the first volume of which was published 13 years ago) up to date at the time of publication of the last volume.

The main emphasis in these two volumes is again placed on the industry. Of the 128 contributors, only 24 are employed at universities and public research establishments. The industrial contributors deal not only with problems of applied science, but also with basic research themes such as thermoelectricity, superconductivity, tellurium and its compounds, and veterinary remedies. One cannot quite escape the impression that the universities in Germany do not play any great part in the investigation of topics that are important in industry, even when these topics lie in the field of pure science and theory.

The article on steel is by *I. Class*, who has for some time been manager of the BASF Materials Division. The aim of the

article is "to describe the relationships between the composition and history of a steel and its properties and to offer the chemist or chemical engineer a guide to the selection of a steel suitable for a special application." Theory and practical experience are skilfully blended in this well-founded discussion. It would have been better if the use of different type sizes and faces (bold, italic, spaced) to indicate main sections and subsections had been more consistent throughout the work. The article on the clay industry is a joint contribution by 12 authors, with a very good introduction by *U. Hofmann*, Heidelberg. It gives an all-round detailed picture of the perfusion of this, the oldest industry in the world, with modern technology.

The articles on textile bleaches, textile printing, textile processing aids, and textile technology show how important textile problems have become in the chemical industry. The bleaches are discussed by two former colleagues at Degussa. Current developments in this field are marked by an increase in the importance of peroxy compounds. A detailed description of textile printing is given by two authors from Farbenfabriken Bayer, and textile processing aids are discussed in similar detail by two colleagues from Böhme Fettchemie. The Deutsche Forschungsinstitut für Textilindustrie and the Staatliche Ingenieurschule für Textilwesen, both in Reutlingen, are largely responsible for the article on textile technology. Since this chapter is intended for those who do not work in this field, short explanations of technical terms would have been useful. Thus it is difficult for the layman to distinguish between "Wirkerei" and "Strickerei". Similarly, the "degree of pilling" is described as ranging from pill-free to "verpillt" (literally "completely pilled"), but these terms are not explained, nor is the reader told where to find explanations. In pressing forward into the textile field, chemistry has not only gained a large new production sector, but it has also come into very close contact with the consumer with its new products. This field is scientifically and technically very interesting; however, it is not an easy field to work in, since it is not the chemical composition of the products that is of primary importance, but some rather intangible technological properties. Moreover, the chemist and the physicist are forced to match their products to many old-established processing methods. The discussion is very instructive to anyone concerned with this cooperation. The chapter on textile technology is particularly instructive to the chemist.

The article on synthesis gas can be read in conjunction with the earlier articles on ammonia, the hydrogenation of carbon monoxide, the synthesis of methanol, and the oxo synthesis, and presents a concentrated progress report and an account of the present situation with respect to the production of synthesis gas. This situation is characterized by the increased importance of the production of synthesis gas from liquid and gaseous raw materials in relation to the classical gasification of solids. The number of synthesis gas processes is now so large that it is to the author's credit that he managed to compress the essentials into 37 pages. In no other process does the choice of procedure depend so strongly on the point of view and on the manner of insertion into the rest of the production program. The article also contains a comparison of the cost of production of synthesis gas by pressure gasification of coal, by reaction of natural gas at normal pressure, and by partial combustion of oxygen under pressure, the costs for all these processes being given as a function of the cost of the raw material and the size of the processing units.

The article on tobacco deals with the botany, the production, and the chemistry of tobacco. The pharmacological and toxicological aspects are discussed authoritatively and impartially by a pathologist and a clinical physician. The article on uranium, uranium alloys, and uranium compounds (including processing of spent fuel elements and fuel material) was written by three authors from Nuklear-Chemie und Metallurgie, GmbH, Hanau. It presents a good picture of the intensive technological investigation and the spirited efforts that have been devoted to this important problem. The rapid technical development is reflected in the changes in the price of the products. The article on spirits, which is confined to ethyl alcohol, is somewhat rambling in many places. The short section on sulfite spirit is good. The State Monopoly's term "Primasprit" (refined spirit), as can be seen from the legal section, is not entirely rational; on the one hand the spirit must be produced from agrarian raw materials, while on the other it must be so highly purified that its source is no longer recognizable. The section on physiology and toxicology presents a gloomy picture of the unpleasant effects of the consumption of alcohol on behavior, judgement, self-criticism, and finer psychic coordination.

In the article on veterinary remedies, two colleagues from Farbenfabriken Bayer present the essential viewpoints and methods of veterinary medicine. We learn that useful animals and pets are two fundamentally different groups of patients. The veterinary medicine of useful animals is mainly concerned with the prevention and cure of herd diseases, whereas pet therapy is very much more like human medicine, since treatment is individual. The article deals mainly with the fight against parasite and bacterial infection.

Lack of space prevents us from evaluating any more of the articles. In Ullmann, chemistry is treated from the point of view of its practical importance. Consequently, many problems of every-day life are also discussed. These practical problems are often theoretically very complex, so that one often tends not to discuss them scientifically. However, modern physical and chemical methods and the progress of analysis are constantly winning over traditionally empirical fields to the systematic, scientific approach. Ullmann goes into both the practical and the theoretical sides of this problem, and so presents a piece of research that is of interest outside the boundaries of industrial chemistry.

[*] Cf. Angew. Chem. *78*, 652 (1966); Angew. Chem. internat. Edit. *5*, 618 (1966).

Chemie photographischer Prozesse. (Chemistry of Photographic Processes.) By *H.-M. Barchet*. Wissenschaftliche Taschenbücher, Volume 31. Akademie Verlag, Berlin 1965. 1st Edit., 167 pp., DM 8.–.

The author of this little book gives a lucid explanation, from the viewpoint of an organic chemist, of the reactions that are of importance in the formation of photographic images. The division of the subject matter is excellent: Descriptions of substances incorporated in photographic materials and involved in their processing are followed in each case by a discussion of the corresponding chemical reactions and in some cases by a detailed account of their syntheses.

Physicochemical and purely physical aspects are dealt with only so far as is necessary in order to indorporate the purely chemical processes into the photographic process as a whole. Understandably, color photography occupies an important place in the book. Processes not involving siver halides are only mentioned briefly

The book thus provides a general review of the many problems associated with the chemistry of photographic processes, with reference to specialized literature; this information will hardly be encountered elsewhere in such a concise form.

E. Klein [NB 578 IE]

Anorganische und allgemeine Chemie in flüssigem Ammoniak (Inorganic and General Chemistry in Liquid Ammonia). By *J. Jander*. Chemie in nichtwäßrigen ionisierenden Lösungsmitteln (Chemistry in non-aqueous ionizing solvents), edited by *G. Jander*, *H. Spandau*, and *C. C. Addison*, Vol. I, Part 1. Friedr. Vieweg & Sohn, Braunschweig – Interscience Publishers, a Division of John Wiley & Sons, Inc., New York-London 1966. 1st Edit., xxiv, 561 pages, 75 figures, 213 tables, DM 110.–; subscription price DM 96.–.

This series of monographs, which was started by *G. Jander* and *H. Spandau* and is being carried on by *H. Spandau* and *C. C. Addison*, is to consist of eight volumes on chemistry in non-aqueous inorganic and organic solvents. The inorganic solvents discussed include ammonia, sulfur dioxide, dinitrogen tetroxide, a few halides and oxyhalides, and a number of salt melts, while the organic solvents include the lower fatty acids and their derivatives, nitrogen bases, alcohols, ethers, and esters.

The first part of the first volume deals with inorganic and general chemistry in liquid ammonia. The author has taken great pains to cover all the literature on inorganic and physical chemistry in liquid ammonia. The resulting article covers 500 printed pages, including a 42-page list of about 2000 references (from 1826) and more than 200 tables, the longest of which occupies 32 pages.

This passion for completeness is not always to the reader's advantage, since all the published values for one quantitative measurement are often presented on an equal footing and without discussion, and the reader has to decide which value is correct. This is not troublesome *e.g.* in the case of the boiling point and the melting point of pure ammonia or its critical temperature, since the numerous values differ by less than 1 deg, and the best values can be found in suitable tables anyway. However, the inclusion of all the values *e.g.* for solubilities (Table 86) is confusing. For example, the following values are given for the solubility of NaCl between −76.9 and −74.9 °C: 0.232, 0.074, 0.28, 0.123, and 0.306 g/100 g and 0.203 g/100 ml. A similar situation is found *e.g.* in Table 152 (phase separation in metal-NH_3 solutions): the existence of a miscibility gap in Li−NH_3 solutions is given as "not detectable", "uncertain", and "certain" and in K−NH_3 solutions as 'not detectable" and "uncertain' (in fact both systems have a miscibility gap with an accurately known critical temperature). Similar lack of clarity is found in the subsequent tables on the metal adducts.

References to other parts of the book are given, not as a page number containing up to three digits, which would be easy to remember and could be found quickly, but as a key number for the section in question, which may contain up to seven digits, *e.g.* 2.9.2.2.2.1.6. (Oxidation of ammonium azide with exclusion of solvent molecules as reactants). The key numbers in the supplementary chapter, in which the latest literature is collected do not agree with those of the principal chapters.

Apart from these and similar failings, however, the book probably fulfils the purpose expressed in the Preface, *i.e.* to be of use to all chemists in the laboratory and in practice. Owing to its completeness, it can replace all past volumes of Chemical Abstracts or of Chemisches Zentralblatt for the chemist who is working with liquid ammonia.

U. Schindewolf [NB 598 IE]

Molecular Photochemistry. By *N. J. Turro*. W. A. Benjamin, Inc., New York-Amsterdam 1965. 1st Edit., xiii, 286 pages, numerous figures, DM 55.−.

Photochemistry. By *J. Calvert* and *J. N. Pitts jr.* John Wiley and Sons, Inc., New York-London-Sydney 1966. 1st Edit., xvii, 899 pages, numerous figures, DM 84.−.

The reviewer can recall the earnest discussions only 10 years ago on whether a light-induced reaction in the course of a total synthesis made such a synthesis doubtful as structural evidence. Photochemistry has now been emancipated, and chapters on this field are now no longer found only in textbooks of physical chemistry, but have recently also earned a firm place in textbooks of organic chemistry. The preparative chemist now values light as a cheap reagent; the MO theory, which should already have been met in basic chemistry reading, provides a structural model that is partly based on consideration of the primary photophysical processes, and that offers an explanation of the primary photochemical processes. The further development of photochemistry will open up new preparative routes; it will add to and improve the model concepts of the structure and structural changes of molecules. Accordingly, a steadily growing number of workers will wish to enter this field and to take part in its development. The two monographs reviewed here may help them to do this.

Both books are recommended to a wide circle of readers. Their aim is to provide information required in order to understand current publications on photochemical investigations, and hence to provide the newcomer with a foundation on which to base his own investigations.

In the book by *Turro*, an eight-page introduction is followed by four chapters on photophysical processes and problems (electronic excitation, 11 pages; electronic spectra and electronic excitation states, 48 pages), and the transfer of electronic energy, 45 pages). Four further chapters deal with photochemical processes and problems (photoreductions and related reactions, 25 pages; photo-rearrangements and photoisomerization, 32 pages; photo-cycloadditions 30 pages; photofragmentation and related processes, 21 pages), and a final chapter (11 pages) touches on a number of experimental aspects. This book is based on a lecture manuscript, and is naturally selective in character. The fact that the author belongs to one of the leading schools of photochemistry guarantees the significance of the material.

Calvert and *Pitts* have succeeded in producing *the* standard work on photochemistry. Every conceivable field apart from photoblology and photography is covered. The first four chapters (lightand the laws of photochemistry, 22 pages; the action of light on atoms and reactions photosensitized by atoms, 90 pages; the action of light on simple molecules and their photochemistry, 100 pages; the primary photophysical processes of polyatomic molecules, 112 pages) provide a fundamental description of photophysical principles. The fifth chapter (190 pages) presents a colorful review of the photochemistry of polyatomic molecules, which systematically embraces all the known classes of photoreactive substances. Two further chapters (determination of the mechanism of a photochemical reaction, 83 pages; the experimental methods of photochemistry, 111 pages) deal with the fundamental methods used in the study of reaction mechanisms and with the detailed procedures used.

The book contains a comprehensive author and subject index and more than 1500 references.

To those who wish to buy only one of these books, the reviewer would recommend that by *Calvert* and *Pitts*.

G. Quinkert [NB 607 IE]

Encyclopedia of Chemical Technology. By *R. E. Kirk* and *D. F. Othmer*. Edited by *A. Standen*. Vol. 9: Ferroelectrics to Foams. Interscience Publishers, a Division of John Wilev & Sons, Inc., New York-London-Sydney 1966. 2nd Edit., xvi, 901 pages, numerous illustrations, bound 338s; subscription price 260s.

Volume 9 of Kirk-Othmer[*] contains 22 articles having an average length of 41 pages, including fluorine chemistry (341 pages), fertilizers (126 pages), fluidization (47 pages), flavors and spices (44 pages), fluid mechanics (38 pages), foamed plastics (37pages), and ferroelectrics (25 pages), as well as fibers, films, filtration, fish, fire prevention, fluorescent pigments, and foams. The second edition is largely rewritten, mainly by new authors (of the 60 contributors to this volume, only 10 were connected with the first edition). The volume has increased in size to about 900 pages, as opposed to 445 pages in the edition published 15 years ago. The detailed coverage of new developments is very pleasing, though the increase in the quantity of material to be included forces the editorial staff to abbreviate and compress in order that the required information may still be quickly accessible.

The particularly marked growth of fluorine chemistry in the past few years can be seen in the article: Fluorine (21 pages); Fluorine Compounds, Inorganic (159 pages); and Fluorine Compounds, Organic (161 pages). It is clear that the rapid development of this field has been largely due to two important applications, *i.e.* the use of fluorochlorocarbons as refrigerants and the use of uranium hexafluoride for the separation of the isotopes of uranium. The discussion of the subject is the work of 37 authors from no fewer than 16 firms, Purdue University, and the US Naval Research Laboratory.

The article on elementary fluorine presents a clear picture of properties, occurrence, production, storage, and dispatch. In plants producing several tons per year, the costs can be as low as about $ 1 per lb. In the following article, the inorganic fluorine compounds are described alphabetically in 27 subsections by several authors. Since no reviews of a general nature are included, the article gives the impression of being somewhat lacking in coherence. On the other hand, the article on organic fluorine compounds, has a good introduction (18 pages) and a very good section on the surface chemistry of fluorine compounds (32 pages). All the sections are provided with full lists of references.

The article on fertilizers has also been rewritten, and has expanded in the process from 76 to 126 pages. However, this chapter could have been appreciably shortened or its content increased. The section on the nutrient function of chemicals presents a general account, and even contains historical reminiscences, but no numerical data. It does not go into the laws of plant metabolism or into crop yields; for example, the antagonism of potassium and calcium with respect to the water balance is not mentioned. The arrangement of the article as a whole is not very good. The author deals with questions on the structure of the industry, mixed fertilizers, production, costs, and locations before discussing the properties of the main products. Consequently, repetitions cannot be avoided. The author mentions several times that the fertilizer industry has changed more since 1950 than ever before; however, he does not specify the changes, but simply states that products of minor importance have become more important, the industry has become more reserch-conscious, *etc.* More information could have been presented in a smaller space if the arrangement had been better and the discussion more concrete.

The well-written article on filtration has been substantially retained from the first edition. In spite of additions to the content, it has been possible to compress the article from 24 pages to 22, mainly by the omission of photographs were diagrams were sufficient. A full and well-executed treatment is given to flavors and spices. Flavors are those components of foods that can be detected by their taste and smell. They have acquired great economic importance, since next to appearance they determine the sale of foods.

The article on flavor characterization describes the use of modern analytic methods such as gas chromatography and IR and mass spectroscopy for the recognition of the active substances. The aim of a complete analysis is now very much nearer; thus 93 "aromaphores" have been detected in and isolated from a few ml of oil of orange. The food industry makes wide use, not only of natural and synthetic flavors, but also of flavor precursors (some enzyme-based) and flavor potentiators. The chapter also contains recipes. The section on spices contains a very instructive historical survey of the spice trade, describes quality control, and then proceeds to discuss the individual spices. The term "spice" is reserved for flavorings of exclusively natural origin.

The article on fluidization has been largely taken over from the first supplement to the first edition, with revision and inclusion of additional material, but with no appreciable increase in size. The main new feature is the description of the material exchange between the gas bubbles ascending in the fluidized bed and their surroundings. The article is comprehensive and instructive, but is largely confined to the situation in America. A table is given with 101 examples of the use of fluidized bed processes, of which there are only one each from England, India, Belgium, Czechoslovakia, and Yugoslavia, and five from Germany. No mention is made of *Fritz Winkler*, the inventor of the fluidized bed process, or of the fluidized bed process for the roasting of pyrites developed by BASF after the war and now used internationally on the large scale.

The present volume also contains other contributions, but these cannot all be reviewed individually. In view of the rate of industrial expansion, any attempt to present a survey is very welcome. Though Kirk-Othmer is mainly confined to the situation in the USA, it is also useful to the German reader, since it is backed by the largest and most diversified chemical industry in the world. It is to be hoped that the publication will have much success in the future.

H. Sachsse [NB 594 IE]

[*] Cf. Angew. Chem. *77*, 359 (1965); Angew. Chem. internat. Edit. *4*, 378 (1965).

Experimental Organic Chemistry. By *J. Baldwin.* McGraw-Hill Book Company, New York - St. Louis - San Francisco-Toronto-London-Sydney 1965. 2nd Edit., 183 pages, numerous figures, paper 52s.

The present volume, which is presented in brochure form, follows an unconventional path for a practical textbook. It begins with the isolation of caffeine from tea, explaining some of the elementary operations such as extraction, filtration, and sublimation. This is followed by a section on the purification of hydrocarbons, in which chromatography is used and discussed. IR and NMR spectra are used as early as Chapter 6 for the characterization and identification of preparations, and are subsequently used repeatedly throughout the book (with illustrations).

The experiments are grouped according to reaction mechanisms, such as nucleophilic substitution, nucleophilic addition, electrophilic addition and substitution and molecular rearrangements. Experiments on stereoselective reactions and on structure and equilibrium, which are often ignored in practical textbooks, are not forgotten.

Further chapters are devoted to heterocyclic compounds (synthesis of 1,2-diphenyl-5-nitrobenzimidazole), the synthesis of peptides, and ion-exchange chromatography. Each chapter closes with a selection of questions and problems.

The experiments and preparations are so chosen that the student has a sense of tackling current problems and that the time required is relatively short. The appendix contains the IR and NMR spectra of about 40 compounds mentioned in the book. These are accompanied only by the empirical formulae, so that the student has ample opportunity for practice in the interpretation of spectra.

The book by *Baldwin* is full of suggestions both for the demonstrator and for the student. Unfortunately, the presentation is not very suitable for bench-use. However, a copy of "Practical Organic Chemistry" should be available in every laboratory. Demonstrators are recommended to use various preparations from the book as a change from the "hackneyed" standard preparations.

H. J. Bestmann [NB 593 IE]

Atomic Absorption Spectroscopy. By *J. W. Robinson.* Marcel Dekker, Inc., New York 1966. 1st Edit. xi, 204 pp., 40 illustrations, many tables, $ 9.75.

Authors of monographs about rapidly developing subjects suffer from the fact that many parts of their books are out of date when they appear; the author of the present book about atomic absorption spectroscopy is no exception. He is aware of the fact that his presentation is merely a momentary aspect of a rapidly changing overall picture. For this reason he has placed the greatest emphasis on the chapters headed "Instrumental Equipment" and "Analytical Parameters".

On the other hand, the chapter about analytical applications, which is arranged according to elements and which contains a subsection on commercially available equipment, will appear too short for many analytical chemists who are interested in this new technique. In spite of the closing chapter about subjects which are closely connected with atomic absorption, for example, oscillator strength, vacuum UV, and fluorescence effects, the book leaves many questions open because of its somewhat oversimplified style. For instance, the discussion of burner types makes no mention of important possible interferences such as light scattering effects and variations in flame profiles. In the section on applications, the characteristics of various flame types are given incompletely. The reader misses a critical comparison between turbulent and laminar flames. The acetylene-nitrous oxide flame is mentioned only very briefly, this being a field of study in which great improvements in sensitivity have been made in the last two years. The literature is covered up to the beginning of 1965. With more than 100 papers being published each year, it is no mean feat to provide a review which represents something more than an interim report.

Such limitations, however, tend to mask the achievement of the author, who has after all succeeded in presenting a comprehensible introduction to atomic absorption to all who are interested in this topic which has proved very useful in many branches of applied analytical chemistry. Nevertheless, before wishing the book a wide readership, the reviewer would recommend a thorough revision of the work.

J. Ringhardtz [NB 625 IE]

Applications of Statistical Mechanics. By *W. A. Guggenheim*, Clarendon Press/Clarendon University Press, London 1966. 1st Edit., 211 pp., numerous illustrations, 55 s.

This book is an extended reproduction of the author's "Baker Lectures" at Cornell University in 1963, and may be regarded as a modern appendix to "Statistical Thermodynamics" by *Fowler* and *Guggenheim*. The eleven chapters deal with:

"Absolute activities and grand partition functions", "Crystalline argon", "Corresponding states", "Argon at the triple point and equations of state for liquid argon and gases at high densities", "Sodium and potassium chlorides and the repulsion between their ions", "Symmetrical mixtures", "Athermic mixtures and solutions of macromolecules", "Ion distribution in dilute aqueous solutions", "Aqueous solutions of simple electrolytes", "Aqueous solutions of several electrolytes", and "Adsorption of gases in single and multiple layers".

This new book by *Guggenheim* is again a model of correctness and clarity. It presents a good survey of recent developments in the fields mentioned, with special reference to recent work by the author. However owing to the small size of the book and the lecture style of the presentation, a number of interesting recent developments have not been included, *e.g.* work on ions in concentrated electrolyte solutions or on the salt lattice under high hydrostatic pressure. Nevertheless, this informative and comprehensible book is warmly recommended.

E. U. Franck [NB 590 IE]

Dictionary of Organic Compounds. Edited by *R. Stevens*. 2nd Supplement Eyre & Spottiswoode Publishers Ltd. E. & F. N. Spoon Ltd., London 1966. 4th Edit., 216 pp., cloth £ 10.00.

It is normally unnecessary to review a supplement. If the main work[1] is good, then one assumes (correctly, in the present instance) that the same will be true of the supplement; if the main work is bad (which this dictionary is not), then supplements are rarely of much help.

The second supplement to the "Dictionary of Organic Compounds", however, deserves mention in that some minor changes are introduced (spelling of systematic names, alphabetical order of elements in empirical formulae, quoting abbreviated Christian names in literature references), which bring the text more into line with international usage and make it easier to follow. Additions to entries in the main work are indicated by an asterisk. Whenever the additions are particularly extensive, the entire entry is repeated, collating all the information. Literature up to the end of 1965 is included. With the two supplements, the Dictionary provides a handy reference tool giving all the information that may be required on the compounds listed. It is, moreover, exceptionally up-to-date; further supplements are to be published to ensure that it remains so.

A Topological Approach to the Problem of Ring Structures

BY R. FUGMANN, U. DÖLLING, AND H. NICKELSEN [*]

In the mechanized documentation of chemical literature, the definition of structural concepts is very important. The usual definitions for ring structures are inadequate. Essential ring structures are sometimes not recognized on the basis of these definitions and are therefore missed in a literature search. This is particularly true of bridged ring systems. The ring concept and ring condensation types are now redefined on a topological basis in the closest possible analogy to the intuitive approach of the chemist. In complicated molecular structures, these "fundamental rings" can be easily determined, either manually or by means of a programmed computer. The concept of the "ring complex" is defined and suggested as a preliminary screen in literature searches for ring structures. This will save machine time, and so reduce the cost of searches.

1. Introduction

A great deal of chemical research is concerned with studies on characteristic ring structures. These rings often impart certain characteristic properties to the substances in question, or they may have acquired considerable importance in the theory of the chemical bond. The literature in this field is very extensive.

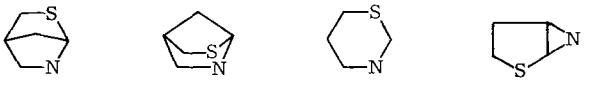
In undertaking a search for literature in which molecules having a given ring structure are described, one is faced with inherent difficulties that can mainly be traced to two causes. On the one hand, the formula may be projected in such a way that the desired ring is difficult to recognize. On the other, the conventions used in the common filing systems to recognize a ring structure in a molecule do not always coincide with the ideas of the chemist who is making the search.

1.1. The Influence of the Projection Plane on the Recognizability of a Ring Structure

If a three-dimensional molecule is to be represented by a structural formula, it must be projected on a plane. The resulting projection can vary considerably according to the plane selected, so that a given ring structure in the structural formula may be obvious in one projection yet not apparent in another. For example, A and B are different projections of the same molecule.

A B

Projection A ("side view") shows a six-membered ring and a five-membered ring, while a second five-membered ring remains hidden. Conversely, projection B ("top view") clearly shows two five-membered rings, while the six-membered ring is hidden. To eliminate the arbitrariness associated with the adoption of a given projection plane, the three ring structures (two five-membered and one six-membered rings) must be treated as being of equal importance.



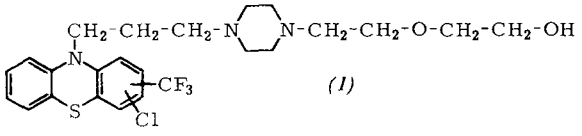
Great demands are occasionally made on the imagination and patience if one is to recognize all the ring structures present from an arbitrarily chosen projection of a molecule, and there is always a danger that essential rings may be overlooked.

1.2. The Influence of the Filing Principle on the Retrieval of Literature on Ring Structures

Provided that the chemist confines his search to perusal of the recent literature, his intuitive judgment as to whether the desired ring system is or is not present in a

[*] Dr. R. Fugmann, Dr. U. Dölling, and Dr. H. Nickelsen
Farbwerke Hoechst AG., vormals Meister Lucius & Brüning
623 Frankfurt/Main-Höchst (Germany)

structural formula is sufficient. However, this is not so when he wishes to make use of the earlier literature, since he must then consult an index or file, in which a specific subject heading exists for the desired ring. In this case the searcher is wholly dependent on the principles by which the ring structures are defined in the index in question. Whether the expected references will in fact be found under a given subject heading depends on whether its definition in the index agrees with the searcher's views.



C 1 C 2 D E

For example, in an index in which structure C is regarded only as a system of two condensed five-membered rings (C1), so that the six-membered ring structure (C2) is not taken into account, references to structure C will not be found in a search for six-membered rings with nitrogen and sulfur in the ring (D) (1,3-thiazine derivatives). On the other hand, if the structure E is purely formally regarded in the index as a six-membered ring, the searcher will also be directed to articles on E, which will be of no interest. These two phenomena, loss of relevant information and retrieval of irrelevant information, are the unmistakable signs of the disorder which is inevitably caused by an expressly formal index principle.

The procedure normally used to determine the number of ring structures in a molecule is also formal. According to *Frèrejacque's* rule[1], the number of rings in a molecule is equal to the number of cuts required to obtain a coherent open-chain structure. Thus structure C would have only two rings, and one must decide which of the three rings that are undeniably present is to be regarded as non-existent. Similarly, a cubic structure such as occurs in the cubanes, which clearly contains six four-membered rings, would be presented as having only five. This procedure has been criticized by various authors[2], but no satisfactory alternative has yet been suggested.

Thus all the common indexing principles can give misleading results when used to determine the number and nature of the ring structures in a molecule. This is true no matter what technical assistance is ultimately available for the literature search, whether a manual punched card system, a mechanical punched card system, or the magnetic-tape file of a programmed computer. No technique, however sophisticated, can overcome the obstacles resulting from an excessively formal classification system. Moreover, in the case of an index in the form of a book or a vertical card file, technical inadequacy is added to conceptual obstacles. Thus for purely technical reasons, it is impossible in such systems to cite literature under every heading that might apply. This is due to the necessarily linear, "one-dimensional" arrangement[3] in an index. In particular, it is impossible to give a structural formula under each relevant heading in the index or card file.

(1)

For example, compound *(1)* is a phenothiazine as well as a propylenediamine, a piperazine, an ethanolamine, an ethylene glycol, a condensed 1,4-thiazine, a condensed trifluoromethylated and chlorinated benzene, *etc.* However, the compound cannot be given in the index under all these headings. In the extreme case, an order of precedence of the various headings is established on a purely formal basis, and a compound is entered only under one single heading, namely under that having the highest precedence.

Thus in a generic literature search for related compounds having *e.g.* the same substructure in common, the difficulties encountered in a one-dimensional file are not all of a conceptual nature. The technical peculiarities of these systems are also partly responsible. It has been shown that in an otherwise excellently organized subject index, some 30 % of all the relevant articles are not cited under the heading "phenothiazines", though they are in fact included in the index[3a].

One-dimensional aids and conventional indexing principles can give satisfactory results only in a search for literature on an individual compound. The fact that related compounds are scattered more or less randomly in the index is not detrimental in this case. An individual compound can always be reliably located in the conventional one-dimensional file.

It is an inherent feature of "multidimensional" documentation techniques (punched cards, electronic computers) that a structure can in principle be found under any relevant heading, and particularly under any combination of headings. If these headings are the designations of substructures, there is no hindrance to a generic search for substructures, as far as purely technical aspects are concerned.

However, multidimensional aids can be effective only if the conditions for a generic search are also satisfied from the conceptual viewpoint. No indexing principle is justified in a mechanized, i.e. multidimensional documentation, if this principle had been originally designed for one-dimensional locating of individual compounds. Its use should strictly be limited to a simple one-dimensional index or card file, or else the efficiency of the multidimensional searching device will be seriously impaired. No conventional documentation can really be "modernized" by mere transition from a one-dimensional technique to a mechanized technique without establishing the respective conceptual preconditions in the indexing principle.

[1] *M. Frèrejacque*, Bull. Soc. chim. France *6*, 1008 (1939). However, *Frèrejacque* was interested in other objectives when he formulated his rule, and limitations were imposed regarding its application to non-planar structures.

[2] *W. E. Cossum* and *G. M. Dyson*, American Documentation Institute, Washington, Annual meeting 1963, Short papers 15-18.

[3] In a "one-dimensional" file, a selection can only be made using a single heading, *i.e.* a combination of headings cannot be used in machine selection. The selected references must then be examined intellectually to determine whether they contain the desired combination of headings.

[3a] *B. Loev*, J. chem. Documentation *1961*, 27.

To permit a generic inquiry concerning the presence of a ring as a substructure in various molecular structures, the indexing principle must be capable *e.g.* of showing the relationship between the two structures F and G, *i.e.* that they both contain a nine-membered ring (shaded).

F G

After any change in the structure F that does not affect any of the atoms of the nine-membered ring, the indexing principle should still recognize the nine-membered ring. Otherwise this would point to some vestige of formalism, to random scattering of closely related information, to limited ability of the indexing principle to deal with generic inquiries, and hence, finally, to limited suitability for mechanization.

2. The Fundamental Rings and their Aggregations with One Another

None of the ring-indexing principles known at present satisfies the requirements illustrated in the above example. In an attempt to eliminate this shortcoming, we propose a new definition of the ring concept that is closer to the chemist's idea than the existing formal approach (cf. Section 2.1.). According to this definition, a ring structure is always reliably recognized, even if it occurs as a substructure in any higher system of condensed rings. To find a ring structure by this principle, it is immaterial whether one starts with the three-dimensional model of the molecule or from any of its projections. The same rings and the same number of rings are always recognized. This ring concept will be referred to in future as the "fundamental ring". In establishing this ring concept, mathematical methods, particularly topological methods, were applied.

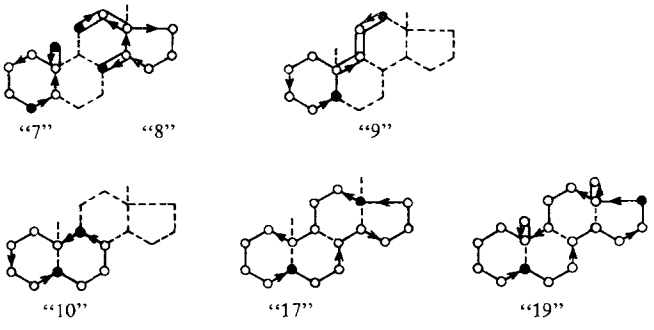
Two ring structures can be condensed in various ways, at least one ring atom always being shared by at least two rings. The literature contains various definitions of the condensation types of ring structures, some of which are contradictory, and which are again unsatisfactory because of their formal character. We therefore propose new definitions for the condensation types of pairs of ring structures. These definitions are also based on topology.

Ring structures can combine with one another in many ways to give higher aggregates. The mode of aggregation of ring structures is an extremely characteristic feature of a molecule, and can therefore be used as a very effective screen in a mechanized search. With the aid of such a screen, irrelevant structures can be very quickly recognized and rejected in the mechanized scrutiny of a file. Methods of this type for shortening a mechanical selection are particularly desirable in a purely topological search, since the machine time required, and hence the cost of the search, can otherwise become considerable. Topological methods can also be used for handling these aggregations of ring structures, as will be shown later.

Furthermore, in order to enable the chemist to recognize fundamental rings reliably, even in complicated structures, a manual procedure was designed.

Finally, this procedure was used to develop an algorithm by means of which a programmed computer would be able to determine the nature and number of all the fundamental rings present in a given structural formula. This technique is particularly interesting in connection with modern methods for the topological documentation of structural formulae. Thus if a file already contains a topological representation of a structural formula, the machine can relieve man of the work of analysing a structure to find the rings present.

It should be realized that even with the conventional indexing principles, it is not always easy to name a polycyclic structure correctly. A surprising number of errors can occur, despite the greatest care. This recently became clear when an electronic computer was programmed for the von Baeyer nomenclature[4], the names given by the machine then being compared with those found purely intellectually by application of the rules[5].



2.1. Definition of the "Fundamental Ring"

"*Cycle*"

A cycle[6] exists in a molecule if it is possible to proceed from one atom to another along the interatomic linkages by two different routes. The cycle is formed by combination of the two routes between the two atoms in question ("•" in Scheme 1). In other words, a cycle is a coherent, closed sequence of lines of the "graph" of the molecule. However, such a definition of a cycle would not agree with the chemist's intuitive idea of ring structures.

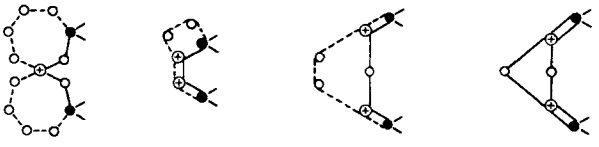
"*Fundamental path*" and "*Fundamental ring*"

Cycles that satisfy the above definition cannot all be recognized as ring structures from the chemical point of view. This would lead to devious results in many

Scheme 1. Cycles formed by combination of two different routes between two atoms (•) in the steroid skeleton, with numbers of ring atoms.

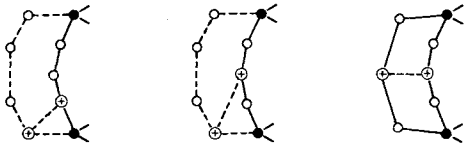
[4] IUPAC: Nomenclature of Organic Chemistry, Sections A & B. 2nd Edit., Butterworths, London 1966, p. 32.

[5] *K. Conrow*, Chem. Engng. News *44*, No. 51, p. 84 (1966).



[6] Cf. *C. Berge*: The Theory of Graphs. John Wiley and Son, New York (General Definitions, p. 9).

cases. The steroid skeleton, for example, contains "cycles" of every size from five-membered to nineteen-membered (see Scheme 1).



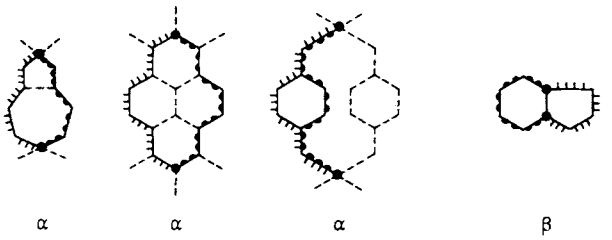
To obtain an answer that agrees with the view of every chemist, namely that the steroid skeleton contains only one five-membered ring and three six-membered rings, cycles with "double points" [7] and with pairs of "neighboring points" [8] must be excluded. Thus it must be stipulated that the routes are combined only in accordance with rules a and b.

a) Routes that are "coupled" with a shorter route cannot be used for combination. The remaining paths are named "fundamental paths".

Two routes between two given atoms are "coupled", α) if they pass through at least one common atom (⊕) (α coupling):

or β) if two atoms (⊕) on different routes are directly joined by a linkage that does not form part of either of the two routes (β coupling):

In the examples, the fundamental paths between the atoms in question are represented by a continuous line. The coupled longer route is indicated by a broken line. When a route is coupled only with another route of the same length, both are fundamental paths (see the last example in each case).



b) To find the fundamental rings for two given atoms, the fundamental paths are combined in pairs. However, all possible combinations of two fundamental paths between these two atoms are not necessarily permissible. In particular, combinations of fundamental paths that would give a cycle containing a double point or a pair of neighboring points are not admissible. The combination of fundamental paths must be in accordance with (i) and (ii) (see Scheme 2).

[7] A double point in a cycle is one that is passed through at least twice when the ring is traced out.

[8] If in tracing out a cycle one passes through two points that are directly connected (neighboring), and if the direct connection between these points is not a part of that cycle, this ring contains a pair of neighboring points.

Cycle with a double point (⊕) cycle with a pair of neighboring points (⊕ ··· ⊕) in the steroid skeleton.

α α α β

Scheme 2. Examples of fundamental paths that cannot be paired to give fundamental rings (⎯⎯ and ⏑ ⏑ ⏑).

i) If two atoms are joined by a number of fundamental paths of equal length, such that one can pass over from any one of these fundamental paths to all the others by simply proceeding *via* a coupled fundamental path, these fundamental paths form a class of their own. The combination of fundamental paths from the same class to form a fundamental ring is not permitted.

ii) If the two atoms are directly linked, the remaining fundamental paths between these two atoms also form a class of their own. Fundamental rings again cannot be formed by combination of fundamental paths from the same class, but only by combination of each fundamental path of such a class with the direct linkage between the two atoms in question.

2.2. Relationships between Two Fundamental Rings (Definitions)

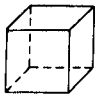
"Isolated fundamental ring"

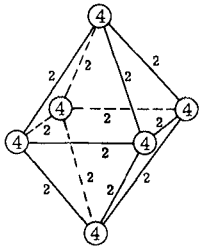
If a fundamental ring has no ring atom in common with another fundamental ring, it is named "isolated".

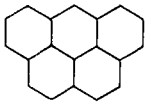
"Condensed fundamental ring"

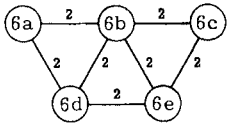
If a fundamental ring has at least one ring atom in common with another fundamental ring, it is said to be "condensed" with this other ring.

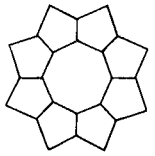
"Condensation types"

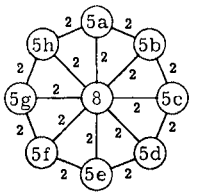






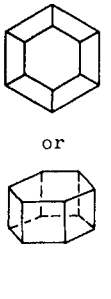


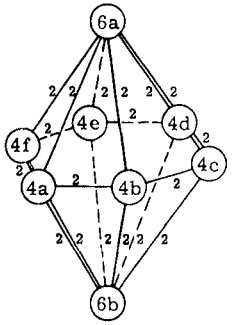


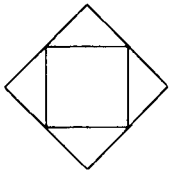


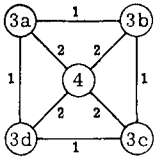
If two fundamental rings are condensed, the system contains a sequence of atoms, consisting of at least one atom, that is common to both fundamental rings. Such a sequence constitutes a "condensation zone" for these two fundamental rings.

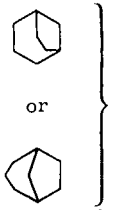
A monatomic condensation zone is characteristic of two spiro-condensed fundamental rings [9].

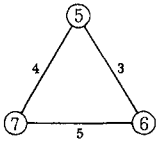


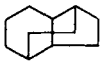


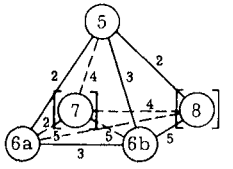












A diatomic condensation zone is characteristic of two ortho-condensed fundamental rings (corresponding to "ortho-fused") [10].

[9] The usual definition ("only one atom is common to two ring structures") does not allow for the possibility that two large ring structures may be spiro-condensed at two points, so that they have more than one ring atom in common.

[10] In the IUPAC nomenclature, for example, there is no consistent designation for the condensation type of two condensed rings. Depending on whether a ring contains the "maximum number of noncumulative double bonds" or not, it is referred to as "fused" or "bridged". "Fused" is always preferred for saturated six-membered rings.

No.	Structure	Fundamental ring	Ring complex
1.		1 six-membered ring	
2.		2 six-membered rings	
3.		2 six-membered rings no ten-membered ring	
4.		6 four-membered rings not 5 four-membered rings	
5.		5 six-membered rings no ten-membered ring no fourteen-membered ring and so on	
6.		1 eight-membered ring 8 five-membered rings no sixteen-membered ring no fifteen-membered ring and so on	

Scheme 3. Fundamental rings and ring complexes for selected structures.

No.	Structure	Fundamental ring	Ring complex
7.		2 six-membered rings 6 four-membered rings no eight-membered ring	
8.		1 four-membered ring 4 three-membered rings no eight-membered ring and so on	
9.		1 five-membered ring 1 six-membered ring 1 seven-membered ring	
10.		1 five-membered ring 2 six-membered rings [1 seven-membered ring 1 eight-membered ring][*]	

[*] Cf. page 729.

A condensation zone containing more than two atoms is characteristic of two "bridged" fundamental rings [10].

"*Degree of condensation of two fundamental rings*"

The numerical value of the degree of condensation gives the number of ring atoms that are common to both rings.

"*Condensation point*"

A condensation point is an atom of a fundamental ring that is linked with at least three other atoms, provided that these atoms are themselves members of fundamental rings [11].

2.3. Aggregation of Fundamental Rings

To permit the topological definition of the types of aggregation of fundamental rings, we have introduced the concept of the "ring complex". The ring complex is a graph that systematically represents the rings and their condensations in a molecule. It does not embody any familiar chemical concept that might be expected to be used by the chemist in a literature search, but is in fact a topological figure, which, if necessary, is automatically constructed and further processed by a computer. The object of this process is merely to facilitate the search by the machine for a system of condensed ring structures.

To construct the ring complex, each fundamental ring in the molecule is assigned a point such that each ring uniquely corresponds to one point and each point uniquely represents one ring. To each linkage of two fundamental rings by condensation is assigned a line in the ring complex. Each of these lines is given a positive integer equal to the degree of condensation of the pair of fundamental rings in question. Each point in the ring complex, and hence each fundamental ring, is given a symbolic name. In the examples in Scheme 3, the number and nature of the fundamental rings present are indicated. The fundamental rings are represented in the ring complexes by circles, in which is shown the symbolic name of the fundamental ring, starting with a figure giving the ring size.

Another topological method for the treatment of condensed ring systems was developed by *Lederberg*. The aim of this method is to permit the mechanical establishment of a notation for systems of condensed rings for which a planar representation is possible, as well as the mechanical deduction and cataloging of every conceivable type of such systems. Unlike the "fundamental ring" concept, however, it is not intended to display relationships between condensed ring systems that are based on the nature, number, and mode of condensation of their constituent rings.

[11] The condensation points correspond to the "vertices" referred to by *Lederberg*; DENDRAL-64. A System for Computer Construction, Enumeration and Notation of Organic Molecules as Tree Structures and Cyclic Graphs, Part II. Topology of Cyclic Graphs. Interim Report to the National Aeronautics and Space Administration. Grant NsG 81–60, December 15, 1965.

2.4. Procedure for the Determination of the Fundamental Rings

Since the definition of the fundamental ring closely follows the chemist's intuitive approach, the fundamental rings in a molecular structure can generally be distinguished by direct inspection, without the need for any special instructions. A number of characteristic ring systems are given in Scheme 3 as examples.

The situation is least favorable in ring systems in which the bridged condensation type occurs together with other condensation types. The fundamental rings are then less obvious on projection on only one plane. To permit the recognition of all the fundamental rings in these cases, irrespective of the projection, a detailed general procedure is given, together with an example (see Scheme 4).

a) Find all the condensation points. Rings that contain only one condensation point or none at all are already fundamental rings.

b) In any order, number the ring atoms of the cycles containing at least two condensation points.

c) Form all possible combinations of two condensation points and mark those in which the condensation points are directly linked.

d) Determine all the possible routes between a selected pair of condensation points and mark those that are coupled in accordance with α or β (cf. Section 2.1.a). The shortest of a set of coupled routes is a fundamental path between the selected pair of condensation points. All other routes are shown in brackets in Scheme 4.

The α-coupling of two paths is recognized by the fact that at least one of the linking atoms is common to both routes (cf. Section 2.1.a)α).

For β-coupling of two routes, the structure must contain at least one pair of directly linked condensation points. One of the condensation points of this pair must lie on one of the two routes and the other condensation point on the other route (cf. Section 2.1.a)β).

e) Form all possible pairs of fundamental paths between the selected condensation points, with the exception of pairs consisting of fundamental paths of the same class (see Section 2.1.b). The rings formed when the fundamental paths are combined in this way are fundamental rings.

f) Arrange the ring atoms named in each fundamental ring in a numerical order. This makes it easy to recognize a fundamental ring when it recurs for another pair of condensation points.

g) Repeat steps d to f for all the other pairs of condensation points.

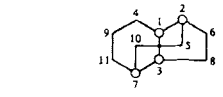
h) Eliminate repetitions of the same fundamental ring.

i) Add the fundamental rings found in step a.

This procedure gives the nature and number of all the fundamental rings in the structure.

In the fundamental rings resulting from this procedure the intuitive approach of the chemist is very closely approximated. However, application of this procedure sometimes results in the quoting of special kinds of fundamental rings, which a chemist would hardly recognize as acceptable ring structures. To take remedial measures, one can again differentiate special groups among the fundamental rings. The members of each group are characterized by the fact that they correspond to each other in a definite manner, and

only the smallest fundamental ring of such a group of corresponding fundamental rings is finally recognized.



The other fundamental rings are eliminated. It is, for example, the result of such an elimination, at present still manually performed, that in Figure 7 in Scheme 3 eight-membered rings are suppressed. These rings would extend over "bottom" and "top" of the six-cornered column.

The same correspondence principle would lead to the elimination of the seven-membered and of the eight-membered fundamental ring in Figure 10 in Scheme 3 (fundamental rings D and E in Scheme 4). The reader himself may judge whether or not he would intuitively state these ring structures as being present.

Fundamental rings can also be recognized by applying a slightly modified procedure: In order to find the fundamental paths, one can combine a condensation point only with one of its neighboring condensation points at a time. Among the routes found between two of these condensation points those which are coupled with a shorter fundamental path are eliminated. Since this procedure has not yet been programmed for the computer we shall not describe it in detail here.

One might be inclined to look out for definitions of ring structures which are simpler to handle than the proposed concept of the fundamental rings. One could, for example, drastically cut short the procedure of ring recognition by considering only neighboring condensation points and by restricting oneself to the combinations of the two shortest routes between these condensation points in order to recognize ring structures with them as members. However, this would result *e.g.* in the failure to recognize the four-membered central ring in Figure 8 in Scheme 3.

There are many other possible ways of defining ring structures in a simpler manner than proposed, but they are all more or less formal, as was already pointed out for the conventional definitions. This inevitably

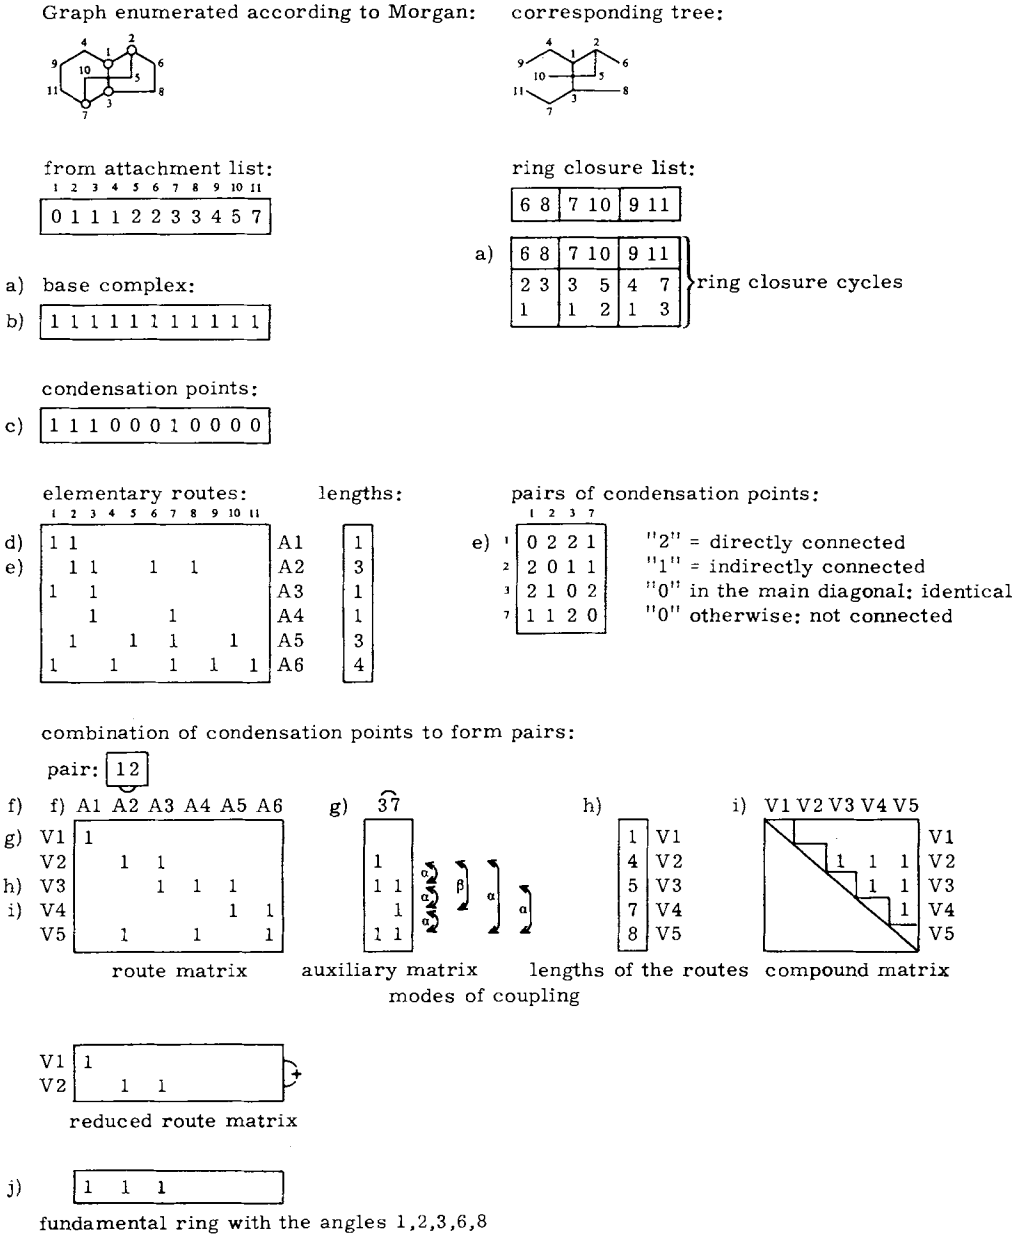
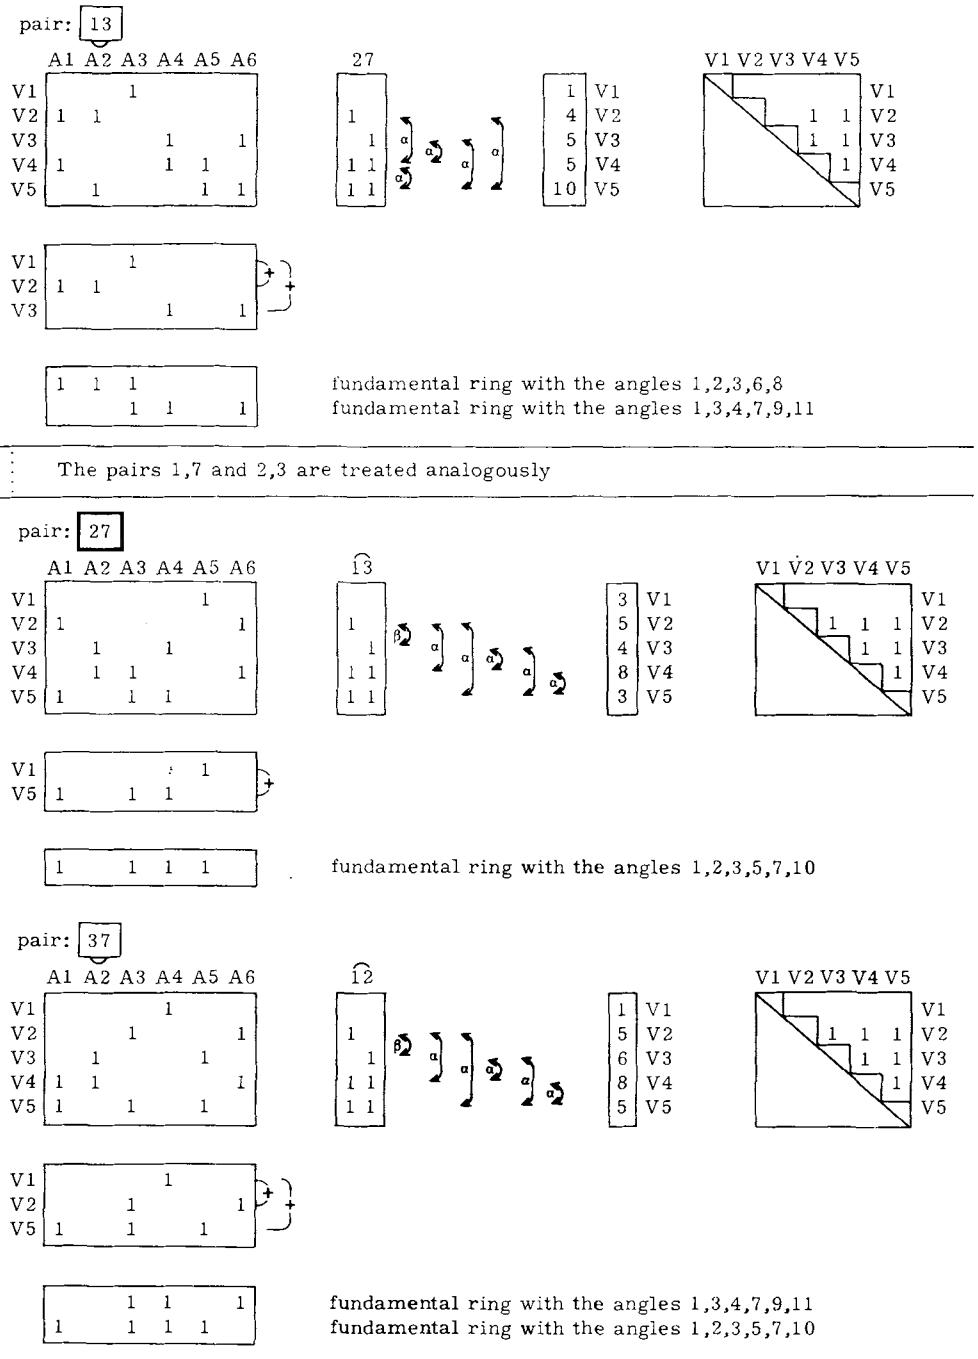
Cycles that are not fundamental rings:

Scheme 4. Example of the determination of the fundamental rings in a given structure.

leads to results that frequently are far distant from the intuitive ring concept of the chemist, which, however, has proved much too complicated to be satisfactorily represented by a simple formal definition. If one aims at such an approximation of the chemist's point of view, as has been achieved in the fundamental ring concept, a certain amount of effort is required in defining ring structures. At present extensive investigations are being undertaken to economize the recognition of fundamental rings.



If the structural formula satisfies certain requirements, the process can be considerably shortened by the use of simplifications. In the majority of cases the fundamental rings can be recognized by direct inspection of the structural formula, particularly if no bridged structures are present. For example, it can be easily shown that the only fundamental rings present in condensed aromatic hydrocarbons are the obvious benzene rings, so that analysis by the above procedure is unnecessary. However, this will not be discussed further here.



3. An Algorithm for the Mechanical Determination of Fundamental Rings

If the atoms of a structural formula are represented by points ("angles") and the bonds by "lines", one obtains a graph corresponding to the structural formula. In the determination of the fundamental rings present by means of an algorithm, the hydrogen atoms may be ignored, as can the nature of the skeletal atoms and the details of their bonding (*e.g.* multiple bonds).

Such a graph can also be completely represented in a numerical form by enumerating all its angles and listing the connections between them. For example, in a procedure given by *H. L. Morgan*[12], a "from attachment list" gives for each angle one of the directly connected angles ("ligands"), the particular ligand given being the one with the lowest number out of all the ligands of this angle.

[12] *H. L. Morgan*, J. chem. Documentation *1965*, 107.

Scheme 5. Mechanical determination of fundamental rings.

All the lines represented in the list in this way combine to form a tree that contains all the angles of this graph. This list cannot contain lines that would lead to ring closures in the graph. These are given in an additional "ring closure list". All these lists can be readily compiled by hand for a given structural formula. However, they can also be produced by a programmed electronic computer[7] from a suitable representation of the formula.

To find the fundamental rings from a numerical representation of the graph, the computer must carry out the following steps (see Scheme 5).

a) The cycle corresponding to each ring closure in the "ring closure list" is constructed. To do this, the two ends of the ring closure line are joined by the sequence of lines in the tree. This sequence of lines, together with the ring-closure line, makes up the cycle.

b) Every cycle present in the graph, and hence all the fundamental rings, can be found from these "ring-closure cycles". Thus the fundamental rings can be found by analysis of the sub-graph consisting of the ring-closure cycles, *i.e.* the "base complex".

c) All the condensation points in the structure are then determined. These are the angles in the graph having more than two ligands in the base complex. If a ring-closure cycle contains only one condensation point or none at all, this cycle is already a fundamental ring.

d) If a ring-closure cycle has more than one condensation point, "elementary routes" are formed to find fundamental rings. An elementary route runs between two condensation points in the base complex. It contains no double points, and has no condensation points except at its ends.

These elementary routes are then combined to form the fundamental paths, which will give the desired fundamental rings on combination with other fundamental paths. The elementary routes are marked in a matrix of the type (number

of angles, number of elementary routes). A 1 is inserted in position (i,k) if the i-th angle occurs in the k-th elementary route A_k. All the other matrix elements have the value zero. The length of any elementary route A_k is equal to one less than the number of angles.

e) The next step is the formation of all possible combinations of two condensation points that are joined in the base complex. In a matrix of the type (number of condensation points, number of condensation points), a 2 is inserted in position (i,k) if the i-th condensation point is directly linked to the k-th. A 1 is inserted in this position if the condensation points are only indirectly linked. Otherwise a 0 is inserted.

A pair (l,m) of directly linked condensation points is selected from all these points, provided it is present.

f) All routes V_i between l and m that do not contain double points are now expressed by elementary routes. This is done in the route matrix of the type (number of routes, number of elementary routes). A 1 is inserted in position (i,k) if A_k occurs in the i-th route V_i. All the other elements are equal to zero.

g) Coupled routes are now found by means of an auxiliary matrix. Since two routes can be coupled only by condensation points, a check is made to determine whether route V_i contains any condensation points other than those at its ends. This is indicated by a 1 in the column of the condensation point in question.

α) Coupling of two routes by a common angle is shown by the occurrence of this angle on both paths.

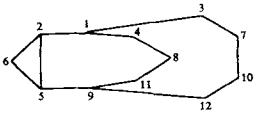
β) Coupling of two routes by the direct linkage of two angles, each of which lies on a different path, is recognized as follows.

If one checks only the columns in the auxiliary matrix that are assigned to two directly linked condensation points l' and m' the occurrence of this type of coupling is shown by a characteristic arrangement of the elements 0 and 1 at the positions assigned to the routes in question, V_o and V_p, *i.e.* either:

	l'	m'	or:		l'	m'
V_o	0	1		V_o	1	0
V_p	1	0		V_p	0	1

If one of these criteria shows that two routes are coupled, the longer of the two routes is not considered further.

h) To establish this, a V-membered vector is formed for the individual route lengths. Its i-th element is equal to the scalar product of the i-th row vector of the route matrix and the elementary route-length vector.



i) The coupling of two routes is marked in a compound matrix of the type (V,V). A 1 is inserted in position (i,k) if the i-th route is coupled with the k-th route. All the other matrix elements are equal to zero. With the aid of this compound matrix and the route-length vector, the longer of two coupled routes is eliminated from the route matrix. The resulting simplified route matrix only contains all the fundamental paths between the pair of condensation points in question.

j) To form the fundamental rings from the fundamental paths, the row vector representing the direct linkage of a pair of condensation points is added modulo two to each of the other row vectors.

All the other pairs of directly linked condensation points are treated in the same way.

The fundamental paths between pairs of indirectly linked condensation points are determined in a similar manner. In this case, however, the fundamental paths must be combined mainly in pairs, *i.e.* each with every other, to form rings. "Mainly" is intended to indicate that care must be taken in the program to ensure that fundamental paths of the same class (cf. Section 2.1.) are not combined with one another.

This procedure finally gives all the fundamental rings that can be found by considering pairs of condensation points. The total number of rings in the graph is then found by adding this number to the number of fundamental rings, obtained by consideration of the base rings with a maximum of one condensation point.

Scheme 6. Some results of the recognition of fundamental rings by machine.

The machine program for the determination of fundamental rings is written in the problem-oriented FORTRAN language. It has already been tested on the IBM® 7010, 7090, and 360 Model 40 machines (the last with a 64 K core memory). A series of different structural-formula graphs with up to 12 condensation points were fed into the machine in the short topological form described by *Morgan*[*], and the fundamental rings present in each were determined by computer. The results were expressed in the form of a list: a heading line that can accommodate up to 24 two-digit numbers gives the various ring sizes. Under these, in a fourteen line matrix, the individual ring members are given in the order of their occurrence in the ring (cf. Scheme 6).

[*] Cf. Section 3, [12].

It may happen that in a highly complicated molecule so many condensation points and fundamental rings exist that the available space in the memory of the computer does not suffice for all steps of the complete ring-recognition process. Then the machine prints a message showing which of the condensation points it was unable to consider. After that the result can easily be completed by intellectually completing the algorithm. These limitations can be overcome, if necessary, by using a computer with a larger memory or by writing the program in a machine-oriented language instead of FORTRAN.

The authors would like to thank W. Schwier and M. Wildgrube for substantial mathematical contributions.

New Methods of Preparative Organic Chemistry[**]

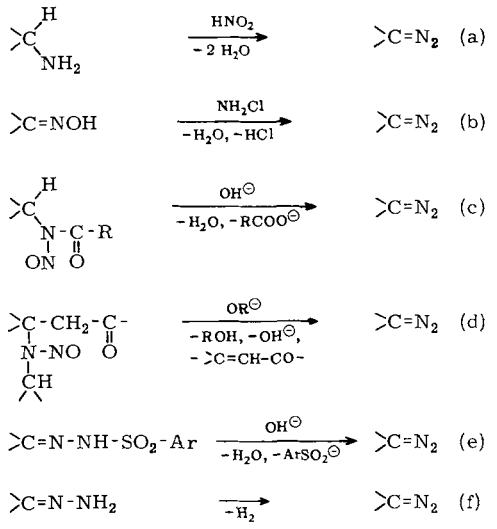
Transfer of Diazo Groups[1]

BY M. REGITZ[*]

BASED ON WORK CARRIED OUT WITH D. STADLER, H. SCHWALL, A. LIEDHEGENER, H. J. GEELHAAR, F. MENZ, J. HOCKER, J. RÜTER, AND W. ANSCHÜTZ

When an arenesulfonyl azide, particularly p-toluenesulfonyl azide, reacts, in the presence of a base, with a compound containing an active methylene group, the two hydrogen atoms of the active methylene group are replaced by a diazo group to form a diazo compound and an arenesulfonamide. The method may be used for the synthesis of the diazo derivatives of cyclopentadienes, cyclohexadienes, 1,3-dicarbonyl, 1,3-disulfonyl, and 1,3-ketosulfonyl compounds, ketones, carbonic acid esters, and β-iminoketones. Secondary reactions can lead to azo compounds and heterocycles such as 1,2,3-triazoles, 1,2,3-thiadiazoles, and pyrazolin-4-ones. Azidinium salts react in the same way, but in this case an acidic reaction medium is necessary, a fact that is sometimes advantageous.

I. Introduction



Two main routes have been used so far for the synthesis of aliphatic diazo compounds. In one case, compounds in which the future diazo C atom already carries a substituent containing nitrogen are converted into diazo compounds by condensations, *e.g.* by diazotization of amines in accordance with eq. (a) or by the Forster reaction (b). The starting materials for the second route are substances in which the future diazo C atom carries a functional group with two adjacent N atoms. Some important examples are the deacylation (c) of the *N*-acyl-*N*-nitrosoalkylamines, the cleavage (d) and (e) of β-(*N*-alkyl-*N*-nitrosoamino)-ketones and arenesulfonyl hydrazones by alkali, and the dehydrogenation (f) of hydrazones[2].

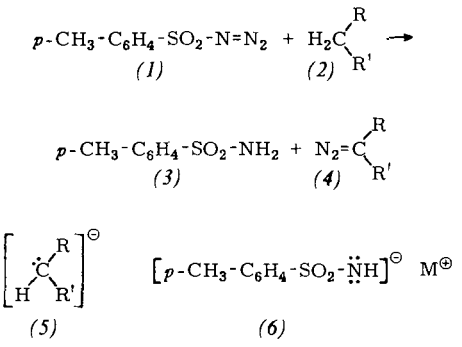
[**] The articles in this series have been published in five volumes by Verlag Chemie, Weinheim/Bergstrasse. An English edition has also been published. The present article, together with procedures will appear in Volume VI of the series.

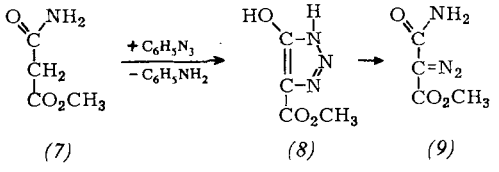
[1] XIIIth report on reactions of compounds containing active methylene groups with azides. From the Habilitation Thesis of *M. Regitz*, Universität des Saarlandes, Saarbrücken, 1965; supplemented by more recent work.

[2] For individual methods, see *B. Eistert* in: Neuere Methoden der präparativen organischen Chemie. 3rd Edit., Verlag Chemie GmbH., Weinheim/Bergstr. 1949, Vol. I, p. 359; *R. Huisgen*, Angew. Chem. *67*, 439 (1955); *F. Weygand* and *H. J. Bestmann*, Angew. Chem. *72*, 535 (1960).

In contrast to these methods, the transfer of the diazo groups in accordance with reaction (g) involves the transfer of an existing N_2 group from a donor to an acceptor in exchange for two H atoms, with formation of a new diazo compound.

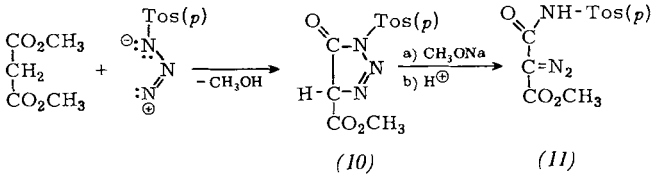


The first compounds that come to mind as donors might be the aliphatic diazo compounds. However, these can be ruled out on two grounds. Firstly, they react in accordance with eq. (g) only in special cases[1,3]; secondly they would have to be prepared by one of the conventional methods (reactions (a) to (f)), so that any advantage of the present method is lost.



II. Transfer of Diazo Groups from Sulfonyl Azides

Sulfonyl azides, which can be readily obtained from sulfonyl chlorides by halogen-azide exchange, do not suffer from the above disadvantage. The surprising discovery that azides transfer N_2 groups is plausible since they are isoelectronic with diazo compounds, so that *e.g.* sulfonyl azides may be regarded as sulfonyl diazoamides. Azides and diazo compounds also exhibit pronounced similarities in reactivity, as is seen *e.g.* in the Curtius degradation of carboxylic acid azides as a counterpart of the Wolff rearrangement, the formation of imenes and carbenes, or even the 1,3-dipolar cycloadditions of both classes of compounds.



The N_2 group of *p*-toluenesulfonyl azide *(1)*, which is the azide component used in almost every case, is exchanged in a one-step reaction for two H atoms of an active methylene compound *(2)*, with formation of *p*-toluenesulfonamide *(3)* and the diazo compound *(4)*. The transfer of the diazo group is carried out in the presence of a base whose strength corresponds to the proton activity of *(2)*, since the carbanion *(5)* is the actual reacting species. The acidic *p*-toluenesulfonamide *(3)* is generally separated from *(4)* as a salt *(6)*.

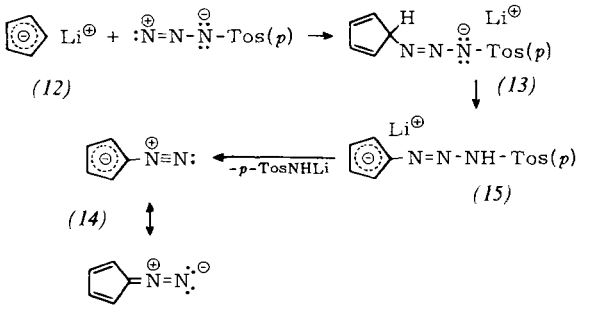
The preparation of a diazo compound from an azide (phenyl azide) was first carried out by *O. Dimroth*[4] in 1910. The reaction with the malonic ester amide *(7)* led *via* the triazole *(8)* to the diazomalonic ester amide *(9)*.

Curtius and *Klavehn*[5] later prepared methyl diazomalonate amide *(11)* from dimethyl malonate and *p*-toluenesulfonyl azide, the triazolone *(10)* being assumed to occur as an intermediate.

More recently, *Doering* and *De Puy*[6] synthesized diazocyclopentadiene *(14)* (see Section A.1), evidently with no knowledge of the above-mentioned work. This synthesis provided the incentive for our own investigations in this field, which, along with other investigations, are reported below.

A. Synthesis of Diazo Compounds

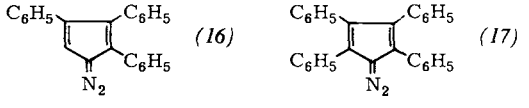
1. Diazocyclopentadienes



Cyclopentadienyl-lithium *(12)*, which can be obtained from cyclopentadiene and phenyl-lithium, reacts with *p*-toluenesulfonyl azide in ether to form diazocyclopentadiene *(14)*[6]. The "azo coupling product" *(13)* and the triazene *(15)* are regarded as hypothetical intermediates, the decomposition of which yields

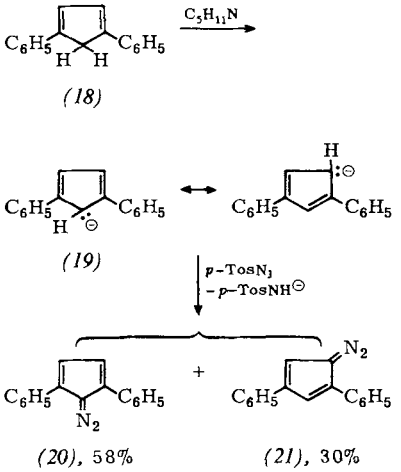
[3] *D. G. Farnum* and *P. Yates*, Proc. chem. Soc. (London) *1960*, 224.

[4] *O. Dimroth*, Liebigs Ann. Chem. *373*, 356 (1910).



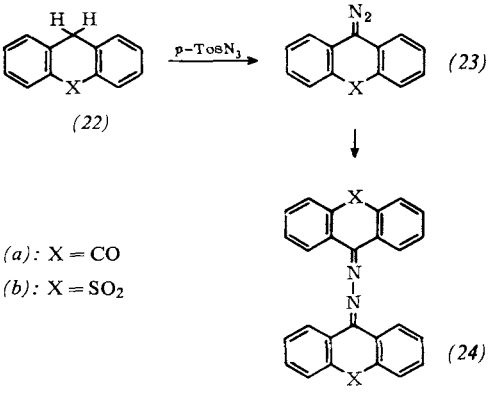
[5] *Th. Curtius* and *W. Klavehn*, J. prakt. Chem. [2] *112*, 76 (1926).

[6] *W. v. E. Doering* and *C. H. De Puy*, J. Amer. chem. Soc. *75*, 5955 (1953).



lithium *p*-toluenesulfonamide and diazocyclopentadiene *(14)*.

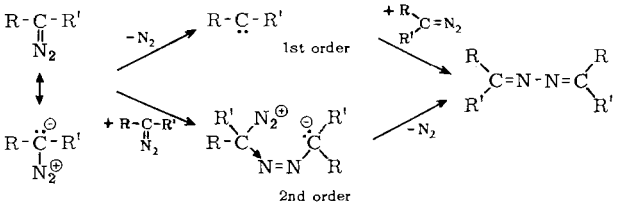
The use of the rather expensive phenyl-lithium as the base can be avoided by carrying out the reaction in the presence of diethylamine without a solvent [7], or even better, in acetonitrile (yield of *(14)* 84 %) [8]. The analogous synthesis of 1-diazo-2,3,4-triphenylcyclopentadiene *(16)* (yield 97 %) and 1-diazo-2,3,4,5-tetraphenylcyclopentadiene *(17)* (yield 95 %) in acetonitrile/piperidine [8] is superior to the transfer of diazo groups with phenyl-lithium [9,10] and with diethylamine [11]. 2,5-Diphenylcyclopentadiene *(18)* gives the



two isomeric diphenyldiazocyclopentadienes *(20)* and *(21)* [8]. The formation of these products is readily explained as involving the mesomeric carbanion *(19)*, formed from *(18)* and piperidine, which contains two nucleophilic centers.

(20), 58% *(21)*, 30%

2. Diazocyclohexadienes

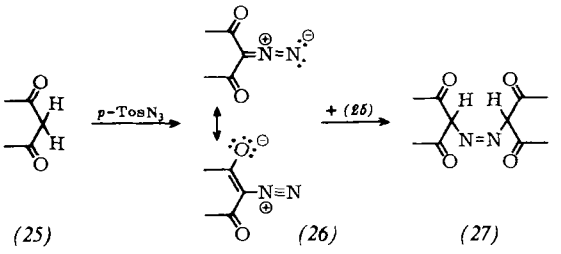


The only dibenzocyclohexa-1,4-diene derivatives *(22)* that have been used so far for diazo group transfers are those in which the CH_2 group is further activated by

an additional CO or SO_2 group in the meso position (vinylogy principle).

Diazoanthrone *(23a)* is obtained in this way in 94 % yield from anthrone *(22a)* and *p*-toluenesulfonyl azide in ethanol/piperidine [12]. A compound to which the same structure was assigned, and which was formed from *(22a)* and methylsulfonyl azide in pyridine/piperidine [13], was found to be a mixture of 66 % of anthraquinone azine *(24a)* and 27 % of 9-diazoanthrone *(23a)* [12]. This conversion of a methylene component into an azine is generally possible only if the initially formed diazo compound is unstable to bases, and if the reaction conditions for the diazo group transfer coincide with those required for the decomposition of the diazo compound.

Base-catalysed decompositions of diazo compounds into azines and nitrogen are known. Compound *(23)* also decomposes to give *(24)* when treated with pyridine/piperidine. Consequently, it is very doubtful that *Pelz* [13] isolated a compound *(23)*, since this is not stable under the reaction conditions used. The two mechanistically possible paths A (first order) and B (second order) were not studied kinetically.



Since the proton-activating action of the arenesulfonyl group is weaker than that of the carbonyl group [14], the transfer of a diazo group onto thioxanthene *S,S*-dioxide *(22b)* requires the use of potassium ethoxide as the base, but it then gives a 98 % yield of *(23b)* [12]. However, if the addition of azide is carried out over a relatively long period (*ca.* 30 min), the 9-diazothioxanthene *S,S*-dioxide *(23b)* that is formed undergoes $C_2H_5O^{\ominus}$ - catalysed decomposition into nitrogen and 10,10'-azinobis(thioxanthene *S,S*-dioxide) *(24b)*. The reaction of *(22b)* with *p*-toluenesulfonyl azide in ether/tetrahydrofuran gives only 45 % of *(23b)* [10].

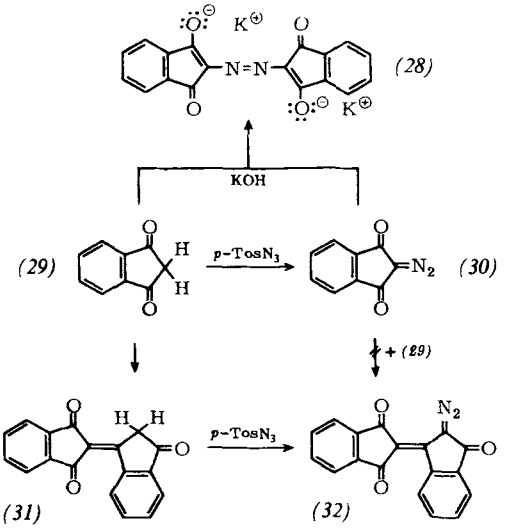
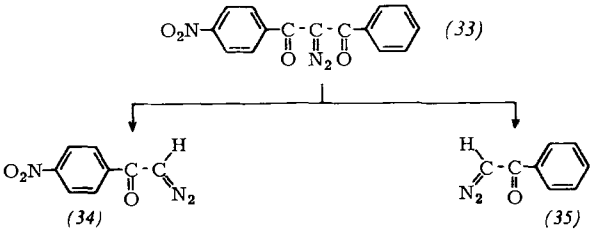
3. 2-Diazo-1,3-dioxo Compounds

2-Diazo-1,3-dioxo compounds *(26)* are usually synthesized by diazotization of suitable amines. Since these amines are generally prepared from the β-dicarbonyl compounds *(25)*, the synthesis is considerably shortened by the transfer of diazo groups onto *(25)*.



The possibility of keto-enol tautomerism in the β-diketones is of no importance to the transfer reaction, since the keto form and the enol form react with bases to give the same mesomeric anion, which reacts with the sulfonyl azide. Owing to the high CH or OH (enol) acidity of *(25)*, even weak bases such as piperidine or triethylamine can cause anion formation. Whenever possible the use of such weak bases is preferred to the use of alkali metal hydroxides or alkoxides since side reactions can often be avoided and higher yields can be obtained. Cyclic β-dicarbonyl compounds fixed in the *trans* configuration occasionally also give azo compounds *(27)* or tautomers as secondary products of the diazo synthesis, which will be discussed more fully in Section II.B.



a) 2-Diazo-1,3-diketones

Investigations on the structure of hydrindantin [15] led to the synthesis of 2-diazoindan-1,3-dione *(30)* by diazo group transfer. The reaction was found to proceed satisfactorily, not only in ethanol/potassium ethoxide [16,17] but also in ethanol/triethylamine [15], which gives *(30)* in 85 % yield; in aqueous-ethanolic potassium hydroxide solution, on the other hand, the reaction leads to 2-diazo-1',3,3'-trioxo-1,2'-bisindanylidene *(32)* [16].

The transfer of diazo groups onto *(31)* is preceded by autocondensation of the indan-1,3-dione in the presence of KOH (*(29)* → *(31)*). Since *(29)* couples with *(30)* to give the dipotassium salt *(28)*, the formation of *(32)* *via* 2-diazoindan-1,3-dione *(30)* may be ruled out.

Diazo group transfers onto β-diketones of the benzoylacetone or dibenzoylmethane type are best carried out in methylene chloride/piperidine. In contrast to the usual high yields (see Table 1), *p*-nitrodibenzoyldiazomethane *(33)* is formed in a yield of only 29 %. This is mainly due to deacylation of *(33)* in both of the

possible directions to give *p*-nitrobenzoyldiazomethane *(34)* and benzoyldiazomethane *(35)* [18]. This cleavage is prevented by reaction of *p*-nitrodibenzoylmethane with *p*-toluenesulfonyl azide in ethanol in the presence

of catalytic quantities of triethylamine (yield of *(33)*: 80 %)[18]. The versatility of the reaction for the synthesis of 2-diazo-1,3-diketones can be judged from Table 1.

b) Diazomalonic Ester and α-Diazo-β-oxocarboxylic Esters

Diethyl diazomalonate *(39)* can be obtained by diazo transfer in ether/diethylamine (yield 75 %)[20] or in acetonitrile/triethylamine (yield 95 %)[18], the resulting product being almost pure. It can be purified by low-temperature recrystallization (distillation is sometimes dangerous) from ether, a process that is very useful for the purification of liquid diazo compounds [18,42]. The rate of the triethylamine-catalysed transfer reaction decreases with decreasing polarity of the solvent, *i.e.* in the order acetonitrile > methylene chloride > ether.

Diethyl diazomalonate *(39)* is formed only in traces (3 %) from diethyl sodiomalonate *(36)* and *p*-toluenesulfonyl azide; the main product (97 % yield) is the sodium salt of ethyl *N*-(*p*-toluenesulfonyl)diazomalonamide *(40)*, which is formed by displacement of an ethoxy group, and which gives *(41)* on acidification[18,21].

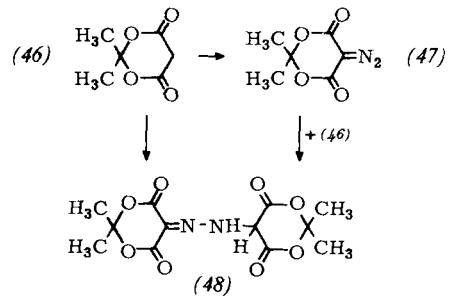
The reaction cannot proceed *via* diethyl diazomalonate *(39)*, which does not react with sodium *p*-toluenesulfonamide to give *(41)* under the conditions used. A cyclic intermediate, the triazoline *(38)* must be involved, *(40)* being formed by ring cleavage between the azo and sulfonamide nitrogens with elimination of ethanol[22]. The formation of traces of diethyl diazomalonate *(39)* can be explained in a similar manner, but with elimination of sodium *p*-toluenesulfonamide; however, *(39)* could also be formed by a mechanism involving the triazene *(37)*[18,23].

Ethyl acetoacetate reacts with *p*-toluenesulfonyl azide in ethanol/sodium ethoxide to give only 31 % of α-diazo-*N*-(*p*-toluenesulfonyl)acetoacetamide *(44)*, together with a considerable quantity of ethyl α-diazoacetoacetate *(42)*, which is contaminated with ethyl diazoacetate *(43)*[18,21]. *(43)* is evidently formed by deacylation of *(42)*.

A mechanistic argument similar to that outlined for diethyl malonate also applies to the formation of *(42)* and *(44)*, particularly since *(42)* does not react with sodium *p*-toluenesulfonamide to give the diazo derivative *(44)*. Further evidence of the cyclic intermediate in the displacement reaction (triazoline formation in accordance with *(36)* → *(38)*; $CO-CH_3$ instead of $CO_2C_2H_5$) is provided by the fact that the reaction of t-butyl acetoacetate yields only traces of *(44)*, clearly because of steric hindrance to triazoline formation.

On the other hand, the synthesis of α-diazo-β-oxocarboxylic esters *(45)* under the conditions given for the malonic ester, *i.e.* with acetonitrile/triethylamine, proceeds without side reactions. Some examples are listed in Table 2[18,24].

Table 2. Esters *(45)* of α-Diazo-β-oxocarboxylic acids $CH_3-CO-CN_2-CO_2R$.



R	Yield (%)	IR Diazo band (Film) (cm^{-1})

being in the tautomeric hydrazone form *(48)* (20%) [19]. This secondary reaction, which greatly reduces the yield of *(47)* is mainly due to the nucleophilic nature of the carbanion of *(46)*.

4. Diazomethylene Disulfones

The methylene disulfones *(49)* are sufficiently acidic for conversion into diazo derivatives *(50)* with *p*-toluenesulfonyl azide, even in aqueous-ethanolic potassium hydroxide solution; however, the less acidic diamide *(49f)* must be converted into its lithium compound by treatment with methyl-lithium in ether before it will react in the usual manner to give diazomethionic bis(ethylanilide) *(50f)* [10]. A number of data are given in Table 3.

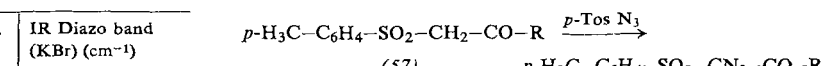
Attempts to synthesize the α-diazo sulfones R-SO_2-CN_2-R', which have only recently become obtainable by another route [25], we e unsuccessful in the case of (2,4-dinitrobenzyl)-*p*-toluene sulfone [26, 27].

5. α-Diazo-β-oxo Sulfonyl Compounds



Until recently, the α-diazo-β-oxo sulfones were an unknown class of compounds, and it is only by the use of diazo group transfers that they have become available. Attempts to synthesize the sulfonyl analogue *(55)* of 2-diazoindan-1,3-dione *(30)* by the Forster reaction (eq. b) were unsuccessful, since the β-oxo sulfone gave *(54)* on oxidation (*(51)* → *(54)*). Compound *(51)* was therefore treated with *p*-toluenesulfonyl azide in ethanolic potassium hydroxide solution.

As in the case of "Meldrum's acid" (see Section II.A.3.b), the initially formed diazo compound *(55)* immediately couples with the starting material *(51)* to form the dipotassium salt of 3,3'-dihydroxy-2,2'-azothionaphthene 1,1,1',1'-tetroxide *(52)* [28], which is converted into the hydrazone *(53)* on acidification.

The experiments would probably have stopped at this point, had their continuation not been made possible by a completely unexpected reaction. When attempts were made to recrystallize the hydrazone *(53)* (which is sparingly soluble in the usual solvents) from ethylene glycol or dimethylformamide, "decoupling" [29] took place to give the β-oxo sulfone *(51)* and the desired α-diazo derivative *(55)*. The reaction probably proceeds *via* an anionic intermediate *(56)*, the polar solvent acting as a proton-transfer agent. This assumption is supported by the fact that the reaction does not take place in tetralin, even at 200 °C [28].

On the other hand, open-chain β-oxo sulfones such as *p*-toluenesulfonylacetone *(57a)* or *p*-toluenesulfonylacetophenone *(57b)* react smoothly with *p*-toluenesulfonyl azide in ethanol/water/triethylamine to give the diazo derivatives *(58a)* and *(58b)* [27]. Ethyl *p*-

toluenesulfonylacetate *(59a)* and ethyl (1,1-dimethylethanesulfonyl)acetate undergo diazo transfer only in the presence of sodium ethoxide in ethanol/ether, but the reaction then leads to the displacement of the alkoxy group to give the sodium salts *(60a)* and *(60b)* of *N*-(*p*-toluenesulfonyl)-α-diazo-α-sulfonylcarboxylic amides [27] (for the analogous reaction of the esters of β-oxo acids, see Section II.A.3.b).

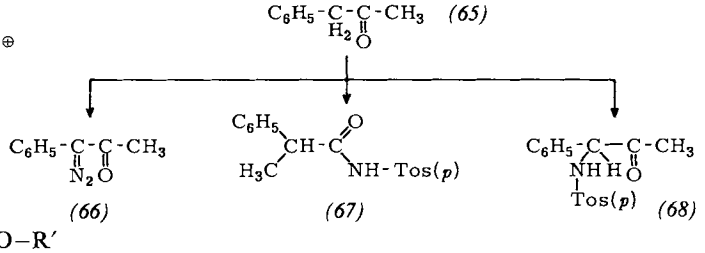
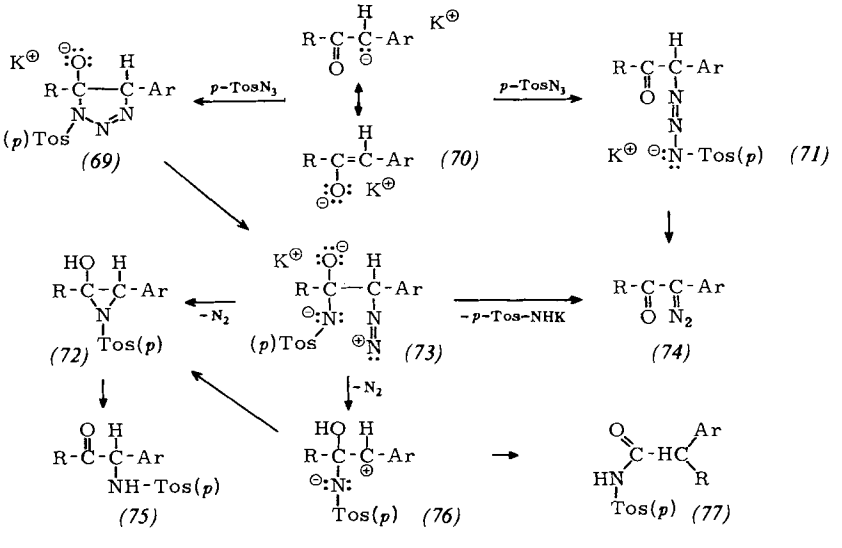
6. α-Diazocarbonyl Compounds



a) From Arylmethyl Ketones

Carbonyl compounds of the type $R{-}CH_2{-}CO{-}R'$ react with sulfonyl azides in the desired manner only when their CH_2 group is additionally activated by an aromatic residue [14]. Desoxybenzoin *(61)* reacts with *p*-toluenesulfonyl azide in ethanol/potassium ethoxide



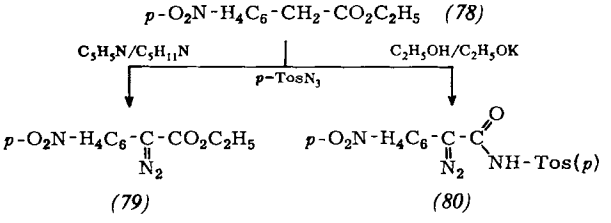
at 5 to 10 °C to give 23 % of benzoylphenyldiazomethane ("azibenzil") *(63)*, together with its decomposition product benzil monoazine *(64)* (24 %) and *N*-(*p*-toluenesulfonyl)diphenylacetamide *(62)* (25 %). Compound *(62)* is formally a Wolff rearrangement product of *(63)* with *p*-toluenesulfonamide; however, it was only partly obtained from *(63)* [30, 31].

Both side reactions can be avoided by the use of a short reaction time at 0 to 5 °C. The initially formed unstable adduct of *p*-toluenesulfonyl azide and the anion of *(61)*, which probably has the structure *(69)* (R = Ar = phenyl), decomposes on addition of a second equivalent of base to give the desired "azibenzil" *(63)* (70 %) and potassium *p*-toluenesulfonamide [22]. Decomposition by acids, on the other hand, leads to elimination of N_2 and formation of *N*-(*p*-toluenesulfonyl)diphenylacetamide *(62)* in 80 % yield. Similar behavior is observed with benzyl α-naphthyl

and β-naphthyl ketones, which give phenyl-α(or β)-naphthoyldiazomethane and *N*-(*p*-toluenesulfonyl)-α-(or β)-naphthylphenylacetamide [30, 31]. The "diazo-synthesis" proceeds normally with phenylacetone *(65)* to give *(66)*, whereas acid hydrolysis of the reaction mixture yields *N*-(*p*-toluenesulfonyl)-α-phenylpropionamide *(67)* and α-(*p*-toluenesulfonyl)amino-α-phenylacetone *(68)*.

One mechanistic interpretation of these results is as follows. Two isomeric structures *(69)* and *(71)* are conceivable for the $TosN_3$ adducts with the mesomeric anion *(70)*. Structure *(71)* can be ruled out simply because it does not explain the formation of the rearrangement product. The 1,2,3-triazoline salt *(69)*, on the other hand, can undergo ring cleavage with formation of α-diazo ketones *(74)* *via* the hypothetical diazonium betaine *(73)* (with elimination of potassium

p-toluenesulfonamide), or alternatively N_2-elimination to form the carbonium ion *(76)* may be followed by anionotropic rearrangement to give the *N*-(*p*-toluenesulfonyl)carboxylic amide *(77)*. The formation of the amino ketone *(68)* could result from a "short circuit

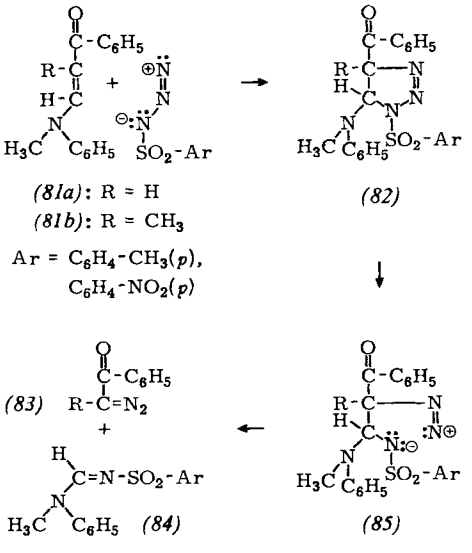


[30] *M. Regitz*, Tetrahedron Letters *1964*, 1403.
[31] *M. Regitz*, Chem. Ber. *98*, 1210 (1965).

mechanism" leading *via (72)* to the isomer *(75)*, R = CH_3, Ar = C_6H_5 [31].

A number of substituted "azibenzils" were synthesized under the above conditions, except that in the case of 4-nitrophenylbenzoyldiazomethane (yield 80 %), triethylamine was used instead of potassium ethoxide [32].

b) From Esters of Arylacetic Acids

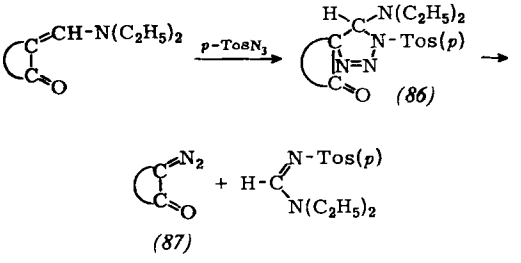


The diazo transfer onto ethyl *p*-nitrophenylacetate *(78)* confirms the observations made on β-oxo esters and malonic esters (see Section II.A.3.b). In ethanol/potassium ethoxide, displacement of the ethoxy residue gives *N*-(*p*-toluenesulfonyl)-diazo-(*p*-nitrophenyl)acetamide *(80)* (yield 61 %), while reaction in pyridine/piperidine leads to the diazo ester *(79)* (yield 72 %); methyl diazo-(2,4-dinitrophenyl)acetate is synthesized in a similar manner (yield 88 %) [31].

The product obtained from *(78)* and methylsulfonyl azide in methanol/potassium hydroxide, which was thought to be *(79)* [13], is in fact *N*-(methylsulfonyl)-diazo-(*p*-nitrophenyl)acetamide (*(80)* with CH_3SO_2 instead of *p*-Tos) [31].

c) From α-En-β-amino Ketones

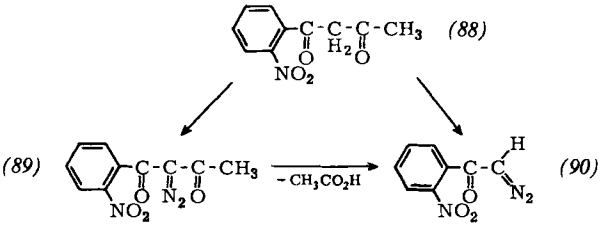
α-En-β-amino ketones of the type *(81)*, which can be obtained from benzoyl-acetaldehydes and *N*-methylaniline, form α-diazo ketones *(83)* and formamidines *(84)* when heated with sulfonyl azides in chloroform [33]. The formation of these products points to



[32] *W. Jugelt*, Z. Chem. *5*, 455 (1965).

[33] *R. Fusco, G. Bianchetti, D. Pocar*, and *R. Ugo*, Chem. Ber. *96*, 802 (1963).

the intermediate occurrence of a 1,2,3-triazoline *(82)* [34], which isomerizes with ring cleavage to give the diazonium betaine *(85)*.



This principle can be used for the synthesis of α-diazocycloalkanones *(87)* (diazocyclohexanone and diazocamphor); the decomposition of the triazoline adduct *(86)* has been formulated somewhat differently [20].

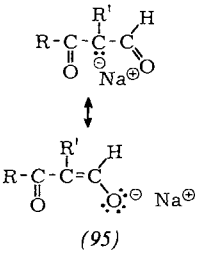
The same principle has also been used for the synthesis of α-diazobutyraldehyde from α-ethyl-β-dimethylaminoacrolein [35].

d) From 1,3-Diketones or β-Oxo Aldehydes

The transfer of diazo groups onto *o*-nitrobenzoylacetone *(88)* can be directed in such a way as to yield acetyl-*o*-nitrobenzoyldiazomethane *(89)* (methylene chloride/piperidine) or with additional deacetylation to give *o*-nitrobenzoyldiazomethane *(90)* (ethanol/water/piperidine) [18].

This principle may be used for the synthesis of α-diazo carbonyl compounds from methylene components whose proton activities are too low for N_2-transfer from sulfonyl azides. However, the reaction proceeds satisfactorily and uniformly only when the reactivities of the two acyl groups are very different (for non-specific cleavage, see Section II.A.3.a). Thus the cleavage of arylcarbonylacetyldiazomethanes (cf. Section II.A.3.a) with aqueous potassium hydroxide leads mainly, but not exclusively, to arylcarbonyldiazomethanes [23, 36]. The deacetylation of α-diazoacetoacetic esters *(45)* (for synthesis see Section II.A.3.b) under solvolytic conditions that leave the ester group intact (see Table 4) leads to very high yields of diazo-

$$CH_3{-}CO{-}CN_2{-}CO_2R \rightarrow N_2{=}CH{-}CO_2R$$
(45) *(91)*



[34] The orientation of the addition to azides is similar to that of the addition to enol ethers. See *R. Huisgen, L. Möbius*, and *G. Szeimies*, Chem. Ber. *98*, 1138 (1965); *R. Huisgen* and *G. Szeimies*, Chem. Ber. *98*, 1153 (1965).

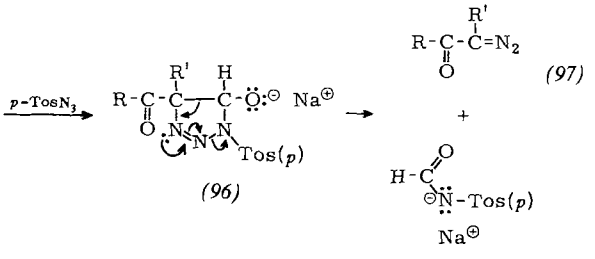
(95)

acetic esters *(91)*, and can compete with the usual diazotization of amines [24]. In the case of t-butyl diazoacetate [37] it is actually superior to the conventional syntheses [38, 39].

β-Oxo aldehydes are more suitable for use in the α-diazo ketone synthesis. The formyl group has a stronger proton-activating effect in the diazo transfer reaction [14], and can also be more readily removed by solvolysis than acetyl or arylcarbonyl groups. Thus the sodium salts *(93)* react with *p*-toluenesulfonyl azide in

(92) *(93)* *(94)*



ethanol to give α-diazo carbonyl compounds *(94)*. Methylcarbonyl compounds *(92)* that do not undergo diazo transfer directly (see Section II.A.6.a) can be smoothly converted into their diazo derivatives *(94)*

Table 5. Diazomethyl carbonyl compounds $R-CO-CH=N_2$ *(94)* obtained by diazo transfer with deformylation.

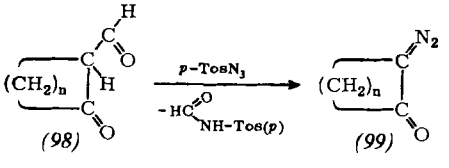
Ferrocenyl	84	68	2110

after introduction of a formyl group by Claisen condensation [40–42]. The scope of this principle can be seen from Table 5.

While the diazo transfer with deformylation has so far been used only for the synthesis of diazomethylcarbonyl compounds *(94)*, the analogous reaction of the sodium salt of α-alkyl-α-acylacetaldehydes *(95)* can be used for the synthesis of compounds of the type *(97)* [41].

(96) *(97)*



The cycloadduct *(96)* is assumed to occur as an intermediate, since the decomposition of this adduct would explain the formation of the sodium salt of *N*-(*p*-toluenesulfonyl)formamide together with *(97)*. Some examples of this type of reaction are given in Table 6.

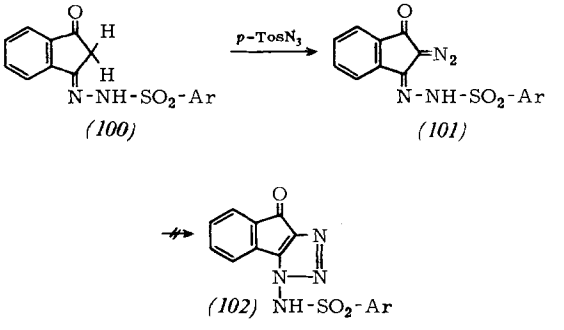
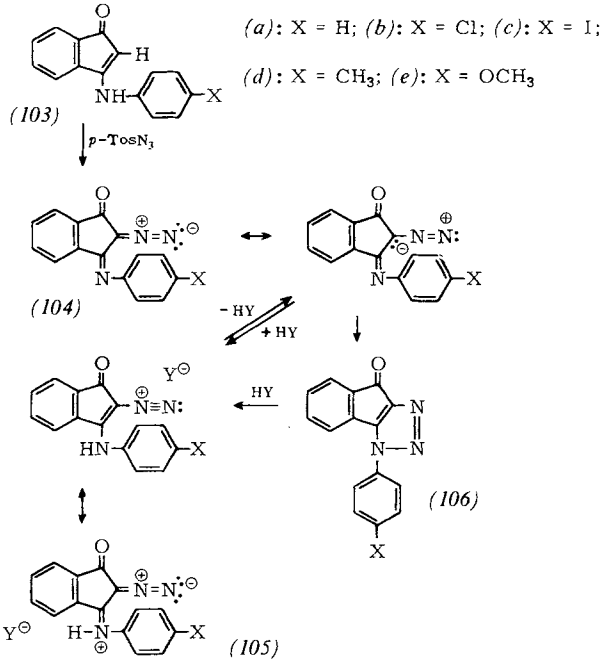
[43] *J. Rüter*, Diploma Thesis, Universität Saarbrücken, 1966.

Condensation of the α-formylcycloalkanones with diethylamine to form enamines, which precedes the addition of azide to form the triazoline *(86)*, is impossible in this case on grounds of constitution.

Further evidence of the occurrence of a triazoline in the reaction *(98)* → *(99)* is provided by the fact that about 50 % of cyclododecanone-α-carboxylic *p*-toluenesulfonamide (98′) is also formed in the synthesis of 2-diazo-cyclododecan-1-one *(99f)*. One scheme that appears plausible is a competitive



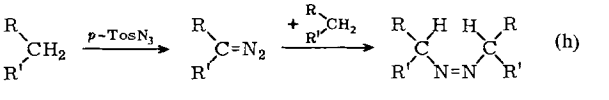
decomposition of the adduct by two routes, one leading to the formation of the diazo ketone *(99f)*, while the other leads to elimination of N_2 to form a carbonium ion, which then forms the β-keto amide by hydride shift. The same reaction branching has been observed, though to a smaller extent, in the synthesis of 2-diazocyclohexanone *(99b)* [43].



7. α-Diazo Imines and α-Diazo Imonium Salts

α-Diazo imines are generally regarded as nonexistent since *L. Wolff* [44] obtained, not α-diazo-β-imino ketones, but their cyclic isomers, 1,2,3-triazoles, from acyclic α-diazo-β-diketones and ammonia or primary amines.

True α-diazo imines, *i.e.* 3-(arenesulfonylhydrazono)-2-diazoindan-1-ones *(101)*, which show no tendency toward cyclization to give *(102)*, have been obtained by diazo group transfer onto 3-(arenesulfonylhydrazono)indan-1-ones *(100)* [16].

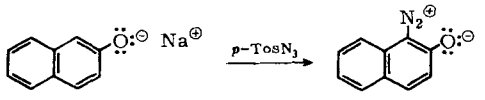


Under the same conditions (ethanol/potassium ethoxide), the 3-aminoindenones *(103a)* and *(103b)* also react to give stable diazo compounds *(104a)* and *(104b)*, whereas *(103c)* to *(103e)* are converted directly into 1-aryl-4-oxoindeno[2,3-*d*]triazoles *(106c)* to *(106e)* [45]. The triazole formation becomes understandable if the ring closure in the diazo imine is considered from the point of view of the 1,3-dipolar cycloaddition of the $C{=}N_2$ dipole across the azomethine bond, since substituents having a -E effect undoubtedly increase the nucleophilic strength of the imino N atom.

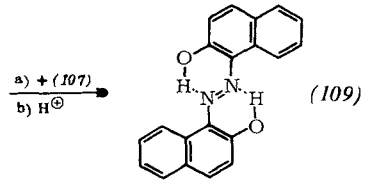
The diazo imines *(104a)* and *(104b)* and the triazoles *(106c)* to *(106e)* add on mineral acids such as HCl, HBr, $HClO_4$ (the addition of HX is accompanied by ring cleavage in the case of *(106c)*–*(106e)*) to give salts of the 3-arylimino-2-diazoindan-1-ones *(105a)* to *(105e)*. On deprotonation with aqueous potassium hydroxide, the diazo compounds *(104c)* and *(104e)* can also be isolated, whereas *(104d)* immediately cyclizes to form the triazole *(106d)*.

B. Synthesis of Azo Compounds or Their Tautomers

Though the combination of two molecules having active methylene groups by reaction with *p*-toluenesulfonyl azide is a one-step preparation, it is actually a two-step reaction (both steps requiring a basic medium) involving transfer of a diazo group followed by azo coupling (eq. h).



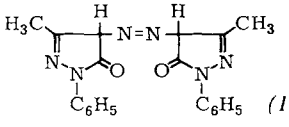
The azo synthesis from the methylene components naturally requires only a half equivalent of sulfonyl azide. For the second step, *i.e.* the actual azo coupling, the diazo component must be strongly electrophilic; this condition is generally satisfied when the N_2 group is flanked by strongly electron-attracting substituents.



[44] *L. Wolff*, Liebigs Ann. Chem. *325*, 129 (1902); *394*, 23 (1912).

[45] *M. Regitz*, Tetrahedron Letters *1965*, 3287; Angew. Chem. *77*, 735 (1965); Angew. Chem. internat. Edit. *4*, 710 (1965).

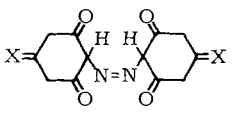
Sodium β-naphthoxide *(107)* reacts with a half equivalent of *p*-toluenesulfonyl azide in ether to give 2,2'-dihydroxy-1,1'-azonaphthalene *(109)* together with a small amount of *(108)* [46].



(107) *(108)*

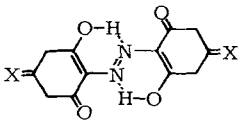
(109)

Even when an excess of *p*-toluenesulfonyl azide is used, the diazo compound *(108)* is formed in a yield of only 9 %, together with *(109)*. A number of other examples are known, such as the synthesis of 3,3'-dimethyl-1,1'-diphenyl-4,4'-azopyrazol-5-one *(110)* using phenyl azide/piperidine [13].



(110)

β-Dicarbonyl compounds fixed in the *trans* configuration, which satisfy the conditions given in Section II.A.3.b for the diazo synthesis, can be readily converted into α,α'-azo compounds [19,47]. Thus the 2,2'-azocyclohexane-1,3-diones *(111a)* to *(111c)* were obtained when the β-diketones were heated with *p*-toluenesulfonyl azide in ethanol/piperidine, *i.e.* under conditions that appear remarkable for azo coupling.



The azo compounds *(111)* and *(113)* exist as dienol chelates *(112)*, at least in methylene chloride and chloroform [19,48]. They exhibit a high absorption in the visible region (for *(111b)*: $\lambda_{max} = 425$ mμ, $\varepsilon = 18650$, CH_2Cl_2), and their NMR spectra in $CDCl_3$ contain no signal corresponding to the proton between the two carbonyl groups. Instead, they show singlets at very low fields for the OH protons chelated in accordance with *(112)* (for *(111b)*: $\delta = 12.44$ ppm) the ratio of the areas of the signals corresponding to that of the other protons present in the molecule.

3,3'-Azo-(2,4-dioxo-1,8,8-trimethylbicyclo[3.2.1]-octane) *(113)* is formed under the same conditions. Azo compounds containing heterocycles, such as 4,4'-dihydroxy-6,6'-dimethyl-3,3'-azo-2-pyrone *(114)* or the hydrazones *(115b)* and *(115c)*, are obtained by the same principle. Compounds *(115b)* and *(115c)* are derived from unenolized β-dicarbonyl compounds [49]; it is therefore understandable that the high-energy unconjugated azo form *(111)* is by-passed. (Further examples may be found in Sections II A.5 and II D.)

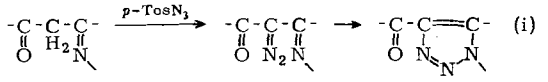
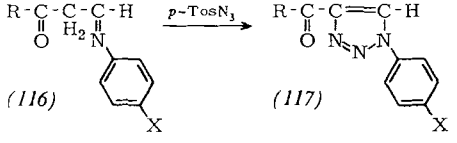
(113)

(114)



(115b), (115c)

C. Synthesis of Heterocycles



1. 1,2,3-Triazoles

Diazo transfers onto β-imino ketones generally lead directly to 1,2,3-triazoles (eq. (i)).

(i)

Apart from the exceptions in the indan system (Section II.A.7), the anils of *trans*-fixed β-diketones such as cyclohexane-1,3-dione, 5,5-dimethyl-cyclohexane-1,3-dione, and 5,5-pentamethylenecyclohexane-1,3-dione follow scheme (i) [50]. Only some triazoles are contaminated with small quantities of the diazo isomer, as can be seen from the presence of weak diazo bands in the IR spectrum of the crude products. The anils of open-chain β-dicarbonyl compounds can also be cyclized to 1,2,3-triazoles by diazo group transfer in ethanol/potassium ethoxide. Thus benzoyl (or

(116) *(117)*

(a): R = C_6H_5; *(b)*: R = CH_3
X = H, CH_3, Cl, I, OCH_3, NO_2

acetyl) acetaldehyde anils *(116a)* and *(116b)* give high yields (60–90 %) of 1-aryl-4-benzoyl-(or acetyl-)1,2,3-triazoles *(117a)* and *(117b)* [40].

Dehydrogenation of α-pyridinealdehyde hydrazone *(118)* yields, not α-pyridyldiazomethane *(119)*, but

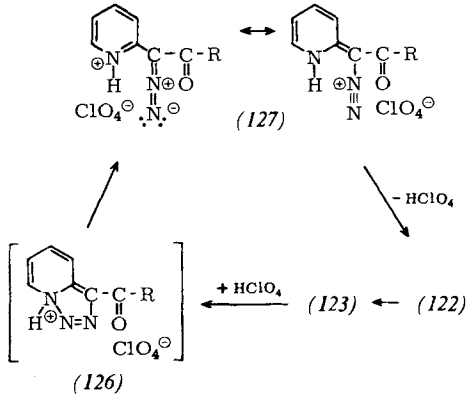
(118) (119) (120)

the cyclic isomer 1,2,3-triazolo[3,4-*a*]pyridine *(120)* [51,52].



A similar ring closure was observed in diazo group transfers onto alkyl and aryl (2-pyridyl)methyl ketones *(121)* in ethanol/potassium ethoxide [50,53]. The diazo stage *(122)* could not be isolated, but high yields of

(121) (122) (123) (124) (125)

3-acyl-[1,2,3]triazolo[3,4-*a*]pyridines *(123)*, their 7-methyl derivatives *(124)*, and 3-acyl-[1,2,3]triazolo-[3,4-*a*]quinolines *(125)* were obtained. Some examples are given in Table 7.

The ring cleavage of indeno[1,2-*d*][1,2,3]triazoles with mineral acids to give salts of the isomeric diazo imines was mentioned in Section II.A.7. This ring cleavage also takes place on treatment of the 1-acyl-[1,2,3]triazolo[3,4-*a*]pyridines *(123)* with perchloric acid in dioxane, and leads *via* the hypothetical compound *(126)* to the yellow-orange perchlorates *(127)* of the diazo stage *(122)*, which could not be isolated during the diazo transfer onto *(121)* [53]. This is

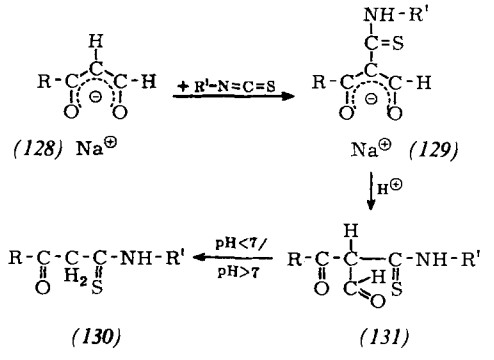
understable in that the salts *(127)* are cyclized by loss of $HClO_4$, even in ethanol, with regeneration of the triazoles *(123)*, and the diazo compounds *(122)* expected initially cannot be isolated.

2. 1,2,3-Thiadiazoles

Diazo group transfer and intramolecular cycloaddition can be used in accordance with equation (j) for the synthesis of 1,2,3-thiadiazoles. As has been known

(j)



for some time, this ring closure also takes place when 2-diazo-1,3-dioxo compounds are treated with hydrogen sulfide/ammonium hydrogen sulfide [54].

β-Thioxo carbonyl compounds *(130)* have recently been described [55,56]. A variant of this process, *i.e.* the reaction of the sodium salts of β-oxo aldehydes *(128)* (instead of the sodium salts of 1,3-diketones) with isothiocyanates in acetonitrile leads *via* the sodium salt *(129)* to high yields of formylacylthioacetamides *(131)*.

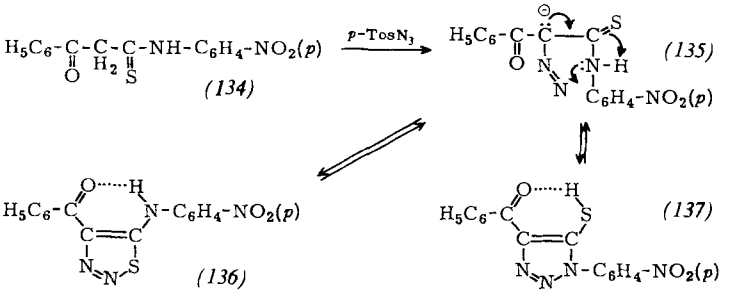
These can be used directly or after deformylation to give *(133)* by diazo-group transfer [57].

Diazo transfer from *p*-toluenesulfonyl azide onto acylthioacetamides *(130)* takes place in ethanol (variant A) or in methylene chloride/triethylamine (variant B) and gives high yields of 4-acyl-5-aryl(or alkyl)amino-1,2,3-thiadiazoles *(133)* [57] (for examples see Table 8). In a few cases the same thiadiazoles were obtained by 1,3-dipolar cycloaddition of diazo carbonyl compounds to isothiocyanates, though only



(132) (130) (133)

in moderate yields [58]. The diazo isomer *(132)* could not be isolated, since the cycloaddition *(132)* → *(133)* is evidently faster than the transfer reaction *(130)* → *(132)*.

The formylated acylthioacetamides *(131)* also give thiadiazoles *(133)* on diazo transfer in acetonitrile/diethylamine (variant C!) (see also Section A.6.c and d).

However, the formyl group is split off as diethylformamide (*(131)* → *(130)*) before the transfer reaction takes place [57].

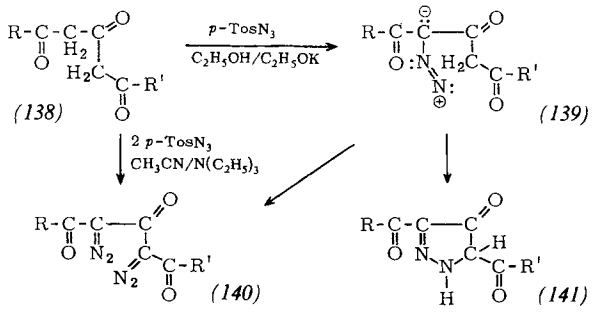
The transfer of diazo groups onto *N*-(4-nitrophenyl)benzoylthiaocetamide *(134)* in ethanol gave 55 % of thiadiazole *(136)* together with 21 % of isomeric 1-(4-nitrophenyl)-4-benzoyl-5-mercapto-1,2,3-triazole *(137)*, which isomerizes at its melting point, probably *via* the diazo isomer *(135)*, to the

(134) (135) (136) (137)

thiadiazole *(136)*. It is concluded from the experiments carried out so far that *(135)* can cyclize by two routes, the very high yield of *(137)* in the present case being due to a particularly high NH activity (NO_2 group in the *p* position). However, it has also been shown that *(136)* isomerizes *via* *(135)* to the triazole *(137)* under the conditions of the diazo transfer (ethanol/triethylamine), though only to a very small extent [57]. Thus the thiadiazole and the isomeric triazole are evidently interconvertible by a Dimroth rearrangement [59] *via* a diazo isomer.

3. 3,5-Diacylpyrazolin-4-ones and 2,4-Bisdiazo-1,3,5-triketones

Diazo-transfer reactions of 1,3,5-tricarbonyl compounds *(138)* in ethanol/potassium ethoxide yield neither monodiazo compounds *(139)* nor 2,4-bisdiazo-1,3,5-triketones *(140)*, but give cyclic isomers of *(139)*; these are the 3,5-diacylpyrazolin-4-ones *(141)* [60], a class of compounds that had previously been unknown.



Their formation can be interpreted as follows. The initially formed *(139)* cyclizes by intramolecular azo

[57] *M. Regitz* and *A. Liedhegener*, Liebigs Ann. Chem., in press. The keto-enol equilibrium of benzoylthioacetanilide *(130)*, R=R′=C_6H_5, is also discussed.

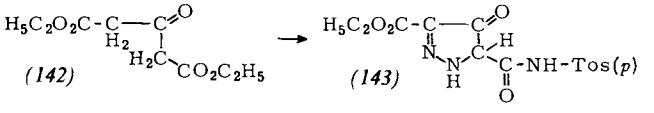
[60] *H. J. Geelhaar*, Diploma Thesis, Universität Saarbrücken, 1966.



coupling (see also Sections II.A.5 and B) to give the pyrazolin-4-one *(141)* (tautomeric relationships uncertain) before a second diazo group is introduced (*(139)* → *(140)*). (For examples see Table 9.)

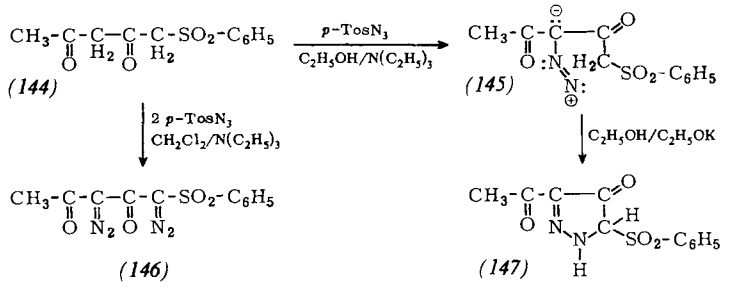


Table 9. 3,5-Diacylpyrazolin-4-ones synthesized.

	R′	Yield (%)	M.p. (°C)
Benzoyl	Benzoyl	88	263
4-Methoxybenzoyl	Benzoyl	79	236
Acetyl	Benzoyl	61	265

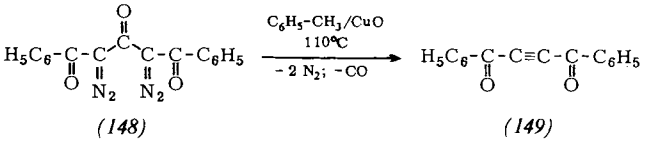
3-Pyridylcarbonyl	Benzoyl	63	271
4-Pyridylcarbonyl	Benzoyl	91	267
4-Chlorobenzoyl	4-Chlorobenzoyl	81	293

Diethyl acetonedicarboxylate *(142)* reacts in accordance with the same scheme, but with simultaneous replacement of an ethoxy group by a *p*-toluenesulfonamide residue to give *(143)* (see also [18]). In the case

of 1-benzenesulfonylacetylacetone *(144)*, the monodiazo compound *(145)* can be isolated and then converted into the pyrazolin-4-one *(147)* by ring closure.



Double transfer to form the bisdiazo compound *(146)* also takes place in this case [60]. Double transfer is also possible with the 1,3,5-triketones *(138)* if their

Table 10. 2,4-Bisdiazo-1,3,5-triketones *(140)* prepared.

R	R′	*(140)* Yield (%)	M.p. (°C)	IR Diazo band (KBr) (cm^{-1})

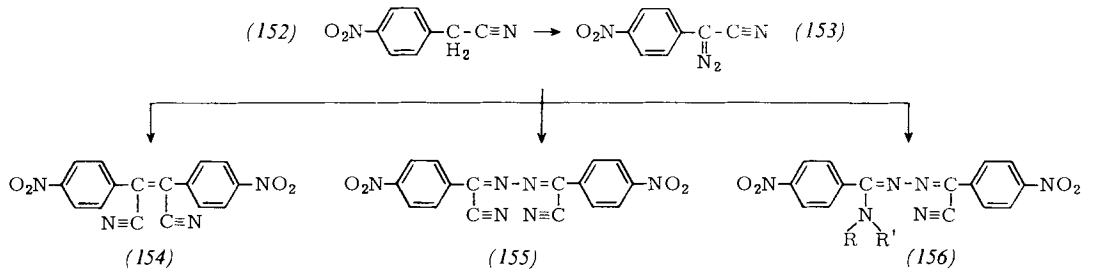
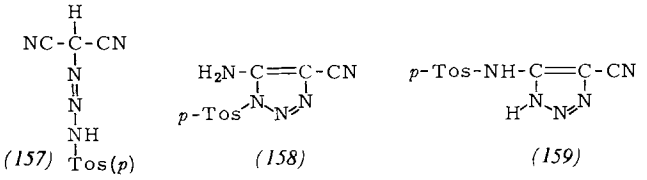
solutions in acetonitrile/triethylamine are added dropwise to *p*-toluenesulfonyl azide. (For examples see Table 10.)

However, the simultaneous pyrazolin-4-one ring closure cannot be entirely prevented. A surprising reaction is the thermal decomposition of 2,4-bisdiazo-1,3,5-trioxo-1,5-diphenylpentane *(148)* in toluene, which yields 65 % of dibenzoylacetylene *(149)* as the principal product [61].



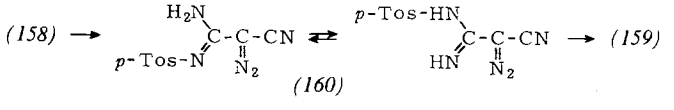
D. Reactions of Methylene Groups Activated by Cyanide

The diazo transfer reactions of α-cyanoacetophenone and ethyl cyanoacetate in ethanol/potassium ethoxide are immediately followed by azo coupling to give the azo enol *(150)* and the hydrazone *(151)* respectively [13,19,48] (see Section II.B).



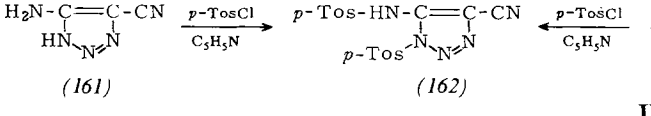
On the other hand, the behavior of 4-nitrobenzyl cyanide *(152)* is very complex. The primary product is evidently always cyano-4-nitrophenyldiazomethane *(153)*, which is very unstable to bases. Thus when triethylamine or bulky secondary amines such as diisopropylamine are used, the main product is the "carbene dimer", *i.e.* α,α′-dicyano-4,4′-dinitrostilbene *(154)*. Potassium ethoxide in ethanol or potassium hydroxide in methanol give partial retention of nitrogen and formation of α,α′-dicyano-4,4′-dinitrobenzaldehyde azine *(155)*. Ammonia, primary amines (methyl-, ethyl-, i-propyl-, or ethanolamine), and sterically unhindered secondary amines (dimethylamine, piperidine, or morpholine) are incorporated directly into the reaction product; a cyanide group is displaced with formation of α-amino-α′-cyano-4,4′-dinitrobenzaldehyde azines *(156)* [48].

[61] *H.J.Geelhaar*, Dissertation, Universität Saarbrücken, 1967.



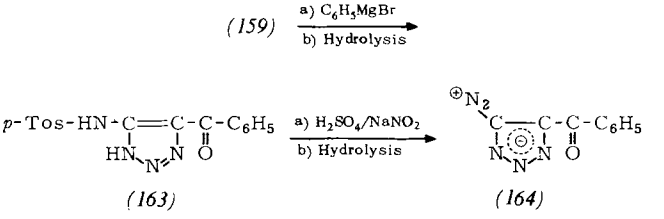
(152) (153) (154) (155) (156)

Malonodinitrile exhibits a reaction that had not been previously observed in reactions with *p*-toluenesulfonyl azide. In aqueous sodium hydroxide [62] or ethanol/potassium ethoxide [48], a very stable 1:1 *p*-toluenesulfonyl azide adduct is formed. Formulae under discussion at present are the triazene structure *(157)* [62] and the triazole formulae *(158)* [48] and *(159)* [63].



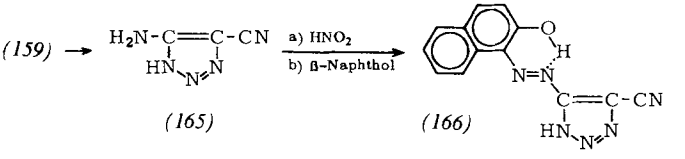
(157) (158) (159)

Formula *(158)* may be ruled out since it is incompatible with the dissociation constants of the adduct (water/acetone (9:1), 20 °C, $pK_1 = 3.2$, $pK_2 = 7.8$ [64]). Moreover, *N*-acylated nitrogen heterocycles are very readily hydrolysed [65,66], whereas the above adduct is stable. However, *(158)* may be an intermediate in the formation of *(159)*, since azide additions to malonodinitrile in accordance with *(158)* have been known for some time [67,68]. Compound *(158)* should then readily be converted into *(159)* by Dimroth rearrangement (see Section II.C.2), particularly since the strongly electron-attracting *p*-toluenesulfonyl group favors ring cleavage to form the diazo



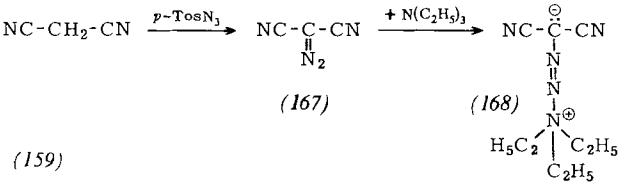
(158) (160) (159)

isomer *(160)*. The subsequent ring closure *(160)* → *(159)* of the electron-deficient terminal diazo nitrogen atom now takes place with the more strongly nucleophilic amidine nitrogen atom, *i.e.* with the nitrogen that is not *p*-toluenesulfonylated.



(161) (162)

The dissociation constants of the adduct agree with the formula *(159)* [63]; the cyclic structure is confirmed by the *p*-toluenesulfonylations *(161)* → *(162)* and *(159)* → *(162)*. Compound *(162)* also has the expected high acidity ($pK_a = 3.3$ in acetone/water (1:1) at 40 °C), and loses the ring *p*-toluenesulfonyl group on alkaline hydrolysis [63].



(159) (163) (164)

(159) reacts with phenylmagnesium bromide to give *(163)*, which yields the diazonium betaine *(164)* on removal of the *p*-toluenesulfonyl group and diazotization [48]. Cleavage of *(159)* with naphthalenesodium in tetrahydrofuran yielded the corresponding aminotriazole *(165)*, which was diazotized directly with nitrous acid and coupled with β-naphthol to form the azo compound *(166)* [63].

(159) (165) (166)

When the reaction of malonodinitrile is carried out in the presence of a weaker base such as triethylamine, diazomalonodinitrile *(167)* is clearly formed first but then adds on the base to form the betaine *(168)* [64].

(167) (168) (159)

III. Diazo Group Transfer with Azidinium Salts

The preparative scope is considerably widened by diazo transfers with azidinium salts. These are salts (mainly tetrafluoroborates) of mesomeric cations having the general formula *(169)*, and may be derived *e.g.* from benzothiazole, benzimidazole, pyridine, or quinoline [69]. In view of the relatively short-wave

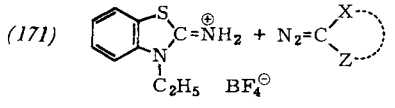
[69] *H. Balli* and *F. Kersting*, Liebigs Ann. Chem. *647*, 1 (1961).

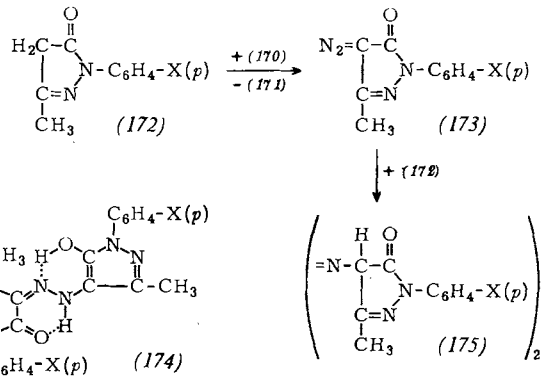
asymmetric stretching bands of the N_2 groups (2175 cm^{-1}), the azidinium salts may be regarded as *N*-diazonium salts (or diazonium amidines) [70]; this



(169)

explains their ability to act as N_2-transfer agents. The overall transfer reaction for 3-ethyl-2-azidobenzothiazolium fluoroborate *(170)* is as follows:

(170)



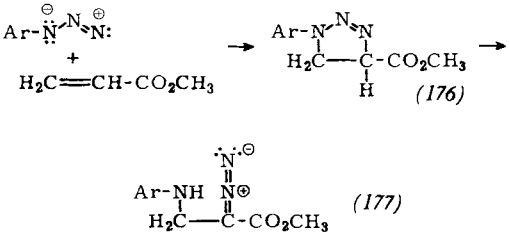
(171)

Thus the azidinium salt *(170)* gives a resonance-stabilized amidinium salt *(171)* [71], which is probably partly responsible for the smoothness of the reaction. The reaction takes place in aqueous-alcoholic solution or suspension at 0 to 80°C and at pH values of 0 to 8. Since the reaction proceeds only in the neutral and acid ranges, in which sulfonyl azides are unreactive, it is particularly suitable for diazo compounds that undergo coupling. Thus it has given good results in the synthesis of 2-diazo-2,3-dihydrothionaphthen-3-one 1,1-dioxide *(55)* (68 %) [72], α-cyano-α-diazoacetophenone (88 %) [71], and 4-diazo-3-methyl-1-phenylpyrazol-5-one (96 %) [71], whereas the transfer from *p*-toluenesulfonyl azide in basic media yields only coupling products (see Sections II.A.5, B, and D). Finally, the method has also proved suitable for the synthesis of α-diazo-α-nitro carbonyl compounds [73]. In addition to diazonitromethyl phenyl ketone (yield 23 %), methyldiazonitroacetate (yield 18 %) was synthesized for the first time. Some preparative examples are shown in Table 11.

Table 11. Results of diazo transfers with 3-ethyl-2-azidobenzothiazolium tetrafluoroborate.

Diazo compound	M.p. (°C)	Yield (%)
5-Diazobarbituric acid	278	84
2-Diazoindan-1,3-dione	149	84
2-Diazo-5,5-dimethylcyclohexane-1,3-dione	108	77
2,4-Bisdiazocyclohexane-1,3-dione	83	31
1,3,5-Trisdiazocyclohexane-2,4,6-trione	220	95
4-Diazo-3-phenyl-isoxazolone	74	77
1-Diazo-2-oxo-1,2-dihydronaphthalene	94	21

The requirement of an acidic to neutral reaction medium appears to form the limit of the preparative scope of the N_2 transfer with azidinium salts. This limit is probably reached when the proton activity of a methylene compound is so low that anion formation no longer occurs.

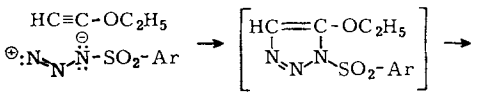


(a): X = H (97%) *(b)*: X = Cl (85%) *(c)*: X = COOH (80%)
(d): X = $CO_2C_2H_5$ (85%) *(e)*: X = NO_2 (77%) *(f)*: X = SO_3Na (58%)

2 - Azido - 3 - ethylbenzothiazolium tetrafluoroborate *(170)* reacts directly with 1-aryl-3-methylpyrazol-5-ones *(172)* (molar ratio 1:2) to give azopyrazolones *(175)* [74] (see also Section II.B), for which the chelated hydrazono-enol form *(174)* is deduced spectroscopically. The reaction proceeds in dimethyl-formamide/water (1:1) and at pH = 8. The diazopyrazolone *(173)* occurs as an intermediate, and then couples with *(172)* to give the dye. (The multi-stage mechanism is confirmed by kinetic measurements.) In the more strongly acidic region (pH = 3 to 4), on the other hand, the transfer reaction stops at the diazo stage *(173)*.

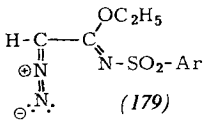
IV. Ring Cleavage of Adducts of Azides to Carbon-Carbon Multiple Bonds

Methyl acrylate adds on azides at room temperature to form the colorless 1,2,3-triazolines *(176)*, which are converted by basic catalysis (triethylamine) into the previously unknown esters *(177)* of β-arylamino-α-diazocarboxylic acids [75]. Esters of fumaric and crotonic acids and some α,β-unsaturated ketones react similarly,



(176)

(177)



except that the ring cleavage takes place even under the conditions for cycloaddition, *i.e.* without the addition of a base.

A cyclic stage *(178)* could also be involved in the formation of ethyl α-diazo-*N*-arenesulfonylacetimid-

(178)

(179)

ates *(179)* from ethoxyacetylene and benzenesulfonyl azides[76]. Neither of these reactions involves a CH-acidic starting material, but they are mentioned here because the diazo groups in *(177)* and *(179)* are derived from azides.

The author and his co-workers are grateful to Professor Dr. B. Eistert for his interest in and support of this work. Thanks are also due to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their generous financial support.

Higher Coordination Numbers of the Typical Elements[**]

BY R. F. HUDSON[*]

The bonding in electron-deficient molecules, e.g. the boron hydrides and certain metal alkyls, and in molecules which appear to violate the rare gas rule, e.g. hydrogen bonded complexes, interhalogen compounds and compounds of the typical elements with high coordination numbers such as PCl_5 and SF_6 can be described by a simple molecular orbital treatment involving delocalized σ-bonds. The contribution of d-orbitals to the bonding in the interhalogen compounds and rare gas fluorides is very small. The stereochemistry and physical properties of the PX_5 system are explained readily by the delocalization treatment and it is likely that here also the importance of spd hybridization has been overemphasized in the past.

1. The Basis of the Octet Rule

The electronic structure of an atom is determined by two main principles.

a) According to the Pauli principle, no two electrons may have the same set of quantum numbers, and hence only a limited set of orbitals is available.

b) In the ground state, the electrons occupy the lowest levels, and Hund's rule states that electrons (which have the same spin) will occupy separate degenerate levels until such levels are filled.

Spectroscopic examination leads to values of orbital energies, which enables two fairly distinct kinds of atom to be recognised:

i. Typical elements

	core	valency electrons	excited levels
Silicon	$1s^2\ 2s^2\ 2p^6$	$3s^2\ 3p^2$	$3d^0\ 4s^0$
Phosphorus	$1s^2\ 2s^2\ 2p^6$	$3s^2\ 3p^3$	$3d^0\ 4s^0$
Sulfur	$1s^2\ 2s^2\ 2p^6$	$3s^2\ 3p^4$	$3d^0\ 4s^0$

Here the difference in energy between 3s, 3p, and 3d, 4s levels is very high[1] (*ca.* 8–10 eV) so that the characteristic compounds of these elements use 3s and 3p orbitals only[***] in most of their compounds. Thus the typical valency of sulfur is 2, of phosphorus 3, and of silicon 4 (through 3s → 3p promotion). It is the size of the 3s → 3d energy difference, such that the 3d orbitals are close to the continuum, which is responsible for the octet rule.

ii. Transition elements

For example:

	core	valency electrons
Scandium	$1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6$	$3d^1\ 4s^2\ 4p^0$
Manganese	$1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6$	$3d^5\ 4s^2\ 4p^0$

Here the 4s and 3d levels have similar energies and the 3d levels are partially occupied, leading to spd hybridisation of the orbitals. The use of 3d orbitals and their importance in determining the stereochemistry and

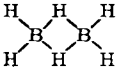
[**] Based on a lecture given at the Review Symposium on "Modern Views of Valency and Bonding" at Southampton on April 21st and 22nd, 1966.

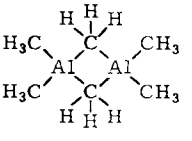
[1] *E. Moore,* Atomic Energy Levels, Vol. 1, Circular 467 Nat. Bur. Standards, 1949.

[***] Excited levels contribute to all bonding orbitals, but this is a secondary effect and will be neglected at this point. The influence of these orbitals will be considered in some cases at a later stage.



physical properties of transition metal compounds is beyond doubt.

This review deals solely with typical elements (*i.e.* non-transition elements) and particularly the electronic structures of compounds which appear to violate the octet rule. We shall not consider donor-acceptor complexes of the kind $H_2\overset{\oplus}{O} \rightarrow H$, $H_3\overset{\oplus}{N} \rightarrow H$ and $Cl\overset{\oplus}{I} \rightarrow Cl$, since in these cases the electron octet is maintained around the central atom. It is noted that the interhalogen cations *e.g.* $ICl_2^{\oplus}$, but not the corresponding anions $ICl_2^{\ominus}$, conform to the octet rule.



Abnormally high coordination numbers are found for molecules where too few electrons are available for electron-pair bonding (so-called electron-deficient compounds) and also in molecules where more than 4 electron pairs appear to be localized around a central atom. These two types of compound are considered further in the following sections.

1.1. Electron-Deficient Compounds

The structure of the boron hydrides [2] posed a classical problem of the nature of bonding in compounds in which the number of bonding electron pairs is less than the number of bonds. No progress in understanding their structures was made while the boron hydrides were regarded as abnormal relatives of hydrocarbons, and while the 2-electron bond was assumed to be necessary for σ-bonds, although many kinds of resonance structures were proposed [3]. The first structural determination (of B_4H_{10}) by *Kasper et al.* [4] established hydrogen bridges of the kind now known to be present in diborane *(1)*.

(1)

(2)

The same type of bonding by alkyl groups in certain metal alkyls was recognized about the same time [5], *e.g.* the structures of $Al_2(CH_3)_6$ *(2)*, $[(CH_3)_2Be]_n$, show carbon to be 5-coordinated.

Recent work [6] has shown that the carbon atoms in lithium alkyls are 6-coordinated in the solid state (cf. the CH_3Li tetramer in Fig. 1). Here the CH_3 groups in the bridges play the same role as the hydrogen atoms in boron hydrides, *i.e.* forming one electron bonds, *e.g.* as in *(3)*.

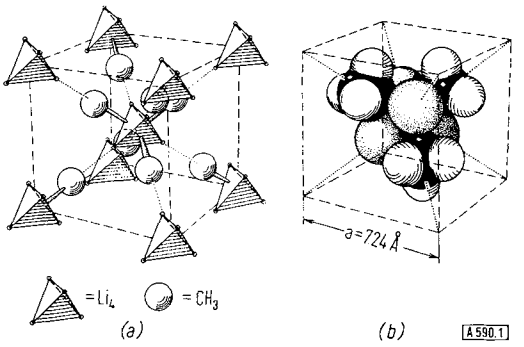

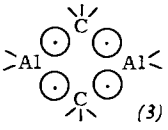

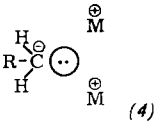

Fig. 1. (a) Unit cell of methyl-lithium. (b) Stuart-Briegleb atomic model of a tetrameric structural unit $(CH_3Li)_4$.

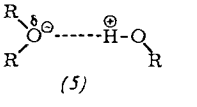
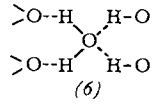
Electrostatic bonding of a carbanion to two cations could explain some of these structures, as for example in electrophilic substitution at a saturated carbon atom [7] *(4)* (shown

(3)



(4)

by the observed retention of configuration). Such an explanation can hardly hold for the boron hydrides in view of the similar electronegativities of boron and hydrogen. It will be shown that a simple MO description leads to a satisfactory treatment of the bonding in electron-deficient compounds, as well as "electron-excess" compounds which will now be considered.



1.2. "Electron-Excess" Compounds

1.2.1. The Hydrogen Bond [8]

The hydrogen atoms in the boron hydrides have the unusual coordination number 2, although the electrons around the hydrogen atom can be accommodated in the 1s level. This is not the case for hydrogen bonded species, as it is quite clear from the Pauli exclusion principle that two localized electron-pair bonds cannot be formed by hydrogen. *Pauling* [9] recognised the electrostatic nature of the bonding, *e.g.* as in

(5)

(6)

structure *(5)*, and *Lennard-Jones* and *Pople* [10] calculated the hydrogen bond energy of water (~ 6 kcal/mole) using a localized point charge model, which took into consideration the lone pairs, as in *(6)*. In ice and in the ordered form of water, oxygen is 4-coordinated. In the solid state, ammonia also assumes a symmetrical structure [11] with nitrogen

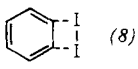
[11] *I. Olovsson* and *D. H. Templeton*, Acta crystallogr. *12*, 832 (1959).

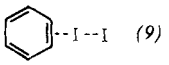
6-coordinated, as in *(7)*; in view of the long NH–N bond length of 3.4 Å compared with the N–H covalent bond distance of 1.13 Å, the bonding is predominantly electrostatic.

(7)



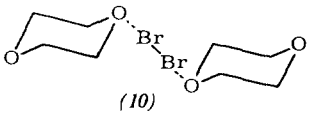
Several difficulties are however encountered, *e.g.* the infrared –OH vibration frequency of water is too high to be explained by electrostatic factors alone; more recent studies estimate at least 7–8 % covalent character[12].

The electrostatic model has been applied[13] to $HF_2^{\ominus}$, but here the molecule is symmetrical and the additional bond energy is 26 kcal/mole (*i.e.* 80 kcal/mole for each bond compared with 135 kcal/mole for HF). Considerable covalent bonding must be present in this molecule, but again we have the question – what kind?



1.2.2. Polyhalogen Compounds[14]

There are three kinds of polyhalogen compounds, a) anionic, *e.g.* $Br_3^{\ominus}$, b) cationic, *e.g.* $ICl_2^{\oplus}$, and c) those made up of neutral molecules. All the complexes have an even number of electrons and with one exception (IF_7)[*] all the bond angles are 90° or 180°. The $X_3^{\ominus}$ molecules are linear (which may be compared with the linear reaction coordinate of a Walden inversion on carbon[15]), whereas $IX_2^{\ominus}$ is triangular. The bond lengths of the triiodide ion[16] in $As^{\oplus}(C_6H_5)_4I_3^{\ominus}$ are equal, whereas in NH_4I_3 and CsI_3 one bond is longer than the others[17], probably due to crystal field effects.



These compounds may be compared with the so-called charge-transfer compounds formed by the halogens, interhalogens, and halogen compounds (*e.g.* CCl_4, CHI_3) with electron donors (n or π). The original structure *(8)* proposed by *Reid* and *Mulliken*[18] was shown to be incorrect[19], as the influence of the ionic form, $D^{\oplus}\,I^{\ominus}$, is over-exaggerated[**], and in all the structures so far examined, the linear form *(9)* is observed.

(8)

(9)

(10)

The amount of charge transfer varies greatly with the type of donor as shown for example by the X–X distances[19] (Table 1).

Table 1. Iodine-iodine distances in charge-transfer complexes.

	r_{I-I} (Å)		r_{I-I} (Å)
I_2	2.67	$(CH_3)_3N{-}I_2$	2.83
1,4-Dithione-I_2	2.79	γ-Picoline-I_2	2.83
1,4-Diselenone-I_2	2.87	$(C_6H_5)_4As^{\oplus}I_3^{\ominus}$	2.90

The Br–Br distance in $C_6H_6{-}Br_2$ is equal to the bond distance of Br_2 within experimental error[19].

It is obvious therefore that the bonding in these compounds varies regularly from weak interactions, which may be described in terms of polarization forces, to strong interactions, described as covalent half-bonds. From this point of view the situation is similar to that encountered in hydrogen bonding. In connection with this gradual change, it is interesting to note that the charge on the terminal halogen atom is small in the case of weakly bonded complexes which may therefore form bridged structures[21] such as *(10)*. In these compounds the Br–Br length is 2.31 Å compared with 2.28 Å in Br_2. Tertiary amines, being better electron donors than ethers, do not form bridged structures and the Br–Br distance is considerably increased (2.43 Å).

In most of these anions the central halogen adopts a coordination number 2, but in some cases, as for most neutral interhalogen compounds, higher coordination numbers are observed (see below). In all these cases, the more electropositive atom is at the center of the structure. This will be discussed later when the nature of the bonding in these compounds is considered from a simple MO point of view.

As pointed out by *Rundle*[22], the rare gas fluorides (see Section 2.1.) are isoelectronic with the corresponding interhalogen anions. Thus XeF_2, like $ICl_2^{\ominus}$, is linear and XeF_4, like $ICl_4^{\ominus}$, is planar. This indicates a similar type of bonding, which will be discussed in a later section.

1.3. Second Row Typical Elements

In the introduction it was mentioned that the electronic structures of silicon, phosphorus, and sulfur (and their homologues) predict their typical valencies of 4, 3, and 2, respectively, if the octet rule is maintained. However, these elements form a considerable number of compounds with high coordination numbers, in particular octahedral compounds *e.g.* SF_6,

[22] *R. E. Rundle*, J. Amer. chem. Soc. *85*, 112 (1963).

SeF_6, TeF_6, $PF_6^{\ominus}$ $SnCl_6^{2\ominus}$, $SiF_6^{\ominus}$, and also $F_5S\text{-}SF_5$, and pentacoordinated molecules of phosphorus, arsenic, and antimony, silicon, germanium, and tin.

The structures of oxyanions *e.g.* $SO_4^{2\ominus}$, $PO_4^{3\ominus}$, $ClO_3^{\ominus}$, $ClO_4^{\ominus}$, and higher oxides, such as SO_3 and IO_4, will not be considered here as these involve a detailed discussion of $p_\pi-d_\pi$ bonding [*] (this has been discussed in detail elsewhere). It should be pointed out, however, that these higher oxides and oxyacids are in general the most stable ones, and any interpretation of their bonding should bear this in mind.

In view of the unusual symmetry features of the MX_5 system, recent structural investigations of these molecules will be briefly reviewed.

1.4. The Pentacoordinated System

The MX_5 system cannot adopt the configuration of a regular polyhedron, but two geometrical forms, the trigonal bipyramid and the square pyramid represent systems of maximum symmetry. Until recently, only a few 5-coordinated molecules (*e.g.* PF_5, PF_3Cl_2, PCl_5, PBr_5SbCl_5) were known, and their structures were found to be bipyramidal [23] with the axial bonds significantly longer than the equatorial ones (Table 2).

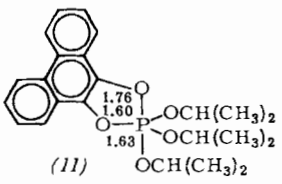

Table 2. Axial and equatorial bond lengths in PX_5 molecules.

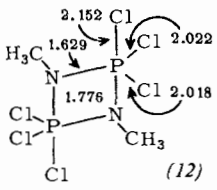
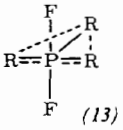
	PF_5	PCl_5	Ph_5P	$(Cl_3P{=}NCH_3)_2$	
				P–Cl	P–N
P–X (axial) (Å)	1.55	2.19	1.99	2.152	1.776
P–X (equatorial) (Å)	1.50	2.04	1.85	2.02	1.629



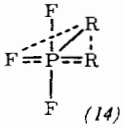
A range of 1:1 adducts of the tetrahalides of Si, Ge, and Sn have been reported in recent years [23] and some certainly exist in the ionized state, *i.e.* $R_3\overset{\oplus}{N}SiCl_3Cl^{\ominus}$, the tendency towards ionization increasing in the order Sn < Ge < Si. The structure of $(CH_3)_3Sn\,Cl{\cdot}C_5H_5N$ has been found to be bipyramidal with the most electronegative ligands, Cl and pyridine in the axial positions.

The compounds $(C_6H_5)_5P$ and $(C_6H_5)_5As$ also have the same structure (trigonal bipyramid) [**], whereas $(C_6H_5)_5Sb$ adopts a square pyramidal form [**] [24]. $SbCl_5$ is however bipyramidal [23] with $r_{ax.} = 2.34$ Å, $r_{eq.} = 2.29$ Å. As anticipated, therefore, the energy differences between the two forms is quite small.

A wide range of cyclic oxyphosphoranes has been prepared by *Ramirez et al.* [25], the ^{31}P–NMR shifts supporting the cyclized form [***]. The X-ray analysis of the phenanthrene derivative *(11)* shows this to be also pyramidal with one of the axial bonds longer than the other P–O bonds [27].

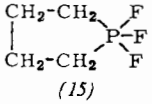


(11)



(12)

Recently the structure of the phosphinimine in the dimeric form *(12)* has been determined [28]. Here also the axial P–Cl and P–N bonds are longer than the corresponding equatorial bonds.



An extensive study has been made of a wide range of fluoro-phosphoranes [29], R_nPF_{5-n}. As in the case of F_3PCl_2 the more electronegative atoms occupy the axial positions. In R_3PF_2 compounds, the R groups and F groups are shown to be equivalent, and interatomic exchange was shown to be absent by F–H coupling of the NMR frequencies. These observations are in agreement with structure *(13)*.

(13)

(14)

(15)

^{19}F–NMR measurements on R_2PF_3 compounds indicate the presence of two kinds of fluorine atom, which is in agreement with structure *(14)*; however, the fluorine atoms are equivalent in *(15)*, except at low temperatures. All the fluorine atoms are equivalent in RPF_4, indicating either a square pyramidal structure or rapid interchange of the fluorine atoms. The latter explanation is supported by the observation that $(C_2H_5)_2NPF_4$ shows nonequivalence at low temperatures, and by the temperature effect on *(15)*. This positional exchange has been termed [30] "pseudorotation" since it involves the internal rotation of valency bonds as follows (Fig. 2).

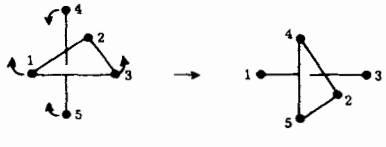


Fig. 2. Schematic representation of pseudorotation in the trigonal bipyramid.

[*] Their structures can be represented by coordinate bounds, thus conforming to the octet rule, *e.g.*

The participation of $d_\pi-p_\pi$ bonding involves the partial delocalization of the electrons on the oxygen atoms into the d orbitals of the central atom.

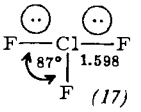
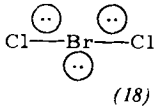
[30] *R. S. Berry*, J. chem. Physics *32*, 933 (1960).

Muetterties and *Schmutzler* [29] have calculated a value of 13 kcal·mole^{-1} for the activation energy of this process for $(C_2H_5)_2NPF_4$. Quite recently [31], the structures of CH_3PF_4 and $(CH_3)_2PF_3$ have been found by X-ray analysis to be distorted trigonal bipyramids with the fluorine atoms in the axial positions and the axial P–F bonds longer than the equatorial ones. For CH_3PF_4, $r_{P-F(ax)} = 1.612$ Å, $r_{P-F(eq.)} = 1.543$ Å. For $(CH_3)_2PF_3$, $r_{P-F(ax)} = 1.643$ Å, $r_{P-F(eq.)} = 1.553$ Å.



1.5. Analogous Systems with Lone Pairs

The PX_5 structure may be regarded from an electronic point of view [32] as involving the distribution of electron pairs in five bonds in the trigonal bipyramidal structure (as for an sp^3d hybridized system, although an alternative view will be presented in the following section). The same distribution in space readily explains the somewhat irregular structures of MX_4 molecules with a lone pair on M (*e.g.* $TeCl_4$), and MX_3 molecules with two lone pairs on M (*e.g.* ClF_3).



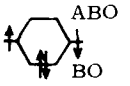
As already mentioned, the most electronegative groups tend to occupy the axial positions, so that the lone pair in MX_4 and the two lone pairs in MX_3 should occupy the equatorial positions as shown in *(16)* and *(17)*.

(16)

(17)

(18)

The relatively large X–M–X angles between the axial bonds may be attributed to repulsion between the electrons in the M–X bonds and the more diffuse lone pair. Finally, the trihalide ions (*e.g. (18)*) are ten-electron systems with the three lone pairs occupying the equatorial positions, the most electronegative atoms the axial ones.



The following question is now posed. How can the bonds in all the structures so far considered be explained in a consistent manner? There are two general ways, (a) to assume the specific participation of high energy orbitals to accommodate electron pairs (*e.g.* 2s in the case of $HF_2^{\ominus}$ and 3d for $Br_3^{\ominus}$) or (b) to retain the octet rule as the main guide, as in the following section.

2. Theoretical Treatment

Let us take the simple view that the octet rule holds for typical elements [33] and that the small contributions of high-energy orbitals do not alter the general argument.

Consider the formation of a homopolar diatomic molecule. The combination of two atomic orbitals, each containing one electron gives two molecular orbitals, as shown by the following secular equation [*].

$$\begin{vmatrix} E-\alpha & \beta \\ \beta & E-\alpha \end{vmatrix} = 0 \qquad \alpha+\beta \quad \alpha-\beta$$

The two electrons in the bonding orbital produce a quantum-mechanical stabilization energy of 2β.

This simple treatment provides a theoretical basis for the stability of two-electron bonds, and of the Lewis-Langmuir extension [34] that a stable atom (other than hydrogen and transition elements) in a molecule, has four electron pairs distributed around the core. It does not however imply that one-electron bonds (or $1^1/_2$-electron bonds for that matter) necessarily lead to unstable structures. On the contrary, π-conjugated systems in which the bonds may be described by fractional orders are among the most stable organic compounds. The principle of electron delocalization leads to the important conclusion that $2n$ electrons are not necessary for the formation of n bonds of a stable molecule, whether the bonding is of the σ- or π-type [36].

This principle can be examined more closely by referring to the linear combination of three orbitals centered on three atoms [**]. In this case the corresponding secular equation leads to three solutions corresponding to bonding, non-bonding, and anti-bonding molecular orbitals as follows.

$$\begin{vmatrix} E-\alpha & \beta & 0 \\ \beta & E-\alpha & \beta \\ 0 & \beta & E-\alpha \end{vmatrix} = 0 \qquad \begin{matrix} \alpha+\sqrt{2}\beta \\ \alpha \\ \alpha-\sqrt{2}\beta \end{matrix} \qquad \begin{matrix} \text{ABO} \\ \text{NBO} \\ \text{BO} \end{matrix}$$

Now, so far, it has not been mentioned that bonding is only possible by the combination of two orbitals characterized by wave functions of the correct symmetry. The possible combinations of s and p orbitals to give resulting 3-center molecular orbitals can be represented as in Fig. 3.

It is a general principle that the configuration leading to maximum (bonding) overlap will be preferred, other things being equal. This can be readily understood in a general way since if two atomic orbitals do not overlap a bond cannot be formed.

---

[*] Of course in a complete treatment of σ-bonds, repulsion and Coulombic terms, changes in electronic kinetic energy, spin-spin interaction, and the overlap integral must be considered. At the present time, semiempirical treatments of the Pariser-Parr-Pople type [35] are being developed, but are beyond the scope of this review.

[**] A linear combination of atomic orbitals does not of course imply that the molecule is linear.

[*] Here the central atom is an s orbital.

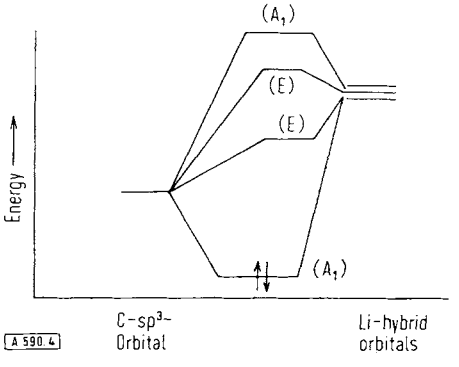
Fig. 3. Combination of s and p orbitals to give 3-center molecular orbitals (schematic).

One can see therefore why systems (b), (c), and (d) adopt these particular configurations in which overlap is a maximum[*]. In system (a) the configuration is fixed by the σ-bond skeleton.

The orbital energies for these systems show that when two electrons occupy the bonding orbital (as in the 3-center bonds of electron-deficient compounds[36]) the bond energy of the system is $2\sqrt{2}\beta$.

This treatment may be extended to more complex structures *e.g.* the alkyl-lithium tetramer (see Fig. 1). The simplest view[37] is a 4-center bond formed by orbital interaction as shown in Fig. 4. Thus each C–Li bond is formally a $^1/_3$ bond with significantly greater bond distances than estimated for a single C–Li bond.

More general treatments cover the whole structure and introduce Li–Li interactions (of s and p orbitals) in view of the small Li–C–Li angles (68 ° in CH_3Li).



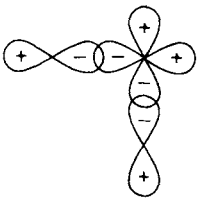


Fig. 4. Simplified energy-level diagram of molecular orbitals in tetrameric methyl-lithium.

A 4-electron system may adopt structure (c) (of Fig.3), or the alternative structure, *(19)*, in which two separate orbitals (p_x and p_y) of the central atom participate in the bonding.

[*] Hydrogen bonded structures adopt configuration (c) in preference to (d) owing to the strong repulsion between the negative charges on the terminal atoms (which are highly electronegative).

[37] *E. A. C. Lucken* and *E. Weiss*, J. organometallic Chem. *2*, 197 (1964).

(19)

In this structure, two single electron bonds are formed with a total energy of 2β. This is equal to the exchange energy of the $X^- + X_2$ system, hence structure *(19)* has no stabilization energy. The linear form, with 0.83 β units of stabilization energy is therefore preferred[*].

It must be noted, however, that these estimated stabilization energies are not absolute values – for the reasons already mentioned. Thus, this procedure predicts that the H_3 molecule and $H_3^{\ominus}$ ion are stable; but this is not the case[38]. The instability may be due to interelectronic repulsions, which will be large for small interatomic distances. On the other hand, hydrogen bonded molecules (*e.g.* $HF_2^{\ominus}$) are stabilized by the high Coulomb energies, and electronegativity differences can be included in the α values in the above treatment, which then enter into the final bond energy expressions.

Havinga and *Wiebenga*[14] have applied this simple treatment to all the known interhalogen compounds, and by using the approximation that $\alpha' = \alpha + n\beta$ where n increases in the order I < Br < Cl < F have

Table 3. Prediction of structures of $I_5^{\ominus}$ and BrICl [14].

Structure of $I_5^{\ominus}$	Zero approx.	1st order approx.
I–I–I I I	1.66 β	1.76 β
I–I–I I	1.66 β	1.67 β
I I		
I–I–I I	1.66 β	1.49 β
I–I–I–I–I	1.46 β	–
I–I–I–I I	1.23 β	–
Experimental values for $(CH_3)_4NI_5$	I–I–I 2.82, 3.17, 175°, 95° 3.17 I 2.82 I	
Structure of BrICl Br–I–Cl 16 α + 5.04 β	I–Br–Cl 16 α + 4.06 β	I–Cl–Br 16 α + 4.87 β

[*] Although the linear form of $X_3^{\ominus}$ is stable, a simple consideration of the orbitals in $X_3^{\ominus}$ shows the triangular form to have an exchange energy of 4β if two p orbitals can be used (as in the interhalogen compounds for example), and this should be more stable than the linear form. X-Ray measurements [39] on $ICl_2 \cdot SbCl_6$ and $ICl_2 \cdot AlCl_4$ support this prediction.

[38] *J. N. Bradley*, Trans. Faraday Soc. *60*, 1553 (1964); *H. C. Bowen* and *J. W. Linnett*, *ibid.* *60*, 1185 (1965); *H. Preuss*, Theoret. chim. Acta *2*, 344, 362 (1964).

[39] *C. G. Vonk*, Dissertation, Groningen, 1957, quoted in [13].

correctly predicted all the structures (with the exception of IF_7). Examples of their calculations for the $I_5^{\oplus}$ ion and BrICl are given in Table 3.

This treatment shows that the charge is located in the non-bonding orbital, *i.e.* on the terminal atoms, so that in unsymmetrical molecules, the more electronegative atoms (with high n values) occupy these positions. This conclusion is fully supported by the available experimental evidence. In particular, ^{35}Cl NQR frequencies[40] (which are sensitive to ionic character) of 19.2 and 22.3 MHz are found for $ICl_2^{\oplus}$ and $ICl_4^{\ominus}$. These are approximately one half of the value for I–Cl, indicating considerable localization of charge on the terminal chlorine atoms. The extent of participation of 5d orbitals in these bonds is thought to be low.

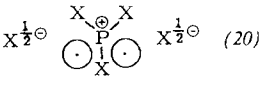
2.1. Rare Gas Fluorides[41]

The preparation of stable compounds of xenon stimulated intense interest in the nature of the bonding in such compounds[*]. Before the structures had in fact been determined, *Rundle*[22] explained the bonding as involving 5p orbitals by analogy with the interhalogen compounds of iodine, and subsequent more detailed calculations, and the measurement of the spectroscopic properties, have fully supported this interpretation[42,43]. As pointed out by *Pitzer*[44] the energy of formation, ΔE, is determined mainly by the ionization potential of the central atom (see Table 4).

Table 4. Ionization potentials (I_X) of the rare gases and halogens; tabulation of fluorides formed.

Atom	I_X (eV)	Fluorides formed
I	10.44	IF, IF_7, IF_5
Br	11.84	BrF, BrF_3, BrF_5
Xe	12.13	XeF_2, XeF_4, XeF_6
Cl	13.01	ClF, ClF_3
Kr	14.00	—

Thus assuming an electrostatic model, ΔE is given by,



$$\Delta E = I_X - E_F + D_{F_2} - B\,(F{-}X{-}F)$$

where E_F is the electron affinity of fluorine, D_{F_2} its bond energy and B(F–X–F) the bonding term. As the last term will be determined mainly by the radius of X, and the X–F distances for I, Br, Xe, and Cl will be similar, the stability is determined mainly by the value of I_X.

A more complete MO treatment by *Boudreaux*[42] shows that the 5d, 6s, and 6p orbitals produce only small modifications of the orbital energies, and similarly *Coulson*[43] has concluded that the VB and MO methods which give equivalent descriptions of the systems are more correct than the alternative treatments invoking spd hybridization. The MO method is to be preferred for the interpretation of the spectroscopic properties[41].

2.2. Extension to MX_5 and MX_6 Systems

The same explanation given for the polyhalide ions may be applied[33] to the molecules PX_5, SX_6, and their analogues. Thus if we consider three of the P–Cl bonds in PCl_5 to be in the sp^2 state, then the interaction of the remaining p orbital with two chlorine atoms, *(20)*, gives molecular orbitals of the kind discussed for $X_3^{\ominus}$.

(20)

This is an MO description of the resonance structure, $\overset{\oplus}{P}X_4\overset{\ominus}{X}$, proposed originally[*] by *Pauling*[9].

The lower coordination numbers of first row elements[**] may be explained by increased non-bonded repulsions (and also perhaps by increased repulsion between bonding electrons) owing to the considerably smaller radius of first row atoms. Such repulsions are indicated by the large decreases in stability along the series $CF_4 \rightarrow CI_4$ and $BF_4^{\ominus} \rightarrow BI_4^{\ominus}$ *e.g.* CH_3I is quite stable whereas CI_4 readily dissociates. Various estimates of non-bonded repulsions have been made, where usually the ligands are regarded as hard spheres with a given van der Waals radius, *e.g. Rundle*[33] has calculated coordination numbers in this way (see Table 5).

These steric factors may also be important in coordination compounds of transition metals.

Table 5. Computed coordination numbers of MX_n from steric considerations.

M = Carbon				M = Phosphorus			
X	r_v [a]	d_c [b]	n [c]	X	r_v [a]	d_c [b]	n [c]
H	1.2	1.09	3.6	H	1.2	1.42	5.5
C	1.6	1.54	3.9	F	1.35	1.74	6.5
O	1.40	1.43	4.2	Cl	1.80	2.09	5.4
F	1.35	1.41	4.3	Br	1.95	2.24	5.3
Cl	1.80	1.76	4.0	I	2.15	2.43	5.1
Br	1.95	1.91	4.0				
I	2.15	2.10	4.0				

[a] r_v is the van der Waals radius of X.

[b] d_c is the M–X distance (sum of covalent radii).

[c] $n = 4\,d_c^2/2\sqrt{3}\,r_v^2$

[*] Electrostatic treatments [45], which take into account non-bonded repulsions (see below), show that the bipyramidal form is slightly more favored energetically than a square pyramidal form. Kinetic studies with optically active 4-coordinated phosphorus compounds also lead to the same conclusion [46]. Thus it is not necessary to postulate sp^3d hybridization to explain the stereochemistry.

[**] Except for electron-deficient compounds where a maximum of eight electrons around each atom is possible. Symmetry arguments show that d orbitals cannot be used here [47], and the energy requirements would also limit d-orbital participation considerably.

[47] *M. J. S. Dewar*, J. chem. Soc. (London) *1953*, 2885.

It might be mentioned at this point that such a structure as *(20)* is energetically possible [*] as indicated by the following empirical calculation [49]:

$$PCl_3 + Cl_2 \longrightarrow \overset{\oplus}{PCl_4}\,\overset{\ominus}{Cl} \xrightarrow{E\pm} \overset{\ominus}{Cl}\cdots\cdots\overset{\oplus}{PCl_4}$$

$$E = I - E_{Cl} + D_{Cl_2} - [D_{P-Cl} + E\pm] \approx 2\ \text{eV}\ \text{(experimental value} \approx 3.3\ \text{eV)}$$

where I is the ionisation potential of PCl_3, E_{Cl} is the electron affinity of chlorine, and D_{P-Cl} is taken as the P–Cl dissociation energy of PCl_3.

Although such a calculation is very crude, the same conclusion was drawn by *Pitzer* [50], who was also concerned about the source of the promotion energy if 3d orbitals are used. The recent experimental data [31] on the compounds RPF_4 and R_2PF_3 discussed in Section 1.4. can be explained readily on the basis of this model. Thus the longer and more polar axial P–F bonds, and the tendency for the most electronegative atom to occupy the axial position, follow directly from the model, but these observations cannot be explained in an obvious way by treatments based on extensive sp^3d hybridization of phosphorus [48]. The d-orbital angular functions certainly have the correct symmetry for hybridization with s and p orbitals (*e.g.* the d_{z^2} in the case of structure *(16)* and $d_{z^2-y^2}$ in the case of SF_6). From this point of view therefore, the formation of 5- and 6-coordinated compounds of second row elements involving ten to twelve valency electrons, and the inability of first row elements to form such compounds follows naturally from 3s3p3d hybridization, which would be more effective than 2s2p3d hybridization.

The radial functions however present a bigger problem. If one uses Slater orbitals (which are known to give rather poor descriptions of orbitals), the 3d orbitals are found to be too diffuse for bonding with p_σ or p_π orbitals unless the central atom carries a positive charge [48]. This is equivalent to assuming a partial ionization of the electrons from the spd hybrid orbital onto the electronegative terminal atoms [48]. On the other hand, recent Hartree-Fock calculations [51] using SCF orbitals suggest that the overlap is appreciable even for an uncharged central atom. (The recently reported stability of the $H_2S^{\ominus}$ radical anion [52] seems to lend some support to this view.)

There still remains the problem of the high 3s → 3d promotion energy, and although the 3d level must modify the energy of the NBO to some extent, the contribution may well be too small to determine the physical properties, in particular bond lengths and stereochemistry. The octahedral SF_6 system is simpler to deal with theoretically than the PCl_5 system and has been the subject of recent detailed treatments. In an electrostatic model, *Craig* and *Magnusson* [53] regard the sulfur atom as surrounded by six positive charges (representing electronegative ligands). The diffuse 3d Slater-type orbitals are contracted to become commensurate with the 3s and 3p orbitals, but the 3d promotional energy is greatly increased by the electrostatic field.

A later treatment by *Craig* and *Zauli* [54] replaced the electrostatic field model by a molecular model with six fluorine atoms surrounding the sulfur, and *Cruickshank* [55] has very recently introduced SCF orbitals into this treatment. The detailed calculations suggest that the ligand field (in contrast to the electrostatic field) stabilizes the system through 3d orbital participation to the extent of several electron volts.

It is reasonable, on general grounds, to suppose that $\equiv\overset{2\oplus}{S}\equiv$ uses d-orbitals (and other excited levels) more extensively than $\equiv\overset{\oplus}{P}=$; this is reflected in the different properties of the SO group in sulfones and sulfoxides (which can probably be represented satisfactorily by a coordinate bond). Moreover, the stability of molecules such as [56] $N\equiv SF_3$ seems to require the participation of strong p_π–d_π bonds, and the sp^3d^2 hybridization of sulfur.

In conclusion, however, the importance must be stressed of detailed spectroscopic investigation (particularly NMR, ESR, and NQR studies) in estimating the extent of participation of excited levels in the bonding of the types of molecules described here. Care should be taken in drawing conclusions as to the nature of bonding from bond length, bond energy, and stereochemical considerations. Similarly, the influence of conjugation on the energy of organic π-bonded systems [57] is difficult to determine from these properties, as changes in hybridization influence σ bonds to carbon to a considerable extent.

German version: Angew. Chem. 79, 756 (1967)

[*] The ionization potential of PH_3 ($\sim$ 10 eV) and PCl_3 ($\sim$ 12.3 eV) lie within the range given in Table 4. Thus if the contribution of 5d orbitals in XeF_2 is small, the contribution in the less available 3d orbital in the axial X–P–X bond, by analogy, should also be small.

Electrochemical Processes for the Enrichment of Isotopes

BY H. D. FREYER AND K. WAGENER [*]

The principles of electrochemical methods of isotope separation and the results obtained are described. The migration of ions in salt melts and solutions, complex formation in the homogeneous phase, electrolysis, ion-exchange equilibria, and exchange electrolysis are discussed in detail.

1. Introduction

With very few exceptions, any desired isotope separation can in principle be carried out nowadays without appreciable development work. Electromagnetic separators [1a] give almost complete separation of mixtures (even those containing more than two isotopes) in a single step. However, the equipment is very costly and many problems are encountered in its operation. This type of separator cannot be considered for use in industrial-scale separation.

Apart from the various forms of electromagnetic separation, the main processes are based on distillation, diffusion, chemical exchange, thermal diffusion, and ionic migration [1b]; these processes are described as statistical processes. All the methods described below also belong to this group.

A common feature of these "physico-chemical" processes is that a very small separation effect ("elementary effect") must be repeated many times in order to achieve a greater separation (which can then be continued to any desired degree). Elementary separating effects can occur in equilibrium states (*e.g.* equilibrium between two phases, chemical exchange) as well as in irreversible transport processes (*e.g.* diffusion, ionic migration). The magnitude of the elementary effect is characterized in the former case by the ratio of the distribution coefficients of the two components and in the second case by the ratio of their kinetic coefficients. If separation takes place, these ratios differ from 1, and their values are generally expressed in the form $1 + \varepsilon$.

The only processes suitable for most practical separations are countercurrent processes, in which the elementary effect is repeated many times in a continuous manner. In processes such as distillation and thermal diffusion, this can be very readily achieved by "self-cascading" *e.g.* in rectifying columns and in the Clusius-Dickel thermal diffusion separating tube. Self-cascading can also be achieved in other processes, but the establishment of a satisfactory countercurrent flow (particularly in two-phase processes) is sometimes difficult, or at least involves considerable expense.

A characteristic of electrochemical separations is that they are generally adaptable without modification of the apparatus or of the method. They are therefore particularly well suited to conditions in the laboratory.

The elementary effect $(1 + \varepsilon)$ is related to the separation achieved by this process as follows:

$$\text{Separation factor } Q = \frac{([\text{component 1}]/[\text{component 2}])_{\text{end of column}}}{([\text{component 1}]/[\text{component 2}])_{\text{beginning of column}}} = (1 + \varepsilon)^{n_B}$$

where n_B is the number of repetitions of the elementary effect, *i.e.* the number of theoretical plates in the column.

2. Processes Based on Ionic Migration

2.1. General

The isotope effect in ionic migration is described by the ratio of the mobilities of the ions u ($cm^2V^{-1}sec^{-1}$) of the isotopes in question:

$$\frac{u_1}{u_2} = 1 + \varepsilon.$$

Since ε is generally much smaller than 1,

$$\varepsilon = \frac{u_1 - u_2}{u_2} \approx \frac{u\Delta}{\bar{u}},$$

where $\bar{u} = \gamma_1 u_1 + \gamma_2 u_2$ (with $\gamma_1 + \gamma_2 = 1$) is the mean mobility of the isotope mixture.

The migration of isotopic ions has been studied in aqueous solution, in ionic crystals, in salt melts, in liquid metals, and in molten iodine. The observed

[**] Present address: Scripps Oceanographic Institute, La Jolla, Calif. (U.S.A.).

[1a] Cf., e.g. *J. Koch*: Electromagnetic Isotope Separators and Applications of Electromagnetically Enriched Isotopes. North Holland Publ. Co., Amsterdam 1958,

[1b] These processes are described in detail in *H. London*: Separation of Isotopes. George Newnes Ltd., London 1961. The earlier publications are cited by *G. M. Begun*: Isotope Separation and Isotope Exchange. Oak Ridge National Lab., Tenn., Rept. ORNL-2852 (1959). Publications on isotope separations based on ionic migration are listed in the form of tables by *M. Gazith* and *A. Roy*: Separation of Isotopes by Electromigration. Israel Atomic Energy Commission, Rept. IA-832 (1963); Electrochem. Technol. *2*, 85 (1964).

isotope effects can be compared by means of *Klemm*'s "mass effect".

$$\mu = \frac{\Delta u/\bar{u}}{\Delta \bar{m}/m}$$

where $\Delta m = m_1 - m_2$ is the difference in mass and $\bar{m} = \gamma_1 m_1 + \gamma_2 m_2$ is the mean mass of the isotopes.

Since this equation relates the relative difference in the mobilities of isotopic ions to the relative difference in mass, the mass effect defined by the equation should have a value of -0.5 according to the simplest kinetic model (ionic mass low in relation to the molecular weight of the medium; isotropic scattering) [*]. μ values very close to this figure have occasionally been observed in ionic migration in crystals; however, the values are generally much lower (some examples are given in Table 1).

Table 1. Isotope and Mass Effects in Ionic Migration.

Isotope pair	Medium	$\Delta u/\bar{u}$	μ
$^{22}Na/^{24}Na$	NaCl single crystal	0.040	−0.46
$^{22}Na/^{24}Na$	$NaNO_3$ — melt (300 °C)	0.00957	−0.11
$^{22}Na/^{24}Na$	10 % aq. $NaNO_3$ soln.	0.00296	−0.034
$^{39}K/^{41}K$	Molten potassium (100 °C)	0.00000067	+0.0000134

The only experiments of any practical importance at present are those carried out in salt melts and in aqueous solution. Though ionic crystals give large isotope effects, the yields are too low because of the generally low ionic conductivity [2,5]. In metals, on the other hand, the isotope effects are extremely small, and the efficiency is very low owing to the large amount of electronic transport [3]. The experiments in molten iodine also failed to show any advantage, since the isotope effect, for rubidium in the case in question, is smaller than in aqueous solution [4].

[*] The expected value $\mu = -0.5$ is obtained when the drift velocity (or ionic mobility) of a particle in an external force field is inversely proportional to the root of the particle mass. The ratio of the ionic mobilities of two isotopic particles 1 and 2 would thus be

$$u_1/u_2 = (m_2/m_1)^{1/2}$$

which, for $\Delta m/\bar{m} \ll 1$ (as is nearly always the case for isotopes), gives

$$\frac{\Delta u/\bar{u}}{\Delta \bar{m}/\bar{m}} \approx -1/2.$$

Deviations from this expected value can be explained by failure of the system to satisfy the conditions of this model (*e.g.* because of solvation of ions in solution or because of coupling effects between ions in salt melts: cf. [7b,22b].

[2] *M. Chemla* and *P. Sue*, C. R. hebd. Séances Acad. Sci. *236*, 2397 (1953); *M. Chemla* in: Proc. Intern. Symp. Isotope Separation, Amsterdam 1957. North Holland Publ. Co., Amsterdam 1958, p. 288.

[3] In cation migration in liquid metals, in contrast to other media, the light isotope accumulates at the anode. This phenomenon was first observed by *E. Haeffner* [Nature (London) *172*, 775 (1953)], and was named after this author; *A. R. E. Lodding* [J. Chim. physique *60*, 254 (1963)] played a particularly prominent part in further investigations.

[4] *K. Clusius*, Private Communication.

Isotope separation by ionic migration in salt melts was studied by *Klemm*, following his observation in 1944 that the passage of a current through solid α-AgI resulted in separation of the silver isotopes [5]. The first successful separation by ionic migration in salt melts was achieved with lithium and potassium in 1947 [6]. Since then the process has been applied to other isotope mixtures, usually as the readily fusible halides or nitrates.

The melt electrolysis is generally carried out in countercurrent flow. A typical experimental set-up, which was used for the separation of the lithium isotopes, is shown in Figure 1 [7a,7b]. The U-shaped electrolysis tube contains molten LiCl. To reduce convection, the tube is packed with a fine-grain zirconium dioxide powder. To keep the overall concentration of the lithium ions constant at each part of the apparatus during the electrolysis, cathodic deposition of lithium is prevented by the continuous introduction of chlorine. The separation of the lithium isotopes within the stationary salt distribution is due to their difference in mobility. The current is transported by the chloride ions migrating in one direction. To permit the removal of the ^{7}Li-enriched LiCl from the anode compartment without interruption of the process, $PbCl_2$ is used before the anode as an auxiliary electrolyte. The boundary between the LiCl and the $PbCl_2$ remains sharp because of the higher mobility of the lithium ions in the melt.

Other isotopic cations can be separated in a similar manner. Results have been reported for Li [7a,7b,9,23], K [10], Rb [11], Mg [12], Ca [12–14], Sr [12], Ba [12], Cu [15], Zn [16], Ag [17], Cd [14], Tl [18], and Pb [14,19].

An example of the separation of isotopic anions is the enrichment of the chlorine isotopes in fused TlCl [8]. In this case the anode consists of a reservoir of molten thallium, which reacts at the contact surface with electrically transported chlorine. The separation of bromine isotopes has also been recorded [20].

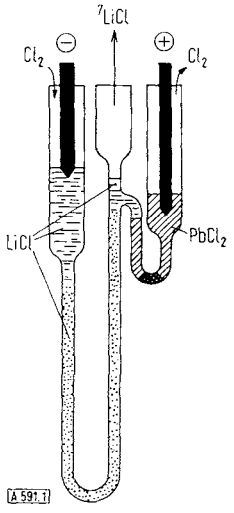

Fig. 1. Apparatus used by Klemm [7b] for the enrichment of ^{7}Li at the boundary between fused LiCl and fused $PbCl_2$.

Melt electrolysis on the industrial scale is associated with certain difficulties[21]. Since salt melts are highly corrosive, the electrolytic cells must be made of corrosion-resistant materials (Supremax glass, Pyrex glass). Special care must be taken to avoid the cathodic deposition of alkali metals. To avoid air bubbles in the tube packing, the salt melts are introduced into the cells under vacuum.

The mass effect in the migration of isotopic ions in salt melts is generally much smaller than $|0.5|$. This is evidently due to coupling effects, so that the mobility of the "jumping" ion is not determined solely by the mass of the isotope. The mass effect μ_+ found for isotopic cations in salt melts can be represented by the empirical formula

$$\mu_+ = \mu' \cdot \frac{2.1\ m_-}{2.1\ m_- + m_+}$$

(m_- = mass of the anion; m_+ = mass of the cation; $\mu' \approx \mu_+$ for $m_- \gg m_+$)

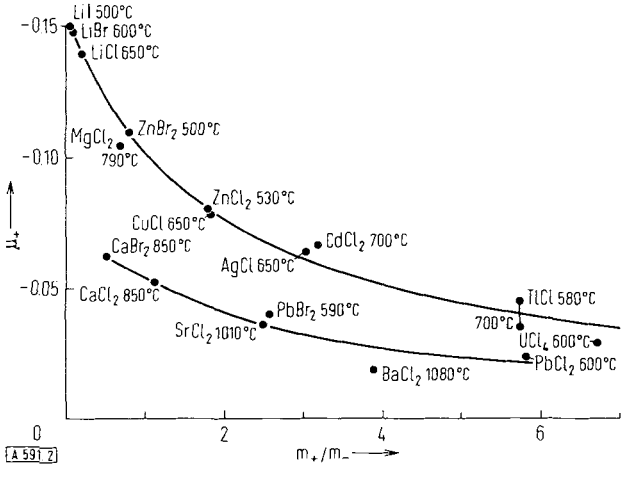

Fig. 2. Mass effect μ_+ of the cations in fused halides at various temperatures [22b].

Upper curve: $\mu_+ = -0.15\ [2.1\ m_-/(2.1\ m_- + m_+)]$;
Lower curve: $\mu_+ = -0.079\ [2.1\ m_-/(2.1\ m_- + m_+)]$.

In this way one obtains variously correlated μ_+ values for the halides, depending on the valence relationship and lattice type of the salt in question[22a,22b]. Such a relationship for pure salts is shown in Figure 2. It is interesting to note that mass effects in binary salt mixtures also depend on the composition of the mixture.

Isotope separation by ionic migration in fused salts is of industrial interest in view of the large isotope effects and the basically simple procedure. Thus a continuous process based on this method has been developed for the isolation of ^{7}Li in a purity of 99.97 %[23].

2.3. Controlled Countercurrent Processes in Aqueous Solution

Ionic migration in aqueous solution was the method used in the earliest attempts to separate isotopes. Following the suggestion by *Lindemann* (1921)[24] that it should be possible to enrich isotopes in this way, *Kendall* and others[25] carried out a number of experiments based on the zone-electrophoresis principle. These experiments were unsuccessful, but probably only because isotope analysis by chemical atomic weight determination was too inaccurate to permit the detection of the effect, since very similar experiments carried out by *Chemla et al.*[2,26] in 1956 did in fact show the expected separation. Though electrophoretic experiments of this nature very quickly show the magnitude of the isotope effect in ionic migration, they cannot be used for the preparation of isotopes in reasonable quantities.

However, a process suitable for the continuous separation of substances had been developed by *Brewer et al.*[27] as early as 1941 (but was kept secret until 1946). This process is countercurrent ionic migration. In this process, which was novel at that time, the isotopic ions migrating in the electric field move countercurrent to the solvent. With a suitable countercurrent flow, the position of the center of gravity remains constant, the faster (lighter) isotopes migrating upstream while the slower (heavier) isotopes are gradually washed back. *Brewer*'s countercurrent principle has two decisive advantages: (i) a much larger quantity of salt can be electrolysed than in electrophoresis and (ii) the mixture of ions can be allowed to

[21] The technological problems are summarized in the dissertation by *A. Lunden*, Doktorsavhandl. Chalmers Tekn. Högskola, No. 12 (1956).

migrate for very large distances (*e.g.* several hundred meters) in relation to the solvent, so that pronounced separations are possible. Owing to the countercurrent operation, the whole process takes place over only a short distance. *Brewer*'s work led to the first separation of an isotope mixture by ionic migration, the isotopes in question being those of potassium, chlorine, and copper.

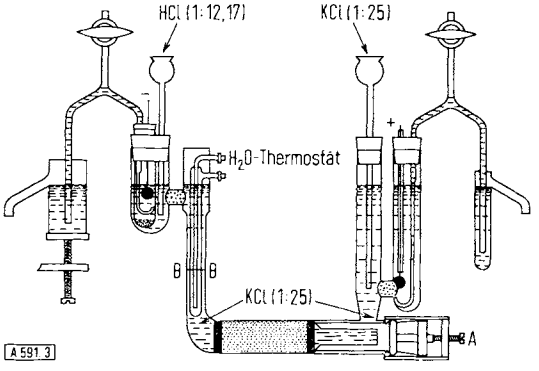

Fig. 3. Cell for the enrichment of potassium isotopes, after *Brewer* and *Madorsky* [27]. The anode compartment is continuously flushed with natural KCl solution. The feed of HCl solution into the cathode compartment is controlled in such a way that the boundary B—B remains constant.

Figure 3 shows a typical cell as used for the enrichment of potassium isotopes. It is made of glass, and the central part is packed with sand between a fixed and a movable diaphragm, which can be compressed by the device A to minimize channel formation. The electrodes are made of platinum gauze. The lower and right-hand part of the cell is filled with KCl solution, and the cathode compartment is filled to the boundary B—B with HCl solution. The boundary between the HCl and KCl solutions remains stable while the current is flowing, provided that the condition

$$\frac{[HCl]}{[KCl]} = \frac{t_{H^+}}{t_{K^+}}$$

is satisfied (t = transport number). If the solution were stationary, the passage of 1 F would move the boundary in such a way that it passes over a volume of

$$\frac{t_{K^+}}{[KCl]}$$

in the tube. To keep the boundary stationary, the same volume of solution must be introduced into the cathode compartment for every 1 F. The solution must also contain one equivalent of HCl. The condition that no overall transport of potassium should take place

$$E \cdot \bar{u}_+ + v_L = 0$$

with $\bar{u}_+ = \gamma_{39_K} u_{39_K} + (1-\gamma_{39_K}) u_{41_K}$,

[E(V cm^{-1}) = electric field strength, $\bar{u}_+$ (cm^2·V^{-1}·sec^{-1}) = mean mobility of the potassium ions, v_L (cm·sec^{-1}) = flow rate of the liquid in the separating column].

would then be satisfied, and the flow rate (averaged over the cross section) would lie between the migration velocities of the two isotopes:

$$v_{39_K} > |v_L| > v_{41_K}.$$

An attempt was made to control the process in this sense with the aid of remote sensing elements and an automatic control system.

However, the columns used by *Brewer* proved unreliable in continuous use owing to channel formation in the sand packing and to the ultimate formation of gas bubbles which, because they could not escape, caused a decrease in cross section and thus led to local overheating. Trouble regularly started after an operating time of a few hundred hours. The plate heights, which were, in favorable cases, of the same order of magnitude as the particle diameter, were smallest at the end of the sand packing nearer the cathode, *i.e.* the end at which the solution entered. However the height of the theoretical plate increased rapidly with increasing penetration depth in the packing, until any further increase in the length of the column (beyond about five times the diameter of the tube) had no effect.

An important advance was made by *Clusius*, *Ramirez*, and *Huber* [28], who did not use a column packing and deliberately did not suppress convection, but used a large number of diaphragms to confine convection to directions perpendicular to the field direction. This leads to faster equalization of concentration within the electrolyte and good heat dissipation. At the same time channel formation and trouble due to gas bubbles (which can escape through openings on the top of the horizontal separating tube) are avoided. This arrangement was used for the separation of the rare earths and of the isotopes of lithium and rubidium. The liquid countercurrent flow was controlled by oxygen-hydrogen electrolytic cells; the gas evolved displaced a corresponding quantity of liquid from a storage vessel, and the liquid was then led in countercurrent to the separating column. The current strength in the oxygen-hydrogen cells was controlled by a conductivity measuring cell in series, this cell being situated in the separating column.

Martin et al. [29], who developed a countercurrent process independently of the American workers, carried out the electrolysis in packed columns between the anode and cathode compartments, which were in the form of containers at the ends of the column. They enriched deuterium and ^{26}Mg, and also achieved a separation of rare earths. However, the control of this process is more elaborate than that used by *Brewer* and *Clusius*.

Konstantinov et al. [30] have recently reported experiments similar to those carried out by *Brewer*. Solutions of lithium, potassium, and rubidium salts were electrolysed and the isotope effect in ionic migration was determined.

These four groups of workers all used ionic migration countercurrent to the solvent, the "equilibrium"

between the electrical transport of the ions and their convective backward motion being controlled by remote sensing elements and control units. The countercurrent equilibrium necessary for the separation of the components requires that the flow rate of the liquid should lie between the migration velocities of the faster and of the slower ionic species. However, if the difference in mobility is very small, as is naturally the case in mixtures of isotopes, the sensitivity required for this control is so great that any attempt to regulate the electrolysis is extremely expensive. On the other hand, any disturbance of the countercurrent equilibrium endangers the efficiency of the separation. According to *Wagener* [31a, 31b], this difficulty can be avoided by the method described in Section 2.4.

2.4. Self-stabilizing Countercurrent Electrolysis in Solution

Self-stabilizing countercurrent electrolysis can be most readily understood if the process is thought of as being divided into two steps. The first step comprises the mechanism that leads to a stationary distribution of the mixture as a whole in the separating column (all the ions in the mixture being assumed for the time being to migrate at the same velocity). The second step comprises the actual separation of the components within the stationary overall distribution. The essential novel idea of this method is contained in the first step. This idea is that the required "equilibrium" between the electric transport of ions and entrainment by the solvent is no longer achieved by control of the liquid flow, but follows automatically under the given (but more or less arbitrary) operating conditions.

The principle is based on the fact that at a given current intensity the local field strength in the column, which determines the equilibrium ($E.u + v_L = 0$), depends on the local salt concentration. At the start of electrolysis this involves displacement of the salt concentration in the column, whereas it is necessary in the controlled countercurrent process to prevent any concentration displacements.

A scheme of a plant for use in this process is shown in Figure 4. The main part of the apparatus, *i.e.* the separating column 6, is shown here as a trough divided into compartments by diaphragms. The shape and dimensions of the trough may be adapted to suit widely varying requirements, and various forms, ranging from capillary tubes [32] to troughs having a capacity of about 10 l (which may also be connected to an end container) have proved suitable [31a, 31b]. The operating conditions that have to be chosen in advance are the flow rate of the electrolyte solution, the electric field strength (or the electric current), and the temperature of the solution. Items 1 to 5 (storage vessel, constant-level intermediate tank, filter, and thermostatted capillary) ensure that the electrolyte solution is supplied at a constant feed rate. This solution passes through the separating column in the longitudinal direction and then runs through an overflow 7 into a collector vessel 8, from which it can be returned to the storage vessel.

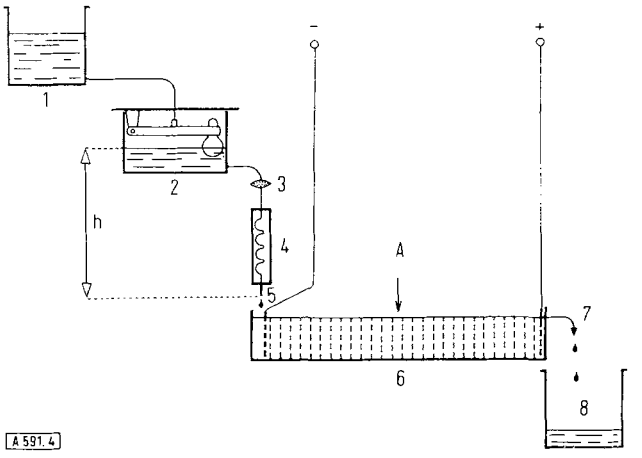

Fig. 4. Construction of an electrolytic separation plant for the self-stabilizing countercurrent process (schematic).

Explanations are given in the text.

The stationary salt distribution extends over the greater part of the separating column, but ends shortly before the overflow end. The separated components are withdrawn in solution at the ends of the salt distribution; fresh solution is added in the middle of the salt distribution. Both operations can be carried out discontinuously (*e.g.* every 24 hours).

The electrodes produce an electric field whose direction and strength are so chosen that all the ions of the mixture in question (which are introduced into the column as a salt solution at an arbitrarily chosen point A) migrate countercurrent to the liquid toward the "upstream" end of the column, where they accumulate. (An eventual deposition of the ions on the electrode can be avoided by the use of a protective electrolyte [31b].) During this migration of the mixture of ions, the condition

$$| E \cdot \bar{u} | > | v_L |$$

is satisfied. If the introduction of the salt solution into the trough is continued, ions continue to accumulate at the "upstream" electrode, and the conductivity of the solution increases in this part of the column [*]. The driving force for the migration of further ions into the neighborhood of those already present is the electric field. According to Ohm's law, the strength of this field, at a given current density j depends only on the conductivity $\varkappa$ of the solution. If we assume for simplicity that the conductivity of the electrolyte (acid, base, or a buffer mixture) dissolved in the countercurrent liquid is negligible in the salt sphere, an approximately reciprocal relationship exists between the field strength related to the salt concentration c_s (Λ_s = equivalent conductivity of the salt):

$$E = \frac{j}{\varkappa} \approx \frac{j}{\Lambda_s c_s}$$

Thus as further salt ions migrate, the field strength decreases until the salt concentration reaches its maximum value under the experimental conditions:

$$c_s = \frac{I.t}{F.\dot{M}} \text{ (mol·cm}^{-3}\text{)}.$$

[I (A) = current, t = transport number of the mixture of ions in question, F = Faraday constant, $\dot{M}$ (cm³·sec⁻¹) = feed rate of countercurrent solution].

[*] In the separation of isotopic cations, the upstream electrode is the cathode. The mixture of cations is then at rest in relation to the separating column, while the anions migrate through the column with a velocity $| v_- | = | E \cdot u_- | + | v_L |$. The principle of electric neutrality is always satisfied. To separate isotopic anions, one need only reverse the direction of the field; generally a different countercurrent electrolyte is used.

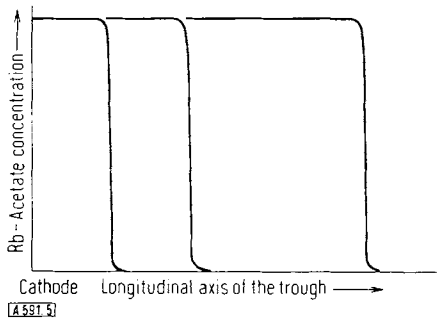

Fig. 5. Concentration distribution of rubidium acetate in the trough of the apparatus shown in Figure 4 with stepwise addition of salt and at a given current intensity I.

(Data: I = 1 A at an electrolysis voltage of about 1000V; transport number of Rb^+ in rubidium acetate solution = 0.66; feed rate of countercurrent liquid: $\dot{M}$ = 0.1 cm³ sec⁻¹, from which the stationary salt concentration (see Section 2.4) is calculated to be c_S = 0.07 N, as is in fact observed).

Further added ions do not increase the concentration, but accumulate in compartments situated farther away from the electrode (a right-angled distribution is obtained for the salt concentration, see Fig. 5). As can be seen from the last equation, arbitrary values of c_S can be obtained by an appropriate choice of the ratio $I/\dot{M}$. It can also be seen that the concentration distribution of the salt is stable, provided

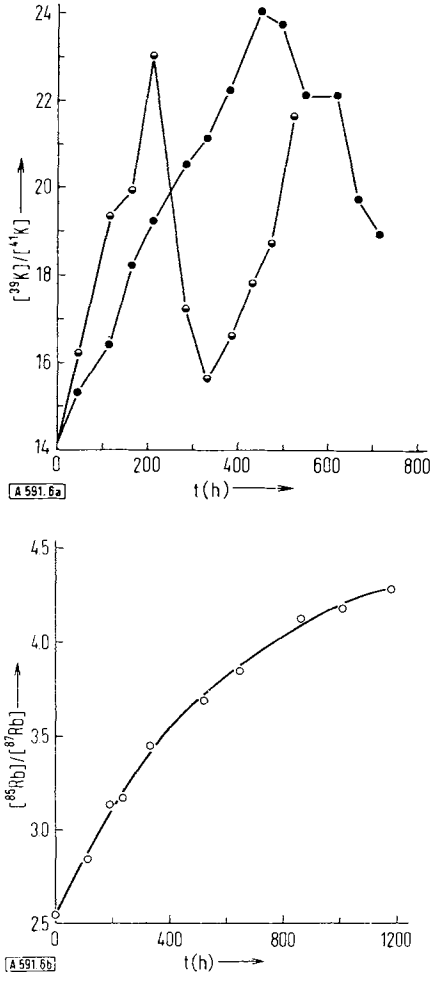

Fig. 6. Isotope ratio at the end of the column (cathode compartment) as a function of time.

Upper diagram: Example of the separation of potassium by the *Brewer* method with the cell shown in Figure 3. The discontinuity is due to disturbances of the countercurrent equilibrium.

Lower diagram: Example of the separation of rubidium in the apparatus shown in Figure 4.

that the operating conditions are kept constant. Thus if a small local disturbance (increase or decrease) of the salt concentration occurred, the field strength at this point would immediately change, and ions would migrate away from or toward this point to compensate for the disturbance.

The effectiveness of this self-stabilization mechanism can be very clearly seen from Figure 6, which shows a comparison of the course of enrichment at the column end with time in the Brewer and in the Wagener methods.

The apparatus required for self-stabilizing countercurrent electrolysis is very simple, since no control equipment is required, and the plant consequently no longer contains any moving parts. Numerous continuous tests extending over periods of weeks and months have shown that this process is very reliable. An interesting result is the sharpness of the separation obtained with separating columns consisting of troughs divided into compartments. The number of theoretical plates per meter is generally of the order of 1000.

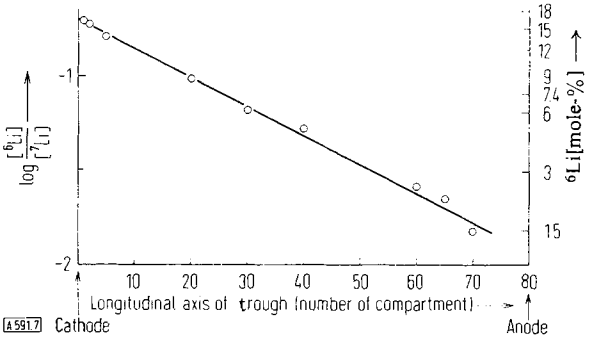

Fig. 7. Distribution of lithium isotopes (natural mixture: 7.4 mole-% of ^6Li) along a separating column in the final separation state in the apparatus shown in Figure 4. The separation effect acts over the whole of the column.

(The column consisted of 80 compartments and was constructed by the filter-press principle with an alternation of U-shaped rubber seals and square separating plates (total length of the column about 65 cm, volume of column about 1.2 l). The openings in the separating plates were covered with fine-pore nylon gauze (pore width 53 microns).

The process has been successfully used for the separation of isotopes of lithium[33,34] (see also Fig. 7), potassium[35,36], rubidium[37], calcium[38], strontium[35], and carbon (formate)[39], as well as for the separation of rare earths[35] and the extreme purification of various alkali metal salts[40]. Figure 8 shows arrangements (with one end container) suitable for the enrichment of the fastest or slowest components of a mixture of ions.

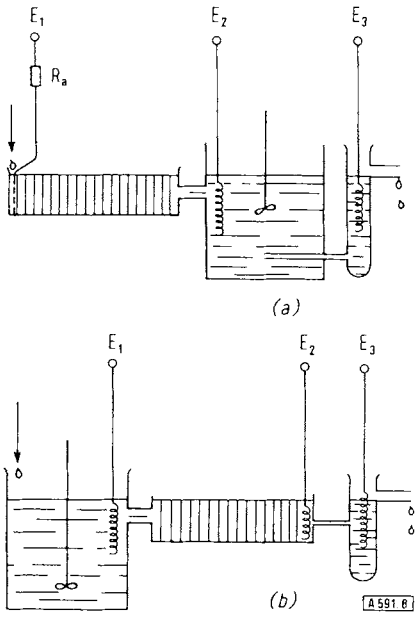

Fig. 8. (a) Apparatus for the enrichment of the faster-migrating component. Reservoir vessel containing the natural isotope mixture at the overflow end of the column.

(b) Apparatus for the enrichment of the slowest component. Reservoir vessel at the feed end of the column.

The separation takes place between the electrodes E_1 and E_2. An additional potential difference is applied between E_2 and the auxiliary electrode E_3; this potential difference must be so great that no salt can escape from the reservoir container and the trough, despite the flow. The ohmic resistance R_a can be used for stabilization (cf. [31b]).

3. Utilization of Dissociation and Complex Formation Equilibria in the Homogeneous Phase

The isotope effects observed in ionic migration in aqueous solutions are of the order of $\Delta u/\bar{u} \approx 10^{-3}$ in the cases known at present (except in the case of hydrogen isotopes). In chemical exchange equilibria, on the other hand, the isotope effects are generally about ten times as great, *i.e.* (for nuclides that are not too heavy) $\Delta K/\bar{K} \approx 10^{-2}$ (= relative difference in the equilibrium constants) [41], so that these equilibria would seem much more useful for the enrichment of isotopes.

To combine the advantages of the countercurrent electrolytic separation process (self-cascading, large number of theoretical plates) with the generally large isotope effect of an exchange equilibrium, one must seek for suitable ion-exchange equilibria (complex formation) in the homogeneous phase [42]. The simplest model case would be the dissociation of a 1,1 salt, where *e.g.* the metal M consists of two isotopes. Only the ions migrate in the electric field, while the flowing liquid transports charged and uncharged particles to the same extent. The result of an isotope effect in the dissociation equilibrium $MX \rightleftharpoons M^+ + X^-$ is that the time-average charge numbers $\bar{z}_1$ and $\bar{z}_2$ of the two isotopes are different, since the isotope having the greater dissociation constant will exist preferentially in the ionic form [*].

The isotope effect in the dissociation equilibrium is translated in this way into the isotope effect in the migration velocity of the isotopic components. Since the equilibrium isotope effect is much greater than that shown in the migration of the free isotopic ions, the separation can be optimized by determination of the conditions under which $\Delta\bar{z} = \bar{z}_1 - \bar{z}_2$ has its maximum value, since the difference in the rates of migration of the two isotopes is then greatest. In the simple dissociation equilibrium mentioned, $|\Delta\bar{z}|$ reaches a maximum when the degree of dissociation is 0.5 (based on the element M, and not on one of its isotopes) [**]. The concentrations in the electrolyte (salt, complex former) must therefore be such that $[MX] \approx [M^+]$. Under these conditions $\Delta\bar{z}/\bar{z} = (\Delta K/\bar{K})/2$, *i.e.* the isotope effect that is used in the ionic migration and which can be multiplied by cascading is half as great as the isotope effect in the dissociation equilibrium [43].

In order to be suitable in this respect for isotope separation by ionic migration, a complex must exhibit a sufficiently large isotope effect $\Delta K/\bar{K}$ in its formation equilibrium. Moreover, the value of the complex formation constant must not be too extreme, but should lie between 1 and 10^2, *i.e.* weak complexes are necessary.

Figure 9 shows the concentration-dependence of the isotope effect observed in the migration of lithium ions in the acetate system [34]. The effect is independent of concentration in very dilute solutions, undoubtedly because of the difference in the mobilities of the free isotopic ions. The isotope effect increases rapidly with increasing lithium acetate concentration; from the above arguments, a maximum should be expected in approximately 1 N solution.

The disadvantage that only part of the elementary effect is utilized in the multiplication of the equilibrium isotope effect by ionic migration is probably compensated for in most cases

[41] Cf. *e.g. S. S. Roginski*, Theoretische Grundlagen der Isotopenchemie. Deutscher Verlag der Wissenschaften, Berlin 1962. In the case of the lithium isotopes, isotope effects of up to 7.6% have been found by *D. A. Knyazev* and *E. V. Sklenskaya* [Ž. fiz. Chim. *37*, 2094 (1963)] by exchange between the aquo complex and the complex with uramil-7,7-diacetic acid.

[42] *H. Martin* (cf. [29]) had already suggested in 1949 that any isotope effect existing in the equilibrium of an incomplete dissociation should be utilized for the separation of the components by ionic migration. However, the isotope effect obtained in 1958 by this author for magnesium was so small that he expressed the view, in 1964, that the effects are predominantly of a kinetic nature, *i.e.* that they are due to differences in rate between the free ions.

[*] In the above example we have for the isotope 1:

$$\bar{z}_1 = \frac{[M_1^+]}{[M_1X]\,[M^+]} \quad \text{and} \quad K_1 = \frac{[M_1^+]\,[X^-]}{[M_1X]}.$$

The charge number and the dissociation constant are related by:

$$\frac{1}{\bar{z}_1} = \frac{[X^-]}{K_1} + 1.$$

[**] $\Delta\bar{z} = \bar{z}_1 - \bar{z}_2 = 1/([X^-]/K_1 + 1) - 1/([X^-]/K_2 + 1)$

$$\approx \frac{[X^-]/K}{([X^-]/\bar{K} + 1)^2} \cdot \frac{\Delta K}{\bar{K}}$$

The value of this fraction is greatest for $[X^-]/\bar{K} = 1$, *i.e.* when the degree of dissociation is 0.5.

by the advantages and the convenience of a continuous process such as ionic migration in solution as compared with an exchange between two phases (cf. *e.g.* Section 5).

4. Direct Electrolysis

Isotopic ions are deposited at different rates during electrolysis. This effect is particularly pronounced for the hydrogen isotopes in the electrolysis of water. Light hydrogen is liberated more rapidly, so that as electrolysis proceeds, the deuterium concentration in the aqueous residue increases. Using this method, *Lewis* and *MacDonald* (1933) prepared pure D_2O for the first time from an aqueous alkali solution [44].

The elementary separation factor α (= ratio of the H/D values in the gas liberated and in the aqueous electrolyte) is about 3 to 12, depending on the experimental conditions. A value of about 5 is reached in industrial electrolytic cells. The exchange reaction

$$HD_{gas} + H_2O_{liq.} \rightleftharpoons H_{2gas} + HDO_{liq.}$$

which is catalysed by the electrode metal, reaches equilibrium when no current is passing; at 25 °C the equilibrium constant $K = \frac{[H_2]\,[HDO]}{[HD]\,[H_2O]} = 3.8$. An external current imposes a kinetic separation effect, which reaches a maximum at a current density of about ten times the exchange current density. An earlier belief that the kinetic separation effect is related to the hydrogen overvoltage on metals appears from recent investigations to be incorrect [45]. However, α is strongly dependent on the electrode metal and on the state of its surface (α is always decreased by impurities or by aging of the cathode surface). On the other hand, the nature and concentration of the electrolyte solution and the deuterium content appear to have little influence on α. An increase in temperature generally leads to a decrease in α [46]. The discharge reaction is assumed to be responsible for the kinetic isotope effect in the liberation of hydrogen [47].

Industrially, the electrolysis is carried out in cells containing NaOH or KOH solutions and equipped with nickel or iron cathodes, the cells being arranged in cascades. At each stage the electrolysis is continued until only about 1/10 of the quantity of water used is left. The water (after neutralization with CO_2) is then distilled out of the electrolyte and passed on to the next stage. The hydrogen liberated, which also contains considerable quantities of deuterium in the final stages, is burnt to form water and returned to the preceding stage. Since the ratio of heavy hydrogen to light hydrogen in natural water is only about 1:7000, very large quantities of water must be processed [48].

The power consumption in the electrolytic process is particularly high in comparison with other processes for the production of heavy water. Other methods are therefore used nowadays for preconcentration (isotope exchange between H_2S and H_2O or NH_3 and H_2, distillation of water, low-temperature rectification of liquid hydrogen) [49]. However, electrolysis plants are still used for final concentration, since in addition to the high separation factor, the valuable enriched material can be processed safely.

The elementary separation factors for other elements are much lower. A value of $\alpha = 1.069$ has been reached in the separation of the lithium isotopes on mercury cathodes [50]. *Selecki* proposed a continuous process in which the cathodic mercury phase and the aqueous electrolyte solution are fed past each other in countercurrent flow [51]. A value of $\alpha = 1.0054$ [52] was obtained for the separation of potassium isotopes on mercury cathodes.

Fractionation of the oxygen isotopes also takes place during the electrolysis of heavy water; however, the elementary separation factor of 1.03 [53] is much too low to be of any practical use. An α value of 1.006 was obtained for the nitrogen isotopes in the electrolysis of ammonium chloride on mercury cathodes [54].

5. Processes Involving Heterogeneous Isotope Exchange

5.1. Ion-Exchange Equilibria

Ion-exchange chromatography has not acquired much importance for the separation of isotopes. The advantages of this method are that with very little outlay on apparatus, it is adaptable and affords a large number of theoretical plates. However, these advantages are opposed by a number of serious disadvantages[55]. Thus it has been found that the isotope effect in the exchange equilibrium between the exchanging phase and the aqueous electrolyte solution is only of the order of 10^{-3} or even less in most cases. The difference in free energy between the bound state and the dissolved state is practically the same for isotopic ions[56]. Moreover, the exchange equilibrium between the solid ion-exchanging phase and the electrolyte solution is reached only very slowly in most cases, so that the throughput through an ion-exchange column must be kept very small if the number of the theoretical plates is to be kept high. Another disadvantage is that the process must be carried out discontinuously because of the immobile solid phase.

The first successful isotope separation, *i.e.* the separation of lithium isotopes, was achieved in 1938 by *Taylor* and *Urey* on a zeolite ion exchanger[57]. The elementary separation factor for this process was calculated to be 1.022; however, this value seems doubtful, and later measurements on zeolites gave much smaller values[58] (1.004 to 1.005). Experiments on ion-exchange resins (Dowex-50 type) gave values of between 1.002 and 1.0027 for the elementary separation factor of the Li isotopes[59].

The dependence of the isotope effect on the degree of cross-linking and on the eluent were also studied[60]. *Dickel* and *Richter*[61] determined the elementary effect directly in equilibrium experiments, and were able to study the dependence of this effect on concentration. They found a pronounced maximum in approximately 0.1 N solutions, in which the separation factor reaches a value of 1.012. The light isotope ^{6}Li is preferentially bound by the exchanger.

The ^{10}B content of boric acid solutions could be reduced from 19.7 % to 14.8 % on an anion exchanger (Amberlite CG-400)[62]; the elementary separation factor was found to be 1.016. The separation of the radioisotopes ^{22}Na and ^{24}Na on Dowex 50 was studied[63]; the elementary separation factor varied in this case between 1.00007 and 1.00018, depending on the temperature[64]. In the case of uranium isotopes the ^{234}U-abundance could be changed by about 4–5 % on a Dowex-50 column[65].

The best results with exchange resins were obtained by *Spedding*, *Powell*, and *Svec*[66] in the separation of the nitrogen isotopes *via* $NH_4^{\oplus}$ ions. The elementary separation factor in this case is particularly high, the value obtained being 1.025. This is because two equilibria are superimposed on each other, *i.e.* that of the exchange between bound and free $NH_4^{\oplus}$ ions and that of the exchange between free ammonium ions and dissolved ammonia, the latter of these equilibria evidently makes the greater contribution to the total separation factor. The authors connected several columns in a cycle, through which the exchanger zone containing $NH_4^{\oplus}$ ions could be passed over very large distances by successive elution with NaOH; moreover, the front of the migrating zone, in which the ^{15}N concentration had been reduced, was regenerated at intervals with fresh solution having the natural isotopic composition. The ^{15}N content could be increased from 0.36 to 44.8 %, corresponding to a separation factor of 225, by this chromatographic process.

Panchenkov[67] described a continuous countercurrent ion-exchange process which is similar to the method described by *Spedding* and *Powell*, and which should allow an even more efficient separation because of the use of a mobile exchanger phase.

Blasius and *Neumann*[68] tried to combine heterogeneous isotope exchange on ion exchangers with electrolytic ionic migration. Their experiments with ^{134}Cs and ^{137}Cs on a Dowex-50 column gave an elementary isotope effect of 1.0011, which is practically the same as that obtained in ionic migration in fused sodium nitrate[2]. It is therefore concluded that the isotope effect in the heterogeneous ion exchange must be very small. Similar experiments carried out with lithium isotopes in a two-dimensional arrangement by a group of Japanese workers[69] gave elementary isotope effects of 1.0049 to 1.0069 (depending on the anion and the experimental conditions), which are made up from equilibrium effects and kinetic contributions.

5.2. Exchange Electrolysis

The separation effect on which this process is based occurs in the exchange equilibrium between an amalgam phase and an electrolyte solution, *i.e.* an electronically and an ionically conducting phase. Ion exchange between these two phases is described as exchange electrolysis. The elementary separation effect of such an exchange electrolysis can be multiplied if the two phases are passed through a column in countercurrent flow.

This process was first used in 1936 by *Lewis* and *MacDonald*[70] for the separation of the lithium isotopes. Droplets of amalgam were allowed to fall through an alcoholic lithium chloride solution moving upward in a vertical tube. The lithium was washed out of the amalgam phase at the base of the column with alcoholic hydrochloric acid, and the resulting LiCl solution was reprocessed in the same manner. In this way the authors enriched ^{6}Li from 8 % to 16.3 % within 24 hours; the elementary separation factor was given as 1.02. Two patents concerning improvement of this separation were published recently, but no details of the experimental conditions are given[71]. The essential improvement appears to be the use of dimethylformamide as the solvent. The elementary separation effect between the amalgam phase and dimethylformamide is about 1.05[72].

Arkenbout et al.[73] recently described an exchange electrolysis using the same principle; the authors are of the opinion that this process is suitable for use in the enrichment of lithium isotopes on the industrial scale. In a sand-packed column 2 m long and 2.5 cm in diameter, approximately 10 theoretical plates were obtained when the flow rate of the two phases was 0.2 ml min^{-1} cm^{-2}. Technical difficulties involving phase inversion at the top of the column (cathodic reflux), where the lithium must be transferred from the electrolyte phase into the amalgam phase, could be avoided by the use of n-propylamine (instead of dimethylformamide) as the solvent for the electrolyte phase.

Similar processes based on exchange electrolysis have also been used for chemical separations (separation of rare earths and U/Th mixtures, and removal of fission products from nuclear fuels)[74]. In these cases the exchange takes place in the melt between a metallic phase (liquid Bi or Zn) and a salt phase (LiCl/KCl melt).

6. Concluding Remarks

The most important factor in the selection of a process for a given separation is the quantity of product desired.

If small quantities (*e.g.* 1 mole or less) are required once only, economic factors are generally of no importance. It is much more important to obtain a high concentration in a single column if possible. Another important point for laboratory work is that the apparatus should, if possible, be suitable for use in various isotope separations.

On the other hand, the most important factor in the case of kilogram or ton quantities is the economic factor. The size of the plant required to obtain a product of the desired concentration and in the desired quantity per unit time, the time taken to reach the desired degree of concentration, and the power consumption are all proportional to $1/\varepsilon^2$. Consequently, in isotope separations on the industrial scale, it is generally more important to achieve a large elementary effect than to give a reversible separation process preference over an irreversible process (see Introduction). The choice of a process will also be determined by the possibility of multiplication of an elementary effect. The best solution to this problem must be established specially for each individual separation.

The feasibility of using electrochemical separation processes for the enrichment of isotopes on the industrial scale must be checked for each individual case. The possibility is likely to be good only for light to medium-heavy elements. Estimated production costs for a product of a given concentration are available for a number of processes on the laboratory scale (ionic migration in salt melts[12] or in solution[35] and exchange electrolysis[73]). However, these figures are not sufficient for a critical comparison of various processes, since each process will present its own technological differences.

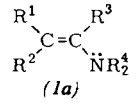
Synthesis and Reactions of the Alkynylamines[1]

BY H. G. VIEHE[*]

Alkynylamines $R-C\equiv C-NR_2^1$ have been known for only a few years. They are stable compounds, some of which have now become commercially available. Their high reactivity toward electrophiles as well as toward nucleophiles (particularly on acid catalysis) makes them very versatile starting materials. An interesting practical application is their use as condensing agents in peptide syntheses. They are superior to dicyclohexylcarbodiimide as dehydrating agents for organic acids. They condense with polar multiple bonds and dipolar systems to form cyclic structures.

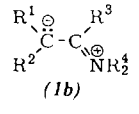
1. Introduction



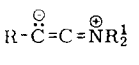
Whereas alkenylamines *(1)* (enamines) have been well known for many years[2, 3], the first alkynylamines *(2)* (ynamines[4][**]) were not prepared until 1958.

(1)

$R-C\equiv C-NR_2^1$ *(2)*



Both classes of compounds are characterized by conjugation of the multiple bond with the amino group. This means that both the nitrogen atom and the β-carbon atom can react as nucleophilic centers, as indicated by the resonance structures *(1a)* and *(1b)* as well as *(2a)* and *(2b)*.



(1a)

$R-C\equiv C-\ddot{N}R_2^1$

(2a)

(1b)

(2b)

Experience so far indicates that the amino group in the ynamines must be tertiary. All attempts to synthesize ynamines with primary amino groups have led to the tautomeric nitriles[5–8].

$[R-C\equiv C-NH_2] \rightarrow R-CH_2-C\equiv N$

The reactions of the ynamines are also related to those of the acetylene ethers *(3)*[9]. The ynols, on which the latter are based, are known only in the form of the

$R-C\equiv C-OR^1$

(3)

tautomeric ketenes. If the basic reaction for the industrial preparation of ketene, *i.e.* dehydration of acetic acid, could be applied to *N,N*-disubstituted acetamides, it should give ynamines. However, only the reverse reaction is known at present, *i.e.* ynamines, like the acetylene ethers, are versatile dehydrating agents.

On the basis of these formal comparisons, the ynamines may be expected to undergo numerous reactions. Since the first ynamines were synthesized only a few years ago, the reactions described below probably represent only the beginning of this development.

2. Stability and Principles of Synthesis

V. Wolf and *F. Kowitz* thought that they had synthesized the first ynamine in 1960 when they obtained *N,N*-diethylphenylethynylamine *(4)* in a yield of 1.7 %[10].

$$C_6H_5-C\equiv C-Li + ClN(C_2H_5) \rightarrow C_6H_5-C\equiv C-N(C_2H_5)$$

(4)

The synthesis of compound *(4a)*[11], which was first achieved in 1958 but was regarded as doubtful[10], was not confirmed[12] until 1965.

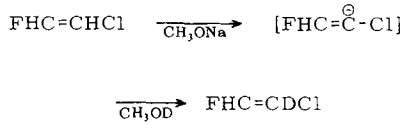
(4a)

On the other hand, all other reports of syntheses published since 1892 [13–15] appear to be based on errors, as was demonstrated later mainly by spectroscopic analysis [16, 17]. Nevertheless, the original belief that the ynamines are too unstable to be isolated in practical quantities had been proved incorrect. After the ynamine *(4)* had become available in yields of more than 80 % [4] as a result of our attempted nucleophilic substitution of halogen on an acetylenic carbon atom [8, 18], this and other ynamines were found to have a surprising thermal stability, in addition to the expected reactivity.

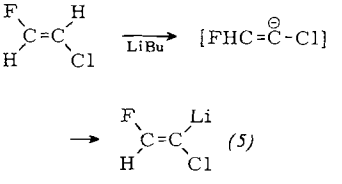
Most ynamines are water-clear, stable liquids with a more or less pronounced amine odor. They have now become commercially obtainable [19], and they can normally be handled in air without deterioration. Alkylethynyldiethylamines showed no appreciable decomposition even on vacuum distillation through porcelain tubes at 400 °C [20].

Thus the thermal stability of acetylenes substituted with elements of the first period increases with decreasing electronegativity of the substituent, from the extremely unstable 1-fluoroalkynes [8, 21–23], which oligomerize, *via* the more stable, but often readily fragmentable, acetylene ethers [9], to the ynamines and the dialkylacetylenes:



$$F-C\equiv C-R < R^1O-C\equiv C-R < R_2^1N-C\equiv C-R < R_3C-C\equiv C-R$$

The stability varies in the same order, though the variation is less pronounced, in the heterosubstituted olefins, particularly fluoroethylenes [24]. Thus the stability of a molecule in which an electronegative carbon atom (*i.e.* an sp or to a smaller extent an sp^2 carbon atom) carries an electronegative substituent decreases with increasing electronegativity of the substituent [25]. For substituents of the second and higher periods, stabilizing d-orbital resonance is superimposed on the above effect. Thus 1-chloroalkynes, for example, are thermally more stable than 1-fluoroalkynes.



It therefore follows that for hetero-substituted acetylenes and olefins:

a) The ease of addition of anions or free radicals to the multiple bond increases with increasing electronegativity of the substituent.

b) A negative charge (or a free-radical electron) on the carbon atom α to the hetero substituent is best stabilized by the hetero atom if the latter belongs to the second or a higher period of the periodic system. Consequently, in *cis*- and *trans*-chlorofluoroethylene, for example, the hydrogen α to the chlorine atom is replaced by deuterium much more readily than the hydrogen α to the fluorine atom [25].

Similarly, the reaction of *trans*-chlorofluoroethylene with butyl-lithium yields only the lithium compound *(5)*, in which the chlorine and the metal are attached to the same carbon atom.

(5)

Where attack takes place in only one of two possible directions, as in this example, the reaction is described as "directiospecific". If one direction of attack predominates, the reaction is "directioselective". These two phenomena are observed, not only in substitutions but also in additions and eliminations [26].

Like all substituted acetylenes, the ynamines can be prepared *a priori* by three possible routes: (i) The triple bond may be formed by elimination from a molecule in which the substituent is already present; (ii) an acetylene group may be joined to the substituent, the acetylene group being supplied as an acetylide or, less commonly, as a halogenoacetylene (or acetylene ether); and (iii) the isomerization of propargyl derivatives.

All these routes were originally subject to difficulties. The eliminations were readily suppressed by substitution of the halogen, *e.g.* in the reactive amide chlorides [27]. Only a few chloroenamines (which are often unstable) are available, and there is a lack of suitable catalysts for the isomerizations leading to *N*-dialkylynamines. The synthesis that seems simplest, *i.e.* the substitution of chloroalkynes, is hindered by the low reactivity of the halogen [4] when the acetylene

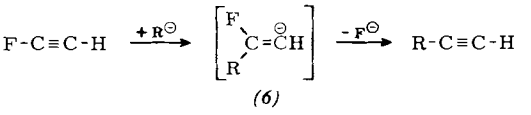
$$R{-}C{\equiv}C{-}CH_2{-}NR_2^1 \rightarrow [R{-}CH{=}C{=}CH{-}NR_2^1] \rightarrow R{-}CH_2{-}C{\equiv}C{-}NR_2^1$$

group does not carry an electronegative substituent [8]. The limitations of the reaction of acetylides with chloroamines, which are not very susceptible to nucleophilic substitution of the chlorine, are shown by the low yield of 1.7 %, which was obtained by *Wolf* and *Kowitz* [10].

However, all the routes outlined have now been successfully used. Moreover, in the study of nucleophilic substitution on chloroalkynes, a rearrangement reaction of general importance was discovered. This is the "onium rearrangement" [28], which is particularly useful for the synthesis of ynamines.

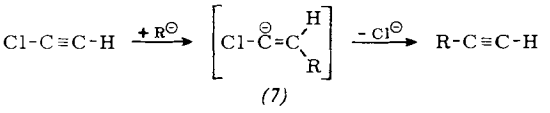
3. Ynamines by Substitution



3.1. Ynamines from 1-Halogenoalkynes and Metal Amides. A New Mechanism of Nucleophilic Substitution of Halogen Attached to Multiply Bonded Carbon Atoms

The normal, low reactivity of chloroalkynes is illustrated by the following reaction, which gives an overall yield of 82.5 % when carried out as a single-vessel reaction in liquid ammonia [29].

$$Cl{-}CH{=}CH{-}Cl \xrightarrow{NaNH_2} [HC{\equiv}C{-}Cl] \xrightarrow{NaNH_2} Na{-}C{\equiv}C{-}Cl$$



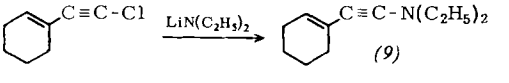
$$\xrightarrow{Br(CH_2)_2Br} Cl{-}C{\equiv}C{-}(CH_2)_4{-}C{\equiv}C{-}Cl$$

Nucleophilic substitution of the halogen [4] *is much easier in fluoroalkynes than in chloroalkynes.* This is plausibly explained on the basis of the discussion of the stability of hetero-substituted acetylenes and the directiospecificity of their reaction (Section 2). Fluoroacetylene adds on the nucleophilic reagent at the α carbon atom. The hypothetical intermediate *(6)* can

(6)

readily lose the fluoride ion by β-elimination. In chloroacetylene, on the other hand, the nucleophilic reagent adds to the β-carbon atom, since the chlorine atom can stabilize a negative charge on the α-carbon atom by d-orbital resonance. The chloride ion must then be lost from the hypothetical intermediate by α-elimination, which is energetically less favorable [28].

(7)



Accordingly, the ynamine *(7a)* can be prepared from lithium diisobutylamide only with fluoroacetylene, and not with chloroacetylene [20].

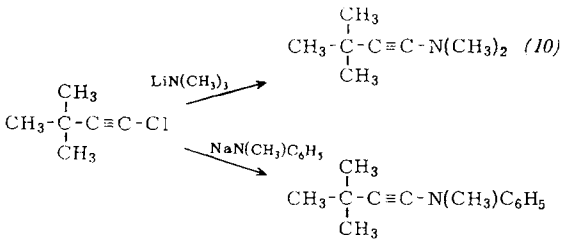
$$F{-}C{\equiv}C{-}H \xrightarrow{2\ LiN(-iC_4H_9)_2} Li{-}C{\equiv}C{-}N(i{-}C_4H_9)_2$$

$$\xrightarrow{CH_3OH} HC{\equiv}C{-}N(i{-}C_4H_9)_2 \quad (7a)$$

The chlorine in chloroalkynes can be readily substituted by means of *N,N*-disubstituted alkali metal amides if the acetylene carries an "electronegative" substituent [8, 30]. Thus chlorophenylacetylene reacts with lithium dimethylamide to give the ynamine *(8)* in 87 % yield [31], and even chlorocyclohexenylacetylene reacts with lithium diethylamide to give the ynamine *(9)* in 64 % yield [20]; however, these reactions probably proceed *via* α-additions.

$$C_6H_5{-}C{\equiv}C{-}Cl \xrightarrow{LiN(CH_3)_2} C_6H_5{-}C{\equiv}C{-}N(CH_3)_2 \quad (8)$$

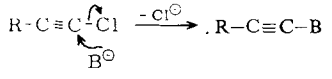
(9)



t-Butylchloroacetylene reacts with lithium dimethylamide only in the strongly polarizing solvent hexamethyl phosphorus triamide (HMPT) recommended by *H. Normant*, the reaction being exothermic and giving the ynamine *(10)* in a yield of about 70 %. The chlorine in t-butylchloroacetylene can also be substituted by means of sodium *N*-methylanilide if the mixture is heated at 100 °C for 6 hours in a sealed tube.

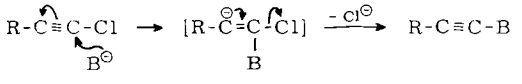
[28] *H. G. Viehe* and *S. Y. Delavarenne*, unpublished.

[29] *H. G. Viehe*, Chem. Ber. *92*, 1270 (1959).

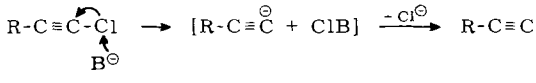


[30] Review on halogenoacetylenes: *S. Y. Delavarenne* and *H. G. Viehe* in [1].

[31] *H. G. Viehe* and *M. Reinstein*, Angew. Chem. *76*, 537 (1964); Angew. Chem. internat. Edit. *3*, 506 (1964).

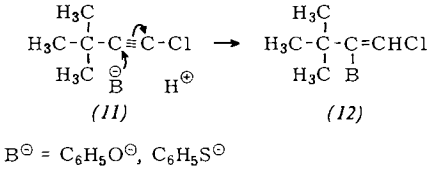


Various reagents have been used with t-butylchloroacetylene in efforts to obtain information about the substitution mechanism. As a result of this work, a new mechanism has been proposed for the substitution of halogen on multiply bonded carbon atoms [28]. Three mechanisms had formerly been discussed for the nucleophilic substitution of halogen (chlorine, bromine, iodine) on multiply bonded C atoms [18,28,32,33]; these mechanisms are illustrated below for an alkylchloroacetylene.



Direct substitution:

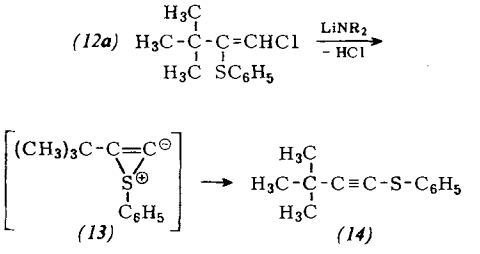
α-Addition and β-elimination:



Attack on the hetero atom followed by direct substitution [34]:

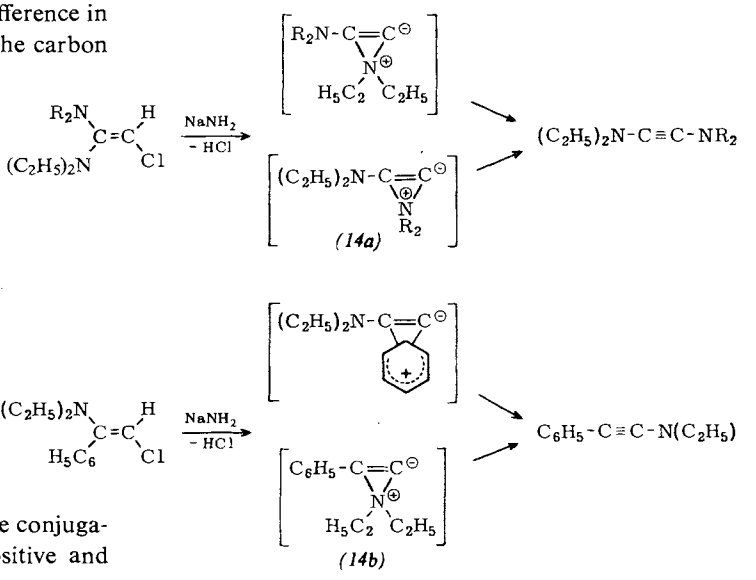
Direct substitution is unlikely for several reasons [1,28]. The reactivity of chlorine attached to a triply bonded C atom is very low, evidently because the difference in electronegativity between the chlorine and the carbon is smaller than in chloroalkanes, and because conjugation makes the chlorine atom more positive and strengthens the C–Cl bond [18,30].

The attack on the hetero atom with subsequent direct substitution is also conceivable only in special cases. Thus alkoxide $RO^{\ominus}$ or amide $R_2N^{\ominus}$ as $B^{\ominus}$ would lead to the little-reactive hypochlorites ROCl or to the similarly weakly reactive chloroamines R_2NCl.



Consequently, the route generally regarded as most likely is the α-addition and β-elimination [28,32,33]. However, this mechanism is refuted by the directiospecificity of the β-addition of phenoxide and of thiophenolate to t-butylchloroacetylene *(11)*, despite steric hindrance by the t-butyl group.

(11) *(12)*



$B^{\ominus} = C_6H_5O^{\ominus}, C_6H_5S^{\ominus}$

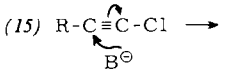
The thiophenolate adduct *(12a)*, like many β-chloroenamines can rearrange with α-elimination of HCl to give the acetylene derivative *(14)* [26]. This rearrangement apparently proceeds *via* the onium compound *(13)*.

(13) *(14)*

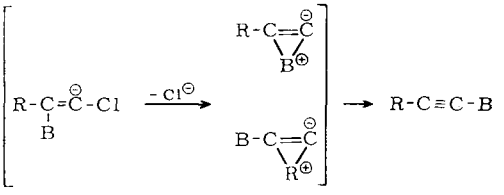
Examples of this reaction, of which the Fritsch-Wiechell-Buttenberg reaction is a special case [33], have been described in detail elsewhere [26,28]. We shall therefore consider only two examples, which are interesting in that the onium intermediates *(14a)* and *(14b)* both contain two groups that can migrate. It is not yet known whether both groups do in fact migrate, and if so in what ratio. However, it is now conceivable

(14a)

(14b)



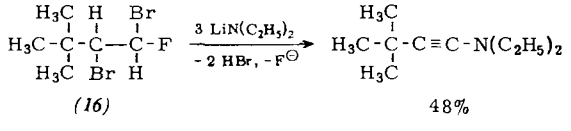
[32] *E. R. Ziegler, C. A. Welch, C. E. Orzech, S. Kikkaway,* and *S. I. Miller,* J. Amer. chem. Soc. *85*, 1648 (1963).



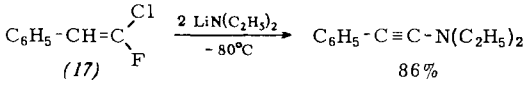
[33] *G. F. Köbrich* and *P. Buck* in [1].

[34] *J. F. Arens,* Recueil Trav. Chim. Pay-Bas *82*, 183 (1963).

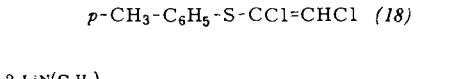
that in the substitution of halogens on olefins and aromatic compounds, the nucleophile can not only attack the β-carbon atom, but can also remain there.



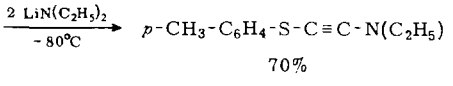
The new mechanism of nucleophilic substitution of halogen by α-elimination and onium rearrangement could also be involved in the synthesis of ynamines from t-butylchloroacetylene and similar halogenoalkynes *(15)* (but not for the fluoroacetylenes)[28].



3.2. Ynamines from Dihalogenoalkenes and Trihalogenoalkanes with Alkali Metal Amides

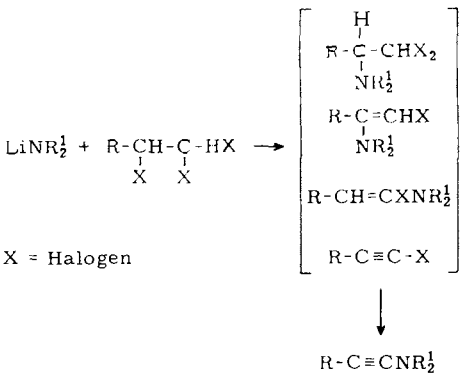


Though the fluoroalkynes had been found to be the most suitable halogenoalkynes for the preparation of ynamines by substitution of halogen[18], the limited availability of these starting materials prevented any practical utilization of this knowledge. However, instead of fluoroalkynes or reactive chloroalkynes, it is possible[4,31] to use compounds, *e.g. (16)* to *(18)*, that may be regarded as precursors of the halogenoalkynes under the conditions of the reaction with *N,N*-disubstituted lithium amides:

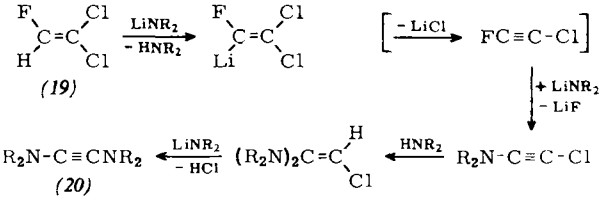


(16) 48%

(17) 86%



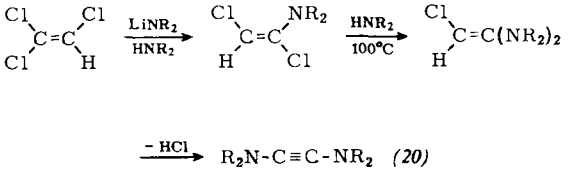
p-CH_3-C_6H_5-S-CCl=CHCl *(18)*



70%

It is not necessary to assume that the halogenoalkynes are formed first, since primary substitution of the halogen on the olefin or alkane can lead to ynamines on subsequent α- or β-elimination with or without onium rearrangement.

An example of a practically simple ynamine synthesis whose mechanism involves several steps, as could be shown by the isolation or interception of the formulated intermediates (except that in brackets)[26], is the



condensation of 2,2-dichloro-1-fluoroethylene *(19)* with 3 mol. equiv. of lithium diethylamide in ether at −80 °C. The yield of *(20)* (based on *(19)*) is about 60 % for R = C_2H_5[31].

(19)

(20)

The isolation of the ynediamine *(20)* again shows the thermal stability of the ynamines, particularly when one remembers that difluoroacetylene FC≡CF has so far only been detected spectroscopically[35] and that no acetylene diethers RO–C≡C–OR have yet been isolated[9]. Ynediamines *(20)* are also obtained from trichloroethylene by dehydrochlorination and onium rearrangement[26].

3.3. Ynamines from Acetylene Ethers with Tertiary Alkali Metal Amides

In the laboratory of *F. Arens*, who is responsible for most of our knowledge on the chemistry of acetylene ethers (since their discovery by *T. L. Jacobs*[9]), *P. Montijn*, *E. Harryvan*, and *L. Brandsma*[36] found that the acetylene ethers also react readily with *N,N*-disubstituted alkali metal amides, with replacement of the alkoxy group and formation of ynamines. This method is particularly useful for the preparation of *C*-alkylynamines *(21)*.

(21), 67%

[36] *P. P. Montijn*, *E. Harryvan*, and *L. Brandsma*, Recueil Trav. Chim. Pays-Bas *83*, 1211 (1964).

3.4. Ynamines from 1-Halogenoalkynes and Tertiary Aliphatic Amines

Ynamines should be weak N-bases. This is in agreement with the fact that halogenoalkynes and tertiary aliphatic amines react to form ynamines *(23)*, with elimination of halogenoalkane from the initially formed ammonium salt *(22)* [1, 20, 37].

$$C_6H_5-C\equiv C-X \xrightarrow[N(CH_3)_3]{40\ h/55^\circ C} C_6H_5-C\equiv C-\overset{\oplus}{N}(CH_3)_3\ \overset{\ominus}{X} \xrightarrow{-CH_3X}$$

(22)

$$\longrightarrow C_6H_5-C\equiv CN(CH_3)_2 \quad (23)$$

X = Cl, Br

This reaction, which is closely related to the von Braun degradation of tertiary amines with cyanogen bromide [38], readily gives ynamines on a 100 g scale. It has also been used to prepare the diynamines *(24)*, which, under special conditions, are able to regenerate the salts by *N*-alkylation [12].

$$C_6H_5-C\equiv C-C\equiv C-Br \xrightarrow{N(CH_3)_3} C_6H_5-C\equiv C-C\equiv C-\overset{\oplus}{N}(CH_3)_3Br$$

$$\overset{+\,CH_3Br}{\underset{-\,CH_3Br}{\rightleftharpoons}}$$

$$C_6H_5-C\equiv C-C\equiv C-N(CH_3)_2$$

(24)

In addition, the reaction has been employed for the preparation of ethyl chloroethynylphosphate *(25)* [39].

$$(C_2H_5O)_2\overset{O}{\overset{\|}{P}}-C\equiv C-Cl \xrightarrow[25^\circ C]{N(C_2H_5)_3} (C_2H_5O)_2\overset{O}{\overset{\|}{P}}-C\equiv C-\overset{\oplus}{N}(C_2H_5)_3\overset{\ominus}{Cl}$$

(25)

$$\xrightarrow[10\ min,\ 80^\circ C]{C_6H_6(-C_2H_5Cl)} (C_2H_5O)_2\overset{O}{\overset{\|}{P}}-C\equiv C-N(C_2H_5)_2$$

3.5. Ynamines by Alkylation of Lithium Aminoacetylides

J. Ficini and *C. Barbara* [40] prepared the now easily accessible lithium aminoacetylides *(26a)* and *(26b)* and converted them in good yields into ynamines by

$$C_6H_5(CH_3)N-C\equiv C-Li \xrightarrow{C_4H_9Br} C_6H_5(CH_3)N-C\equiv C-C_4H_9$$

(26a) 76%

$$(C_2H_5)_2N-C\equiv C-Li \xrightarrow{CH_3O-Tosyl} (C_2H_5)_2N-C\equiv C-CH_3$$

(26b) 50%

alkylation in hexamethyl phosphorus triamide (HMPT) or in HMPT/ether, thereby opening a general route to ynamine derivatives.

4. Ynamines by Elimination

4.1. Elimination of Halogen from α,β-Dichloroenamines

α,β-Dichloroenamines *(27a)* and *(27b)* are readily available. *J. Ficini* and *C. Barbara* [40] have shown that ynamines can be obtained in high yields from these compounds with n-butyl-lithium.

$$C_6H_5-\underset{Cl}{\overset{|}{C}}=\underset{Cl}{\overset{|}{C}}-N(C_2H_5)_2 \xrightarrow[-Cl_2]{Li-C_4H_9} C_6H_5-C\equiv C-N(C_2H_5)_2$$

(27a) 70%

$$Cl-\underset{Cl}{\overset{|}{C}}=\underset{Cl}{\overset{|}{C}}-N(CH_3)C_6H_5 \xrightarrow{2\ Li-C_4H_9} Li-C\equiv C-N(CH_3)C_6H_5\ [*]$$

(27b)

$$\xrightarrow{H^\oplus} HC\equiv C-N(CH_3)C_6H_5 \quad 72\%$$

4.2. Ynamines by Dehydrohalogenations from Dihalogenoalkylamines

It should be formally possible to synthesize ynamines from the following dihalogenoalkylamines:

(i) Amide chlorides $R-CH_2-CCl_2NR_2^1$.

(ii) Halogen adducts of enamines $R-CHX-CHXNR_2^1$ *(28)* or $R-C(NR_2^1)X-CH_2X$ *(29)* (elimination of HX with onium rearrangement).

(iii) β,β-Dihalogenoalkylamines $RCX_2-CH_2NR_2^1$ or $R-CH(NR_2^1)-CHX_2$ (elimination of HX with onium rearrangement).

Ynamines have so far been synthesized mainly from amide chlorides [41], but compounds of the type *(28)* have also been used [20]. β,β-Dichloroalkylamines *(30)* have recently been prepared by the addition of *N*-chloroamines to chloroolefins [42],

$$R-\underset{Cl}{\overset{|}{C}}=CH_2 + ClNR_2^1 \longrightarrow R-CCl_2-CH_2NR_2^1 \quad (30)$$

but they are surprisingly inert and are unaffected by attempts to eliminate HCl with bases as strong as sodamide in liquid ammonia [43]. Interesting reactions have been observed with *N,N*-disubstituted lithium amides, but the desired ynamines were not formed [43].

Thus, for the present at least, practically the only dihalogenoalkylamines that can be used for the synthesis of ynamines are the amide chlorides, which

[37] *H. G. Viehe, S. I. Miller,* and *J. I. Dickstein,* Angew. Chem. *76*, 537 (1964); Angew. Chem. internat. Edit. *3*, 582 (1964).

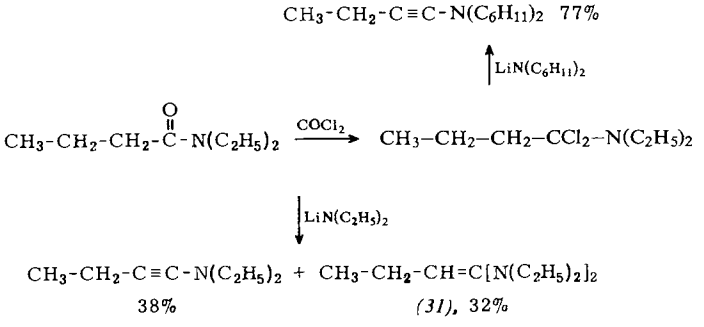
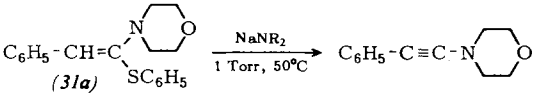
[*] According to *J. Ficini, A. Dureault,* and *C. Barbara* (personal communication) these lithium acetylides undergo the expected reactions with carbonyl compounds.



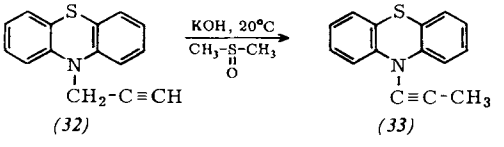
[41] *R. Buijle, A. Halleux,* and *H. G. Viehe,* Angew. Chem. *78*, 593 (1966); Angew. Chem. internat. Edit. *5*, 584 (1966).

[42] *R. S. Neale,* Tetrahedron Letters *1965*, 483.

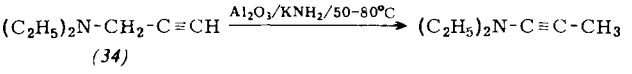


[43] *A. Halleux* and *H. G. Viehe,* unpublished.

are readily obtainable from tertiary amides and phosgene [27]. Several ynamines have been prepared from amide chlorides and *N,N*-disubstituted lithium amides [41]. The ynamine formation frequently proceeds smoothly, depending on the amide chloride and the base, but is often accompanied by the formation of alkenylidenediamines *(31)*.

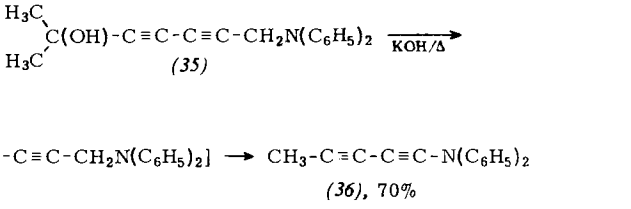


The elimination of thiolate from ketene *S,N*-acetals *(31a)* with alkali metal amides has been described as another method for the synthesis of ynamines [41] [*].



5. Ynamines by Isomerization of Propargylamines

The first (accidental) ynamine synthesis [11] was the reaction of phenothiazine with sodium hydride and propargyl bromide. This reaction could involve the intermediate formation of propargylamine *(32)*, which was later isolated under different conditions [12] and which isomerizes to the ynamine *(33)* in the presence of potassium hydroxide.



Only tertiary *N*-arylpropargylamines can isomerize to ynamines under such mild conditions [12]. *N,N*-Diphenylpropargylamine gives the ynamine in a yield of 51%. However, catalysts have recently been found

[*] The reaction of t-butylate with enamines and chloroform constitutes an interesting synthesis of enynamines – *T. C. Shields, W. E. Billups,* and *A. N. Kurtz* (Angew. Chem., in press).

that also permit the preparation of ynamines in high yields (60 to 90%) from the readily obtainable *N,N*-dialkylpropargylamines, *e.g. (34)* [44].

N-Arylmethyldiynamines *(36)* have been obtained from the dimethylcarbinols *(35)*, which can be cleaved under the isomerization conditions [12].

6. Properties of the Ynamines

More than fifty ynamines have now been prepared [1]. The substituents on the nitrogen may be alkyl, aryl, or heterocyclic groups, while the substituents on the acetylenic carbon may be alkyl or aryl groups, H, lithium, NR_2, SR, $PO(OC_2H_5)_2$, or halogen.

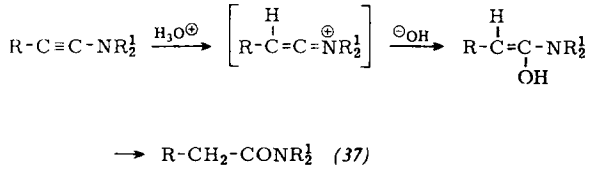
Despite their high reactivity, the ynamines are generally stable liquids or crystals. However, compounds with special substituents, such as the halogenoynamines, are very unstable and have not yet been obtained in the pure state [20,45]. Consequently, the (so far unreproducible) synthesis of a bromoynamine [46] by heating of *N,N*-diethylbromoacetamide with PCl_5 appears improbable.

Like the fluoroalkynes and the acetylene ethers, the ynamines generally give a stronger C≡C absorption in the IR spectrum than their group homologues (*e.g.* with Cl, S, P as substituents). For most substituted ynamines, this absorption band is situated at 4.5 μ (2220 cm^{-1}); it is displaced in particular by *C* substitution, SR causing a shift to about 4.6 μ (2173 cm^{-1}), H to about 4.7 μ (2127 cm^{-1}), and lithium to about 4.9 μ (2050 cm^{-1}).

7. Reactions of the Ynamines

7.1. General Reaction Behavior

Ynamines are characterized by the possibility of resonance interaction between the lone pair of electrons on the nitrogen and the triple bond.



The ynamines are therefore effective nucleophilic reagents. However, they also react as if they were electrophiles, particularly on acid catalysis, though, in reality, reactions of this type probably proceed *via* ketene-iminium structures. An example of such a

[44] *A. Hubert* and *H. G. Viehe*, unpublished.

[45] *J. Ficini*, personal communication.

[46] *Yu. Yu. Tsmur* and *V. I. Ivanik*, Ž. obšč. Chim. *33*, 1653 (1963).

$\longrightarrow$ R-CH_2-$CONR_2^1$ *(37)*

reaction is the exothermic acid-catalysed addition of water [10,47] to form amides *(37)*.

The addition of alcohols also proceeds readily under acidic conditions or with BF_3-ether as a catalyst [48,49]; however, it is also possible to add on *e.g.* methanol under basic conditions [20]. In the acid-catalysed addition of various primary and secondary amines, strongly basic amines evidently hinder the formation of the ketene-iminium structure and thus react more slowly than their less basic counterparts [48].

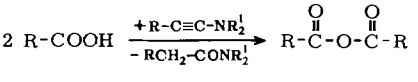
The reaction behavior of the ynamines is strongly dependent on the substituents. Thus *N,N*-diarylynamines are weaker nucleophiles than the *N,N*-dialkyl compounds [40].

Ynamines whose substituents permit the formation of an allene structure frequently react less readily than ynamines with *C*-substituents such as phenyl, t-butyl, or SR. Consequently, compounds having these last-named substituents should always be used to test an unknown ynamine reaction.

7.2. Hydration of Ynamines

7.2.1. Formation of Acid Anhydrides by Ynamines

Ynamines are superior to dicyclohexylcarbodiimide and ethoxyacetylene as dehydrating agents for the formation of acid anhydrides (Table 1).



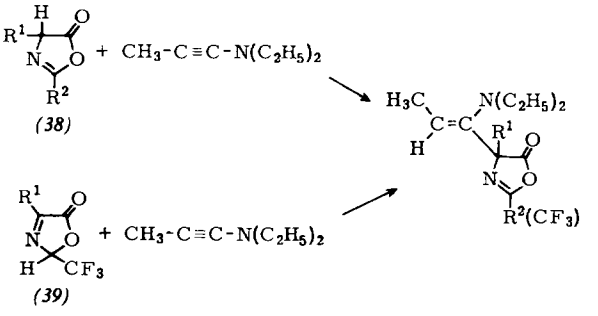


Table 1. Yields in the formation of acid anhydrides with ynamines, dicyclohexylcarbodiimide, and ethoxyacetylene (5 min at 10 °C in benzene).

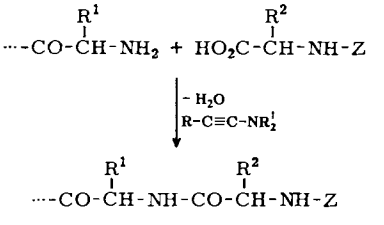
R	Anhydride formation with			
	C_6H_5–C≡C–$N(CH_3)_2$	t-C_4H_9–C≡C$N(CH_3)_2$	$(C_6H_{11}$–N=$)_2$C	HC≡C–OC_2H_5
n-C_3H_7	96 %	93 %	70 %	0 %
C_6H_5	98 %	97 %	63 %	0 %

7.2.2. Peptide Synthesis and Formation of Amides with Ynamines [47,50,51]



The use of ynamines for the synthesis of peptides has been described in several articles [47,50,51]. The yields reported are almost quantitative, but the reaction conditions must be rigidly controlled to avoid racemization [52]. Thus in the stepwise synthesis of polypeptides, the peptide chain carries the free amino group, while the amino acid to be attached carries the free acid group in order to avoid racemization by azlactone formation. According to *F. Weygand*, it has not so far been possible to avoid partial racemization in the linking of two peptides with ynamines.

Side reactions were observed in some cases [50,52]. Thus the ynamines can add onto intermediate oxazol-5-ones *(38)* or 2-trifluoromethylpseudooxazol-5-one *(39)*.

Another side reaction, *i.e.* the addition of *N*-acylamino acid anhydrides to ynamines, is described in Section 7.5.

One advantage claimed for the ynamines as compared with the widely used carbodiimides in the synthesis of

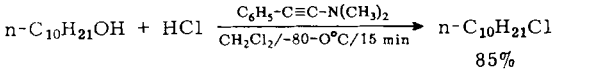
peptides, apart from their greater reactivity, is the greater ease of processing of the reaction mixture [51,52]. Ynamines give *N,N*-disubstituted amides, which can generally be easily extracted from the peptides with petroleum ether, whereas the disecondary urea derivatives formed from carbodiimides can often be removed only by recrystallization of the peptides.

7.2.3. Ester Formation with Ynamines

Since ynamines react with an excess of dry HCl to give amide chlorides, which convert alcohols into alkyl chlorides [27], it is not surprising that HCl, HBr, and HF react with alcohols in the presence of ynamines to

[47] *R. Buijle* and *H. G. Viehe*, Angew. Chem. *76*, 572 (1964); Angew. Chem. internat. Edit. *3*, 582 (1964).

[48] *H. G. Viehe, R. Fuks*, and *M. Reinstein*, Angew. Chem. *76*, 571 (1964); Angew. Chem. internat. Edit. *3*, 581 (1964).



[49] *J. Ficini* and *C. Barbara*, Tetrahedron Letters *1966*, 6425.

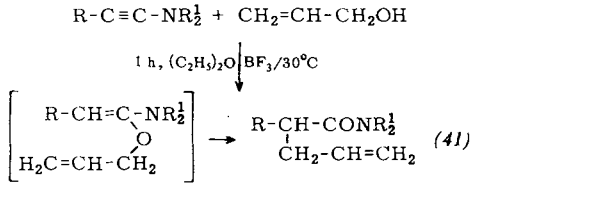
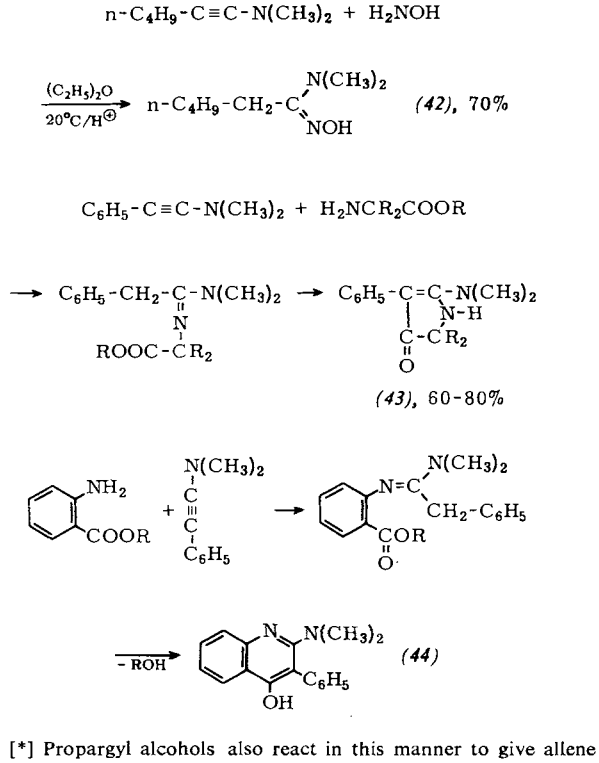
[52] *A. S. Van Mourik, E. Harryvan*, and *J. F. Arens*, Recueil Trav. Chim. Pays-Bas *84*, 1 (1965).

form alkyl halides[48]. However, it is not yet certain whether the reaction proceeds *via* the amide chloride or the α-chloroenamine.

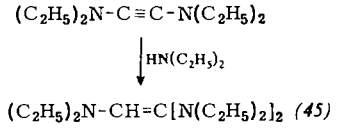


The synthesis of activated esters, *e.g.* *(40)*, which is easy to achieve with ynamines, and which is useful in peptide chemistry, could be of practical importance[1,20].



7.3. Addition of Alcohols and Amines to Ynamines

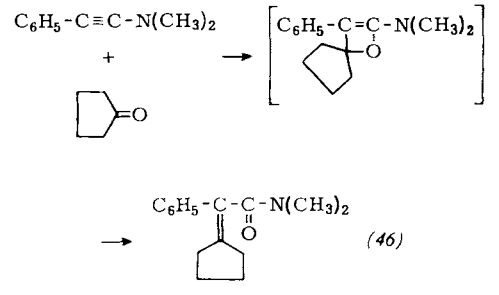
The easy addition of alcohols to ynamines is preparatively useful in the case of allyl alcohols, since subsequent Claisen rearrangement yields γ-acrylamides *(41)*[49][*].



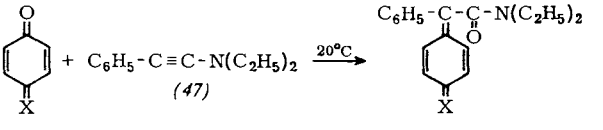
A similar reaction sequence is occasionally observed with allylamines[49], but the rearrangement occurs at about 250 °C[*].

[*] Propargyl alcohols also react in this manner to give allene amides — *J. Ficini* and *J. Pouliqueu*, personal communication.

More commonly used reactions are the addition of primary and secondary amines to amidines *(42)* and to alkenylidenediamines[48]. These reactions are particularly useful for the formation of derivatives of secondary amines and for the incorporation of amino acids into heterocycles *(43)*, *(44)*[53].



Ynediamines react with secondary amines to give high yields of enetriamines *(45)*[26], which had previously been unknown, and which are interesting for comparison with the enetetramines.

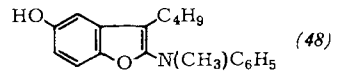


7.4. Addition Reactions of Ynamines

7.4.1. Addition Reactions with Carbonyl Compounds and their Imines

Ynamines react more readily than other acetylenes with aldehydes, ketones, and reactive carbonyl compounds[54], such as ethyl formate and dimethylformamide, to give derivatives of α-acrylamides *(46)*. With BF_3 or acid catalysts in ether, the reaction is generally exothermic.

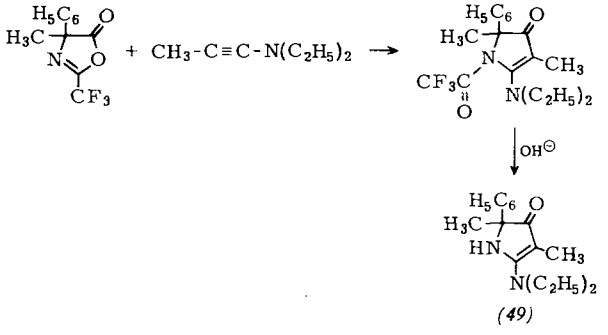
Allylamines can be readily obtained from the α-acrylamides by reduction with lithium aluminum hydride. The condensation of ynamines with acid anhydrides[51] (see Section 7.5) and with *p*-quinone and *N*-phenyl-*p*-quinonimine is also of preparative interest. The condensations of these last two compounds with diethylphenylethynylamine *(47)* are exothermic in benzene, and require no catalyst[55][*].



[53] *R. Fuks* and *H. G. Viehe*, unpublished. Review: *R. Fuks* and *H. G. Viehe* in [1].

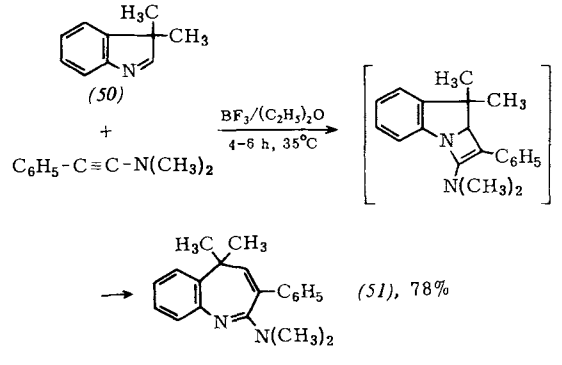
[54] *R. Fuks*, *R. Buijle*, and *H. G. Viehe*, Angew. Chem. *78*, 594 (1966); Angew. Chem. internat. Edit. *5*, 585 (1966).

[55] *J. Ficini* and *A. Krief*, Tetrahedron Letters *1967*, 2497.



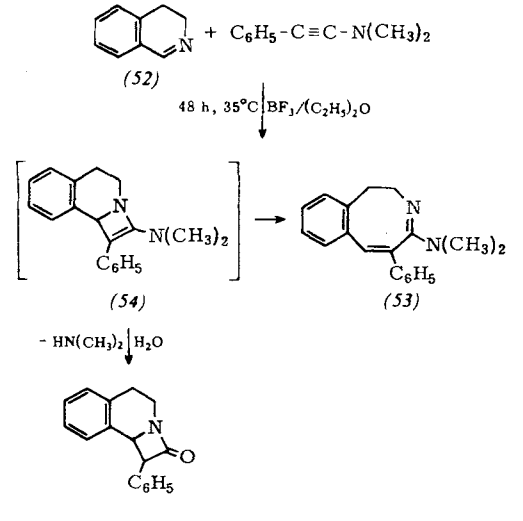
[*] *J. Ficini* and *A. Krief* (personal communication) have condensed ynamines with aryl isocyanates to give 6-membered ring systems.

p-Quinone and n-C_4H_9–C≡C–$N(CH_3)C_6H_5$ give the benzofuran derivative *(48)* in 13 % yield, together with polymers.



(48)

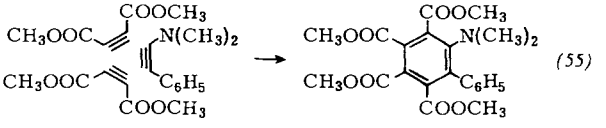
The reaction of 4,4-disubstituted oxazol-5-ones with ynamines yields 3-oxopyrroline derivatives [51], *e.g. (49)*.



(49)

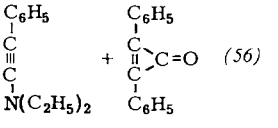
The imines of the carbonyl compounds mentioned here react in the same manner as the carbonyl compounds themselves, though generally less readily. The condensation of ynamines with cyclic imines leads to ring expansion [53,54].

(51), 78%



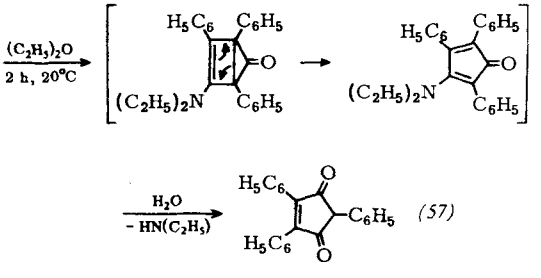
Dihydroisoquinoline *(52)* reacts with expansion of the six-membered hetero ring into the eight-membered ring of *(53)*. The intermediate azetidine *(54)* can be detected in this case by competitive hydrolysis [53].

(54) *(53)*



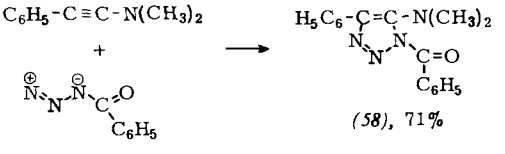
7.4.2. Addition Reactions with Polar C≡C and C=C Bonds

Whereas enamines react with esters of acetylenedicarboxylic acid, to give cyclobutene derivatives, most of which are unstable [56], the reaction with ynamines yields benzene derivatives, *e.g. (55)* [40,48].

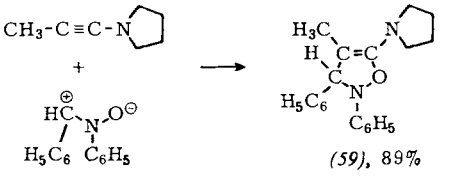


(55)

1,3,4-Triphenylcyclopentene-2,5-dione *(57)* can be synthesized from diphenylcyclopropenone *(56)* [57].



(56)



(57)

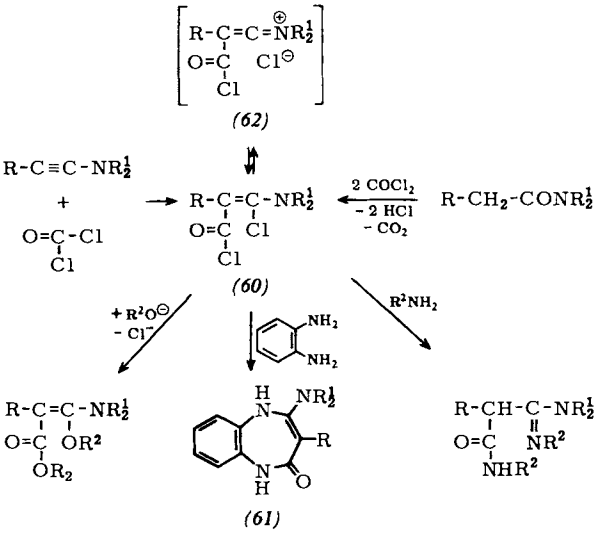
7.4.3. Addition of 1,3-Dipoles

As expected, the readily polarizable ynamines react with 1,3-dipoles to give compounds of the types *(58)* and *(59)* in good yields. For example, the reactions leading to *(58)* and *(59)* [54] proceed in accordance with thoroughly investigated models [58].

(58), 71%

(59), 89%

7.5. Acylation of the Ynamines



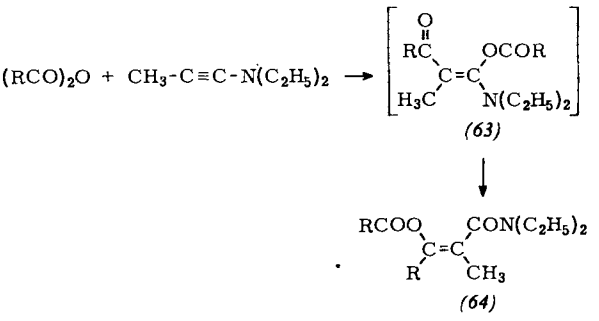
Ynamines react with chlorides of organic and inorganic acids, generally with almost quantitative addition. The phosgene adducts *(60)*, which can be obtained from

[56] *K. C. Brannock, R. D. Burpitt, V. W. Goodlett*, and *J. G. Thweatt*, J. org. Chemistry *38*, 1464 (1963); *29*, 818 (1964).

[57] *M. Franck-Neumann*, Tetrahedron Letters *1966*, 341.

[58] *R. Huisgen*, Angew. Chem. *75*, 604 (1963); Angew. Chem. internat. Edit. *2*, 565 (1963).

amides, are particularly useful. They act as bifunctional reagents toward amines and alkoxides, and so permit *e.g.* the synthesis of heterocycles such as *(61)* [59].

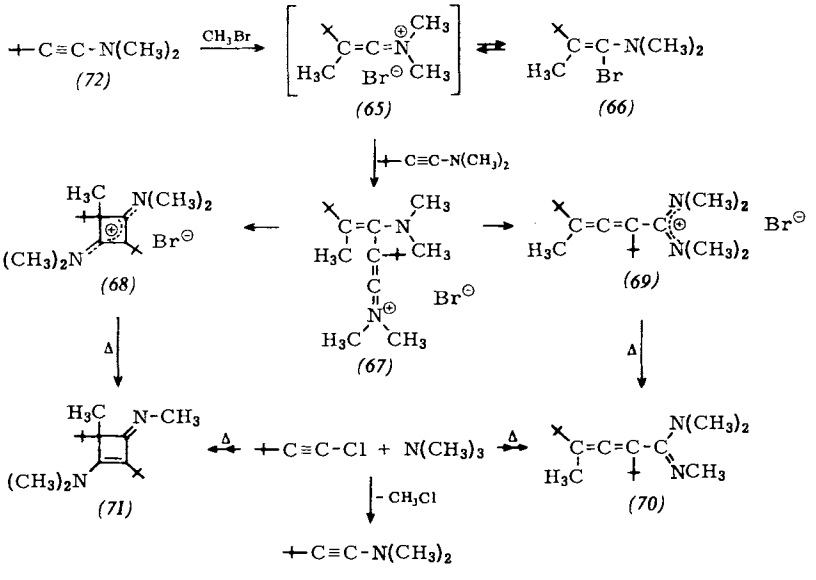


(62)

(60)

(61)

The new β-acyl-α-chloroenamines are very stable (they can often even be distilled) possibly because the β-acyl group opposes the formation of the polar ketene-iminium resonance structure *(62)* (see Section 7.6.).



(63)

(64)

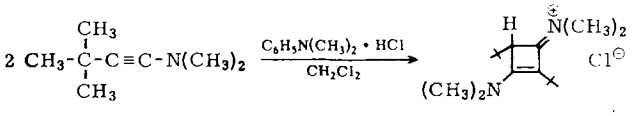
way from reaction with esters of amino acids. However, the side reaction can be avoided if the ynamine is added dropwise to the acid, and is not used in excess [50].

7.6. Dimerization of Ynamines with Nucleophiles [61]: Alkylation, Halogenation, and Protonation (with Strong Acids)

The alkylation of 3,3-dimethyl-1-butynyldimethylamine with methyl bromide provides an interesting comparison with the enamines. β-*C*-Alkylation probably leads to the inisolable ketene-iminium compound *(65)*, which probably exists in equilibrium with the

(72) *(65)* *(66)* *(68)* *(67)* *(69)* *(71)* *(70)*

Acid anhydrides add on smoothly to ynamines in the same manner as the acid chlorides [51]. However, the initially formed β-acyl-α-acyloxyenamines *(63)* are unstable, and immediately rearrange under the reaction conditions to give enol esters of the β-keto acid dialkylamides *(64)* [60].

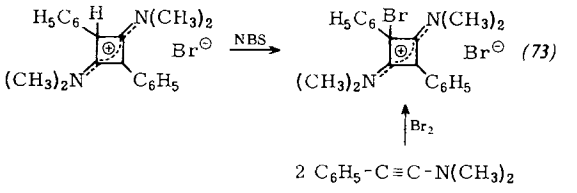


The enol esters *(64)* can also be prepared from the β-acyl-α-chloroenamines *(60)* and carboxylates [51]. The acylation of ynamines by anhydrides is particularly important in peptide syntheses, since the intermediate *N*-acylamino acid anhydrides can be withdrawn in this enamine structure *(66)*. With a further mole of ynamine, the enamine-ketene-iminium salt *(67)*, which is capable of intramolecular *C*- and *N*-alkylation, should be formed. The salt mixture, which is isolated in a yield of 73 %, contains 35 % of cyclobutenecyanine salt *(68)* and 65 % of the allene amidinium salt *(69)*. The two salts can be separated by crystallization. Pyrolysis of *(69)* leads to dealkylation and formation of the allene-amidine *(70)*, whereas the cyanine salt *(68)* decomposes to give aminocyclobutenimine *(71)*.

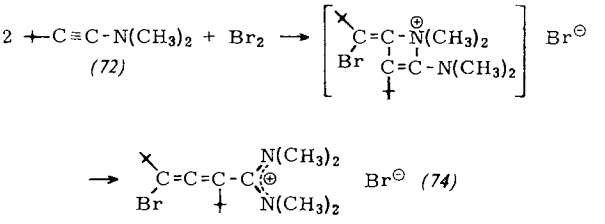
[59] *R. Buijle* and *H. G. Viehe*, unpublished.

[60] *R. B. Woodward* and *R. A. Olofson*, J. Amer. chem. Soc. *83*, 1007 (1961); Tetrahedron Suppl. No. 7, 415 (1966).

[61] *H. G. Viehe, R. Buijle, R. Fuks, R. Merényi*, and *J. M. F. Oth*, Angew. Chem. *79*, 53 (1967); Angew. Chem. internat. Edit. *6*, 77 (1967).



As can be seen from the above scheme, the compounds *(70)* and *(71)* are also obtained as by-products in the synthesis of ynamines from t-butylchloroacetylene and trimethylamine (which is described in Section 3.4.). On slow addition (to avoid amide chloride formation and side reactions) of strong acids to the ynamine *(72)*, the only product formed in the presence of tertiary amines, *e.g.* dimethylaniline, is the salt *(73)* (yield 95 %) corresponding to the cyclobutene cyanine *(68)* – the reaction probably takes this course for steric reasons [53].



(72) *(73)*, 95%

The cyclobutene cyanine can be readily synthesized in the presence of HBF_4 even without special precautions [49,61], possibly because the weakly nucleophilic $BF_4^{\ominus}$ anion makes the conversion of the ketene-iminium structure *(65)* into the less polar enamine structure *(66)* impossible.

A number of phenylethynyldialkylamines react smoothly with strong acids to form the corresponding cyanines, which can be converted into bromine derivatives *(73)* by treatment with *N*-bromosuccinimide (NBS); *(73)* can also be obtained by direct bromination of the ynamine in dioxane [53]:

Bromination of the t-butylethynylamines instead of the phenyl compounds leads to only the allene amidinium salts *(74)* in yields of up to 87 %; this is apparently due to steric factors [53].

(74)

I am grateful to Prof. Weygand for stimulating discussions and for the exchange of information on peptide reactions and to Prof. Jacqueline Ficini for interesting discussions and for the communication of unpublished results. I should also like to express my thanks to my colleagues, particularly R. Buijle, S.Y. Delavarenne, E. Franchimont, R. Fuks, A. Gerondal, A. Halleux, A. Hubert, M. Reinstein, W. Rennerts, and P. Valange, for their valuable contributions.

Spatial Arrangement and Preparative Organic Synthesis

BY L. VELLUZ, J. VALLS, AND J. MATHIEU [*]

This review deals with the stereoselective formation of organic compounds. A number of examples of such syntheses, especially those of alkaloids and steroids, are described. An asymmetric synthesis, which avoids the intricacies and wastefulness of optical resolution, has been successful in a few cases only. The procedures of configurational change and of optical resolution, as well as the planning of multi-step stereoselective syntheses, are discussed.

From a technical or economic point of view the total synthesis of sterically intricate carbon compounds has become so important that a new field of preparative stereochemistry has been established which embodies a number of specially developed techniques. This is especially the case in the syntheses of alkaloids and antibiotics, and above all in the plant-scale production of hormonal steroids [1].

Three possible approaches are open for the synthesis of an optically active isomer of a compound having several asymmetric centers:

a) As is the case for most of the syntheses described in the literature, the reactions can be performed stereoselectively in the racemic series, optical resolution then being undertaken only at the end of the reaction sequence.

b) Conversely, for preparative purposes it is desirable to exclude unwanted optical isomers at the earliest possible stage, thus avoiding the expense, in time and effort, of having to treat a reaction mixture laden with products of no interest.

[1] *L. Velluz, J. Valls,* and *G. Nominé*, Angew. Chem. 77, 185 (1965); Angew. Chem. internat. Edit. 4, 181 (1965).

c) The resolution problem can be theoretically avoided by asymmetric synthesis, but this promising method has not yet been applied on a truly preparative scale.

Thus it is only after a thorough study of the stereochemical possibilities that the chemist finally adjusts the sequence of the reactions, usually after a consideration of convergence, and the economics involved.

The present paper is devoted to the study of this practical aspect of the relations between spatial arrangement and preparative organic synthesis.

In addition to examples taken from the literature we have referred in several instances to investigations concerning the total synthesis of steroids that have been carried out at our research center during the past ten years[1], and in which measurements of optical circular dichroism[2,3] contributed to the solution of a number of stereochemical problems.

I. Selective Creation of Chiral Carbon Atoms[*]

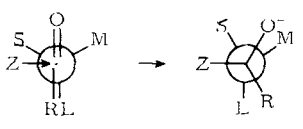
Asymmetric centers arise mostly as the result of a conversion of trigonal carbon atoms into tetragonal ones at the site of unsaturated functions such as carbonyls, enols, enamines, and at isolated or conjugated olefinic double bonds.

In order to predict the stereochemical course of these conversions, the following factors must be considered:

a) Initial conformation of the molecule.

b) Ease of approach of reagents.

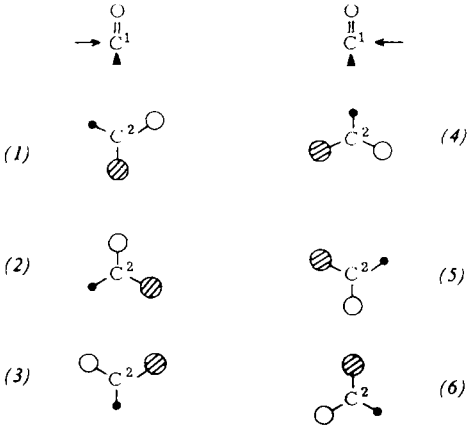
c) Energy of the transition states.



d) Stability of the reaction product.

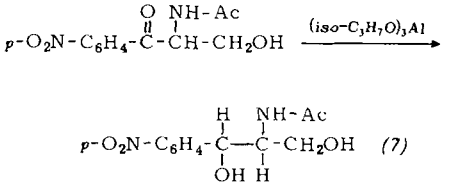
It is necessary also to consider the stereochemical possibilities offered by

e) indirect methods.



a) Initial Conformation

The importance of the initial conformation of the molecule is illustrated by the semi-empirical rule of *Cram*[4], according to which the preponderant isomer is the result of attack from the least hindered side, *i.e.* as in Scheme 1 when the carbonyl group is already situated between the two smallest substituents.



Scheme 1. Relation between direction of attack and size of substituents. S = smallest, M = medium sized, and L = largest substituent.

However, it must be noted, with respect to the six characteristic conformations of a carbonyl compound whose α-arbon atom bears three groups of different size, that the attack on the conformations *(2)* and *(3)* from the least hindered side would yield the same isomer as that resulting from attack on *(1)*, whereas the other epimer would result from an attack, under the same conditions, on a conformation such as *(4)*, *(5)*, or *(6)*.

In other respects, Cram's rule must be modified if a substituent complexes the reagent and thereby enforces a particular conformation at the time of attack[4–7].

This influence is especially encountered in the synthesis of chloramphenicol where it favors formation of the intermediate *(7)* in the *threo* form[8].

Johnson and *Malhotra* have also shown the importance of the initial conformation of the molecule in cyclic compounds and in the case of exo- or endocyclic enols[9,10]. In structures of type *(8)*, steric interaction between R and Z leads to a conformational inversion where R becomes axial. This phenomenon was utilized for a total synthesis of antibiotics of the cycloheximide series such as *(10)*, where the final configuration resulted from the acylation of an enamine in a half-chair conformation of the type *(8b)*[11,12]. The form

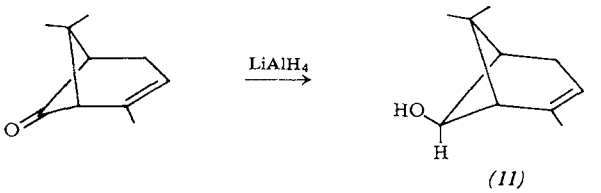
(9a) *(9b)*

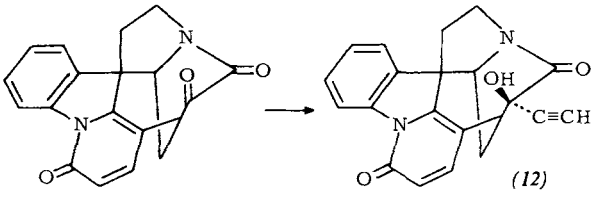
(10)

(9b) corresponding to *(8b)* is formed by the prior epimerization of the 2-methyl group from the equatorial α-orientation to the β-axial orientation.



b) Ease of Approach of Reagents

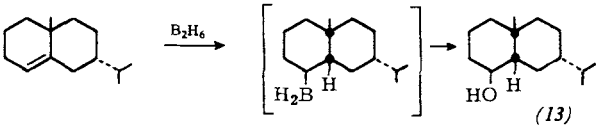
The influence of steric factors on the approach of reagent has been studied, especially by *Barton* and *Dauben*. However, it remains a subtle and much-discussed problem, even in such simple cases as the cyclohexanones [1, 13–16].



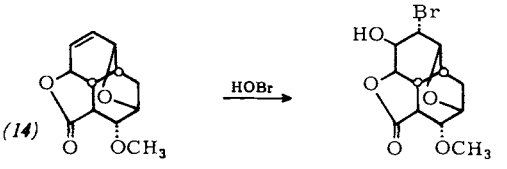
From the preparative point of view, however, the presence or absence of hindrance on one side of the molecule remains the safest means of governing the direction of attack.

In the case of the carbonyl compounds the difference of accessibility allows selective reactions, *e.g.* in a reduction step of the synthesis of chrysanthenol *(11)* [17] or an ethynylation step in the synthesis of an intermediate of strychnine *(12)* [18], to take place.

At the site of olefinic double-bonds this steric factor acts as well for *cis* reactions, such as the stereoselective hydroboration to give the intermediate *(13)* in the synthesis of valeranone [19] as it does for *trans* reac-

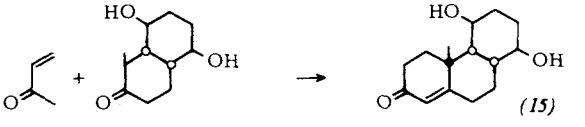


(11)



(12)

tions. Its importance in *trans* reactions is exemplified by the synthesis of reserpine [20] where the hindrance of the concave side of a folded molecule *(14)* leads to attack of the convex side.



(13)

(14)

The folding of molecules can also determine the mode of attack in reactions of enols, as is shown by *Sarrett*'s synthesis of cortisone, where the tricyclic structure *(15)* is obtained *via* a stereoselective attack of this type [21].

(15)

In the presence of polar substituents unexpected stereoisomers may be formed if the polar assistance prevails over steric influences. This phenomenon has been studied by *Henbest* and others for the attack on olefins by peracids [22–24] or by carbenes [25–28]. It was

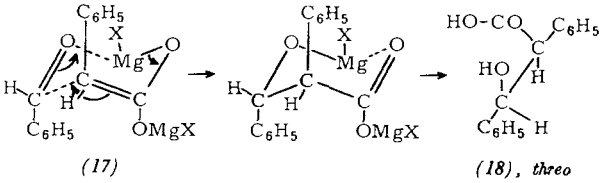
[28] *R. Ginsig* and *A. D. Cross*, J. Amer. chem. Soc. *87*, 4629 (1965).

applied in an essential step of the synthesis of thujopsene [29].

A similar example of an hydroxyl-assisted reaction has been used by *Woodward* for the reduction of an intermediate product at the most hindered side of the molecule during the synthesis of strychnine [18]. Another example is provided bythe inversion of the direction of alkylation of a bicyclic derivative *(16)* under the directing effect of a carbethoxyl group [30].

(16)

c) Energy of the Transition States

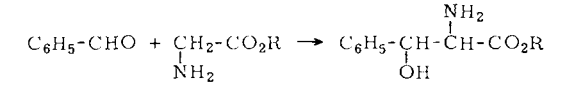


A number of transition states correspond to the different possible modes of approach of the reagent. The structure of the energetically favored state often plays a decisive role in the stereochemistry of the addition of reagent. Furthermore, according to the Curtin-Hammett principle this role is in general more important than the influence of the initial conformation of the molecule.

Accurate analysis of the transition states corresponding to the transformation of unsaturated functions is not possible because of the lack of knowledge of their true nature. Too little is known about the degree of hybridization of the atoms which can be either close to the initial trigonal state or close to the final tetragonal one.

Nevertheless, despite these difficulties an approximate analysis is often possible [1]. The energy level of these transition states depends on the stereoelectronic factors originating from the principle of maximum overlap of the reacting orbitals, and on steric or polar interactions which lead to internal and torsional stress.

Thus, steric interactions occur at the level of the transition state of hydroxy-alkylation reactions of acyclic compounds, according to a scheme whose general validity was emphasized by *Toromanoff* [31].



An example of this is the condensation of the magnesium enolate of phenylacetic acid with benzaldehyde where the

(17) *(18), threo*

intermediate state *(17)*, in which the remoteness of the two phenyl groups reduces steric interaction, is favored and leads to the *threo* compound *(18)* [32].

These concepts are applicable to condensations between aromatic aldehydes and glycine derivatives (sodium salts or esters) which yield derivatives of phenyl serine [33, 34, 35]. This type of condensation occurs in a synthesis of chloramphenicol [36, 37].

(19), threo

During our investigations on cyclic compounds *Valls* and *Toromanoff* analysed the stereochemistry of the attacks on cyclohexane enols and olefins already studied by *Corey* [38]. *Valls* and *Toromanoff* considered the conformations of the transition states according to the underlying steric, polar, and stereoelectronic interactions. It is well known that this study has led to the concept of "antiparallel" and "parallel" attack [1, 39]. These modes of attack play a part *e.g.* in the total synthesis of steroids, especially in the creation of the asymmetric centers at C-10 and C-13 [1].

The alkylation of the 13-position of D-homo-18-nor-steroidal structures, studied by *Johnson* during the "hydrochrysene synthesis", shows especially that its stereochemical course can be controlled by influencing the transition-state conformation. This effect is obtained by the introduction of a double-bond into ring C; the results are readily interpreted with the aid of the theoretical concepts proposed by *Bucourt* [1].

Toromanoff stressed that stereochemical control of the transition states in the case of reactions of α,β-ethylenic carbonyl functions is of still more importance, both when 1–4 and when 1–2 additions are involved [40, 41].

Such stereochemical control is evident in the 1,2-addition of hydride ion to 3,5-dimethyl-2-cyclohexen-1-one *(20)*, which leads to a preponderance of the *cis*-isomer (anti-parallel attack) [42], and in the 1,4-addition of methyl magnesium iodide to 5-methyl-2-cyclohexen-1-one *(21)* [43], where the perpendicular anti-parallel attack on the most stable envelope form [*]

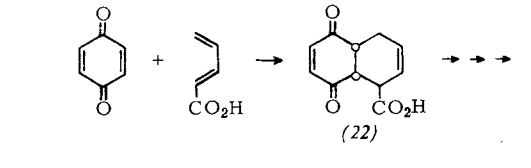
(CH_3 equatorial) favors access to an enolate in half-chair form. The steric aspects of a great number of angular alkylations of polycyclic derivatives of this type can be interpreted in a similar manner.

(20) cis, 90% trans, 10%

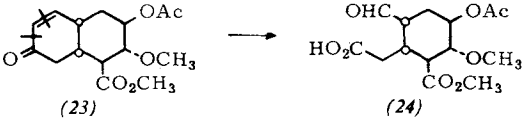
(21) 95% 5%

d) Stability of the Reaction Product



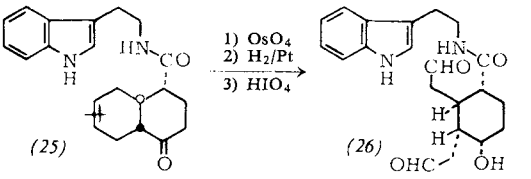
The action of various stereochemical factors at the site of the attacked conformation, the influence of approaching reagents, and the energy of transition states, lead to a primary product the steric structure of which is not necessarily in agreement with that of the thermodynamically most stable isomer. If the structure of this thermodynamic isomer differs from that of the primary "kinetic" product, one must take into account the conditions of the reaction. If a reversible reaction is possible and if the reaction conditions lead to an equilibrium, the "kinetic" product is converted to the "thermodynamic" isomer which can then be isolated.[1]. This aspect of the epimerization problem will be discussed in Section III.

e) Indirect methods



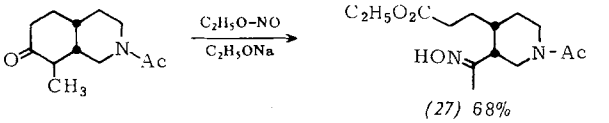
An ingenious method for the synthesis of a stereochemically complex molecule is that which involves the insertion of asymmetric carbon atoms into a rigid polycyclic system in which the supplementary rings are cleaved at a later, and suitable, time. This method is all the more avdantageous as some cyclization reactions are themselves highly stereoselective, for example the diene synthesis and the cyclization of polyenes.

Thus in the total synthesis of reserpine according to *Woodward*[20], the configurations of the five asymmetric centers of the monocyclic derivative *(24)*, the key product of the synthesis, have been obtained by transformation of the derivative *(22)* (obtained by diene synthesis) into *(23)*, followed by cleavage of the latter.

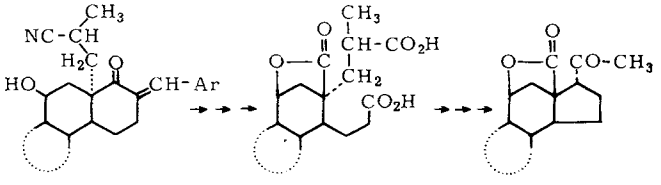


The same type of transformation is used in many other syntheses of alkaloids. In a synthesis of yohimbine by *Van Tamelen*[44] the intermediate *(26)* necessary for the formation of rings C, D and E has been obtained by oxidative cleavage of the derivative *(25)*.

(22)



(23) (24)



(25) (26)

The synthesis of quinine[45] affords another similar example of formation of a monocyclic compound *(27)* having two side chains in a *cis* configuration.

(27) 68%

In the steroid field this method has been used for the construction of the C,D-*trans*-hydrindan structure from the C,D-*trans*-decalin derivatives. *Johnson*'s "hydrochrysene synthesis" (cf. Section 1c)[1], and an aldosterone synthesis[46], in which a carbon atom of the chain introduced at 13α becomes part of the five-membered ring, serve as examples.

A similar example is the indirect method for the angular introduction of a carboxylic function in the synthesis of a derivative of podocarpanone[47].

II. Optical Resolution

In the synthesis of a natural product the main problem is the obtention of the desired compound in exactly the same structural form in which it occurs in nature.

Each of the three main methods of resolution have been used for preparative purposes (cf.[48–56]):

[44] *E. E. VanTamelen, M. Shamma, A. W. Burgstrahler, J. Wolinsky, R. Tamm*, and *P. E. Aldrich*, J. Amer. chem. Soc. *80*, 5006 (1958).

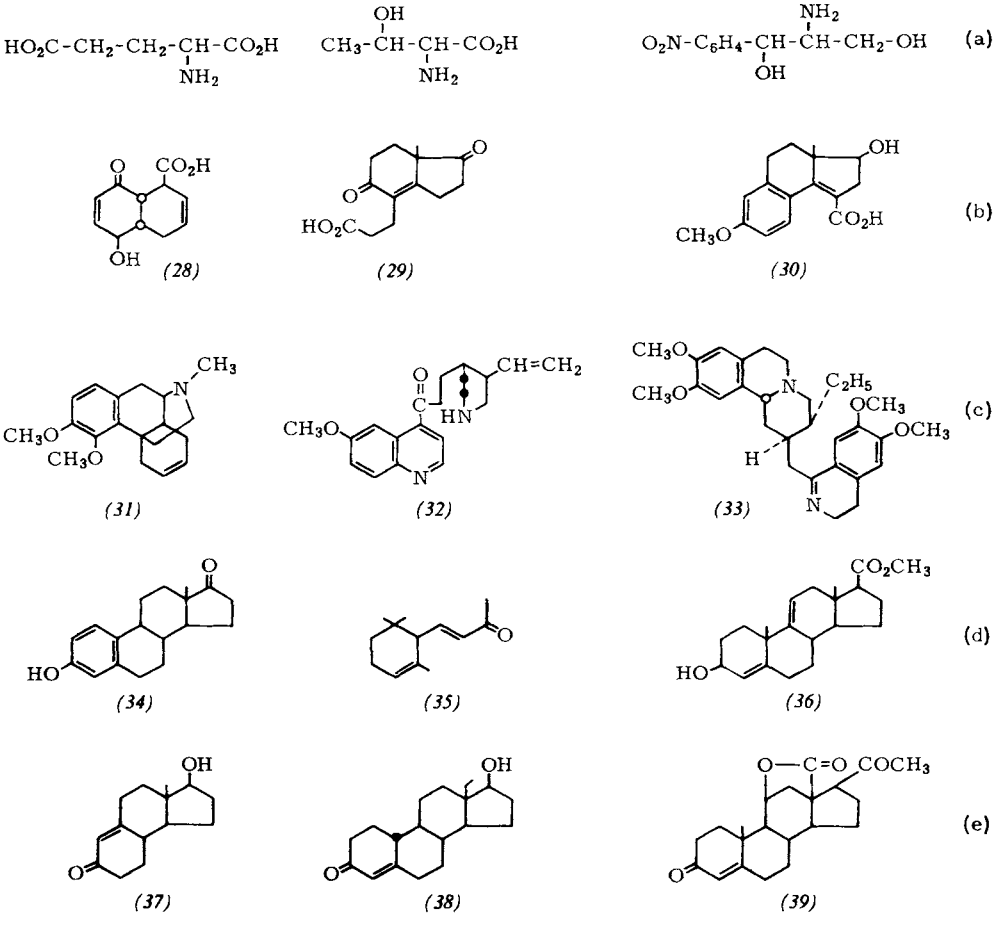
a) Methods without asymmetric agents.

b) Methods involving formation and separation of diastereoisomers.

c) Methods using selective reactions.



a) Methods without Asymmetric Agents

The method of selective crystallization has been used for the resolution of adrenaline[57] and histidine stereoisomers[58]. The entrainment method[*], which is insensitive to extraneous seed crystals, ensures a reliability and reproducibility that is not encountered in the inoculation method.

The method of entrainment is recommended by *Velluz*, *Amiard*, and *Joly* for the resolution of the racemic base of chloramphenicol[59]. In spite of some limitations relating to the solubility parameters of the products[60] this method has many interesting applications, such as in the resolution of threonine[61] and of other amino acids[62,63].

b) Methods Involving Formation and Separation of Diastereoisomers

Since the time of *Pasteur*, by far the most generally used methods of optical resolution have been those involving the formation and separation of diastereoisomers with the aid of optically active bases or acids. An example

of such a resolution is that which was carried out by *Pasteur* as long ago as 1853, when he resolved tartaric acid with the aid of the alkaloid base quinotoxine [64]. The underlying principle of this method has, during a century or more, given rise to countless variants currently used in both laboratory and industrial syntheses. Ephedrine and the intermediate base in the synthesis of chloramphenicol are especially valuable for the resolution of the intermediates *(28)–(30)* in the total synthesis of reserpine derivatives [65], and of steroid hormones [66,67], on a large scale (see Scheme 2).

Resolution with the aid of an active acid is based on the same principle; however, the occurrence in nature of active acids is much scarcer than that of alkaloids. Apart from tartaric acid, which for a long time permitted the resolution of cocaine [68] or adrenaline [69], the only acid which has found favor in optical resolution has been dibenzoyltartaric acid. This acid was chiefly used for the resolution of the intermediates *(31)–(33)* at the end of the total synthesis of morphine [70], of quinine [45], and of emetine [71]. β-Camphorsulfonic acid has been used for the resolution of sparteine [72] and of the free amine of chloramphenicol [36]. It is well known, however, that the use of these general methods is rarely devoid of difficulties.

With non salt-forming molecules diastereoisomeric compounds such as esters or hydrazones must be prepared. Thus synthetic estrone *(34)* has been resolved with the aid of menthoxyacetic acid [73]. Menthyl carbazate permits the resolution of α-ionone *(35)* [74]. α,β-Unsaturated carbonyl compounds can be converted into iminium salts that are stable enough to be resolved with camphorsulfonic acid [75]. Sometimes the formation of molecular complexes can be utilized; for example, those formed with digitonin, which have permitted the resolution of the synthetic steroid *(36)* [76].

c) Methods Using Selective Reactions

Selective methods in which an enantiomer reacts either alone or at least in a predominant amount with an optically active reagent have found only few applications, although *Marckwald* [77] described, as early as early as 1899, the esterification of (–)-menthol with the dextrorotatory enantiomer of mandelic acid. The well-known specificity of enzymatic reactions has, however, been used in the steroid field to convert selectively only one of the two enantiomers of tricyclic intermediates such as *(37)* [78], as well as of tetracyclic derivatives such as *(38)* [79] or *(39)* [80].

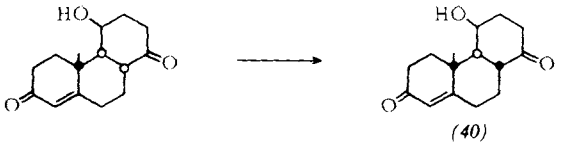
III. Steric Correction

There are two kinds of steric correction; it may often be necessary to convert one diastereoisomer into another diastereoisomer (epimerization) or to recover the unwanted optical antipode after a resolution (racemization).

a) Epimerization

In the course of a synthesis, a diastereoisomer can be formed which differs in structure from the desired product in respect of the configuration of one or sometimes of several asymmetric centers. This drawback is often overcome with the aid of adequate steric corrections. Such epimerizations are easy in the case of reversible reactions if the product obtained under kinetically controlled conditions is to be converted into the thermodynamically more stable isomer (cf. Section 1d). This can be readily achieved under equilibrium conditions.

Epimerization generally involves the conversion of a tetragonal asymmetric carbon atom through an intermediate trigonal state back to a tetragonal state of the most stable configuration. This reaction sequence can be performed by keto-enol tautomerism, by oxidation-reduction, or by cleavage-condensation either directly on the "kinetic" product or indirectly on a simple derivative of the latter. Although these conversions lead nearly always to the most stable structure, the least stable epimer can sometimes be obtained from the stable one by selective inversion of a suitable derivative (cf. Section 1a).



1. The epimerizations of substituents α to the carbonyl group by keto-enol tautomerism are classical methods which have been successfully applied to the total synthesis of steroids *(40)* [21] or alkaloids *(41)* [18].

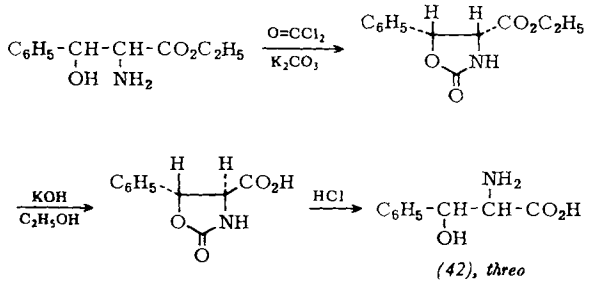
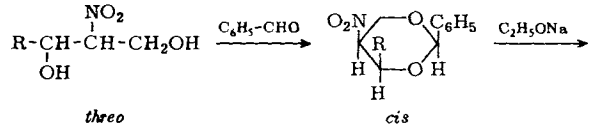
[80] *E. Vischer, J. Schmidlin*, and *A. Wettstein*, Experientia *12*, 50 (1956).

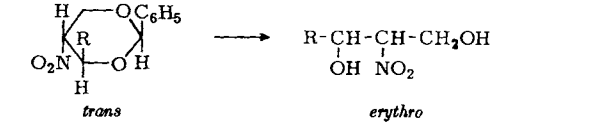


(40)

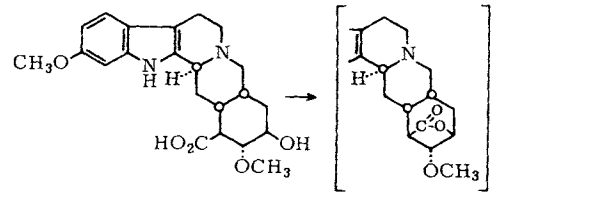


(41)

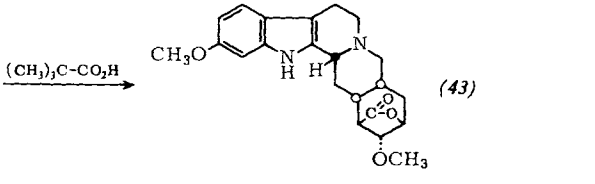
Similarly hydrogen atoms activated by an indole ring can give rise to equilibria. Thus alloyohimbane can isomerize into epialloyohimbane[81] or reserpine into 3 iso-reserpine[82]. A phenomenon of the same kind has been utilized in the synthesis of emetine in order to separate either of the two interconvertible diastereoisomers as insoluble salts[83].



The indirect epimerization by keto-enol tautomerism of a simple derivative of the molecule involved has



(42), *threo*

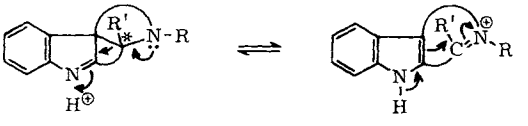


threo *cis*

trans *erythro*

(43)

been especially applied to phenylserine derivatives (*e.g.* intermediate *(42)* in the synthesis of chloramphenicol[84]), to a sphingosine synthesis described by *Grob*[85], and to the reserpine series at the intermediate lactone *(43)*[86].



A more subtle epimerization, which in the case of α-substituted cyclohexanones allows the conversion of one epimer to the least stable isomer, takes advantage of the preferential conformation of an enamine intermediate with an axial α-substituent, the mild hydrolysis of which affords the least stable ketonic epimer. This type of epimerization has been utilized especially in the synthesis of antibiotics of the cycloheximide type (cf. Section 1a).

2. Reversible redox reactions are often the source of epimerization.

Thus, the reduction of a carbonyl group with aluminum alkoxide, by perpendicular attack on the most accessible side of the molecule, may yield the "kinetic" alcohol which can be converted into the "thermodynamic" alcohol. Similar equilibria are obtained with certain alcohols in the presence of a base, a ketonic intermediate being formed. This phenomenon has been known for a long time with regards to both acyclic and cyclic compounds. It has been applied to the synthesis of chloramphenicol, an L-*erythro* derivative being converted to the D-*threo* compound by permanganate oxidation followed by calcium borohydride reduction[87].

A well known example of its application in the cyclic series of compounds is, among others, the epimerization of yohimbine (axial 17-OH → equatorial 17-OH) on treatment with t-butoxide[88].

3. The reversibility of a few condensation reactions is also used for the creation of asymmetric centers that correspond to a more stable structural unit. The reversibility of the Mannich reaction enables equilibrations of the type *(44)* ⇌ *(45)*, especially in the alkaloid field, *e.g.* in the synthesis of strychnine[18], of akuammicine[89], and of aspidospermine[90].

(44) (45)

Similarly, the reversibility of the Micheal reaction often permits, as in the case of the synthesis of emetine[71], the epimerization of the primary "kinetic"

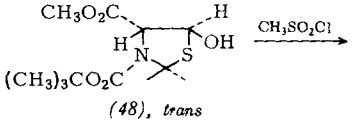
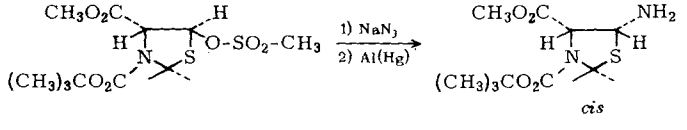
(46), trans

products (formed by 1,4- and 1,6-additions) to the more stable isomers such as *(46)* [91–93] in 76 % yield.



4. S_N2-substitution reactions can be considered as indirect methods for the inversion of an asymmetric center but it is beyond the scope of the present review to deal with this question as a whole. Only a few examples are given of the application of such reactions.

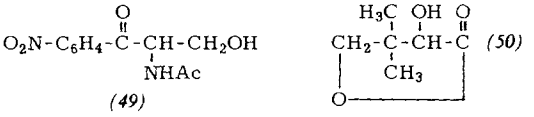
In the synthesis of chloramphenicol the *erythro*⟶*threo* conversion is achieved by an S_N2 substitution of a cyclic intermediate *(47)* [94,95] or otherwise by an intramolecular substitution obtained *via* cyclization and subsequent ring cleavage [96].



erythro *(47)* *threo*

Another example is *Woodward*'s recent synthesis of cephalosporin C, where the configuration of an asymmetric center of the intermediate *(48)* is changed by S_N2 substitution [97].

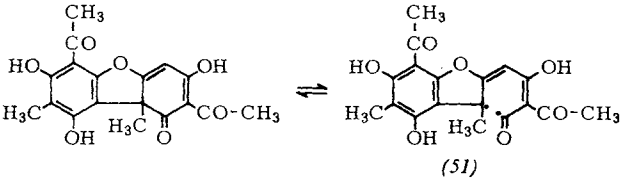
(48), trans



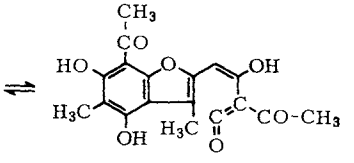
cis

b) Racemization

A study of the methods available for the racemization of a non-natural isomer is, of course, an essential feature of preparative total synthesis because it is theoretically possible for the total yield to be doubled with respect to the amount of starting material involved.

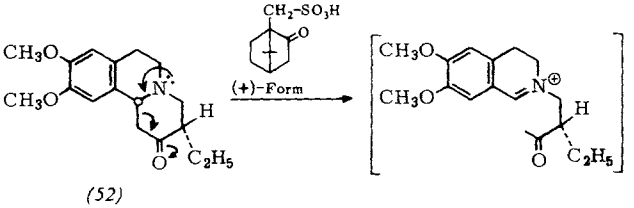


1. If the molecule possesses only one asymmetric carbon atom, racemization, like epimerization, is mostly achieved *via* an intermediary plane trigonal carbon atom (cf. Section IIIa). In the synthesis of chloramphenicol [98] or of pantothenic acid [99] intermediate products such as *(49)* or *(50)* are thus recovered by enolization.

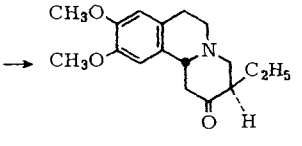


(49) *(50)*

The racemization of compounds by redox reactions especially in secondary alcohols, has been studied by *Doering* [100].



Racemizations are sometimes obtained by cleavage, followed by cyclization of an achiral intermediate; this is the case in the racemization of usnic acid *(51)* [101].



(51)

2. If the molecule possesses several asymmetric centers a racemization is rarely achieved. An example, however, is in the synthesis of emetine; a tricyclic intermediate *(52)* is formed which can be racemized quite successfully by cleavage and re-cyclization [102] (yield of optically active product 80 % referred to original racemate).

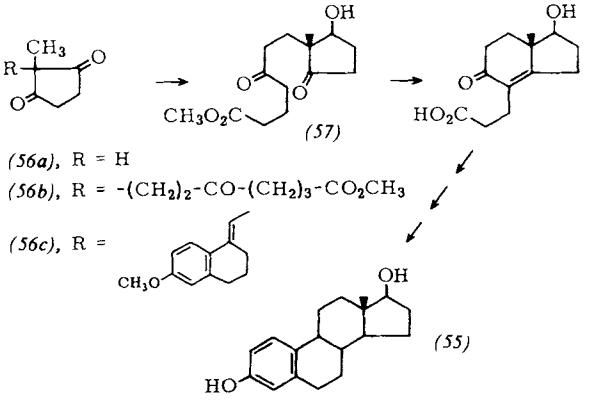
IV. Asymmetric Synthesis

Many organic chemists have investigated the problem of direct synthesis of optically active compounds without optical resolution [*], and interest in such a topic has been greatly enhanced by the progress that has been made in the total synthesis of natural products. Asymmetric synthesis may be defined as the creation of a chiral molecule from an achiral or prochiral molecule. This definition excludes the above mentioned selective reactions, which are carried out on antipodes already contained in a racemic product and which belong to the sphere of optical resolution (cf. Section II).

There are two types of method in use in asymmetric synthesis – direct methods and indirect methods. The direct methods involve the reaction of an asymmetric agent with a symmetric molecule. On the other hand the indirect methods require the preliminary attachment of an asymmetric link which must specifically induce the action of a symmetric agent. From an academic point of view, a poor yield of the desired product may be tolerated, but for a synthesis to be useful for preparative purposes it must ensure relatively good yields of a product of high optical purity.

a) Direct Asymmetric Syntheses

Stereospecific reactions with the aid of asymmetric catalysts have been attempted on several occasions. An example of this type of reaction is the catalytic hydrogenation of ketones such as *(53)* with Raney nickel pretreated with amino or hydroxy acids [112]. Camphorsulfonic acid induces asymmetry in the cyclization of a chalcone *(54)* [113].



(53)

(54)

Another example is the use of quinine as a catalyst for the condensation of ketene with an alcohol, which at low temperature leads to the formation of optically active esters [114].

Worthy of special mention is enzymatic catalysis, which is highly selective and which is of especial use in the preparative reduction of carbonyl functions of achiral molecules. For example it can be used for the preparation of (–)mandelic acid from benzoylformic acid [115] and of L-malic acid from oxalacetic acid [116]. We have shown how the selective action [117] of enzymes on prochiral melecules may be used with advantage in the total synthesis of steroids [118]. It permits access to natural estradiol *(55)* from methylcyclopentanedione *(56a)* on a preparative scale and without optical resolution. The reduction of *(56b)* by *Rhizopus arrhizus* leads to an intermediate *(57)* having its two asymmetric centers in the configuration of natural steroids. A similar method using *Saccharo myces uvarum* for the reduction of an analogous prochiral derivative *(56c)* has been described [119].

Asymmetric reagents have been developed principally for the reduction of carbonyl derivatives. As early as 1946, *Vavon* obtained especially favorable results with various terpenic Grignard compounds [120, 121]. *Mosher* [122] extended the use of the method to simpler organomagnesium compounds such as the 2-methylbutylmagnesium halide. The transfer of the asymmetry of the Grignard compound to the carbonyl group must take place within a pseudocyclic transition state [123, 124].

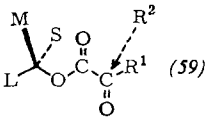
[123] *R. MacLeod, F. S. Welch*, and *H. S. Mosher*, J. Amer. chem. Soc. *82*, 876 (1960).

[124] *W. M. Foley, F. J. Welch, E. M. LaCombe*, and *H. S. Mosher*, J. Amer. chem. Soc. *81*, 2779 (1959).

The use of asymmetric alcoholates in the Meerwein-Ponndorf method also induces asymmetric reductions. The same is true for mixed alkoxyaluminum hydrides, which are obtained by the reaction of optically active alcohols with lithium aluminum hydride. According to *Cervinka* [125,126] however, only the use of amino alcohols gives good results.

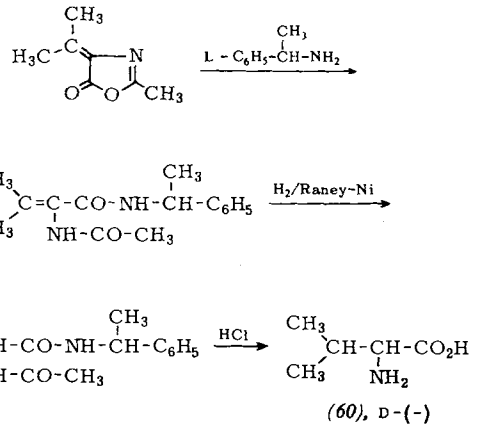


Another especially useful reagent has been prepared by *Brown* by the reaction of two molecules of α-pinene with diborane. The reaction of such a reagent on *cis*-3-hexene is highly stereoselective; after oxidation of the intermediate borane compound, the optical purity of the alcohol *(58)* obtained amounts to 90 % [127,128].

(58)

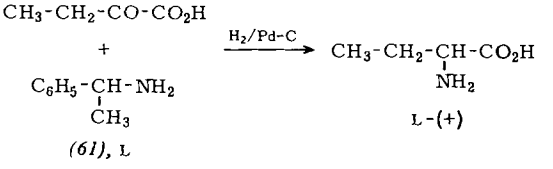
b) Indirect Asymmetric Synthesis

In the indirect methods an optically active link, which can be easily cleaved afterwards, must be attached to the molecule bearing the trigonal carbon atom. As early as 1904, McKenzie synthesized mandelic acid by esterification of benzoylformic acid with menthol followed by reduction with aluminum amalgam and subsequent hydrolysis [129]. This method has been extended to the condensation of Grignard compounds with α-keto esters of optically active alcohols. But it was the work of *Prelog* [130] that first permitted a rationalization of these results by assuming a selective attack of the molecule from the least hindered side of the conformation *(59)*.



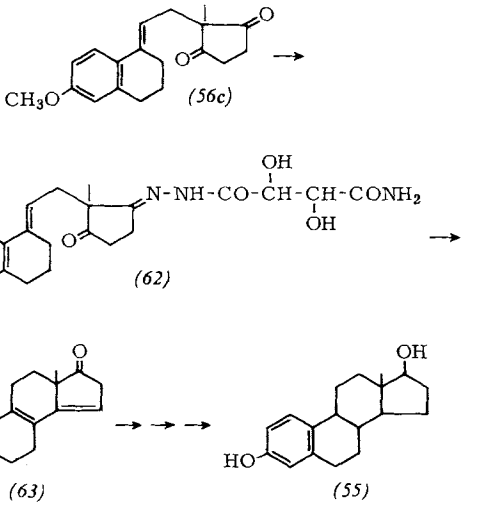
(59)

S = small, M = medium, L = large.



The optical yield varies with the asymmetry of the inducing alcohol; it attains 66 % in the case of 1-(2,4,6-tricyclohexylphenyl)ethanol.

The same general principle is also used for the preparation of optically active valine *(60)* from the corresponding azlactone [131].



(60), D-(-)

An elegant synthesis of an amino acid involves the condensation of an α-keto acid with L-aminoethylbenzene followed by hydrogenation and hydrogenolysis [132].

(61), L

Finally, according to recent observations [133] one can utilize, in the total synthesis of an asymmetric steriod on a preparative scale, the preferential formation of one of the two compounds *(62)*, which arise in the reaction of a tartramic hydrazide with a carbonyl group of the prochiral compound *(56c)*. Cyclization and hydrolysis of *(62)* leads to the derivative *(63)*, which has a "natural" configuration and can be converted by conventional methods into estradiol *(55)*.

(56c) *(62)* *(63)* *(55)*

V. Linear versus Convergent Synthesis

From the point of view of the most economical use of raw materials, of reagents, and of man-power, two types of synthesis must be considered:

[125] *O. Cervinka*, Collect. czechoslov. chem. Commun. *30*, 1684 (1965).

[126] *O. Cervinka, S. Suchan*, and *B. Masar*, Collect. czechoslov. chem. Commun. *30*, 1693 (1965).

[127] *H. C. Brown* and *G. Zweifel*, J. Amer. chem. Soc. *83*, 486 (1961).

[128] *G. Zweifel, W. R. Ayyangar*, and *H. C. Brown*, J. Amer. chem. Soc. *84*, 4342 (1962).

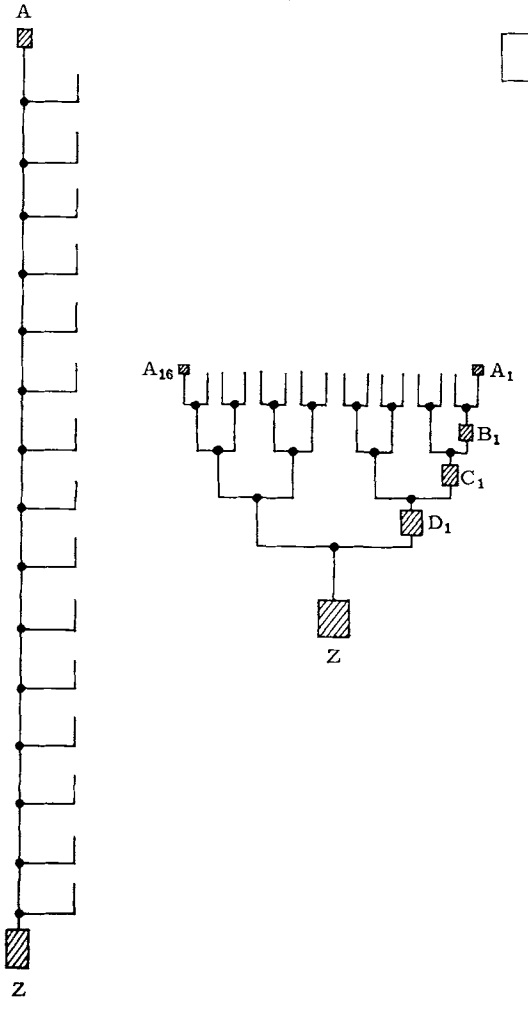
[129] *A. McKenzie*, J. chem. Soc. (London) *85*, 1249 (1904).

[130] *V. Prelog*, Bull. Soc. chim. France *1956*, 987.

[131] *J. C. Sheehan* and *R. E. Chandler*, J. Amer. chem. Soc. *83*, 4795 (1961).

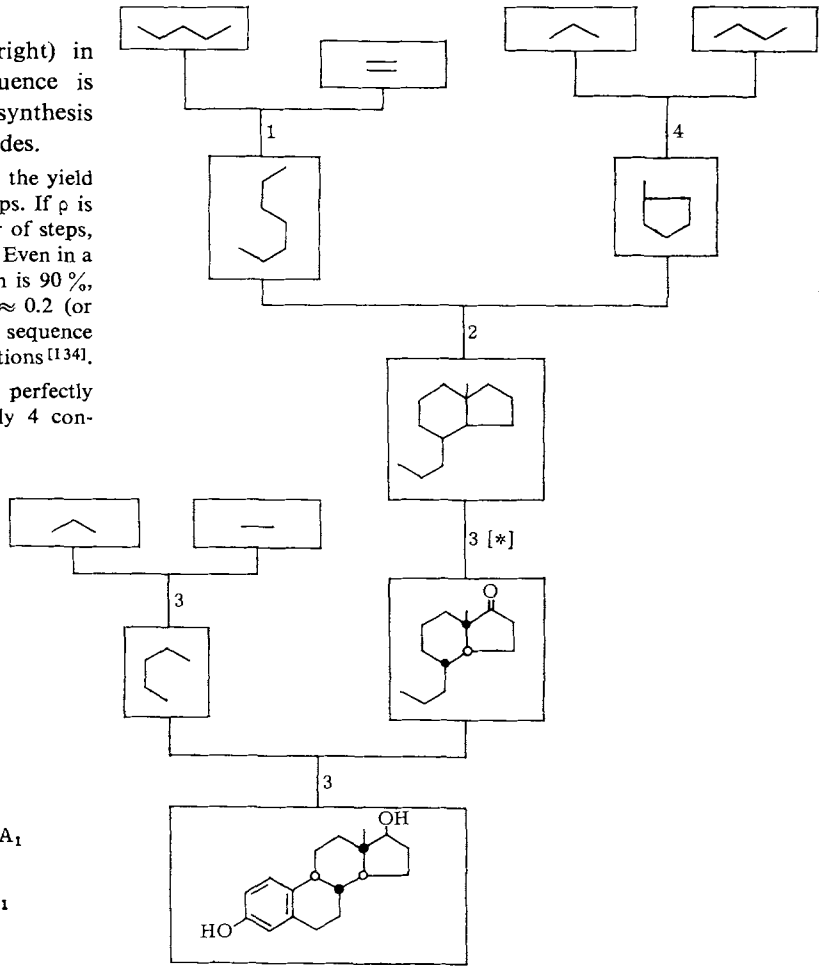
[132] *R. G. Hiskey* and *R. C. Northrop*, J. Amer. chem. Soc. *83*, 4798 (1961).

[133] *R. Bucourt, L. Nedelec, J. C. Gasc*, and *J. Weill-Raynal* Bull. Soc. chim. France *1967*, 561.



a) Linear syntheses (see Scheme 3, left) in which the starting product is gradually converted by the stepwise introduction of the elements of the final structure through a linear reaction sequence. Schemes of this nature are generally encountered in the partial syntheses of steroids, especially in the formation of cortisone-like structures.

b) Convergent syntheses (see Scheme 3, right) in which each product of the reaction sequence is obtained from two precursors. This type of synthesis is in frequent use in the preparation of peptides.



It is well known that in a given reaction sequence the yield R drops rapidly with the number of successive steps. If ρ is the mean yield of each reaction and n the number of steps, the over-all yield is given by the expression $R = \rho^n$. Even in a sequence in which the mean yield of each reaction is 90 %, the over-all yield after 15 steps drops to $(0.9)^{15} \approx 0.2$ (or 20 %). It is therefore desirable to split up the longest sequence as far as possible and to divide it into convergent sections [134].

If it were possible to arrange the 15 steps in a perfectly convergent pattern, the sections would have only 4 consecutive steps and the starting materials would be converted to the final product with a yield of $(0.9)^4 \approx 65$ %.

It is difficult to reach a perfect convergence; on the one hand the steps involving simple changes of intermediates are necessarily linear and on the other the requirement, on steric grounds, for a sort of asymmetric backbone on which achiral fragments can be grafted must be provided for.

Scheme 3. Left: Linear synthesis. Right: Convergent synthesis. A = Starting materials, Z = end product.

Scheme 4. Total synthesis of estradiol, schematic. The figures between the individual stages indicate the number of reaction steps.

[*] Optical resolution here.

An example of a compromise between all these requirements is shown in the total synthesis of estradiol, which was recently carried out by *Velluz, Nominé, Amiard et al.* [67] (Scheme 4). Six starting products require a total of twenty reaction steps (exclusive of the resolution). Five steps are condensation reactions and fifteen are simple intermediate changes. The convergence is obvious since the longest sequence includes only three condensation steps and ten consecutive steps involving simple reactions.

The Active Species in Homogeneous Ziegler-Natta Catalysts for the Polymerization of Ethylene[**]

BY G. HENRICI-OLIVÉ AND S. OLIVÉ [*]

Cp_2TiCl_2 and $Cp_2TiEtCl$ (Cp = cyclopentadienyl, Et = ethyl), in combination with aluminum alkyls, have been studied as model catalyst systems for the polymerization of ethylene in toluene. The activity of these systems resides in the presence of a complex molecule involving an alkylated Ti(IV) and an alkylated Al species, linked together by chlorine bridge bonds. The environment of the Ti is of octahedral symmetry with one vacant site available for the coordination of ethylene. The bridged Al-alkyl causes a destabilization of the Ti-alkyl bond ("trans effect"), thus rendering it active for polymerization. The reduction Ti(IV) → Ti(III), inevitable in these systems, involves the irreversible change from octahedral to tetrahedral symmetry with loss of the catalytic activity. Polymerization and reduction are supposed to occur at the same catalyst site. Magnetic methods (susceptibility and EPR) as well as the kinetics of polymerization were used in the investigation of these catalyst systems.

Introduction

The first "mixed catalysts" developed by *Ziegler* [1] for the low pressure polymerization of ethylene and the stereospecific polymerization of α-olefins are insoluble in the reaction medium. For some time it was taken for granted that the "catalytic surface", *i.e.* heterogeneity, is essential for the extraordinary catalytic activity.

In the meantime, however, it has been shown, especially from the work of *Natta et al.* [2] as well as by that of *Breslow* and his co-workers [3], that certain soluble complex catalysts are well able to accomplish at least part of the numerous tasks of the heterogeneous catalysts. Of course such homogeneous systems are very attractive from the point of view of polymerization kinetics, since they allow one to bypass serious problems inherent in heterogeneous systems, such as particle size and surface quality of the catalytic species, stirring, and mass-transport phenomena. The prospects of elucidation of the mechanism of this type of coordinative polymerization is certainly greater with soluble systems. The results of such an investigation may allow one to draw conclusions about the technically more interesting heterogeneous systems.

The complex Ziegler-Natta catalysts are in general composed of a transition metal salt (or chelate) and an organometallic (reducing) compound containing a Group I–III metal. (In some cases combinations of two transition metal compounds of different valency and (or) ligand environment have been found useful [4].)

The most frequently used transition metal compound in soluble systems is bis(cyclopentadienyl)titanium dichloride (Cp_2TiCl_2). Fig. 1 shows schematically how the four ligands are arranged in an approximately tetrahedral fashion, around the central titanium atom [5,6], the cyclopentadienyl rings being π-bonded to the metal.

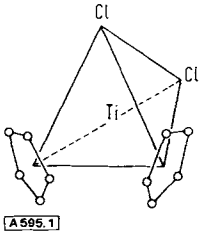

Fig. 1. The structure of bis(cyclopentadienyl)titanium dichloride.

A catalyst for the polymerization of ethylene is formed from this Ti-compound in combination with aluminum alkyls. The basic question of the present work is the following: In which way do the two components of the complex catalyst interact in order to yield an active species, and what is its configuration? Magnetic measurements, namely those of magnetic susceptibility and of electron paramagnetic resonance (EPR), are particularly suited to answer this kind of question, if used in combination with polymerization kinetic data.

In Section I of this Paper the system $Cp_2TiCl_2/EtAlCl_2$ (Et = ethyl) in toluene is dealt with. Valency and ligands of the Ti in the active species are determined. This investigation leads to the recognition of the system $Cp_2TiEtCl/EtAlCl_2$ as especially suitable for a mechanistic study of the catalytic process. This is reported in Section II. The combination of all data obtained with both systems allows an interpretation of the reasons for catalytic activity and the proposal of a mechanism (Section III). Finally the homogeneous systems are compared with the technically more important heterogeneous catalysts (Section IV).

I. The System $Cp_2TiCl_2/EtAlCl_2$ in Toluene

a) Valency of Titanium in the Active Species

Aluminum alkyls are reducing agents, and therefore a reduction Ti(IV) → Ti(III) inevitably takes place if the two components Cp_2TiCl_2 and $EtAlCl_2$ are brought together. The first question to be answered is: what is the valency of the titanium in the catalytically active species? This question can easily be investigated by means of magnetic-susceptibility measurements since Ti(III), with the electronic configuration $3d^1$, is paramagnetic, whereas Ti(IV) is diamagnetic ($3d^0$). The course of the reduction Ti(IV) → Ti(III) may therefore be followed by measuring the susceptibility of the reaction solution as a function of time. The concentration of Ti(III) is calculated from the experimental volume susceptibility, $\varkappa$, and the molar susceptibility, χ_m (for one unpaired electron per molecule $\chi_m = 1270\times10^{-6}$ emu, corresponding to a magnetic moment of 1.73 B.M.), according to

$$[Ti(III)] = \varkappa/\chi_m. \qquad (1)$$

The concentration of Ti(III) is represented, in Fig. 2, as a function of time. The relatively high titanium concentration of 20×10^{-3} mol/l used in this experiment allows susceptibility measurements to be carried out with a satisfactory degree of accuracy. The solubility of Cp_2TiCl_2 is not high enough to prepare solutions in toluene of such concentrations; however, it becomes more soluble by complex formation with the aluminum alkyl. A certain excess of the latter is necessary to dissolve the Ti compound in a reasonable time. Therefore a ratio of Al/Ti = 2 was chosen. Preliminary trials had shown that the polymerization of ethylene is also optimal at this ratio (compare also reference [7]).

Fig. 2 shows that reduction occurs initially with a relatively high rate, but slows down after some 30 hours, when roughly one half of the Ti(IV) has been reduced, thus indicating the parallel occurence of at least two reactions. We shall come back to this point in Section Ib. For the moment, the curve will be used only to determine the actual concentrations of Ti(III) and Ti(IV) after different times. About 90 % of the titanium is present as Ti(III) after some 400 hours; complete reduction is obtained only after some thousand hours. A greater excess of $EtAlCl_2$ does not increase the rate of reduction.

[7] *W. Long*, J. Amer. chem. Soc. *81*, 5312 (1959).

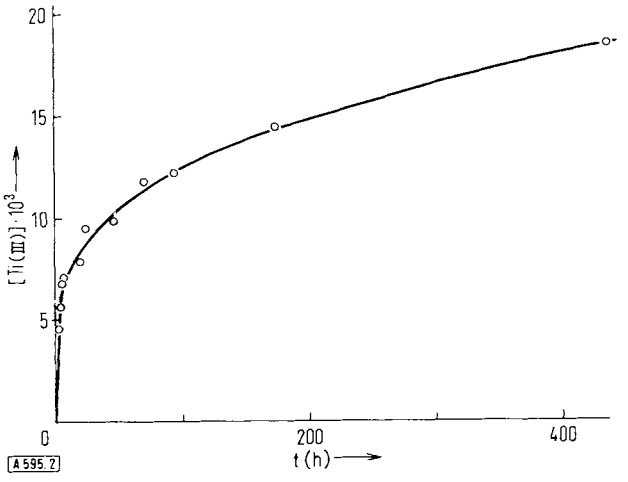

Fig. 2. Concentration of Ti(III) in the mixture $Cp_2TCl_2/EtAlCl_2$ as a function of time. $[Ti(IV)]_0 = 20\times10^{-3}$ mole/l; Al/Ti = 2; T = 20 °C; t = 0 at the moment of mixing of the catalyst components.
Ordinate: $[Ti(III)]\times10^3$ (mol/l).

Catalyst solutions identical with those used for the magnetic measurements (Fig. 2) have been used, after different times of aging, in the polymerization of ethylene. Data obtained from these polymerization runs are shown graphically in Fig. 3.

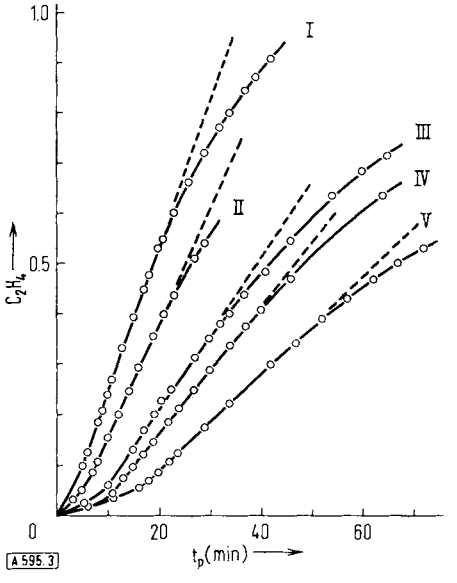

Fig. 3. Polymerization of ethylene at different aging times, t_a, of the catalyst solution. I: t_a = 0; II: t_a = 2h; III: t_a = 16h; IV: t_a = 20h; V: t_a = 66 h.
Ethylene pressure 710 mm Hg; aging temperature T_a = 20 °C; polymerization temperature T_p = 0 °C; polymerization time t_p.
Ordinate: Ethylene consumption in mole/l.

The polymerization rate clearly decreases with increasing aging time. Since the Ti(III) concentration has increased with aging (Fig. 2), this finding precludes Ti(III) species from being responsible for catalytic activity.

On the other hand, it may be seen from Figures 2 and 3 that the polymerization rate is higher when more Ti(IV) is present. The initial rate of polymerization, as obtained from the linear parts of the curves in Fig. 3, proves to depend in an approximately linear manner on the actual concentration of unreduced Ti(IV), which can easily be computed as

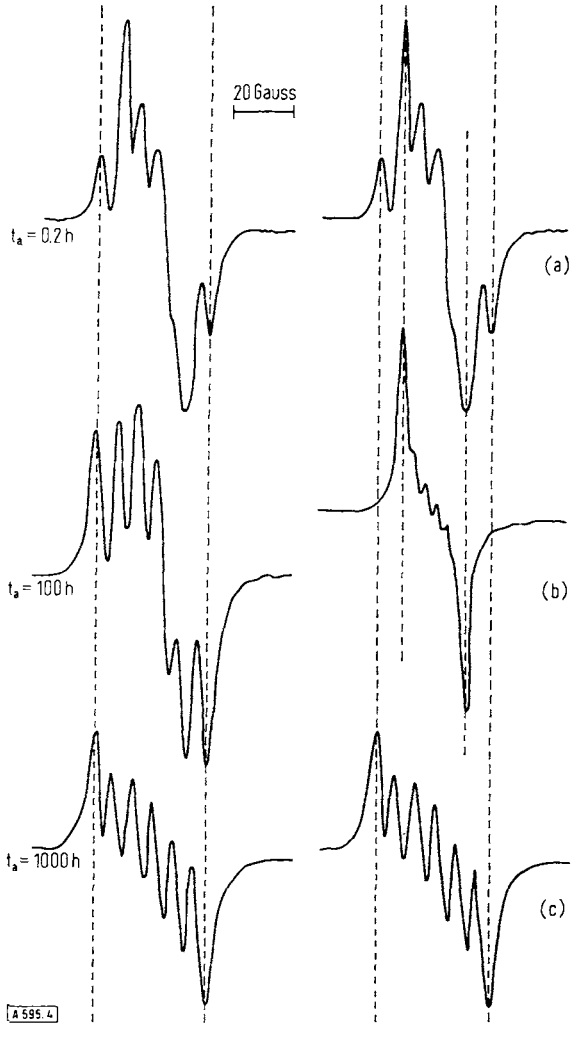
$$[Ti(IV)]_t = [Ti(IV)]_0 - [Ti(III)]_t \quad (2)$$

Therefore, the first question may be answered: The catalytic species must contain the titanium as Ti(IV).

b) EPR Spectra of the Catalyst Solution

The magnetic susceptibility cannot be used to distinguish between different paramagnetic species. EPR however supplies complementary information. Since this method is sensitive to variations in the environment of the paramagnetic ion, it is sometimes possible to observe several paramagnetic compounds simultaneously, and to measure changes in their concentrations.

The EPR signal of the catalyst solution, after different aging times, is given in Fig. 4. Two different Ti(III) species may be distinguished. One six-line signal is present from the very beginning, first superimposed by the signal of another substance, then finally almost pure (Fig. 4, left).



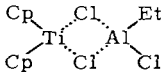


Fig. 4. Left: EPR signal of the system $Cp_2TiCl_2/EtAlCl_2$ represented in Fig. 2, at different t_a. Right: Identification of the components of the spectra shown. (a) Spectrum immediately after mixing of the components; (b) spectrum of compound *(1)*; (c) spectrum of compound *(2)*.

The top of the right-hand side of Fig. 4 shows the EPR spectrum of the catalyst solution immediately after mixing. Below these spectra are shown the signals of compounds *(1)* and *(2)* (taken from the literature [8, 12]).

(1)

(2)

The six lines seen in the spectrum of *(2)* result from the interaction of the unpaired electron of the Ti(III) with the magnetic nucleus of the aluminum (nuclear spin I = 5/2). A control experiment with a crystalline sample of this compound, prepared according to *Natta et al.* [9], shows, in toluene solution, an identical EPR signal (g = 1.9748, a_{Al} = 6.9 gauss).

The bridged structure of this complex was determined by *Natta et al.* [10] by means of X-ray structural analysis. The electron-deficient, three-center bonds Ti...Cl...Al required by this structure plausibly explain why no interaction of the unpaired electron of the Ti(III) with the chlorine atoms (nuclear spin I = 3/2) is to be observed in EPR: The molecular orbital responsible for the interaction of the unpaired electron with the Al nucleus can presumably be represented as a linear combination of the lowest vacant orbitals of the three-center bonds with a suitable Ti orbital. The lowest vacant orbital of a three-center bond has a node at the central atom [11]. Therefore no spin density (or very low spin density) is to be expected at the Cl nuclei.

The signal in the middle of Fig. 4 was ascribed by *Maki* [12] to the Ti(III)/Al complex *(1)*. The six Al-hyperfine lines of the EPR signal of this complex have come so close together that they cannot be fully resolved. The distance of these lines is a measure of the density of the unpaired spin at the nucleus of the aluminum atom. It is remarkable that this density is diminished by the introduction of an electron donating substituent at the Al. This may be interpreted as the consequence of "electron pressure" in the direction Ti ← Cl ← Al ← Et, which counteracts the delocalization of the unpaired Ti(III) electron. This idea was first postulated by *Adema et al.* [8]: "It is as if the alkyl groups push the unpaired electron away from the Al atom". Consistently, the introduction of a second ethyl group at the Al leads to a further narrowing of the signal. The complex with two ethyl groups at the Al shows only a single-line EPR signal with about one half of the line width of that for the complex with one Et [8].

This EPR-evidenced concept of increasing "electron pressure" as a consequence of increasing substitution of Cl by ethyl groups will be used later on in this paper.

The EPR signals in Fig. 4 are characterized not only by number, distance, and width of the lines, but also by their situation in the magnetic field (g-value). The dotted lines connect corresponding parts of the spectra. Thus the attribution of the two superimposed signals in the EPR spectrum of the original catalyst solution to the complexes *(1)* and *(2)* may be regarded as satisfactory and reliable.

At the beginning of the reduction, the concentrations of both complexes increase. The course of this increase

may be estimated from the changes of the EPR spectrum with time – see Figure 5. Although the absolute values of the concentrations given in this figure should not be stressed too much, the simultaneous increases in the concentrations of both complexes indicate clearly the simultaneous presence of two Ti(IV) complexes from which the two Ti(III) compounds originate.

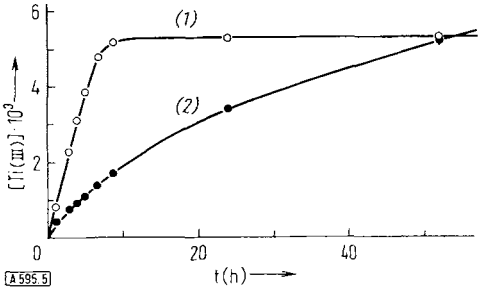

Fig. 5. Changes of the concentrations of the two Ti(III)/Al complexes $Cp_2TiCl_2AlEtCl$ *(1)* and $Cp_2TiCl_2AlCl_2$ *(2)*, as estimated from the changes of the EPR signal with time.
(Ordinate: [Ti(III)]× 10^3 in mole/l).

After some 10 hours, the concentration of the complex $Cp_2TiCl_2AlEtCl$ *(1)* does not increase further, but shows a slight decrease. Presumably this complex is transformed, in a very slow reaction, to the more stable $Cp_2TiCl_2AlCl_2$ *(2)* by substitution of $EtAlCl_2$ by $AlCl_3$. This is in agreement with the EPR spectra of Fig. 4. After *ca.* 1000 h practically pure $Cp_2TiCl_2AlCl_2$ *(2)* is found.

c) Configuration of the Active Complex

The reaction scheme represented in Fig. 6 shows how the simultaneous formation of the two observed Ti(III) complexes may be envisaged.

If Cp_2TiCl_2 is brought together with $EtAlCl_2$, instantaneous complex formation takes place. This follows from an immediate color change (red → brown-green),

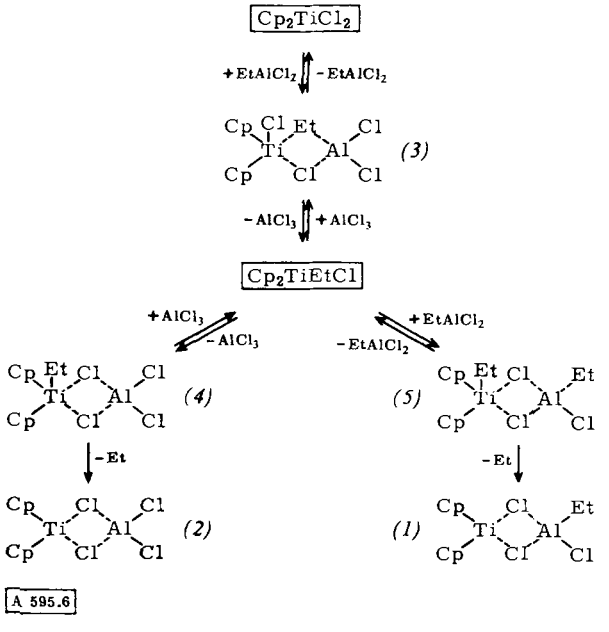

Fig. 6. Reaction scheme for complex formation and reduction in the system $Cp_2TiCl_2/EtAlCl_2$ in toluene at 20 °C.

and from the disappearance of the absorption band of Cp_2TiCl_2 at 515 nm. Although these Ti(IV)/Al complexes have not been isolated, it seems highly probable that the two metal atoms are also linked by bridge bonds, the tendency of both metals to form electron-deficient bonds being known [*]. Possibly the first complex contains two chlorine atoms in the bridge positions and the ethyl group on the aluminum. It is certain that the complex is in equilibrium with its parent substances, Cp_2TiCl_2 and $EtAlCl_2$, although the optical evidence indicates that the equilibrium concentration of the original Ti(IV) compound is rather low.

Part of the complex will doubtlessly be present in the form *(3)* represented in the scheme. In this configuration, it could decompose with loss of $AlCl_3$ to give $Cp_2TiEtCl$. This substance, whose intermediate formation we now postulate (further evidence see below) will play a key role in our further argument.

If $Cp_2TiEtCl$ reacts with $AlCl_3$, the complex *(4)*, in which the ethyl group is bonded to the titanium, may be formed; reaction with another $EtAlCl_2$ yields the doubly ethylated complex *(5)*.

Sinn and *Patat* [14] have shown, by means of ^{14}C-labeled aluminum alkyls, that the reduction of the titanium in similar complexes occurs by elimination of an exocyclic ethyl group on the titanium. Thus only at this stage of the reaction does the reduction process become feasible (and not from compound *(3)* or its analogues with the ethyl group in one of the bridges). Reduction leads to $Cp_2TiCl_2AlCl_2$ *(2)* (left hand route of scheme), and to $Cp_2TiCl_2AlEtCl$ *(1)* (right hand route of scheme); both Ti(III) complexes were found in the system and were identified by means of their EPR signals.

Thus the EPR evidence has guided us to the detection of the simultaneous presence of several Ti(IV)/Al complexes. Knowing that the catalytically active species is a Ti(IV) complex, the immediate question is, which of these complexes is the catalyst?

The answer comes from the "key substance", $Cp_2TiEtCl$. This compound can be prepared in crystalline form [15]. Without an Al-component it is stable in solution, and not catalytically active. If $EtAlCl_2$ is added to such a solution, only the right hand route of the scheme (Fig. 6) becomes feasible; addition of $AlCl_3$ allows the left hand route, and possibly permits the above equilibrium.

The latter system has practically no activity as a polymerization catalyst. In the absence of ethylene a relatively slow reduction (some 7 % in 24 hours) leads exclusively to the Ti(III)/Al complex which shows the six line EPR signal.

However, *via* the right hand route, one obtains a polymerization catalyst $Cp_2TiEtCl/EtAlCl_2$ *(5)* whose

[*] Bridge bonds in a Ti(IV) complex have been reported, by *Watenpaugh* and *Caughlan* [13], for the crystalline dimer of $TiCl_2(OC_6H_5)_2$. In this case the bridges are formed by oxygen.

[13] *K. Watenpaugh* and *C. N. Coughlan*, Inorg. Chem. *5*, 1782 (1966).

[14] *H. Sinn* and *F. Patat*, Angew. Chem. *75*, 805 (1963); Angew. Chem. internat. Edit. *3*, 93 (1964).

[15] *W. P. Long* and *D. S. Breslow*, J. Amer. chem. Soc. *82*, 1953 (1960).

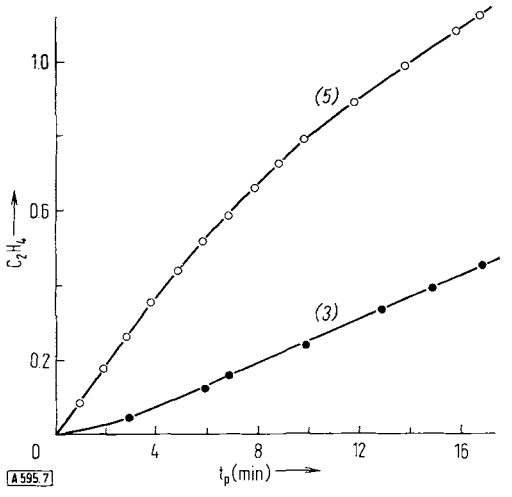

Fig. 7. Time—conversion curves of the polymerization of ethylene with $Cp_2TiEtCl/EtAlCl_2$ *(5)* and $Cp_2TiCl_2/EtAlCl_2$ *(3)*. $[Ti(IV)]_0 = 20\times10^{-3}$ mole/l; ethylene pressure = 720 mm Hg; Al:Ti = 2:1; $t_a = 0$; $T_p = 0$ °C. Ordinate: Ethylene uptake in mole/l.

activity is considerably greater than that of the original system $Cp_2TiCl_2/EtAlCl_2$ (referred to equal titanium concentration). Fig. 7 compares the rate of ethylene uptake in both systems.

From this result we can draw the following conclusion: Only the Ti(IV)/Al complex *(5)* with two ethyl groups, (one exocyclic on the Ti, the other on the Al) is active as polymerization catalyst. In the original system, the possibility of the inactive left hand route (Scheme 6) reduces the catalytic efficiency of the titanium.

II. The System $Cp_2TiEtCl/EtAlCl_2$ in Toluene

a) Second-Order Reduction Ti(IV) → Ti(III)

The investigations reported in Section I have shown that the catalyst combination $Cp_2TiEtCl/EtAlCl_2$ has a unique position inasmuch as it promises a simple, clear-cut, one-way reaction mechanism. This system is therefore expecially suited for mechanistic and kinetic studies of the reduction process as well as of the polymerization activity.

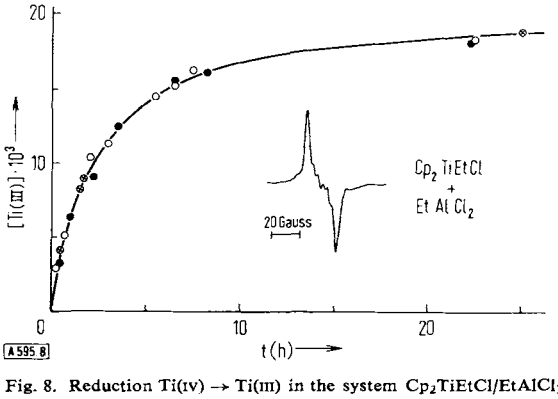

Fig. 8. Reduction Ti(IV) → Ti(III) in the system $Cp_2TiEtCl/EtAlCl_2$ in toluene.
$[Ti]_0 = 20\times10^{-3}$ mole/l; Al:Ti = 2:1; $T = 20$ °C. ●: Concentration of Ti(III) as determined from magnetic susceptibility. o ⊗: Concentration of Ti(III) as determined from EPR spectrum (two parallel runs). Ordinate: $[Ti(III)]\times10^3$ in mole/l.

When $Cp_2TiEtCl$ and $EtAlCl_2$ are mixed together in toluene in the absence of monomer, a relatively rapid reduction (compared with the system described in Section I) occurs. This reduction has been followed by magnetic susceptibility (Fig. 8). In the EPR spectrum only one signal is observed, namely that of the complex $Cp_2TiCl_2AlEtCl$ *(1)*, which increases in parallel with the magnetic susceptibility. Since the signal shape does not change with time, the signal height, h_S, can be taken as a measure of the concentration of the Ti(III) complex (setting $h_{S,\infty} = [Ti(IV)]_0$). These data are also included in the curve of Fig. 8.

This reduction occurs with a remarkable precision and up to some 80 % conversion, according to second-order kinetics. This observation precludes the reduction Ti(IV) → Ti(III) by a spontaneous monomolecular ejection of the ethyl radical, but rather suggests a bimolecular, mutual deactivation of two catalyst molecules (see Section IIc.). The second-order rate constant of this reaction is found to be:

$$k_{II} = 5.0\times10^{-3} \quad (\text{l mole}^{-1}\,\text{sec}^{-1}) \qquad (3)$$

b) Parallelism between the Rates of Reduction and of Polymerization

As already indicated, the $Cp_2TiEtCl/EtAlCl_2$ system is not only the better polymerization catalyst, but also is more rapidly reduced than $Cp_2TiCl_2/EtAlCl_2$. This parallel trend of both types of reaction holds also for other combinations: The system $Cp_2TiEtCl/AlCl_3$ reduces extremely slowly and shows practically no polymerization activity (compare Section Ic). The system Cp_2TiCl_2/Et_2AlCl, on the other hand, reduces and polymerizes very rapidly. Presumably both phenomena have a certain mechanistic correlation.

The four systems compared are summarized in Fig. 9. The Ti(III)/Al complexes observed in the EPR spectrum are also given in the legend.

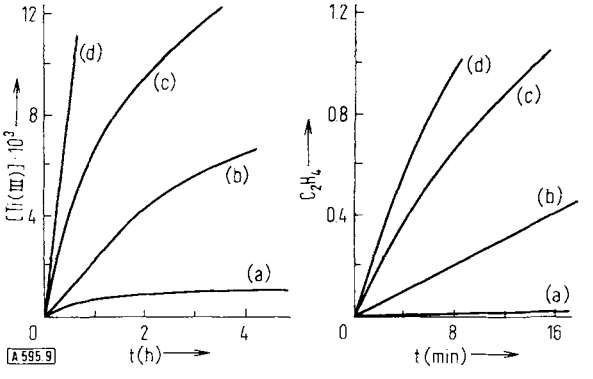

Fig. 9. Comparison of the rates of reduction Ti(IV) → Ti(III) (left) and rates of polymerization (C_2H_4) (right) for different Ti/Al systems. $[Ti]_0 = 20\times10^{-3}$ mole/l; Al:Ti = 2:1. Ordinates: mole l^{-1}.

System	Ti(IV) compound	Al compound	Ti(III)/Al complexes observed in the EPR spectrum
(a)	$Cp_2TiEtCl$	$AlCl_3$	$Cp_2TiCl_2AlCl_2$ *(2)*
(b)	Cp_2TiCl_2	$EtAlCl_2$	$Cp_2TiCl_2AlCl_2$ *(2)* + $Cp_2TiCl_2AlEtCl$ *(1)*
(c)	$Cp_2TiEtCl$	$EtAlCl_2$	$Cp_2TiCl_2AlEtCl$ *(1)*
(d)	Cp_2TiCl_2	Et_2AlCl	$Cp_2TiCl_2AlEtCl$ *(1)* + $Cp_2TiCl_2AlEt_2$

c) Polymerization Kinetics

The polymerization with the catalyst system $Cp_2TiEtCl/EtAlCl_2$ (system (c)) begins without a noticeable induction period (see Fig. 7, upper curve). With system b, on the other hand, induction periods are always observed (see Fig. 7, lower curve, and Fig. 3). From the reaction scheme in Fig. 6 this becomes understandable: In system b the catalytic species *(5)* can be supplied after the beginning of the polymerization, *via* the various equilibria involved, thus giving rise to an increase of polymerization rate until chain termination (see below) begins to dominate. In system c, however, the clear-cut beginning of the polymerization indicates that all available catalyst is transferred to growing chains from the very beginning of the reaction. Thus, in this system the relationship

$$[P^*]_0 = [Ti(IV)]_0 \qquad (4)$$

($[P^*]_0$ = concentration of active sites at times $t = 0$) is assumed to hold. A kinetic evaluation of the polymerization mechanism becomes possible on the basis of this equation. A preliminary estimate, based on the data represented in Fig. 7 (upper curve), is given below.

The polymerization rate can be obtained by graphical differentiation of the time-conversion curve.

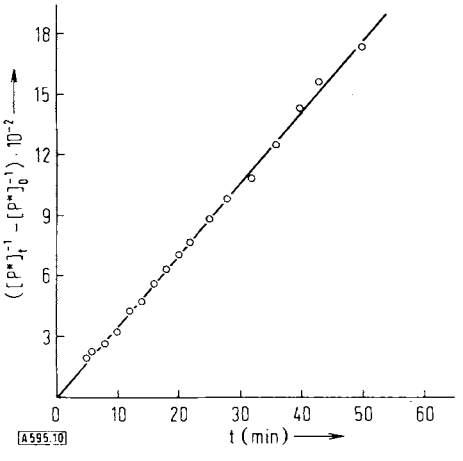

Fig. 10. Polymerization of ethylene with $Cp_2TiEtCl/EtAlCl_2$ at T_p = 0 °C. Second-order kinetics for the disappearance of growing chains. (Ordinate: $[P^*]_t^{-1}-[P^*]_0^{-1}$ in l·mole^{-1}).

The observed decrease of the polymerization rate with time must be ascribed to a chain-termination reaction. The kinetics of this reaction may be determined with the aid of the general equation for the overall polymerization rate:

$$R_p = -\frac{d[M]}{dt} = k_p\,[P^*]\,[M] \qquad (5)$$

([M] = concentration of monomer; k_p = rate constant of chain propagation.)

Taking into account eq. 4, the concentration of P* at any time can be calculated as

$$[P^*]_t = \frac{R_{p,t}}{R_{p,0}}\,[Ti(IV)]_0 \qquad (6)$$

Fig. 10 shows that the disappearance of growing chains follows second-order kinetics, indicating a bimolecular mutual deactivation of growing chains. From the slope of the straight line, the rate constant of this deactivation is obtained:

$$k_t \approx 0.6 \text{ (l mol}^{-1} \text{ sec}^{-1}) \qquad (7)$$

This is an astonishingly high value for this constant (at 0 °C) in comparison with the second-order rate constant of the mutual deactivation of the catalyst complexes in the absence of ethylene ($k_{II} = 5{\cdot}0\times10^{-3}$, at 20 °C; eq. 3).

A check of the concentration of paramagnetic Ti(III) species at the end of the run represented in Fig. 10, *i.e.* after 17 minutes of polymerization, shows that also considerably more Ti(III) has been formed than in the comparable run without ethylene. From the EPR signal height after polymerization and the information given in Fig. 8, it may be concluded that the following relationship holds:

$$[P^*]_t + [Ti(III)]_t \approx [Ti(IV)]_0 \qquad (8)$$

i.e. the chain termination reaction is accompanied by the reduction of the Ti in the active species. (For a mechanistic interpretation of this finding see Section IIIc.)

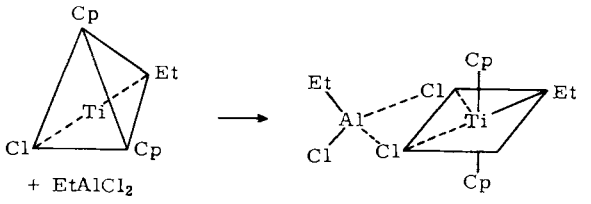
The kinetic study also allows an estimate to be made concerning the rate constant of chain propagation. From eq. 4 and 5 it follows that:

$$R_{p,0} = k_p\,[P^*]_0[M] = k_p\,[Ti(IV)]_0[M] \qquad (9)$$

The concentration of the monomer (ethylene) in the reaction solution (ethylene pressure = 710 mm Hg, 0 °C) has been determined as [M] = 0.065 mole/l. Thus it follows from eq. 9 with $R_{p,0} \approx 8\times10^{-3}$.

$$k_p \approx 6 \text{ (l mol}^{-1} \text{ sec}^{-1}) \qquad (10)$$

Kinetic measurements of the polymerization of ethylene with a similar catalyst system, Cp_2TiCl_2/Me_2AlCl (Me = methyl), have been carried out by *Chien* [16], who used radioactive tracer techniques as an analytical tool. Although the data published by this author indicate that a complicated mechanism analogous to that shown in Fig. 8 may be involved (induction periods), similar values were reported for the rate constants of chain propagation and chain termination (at 0 °C: $k_p = 1.5$, $k_t = 0.5$).



III. Interpretation of Catalytic Activity

a) The Reactive Site in the Complex

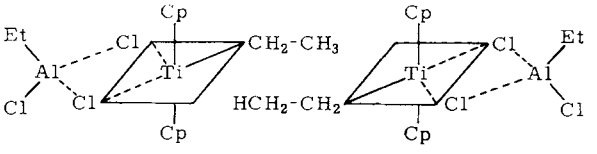
The information given in Sections I and II will now be combined in order to derive a spatial picture of the catalytic complex and of the reasons for polymerization activity.

[16] *J. C. W. Chien*, J. Amer. chem. Soc. *81*, 86 (1959).

In Cp_2TiCl_2, as well as in $Cp_2TiEtCl$, the titanium is present in an approximately tetrahedral environment [5,6]. Since we have seen that catalytic activity requires a titanium-ethylated species we shall consider only $Cp_2TiEtCl$ (Fig. 11).

A 595.11

Fig. 11. Change from tetrahedral to octahedral environment of titanium on complex formation.



On complex formation with an aluminum alkyl, one of the ligands of the Al also requires a place in the coordination sphere of the Ti. We propose that this requirement forces the Ti into an octahedral environment (only tetrahedral and octahedral complexes of Ti have so far been reported [5,17]). By this procedure the Ti–Et bond comes under the *trans*-influence of the bridged aluminum (Fig. 11), and presumably suffers weakening. This weakening, in our opinion, is responsible for the two plenomena, polymerization and reduction.

We now come back to the EPR-evidenced "electron pressure" in the direction Ti← Cl← Al← Et (Section Ib). It may easily be imagined that the higher the electron density at the Ti, the lower the stability of the Ti–Et bond. If all ligands at the Al were chlorines, no such "pressure" would be experienced; the Ti–Et bond would be relatively stable. This is indeed observed in the left hand route of the scheme, Fig. 6, which corresponds to system (a) in Fig. 9. The introduction of one or two ethyl groups leads to an increased destabilization of the Ti–Et bond, and consequently to the observed increase in the rates of polymerization and reduction (systems (b)–(d) in Fig. 9) [*].

This parallel course of polymerization and reduction is, in our opinion, strong evidence that both reactions occur in the same complex configuration and at the same site, namely at the exocyclic Ti–Et bond.

b) Reduction

In the absence of ethylene only the reduction reaction has to be taken into account. The octahedral complex, as represented in Fig. 11, has one coordination site empty. A β-hydrogen atom of the ethyl group of a second complex unit may occupy this site, as shown in Fig. 12. Subsequent transfer of this hydrogen to the other ethyl group would lead to the formation of ethane and ethylene, as has been observed experimentally [14,9]. As a consequence the titanium is reduced to Ti(III).

A 595.12

Fig. 12. Proposed configuration for the bimolecular mutual reduction of two complex units.

Experiments with a comparable Zr complex during which an intermediate compound $\rangle Zr-CH_2-CH_2-Zr\langle$ could be isolated, prompted *Sinn et al.* [18] to formulate the reduction mechanism in a similar manner to that given in Fig. 12. Bimolecular deactivation was also postulated by *de Vries* [19]. We feel that our kinetic data (second-order reduction rate) strongly corroborate such a formulation.

c) Polymerization

Under polymerization conditions, ethylene can coordinate to Ti at the sixth, so far empty, coordination site. The importance of this coordination, which is indispensable for the polymerization of ethylene, has been thoroughly discussed [20]. The most convincing ideas have been forwarded by *Cossee* [21,22], and are adopted with slight changes, in the present discussion.

Ethylene has an especially suitable electronic configuration for complexing with a transition metal. Fig. 13 represents the *x-y* plane of the octahedral complex *(6)*. The bonding π-orbital of the ethylene has σ-symmetry with respect to the *x*-axis of the complex, and therefore matches the $d_{x^2-y^2}$ (vacant) σ-orbital of the Ti. Also the antibonding π*-orbital of the olefin finds a symmetry match within the complex, namely the (also vacant) d_{xy} π-orbital of the Ti (π-symmetry with respect to the *x*-axis).

Part of the electron density will be transferred from the bonding π-orbital of the ethylene to the metal, thus weakening the ethylene double bond and making it susceptible to polymerization.

If, however, a higher transition metal were considered, the d_{xy} orbital could be filled; in this case a "back-donation" of electron density from the Ti to the ethylene could be achieved. The metal-olefin complex may then become so stable that no polymerization occurs. This is probably one of the reasons why useful catalysts for ethylene and α-olefins are found only on the left side of the Periodic Table (Ti, V, Cr), where the d_π orbital is found vacant or only partially filled. This concept also explains why the type of Ziegler-Natta catalysis discussed here is suitable for ethylene and α-olefins, whereas certain vinyl monomers with electron attracting substituents (*e.g.* vinylchloride, tetrafluoroethylene) do not polymerize. The electron density in the bonding π-orbital of the vinyl monomer is reduced by

[17] *F. A. Cotton*, J. chem. Educat. *41*, 466 (1964).

[*] With Et_3Al the reduction rate at room temperature is already too high; no polymerization is observed, presumably because of lack of Ti(IV).

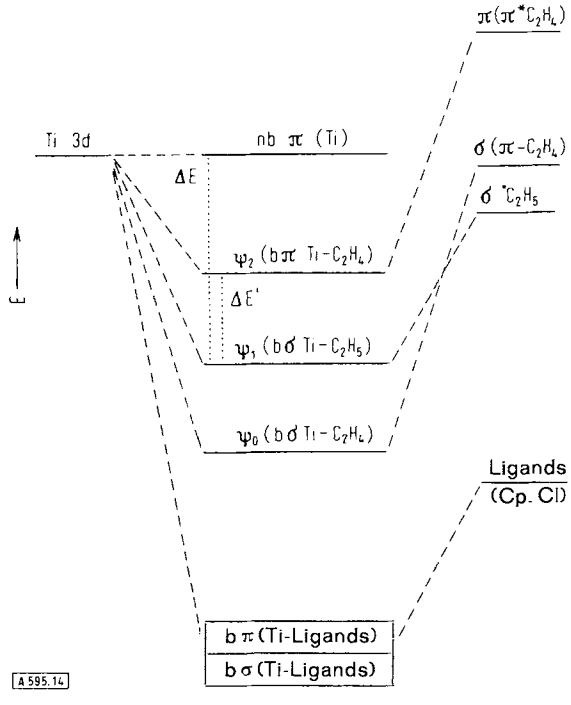
Fig. 13. Left: The octahedral complex of $Cp_2TiEtCl \cdot EtAlCl_2$ with ethylene; right: schematic representation of the relevant orbitals in the *x-y* plane of the complex.

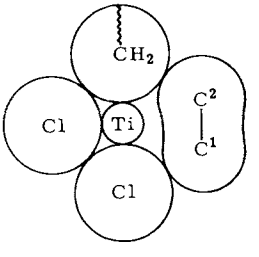
such substituents, the tendency to coordinate to the metal decays, and thus one of the most important conditions for this type of catalysis is not satisfied.



The coordination of ethylene also has a destabilizing influence on the Ti–Et bond – a further factor favoring polymerization. This effect is best elucidated by a qualitative, simplified molecular orbital (MO) description of the coordination process.

The five-coordinate complex (one vacancy) possesses a number of stable, filled σ- and π-bonding orbitals, which unite the titanium with the ligands Cp and Cl (bσ and bπ in Fig. 14). The highest occupied orbital is assumed to be the destabilized (*trans* effect, "electron pushing") bonding σ–MO, ψ_1, which is responsible for the Ti–Et bond. (The ψ_0 and ψ_2 MO's are not present in the pentacoordinated complex, see below.) Furthermore, the Ti has one non-bonding σ-orbital (due to the vacancy), and also non-bonding π-orbitals.

When an ethylene molecule approaches the vacancy, its bonding π-orbital overlaps with the as yet non-bonding Ti σ-orbital to form the bonding σ–MO (ψ_0). This MO presumably has a lower energy than the destabilized ψ_1 [*].



The formation of the π-MO (ψ_2) from a so far non-bonding titanium π-orbital and the antibonding ethylene π*-orbital (compare also Fig. 13) makes available a vacant MO which is energetically favorable for an electron transition $\psi_1 \rightarrow \psi_2$. Whereas before the coordination of the ethylene the energy ΔE was necessary to promote, by thermal exitation, an electron from ψ_1 to the next vacant orbital, now only the energy $\Delta E'$ is required to make the ethyl group available as a radical. (The concept of stabilization and destabilization of transition metal-alkyl bonds by influencing the energy gap between highest occupied and lowest vacant MO was first put forward by *Chatt* and *Shaw* [24].)

The schematic picture of the atomic orbitals in Fig. 13 does not give a clear impression of sizes and distances. Fig. 15 gives a further representation of the *x-y* plane, the diameters of the ligands and of the metal being drawn approximately to scale (according to *Cossee* [21])

A 595.14

Fig. 14. Simplified qualitative MO representation of the influence of ethylene coordination on the stability of the Ti–Et bond (antibonding MO's omitted).

A 595.15

Fig. 15. *x-y* plane of the complex *(6)* represented in Fig. 13, with diameters of metal and ligands drawn approximately to scale (according to *Cossee* [21]).

This representation emphasizes that this arrangement of the ligands, possible only in the octahedral (and not in the tetrahedral) complex, is specially favorable for a "*cis*-migration" of the ethyl-group (or a growing chain) to the coordinated monomer. Only a small "in-plane" displacement of the CH_2-group, which may be possible within the normal vibrational modes, brings it into a position of considerable overlap with

[*] Since *Cossee* [21] did not take into account bridge bonds to the aluminum, but supposed the Al compound to be necessary only to alkylate the Ti, his assignment of the energies of the MO's ($\psi_1 > \psi_0$) was perhaps not quite justified. This was criticized by *Scrocco* [23]. In our opinion the destabilizing influence of the bridge might well be a sufficient reason for postulating that the energy of ψ_1 is higher than that of ψ_0.

[23] *E. Scrocco*, note in reference [21], p. 87.

[24] *J. Chatt* and *B. L. Shaw*, J. chem. Soc. (London) *1959*, 705.

the olefin. (This point of view has been carefully discussed on a qualitative quantum mechanical basis by *Cossee* [22].) The weakened olefinic double bond breaks, a new bond Ti–C_1 is formed, and the ethyl group (or growing chain) bonds to C_2. After the insertion, the coordination site where the ethyl group was situated becomes free. Since this position has the same configuration, with respect to the Al-bridge, as the one where the olefin was coordinated, the process of chain growth can begin again (cf. *(6)*, Fig. 13).

It therefore follows that three influences are cooperative in the catalysis discussed:

1. Destabilization of the titanium-alkyl bond by the alkylated Al bridge, and by the coordination of the monomer (Fig. 14);

2. Destabilization of the olefin double bond by partial electron transfer from the bonding π-orbital to the titanium (Fig. 13);

3. Suitable steric arrangement for the "*cis*-migration" of the ethyl group, or growing chain (Fig. 15).

Presumably the concerted action of all three conditions is only possible in an octahedral environment.

In the presence of ethylene, the bimolecular mutual deactivation of the catalyst complexes has also to be taken into account, as shown in Section IIc. It can be imagined in a similar manner to that depicted in Fig. 12, if one hydrogen of each CH_3 group is replaced by a polyethylene chain. In terms of polymerization kinetics, this mutual deactivation represents a case of a true chain termination reaction, since the reduced (tetrahedral) complex cannot be reactivated. The reaction gives one polymer molecule with a vinyl end group, and one saturated molecule.

It has been shown in Section IIc that mutual deactivation (reduction) occurs considerably faster in the presence of ethylene than in the monomer-free system. The reason could reside, at least in part, in the smaller dissociation energy for a C–H bond in a $>CH_2$ group as compared with a $-CH_3$ group ($\Delta E \simeq 3$ kcal/mol [25]). This difference is known to cause considerable differences in rate constants and activation energies of other hydrogen-abstraction reactions (*e.g.* the free radical hydrogen abstraction, by the polystyryl radical, from toluene or ethylbenzene, $k_{EtB}/k_{Tol} = 4.3$ at 80 °C, $\Delta E_A \simeq 3$–4 kcal/mol [26]). Possibly the β-position of the decisive $>CH_2$ group (growing chain) or $-CH_3$ (ethyl group) to the metal can strengthen this effect considerably.

Summarizing, it may be said that the experimental data of the polymerization are also consistent with the proposed mechanism, which postulates the combination of the exocyclic alkyl group on the titanium and the vacancy as the site of reaction for the polymerization as well as for the reduction.

IV. Comparison with Heterogeneous Systems

It has been stated in the previous sections that the catalytically active species in the treated homogeneous systems contain the titanium exclusively as Ti(IV). Reduction to Ti(III) renders the compounds inactive. On the other hand, some of the most efficient and versatile technical catalysts for the polymerization of ethylene and α-olefins are based on $TiCl_3$.

This apparent contradiction finds its explanation in symmetry considerations. In the present Ti(IV) compounds (Cp_2TiCl_2, $Cp_2TiEtCl$) the four ligands are located tetrahedrally around the titanium. Only by complex formation with the Al-alkyl is an octahedral environment achieved; reduction brings the Ti/Al complex again into an inactive tetrahedral configuration. The various crystalline modifications of $TiCl_3$ (α, β, and γ), however, have the common property that the Ti atoms are located in octahedral interstices of the Cl-lattice [27]. At surface defects, and especially at the lateral faces of hexagonal crystals of, for example, α-$TiCl_3$, titanium atoms are to be found which, because of electroneutrality requirements, exhibit incomplete coordination. The presence of titanium atoms, in which four octahedral sites are occupied by chlorine (two chlorine vacancies) can result in complex formation with an Al-alkyl (bridge) and alkylation of the titanium in an analogous fashion to that described in Figure 6 for Cp_2TiCl_2. (Only the two Cp groups have to be thought of as being replaced by chlorines.) In our opinion these titanium centers having two vacancies are essentially responsible for the activity of the heterogeneous Ziegler-Natta catalysts on the basis of $TiCl_3$. (Cf. also reference [4].) In contrast to the soluble systems dealt with in the present work, the octahedral arrangement of the ligands of titanium in heterogeneous catalysts is guaranteed at the outset by crystal structure.

This comparison of the homogeneous and heterogeneous systems emphasizes that the symmetry requirements for catalytic activity are rather severe, whereas the valency of the titanium seems to be of less importance.

V. Experimental

Cp_2TiCl_2 (Fluka) was recrystallized from methylene chloride several times; $Cp_2TiEtCl$ was prepared according to *Long* and *Breslow* [15]. The aluminum alkyls used were supplied by Schering, Bergkamen. Catalyst preparation and aging, as well as magnetic measurements, were carried out *in vacuo* or under argon. Magnetic susceptibility was determined on a Gouy balance. A Varian V-4502 spectrometer, with 100 kHz field modulation, has been used for the EPR measurements. The rate of polymerization of ethylene was determined at constant pressure; the equipment was essentially that described by *Schnecko et al.* [28].

The authors are grateful to Mr. W. Hess for able and conscientious technical help.

4-Chloro-1α,2α:6β,7β-bismethylene-steroids

By *R. Wiechert* [*]

1,4,6-Triolefinic 3-keto-steroids add diazomethane selectively to the 1,2-double bond, even if the diazomethane is in excess, to yield 1α,2α-pyrazoline derivatives [1]. If these products are cleaved thermally or by Lewis acids, they afford 4,6-diolefinic 1α,2α-methylene-3-keto-steroids.

However, 4-chloro-3,20-dioxo-1,4,6-pregnatrien-17α-yl acetate *(1a)* (m.p. 213.5–214 °C; prepared by chlorination of 3,20-dioxo-1,4,6-pregnatrien-17α-yl acetate with chlorine in dimethylformamide/propionic acid) adds two equivalents of diazomethane. Cleavage of the labile crude bispyrazoline with catalytic amounts of perchloric acid in acetone at room temperature leads to the 4-chloro-1α,2α:6β,7β-bismethylene compound *(2a)* (yield 16%), m.p. 278.5–279 °C; UV: ε_{274} = 12600 (methanol); $[\alpha]_D^{26} = -48.1°$ (c = 1.03 in $CHCl_3$); NMR: no olefinic proton, 19-CH_3 at δ = 1.12 (tetramethylsilane as internal standard in $CDCl_3$).

(a), R = CO-CH_3
(b), R = H

Addition of diazomethane in the δγ-position of an enone system has not been described previously. In *(1a)* it is made possible by the 4-chloro substituent (electron deficiency at C-7.

Compound *(2a)* is also formed by direct methylenation of *(1b)* [m.p. 199–201 °C; formed from *(1a)* by hydrolysis] by the method of *Corey* [2] and *Franzen* [3] with dimethylsulfoxonium methylide [giving a 28% yield of *(2b)*, m.p. 246–250 °C; UV: ε_{274} = 12400 (methanol)] with subsequent acetylation. Because of steric hindrance of the C-1/C-2 bond by the angular methyl group on C-10, attack at the rear side must be assumed, leading to the 1α,2α-methylene group, whereas the β-position of the 6,7-methylene group follows from the position of the NMR signal of the methyl group on C-13 [shift of −0.17 ppm compared with *(1)*].

In animal experiments *(2a)* has an extremely strong gestational and ovulation-blocking activity.

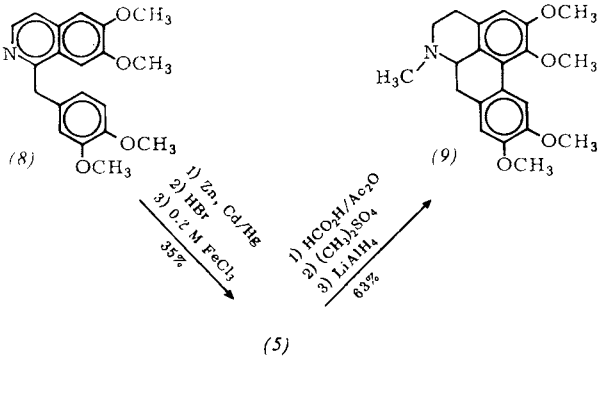
Aporphines from Laudanosoline and Norlaudanosoline [1]



By *B. Franck* and *L.-F. Tietze* [*]

The biogenetic-type preparation of the basic structure of the numerous aporphine alkaloids, *e.g. (4)*, by oxidative condensation of derivatives of laudanosolines *(2)* is a much-studied problem of alkaloid chemistry [2–4]. Laudanosoline *(2)* [3,4] and norlaudanosoline *(3)* [5] yielded solely dibenzopyrrocoline derivatives *(1)* when treated with various oxidizing agents. Progress in this field was made when we [6], and subsequently other authors [8], were able to show that laudanosoline and related compounds undergo oxidative condensation to aporphines when their nitrogen groups are protected by quaternization.

We have now found that laudanosoline *(2)* and norlaudanosoline *(3)* may be converted into aporphines surprisingly simply and in good yields if the formation of an *o*-quinone intermediate *(6)* [3] during oxidation is hindered by complex formation with the pyrocatechol OH groups. This may be accomplished with concentrated solutions of iron(III) chloride, which converts the laudanosoline derivatives into deep green, water-soluble, weak complexes *(7)* and simultaneously acts as oxidizing agent. After reaction of *(2)* or *(3)* with 2.5 equivalents of $FeCl_3$ in 0.2 M solution at 20 °C for 48 h, and subsequent concentration of the reaction mixture, the aporphine *(4)* or *(5)*, respectively, is obtained in 63 or 52% yield as crystals of the hydrochloride. Condensation products of the type *(1)* could not be detected. On the other hand, when the reaction is carried out with the same amount of $FeCl_3$ in very dilute solution (0.015 M), or with $K_3[Fe(CN)_6]$ [3], insufficient complex formation takes place and the chloride of *(1)*, m.p. 305 °C [3], is formed (yield in excess of 70%) *via* the *o*-quinone intermediate *(6)*.

The hydrochloride of *(4)*, $C_{17}H_{17}NO_4 \cdot HCl$ (m.p. 243 °C), gives a UV spectrum [in methanol, λ_{max} = 281 (ε = 13800) and 360 (ε = 13970) nm] that is typical of aporphine alkaloids of the glaucine type *(9)*. The NMR spectrum shows three 1-proton singlets at δ = 6.23, 6.44, and 7.66 (D_2O/NaOD,

DSS[**] = O). The mass spectrum shows the characteristic main peak of tertiary aporphines (M − CH_2=N−CH_3) at *m/e* = 256[9]. The hydrochloride of *(5)* ($C_{16}H_{15}NO_4$·HCl, m.p. 280 °C) was identified similarly. Furthermore, *N*-formylation, methylation, and subsequent reduction of the formyl group yielded the naturally abundant alkaloid glaucine *(9)*. Thus the compound *(5)*, which may be obtained in three steps from papaverine *(8)*, provides the simplest route to glaucine yet discovered.

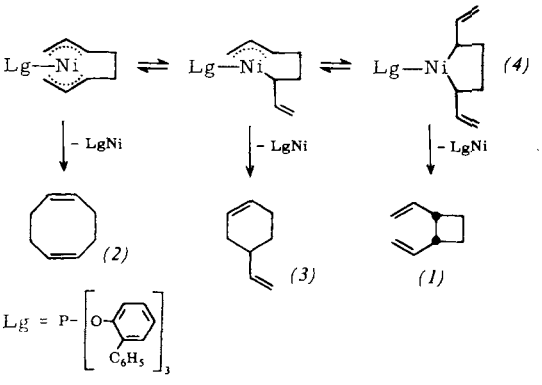
Catalysed Synthesis of *cis*-1,2-Divinylcyclobutane



By *P. Heimbach*[**] and *W. Brenner*[*]

cis-1,2-Divinylcyclobutane *(1)* was first prepared by *Vogel*[1], using a many-stage synthesis. *Vogel*'s description of the Cope rearrangement of this four-membered ring system to *cis,cis*-1,5-cyclooctadiene (COD) *(2)* supported his hypothesis that thermal formation of *(2)* from butadiene[2] proceeds by way of *(1)*. The *cis*-compound *(1)* is also formed (8–17%) in admixture with, *inter alia*, *trans*-divinylcyclobutane in the photosensitized dimerization of butadiene[3]. Butadiene can by cyclodimerized faster in the presence of complexes of zerovalent nickel that contain *e.g.* tris-(2-biphenylyl) phosphite as ligand (Ni:P = 1:1), the rate being *ca.* 1 kg per g of nickel in the catalyst per h at atmospheric pressure and 80 °C, and the reaction yielding *(2)* (97%) and, by a side reaction, 4-vinylcyclohexene *(3)* (2.7%)[4].

If the reaction is carried out in liquid butadiene to incomplete conversion of butadiene, yields of up to 40% of *(1)*, together with *(2)* and *(3)*, are obtained. The table shows the dependence of the yields on conversion of butadiene (catalyst: $Ni^0(COD)_2$[5] + tris-(2-biphenyl) phosphite, molar ratio 1:1).

	Conversion of butadiene (20 °C)			
	30%	85%	95%	100%
(1), yield	36%	36%	14%	–
(3), yield	2.0%	2.0%	2.2%	2.4%
(2), yield	61%	61%	83%	97%

We presume that, with high concentrations of butadiene, the coordination positions on nickel that become free on conversion of π-allyl groups into σ-allyl groups become occupied by butadiene (not taken into account in the formulae given here) and that the synthesis of *(2)* is thus transformed into a synthesis of *(1)*. The product *(1)* is probably formed from the bis-σ-allyl form *(4)*.

The rate of synthesis of *(1)* depends markedly on the nature of the ligand. With short reaction times (*e.g.* 0.5 h), yields exceeding 30% of *(1)* can be achieved even at 80 °C, although thermal rearrangement of *(1)* to *(2)* has then already begun[6]. Pure *(1)* is obtained by distillation under vacuum: b.p. 8 °C/9 mm, $n_D^{20} = 1.4562$[1]. Substituted butadienes can also be converted catalytically into cyclobutanes in good yields[7].

Catalysed Cope Rearrangement of *cis*-1,2-Divinylcyclobutane

By *P. Heimbach*[**] and *W. Brenner*[*]

The yield of *cis*-1,2-divinylcyclobutane obtained on catalysed dimerization of butadiene depends markedly on the extent of conversion[1]. This suggested that the first product *(1)* was further catalytically altered. Our first experiments showed that predominately *cis,cis*-1,5-cyclooctadiene *(2)*, with little 4-vinylcyclohexene *(3)*, is formed from *(1)*. The rate of the catalysed rearrangement of *(1)* could be determined at 24 °C by following the volume contraction and the change of refractive index during the reaction, as well as by gas-chromatographic analysis. The concentration of catalyst in the solution was 0.2 or 0.1 molar (Ni:ligand = 1:1). The rate is directly dependent on the Ni concentration and the nature of the ligand up to *ca.* 97% conversion of *(1)*.

Fig. 1 shows the rate of the catalysed (24 °C) and also of the thermal (uncatalysed) rearrangement (80 °C) of *(1)* to *(2)*.

—×—×— Thermal conversion of *(1)* at 80 °C.

····· ·· Catalysed rearrangement, 24 °C, 0.2 M solution; ligand, tris-(2-biphenylyl) phosphite. · · · Catalysed rearrangement, 24 °C, 0.1 M solution; ligand, tris-(2-biphenylyl) phosphite. — — — Catalysed rearrangement, 24 °C, 0.2 M solution; ligand, triphenylphosphine.

Ordinate: % rearranged *(1)*.

Abscissa: Time (hours).

The latter is a first-order reaction whereas the catalysed rearrangement is a zeroth-order reaction with respect to *(1)*. However, the marked dependence of the composition of the product on the nature of the ligand [tris-(2-biphenylyl) phosphite, 0.5 % of *(3)*, 99 % of *(2)*; triphenylphosphine, 31 % of *(3)*, 60 % of *(2)*; tricyclohexylphosphine, 33 % of *(3)*, 55 % of *(2)*] confirms the assumption that the reactivity of the bis-π-allyl form *(4)* increases with marked back-donation of the nickel to the free d orbitals of the phosphorus (phosphite), but that the reactivity of the π-allyl-σ-allyl form *(5)* is greater when there is weak back-donation (phosphine) [2, 3].

Trebellas et al. [8] recently described the first Cope rearrangement that is induced by transition-metal compounds and yet occurs stoichiometrically. The catalysed Cope rearrangement of *(1)* and the fact the bis-allyl complexes formed as intermediates therein can react with further components are phenomena of a new type. We are engaged in analogous studies of other 1,5-dienes with nickel and other transition-metal catalysts.

[a] The prefixes *cis* and *trans* refer to the configuration of the allyl groups between the C-atoms 2 and 3, or 6 and 7.

[b] In this case, Lg = isoprene.

The α-ω-allyl C_8 chain that is formed from *(1)* as intermediate on the $Ni^{(0)}$-Lg system apparently exists in equilibrium with various other forms.

Only the forms *(4)* and *(5)* react in the catalysed rearrangement of *(1)* to *(2)* and *(3)*. If ethylene is added to the reaction mixture [*ca.* 45 atm, 20 °C, Lg = $P(C_6H_5)_3$], of *cis,trans*-1,5-cyclodecadiene [from *(6)* + ethylene] (73 %) and *trans*-1,4,9-decatriene [from *(7)* + ethylene)](1 %) are formed, as well as *(2)* and *(3)*. Isoprene reacts with *(1)* in the presence of, *e.g.*, cyclododecatrienenickel(0) [4] with formation of *trans, trans, trans*-1-methyl-1,5,9-cyclododecatriene [from *(8)* and isoprene]. These reactions support the assumption that a C_8 chain is formed as intermediate in the synthesis of eight- [5], ten- [6], and twelve-membered rings [7] on complexes of nickel(0) [2].

Structure of Alkali Metal t-Butoxides

By *E. Weiss, H. Alsdorf*, and *H. Kühr* [*]

According to X-ray powder studies, the t-butoxides of potassium, rubidium, and cesium are tetrameric. They have cubic lattices, each unit cell containing one tetrameric formula-equivalent [space group $P\bar{4}3m$, a_0 = 8.47$_5$ Å (K), 8.610 (Rb), 8.902 (Cs)]. The tetrameric structural units have T_d symmetry, the metal and oxygen atoms occupying alternate corners of an only slightly distorted cube with the four t-butyl groups lying on the extended diagonals (see Fig. 1).

The following atomic distances were obtained for the potassium compound: K–O 2.56; C–O 1.39; C–CH_3 1.56 Å; bond angle O–C–CH_3 112.1 °. The non-metallic atoms could not be precisely located in the rubidium or cesium compound. Sodium t-butoxide crystallizes in a lattice of lower symmetry and as yet undefined structure.

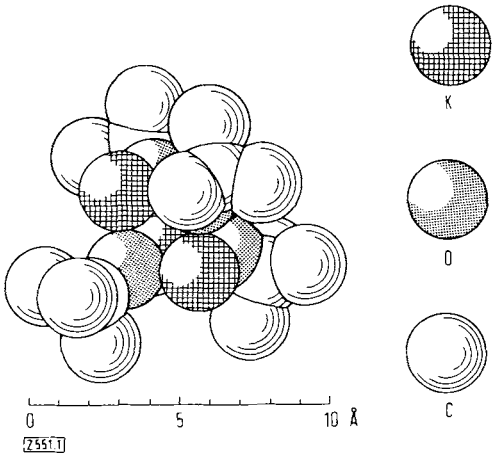

Fig. 1. Structure of potassium t-butoxide.

The following information about internal rotations was obtained from ^{1}H–NMR spectra (broad line resonance): the second moment (S_2)[1] is almost constant (2.4 ± 0.3 G^2) between +20 and −20 °C, rises rapidly between −20 and −50 °C, and at −80 °C reaches a value of 8.0 ± 0.5 G^2; we interpret this as freezing of the rotation of the t-butyl groups about their three-fold axes in the temperature range −20 to −50 °C. As the temperature falls further, the rotation of the individual methyl groups also becomes increasingly hindered as shown by the further increase in S_2, particularly in the region −130 to −160 °C. An end value of about 40 G^2 is reached at −190 °C.

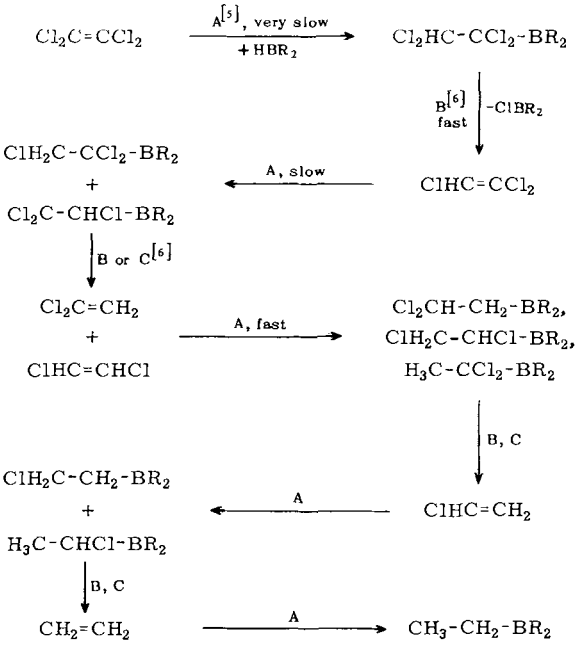
[1] The second moment is defined as $S_2 = \int_{-\infty}^{+\infty} f(H)\Delta H^2 dH / \int_{-\infty}^{+\infty} f(H)dH$. The unit G denotes gauss.

Preparation of Organoboron Halides from Halogenoalkenes and Organoboron Hydrides

By *R. Köster* and *W. Fenzl*[*]



Alkenes and cycloalkenes that are chlorinated or brominated in the vinyl or allyl position can be completely dehalogenated by boron hydrides. Whereas vinyl chlorides[1–4] and vinylidene dichlorides react even at room temperature, it is only above 150 °C that reasonably rapid exchange of chlorine for hydrogen occurs with trichloroethylene, tetrachloroethylene, or analogous compounds (*e.g.* perchloropropylene).

Organoboron chlorides are also obtained in high yield from perchlorocycloalkenes (*e.g.* perchlorocyclopentadiene) or perchlorodienes (perchlorobutadiene) and organoboron hydrides.

Sodium borohydride reacts in the presence of trialkylboranes in the same way as organoboron hydrides (*e.g.* tetraalkyldiboranes, which are always present in equilibrium with dialkylboron hydrides). For the reaction

$$5(C_2H_5)_2BH + Cl_2C{=}CCl_2 \rightarrow 4\ ClB(C_2H_5)_2 + (C_2H_5)_3B$$

hydroboration of the perchlorinated ethylene is the rate-determining step. Partially chlorinated ethylenes do not occur in the product mixture. The hydroborations and removals of Cl–BR$_2$ that constitute successive stages of the reaction lead to boranes with halogen-free alkyl groups (see reaction scheme). They are not catalysed by organoboron chlorides or aluminum chloride.

Experimental

66.4 g (0.4 mole, 55.4 g of Cl on C) of tetrachloroethylene and 151.7 g (2.0 BH equiv.) of tetraethyldiborane (13.29 ‰ of H$^\ominus$) are heated in a 500-ml autoclave at 190–225 °C for 18 h. After cooling, 15.15 l (NTP) of gas (=20 g; C_2H_6 93 %; CH_4 4.8 %; C_2H_4 0.9 %; C_4H_{10} 0.6 %) were released. Distillation of the brown liquid, which is formed in the reaction, gives 146 g of ethylboron chlorides (b.p. 73–92 °C). Yield: 37.7 g of Cl on B (68.1 %). Working up of the residue (52 g) gives, as well as boranes of higher chlorine content and unreacted tetrachloroethylene, 6 g of organocarboranes (b.p. 41–47 °C/10^{-3} mm), which contain mainly 1,3,5,6,7-pentaethyl-2,4-dimethyl-2,4-dicarbaclovoheptaborane(7) (mol. wt. 254).

Alkenes with chlorine in the allyl position are also completely dehalogenated. Thus the organoboron chlorides obtained from perchloropropene and ethyldiboranes contain also propyl groups on the boron. The reactions are clean so long as no boranes more highly chlorinated than diorganoboron monochlorides are formed. It is therefore advantageous to add an excess of trialkylborane to the reaction mixture, particularly when using sodium borohydride as source of B–H.

$$3\ NaBH_4 + 3\ (C_2H_5)_3B + 3\ C_2Cl_3H \rightarrow 9\ (C_2H_5)_2BCl + (C_2H_5)_3B$$

If the concentration of boron hydrides is too high, organocarboranes[7] are formed above 180 °C by condensation (loss of alkane, H_2). Since hexachlorocyclopentadiene is relatively easily hydroborated by tetraethyldiborane, it can be rapidly dehalogenated even at 170 °C.

$$3\ C_5Cl_6 + 24\ (C_2H_5)_2BH \xrightarrow{+\ \rangle BH} 18\ (C_2H_5)_2BCl + 4\ (C_2H_5)_3B + B_2(C_5H_8)_3$$

Experimental

52.8 g (0.196 mole) of hexachlorocyclopentadiene and 124.9 g (1.56 BH equiv.) of tetraethyldiborane (12.5 ‰ of H$^\ominus$) are shaken in a 500-ml autoclave at 170 °C for 2 h. After cooling, and release of 660 l (NTP) of ethane (containing a little CH_4

and traces of H_2 and C_4H_{10}), the 169 g of crude product (21.6 % of Cl on B, corresponding to 89 % of the Cl on C used) affords on distillation 135.6 g of diethylboron chloride and triethylborane (b.p. 79–83 °C; 26.7 % of Cl). There remains 33 g of a brownish viscous liquid (9.6 % of B), which contains, *inter alia*, bisboronated cyclopentane.

Acraldehyde Imine and 2-Methylacraldehyde Imine

By *B. Bogdanović* and *M. Velić* [*]

It was reported earlier [1] that dialkylaluminum *N*-alkylideneamides obtained by addition of dialkylaluminum hydrides to nitriles react with equivalent amounts of acetylacetone, with cleavage of the Al–N bond, to yield aldimines and dialkylaluminum acetylacetonates. This reaction is suitable for synthesis of aldimines on a preparative scale provided that the rather unstable aldimines can be separated from the organoaluminum compounds.

From diisobutylaluminum hydride and acrylonitrile (molar ration 1:1, in pentane at 20 °C) we obtained diisobutylaluminum *N*-allylideneamide *(1a)* as a pale yellow liquid, b.p. 105–110 °C/10^{-4} mm, in 58 % yield. This compound is dimeric in benzene. It reacts with acetylacetone in the molar ratio 1:1 in toluene at −5 °C, yielding acraldehyde imine *(4a)* which is proved to be present in the high-vacuum distillate (0 °C) by conversion into the π-complex *(3a)* on reaction with bis(triphenylphosphine)ethylenenickel [2] (yield 30 %). Solutions of free acraldehyde imine thus obtained are always contaminated by small amounts of diisobutylaluminum acetylacetonate and/or ammonia.

(a), R = H
(b), R = CH_3

Pure acraldehyde imine is isolated in higher yield as follows: *(1a)* reacts with bis(triphenylphosphine)ethylenenickel [2] with removal of ethylene to give high yields of the sparingly soluble, orange (acraldehyde diisobutylaluminoamide)bis-(triphenylphosphine)nickel *(2a)* [3]. The latter reacts with acetylacetone in the same way as *(1a)*, but in this case the imine can be separated from the soluble diisobutylaluminum acetylacetonate as the well crystalline, deep red complex *(3a)* (yield 84 %). The IR spectrum of the products obtained *via* both routes (*(1a)* → *(4a)* → *(3a)* and *(1a)* → *(2a)* → *(3a)*) showed that the compounds are identical. Acraldehyde imine *(4a)* can be removed from the π-complex *(3a)* by means of triphenyl phosphite, being obtained as distillate in pure, solvent-free form in yields of *ca.* 50 %. Yields of *ca.* 65 % are obtained if the imine is separated from *(3a)* in toluene solution and then distilled in a high vacuum.

Acraldehyde imine is a colorless liquid at −80 °C; its mass spectrum shows the molecular ion at *m/e* = 55. The ^{1}H–NMR spectrum of a perdeuteriotoluene solution (50 %) at −70 °C accords with structure *(4a)*: τ = 4.55 (H_A, doublet), τ = 4.47 (H_B, doublet), τ = 3.43 (H_C, multiplet), τ = 1.95 (H_D, double doublet), τ = −1.22 (H_E, doublet) with J_{DE} = 16 Hz; the signal for H_E is found only when the spectrum of the solvent-free compound is measured at −70 °C; the doublet structure is no longer recognizable from −40 °C upwards [4]. From the ^{1}H–NMR spectrum it can be shown that the pure compound is altered within a few hours even at −70 °C [**]; apparently polymerization or oligomerization occurs. In dilute solution, however, polymerization of the compound requires several days.

The aluminoamide *(1b)* (colorless crystals, b.p. 125–130 °C/10^{-4} mm; 98 % yield) was prepared analogously by addition of diisobutylaluminum hydride to methacrylonitrile. Reaction with bis(triphenylphosphine)ethylenenickel afforded the complex *(2b)* (89 % yield). In this case treatment with acetylacetone in the molar ratio 1:1 surprisingly did not lead to complete protolysis of the Al–N bond; a molar ratio of 3:1 was required for quantitative cleavage of the Al–N bond; the sparingly soluble aluminum trisacetylacetonate was then formed thus hindering isolation of the complex *(3b)*. This difficulty was overcome by cleaving *(2b)* with water. The aldimine π-complexes *(3a)* and *(3b)* are stable to hydrolysis. 2-Methylacraldehyde imine *(4b)* is obtained, like acraldehyde imine, by displacement from the π-complex with triphenyl phosphite (yield in toluene, 84 %). ^{1}H–NMR spectrum of *(4b)* in perdeuteriotoluene (50 %) at −70 °C: τ = 4.88 and 4.63 (H_A and H_B, singlets), τ = 8.06 ($CH_{3,C}$ singlet), τ = 2.12 (H_D, doublet), τ = 0.08 (H_E, doublet), J_{DE} = 16 Hz. The mass spectrum shows the molecular ion at *m/e* = 69.

The compounds *(4a)* and *(4b)*, not hitherto isolated, have been discussed as possible intermediates in the ammonoxidation of propene and isobutene to acrylonitrile and methacrylonitrile, respectively [5].

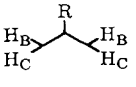
cis- and *trans*-Bis-(π-allyl)nickel Systems [1]

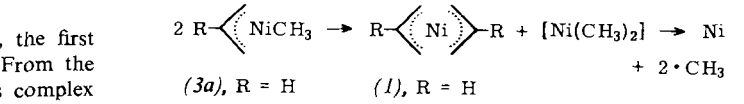
By *H. Bönnemann*, *B. Bogdanović*, and *G. Wilke* [*]



In 1961 we reported on bis-(π-allyl)nickel *(1)* [2], the first "pure" [3] allyl derivative of a transition metal. From the ^{1}H–NMR spectrum it could be shown that this complex exists in *cis-trans*-isomeric forms *(1a)* and *(1b)* [2b]. X-ray structure analysis [5] has proved that bis-(π-methallyl)nickel *(2)* [6] exists as *trans*-isomer [cf. *(1a)*] in the single crystal.

(1a) *(1b)*

The ^{1}H–NMR spectra of *(1)* and *(2)* are independent of temperature, within experimental error, from −70 to +30 °C, *i.e.* the proportions of the isomers in *(1)* (3:1) and *(2)* (2.3:1) remain substantially constant. The same proportions are found if the crystalline complexes are dissolved at −70 °C and their NMR spectra are measured immediately. For the time being, the groups of signals in the ^{1}H–NMR spectra [7] can be assigned to the *cis*- and *trans*-forms only on the basis of the following considerations of models.



Measurement of atomic distances on a scale model shows that on transition of the *trans*- *(1a)* into the *cis*-form *(1b)* (180 ° rotation of the allyl groups around the "σ-bond axis") the most favorable steric arrangement is obtained if the allyl groups are also twisted by about 10 ° around the axes β and β′ [see arrows in *(1b)*]. The *anti*-protons (H_C) are farther from

(1), R = H_A
(2), R = CH_3

the nickel (less shielded) in *(1b)* than in *(1a)*, while the *syn*-protons (H_B) and the *meso*-substituent approach the nickel somewhat more closely (increased shielding); the assignments given in the table then follow.

We obtained products with different proportions of isomers in the following way: (π-Allyl)- *(3a)* [8] and (π-methallyl)-methylnickel *(3b)* [1] disproportionate quantitatively above −78 °C as follows:

(3a), R = H *(1)*, R = H
(3b), R = CH_3 *(2)*, R = CH_3

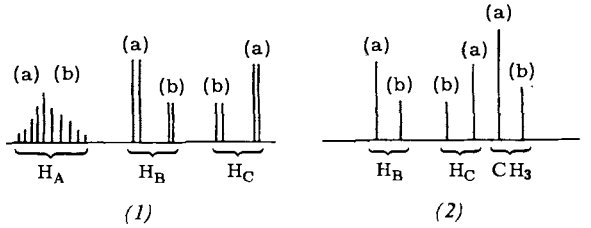
The $Ni(CH_3)_2$ decomposes at once to give CH_3 radicals and elemental nickel. The bis-(π-allyl)nickel compounds *(1)* and *(2)* obtained in this way can be isolated in crystalline form at −100 °C. The crystals were dissolved in deuteriotoluene at −78 °C and the ^{1}H–NMR spectra of the solutions were measured as the temperature increased (the samples were thawed over a period of 5 hours). The following proportions of isomers were calculated from the spectra.

Temp. (°C)	*(1a)* : *(1b)*	*(2a)* : *(2b)*
−70	7.8 : 1	0.5 : 1
−50	3.1 : 1	1.2 : 1
−30	3 : 1	2.3 : 1
+30	3 : 1	2.3 : 1
−70	3 : 1	2.3 : 1

From these results it follows that:

1. Bis-(π-allyl)nickel *(1)* and bis-(π-methallyl)nickel *(2)* occur as mixtures of *cis-trans*-isomers.

2. The *trans*-form is favored.



3. (π-Allyl)methylnickel *(3a)* decomposes largely stereospecifically to the *trans*-isomer (*trans*:*cis* = 7.8:1 instead of 3:1) at −75 °C, whereas under similar conditions the (π-methallyl)methylnickel *(3b)* affords the *cis*-form preferentially (*trans*:*cis* = 0.5:1 instead of 2.3:1).

4. At low temperatures the energetically favored equilibrium of *cis*- and *trans*-forms is established only slowly from these mixtures – with *(2)* more slowly than with *(1)*.

Final proof of the configuration of *(2b)* is currently being sought by X-ray structure analysis of the crystalline bis-(π-methallyl)nickel obtained by disproportionation.

Preparation of Diethylcarbamoyllithium [(Diethylamino)lithiooxycarbene] from Bis(diethylcarbamoyl)mercury

By *U. Schöllkopf* and *F. Gerhart* [*]

In organic chemistry, a reagent for one-stage nucleophilic introduction of carboxyl groups [1] would prove very useful. Alkali-metal compounds of formic acid derivatives should be most suitable for this purpose but are apparently unstable [2]. We are at present studying whether they can be prepared at low temperatures and whether they can be stabilized, perhaps in their tautomeric carbene forms, by complex formation with heavy-metal atoms [3].

When we treated bis(diethylcarbamoyl)mercury *(1)* [4] in tetrahydrofuran at *ca.* −75 °C with two equivalents of n-butyllithium we obtained diethylcarbamoyllithium *(3)*, or an equivalent reagent *(4)* (cf. below), which on reaction with carbonyl compounds gave α-hydroxy-*N*,*N*-diethylcarboxamides *(5)* and with tributyltin chloride gave tributyl(diethylcarbamoyl)tin [b.p. 118 °C/0.1 mm; IR spectrum: $\nu_{C=O}$ 1570 cm^{-1}, NMR spectrum (in CCl_4): N–CH_2– at τ = 6.66 (quartet) and 6.17 (quartet)]. In dilute HCl the compound evolves CO.

The reactions may begin by addition of the butyllithium to the mercury atom of *(1)* to form the dibutylmercury-(diethylamino)lithiooxycarbene complex *(2)*. We cannot yet decide whether this complex reacts directly with the electrophile (*e.g.* the carbonyl compound) (route a) or whether reaction takes place *via* a tautomer [*i.e.* (diethylcarbamoyl)lithium *(3)* or (diethylamino)lithiooxycarbene *(4)*] (route b).

X-ray Structure Analysis of a Dimer of 1-Methylazepine

By *G. Habermehl* and *S. Göttlicher* [*]

On reduction of 1-azepinecarboxylic esters with lithium tetrahydridoaluminate *Hafner* and *Mondt* [1] obtained 1-methylazepine, which dimerized very rapidly above 0 °C to afford two isomers melting at 171 and 66 °C respectively. On the basis of spectroscopic data and its dipole moment, the compound of m.p. 171 °C was assigned the structure of a 13,14 - dimethyl - 13,14 - diazatricyclo[6.4.1.1^{2,7}]tetradeca-3,5,9,11-tetraene *(1)*.

(1)

We have carried out an X-ray structure analysis of the hydrobromide (m.p. 240 °C) of this compound in order to prove the assigned structure and configuration.

The hydrobromide crystallizes, from 50 % methanol, in the triclinic form containing two molecules of water. The space group is P $\bar{1}$; the lattice constants are a = 8.14 Å; b = 8.77 Å; c = 7.15 Å; α = 94.5 °; β = 94.0 °; γ = 125.0 °. The unit cell contains one centrosymmetrical molecule.

Two and three-dimensional electron-density determinations by the heavy-atom method showed that the structure given by *Hafner* and *Mondt* is correct. Refinements were carried out by Fourier difference syntheses and by least-squares calculations. Bond distances and valence angles accord with the theoretical values.

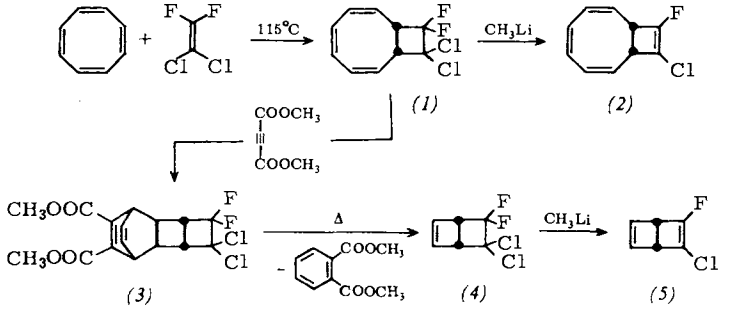
10-Chloro-9-fluorobicyclo[6.2.0]deca-2,4,6,9-tetraene and 3-Chloro-2-fluorobicyclo[2.2.0]hexa-2,5-diene

By *G. Schröder* and *Th. Martini* [*]

We are currently studying the behavior of cyclooctatetraene towards reagents that can undergo 1,2-cycloaddition and we report here its reaction with 1,1-dichloro-2,2-difluoroethylene.



When 30 g of cyclooctatetraene is heated in an ampoule with 40 g of 1,1-dichloro-2,2-difluoroethylene for 70 h at *ca.* 115 °C, 4.7 g of the cycloadduct $C_{10}H_8Cl_2F_2$ *(1)* [1], b.p. 53 °C/0.05 mm, is formed and can be separated from unchanged starting materials by fractional distillation. The spectral data [2] of *(1)* are: UV spectrum, λ_{max} = 246 nm (ε = 1800); NMR spectrum, two multiplets centered at τ = 4.2 and 6.3 (relative intensities 3:1).

Like other derivatives of cyclooctatriene [3], the adduct *(1)* reacts smoothly with dienophiles. This behavior and the general views concerning 1,2/1,2-cycloaddition [4] indicate the *cis*-configuration for the two bridgehead H atoms.

The adduct *(1)* (6.5 g) reacts smoothly with CH_3Li (from 15 g CH_3I and 1.5 g Li) in ether (250 ml) at *ca.* −20 °C, to yield 10-chloro-9-fluorobicyclo[6.2.0]deca-2,4,6,9-tetraene *(2)*. The mixture is treated at 0 °C with aqueous NH_4Cl, the ethereal phase is separated and dried, and the ether is distilled off in a rotatory evaporator at not more than 0 °C and at a pressure of *ca.* 1 mm [crude yield of *(2)*, 70 %]. Column chromatography [basic Al_2O_3, petroleum ether (b.p. 30 to 35 °C)] at 0 °C yields pure *(2)*. The structure of compound *(2)* follows from (i) the assumption that the C skeleton of *(1)* remains intact on dehalogenation by CH_3Li and (ii) the spectral data [2]: UV spectrum, pronounced shoulder at 246 nm (ε = 2400); NMR spectrum, multiplet with little fine structure at τ = 4.3 and a broad multiplet with well-developed fine structure between τ = 6.1 and τ = 7.1 (relative intensities 3:1).

Compound *(2)* is a colorless thermolabile liquid. Its half-life can be determined by means of NMR spectroscopy and amounts to *ca.* 8 h in CCl_4 at 20 °C. When kept at room temperature, 1–2 g of *(2)* rearranges almost explosively with loss of hydrogen halide, to 1-chloro- and 1-fluoro-naphthalene [5].

Gentle warming of a solution of *(2)* in, *e.g.*, CCl_4 affords the same end products in about the same proportions (8 parts of 1-chloro- and 1 part of 1-fluoro-naphthalene, determined by gas chromatography). We suggest that 1,9-dihalogeno-9,10-dihydronaphthalenes are formed *via* 2-chloro-1-fluoro[10]annulene [6] and afford the end products by elimination of HF or HCl.

With dimethyl acetylenedicarboxylate, the adduct *(1)* undergoes a Diels-Alder reaction.

Dimethyl acetylenedicarboxylate (3.8 g) is warmed with *(1)* (5 g) in benzene (40 ml) in an ampoule at 80 °C for 45 h. After removal of the solvent by distillation and recrystallization of the residue from petroleum ether/tetrahydrofuran, the adduct has the composition $C_{16}H_{14}Cl_2F_2O_4$ [1] (yield 80 %; m.p. 82–83 °C). Its spectral data (NMR, IR, and UV) are in accord with structure *(3)*. At 150–160 °C it decomposes into dimethyl phthalate [5] and the derivative *(4)* of bicyclo[2.2.0]-hexene [1] [yield of *(4)*, 65 % after purification by gas chromatography] in accord with the Alder-Rickert mechanism. The NMR spectrum [2] of *(4)* includes a signal, only slightly split, at τ = 3.65 and a triplet with fine structure at τ = 6.3 (relative intensities 1:1).

3-Chloro-2-fluorobicyclo[2.2.0]hexa-2,5-diene *(5)* is obtained from the product *(4)* (2.5 g) and CH_3Li (from 8.5 g CH_3I and 0.6 g Li) in ether (150 ml) at *ca.* −20 °C. The mixture is treated with aqueous NH_4Cl at *ca.* 0 °C and the ethereal phase is separated, dried, and concentrated to *ca.* one tenth of its original volume in a vacuum through a reflux column. The ethereal solution enriched in *(5)* is separated into its components by preparative gas chromatography [yield of pure *(5)*, 70 %]. The NMR spectrum [2] of *(5)* contains only a slightly split signal at τ = 3.50 (relative intensity 1) and two doublets of doublets (relative intensity 1) centered at τ = 6.30 and τ = 6.45. When *(5)* is warmed it gives pure *o*-chlorofluorobenzene [5], the half-life, determined by NMR spectroscopy, being three weeks in CCl_4 at 20 °C [7].

The reaction path *(1)* → *(3)* → *(4)* → *(5)* not only proves the structure of *(1)*, but also provides a convenient route to the "Dewar benzene" *(5)* from cyclooctatetraene. Pure *(5)* is a colorless liquid. It is sensitive to shock and explodes violently on gentle warming, and even when kept at 20 °C. It is advisable to handle the undiluted substance only in small quantities (*ca.* 50 mg).

[1] Satisfactory C,H analyses were obtained for this compound.

[2] The UV spectra were measured with a Beckman DK-2 instrument for solutions in n-hexane or cyclohexane; the NMR spectra were recorded with a Varian A-60 apparatus for solutions in CCl_4 or CS_2 with tetramethylsilane as internal standard.

[3] The Diels-Alder reaction is preceded by valence isomerization of the cyclooctatriene; see, *e.g.*, *G. Schröder* and *W. Martin*, Angew. Chem. *78*, 117 (1966); Angew. Chem. internat. Edit. *5*, 130 (1966); *A. C. Cope et al.*, J. Amer. chem. Soc. *74*, 4867 (1952).

[4] *J. D. Roberts* and *C. M. Sharts*, Organic Reactions *12*, 1 (1962).

[5] Identification was by comparison of the IR and UV spectra with those of authentic material.

[6] Unsubstituted [10]annulene was recently described as a species that exists only at low temperature: *E. E. van Tamelen* and *T. L. Burkoth*, J. Amer. chem. Soc. *89*, 151 (1967).

[7] *E. E. van Tamelen* and *S. P. Pappas*, J. Amer. chem. Soc. *85*, 3297 (1963), give two days as the half-life of unsubstituted "Dewar benzene" in pyridine at room temperature.

Synthesis and Structure of Dialkylgallium Fluorides

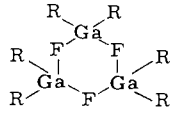
By *H. Schmidbaur*, *H. F. Klein*, and *K. Eiglmeier* [*]

In view of the distinctive position of dialkylaluminum fluorides [1–4] among dialkylaluminum halides, investigation of the corresponding gallium compounds appeared desirable [5–7].

We have found that the treatment of trimethyltin fluoride with trialkylgallium or trialkylgallium-ether complexes yields the desired compounds in good yields (85–95 %) and in high purity; the tetraalkyltin that is formed as by-product is readily separable.

$$(CH_3)_3Ga{\cdot}O(C_2H_5)_2 + (CH_3)_3SnF \rightarrow (C_2H_5)_2O + (CH_3)_4Sn + (CH_3)_2GaF \quad (1)$$

$$(C_2H_5)_3Ga + (CH_3)_3SnF \rightarrow (CH_3)_3SnC_2H_5 + (C_2H_5)_2GaF \quad (2)$$



Trimethylsilicon fluoride does not react with a trialkylgallium, although it does react with a trialkylaluminum[3].

Compounds *(1)* and *(2)* are colorless, viscous liquids that crystallize when cooled (m.p. 20–22 °C and −19 to −18 °C, respectively) and can be distilled without decomposition in a vacuum (b.p. 75 °C/20 mm and 92–94 °C/1 mm, respectively). They are very soluble, without decomposition, in diethyl ether, petroleum ether, cyclohexane, benzene, methylene chloride, and water (!). Cryoscopic molecular-weight determinations in benzene give the triple formula weight in each case.

Both benzene and aqueous solutions of *(1)* show only one ^{1}H–NMR signal for all the methyl groups, namely a singlet, $\delta CH_3 = +37$ or +17.5 Hz at 60 MHz (tetramethylsilane as external standard). The ^{1}H–NMR spectrum of *(2)* in the same solvents and referred to the same standard shows an A_3B_2 multiplet with J(HCCH) ≈ 7 Hz and $\delta CH_3 = +37.5$, $\delta CH_2 = -3$, or $\delta CH_3 = -66$, $\delta CH_2 = -25$ Hz.

The IR spectra contain very few absorption bands in the 4000–400 cm^{-1} region; for *(1)* there are, *inter alia*, the following bands: 613 s, 552 w, 538 m (νGaC$_2$), and 490 s, 420 s (νGaF) cm^{-1} [6]. The corresponding bands for *(2)* are at 597 sh, 582 vs, 525 m (νGaC$_2$) and 487 s, 425 s (νGaF) cm^{-1} [8].

From these spectra and the molecular weights we conclude that *(1)* and *(2)* have a symmetrical six-membered ring structure with coordinatively bivalent fluorine atoms.

(1), R = CH_3
(2), R = C_2H_5

Dimethyl-[3,4] and diethyl-aluminum fluoride[2], on the contrary, are tetrameric and form eight-membered rings. In the ^{1}H-NMR spectrum of dimethylaluminum fluoride $[(CH_3)_2AlF]_4$ containing traces of $(CH_3)_3Al$ we found a 1:2:1 triplet signal, $J(^1H-C-Al-^{19}F) = 4.65$ Hz, proving the presence of coordinatively bivalent fluorine. No comparable triplet signal is found in the spectra of *(1)* and *(2)*; it is presumably eliminated by rapid exchange processes[9].

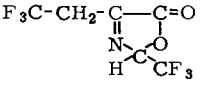
A General Method for the Preparation of β-Perfluoroalkylalanines



By *W. Steglich, H.-U. Heininger, H. Dworschak*, and *F. Weygand*[*]

We recently reported the synthesis of *C*-perfluoroalkylglycines[1] and now describe a general process for the preparation of β-perfluoroalkylalanines *(1)*. Starting materials are the perfluoroacyldiazoacetic esters *(2)* that are readily accessible by treatment of perfluoro carboxylic anhydrides with ethyl diazoacetate. If these esters *(2)* are illuminated in acetonitrile solution (concentration 0.3 mole/l) with a quartz immersion lamp (Hanau TQ 81, 70 W) for 10 h, 60 to 70 % yields of 2-methyl-5-perfluoroalkyl-4-oxazolecarboxylic esters *(3)* are formed[2], which on catalytic hydrogenation in glacial acetic acid in the presence of PtO_2 afford *N*-acetyl-β-perfluoroalkylalanine ethyl esters *(4)* (yield 75–85 %). The amino acids *(1)* are obtained therefrom in about 80 % yields by hydrolysis with conc. HCl (18 h, 90 °C).

	R_F	*(2)*, B.p. (°C/mm)	*(3)*, B.p. (°C/mm)	*(4)*, M.p. (°C)	*(1)*, M.p. (°C)
(a)	CF_3	[2]	80/1.1	88–89	260–265 [3]
(b)	C_2F_5	75–77/10	67–69/2.2	86–87	215 (decomp., subl.)
(c)	C_3F_7	80–81/10	68–70/0.9	49–50	202 (decomp., subl.)

For conversion into the L-form, DL-2-amino-4,4,4-trifluorobutyric acid *(1a)* was first *N*-trifluoroacetylated (*N*-trifluoroacetyl-*(1a)*, 80 %, m.p. 135–136 °C) and cyclized by dicyclohexylcarbodiimide to 4-(2,2,2-trifluoroethyl)-2-(trifluoromethyl)oxazol-5(2*H*)-one *(5)* (70 %), b.p. 58 °C/12 mm. Treatment of the oxazolone with dimethyl L-glutamate in tetrahydrofuran gave a dimethyl *N*-(2-trifluoroacetamido-4,4,4-trifluorobutyryl)-L-glutamate containing 83 % of the L-L- and

(5)

17 % of the D-L-diastereoisomer (determined by gas chromatography[4]). Assignment of configuration to the diastereoisomers follows from the rule that treatment of 2-trifluoromethyl-2*H*-oxazolones with optically active amino esters always give preferentially the diastereoisomer that has the same absolute configuration at both asymmetric centers[5].

After three recrystallizations from ether, pure (gas chromatography) L-L-*N*-(trifluoroacetyl)dipeptide dimethyl ester (m.p. 96 °C, $[\alpha]_{546}^{25} = -4.1°$, $c = 9.6$ in ethyl acetate) was isolated in 33 % yield. Hydrolysis with conc. HCl and removal of the glutamic acid with Amberlite IR 45 gave L-*(1a)* in 87 % yield (m.p. 189.5–190.5 °C, $[\alpha]_{546}^{25} = -6.3°$, $c = 16.4$ in 1 N HCl). To prove that the hydrolysis did not involve any racemization, the product was benzyloxycarbonylated [Cbo-L-*(1a)*, 90 %, m.p. 121 °C] and converted by dicyclohexylcarbodiimide and dimethyl L-glutamate into dimethyl *N*-[2-(benzyloxycarbonylamino)-4,4,4-trifluorobutyryl]-L-glutamate (m.p. 99–100 °C). The ester obtained by removal of the Cbo group and subsequent *N*-trifluoroacetylation shows only the peak of the L-L-diastereoisomer in its gas chromatogram.

A Simple Synthesis of 3,3,3-Trifluoroalanine [1]

By *F. Weygand, W. Steglich*, and *F. Fraunberger* [*]

Although treatment of *N*-acyltrifluoroacetaldimines *(1)* with cyanides yields ethylene derivatives with elimination of fluoride [2], anhydrous hydrogen cyanide reacts smoothly with *(1)* to form 2-acylamino-3,3,3-trifluoropropionitriles *(2)*.

(1) *(2)* *(3)*

(2a), Ac = C_6H_5CO-, yield 81 %, m.p. 127.5–128.5 °C

(2b), Ac = $C_6H_5-CH_2O-CO-$, yield 98 %, m.p. 106–107 °C

The nitriles *(2)* can be hydrolysed to 3,3,3-trifluoroalanine *(3)* by boiling HCl (6 N to 10 N) containing a little glacial acetic acid. Thus boiling *(2b)* for 5 h with 6 N HCl gives an 81 % yield of *(3)*, whose properties correspond to those of a product obtained by a different route [3]. Boiling *(2a)* for only 4 h with 1 N HCl hydrolyses it partially to *N*-benzoyl-3,3,3-trifluoroalanine [3] (65 % yield). Since *N*-acyltrifluoroacetaldimines are readily accessible from *N*-acyl-1-chloro-2,2,2-trifluoroethylamines [4], relatively large quantities of *(3)* can be conveniently prepared in this way.

Experimental

(2b): *N*-Benzoyloxycarbonyl-1-chloro-2,2,2-trifluoroethylamine [4,5] (5 g) in anhydrous tetrahydrofuran (THF) is treated with triethylamine (2.6 ml). The triethylamine hydrochloride is filtered off with exclusion of moisture and washed with THF. The filtrate is cooled to −50 °C and HCN (from 20 g of KCN and 50 % H_2SO_4, dried over P_2O_5) is passed in. The cooling bath is removed, the mixture is left overnight, and the excess of HCN is then removed at 60 °C in a stream of nitrogen. Evaporation of the THF leaves 4.7 g (98 %) of *(2b)*, m.p. 102–104 °C; the m.p. is 106–107 °C after recrystallization from chloroform/petroleum ether.

(3): The compound *(2b)* (14.5 g) is heated under reflux with 6 N HCl (300 ml) and glacial acetic acid (50 ml) for 5 h. After evaporation of the solvent the residue is taken up in water and the solution evaporated, this process being repeated three times. Finally the residue is dried by addition of toluene and subsequent removal thereof under vacuum. The residue is then covered with chloroform (100 ml); most of it dissolves when triethylamine (20 ml) is added with stirring, and the insoluble part (ammonium chloride) is filtered off. Addition of glacial acetic acid precipitates the product *(3)* (yield 6.5 g, 81 %).

Tetramethoxyallene, the Diacetal of Carbon Suboxide

By *R. W. Hoffmann* and *U. Bressel* [*]

1,1-Dihalogenotetramethoxycyclopropanes *(2)* [2], which are obtained from tetramethoxyethylene *(1)* [1] by the action of a haloform and potassium t-butoxide, undergo exothermic reaction at 80–110 °C [3] to afford methyl 2-halogeno-3,3-dimethoxyacrylates *(3)* [4]. Treating *(2b)* with n-butyllithium [5] gives tetramethoxyallene *(4)* in 72 % yield; the same product is obtained on treatment of *(2a)* with n-butyllithium.

Compound	M.p. (°C)	B.p. (°C/mm)	Yield (%)	NMR (τ)	IR (cm^{-1})
(2a), X = Cl	46–48		40	6.47 singlet ($CDCl_3$)	
(2b), X = Br	63–65		47	6.52, singlet ($CDCl_3$)	
(3a), X = Cl		62/1	91	6.04 singlet, 6.18 (1:1:1), 6.28 (CCl_4)	1715,1615, 1290-1310, 1200,1095
(3b) X = Br		92/1	89	as *(3a)*	1710,1595, 1280,1090
(4)	65–67		72	6.54, singlet (CCl_4)	1920,1215, 955
(5)		70–71/1	81	6.80 singlet, 7.92 (9:1) (CCl_4)	

In contrast to unsubstituted allene[6], the product *(4)* is protonated on the central carbon atom owing to the influence of the four methoxy groups, as is shown by the formation of dimethyl malonate *(6)* on treatment of *(4)* with anhydrous HCl. As a double ketene acetal, *(4)* is readily hydrolysed, again affording *(6)*. Addition of methanol to *(4)* leads to hexamethyl orthomalonate *(5)*.

1,1-Dibromotetramethoxycyclopropane (2b):

A suspension of potassium t-butoxide (2.87 g, 25.6 mmoles) in anhydrous petroleum ether (25 ml) is added dropwise to a solution of tetramethoxyethylene (3.78 g, 25.6 mmoles)[1] and bromoform (6.47 g, 25.6 mmoles) in anhydrous petroleum ether (10 ml) at −10 °C, with stirring, under a N_2 atmosphere. After one hour's stirring at 25 °C, enough water is added to dissolve the salts. On extraction with petroleum ether, drying over $MgSO_4$, and concentration, *(2b)* is obtained; recrystallization from petroleum ether gives 3.84 g (47 %) of product, m.p. 63–65 °C.

Tetramethoxyallene (4):

A 1.45 M solution (24 ml) of n-butyl-lithium in pentane is added dropwise over 1 h to a stirred solution of *(2b)* (8.37 g, 26.2 mmoles) in anhydrous petroleum ether (40 ml) at −80 °C under nitrogen. When all the butyl-lithium has reacted, the mixture is filtered at −80 °C under nitrogen through a sintered-glass filter. The residue is washed with three portions each of 50 ml of anhydrous petroleum ether. Concentration of the last 100 ml of wash liquor under nitrogen affords the product *(4)* (3.05 g, 72 %), m.p. 65–67 °C.

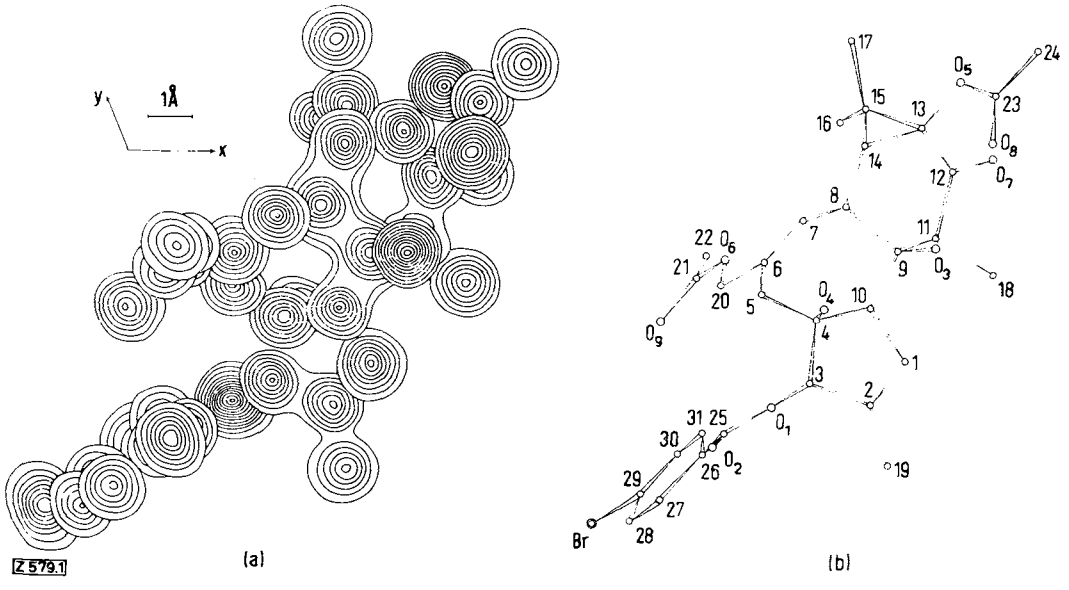
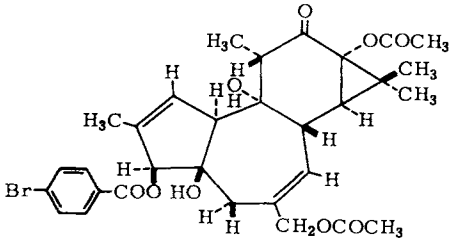
X-ray Structure Analysis of Neophorbol

By *W. Hoppe*, *F. Brandl*, *I. Strell*, *M. Röhrl*, and *I. Gassmann*[*] and *E. Hecker*, *H. Bartsch*, *G. Kreibich*, and *Ch. v. Szczepanski*[**]

In 1966, phorbol *(2)*, the parent alcohol of the tumor promoting compounds from croton oil, was assigned the structure of a 4,9,12,13,20-pentahydroxy-1,6-tigliadien-3-one[1]. The relative configuration of seven of the eight asymmetric centers was established[1,2]. We have now been able to grow suitable single crystals of a derivative of phorbol, neophorbol 13,20-diacetate 3-*p*-bromobenzoate *(1)* [m.p. 216–217 °C, λ_{max} = 245, (282)nm, ε_{max} = 21100, (880) (in CH_3OH)], for X-ray structure analysis. X-ray analysis results[3] indicated the relative configuration shown in Fig. 1 (crystal data: space grouping $P2_1$, $Z = 2$, unit cell dimensions a = 12.31 Å, b = 12.91 Å, c = 9.87 Å, γ = 111.29 °). The site of the *p*-bromobenzoyl residue was determined by means of the convolution-molecule method. A series of successive





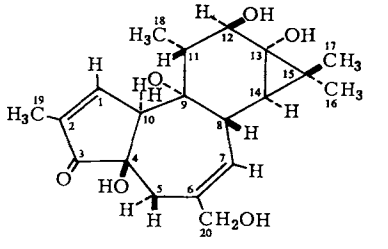


Fig. 1. (a) Fourier synthesis of neophorbol-13,20-diacetate-3-*p*-bromobenzoate. Light atoms: line distance 1e/Å^3; Bromine: 1 line 2e/Å^3; Distance of remaining high lines 5e/Å^3.

(b) Perspective representation of neophorbol-13,20-diacetate-3-*p*-bromobenzoate. Direction of the *z*-axis perpendicular to the *x*/*y* plane.

Fourier syntheses yielded a structure which, referred to H-14, has the configuration 3-*trans*-4-*trans*-9-*cis*-13-*cis*. An automatic structure analysis by the phase-correction method [4] led to the same result. Following our first communications [1–3] a further confirmation of the constitution and

(1)

(2)

relative configuration of phorbol was obtained by X-ray structure analysis of a phorbol 20-(5-bromofuroate) [5].

The absolute configuration of *(1)* was determined by calculation and measurement of approximately 200 selected Bijvoet pairs. It corresponds to the mirror image of the first discussed absolute configuration of phorbol [2] and is (incidentally) the same as the relative configuration referred to in reference [3] and shown in Fig. 1.

On the basis of X-ray structure analysis the absolute configuration of phorbol is represented by *(2)*, in which the reference atom H-14 is situated on the underside of the molecule (α-side). Phorbol is, therefore, a 4,9,12β,13,20-pentahydroxy-1,6-tigliadien-3-one. Accordingly the asymmetry center C-14 has (*R*)-chirality and tiglian [6] has the absolute configuration of a (1a*S*), 1,1,3 ξ,6 ξ,8*c*-pentamethyl-(1a*r*H, 1b*t*H, 4a*t*H, 7a*c*H, 7b*c*H, 9a*c*H)-tetradecahydro-1*H*-cyclopropa[3,4]benz[1,2-*e*]azulene.

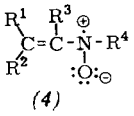
CONFERENCE REPORTS

ESR Spectroscopic Studies of Nitroxide Radicals that are Capable of Mesomerism

By *H. G. Aurich* [*]

N,N'-Substituted *N*-hydroxyamidines have been prepared by various methods. Spectroscopic results suggest that these compounds exist in the tautomeric α-amino nitrone form. Their oxidation leads to nitroxide radicals in which delocalization of the unpaired electron over the azomethine group is possible. ESR spectra provide information about the extent of this delocalization.

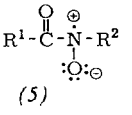
(1) *(2)* *(3)*



(a): $R^1 = R^2 = R^3 =$ aryl
(b): $R^1 = R^2 =$ aryl, $R^3 =$ t-butyl
(c): $R^1 = R^2 =$ aryl, $R^3 = H$
(d): $R^1 =$ t-butyl, $R^2 =$ aryl, $R^3 = H$
(e): $R^1 =$ aryl, $R^2 =$ t-butyl, $R^3 = H$
(f): $R^1 = R^2 =$ t-butyl, $R^3 = H$

Exact analysis of the complicated ESR spectra of the nitroxide radicals *(3a)* to *(3e)* is possible only after the introduction of t-butyl groups into various positions of the phenyl groups. The coupling constants found for the nitroxide- and the azomethine-nitrogen can be used as an approximate measure of the spin density on the nitroxide group and on the azomethine-nitrogen.

	Coupling constants (in gauss)	
	^{a}N(nitroxide)	^{a}N(azomethine)
(3a)	9.8–10.1	0.87
(3b)	10.1–10.3	0.86–0.88
(3c)	7.40–7.46	2.94–3.02
(3d)	8.21–8.30	2.61–2.70
(3e)	8.24	3.49
(3f)	9.25	3.20



As shown by comparison of the coupling constants, the spin density on the azomethine-nitrogen is substantially smaller for the radicals *(3a)* and *(3b)*, with R^3 = aryl or t-butyl, than for the radicals *(3c)* to *(3f)*, with $R^3 = H$. From this it is concluded that in *(3a)* and *(3b)* the nitroxide group is twisted with respect to the azomethine group, so that delocalization of the unpaired electron over the azomethine group is hindered. For steric reasons, groups R^1 and R^3 would then be expected to assume an orientation in the *anti*-position. When $R^3 = H$ a *syn*-arrangement of R^1 and R^3 at the azomethine group is possible, and the nitroxide group with R^2 can be almost coplanar with the azomethine group; this leads to an increase of the spin density on the azomethine group and a decrease of that on the nitroxide group.

For nitroxide radicals with vinyl or acyl groups that can undergo mesomerism, only the coupling constants of the nitroxide-nitrogen (and the phenyl-protons of the neighboring phenyl nucleus) are available for comparison. As

(4)

R^1 to R^4 = aryl or
$R^1 = R^3 = R^4$ = aryl, R^2 = CN

(5)

R^1 = aryl or methyl
R^2 = aryl

would be expected from the steric relations, the coupling constants of the vinyl-nitroxide radicals *(4)* studied are comparable with those of the azomethine-nitroxide radicals *(3a)* and *(3b)*, and those of the acyl-nitroxide radicals *(5)* are comparable with those of the azomethine-nitroxide radicals *(3c)*.

The Biosynthesis of Aromatic Amino Acids and its Control

By *F. Lingens*[*]

The biosynthetic pathway to aromatic amino acids branches at chorismic acid *(1)*. By studying the control mechanism of this biosynthesis by yeast (*Saccharomyces cerevisiae*), the following enzymes could be detected and concentrated: 3-deoxy-2-oxo-*arabo*-heptonic acid 7-phosphate synthetase (DAHP synthetase) (a), chorismate mutase (b), prephenate dehydrogenase (c), prephenate dehydratase (d), anthranilate synthetase (e), and *p*-aminobenzoate synthetase (f).

(1)

DAHP synthetase could be separated chromatographically into three isoenzymes, one of which was allosterically inhibited by phenylalanine (Phe) and a second by tyrosine (Tyr); the third is not inhibited by phenylalanine, tyrosine, or tryptophan (Trp). Chorismate mutase consists of two isoenzymes, both of which are inhibited by tyrosine; tryptophan induces and activates this enzyme. Prephenate dehydrogenase is inhibited by tyrosine; phenylalanine causes both induction and activation. Prephenate dehydratase is inhibited allosterically by phenylalanine and repressed in its biosynthesis. Anthranilate synthetase is inhibited allosterically by tryptophan and repressed. *p*-Aminobenzoate synthetase can be induced by simultaneous addition of phenylalanine, tyrosine, and tryptophan (multivalent induction)[1].

Corresponding studies with an alkaloid-producing strain of *Claviceps paspali* gave the following results. The DAHP synthetase could be separated into three isoenzymes, which are inhibited by phenylalanine, tyrosine, and tryptophan, respectively. The last named isoenzyme shows 60 % of the total activity. The concentrated chorismate mutase is inhibited by phenylalanine or tyrosine; tryptophan activates it. Prephenate dehydrogenase and dehydratase show allosteric inhibition by tyrosine and phenylalanine, respectively. Anthranilate synthetase is not inhibited by tryptophan[2].

Model Experiments on Oxidative Phosphorylation

By *Th. Wieland*[*]

Conversion of the free energy of chemical reactions, in the present case oxidation of bound hydrogen, into the "energy-rich" pyrophosphate linkage of adenosine triphosphate (ATP) by synthesis from adenosine diphosphate (ADP) and orthophosphate (P) is the fundamental process for the life of aerobic organisms. This conversion takes place, in some manner still unknown, in close connection with the "respiration chain" *i.e.* the organized enzyme system of the mitochondria, in which pyridinium nucleotide (NAD), flavine adenine dinucleotide (FAD), (presumably) ubiquinone, and cytochrome bring electrons of the fuel to oxygen. Since oxidative phosphorylation can be prevented by SH blocking agents, the system must contain essential thiol groups in its structural units. Model experiments on the oxidative conversion of an energy-poor phosphoric ester linkage into an energy-rich phosphate linkage have been performed in several laboratories. For instance, hydroquinone monophosphates, as well as *S*-alkyl thiophosphates, have been converted into phosphorylating agents, but oxidative activation of an inorganic phosphate has not previously been achieved in a model system. With *E. Bäuerlein* we have found two classes of compounds that produce oxidative linkage and activation of phosphate: monothiohydroquinone *S*-alkyl ethers *(1)* and thiolactones *(2)* lead to a 20 to 30 % yield of ATP on oxidation of a mixture of ADP and P by bromine

(1) (2) (3)

in an anhydrous medium, *e.g.* in pyridine. The process is prevented by presence of 2,4-dinitrophenol, particularly in the case of compound *(2)*. Thiazolidones *(3)*, in place of the thiolactone *(2)*, can also produce oxidative phosphorylation (*H. Aquila*).

Structures such as *(2)* and *(3)* (with larger rings) can be considered to be produced in the tertiary structures of proteins. The reaction with thiolactone, for which a plausible mechanism can be formulated, can be conceived as occurring at various places in the respiration chain, since the thiolactone could be oxidized, with simultaneous activation of phosphate, by all oxidizing members of the respiration chain (DPN, FAD, quinones, oxidized cytochromes).

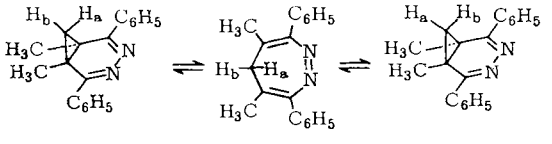
Valence Tautomerism in Heterocyclic Systems

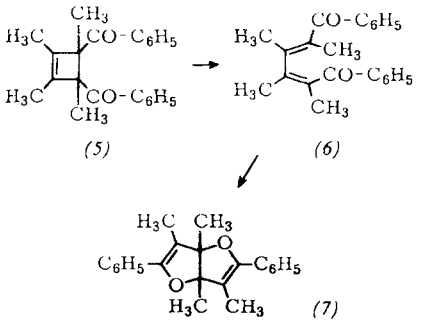
By *G. Maier* [*]



Valence tautomerism of the type *(1)* ⇄ *(2)*, where $n = 1$ or 2, has been described for carbocyclic compounds. We were interested in the question whether analogous changes could be realized if carbon atoms 3 and 4 were replaced by heteroatoms.

(1) (2)

Various *cis*-1,2-diacylcyclopropanes and *cis*-3,4-diacylcyclobutenes [oxidation of hexamethyl(Dewar benzene) by $KMnO_4$ gives 3,4-diacetyl-1,2,3,4-tetramethylcyclobutene] were therefore prepared and converted into cyclic azines by hydrazine.



It transpired that valence-tautomeric relations persist after introduction of nitrogen atoms. This follows from, for instance, the temperature-dependence of the NMR spectrum of 1,6-dimethyl-2,5-diphenyl-3,4-diazanorcaradiene *(3)*. The two geminal cyclopropane protons H_a and H_b give two doublets at room temperature. The resolution is lost on warming to 70 °C, and at 130 °C a singlet arising from the two protons appears at a position midway between the

(3a) (4) (3b)

positions of the original signals. These changes are reversible and indicate the valence-tautomeric equilibrium *(3a)* ⇄ *(4)* ⇄ *(3b)*, which lies entirely on the bicyclic side.

Heating the diacylcyclobutenes also gives products that have been identified. If the reactions occurred in the manner of a Cope rearrangement with participation of two carbonyl groups, cyclic peroxides would be formed, but that is not the case. In the first step, stereospecific ring-opening in accordance with the Woodward-Hoffmann rules leads to *cis,trans*-diacylbutadienes. For instance, the dibenzoyl compound *(5)* is converted at 70 °C into the butadiene derivative *(6)*, and this in a subsequent reaction into the bicyclic compound *(7)*.

Photochemical Studies of Quinizarin

By *H. Labhart* [*]

Photochemical reaction of quinizarin *(1)* (2×10^{-5} molar in degassed hexane) is often markedly accelerated by the presence of other substances (10^{-5} molar), benzophenone and some quinones being particularly effective. Measurements of the quantum yield as a function of the wavelength of the incident light have shown that with benzophenone as accompanying substance the primary step is excitation of that molecule. However, further reaction does not occur by sensitization of the triplet state of the quinizarin but, instead,

(1) (2) (3)

solvent radicals L·, which are first formed by hydrogen abstraction, react with quinizarin to give the photoproducts that are identified mass-spectrometrically. The UV spectrum of these products is very similar to that of 2,3-dihydroquinizarin. It is most probable that the compounds *(2)* and *(3)* are formed.

Periodates

By *H. Siebert* [*]

From the reactions of alkaline periodate solutions it can be concluded that they contain binuclear anions $[H_2I_2O_{10}]^{4-}$ Crystal structure analysis of the salt $K_4H_2I_2O_{10}\cdot8H_2O$ showed that the anion consists of two IO_6 octahedra with a

common edge. According to their IR spectra, many other periodates obtained from aqueous solution must contain an ion of the same structure. Salts containing the ions $[H_3I_2O_{10}]^{3-}$ and $[HI_2O_{10}]^{5-}$ have also been isolated.

Crystal structure analysis of $K_4I_2O_9$ established the structure *(1)*, with three oxygen bridges, for the anion.

(1)

The IO_6 group functions as a bidentate ligand in the periodate complexes of transition metals known hitherto, but it is probably tridentate in the recently prepared complexes containing the anions $[Pt(IO_6)_2]^{6-}$ and $[Pd(IO_6)_2]^{6-}$.

The Theory of Ring-opening Reactions

By *W. Kutzelnigg* [*]

The course of electrocyclic ring-closure and ring-opening reactions can often be elucidated from symmetry considerations alone. However, symmetry considerations alone lead only to the conclusion that ring-opening of the cyclopropyl cation, such as occurs after nucleofugal separation of a toluenesulfonate group from a cyclopropyl toluenesulfonate, should occur in a disrotatory manner. Semiquantitative consideration (by *Hoffmann*'s "extended Hückel method") of the course of reaction, starting from a cyclopropyl cation *in statu nascendi*, explains why, in agreement with experiment, one of the two possible disrotatory cleavages must be favored, namely, that in which the groups originally *trans* to the toluenesulfonate group turn outwards.

It follows that the cyclopropyl cation should be unstable (not even short-lived) and should rearrange to the allyl cation without involving any activation energy. Attempts are now in progress to support this concept by *ab initio* calculations. In agreement with this concept the toluenesulfonate group separates appreciably more easily if separation is accompanied by simultaneous ring opening. As soon as reaction is half complete the cation possesses almost all the π-electron energy of the allyl cation. In bicyclic systems such as were recently studied by *U. Schöllkopf, P. v. R. Schleyer, et al.* [1], complete ring-opening by the most favored route may be sterically hindered; in such cases a species representing an intermediate stage between the cyclopropyl and the allyl cation should be an intermediate of sufficiently long life and should show the reactions that are associated with approximately equal distribution of the positive charge over the three C atoms and with non-planar arrangement of the substituents on the central C atom.

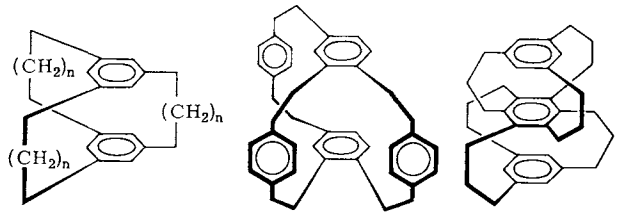
SELECTED ABSTRACTS

The crystal structure of gold trifluoride was determined by *F. W. B. Einstein, P. R. Rao, J. Trotter*, and *N. Bartlett* from a single-crystal diagram. AuF_3 is the least closely packed of the noble metal fluorides. The diamagnetic crystals are hexagonal (space group $P6_122-D_6$). AuF_3 is polymeric: four fluorine atoms surround the gold atom in an almost square arrangement and each "square" shares two *cis* fluorine atoms

with the neighboring squares. The non-bridging fluorine atoms at the same time represent the apexes of octahedrons around neighboring gold atoms, so that a hexagonal helix of AuF_6 octahedrons arises. / J. chem. Soc. (London) A *1967*, 478 / –Bu. [Rd 677 IE]

The crystal and molecular structures of azulenediiron pentacarbonyl *(1)* have been determined by *M. R. Churchill*. *(1)* crystallizes in the triclinic system (space group $C\bar{1}$) with $a = 7.32 \pm 0.01$ Å; $b = 14.48 \pm 0.02$ Å; $c = 14.76 \pm 0.02$ Å; $\alpha = 116.2 \pm 0.2°$; $\beta = 92.3 \pm 0.2°$; $\gamma = 93.0 \pm 0.2°$; $Z = 4$. The carbon atoms of the five-membered ring form a π-cyclopentadienyl system, which is bonded to an $Fe(CO)_2$ group, while three atoms of the seven-membered ring participate in a π-allyl bond to an $Fe(CO)_3$ group. Unequal Fe-C(allyl) bond



(1)

lengths, distortion of the azulene ligand from planarity, and a relatively long iron-iron bond (2.782 Å) indicate that the molecule *(1)* may be strained. / Inorg. Chem. *6*, 190 (1967) / –Sch. [Rd 659 IE]

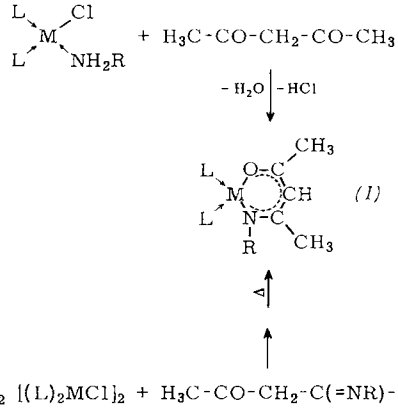
Novel cage compounds such as *(1)*, *(2)*, and *(3)* have been prepared by *A. J. Hubert*. The principle of the synthesis is based on a cyclotrimerization of acetylenes with Ziegler catalysts $[TiCl_4/Al(iso\text{-}C_4H_9)_3]$. *(1)* can be obtained either from α,ω-alkadiynes (<1% yield) or from 1,3,5-tri-ω-alkynylbenzene (yields 16–32%). The starting material for *(2)* is *p*-di-ω-alkynylbenzene (0.4% yield of *(2)*, together with the 1,3,5-isomer and other (mixed) isomers). *(3)* is obtained from hexa(pent-4-ynyl)benzene.

(2) may include 1 molecule of solvent, *e.g.* cyclohexane. *(1)* with $n = 5$ (m.p. 265 °C, b.p. 200–250 °C/0.1 mm) can be obtained in 53% yield, since the bond strain and the π-elec-

(1) (2) (3)

tron repulsion reaches a minimum in this compound. Compounds with even *n* have lower melting points than those with odd *n*. The UV absorptions also alternate with *n*. / J. chem. Soc. (London) *C 1967*, 6, 11, 13 (1967) / –Bu.

[Rd 668 IE]



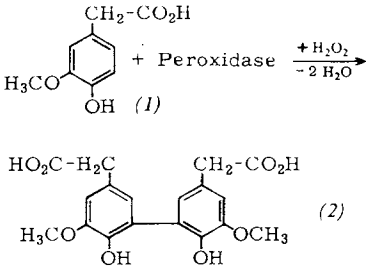
A versatile new enamine synthesis is reported by *W. A. White* and *H. Weingarten*. Stoichiometric quantities of $TiCl_4$, a secondary amine, and a ketone or aldehyde react within a few hours or days to give the desired enamine.

$$2\ R{-}CH_2{-}CO{-}R' + 6\ HNR''_2 + TiCl_4 \rightarrow 2\ RCH{=}C(NR''_2)R' + 4\ R''_2NH_2Cl + TiO_2$$

The yields are between 55 and 94%, *e.g.* 72% in the case of dimethyl(1-isopropyl-2-methylpropenyl)amine. / J. org. Chemistry *32*, 213 (1967) / –WG.

[Rd 669 IE]

Schiff bases of acetylacetone form chelates with Ir(I) and Rh(I). *F. Bonati* and *R. Ugo* were able to prepare dicarbonyl-(2-iminopent-3-en-4-olato)iridium(I) and -rhodium(I) complexes by two routes:



$$\tfrac{1}{2}\ [(L)_2MCl]_2 + H_3C{-}CO{-}CH_2{-}C(=NR){-}CH_3$$

These chelates *(1)* are crystalline, stable in air, sublimable, monomeric, diamagnetic, and soluble in nonpolar organic solvents. It is interesting to note that the Schiff bases are more readily hydrolysed in the form of the complexes than in the free state. A number of chelates and ligand-exchange products are given in the table.

M	L^1	L^2	R	M.p. (°C)	Color
Ir	CO	CO	p-CH_3–C_6H_4	153	yellow

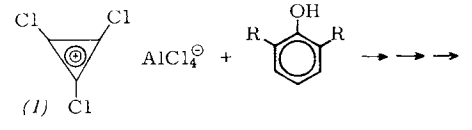
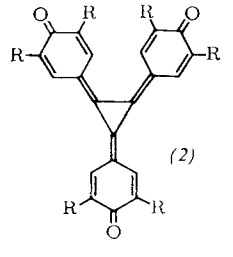
/ J. organometallic Chem. *7*, 167 (1967) / –Jg. [Rd 694 IE]

The fluorimetric determination of oxidases. *G. G. Guilbault*, *D. N. Kramer*, and *E. Hackley* have introduced (4-hydroxy-3-methoxyphenyl)acetic acid *(1)* (homovanillic acid) as a new reagent for the fluorimetric determination of oxidases. For example, when about 0.1 ml of the peroxidase solution under examination is added to 2.7 ml of 0.1 M Tris buffer (pH 8.5), 0.1 ml of 0.3% peroxide solution, and 0.1 ml of a solution of homovanillic acid (2.5 mg/ml), the fluorescent dimer *(2)* is formed (λ_{max}^{abs} = 315, λ_{max}^{em} = 425 mμ). With peroxide concentrations of 3×10^{-3} to 1×10^{-7} mole/l, it was possible to determine peroxidase concentrations of 0.006 to 2.3 units per ml from the time-dependence of the fluorescence



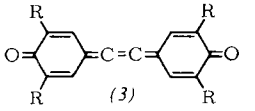
(1)

(2)



intensity. Since the reagent solution is stable, this method is superior to the diacetylfluorescein and scopoletin methods. / Analytic. Chem. *39*, 271 (1967) / –Jg. [Rd 693 IE]

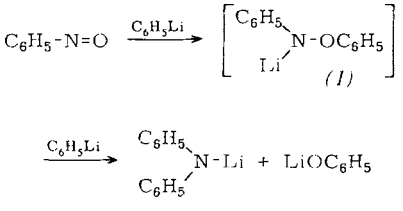
Monomeric diphenylberyllium complexes $(C_6H_5)_2BeL_2$ have been described by *G. E. Coates* and *M. Tanah*. All complexes stabilized by chelating ligands, such as *N,N,N',N'*-tetramethylethylenediamine, glycol dimethyl ether, or glycol dimethyl dithioether, are monomeric and are relatively slowly hydrolysed. For example, the complex $(C_6H_5)_2Be{\cdot}CH_3SC_2H_4SCH_3$ (m.p. 127–128 °C), which is formed from beryllium powder and diphenylmercury in xylene on addition of the dithioether, is not completely decomposed in dilute H_2SO_4 at temperatures below 60 °C. Complexes with monodentate ligands, such as ether, dimethyl sulfide, trimethylamine, or triphenylphosphine, were shown tensimetrically to undergo partial dehydrogenation at low pressures. If one of the complexing heteroatoms carries a hydrogen atom (as in the case of secondary amines or alcohols), benzene is split off with formation of the dimeric, trimeric, and tetrameric complexes $(C_6H_5BeXR)_n$ (X = O, NR; n = 2,3,4). / J. chem. Soc. (London) A *1967*, 236 / –Bu. [Rd 672 IE]



The synthesis of a triquinocyclopropane *(2)*, a diquinocyclopropanone, and a diquinoethylene *(3)* has been described by *R. West* and *D. C. Zecher*. The reaction of $C_3Cl_3^{\oplus}AlCl_4^{\ominus}$ *(1)* with 2,6-di-t-butylphenol in $CHCl_3$ followed by hydrolysis and treatment with triethylamine yields a quinocyclopropene (70%) containing two 3,5-di-t-butyl-4-hydroxyphenyl residues. Oxidation of this compound leads to *(2)*, a dark blue

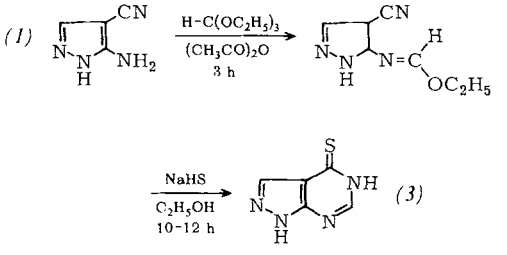
(1)

(2)



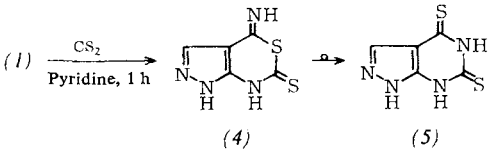
(3)

powder that decomposes at about 280 °C. If the reaction with *(1)* is carried out at 0 °C instead of at room temperature, the product obtained is bis(3,5-di-t-butyl-4-hydroxyphenyl)-cyclopropenone. On oxidation, this gives the violet ketone, whose solutions decompose within a few hours to form the red-purple compound *(3)*. / J. Amer. chem. Soc. *89*, 152, 153 (1967) / –Ma. [Rd 654 IE]



A new berkelium isotope, $^{251}_{97}$Bk, has been isolated by *H. Diamond, R. K. Sjoblom, R. F. Barnes, J. L. Lerner, D. J. Henderson*, and *P. R. Fields*. $^{251}_{97}$Bk is formed by α-decay of $^{255}_{99}$Es. ^{255}Es is present to the extent of 0.01 to 0.001 % in ^{253}Es, which is obtained by reactor irradiation of curium or californium. ^{251}Bk is a β emitter with a half-life of 57.0 ± 1.7 min; 34 and 140 keV γ radiation is also observed (94 and 184 keV γ radiation is probably also emitted). The absence of measurable γ intensities at 58.5 and 81 keV suggests that the ground state of $^{251}_{97}$Bk is not 7/2 + [633], as might be expected by analogy with ^{249}Bk. / J. inorg. nuclear Chem. *29*, 601 (1967) / –WG. [Rd 703 IE]

The inverse addition of phenyl-lithium to nitrosobenzene to give *O,N*-diphenyl-*N*-lithiohydroxylamine *(1)* has been described by *P. Buck* and *G. Köbrich*. *(1)* could not be isolated, since it undergoes rapid nucleophilic substitution by phenyl-lithium, with formation of lithium diphenylamide and lithium phenoxide.



The course of the reaction is shown by the fact that, apart from deprotonation, *N,N*-diphenylhydroxylamine (which is obtainable from nitrosobenzene and C_6H_5MgBr) is inert to phenyl-lithium under the conditions of the reaction. The attack of aryl-lithium compounds on nitrobenzene (against the polarization of the nitro group) also takes place exclusively at the oxygen, as was shown by experiments with phenyl-lithium or *p*-tolyl-lithium and *p*-nitrotoluene or nitrobenzene. The course of this reaction has not yet been elucidated. / Tetrahedron Letters *1967*, 1563 / –Bu. [Rd 665 IE]

One-step syntheses of pyrimidinethiones and pyrimidinedithiones have been described by *E. C. Taylor, A. McKillop, S. Komen*, and *R. Warrener*. These compounds are of pharmaceutical interest. The synthesis can be illustrated for the case of *(3)*, which was formerly obtained in an impure state and in low yields from the same starting material *(1)* by a four-step

synthesis. *(3)* is obtained in a thin-layer chromatographically pure state and in 97% yield without isolation of the intermediate *(2)*. Pyrimidinedithiones such as *(5)* are also obtained from *(1)*. The rearrangement of the thiazine *(4)* into *(5)* (87% yield) is a well-known base-catalysed reaction. / Tetrahedron *23*, 885, 891 (1967) / –Bu. [Rd 666 IE]

BOOK REVIEWS

UV-Atlas organischer Verbindungen, Band 1 – UV-Atlas of Organic Compounds, Vol. 1. Compiled by the Documentation of Molecular Spectroscopy (DMS). Verlag Chemie GmbH., Weinheim/Bergstr. and Butterworths, London 1966. 1st Edit., iv, 32 pages of text, 23 tables, 208 spectra, ring book $ 20.00.

The present volume is the first of a planned five-volume UV atlas, and provides some idea of the care that has been taken in the planning of this work, which is ultimately to include about 1000 spectra. The selection of the substances dealt with is reflected in the following classification:

A. Compounds with C–C multiple bonds.
B. Compounds with C=O and C=S groups.
C. Compounds with C–N multiple bonds
D. Mononuclear aromatic compounds.
E. Polynuclear aromatic compounds.
F. Aromatic compounds containing non-benzoid rings.
G. Mononuclear heterocycles.
H. Condensed heterocycles.
I. Saturated organic compounds.
J. Compounds of biological interest.
K. Inorganic systems.
L. Spectrochemical substances.
M. Solvents.

For ease of comparison, all the spectra are printed on transparent paper and marked with a reference point. They can be superimposed on one another as desired, owing to the loose-leaf form of the Atlas. The plots are always linear in wave numbers and logarithmic in the extinction coefficient. All the spectra are provided with a wavelength scale, which saves calculation. The graphical representations are supplemented in many cases by tables containing further data on the wave numbers and extinction coefficients of the absorption maxima of homologous compounds, derivatives, or ions. After completion, the spectra of the principal groups (A)–(M) will be discussed and interpreted by the editors of the sections in question.

The first volume contains 57 spectra and 13 tables for Group D (editor: *H. H. Perkampus*), 132 spectra and 10 tables for Group H (editor: *S. F. Mason*), and 19 spectra for Group M, which is accompanied by a six-page introduction by the section editor *B. Hampel*, with valuable advice on the purification of various solvents.

The first volume does justice to the promises of the prospectus. We look forward with interest to the early publication of the later volumes[*]. *H. Labhart* [NB 617 IE]

[*] Editorial note: Volume 2 has now appeared. Volume 3 is due to appear in September 1967 and Volumes 4 and 5 should be available in January 1968.

Trivialnamenkartei-1. Ergänzungslieferung (Card Index of Trivial Names – 1st Supplementary Issue). Verlag Chemie GmbH., Weinheim/Bergstr. 1966. 1088 cards, DM 60.–.

In 1964, Verlag Chemie began to compile a card index of trivial names[1]. The first issue contained 8000 cards. Each card bears a number giving its position in the alphabet, the trivial name in question (in German on the left, in English on the right), the structural formula of the compound with stereochemical details (where known), the empirical formula, and a reference to a handbook or journal. It is explained that the aim of this card index is not to foster trivial names, but to provide information wherever none is supplied by the trivial name. For example, it should be of assistance to anyone who does not know what palustrinic acid Centaur X_4, or munetone is. However, he should also possess the first supplementary issue, which contains 1088 cards and which has just been published. It also contains a list of addenda to the cards of the first issue.

Further supplementary issues are planned, and it is really unnecessary to emphasize the value of this card index. Those who already have it at their disposal will have learnt to treasure it, and those who do not yet know it should acquire it as soon as possible for the sake of easy reading in chemical literature. *H. Grünewald* [NB 581 IE]

[1] Cf. Angew. Chem. *78*, 344 (1966); Angew. Chem. internat. Edit. *5*, 326 (1967).

Reactiones Organicae. Organische Reaktionen und Methoden. (Organic Reactions and Methods.) By *H. J. Ziegler*. Georg Thieme Verlag, Stuttgart 1967. Basic stock (12 batches): about 3000 cards; about 250 cards per batch. Price per batch: DM 220.-; 20% reduction when the complete work is ordered.

A greet deal has been done to classify chemical literature in such a way that any desired information can be found quickly and as fully as possible, but without padding. A new attempt to make the knowledge of preparative organic chemistry readily accessible is the card index entitled "Reactiones Organicae" that has been compiled by *H. J. Ziegler*. This index contains all the procedures from "Organic Syntheses", all the reaction types from "Organic Reactions" and (with the exception of the ring-closure reactions) from "Cahiers de Synthèse Organique", and all the reactions from "Namenreaktionen der Organischen Chemie". The basic stock contains 3000 cards. (Eight batches containing a total of 2000 cards have been issued so far.) It will be continuously supplemented and updated by further batches.

The card index consists of punched cards, each of which describes a reaction or a synthesis (sequence of reactions). In the heading on the front of each card, the reaction type is given on the left, the reaction conditions and reagents on the right, and references to Houben-Weyl and to "Cahiers" in the center. In the field below the heading, the reaction described is characterized by a complete formula, data on yields, and a literature reference. On the back of each card is the name of the reaction product, a short account of the procedure in German and in English, and a list of compounds (with yields) that can be prepared in the same way.

The "knack" of "Reactiones Organicae" is that any desired reaction is first reduced to a reaction type. For example, suppose that one wishes to find the possible methods for the oxidation of secondary amines to azomethines. This reaction can be represented in its simplest form by the equation

$$\text{CH–NH–} \rightarrow \text{C=N–}.$$

Code numbers for the partial formula on the left (starting group) and for that on the right (product group) are then found from two formula indexes supplied with the cards in the form of loose-leaf books. These numbers then enable a selector instrument to extract all the cards that describe such reactions. For more specialized problems, code numbers characterizing the reaction conditions and the overall constitution of the product are available.

The entire system is both cleverly conceived and easy to use. Aids (program blocks, color code) are provided to facilitate further the use of the card index and to make it foolproof even for assistants. The greatest advantage of "Reactiones Organicae", however, is the fact that no notation that is not familiar to the chemist, no hypotheses on reaction courses, and no classification of reactions are included, and that neither nomenclature problems nor language problems arise. Thus "Reactiones Organicae" is the ideal literature card index for the organic chemist engaged in preparative work.

H. Grünewald [NB 579 IE]

D-Glucose und verwandte Verbindungen in Medizin und Biologie (D-Glucose and Related Compounds in Medicine and Biology). Edited by *H. Bartelheimer*, *W. Heyde*, and *W. Thorn*. Ferdinand Enke Verlag, Stuttgart 1966. 1st Edit., xv, 1126 pp., 173 figures, 124 tables, cloth DM 228.–.

Contrary to what one might expect from its title and size, this book cannot be summed up in the words "all about glucose". It is not a sort of monograph in which one can quickly find out all about a certain chemical or biochemical property of this sugar or of one of its derivatives, but is rather a eulogy on this compound and its direct and indirect biosynthetic transformation products and precursors. The subject matter covered in the book is by no means narrow. For example, it contains long chapters on "The oxidative final stage of metabolism", *i.e.* on the transformation of the transformation products of the products of transformation of D-glucose, on "The quantum chemistry of photosynthesis, automatically written", where only a few of the compounds described are ultimately converted into or formed from glucose or glucose derivatives. One could, if one were so inclined, say that any carbon compound found in plant or animal cells or in microorganisms is a potential precursor or transformation product of D-glucose, provided that the organism in question can use glucose as a source of carbon. The editors are therefore forced to make a selection, unless they wish to compile a "Beilstein" of natural products. The question that arises now is whether the selection made was a good one. Closer examination shows that is it impossible to give any general answer; in the 45 chapters by 54 authors, the problem of relatedness of the subject under discussion to glucose is solved in various ways.

Almost half of the work is devoted to pharmacological, pathophysiological, and clinical aspects. Several articles in this part deal with the role of glucose in particular and/or of hydrocarbons in general in disease and in the function of various organs (endocrine disorders, diabetes mellitus, kidneys, liver, heart, lungs, joints, brain, skin, eyes, throat, nose, ears, tumors), in surgery, pediatrics, and psychiatry, and in sport. These chapters offer a great deal of valuable information to those with no medical training.

The general chemical and biochemical principles of these special chapters are, unavoidably, not always in agreement with the latest fundamental developments, which always penetrate into the more specialized sectors of a science only after a certain time lapse. Unfortunately, the same is also true of many of the fundamental articles in Section D, "Biochemistry and Physiology" (283 pages).

The length of this time lapse will not be discussed for the various articles. An average minimum value can be estimated from the fact that almost the entire molecular biology vocabulary (*e.g.* induction, repression, operon, messenger, allo-

sterism, end-product inhibition, isozyme, multienzyme complex) is missing from the index. "Enzyme induction" is mentioned in the index, but the passage referred to is simply the unsupported statement that "The adrenocortical hormones increase glyconeogenesis by true enzyme induction".

Section C, which deals with "Formation, occurrence, and importance in plants and microorganisms" (3 articles, 67 pages), concentrates on the discussion of photosynthesis (47 pages). The only article on microorganisms, "Constituent hydrocarbons of the bacterial cell" (20 pages), shows relatively little relation to glucose, but presents a well-rounded account of this field, which is complex from the point of view of structural chemistry. There is no general article on microorganisms, such as might be expected from the title of the book. The 113 pages of Section B, "Methods of determination" (2 articles) will probably be the first pages of the library copy to become grease-spotted and dog-eared; the material in this section appears to be full and carefully written, with a good understanding of the subject. We finally come to an introductory chapter, "Chemistry and pharmaceutical chemistry". This chapter presents a brief outline of carbohydrate chemistry, in which the problems of conformation, which are particularly important in connection with the enzymatic reactions of sugars, are dealt with in detail. The concept of instability factors and Hassel-Ottar and $\Delta 2$ effects are explained with the aid of molecular models.

The air oxidation of D-glucose to D-gluconolactone is discussed as an "Inference from the conformational behavior", and is compared with the enzymatic oxidation of glucose phosphate. The example is ill-chosen. Contrary to the statement that the enzymatic dehydrogenation "evidently depends on the axial position of the hydroxyl group on C-1 of the α-glucopyranose" in the same way as the chemical hydrogenation, glucose 6-phosphate (like all aldoses) is in fact enzymatically oxidized only in the β form. The correct chemical parallel to this should therefore be oxidation with bromine, in which oxidation takes place at the equatorial hydroxyl group of the β form.

There is no doubt that this book contains a great deal of valuable information that may be useful to anyone who is concerned with the biochemical, physiological, and medical aspects of sugars. However, just as a good memory depends on storage capacity and ability to recall, so the value of such a large handbook depends on whether the desired information, which is assumed to be present, can be found quickly and reliably. The index is not the best for ease of recall. This may be the type of index that must be expected in the future when indexes are compiled by machines. It is otherwise difficult to understand *e.g.* why methylglucoside (pp. 24 and 25), α-D-methylglucoside (pp. 22 and 58), β-D-methylglucoside (p. 22), α-methyl-D-glucopyranoside and β-methyl-D-glucopyranoside (p. 106) are listed separately in the index, though the substances are simply anomers of the same compound. The last two are given in English, since they occur in an article written in English. The German keyword "Gluconeogenese" is given in 15 different contexts and with 26 page numbers. However, none of these pages gives a clear definition mentioning the main enzyme reactions on which the phenomenon depends. Nevertheless, this definition is given clearly and precisely in a short section of an article written in English. To find this in the index, one must look under "glyconeogenesis", which comes seven pages after "Gluconeogenese".

What is "maltotriosyl"? It is an orthographic radical that owes its existence to the English terminology (without covalent or coordinate bond?) in the phrase "which transfers maltotriosyl residues".

Nevertheless, the enthusiasm that filled the editor and the authors and that led to the creation of this work is justified. D-glucose and related compounds form a family of imposing might, which plays an important part in all branches of animate nature, and which must fascinate the specialists in every phase of the development of our science.

K. Wallenfels [NB 585 IE]

Laboratory Handbook of Toxic Agents. Edited by *C. H. Gray*. The Royal Institute of Chemistry, London 1966. 2nd Edit., ix, 190 pp. Paperback 24s; 18s to Royal Institute of Chemistry members.

The book comprises five sections: I. General hazards involved in the handling of chemicals (12 pages). II. General precautions and accident prevention, including safe disposal of chemicals (pp. 15–23). III. First aid in cases of skin-contact and internal poisoning, including the different techniques of applying artificial respiration (pp. 27–35).

IV. The main section (pp. 39–166): 250 toxic gases, reagents, and solvents are listed in alphabetical oder (Acetaldehyde to Xylidine). The acute and chronic sings of poisoning are listed in a few key phrases for each substance, as are first aid measures, the TLV(MAC) value, and the necessary warning labeling. Each substance has about half a page devoted to it. Synonyms are referred back to the appropiate passages under their 'approved' names. Occasionally the nomenclature (in the absence of formulae) is difficult to understand for German readers, *e.g.* 'methyl chloroformate'; 'ethyl chloroformate' at least has 'ethyl chlorocarbonate' appended in parenthsis. Chapter V (pp. 169–188) deals with the precautions to be taken during handling of radioactive materials, and contains 14 literature references.

The book attempts to show how careful handling of chemicals can prevent accidents and when these occur, how further chanage can be avoided. A page prefaced to the text is to be filled in by the user with the name of the deputy safety officer, the nearest hospital for casualties, ambulance, doctors, and persons trained to give artificial respiration, as well as telephone numbers of poison information centers. The glossary on the two concluding pages is evidently intended for chemical laboratory workers, in that it explains simple medical terms such as anemia, leukemia, bronchitis, urticaria, *etc.* Unfortunately the book has no index.

The toxicological data contain mistakes – despite the collaboration of *Ethel Browning*. Thus fluorinated hydrocarbons are described as liver poisons but not so chloroform. No warning of the increase in the potency of alcohol intoxication following exposure to aniline and nitrobenzene is given, though this is an important matter for the layman. The book is suitable for obtaining rapid information about potential risks by all those who understand English nomenclature.

H. Oettel [NB 634 IE]

Ylid Chemistry. By *A. W. Johnson*. Organic Chemistry, Vol. 7. Academic Press, Inc., New York London 1966. 1st Edit., x, 388 pages, numerous figures, bound $ 12.50.

The Tower of Pisa leans because the ground subsided while it was being built. Similarly, the structure of organic chemistry, which is built on the three pillars of carbonium-ion chemistry, free-radical chemistry, and carbanion chemistry, cannot be regarded as safe so long as the last of the three pillars is weaker than the other two. This weakness is obvious from textbooks of organic chemistry.

To learn about the theoretical and practical importance of carbanion chemistry, one must turn to special books. A new addition to the ranks of such books is the present work on ylid chemistry by *A. W. Johnson*, who is himself a successful investigator in this field, and has presented a comprehensive picture of its development and its present state.

The author concentrates on the phosphorus ylids, which have been, and still are, intensively studied because of their preparative importance. The bonding in these compounds, which are formed by removal of an α proton atom the phosphonium cation (onium complex), is critically examined on the basis of their physical properties and reactivities. Further chapters are devoted to the olefination of carbonyl compounds and to the iminophosphoranes. This is followed by a discuss-

ion of the nitrogen ylids including the pyridinium betaines and diazo compounds; their rearrangements and their role in the Hofmann degradation are interpreted. The book unfortunately does not contain a chapter on the synthetic importance of this class of compounds, which opens up a new route to phenanthrenes, cyclopolyenes, and isoindoles. The As and Sb ylids, on which relatively little experimental work has been done, are then discussed. The book closes with a long chapter on sulfur ylids, which have attracted special interest as valuable preparative aids. No mention is made of the boron ylids, the study of which is still in its early stages; these are formed by the removal of an α-hydride from ate complexes, and their charge is opposite to that of the types mentioned above.

The reader gains the impression that the ylids and cryptoylids have opened up a field of carbanion chemistry that still conceals a wealth of theoretical and preparative problems inviting further study. The book is strongly recommended to organic and inorganic chemists involved in fundamental research, particularly in the organometallic field.

Electron-Pair Repulsions and Molecular Shape

BY R. J. GILLESPIE [*]

The theory described in this article emphasizes the importance of interactions between the electron pairs in the valence shell of a central atom in determining stereochemistry and it assumes that interactions between the ligands are generally of lesser importance although sufficiently bulky groups, or chelate ligands, may play an important role in determining the stereochemistry. If lone-pair electrons are present in the valence shell of the central atom then the two theories (the theory of interaction of electron pairs and the theory of interaction between ligands) predict different structures. In the great majority of cases the determined structures are those expected if it is assumed that lone pairs are stereochemically active, i.e. if repulsions between electron pairs in the valence shell determine stereochemistry.

1. Introduction

It has not proved possible up to the present time to give a complete and exact quantum mechanical treatment for even a triatomic molecule, because the Schrödinger equation cannot be solved exactly for polyelectronic systems. In the treatment of such systems it is almost invariably assumed that the *n*-electron wave-function of a system can be written as a product, or sum of products, of *n* one-electron hydrogen-like atomic orbitals. In the familiar valence-bond theory directed valency is explained in terms of the directional character of p and d atomic orbitals.

However these hydrogen-like atomic orbitals are often rather unsatisfactory for describing the bonding orbitals in molecules and the concept of hybridization was introduced to obtain more satisfactory orbitals. It is well known that this type of treatment shows that two sp bonds are collinear, three sp^2 bonds lie in a plane at 120 °, and four sp^3 bonds are directed towards the corners of a tetrahedron; but this theory can make no other very useful predictions concerning the stereochemistry of molecules. Even these conclusions are, in fact, largely independent of the form chosen for the original one-electron orbitals and they arise essentially from the operation of the Pauli Exclusion Principle.

[*] Prof. R. J. Gillespie
Department of Chemistry, McMaster University
Hamilton, Ontario (Canada)

The purpose of this article is to outline an approach to stereochemistry which makes direct use of the Pauli Exclusion Principle without attempting to write down any explicit form for the wave functions of the individual orbitals or for the system as a whole.

2. The Pauli Exclusion Principle

The most general statement of the Pauli Exclusion Principle is that the wave function for any system must be antisymmetric to electron interchange. Thus for the coordinates (spatial and spin) of electrons 1 and 2 the Pauli Principle states that

$$\psi(x_1, x_2, x_3 \ldots) = -\psi(x_2, x_1, x_3 \ldots)$$

Now, if two electrons have the same coordinates (spatial and spin) *i.e.* if $x_1 = x_2 = x$, then

$$\psi(x, x, x_3 \ldots) = -\psi(x, x, x_4 \ldots)$$

and hence

$$\psi(x, x, x_3 \ldots) = 0.$$

Thus if two electrons have the same spin and space coordinates the wave function vanishes, or in other words it is not possible for two electrons having the same spin to be at the same point in space. In general there is a

low probability of two electrons of parallel spin being close together in space and a high probability of their being far apart [1,2].

Hence if a nucleus has associated with it two electrons of parallel spin their most probable relative location is at 180° to each other, for three electrons it is in a plane at 120° to each other and the most probable relative location for four electrons of parallel spin is at the corners of a regular tetrahedron. We can imagine that the electrons share the spherical space around the nucleus. Thus when there are two electrons they each occupy a hemisphere and when there are three electrons they each occupy a 120° segment of a sphere (Fig. 1), *i.e.*, the electrons are regarded as occupying

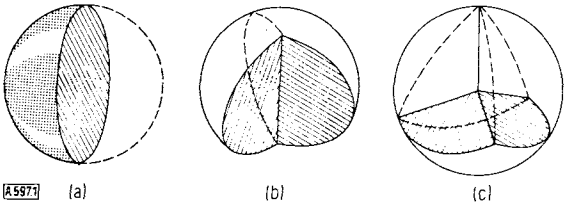

Fig. 1. Segments of a sphere representing orbitals for two, three, and four electron-pairs.

non-overlapping orbitals of these shapes. These electron distributions arise from spin-correlation between the electrons and are therefore a consequence of the Pauli Exclusion Principle. In molecules such as CH_4, NH_3, and H_2O the central atom has a set of four electrons of the same spin which tend to have a tetrahedral arrangement and another set of elctrons of the opposite spin which also tend to have a tetrahedral arrangement. Electrostatic repulsion between the electrons tends to reinforce the tetrahedral arrangements and also to keep the two tetrahedra apart. However the attraction of the other nuclei (the hydrogen nuclei in the above examples) causes pairs of electrons of opposite spin to be drawn into the same region of space, *i.e.* into the same orbital, so that the two tetrahedra come into approximate coincidence and we are led to the picture of pairs of electrons of opposite spin occupying four localized tetrahedrally directed orbitals (Fig. 1). If there are three such electron pairs, as in EF_3, then they occupy three localized orbitals directed at angles of 120° to one another.

3. Electron-Pair Arrangements

A useful model for understanding the most probable arrangements of different numbers of electron pairs around a central nucleus is that in which each electron pair is regarded as a point on the surface of a sphere surrounding the central nucleus [3]. We then ask how these points will arrange themselves, if, in accordance with the Pauli Exclusion Principle, they tend to keep as far apart as possible, or to state it more exactly, if the least distance between any two particles is maximized.

This problem has been treated by several mathematicians [4,5] and the results are shown in Fig. 2. The arrangement of five points is indeterminate in that it may be the trigonal bipyramid or the square pyramid, or any intermediate arrangement. The best arrangement for ten particles has not been determined.

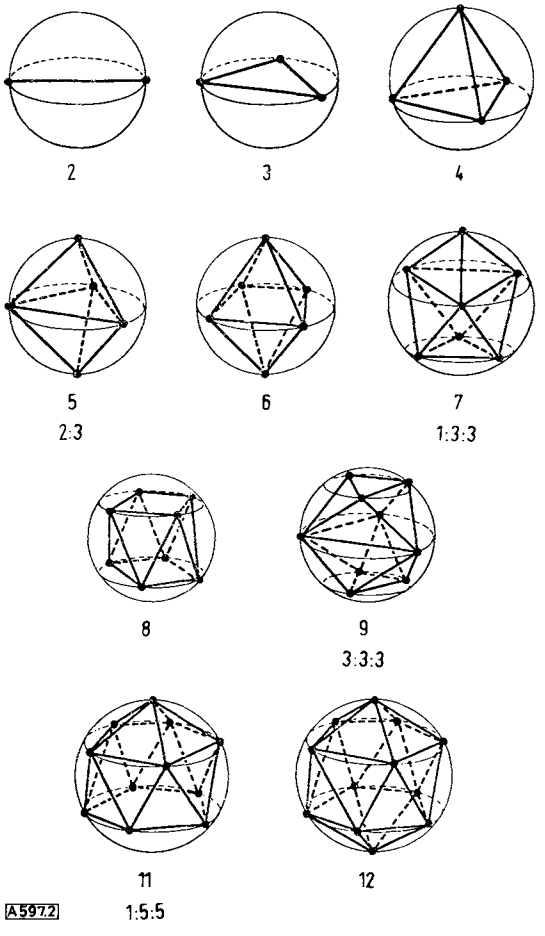

Fig. 2. Arrangements of particles on the surface of a sphere for which the least distance between any pair of particles is maximized.

Alternatively, we may consider the packing of spheres around a central nucleus, each sphere representing the orbital of a pair of electrons. Thus three spheres adopt an equilateral triangular arrangement, four spheres a tetrahedral arrangement, six spheres an octahedral arrangement *etc.* This is the tangent sphere model first proposed by *Kimball* [6] and extensively applied in recent years by *Bent* [7]. The sphere is only a rough approximation to the orbital shape and it can be somewhat improved by adding a conical cap with its apex at the nucleus.

If we describe a polyelectronic system in terms of hydrogen-like one-electron orbitals and combine them to obtain an antisymmetrized molecular orbital (thereby taking account of the Pauli Exclusion Principle), our original simple picture of the individual one-elec-

tron distributions is largely destroyed. If we wish to retain the idea of describing the electron distribution in terms of one-electron orbitals, the best picture is obtained by constructing hybrid orbitals from the original atomic orbital. These hybrid orbitals have the property that they are more concentrated in separate regions of space than the original atomic orbitals and they overlap less. The explicit forms of these hybrid orbitals do not necessarily give a more accurate description of the electron density in a molecule than our crude picture of non-overlapping orbitals.

It seems more logical[*] therefore to start the description of a molecule with localized non-overlapping orbitals rather than with hydrogen-like atomic orbitals which are then transformed into new orbitals by the process of hybridization.

4. Molecular Shapes

The arrangements of electron pairs shown in Fig. 2 may be used to predict the stereochemistry of molecules with coordination numbers up to twelve. Each of the preferred arrangements of a given number of electron pairs can give rise to several molecular shapes depending on the relative numbers of bonding pairs and lone pairs. If A is a central atom, X a ligand, and E a non-bonding pair then the shape of a singly bonded molecule AX_mE_n is determined by the preferred arrangement of the $m + n$ electron-pairs. The various possible molecular shapes that can be obtained in this way are given in Table 1 and Fig. 3 for up to six electron-pairs[8,9]. These are indeed the shapes of the known molecules of the type AX_mE_n.

A5973

Fig. 3. Shapes of singly bonded molecules containing up to six electron-pairs in the valence shell of the central atom.

[*] As the process of hybridizing atomic orbitals has been widely misunderstood and often incorrectly regarded as a phenomenon rather than as a simple mathematical operation there is a certain advantage in any theory that avoids the use of this concept.

[8] *R. J. Gillespie* and *R. S. Nyholm*, Quart. Rev. (Chem. Soc., London) *11*, 339 (1957).

[9] *R. J. Gillespie*, J. chem. Educat. *40*, 295 (1963).

The shapes of molecules containing multiple bonds are also readily understood on the basis of the same arrangements of electron pairs. For example, in ethylene each carbon atom is surrounded by four tetrahedrally arranged electron pairs, two pairs being shared between the two carbon atoms to give the double bond, *i.e.* two bent bonds. It is generally more convenient, however, to consider the two electron-pairs of a double bond or the three electron-pairs of a triple bond as occupying a large double- or triple-bond orbital. The general shape of a molecule AX_mE_n where one or more of the ligands is bonded by a multiple bond is then given by the value of $m + n$ where m is now the number of ligands or bonding orbitals, counting only one four-electron orbital, and one six-electron orbital for each double and triple bond respectively [8,9]. Thus the shape of ethylene is based on 120° arrangement of three bonding-orbitals and no lone pairs while the pyramidal shape of the $SOCl_2$ and XeO_3 molecules is based on the tetrahedral arrangement of three bonding orbitals and a lone pair. Various possible molecular shapes for molecules containing multiple bonds are shown in Fig. 4.

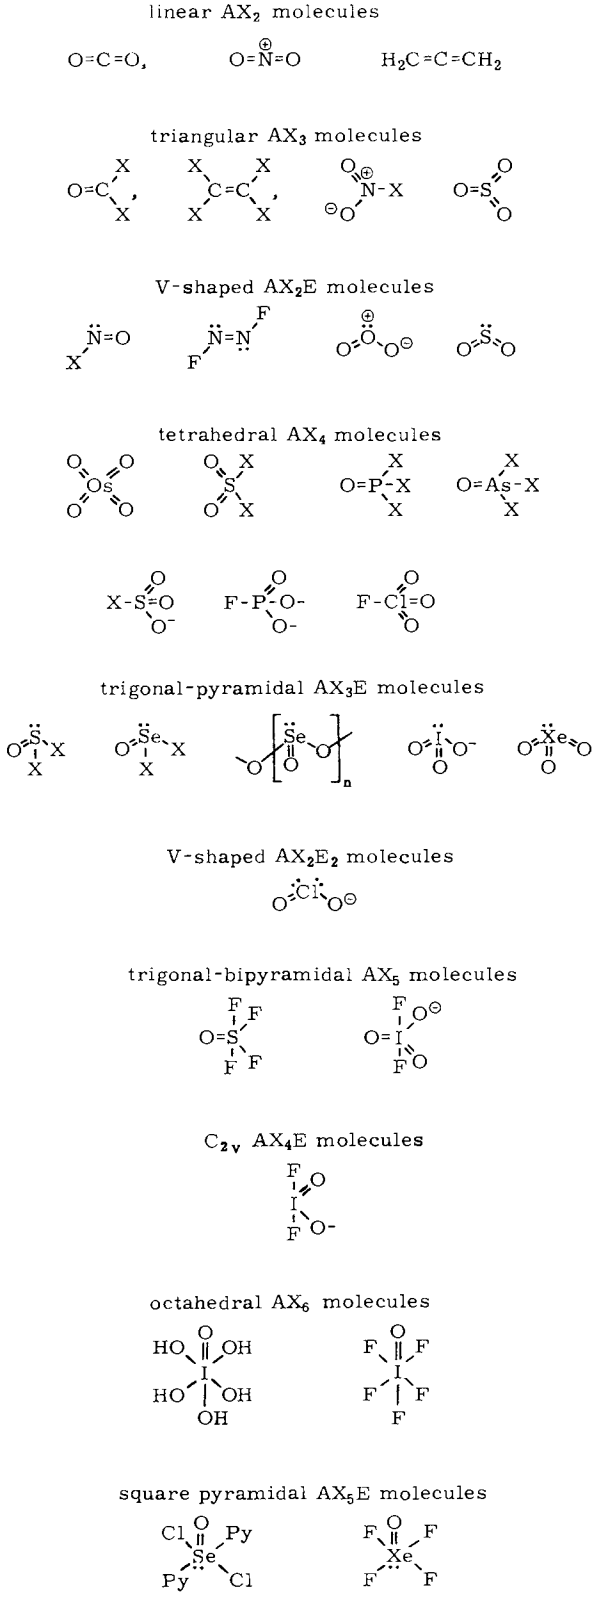

Fig. 4. Shapes of molecules containing multiple bonds.

5. Interpenetrating or "Soft" Orbitals

So far we have considered only the gross shapes of molecules. However our theory can be refined to provide an understanding of many of the finer details of molecular shape. First, it might be argued that electron clouds are not hard objects as we have assumed, but can penetrate each other to some extent. The concept of maximizing the least distance between points on the surface of a sphere is equivalent to assuming that the points exert a repulsive force on each other of $F = 1/r^n$, where $n = \infty$.

If some penetration, or overlap of the orbitals can occur, *i.e.* if the orbitals are regarded as "soft", rather than "hard", then this is equivalent to a force law with $n < \infty$ and probably equal to a value between 6 and 12 [9]. If the interaction between the points were purely electrostatic the force law would be Coulombs law, *i.e.* $n = 2$. The preferred arrangements of particles on the surface of a sphere under the action of an inverse-square force law have been deduced previously [10]. They are the same as those for $n = \infty$ except for the case of seven particles. We conclude then that, except for this case, the arrangements shown in Fig. 2 are independent of the value of n, if $n \geqslant 2$, and that they are, therefore, valid for soft as well as for hard orbitals.

For five electron-pairs the best arrangement for $n = 2$, and indeed for any value of $n < \infty$, is the trigonal bipyramid and not the square pyramid. The special case of seven electron-pairs is discussed in Section 11.

6. Bond Angles in Molecules Containing Lone Pairs

As lone pairs are under the attractive influence of only one nucleus while bonding pairs are attracted by two nuclei, it is reasonable to suppose that the charge clouds of lone-pair electrons are larger and occupy more of the "surface" of the central atom than the bonding electrons (see Fig. 5). This has several important consequences.

[10] *L. Foppl*, J. reine angew. Math. *141*, 251 (1912).

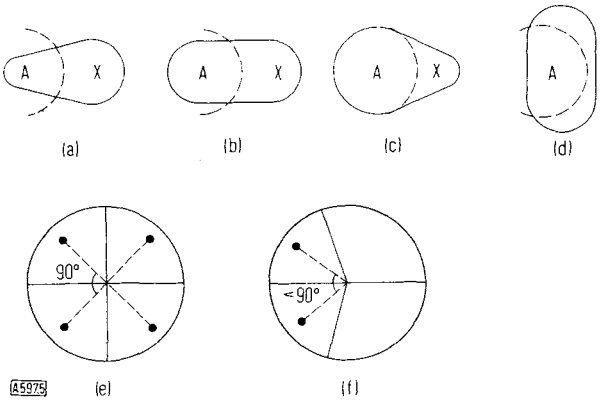

Fig. 5. Shapes of bonding and non-bonding orbitals.

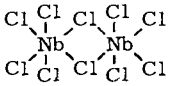
(a), (b), and (c) illustrate the effect of decreasing the electronegativity of the ligand X; the electron pair occupies an increasingly large area of the "surface" of the central atom A. (d) illustrates a lone pair that occupies a still larger area on the surface of the central atom A. (e) represents a two-dimensional arrangement of four equivalent bonding orbitals giving a bond angle of 90° (109.5° in three dimensions). (f) shows the effect of replacing two of the bonding pairs by lone pairs, thereby reducing the bond angle to less than 90° (< 109.5° in three dimensions).

As bonding pairs are replaced by lone pairs the angles between the bonding pairs, *i.e.* between the bonds, will decrease. For example, in the series CH_4, NH_3, H_2O the bond angle decreases from the tetrahedral angle of 109.5° in CH_4 to 107.3° in NH_3 and to 104.5° in H_2O as one and two bonding pairs are successively replaced by lone pairs. Alternatively, one can say that lone pairs of electrons repel other electron pairs more strongly than bonding pairs. If, in an octahedral arrangement of six electron pairs, one is a lone pair, as in molecules such as IF_5 and BrF_5, the bond angle is less than the ideal octahedral value of 90°.



If alternative positions are available for one or more lone pairs in a molecule then, because of their greater size and stronger interaction with other electron pairs, they tend to occupy those positions which give them the most space, which keep two or more as far apart as possible, and which minimize their interactions with other electron pairs. Thus in an AX_4E_2 molecule the lone pairs occupy *trans* positions so that the molecule has a square-planar shape.

7. Variation of Bond Angles with Ligand Electronegativity

An increase in the electronegativity, or effective nuclear charge, of a ligand will cause a decrease in the size of the orbital of the bonding electron-pair [1,8]. This orbital will, therefore, occupy less of the surface of the central atom, leaving more room for the other orbitals. (Fig. 5). Thus, bond angles decrease with increasing electronegativity of the ligands as in the following examples:

F_2O (103.2°) < H_2O (104.5°), NF_3 (102°) < NH_3 (107.3°),
PCl_3 (100°), < PBr_3 (101.5°) < PI_3 (102°),
$AsCl_3$ (98.4°) < $AsBr_3$ (100.5°) < AsI_3 (101°).

An interesting example of a different type is provided by the dimeric molecule of niobium pentachloride which has the structure *(1)* [11]. The bridging chlorine

(1)

atoms carry a formal positive charge and must, therefore, have a higher effective electronegativity than the other chlorine atoms. This distorts the regular octahedral arrangement of chlorine atoms around the niobium so that the two bridging chlorine atoms, which have the smaller orbitals, have a bond angle at niobium of less than 90°, while the other chlorine atoms have bond angles of greater than 90°.

8. Bond Angles in Molecules Containing Multiple Bonds

Since double- and triple-bond orbitals are larger than single-bond orbitals, angles involving multiple bonds will be larger than those involving single bonds [9]. Thus, each carbon atom in ethylene would, to a first approximation, have a 120° arrangement of one double- and two single-bond orbitals, but since the double-bond orbital is larger than the single-bond orbitals, the angle between the double and single bonds is greater than 120°, and the angle between the single bonds is less than 120°. In all other AX_3 molecules we find similar bond angles (cf. Table 2).

Similarly in AX_4 and AX_3E molecules where one of the bonds is a double bond, the angles involving this bond are always greater than the tetrahedral angle

Table 2. Bond angles (°) in some molecules containing double bonds.

while the others are smaller. When two double bonds are present the angle between the double bonds is always the largest angle (cf. Table 2). No octahedral AX_6 molecules containing double bonds have had their structures determined accurately, but it may be predicted that in molecules such as $O{=}I(OH)_5$ and $O{=}IF_5$ the angles involving the double bond will be slightly greater than 90 °.

9. Bond Angles at a Central Atom Having an Incompletely Filled Valence Shell [12]

The orbitals in a filled shell effectively occupy all the available space. Any influence tending to reduce the angle between the orbitals will cause appreciable orbital overlap and hence will be strongly resisted. The valence shells of the elements of the first short period, in particular B, C, N, O, and F, are completely filled by four electron-pairs. Thus for AX_4 molecules where A is a first-row atom and for AX_3E and AX_2E_2 molecules, where X is also a first-row atom, the bond angles are always within a few degrees of 109.5 °.

The orbitals in an incompletely filled shell do not occupy all the available space and the angles between them are therefore more easily changed. If the 3d subshell can be filled, the elements of the second short period can, in principle, have up to nine electron-pairs in their valence shells. In fact, for reasons that are not well understood, the valence shells of these elements are effectively completed by only six electron-pairs, as in $PF_6^{\ominus}$ and SF_6.

For these elements, therefore, it is reasonable to assume that bonding electron-pairs do not interact with each other very strongly until the angle between them is the same as in the octahedron, namely 90 °. Thus, on replacing a bonding pair with a lone pair – *e.g.* in the transition from SiH_4 to PH_3 – the lone pair is able to spread out around the "surface" of the phosphorus atom until the bonding pairs are at an angle of approximately 90 ° to each other. Hence the bond angle in PH_3 is only 93.3 °. Replacing another bonding pair by a lone pair – in the transition from PH_3 to H_2S – causes a further small decrease in the bond angle to 92.2 °.

The same idea would also apply to electron pairs constrained to move in a plane and this is much easier to illustrate diagrammatically. Figure 6 shows an atom that is large enough to accommodate four electron-pairs in its (two-dimensional) valence shell. If the same atom has only three electron-pairs in its valence shell and if they are all equivalent bonding pairs, they will be arranged at 120 ° to each other, but they will not occupy all the space in the valence shell. However, if one of the three pairs is a non-bonding pair, it can expand and push the bonding pairs together until they make an angle of approximately 90 ° to each other. Thus we see that the bond angle is easily distorted from 120 ° towards the limiting value of 90 °.

When an atom with a filled valence-shell and one or more non-bonded electron pairs is bonded to an atom with an incomplete valence-shell, there is a tendency

[12] *R. J. Gillespie*, J. Amer. chem. Soc. *82*, 5978 (1960).

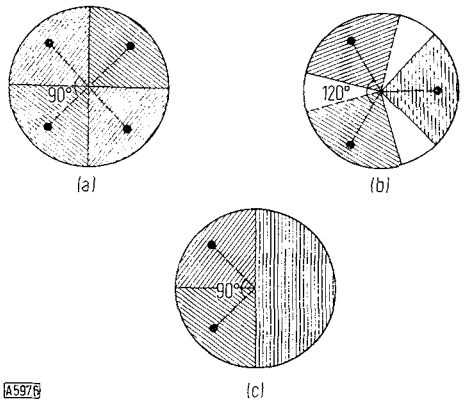

Fig. 6. A two-dimensional representation of the effect of a lone pair in an incomplete valence shell.

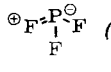
(a) shows a valence shell filled with four electron-pairs. (b) shows an incompletely filled valence shell containing only three electron-pairs. (c) shows the effect of replacing one bonding pair by a lone pair, thereby reducing the bond angle to approximately the same value as in (a).



for the unshared pairs to be transferred from the filled shell to the unfilled shell, because in this way electron-pair repulsions are minimized, or in other words, the lone-pair electrons are able to expand into the vacant space on the adjacent atom rather than crowding together the bonding pairs in the filled shell of the same atom.

In the series of molecules PF_3, PCl_3, PBr_3, and PI_3, and AsF_3, $AsCl_3$, $AsBr_3$, and AsI_3 it might be expected, because of the decreasing electronegativity of the halogen atom and the consequent increasing size of the bonding orbitals, that the bond angle would increase steadily from the fluoride to the iodide. The expected increase in bond angle is observed from the chloride to the iodide, but in both cases the fluoride is anomalous, having the largest rather than the smallest bond angle (see Table 3). This may be attributed to the unshared

Table 3. Bond angles for Group V halides.

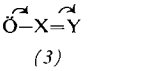
pairs of fluorine having a strong tendency to delocalize into the incomplete shell of the central atom, thereby giving the bonds some double-bond character and, therefore, increasing the size of the bonding orbitals and hence the bond angle. In the other halides the halogen atoms have incomplete shells, so there is little tendency for their electron pairs to delocalize onto the central atom and there is little or no double-bond character in these bonds, *i.e.* the strong interactions between the electron pairs in the valence shell of the fluorine atom compared with the other halogen atoms result in structures such as *(2)*,

(2)



being considerably more important in the fluorides than in the other halides.

In OX_2 and NX_3 molecules where X is a ligand having an incomplete valence shell, delocalization of the lone-pair electrons on O or N occurs giving partial double-bond character to the OX or NX bonds, which, together with the partial removal of the lone-pair electrons from the central atom, causes a considerable increase in the bond angles in these molecules. Thus the SiOSi bond angle generally falls in the range 130–140 ° (see Table 4) while the $N(SiH_3)_3$ molecule is planar with bond angles of 120 °. In SX_2 molecules, however, there is little tendency for the lone pairs of sulfur to be transferred to the ligand and hence the bond angles are less than, rather than greater than, 109.5 ° (see Table 4). When the ligand X in an OX_2 molecule is a very strong acceptor, the transfer of the lone-pair electrons into the OX bonds may be essentially complete, in which case a linear molecule results. Collinear XOX bonds have been found, for example, in the molecules $(Cl_5RuORuCl_5)^{4\ominus}$ and $(TiCl_2(C_5H_5))_2O$.

Similar effects are observed when the ligand, although having a filled valence shell, is part of an unsaturated group *e.g.* as in *(3)*, *i.e.* is forming one or more multiple bonds to other atoms.

(3)

In such a case X behaves as if it had an incomplete shell since one of the electron pairs of the X=Y double bond may be partially transferred to Y leaving X electron-deficient and thus facilitating the transfer of lone pairs on O into the O–X bond. Hence for aliphatic compounds the COC bond angle is always very close to, and generally a few degrees smaller than, 109.5 °, but for aromatic molecules the bond angle is generally in the range 120–125 ° (see Table 4). This may be attributed to the partial double-bond character of the O–C bonds, *i.e.* the importance of contributing structures such as *(4)*.

(4)

The planar 120 ° arrangement of the bonds around nitrogen in urea and formamide can be similarly explained.

10. AX_5, AX_4E, and AX_3E_2 Molecules

Molecules in which the central atom has five electron-pairs in its valence shell present a number of features of interest. In the trigonal-bipyramid arrangement of five points on the surface of a sphere, the axial and equatorial positions are not equivalent. The axial positions have three nearest neighbors at 90 °, while the equatorial positions have only two such nearest neighbors at 90 ° and two at 120 °. For $n \geqslant 4$ the total force on the axial positions is greater than that on the equatorial positions, hence this is not an equilibrium arrangement and equilibrium can only be reached if the axial electron pairs are at a greater distance from the inner core of the central atom than the equatorial pairs.

If we use the hard sphere model and allow each sphere to touch the central atom, then the equatorial spheres do not touch each other and, as mentioned before, the exact arrangement is indeterminate. If, on the other hand, we insist that the spheres touch each other, then

Table 5. Equatorial and axial radii of ten-electron valence-shell central atoms in AX_5, AX_4E, and AX_3E_2 molecules.

the axial pairs cannot be in contact with the central atom and the bipyramid consists, in fact, of two tetrahedra, the distance of the axial pairs from the central atom being $\sqrt{2}$ times that of the equatorial pairs. Several consequences follow:

(a) As the total interactions on the equatorial pairs are less than those on the axial pairs, or in other words, as there is more space in the equatorial positions than in the axial positions, the lone-pair electrons always occupy the equatorial positions and we obtain the molecular shapes shown in Fig. 3.

(b) The covalent radius of the central atom in the axial direction must be greater than in the equatorial direction. In all molecules of this type that have been studied, this has proved to be the case. The ratio $r_{ax}/r_{eq} = 1.1 - 1.2$ which is, as expected, less than the value of $\sqrt{2}$ predicted by the hard sphere model [13–15] (Table 5).

(c) As the lone pairs take up more space than the bonding pairs, the bond angles in AX_4E and AX_3E_2 are in general less than the ideal values of 180 °, 120 °, and 90 ° (see Table 6).

Table 6. Bond angles (°) in AX_4E and AX_3E_2 molecules.

	equatorial-equatorial AX_4E	axial-axial

$C_6H_5ICl_2$	86	

[*] These exceptions are discussed in Section 14.

(d) If there is more than one type of ligand, the least electronegative ligands, *i.e.* those with the largest bonding orbitals, will occupy the equatorial positions and the most electronegative will occupy the axial positions. This is always found to be the case [15]. For example in PCl_3F_2 and PCl_2F_3 the chlorine atoms are in equatorial positions and in CH_3PF_4 and $(CH_3)_2PF_3$, the methyl groups occupy equatorial positions [16, 17].

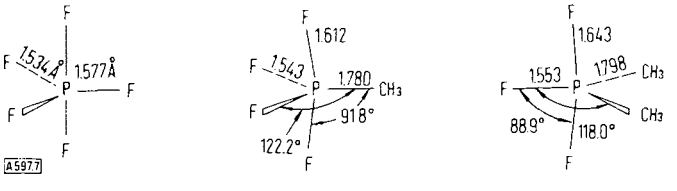

Fig. 7. Molecular parameters for PF_5, CH_3PF_4, and $(CH_3)_2PF_3$.

The molecular parameters [17] of CH_3PF_4 and $(CH_3)_2PF_3$ (Fig. 7) are of considerable interest as they illustrate very well how interaction between electron pairs determines stereochemistry. The methyl groups are less electronegative than the fluorines and therefore the electron pairs forming the bonds to the methyl groups take up more room on the "surface" of the phosphorus atom than do the electron pairs binding the F atoms. Therefore, it follows that: (*i*) the methyl groups occupy the equatorial positions; (*ii*) in the equatorial plane bond angles decrease in the order CPC > FPC > FPF; (*iii*) the FPF angles are all less than 90 ° or 180 °; and (*iv*) successively replacing fluorine by methyl groups in PF_5, CH_3PF_4, and $(CH_3)_2PF_3$ causes an increase in all the bond lengths, as the effective electronegativity of the central atom is decreased, but as the repulsions exerted on the axial bonding electrons are greater than on the equatorial bonding electrons the axial bonds increase in length proportionately more than the equatorial bonds.

Double bonds would always be expected to occupy equatorial positions, as has indeed been found in the case of SOF_4.

Intramolecular exchange of the ligands (pseudo-rotation) occurs very readily in trigonal bipyramidal molecules [14, 15, 17, 18] (Fig. 8). Consider the model of five

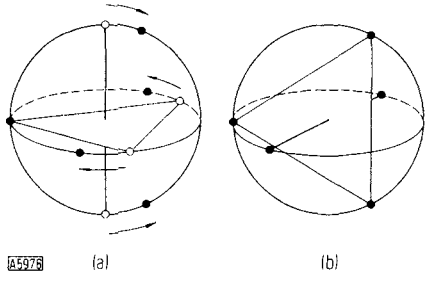

Fig. 8. Pseudo-rotation in a trigonal bipyramid molecule.
(a) o original position of ligands; • final position of ligands. (b) rotated form of trigonal bipyramid.

hard orbitals. The best arrangement is indeterminate and no energy is required to transform the trigonal bipyramid into the square pyramid. The trigonal bipyramid can then be reformed in such a way as to exchange the axial and equatorial positions. For soft orbitals the square pyramid structure has a slightly higher energy than the trigonal bipyramid and the activation energy for the intramolecular exchange of ligands, *via* the square pyramidal configuration as a transition state, is therefore small and exchange occurs rapidly. Thus the ^{19}F spectrum of PF_5 consists of a single doublet due to P–F spin-spin coupling, indicating that all five fluorine atoms are equivalent, whereas two doublets of relative area 2:3 would be expected. This has been attributed to the rapid intramolecular fluorine exchange described above [18]. In this internal motion of the molecule at no time do the electron pairs come closer than the critical angle of 90 °.

In contrast, it may be noted that in a similar internal exchange in an octahedral molecule, for example, the con-

version of a *cis* isomer to a *trans* isomer, would involve a transition state with angles between electron pairs considerably smaller than 90°. Strong orbital repulsions prevent such an internal motion in this case.

11. Coordination Numbers Greater than Six

For seven, eight, nine, eleven, and twelve electron-pairs the hard sphere model predicts the 1:3:3, square antiprism, 3:3:3, 1:5:5, and icosahedral structures, respectively. For eight, nine, and twelve electron-pairs replacing hard orbitals ($n = \infty$) by soft orbitals ($n < \infty$) does not lead to any change in the general shape.

For seven electron-pairs, it has been found that as n decreases the most stable arrangement changes from the 1:3:3 to the 1:4:2, and finally the 1:5:1, or pentagonal bipyriamid (Fig. 9)[3,19,20]. Calculation shows

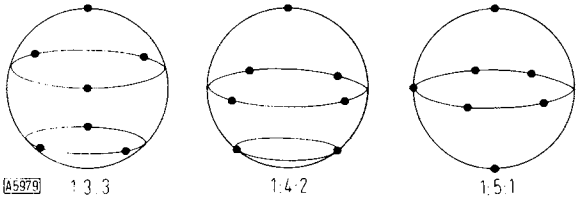

Fig. 9. Arrangements of seven particles on the surface of a sphere.

that the energies of all three arrangements are very similar[19,20] and it does not seem to be possible to predict with any certainty which structure will be adopted in any given case, particularly if the ligands are not equivalent; as for example, if they have different electronegativities, if one or more are multiply bonded, or if they are chelating ligands.

With non-equivalent ligands $NbOF_6^{3\ominus}$ has the 1:3:3 and $UO_2F_5^{3\ominus}$ the pentagonal bipyramid structure. For seven equivalent ligands the 1:3:3 structure has been observed for $ZrF_7^{3\ominus}$, the 1:4:2 structure for $NbF_7^{2\ominus}$, and $TaF_7^{2\ominus}$, and the 1:5:1 structure for $UF_7^{3\ominus}$. Although IF_7 has been reported to have the pentagonal bipyramid 1:5:1 structure[21], this has been disputed[22]. The ^{19}F-NMR spectrum of IF_7 in the liquid state can only be accounted for if all seven fluorines undergo a rapid intramolecular exchange, and thus become magnetically equivalent[23]. This easy intramolecular exchange presumably occurs because of the existence of several forms of seven coordination which differ very little in energy as in the similar case of five coordination[24].

If one of the seven electron-pairs is a lone pair, then because this occupies more space than the other bonding pairs, the molecule is likely to adopt that structure in which the lone pair has the minimum number of nearest neighbors, *i.e.* the 1:3:3 structure in which the lone pair is in the unique axial position. It seems probable that this is the structure of XeF_6[25] and we can also predict that this will be the structure of $IF_6^{\ominus}$.

We expect eight- and nine-coordinated molecules with equivalent ligands and no lone pairs on the central atom to have the square antiprism and 3:3:3 structures, respectively. Unfortunately, there are very few examples of such molecules whose structures have been determined, but, as predicted, $TaF_8^{3\ominus}$ is a square antiprism and $ReH_9^{2\ominus}$ and $Nd(H_2O)_9$ have the 3:3:3 structure. For high coordination numbers in general, several structures will have very similar energies and although for eight coordination and nine coordination one structure appears to be the most stable, for any value of n, other structures may be of very similar energy and a variety of factors, such as the presence of non-equivalent ligands, chelating ligands, or lone-pair electrons, might cause one of these structures to be more stable for a particular molecule than the square antiprism and 3:3:3 structures. The most likely alternative arrangements for any given number of electron pairs can be obtained by using some simple empirical rules relating to the most probable arrangement of particles on a sphere:

(*i*) There may be particles at one or both of the poles.

(*ii*) There will be particles located on circles lying between the poles and perpendicular to the vertical axis joining the poles.

(*iii*) The numbers of particles on successive circles in passing from the pole to the equator must either stay constant or increase by two.

(*iv*) The arrangements of particles on neighboring circles are staggered with respect to each other, two particles by 90°, three by 60°, four by 45° *etc.*

Using these rules we find the following arrangements for six electron-pairs; 1:4:1, 2:2:2, and 3:3, all of which are identical with the octahedron. For seven coordination, we have the 1:3:3, 1:4:2, and 1:5:1 arrangements (see Fig. 9). The apparently possible 1:2:2:2 arrangement is identical with the pentagonal bipyramid. For eight electron-pairs we obtain the 4:4 (square antiprism), 2:2:2:2 (dodecahedron), 2:4:2, 2:2:4, 1:3:3:1, and 1:6:1 (hexagonal bipyramid) arrangements. The cube is a special case of the 1:3:3:1 structure, but considering it as a 4:4 structure shows that it is expected to be less stable than the square antiprism. The apparently possible 2:4:2 structure may be seen to have the same stability as the cube and is, therefore, also less stable than the square antiprism. The 1:6:1 structure is also clearly less stable than the 1:3:3:1 structure. Hence the most probable structures for eight coordination are the 4:4 (square antiprism), 2:2:2:2 (dodecahedron), 2:2:4, and 1:3:3:1 structures (see Fig. 10).

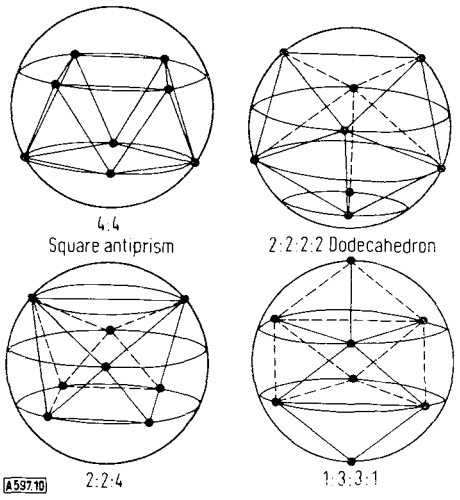

Fig. 10. Most probable structures for eight coordination.

For eight equivalent non-chelating ligands the square antiprism is expected to be the most stable structure and it has been observed in the case of $TaF_8^{2\ominus}$. The dodecahedron has been observed for $Mo(CN)_8^{4\ominus}$ which has non-bonding d electrons and also for a number of chelate complexes such as $Zr(C_2O_4)_4^{4\ominus}$. Several uranyl complexes, *e.g.* $UO_2(OAc)_2$, have the 1:3:3:1 structure and the nitrate $UO_2(NO_3)_2$ has the 1:6:1 structure. In these cases the doubly bonded oxygen atoms occupy the axial positions where they are as far apart as possible. *Hoard* and *Silverton* have discussed the square antiprism and dodecahedron forms of eight coordination in some detail [26].

According to the above rules, the 3:3:3, 1:2:2:2:2, 1:4:4, 1:2:4:2, 1:2:2:4, 1:6:2, and 1:7:1 arrangements are possible for nine electron-pairs. Of these the 3:3:3 arrangement is predicted to be the most stable for nine identical electron-pairs and is, in fact, the only structure that has been observed for nine-coordinated molecules.

12. Noble-Gas Compounds

The structures of all the noble-gas compounds that have been prepared in the last few years are in accord with the general rules for predicting structures that have been outlined in this review. As some apparently possible compounds have not yet been prepared we have the opportunity to make some predictions. Known and predicted structures are given in Fig. 11 [27].

The fluorides XeF_2, XeF_4, XeF_6, and XeF_8 have been prepared. XeF_2 is an AX_2E_3 molecule and has the expected linear structure. XeF_4 is an AX_4E_2 molecule and has the expected square planar structure. XeF_6 is an AX_6E molecule and will, therefore, not be octahedral [25]. Of the possible structures, a distorted octahedron with D_3 symmetry based on the 1:3:3 arrangement of seven electron-pairs seems the most likely be-

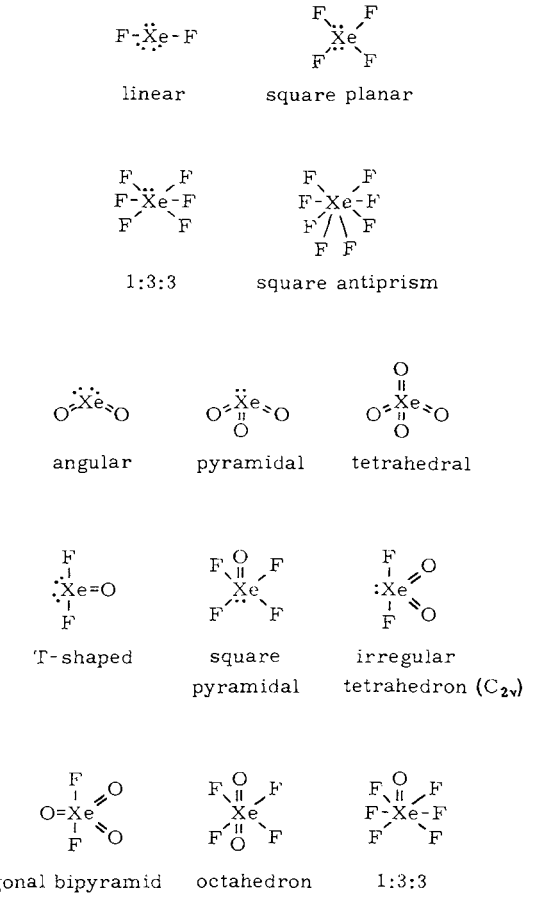

Fig. 11. Known or predicted structures for some noble gas compounds.

cause the lone pair, if it occupies the unique axial position, has only three near neighbors whereas all the other positions have four near neighbors, as does the unique axial position in the otherwise favorable 1:4:2 structure. The structure of XeF_8 has not been determined, but it is predicted to be a square antiprism.

The dioxide XeO_2 is not known but it would be an AX_2E_2 molecule and is, therefore, predicted to be angular in shape. The trioxide XeO_3 is an AX_3E molecule and is, therefore, predicted to be pyramidal as has indeed been observed. The tetroxide XeO_4 is an AX_4 molecule and it must, therefore, be tetrahedral.

The oxyfluorides $XeOF_2$, XeO_2F_2, XeO_3F, $XeOF_4$, XeO_2F_4, and $XeOF_6$ are all possible compounds. Of these only $XeOF_4$ is known with certainty and its structure has been determined; it has the square pyramidal structure predicted for an AX_5E molecule. Because of their greater size the lone pair and the double bond are expected to occupy *trans* positions, as is indeed observed. $XeOF_2$ is an AX_3E_2 molecule and is predicted to be T-shaped (like ClF_3) with the oxygen atom in an equatorial position. XeO_2F_2 is an AX_4E molecule and is predicted to have a shape similar to that of $IO_2F_2^{\ominus}$ with the oxygen atoms and the lone pair in the equatorial positions if a trigonal bipyramid. XeO_3F_2 is an AX_5 molecule and is expected to be a trigonal bipyramid with the three oxygen atoms in the equatorial positions. XeO_2F_4 is an AX_6 molecule and would be expected to be octahedral with the oxygen atoms in *trans* positions. $XeOF_6$ is an AX_7 molecule

[27] *R. J. Gillespie* in *H. H. Hyman*: Noble-Gas Compounds. University of Chicago Press, Chicago 1963.

and is predicted, with somewhat less certainty, to have a 1:3:3 structure closely resembling that of XeF_6 with the oxygen atom replacing the lone pair.

Xenon hexafluoride forms the anions $XeF_8^{2\ominus}$ and $XeF_7^{\ominus}$ [28]. The possible structures of these two anions are of great interest as they are the only known examples of molecules containing a lone pair and seven or more ligands. The $XeF_8^{2\ominus}$ ion is an AX_8E molecule and, therefore, its shape will be based on an arrangement of nine electron-pairs. As all nine electron-pairs are not equivalent, this will not necessarily be the 3:3:3 arrangement. A probable alternative is the 1:4:4 arrangement in which the lone pair occupies the unique position. The shape of the molecule could then be described as a somewhat distorted square antiprism in which the face containing the lone pair would be somewhat enlarged and squashed down towards the central xenon atom. The structure of $XeF_7^{\ominus}$, provided that it does not have a higher effective coordination number as a consequence of fluorine bridging, will have a structure based on the arrangement of eight electron-pairs. Again this may not be the square antiprism arrangement and a probable alternative is the 1:3:3:1 arrangement with the lone pair in one of the axial positions.

13. Transition Elements

In the case of transition elements it is necessary to take into account any interactions between the non-bonding d-shell and the bonding pairs in the valence shell. If the d-shell of the central atom is spherically symmetric *i.e.* d^0, d^5 (spin free), or d^{10}, it will have no effect on the arrangement of the valence-shell electron-pairs and the structures of these molecules will be exactly the same as the corresponding molecules of non-transition elements.

In other cases we must consider how an incomplete and therefore unsymmetrical inner d-shell can affect the arrangement of the ligand electron-pairs. This is best discussed in terms of the ligand-field theory and the Jahn-Teller effect. Any molecule with a degenerate electronic state will distort in such a manner as to remove this degeneracy and to reduce the symmetry of the molecule. This can be visualized as resulting from the repulsion between the d-shell and the valence-shell electron-pairs. In ligand-field theory the repulsion is considered to be between the d-shell and the ligands, but we prefer to relate stereochemistry to the arrangement of the bonding electron-pairs rather than the ligands themselves; in any case the general conclusions are the same.

Consider AX_6 molecules. In the absence of any interaction with a d-shell, or if the d-shell is spherically symmetric these will be strictly regular octahedral molecules. Now ligand-field theory shows that an octahedral arrangement of ligands splits the d-shell into two levels, the d_{xy}, d_{xz}, and d_{yz} orbitals (or t_{2g} orbitals) and the $d_{x^2-y^2}$ and d_{z^2} orbitals (or e_g orbitals). Since the t_{2g} orbitals have a greater electron density between the bonding electron pairs while the e_g orbitals have a greater electron density in the direction of the bonding electron pairs, the former are of lower energy than the latter. If either of these two sub-levels is unsymmetrically occupied then some of the bond pairs suffer a greater repulsion than others and the octahedron is distorted, although the effects produced by the t_{2g} orbitals are expected to be very small and have not been observed. It is easily seen that an unsymmetrical occupation of the e_g orbitals will give rise to a tetragonal distortion so that the symmetry is reduced from O_h to D_{4h}, but it cannot be predicted whether this distortion will give rise to an elongated, or a compressed octahedron, both have been observed for d^7, d^8, and d^9 systems. In these cases it is a reasonable approximation to regard the d-shell as having an ellipsoidal (either prolate or oblate) shape. The arrangement of six electron-pairs around a prolate ellipsoid will give an elongated octahedron, while an oblate ellipsoid would give a compressed octahedron. Strong interaction with the d-shell may cause an octahedral complex to lose its axial ligands (and their electron pairs) thus giving rise to a planar AX_4 complex. Alternatively, such a structure can be regarded as arising from the interaction of an ellipsoidal d-shell with a tetrahedral AX_4 molecule. In some cases where the interaction with the d-shell does not completely dominate the interaction between the four bonding electron-pairs, a distorted tetrahedral structure might be expected, as has indeed been observed for $CuCl_4^{\ominus}$ and $CuBr_4^{\ominus}$. The predicted distortions of an AX_5 trigonal bipyramid molecule have been discussed in detail elsewhere [29].

14. Exceptions

There are only a few cases where the stereochemistry of a molecule appears to be dominated by interactions between ligands. For example, the ions $SeX_6^{2\ominus}$ and $TeX_6^{2\ominus}$, where X = Cl, Br, or I, are of the AX_6E type and, therefore, should have a distorted octahedral structure like XeF_6. In fact they have regular octahedral structures [30, 31]. Here the lone pair has no stereochemical effect and must be presumed to occupy a spherical orbital closer to the nucleus than the bonding orbitals, as was first suggested by *Pauling* many years ago [30]. It has been claimed that the ligands, when they are sufficiently large, can only be packed around the central atom in an octahedral arrangement [31], in other words, it is assumed that this is a case where interaction between ligands dominates over the interaction between valence-shell electron-pairs and the lone pair is forced into an inner orbital.

As the ions $XeF_7^{\ominus}$ and $XeF_8^{\ominus}$ are known it is clear that six fluorine atoms do not take up all the space around the central xenon atom and that there is, therefore, room for the lone pair which accordingly exerts its stereochemical effect, with the result that the structure of XeF_6 is non-octahedral. Since the molecule IF_7 is known, $IF_6^{\ominus}$ may similarly be predicted with confidence as having a non-octahedral structure.

The interesting point arises, however, that eight fluorine atoms might possibly take up all the space around the xenon, in which case the lone pair would be forced into an inner orbital and would thus exert a reduced, or even zero, stereochemical effect. In this latter case the structure would then be predicted to be a regular square antiprism. Similarly, it might be expected that some AX_4E molecules in which X is a large ligand would have a tetrahedral shape, but no examples are

[31] *I. D. Brown*, Canad. J. Chem. *42*, 2758 (1964).

yet known. It is interesting to note, however, that some molecules of this type do have structures that are closer to the tetrahedral shape than is predicted by consideration of the repulsions between five electron-pairs. In the molecules

$(p\text{-}CH_3C_6H_4)_2SeBr_2$, $(p\text{-}CH_3C_6H_4)_2SeCl_2$, and $(C_6H_5)_2TeBr_2$

the angle between the axial ligands is greater than 180° instead of less than 180° as predicted (see Table 6). It seems that the lone pair is not exerting its full stereochemical effect.

These seem to be the only cases where the simple rules discussed in this article do not predict the correct structures. It is perhaps not unreasonable to claim that these rules give a better understanding of the structures of simple molecules than any other theory. For example, no other theory can successfully account for the changes in bond lengths and bond angles in the molecules PF_5, CH_3PF_4, and $(CH_3)_2PF_3$.

Because of the similar energies of different structures, predictions are less certain for high coordination numbers, but this must also be the case for alternative theories. It is to be hoped that in the future, the ideas presented here can be given a sounder theoretical basis and that they can be incorporated into a still more comprehensive and more successful theory of molecular structure.

Chemical Gamma-Resonance Spectroscopy[**]

BY V. I. GOLDANSKII[*]

Two of the most important contributions that nuclear physics has made to modern science and technology have been in the fields of nuclear energy and isotope labeling. In recent years nuclear physics has stimulated the appearance and extremely rapid development of yet another new and equally important scientific discipline, namely gamma-resonance spectroscopy. This new branch of spectroscopy, which is based on the Mössbauer effect[1–3] is playing an increasingly important role in physics, chemistry, biology, geology, and in the elucidation of various technical problems. – This paper deals briefly with the basic physics of the Mössbauer effect and the characteristics of Mössbauer (gamma-resonance) spectra, and then considers various applications of this new type of spectroscopy. Particular attention is paid to the fundamentals and development of chemical gamma-resonance spectroscopy[4–9] as a technique for the resolution of problems in various fields of chemistry and biology and to the range of problems tackled in recent years in our laboratory of nuclear and radiation chemistry at the Institute of Chemical Physics of the Academy of Sciences of the USSR. A number of reviews and monographs dealing with the application of the Mössbauer effect in chemistry have already been written[4–12]. The following work is based mainly on experimental results obtained by research workers in the Soviet Union.

I. The Mössbauer Effect

Let us first consider the Mössbauer effect, the phenomenon of recoil-less resonance absorption and emission of gamma-quanta, which was discovered by *Rudolf Mössbauer* in Germany in 1958 and for which he was awarded the Nobel prize in physics in 1961.

The phenomenon of resonance is known in mechanics, acoustics, optics, and radio engineering. When tuning our radio to the transmitting station we adjust the frequency of the receiver's oscillatory circuit to the same frequency as that of the transmitters oscillatory circuit. Sometimes even considerable revolving of the tuning knob leaves the audibility

almost unaltered, and at other times even the slightest touch may abruptly disturb reception. In the latter instance the resonance is sharper or, in other words, more sensitive to any interference.

Quantum systems, *i.e.* molecules, atoms, and atomic nuclei, represent resonant radiation receivers and transmitters. The radiation frequencies ω of such systems are determined by the energy difference E_r between the excited and the ground state:

$$E_r = \hbar\omega,$$

where $\hbar \approx 6.6 \times 10^{-16}$ sec-eV is Planck's constant (see Fig. 1). Another important characteristic of resonance is its width Γ, which is related to the average lifetime of the excited state τ:

$$\Gamma = \frac{\hbar}{\tau}$$

The ratio Γ/E_r characterizes the resonance sharpness; the lower its value, the better the selectivity of the resonance system.

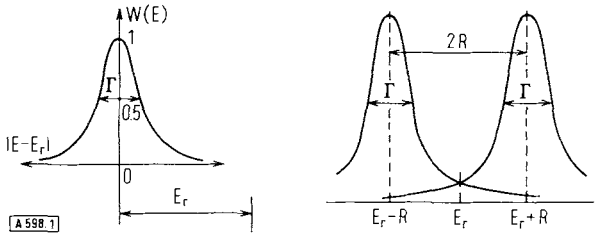

Fig. 1. Illustration of the resonance phenomenon.

Left: Probability of resonance excitation $W(E)$ depending on deviation of the transmitted energy E from resonance value E_r. Γ is the natural resonance width.

Right: Emission and absorption resonance lines displaced by the recoil energy $R = E_r/2mc^2$ towards energies lower than or higher than E_r.

Two characteristic cases of resonance – atomic (yellow D-line of sodium) and nuclear (transition from an excited 23.8 keV state of ^{119}Sn to the ground state) – are given for comparison in Table 1.

Table 1. Main criteria of characteristic atomic and nuclear resonance transitions.

Parameter	Atom (D-line of Na)	Nucleus (^{119}Sn)
Transition energy E_r (eV)	2.1	23800
Lifetime of excited state τ (sec)	1.5×10^{-8}	2.7×10^{-8}
Natural resonance width Γ (eV)	4.4×10^{-8}	2.4×10^{-8}
Resonance sharpness Γ/E_r	2.1×10^{-8}	10^{-12}
Recoil energy R (eV)	10^{-10}	2.5×10^{-3}
Ratio of recoil energy to transition energy R/E_r	$\approx 4.8\times10^{-11}$	$\approx 10^{-7}$
Ratio of recoil energy to resonance width R/Γ	$\approx 2.3\times10^{-3}$	$\approx 10^{5}$

It is obvious that the resonance width Γ of the atom and that of the atomic nucleus are approximately equal, whereas the energy of transition in the nucleus is higher than that in the atom by four powers of magnitude; therefore, the selectivity of nuclear resonance is thousands of times higher than that of atomic resonance. A change in the energy of an emitted or absorbed gamma-quantum by only one trillionth suffices either to destroy or reproduce resonant conditions. (If this degree of accuracy (10^{-12}) were to apply in the measurement of the radius of the entire solar system then figures would be obtained which would be accurate to within the height of a two-storey building.) It can be appreciated that the prospects of observing gamma-resonance seemed very attractive; however, because of the extreme selectivity of this resonance, combined with the great energy of gamma-quanta, the discovery of gamma-resonance was delayed for a number of years.

A gamma-quantum (or an optical quantum) departing from a nucleus (or an atom) imparts to that nucleus (or atom) a momentum in the opposite direction. The energy of the recoil is given by

$$R = E_r^2/2mc^2,$$

where m is the mass of the source of radiation and c is the velocity of light. In the case of an atom, the recoil energy is much less than the resonance width ($R \ll \Gamma$), and consequently recoil does not interfere with observation of the resonance phenomena. The situation is quite different in the case of nuclei; the recoil energy is hundreds of million times greater, and the emission line is displaced far away (by $2R$) from the position of the absorption line ($E_r + R$) towards lower energies ($E_r - R$). The position of the absorption line is accounted for by additional kinetic recoil energy R imparted to the absorbing nucleus excited by energy E_r. Resonance appears to be possible only at the expense of partial superposition of two lines separated by recoil; moreover the shapes of these lines are distorted owing to thermal motion of the nuclei and the resulting Doppler shift of the gamma-quantum frequency.

Recoil-less nuclear gamma-resonance (NGR) was discovered under conditions where the emitting and absorbing nuclei (^{191}Ir in *Mössbauer*'s first experiment) were in a crystal lattice, bound by chemical bonds to billions of nuclei of the same sort. The recoil on emission or absorption of a gamma-quantum is insufficient to break these bonds and therefore the recoil energy is dissipated in excitation of the quanta of atom vibrations in the lattice, *i.e.* of phonons. The case may be, especially at low temperatures, that no phonon excitation is effected, the transition energy is then divided between a quantum and the whole lattice and the denominator of the expression for recoil energy will represent not the mass of an individual nucleus but the mass of the lattice. As in the case of firing an infinitely heavy gun, the recoil energy tends to zero, *i.e.* it becomes much less than the resonance width ($R \ll \Gamma$) and does not interfere with observation of the latter. An intense resonance line, maintaining its position and width, appears on the background of shifted and broadened absorption and emission spectra whose peaks are separated by $2R$ from one another by recoil (see Fig. 2).

It is of interest to note that *Mössbauer* explained his experimental results on the basis of a theory proposed by *Lamb* for the explanation of the appearance of a similar line in experiments on neutron scattering. This

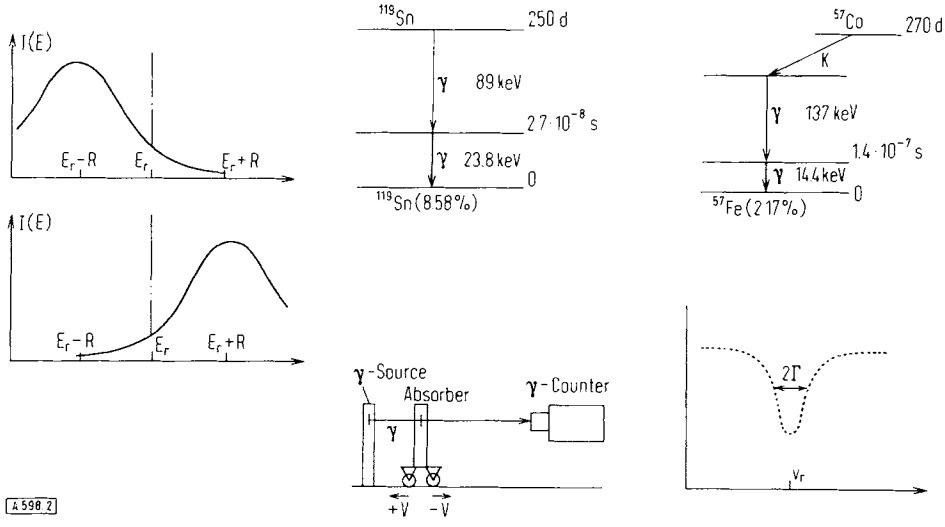

Fig. 2. Illustration of the Mössbauer effect.

Left: The spectra of gamma-quanta emission and absorption. A resonance line of natural width is observed against a background of displaced and broadened spectra (scale of 1:200 in case of ^{191}Ir at 88 °K). Formulae for the Mössbauer effect probability f' in the Debye approximation (Θ = Debye temperature):

$$f' = \exp\{-2W(T)\};\ T \ll \Theta:\ W = \frac{3}{4}\cdot\frac{R}{k\Theta};\ T \gg 0:\ W = \frac{3}{4}\cdot\frac{R}{k\Theta}\cdot 4\frac{T}{\Theta}$$

Top center and right: decay diagrams for ^{119}Sn and ^{57}Co → ^{57}Fe. Half-lives, transition energies, and natural abundances for tin and iron are shown. Bottom center and right: schematic representation of a gamma-resonance experiment (*i.e.* dependence of the gamma-quantum counting rate on the velocity of the absorber (or source) and the approximate shape of such a spectrum.

$$V \approx c\,\frac{\Gamma}{E_r} \approx (10^{-12}\ :\ 10^{-13})\,c \approx (10^{-2}\ :\ 10^{-3})\ \text{cm/sec}.$$

theory had been developed some 20 years before the discovery of recoil-less nuclear gamma-resonance. It is rather unfortunate that, due to excessive specialization, both by those conducting experiments with gamma-quanta and by those concerned with interactions of neutrons in solids, the discovery of the Mössbauer effect should be delayed for such a long time.

From the discussion so far it is clear that the nuclear-resonance line of natural width represents a kind of high-precision measuring instrument. How is the Mössbauer effect observed and quantitatively studied?

First of all, a transmitter and a receiver are needed; their parts are played, respectively, by the excited emitting nucleus and the stable nucleus of the same isotope, *i.e.* a resonance absorber for gamma-quanta. Figure 2 shows decay schemes for two nuclei most commonly utilized in gamma-resonance spectroscopy, namely ^{119}Sn and ^{57}Fe (formed in the radiation source from the ^{57}Co parent nucleus by K-electron capture). Secondly, a control of the gamma-quantum energy is necessary. The frequency and the tone of a sound signal are known to change with displacement of the sound source; such changes are due to the Doppler effect. The same effect was utilized by *Mössbauer* to change the gamma-quanta energy in GR spectroscopy, where, due to extremely sharp resonance, a low velocity movement of the absorber relative to the source is sufficient. This velocity $V = \Gamma \cdot c/E_r$ is estimated according to the value of Γ/E_r, *i.e.* on the properties of the nucleus selected for study, in fractions of mm/sec (^{119}Sn, ^{57}Fe) and occasionally in fractions of micron/sec (^{67}Zn).

Study of the dependence of the counting rate on the velocity of the absorber placed between the source (emitter) and the counter, is the most important experimental step in gamma-resonance spectroscopy. The approximate shape of this function, called the gamma-resonance or Mössbauer spectrum (GR spectrum), is given in Fig. 2. The peak or the resonance line corresponds to minimum counting, *i.e.* to maximum adsorption, when the absorber is moving at some certain velocity. Thus the essence of obtaining gamma-resonance spectra consists in compensation of all external factors affecting the resonance transition energy by appropriate displacement of the absorber or the quanta source, and thereby making a quantitative investigation of these factors.

Mössbauer's discovery provided research workers with a tool for the precise measurement of gamma-quanta energy. However, the potentiality of this new tool was not immediately appreciated. At first the new phenomenon seemed to be confined to the relatively limited scope of elucidating problems of nuclear physics. The development of GR spectroscopy, and its application in solid-state physics, chemistry, biology, geology, and engineering was the result of work carried out by many scientists of various countries.

II. Parameters of Gamma-Resonance Spectra

The motion of atoms within molecules and in crystal lattices, as well as the interaction of the charge and the electric and magnetic moments of the nucleus with surrounding electron shells all affect the gamma-quantum energy; consequently, each of these effects can be investigated by means of gamma-resonance spectroscopy.

A schematic list of Mössbauer spectrum parameters and of information contained therein is presented in Fig. 3.

Let us begin with the probability of the Mössbauer effect f' displayed in the resonance peak area (Fig. 3a). The f' value defines the range of thermal atomic vibrations within molecules and lattices, *i.e.* their mean square amplitude $\overline{r^2}$. A detailed theory connecting the f' value and its temperature dependence with the vibrational frequency spectrum of a composite crystal lat-

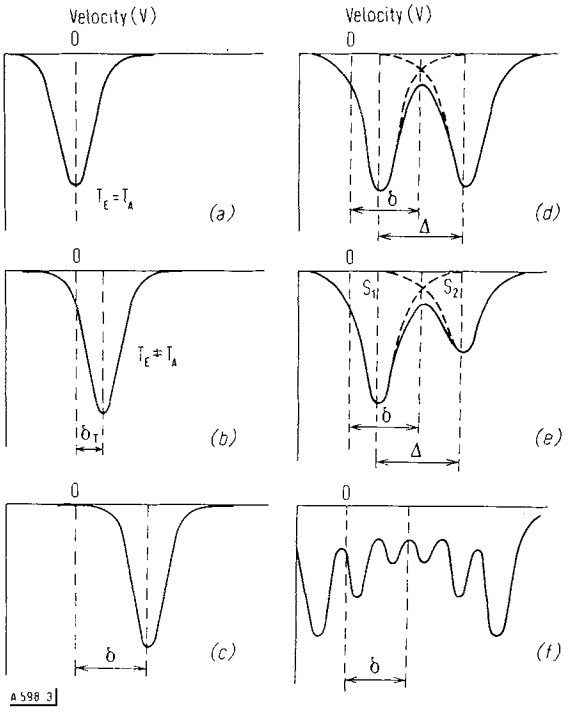

Fig. 3. Parameters of gamma-resonance spectra and information supplied by them (E = source, A = absorber):

a) Source ≡ absorber, the peak area is proportional to $f'(T) \sim \exp[-r^2/(\lambda/2\pi)^2]$ where r^2 is the mean square of the atomic displacement;

b) Source ≡ absorber, the temperature shift of the line $\delta_T = \frac{1}{2} E_\gamma \frac{\overline{V^2}}{c^2}$ gives the value of mean square velocity V^2 of the atom in vibrational motion;

c) Source ≠ absorber, the isomeric (chemical) shift of the line $\delta \sim \frac{\Delta R}{R}\left\{|\psi(0)|^2_A - |\psi(0)|^2_E\right\}$ supplies information on density (square of wave function) of s electrons at the nucleus;

d) Source ≠ absorber, quadrupole splitting $\Delta \sim Qq$ gives the value of the electric field gradient on the nucleus $q = \frac{\partial^2 V}{\partial z^2}$;

e) Source ≠ absorber, the asymmetry quadrupole splitting supplies information about the anisotropy of atomic motion in molecules and lattices: $x^2 \neq \overline{y^2} \neq z^2$ or on electron paramagnetic relaxation;

f) Source ≠ absorber, magnetic splitting ($1/2 \rightarrow \pm 1/2$; $3/2 \rightarrow \pm 3/2$, $\pm 1/2$): $\Delta M \quad \mu/IH$ (where I is the spin, μ the nuclear magnetic moment) characterizes an effective local magnetic field H on the nucleus.

tice and impurity atoms was developed by *Yu. M. Kagan* [13,14].

An important part of this theory deals with the role of the so-called optical branches of vibrational spectra in the probability of recoil-less gamma-resonance. The optical branches possess comparatively high energies (and consequently small amplitudes) and characterize, in the long-wave approximation, the motion of atoms relative to their nearest neighbors in contrast to simultaneous displacements of many atoms in acoustic vibration branches. The existence of optical branches is essential because they provide for the possibility of observing gamma-resonance spectra in systems containing light atoms (this is of particular importance for chemistry), as well as at rather high temperatures. The theory predicted also the possibility of anisotropy of the Mössbauer effect in single crystals [15], which is associated with different amplitudes of atomic vibrations along different crystal axes ($\overline{x^2} \neq \overline{y^2} \neq \overline{z^2}$). Indeed, such an anisotropy in single crystals was soon established [16–18].

It should be noted here that the width of a resonance line also gives a certain amount of information about the diffusion of atoms [19–20]. If the emitter and the absorber of our first example are chemically identical and their temperatures are the same, then maximum absorption occurs with the absorber at rest: $V = 0$. If the absorber temperature T_0 is now changed to T_1, the absorption maximum will shift by a certain value δ_T as shown in Fig. 3b. This temperature shift [21] defines the average kinetic energy of the atomic vibrations in the lattice, and hence their mean square velocity $\overline{V^2}$.

A parameter of paramount importance is the isomeric (chemical) shift of the resonance line (Fig. 3c) due to the difference of chemical state of atoms of the emitter and the absorber. This shift, which is caused by changes in the electrostatic interaction energy of electric charges of the nucleus and the electron shells, was first observed by *Kistner* and *Sunyar* [22] during experiments with various compounds of iron.

Isomeric shift is determined by a product of two magnitudes, one of nuclear origin (relative change of the nuclear charge radius due to nuclear excitation) and the other of extranuclear origin. It is the latter, *i.e.* the difference in squares of electron wave functions (in other words of electron densities) in the region of absorbing and emitting nuclei that is of special interest for chemists since it defines the structures of s-electron shells and the participation of s electrons in chemical bonds.

Interaction between the nuclear electric quadrupole moment (in the ground and/or excited states) with a non-uniform electric field results in quadrupole splitting of gamma-resonance spectrum lines (Fig. 3d) proportional to the product of the quadrupole moment Q and the electric field gradient q. Of these two values the first is nuclear; the second is a molecular value, which defines the properties of p- and d-electron shells. The possibility of describing separately the contribution from s, p, and d electrons to chemical bonds by means of correlating isomeric shifts and quadrupole splitting is an essential advantage of chemical gamma-resonance spectroscopy allowing, for instance, distinction to be made between the role of changes in ionicity and in the extent of hybridization of chemical bonds [22a].

Quadrupole splitting frequently turns out to be asymmetrical even for absolutely isotropic polycrystalline substances (as shown in Fig. 3e) [22b]. Such an integral asymmetry of two peaks with respect to their area was

[22b] The asymmetric quadrupole splitting observed in the Mössbauer spectra of polycrystalline substances is termed the Goldanskii effect.

observed for the first time in spectra of organotin compounds and thoroughly investigated and interpreted at the Institute of Chemical Physics in Moscow [23-25]. This asymmetry is a result of the Mössbauer effect anisotropy in respective crystallites ($\overline{x^2} \neq \overline{y^2} \neq \overline{z^2}$) and its observation opens up possibilities for investigating structural features of single crystals by experimenting with polycrystalline material (in a sense similar to plotting of X-ray debyegrams). Recently, the above mentioned cause of asymmetry of the quadrupole splitting was quantitatively studied and confirmed for single crystals and polycrystals of siderite ($FeCO_3$) [25a].

It is also worth mentioning that investigation of the "anisotropic" asymmetry of quadrupole splitting and its explanation has done away with confusing trivial hypotheses on the overlapping of spectra of various hypothetical admixtures or structural isomers.

A further variant of asymmetric quadrupole splitting is connected with interaction between the electric field and the magnetic field occurring at nuclei under the influence of unpaired electrons of the atomic shells [26]. This "paramagnetic" asymmetry is more intense the longer the time of paramagnetic relaxation, *i.e.* the slower the electron spin flipping. Therefore, unlike the "anisotropic" asymmetry of quadrupole splitting, the "paramagnetic" asymmetry weakens as the temperature increases.

The ordered or very slowly relaxing unpaired electrons of external shells cause polarization of the internal electrons thus cancelling full compensation of the magnetic effect of anti-parallel spins of two s electrons of the shell closest to the nucleus. As a result, enormous magnetic fields are set up inside the atom; these can be determined from magnetic (Zeeman) splitting of gamma-resonance spectrum lines (Fig. 3f).

A number of theoretical papers (cf., for example, [27]) are concerned with problems of the magnetic splitting of nuclear gamma-resonance lines, which can range from a single line to a well-resolved hyperfine structure. The spectrum is temperature dependent, the width of individual peaks being related to the time of paramagnetic relaxation and, of course, to the transition from paramagnetic to ferromagnetic or antiferromagnetic states.

The theory of coherent phenomena [28, 29], for example, of suppression of gamma-resonance absorption in an ordered nuclear setup, as compared to an individual nucleus or a random system, occupies a prominent place in papers on gamma resonance. As a result of this suppression, the lifetime of an excited nucleus in an ordered lattice may turn out to be longer than that in the free state, *i.e.* the width of the excited level will be less than the natural resonance width. Conversely, shorter lifetimes and more rapid disintegrations are also possible [28c]. The problems of coherent effects in emission and propagation of gamma-quanta, the wavelength of which is many thousand times less than that of visible light, are naturally of exceptional interest. There is little doubt that any future achievement in solving these problems will be closely connected with the Mössbauer effect.

A striking variety of experimental methods are currently in use in research on the structure of matter: optical spectroscopy, electron spin resonance, nuclear magnetic resonance, and quadrupole resonance, X-ray structural analysis, electron and neutron diffraction, and neutron scattering. Of course, none of these methods may be considered as a panacea for solution of all problems connected with crystalline or molecular structure. The nuclear gamma-resonance method presents no exception in this respect; despite its potentialities, a given problem can be solved only when it is used in conjunction with other methods.

The greatest limitation of gamma-resonance spectroscopy is that the Mössbauer effect can be observed only for a substance in the solid phase and not for all chemical elements (see Fig. 4). Because of the general increase in energies of the lower levels with decreasing nuclear mass, the recoil energy for light-element nuclei is so great that the Mössbauer effect becomes

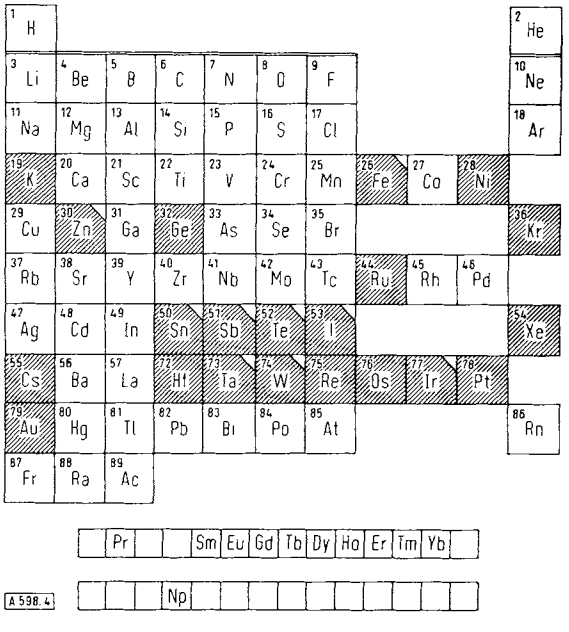

Fig. 4. Elements for which the Mössbauer effect has been observed (shaded squares).

A light top right-hand corner in a shaded square means that the effect has been detected even at room temperature. The effect is to be expected for almost all lanthanides and actinides; chemical symbols in respective squares show for which elements of these series the effect has already been observed. Silver is not shaded since its ratio Γ/E is very low ($\approx 10^{-22}$) and therefore the experiments with Doppler shift of gamma-quanta absorption have not been carried out.

vanishingly small. At present potassium is the lightest of the elements observed to give the Mössbauer effect.

Despite the absence of such common elements as carbon, nitrogen, oxygen, and silicon in the "Mössbauer list", the field of application of gamma-resonance is extremely wide since gamma-resonance nuclei are frequently introduced as observers to elucidate the properties of other systems. In the following sections, a selection of important and impressive examples illustrate the successful application of gamma-resonance spectroscopy in various fields of chemistry and biology.

III. Some Applications of Nuclear Gamma Resonance (NGR) in Solid-State Physics

Brjuchanov, *Deljagin*, and *Kagan*[30] introduced tin into vanadium and compared the temperature dependence of the gamma-resonance probability (Fig. 5a) with that estimated by means of the theory of impurity nucleus vibrations in the cubic lattice[13]. The spectrum of the host-lattice vibrations required for such a theory had been found independently in experiments with sub-thermal neutrons[30a,30b]. The perfect

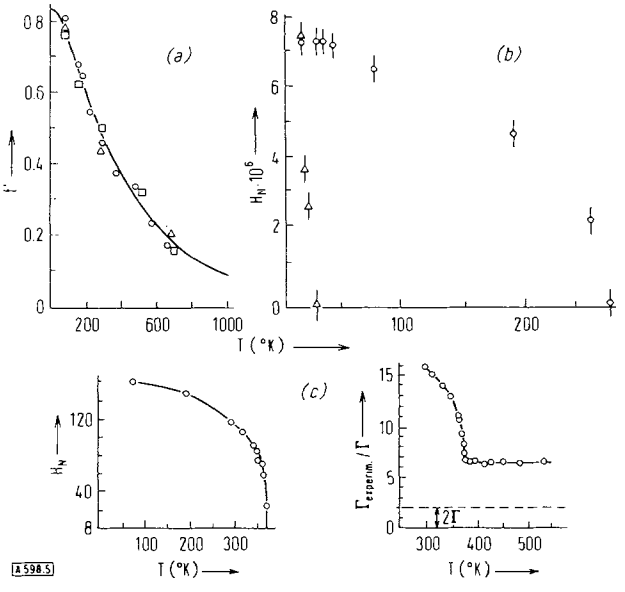

Fig. 5. Application of the Mössbauer effect in solid-state physics.
a) Temperature dependence of the effect probability $f'(T)$ for ^{119}Sn nuclei in vanadium;
b) temperature dependence of the magnitude of the local magnetic field on ^{161}Dy nuclei in gadolinium: $H_N(0) = 7.3$ MOe;
c) temperature dependence of the local magnetic field on ^{57}Fe nuclei (in kOe) and the width of the gamma-resonance spectrum line of ^{119}Sn in $FeSn_2$.

agreement between theory and experiment shows the broad potentialities of quantitative gamma-resonance spectroscopy of simple and complex crystal lattices.

Interaction of unpaired electrons of external shells with internal s electrons of the atom may lead, under certain conditions, to very strong local magnetic fields in the vicinity of the atomic nucleus. The magnitude of these fields is determined directly from the hyperfine structure of NGR spectra, since the magnetic moment of the absorbing nucleus (*i.e.* the nucleus in the ground state) is generally known from other experiments. Fig. 5b shows the temperature dependence of the field (recently obtained[31] at the Kurchatov Institute of atomic energy) for impurity nuclei of dysprosium (^{161}Dy) formed in the metallic gadolinium lattice by neutron capture and two subsequent beta-decay events. At a temperature of 5 °K the local magnetic field attains a value of 7.3 MOe. The nature of the diminution of the field with decreasing temperature indicates that two states of dysprosium occur (for the first the local field disappeared at about 20 °K, for the second – simultaneously with the disappearance of the ferromagnetism of gadolinium – at a Curie temperature of about +290 °K).

A clear correlation between a macroscopic magnetic property, such as the spontaneous magnetization of the sublattices of anti-ferromagnetic $FeSn_2$, and the local magnetic fields at nuclear sites was demonstrated at the same Institute[32]. In this work, the magnitudes of magnetic fields were determined both for iron and for tin (Fig. 5c); for iron directly from the line splitting, for tin from the width of the line with the unresolved hyperfine structure (this width decreases with diminishing local field at the nuclear sites).

Randomization of electron spins through their continuous fast flipping certainly leads to disappearance of the magnetic hyperfine structure of NGR spectra, since in this case the local field on the nucleus averaged over time becomes zero. The general theory of gamma resonance in systems with unpaired electrons, which allows for all these circumstances, has been verified for numerous examples. Only two obvious cases of alteration of the nature of NGR spectra in such systems will be given here.

b) Gamma-resonance spectra of ^{57}Fe in a nickel-zinc-ferrite spinel for different degrees (x) of replacement of iron by zinc in the tetrahedral lattice (Zn_xFe_{1-x}) $[Ni_{1-x}Fe_{1+x}]O_4$. (Ordinate: number of counts in arbitrary units.);

c) Mössbauer effect probability diminishing as a result of increasing mobility of atoms in the ferrielectric lattice of $Pb_2[FeNb]O_2$ near the Curie temperature (114 °C).

Fig. 6a shows dysprosium (^{161}Dy) spectra [33] for a dysprosium-aluminum garnet, which is anti-ferromagnetic at a temperature below 2.49 °K, and becomes paramagnetic at a temperature above this point (the Néel point), Here, the transition to the paramagnetic state does not cause abrupt disappearance of the hyperfine structure. The latter disappears only gradually with diminishing electron-relaxation time, *i.e.* with more frequent flipping of spin with increasing temperature. Such an increase in flipping entails broadening of the hyperfine structure lines in accordance with the theory.

Fig. 6b shows spectra [34] of the ferrite spinels (Zn_xFe_{1-x}) $[Ni_{1-x}Fe_{1+x}]O_4$. Here, iron is incorporated in the tetrahedral sublattice (together with zinc) and in the octahedral sublattice (together with nickel). The interaction between these sublattices induces the occurrence of uncompensated antiferromagnetism (so-called ferrimagnctism). As iron is dislodged in the tetrahedral sublattice by the zinc ions, interaction between the sublattices weakens, and the ferromagnetic material is converted into a paramagnetic material with a very short spin-lattice relaxation time; the magnetic splitting of the spectrum line disappears.

It should be mentioned that the properties of ferrites are not only of theoretical interest but are also of practical interest since their magnetization is not accompanied by substantial loss of energy by eddy currents, even at ultra-high frequencies. Of similar dual interest is the application of the Mössbauer effect to the study of ferroelectrics, which display dielectric polarization even in the absence of an external electric field. The electrical properties of ferroelectrics are in many respects similar to ferromagnetic magnetization. In both cases there is a certain critical temperature (Curie temperature) above which thermal motion destroys the ordering of electrical and magnetic moments, and thus eliminates ferroelectric and ferromagnetic properties.

V. V. Skljarevskii et al. [35] observed a sharp increase in the mobility of atoms in a ferroelectric lattice at a temperature close to the temperature of transition from the ferroelectric state to the paraelectric state *i.e.* phase transition of the second kind. Indeed, Fig. 6c shows that an abrupt decrease in the probability of the Mössbauer effect on iron in the ferroelectric $Pb_2[FeNb]O_6$ was observed close to the Curie temperature (114 °C).

Observations of the Mössbauer effect led also to the discovery of new magnetic phenomena. For example, *Borg et al.* [36] as well as *Craig et al.* [37] found a magnetic ordering of electron spins in highly diluted solid solutions of iron (5 %) in gold (95 %). The conservation of the same magnetic hyperfine structures – the number of lines, their width and splitting values (Fig. 7a) – at an imposed external axial magnetic field of about 30 kOe, indicates that the variant of spin ordering effected in this alloy is antiferromagnetic. Thus, the so-called indirect or super-exchange interaction of unpaired electrons takes place here through the conduction electrons rather than through homopolar valence bonds as, for example in various magnetic oxides or ferrites.

Quantitative analysis of indirect interaction between 3d electrons of iron *via* 4s conduction electrons was carried out by another research group [38, 38a] in experiments with iron containing small amounts of aluminum. Fig. 7b shows the variations in the field strength at the iron nuclei according to the distance between the iron atoms and the closest admixed aluminum atoms.

The magnetic field is proportional to the electron-spin density at a ^{57}Fe nucleus. The electron spin density is made up of contributions of core s electrons and conduction s electrons. It was shown experimentally that in Fe–Al alloys the core contribution remains constant over a wide range of solute concentrations. It was concluded that the change in the field, as obtained with the help of a computer from the GR spectra of Fe at different concentrations of Al (see Fig. 7b), is caused by the changes in the spin densities of conduction electrons. Thus it was shown that the nearest-neighbor and second-neighbor Al atoms decrease the field on iron, *i.e.* the indirect exchange reaction between the localized 3d spins *via* the 4s conduction band is antiferromagnetic in these cases.

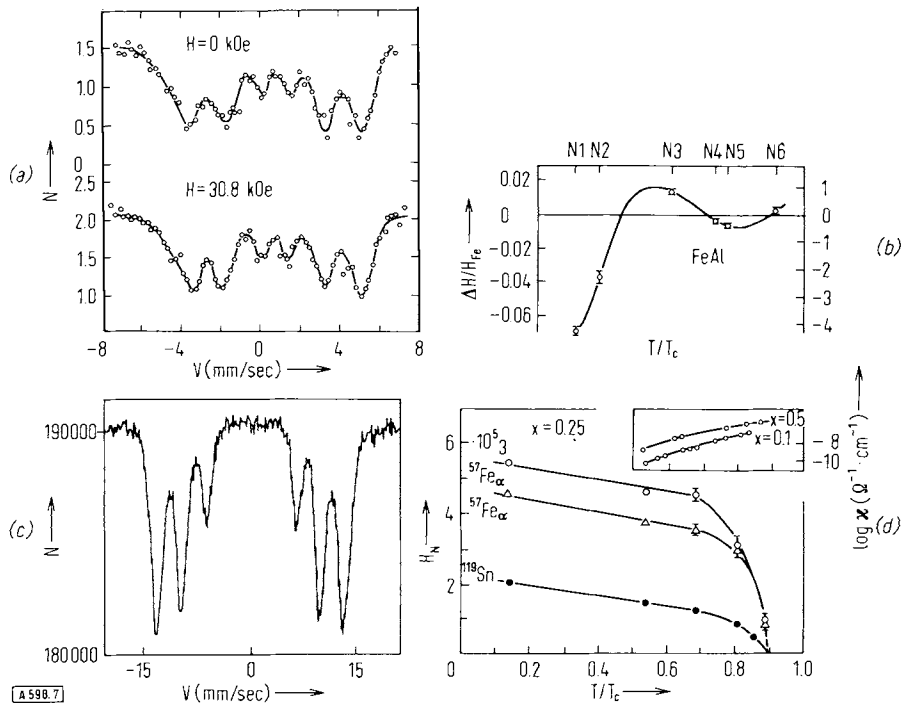

Fig. 7. Application of the Mössbauer effect in solid-state physics.

a) GR spectra of ^{57}Fe in iron-gold alloys ($Fe_{0.05}Au_{0.95}$) in the absence of and in the presence of an external axial magnetic field;

b) the local magnetic field at ^{57}Fe nuclei as a function of the average distance between iron atoms and their nearest-neighbor aluminum atoms (role of the indirect effect *via* conduction electrons);

c) the GR spectrum of ^{119}Sn in the yttric ferrite garnet $\{Y_{3-x}Ca_x\}$ $[Sn_xFe_{2-x}](Fe_3)O_{12}$;

d) temperature dependence of local magnetic field on iron nuclei in two sublattices and on tin nuclei, and of electroconductivity of the ferrite garnet (top right).

A still more peculiar example of indirect magnetic interaction is the super-exchange induction of the magnetic fields on nuclei of diamagnetic tin atoms introduced into yttric ferrite garnets $\{Y_{3-x}Ca_x\}$ $[Sn_xFe_{2-x}]$ $(Fe_3)O_{12}$, This effect was observed independently by *Goldanskii et al.*[39] and by *Belov et al.*[40] about three years ago. Fig. 7c shows the Mössbauer spectrum of the tin in this garnet. The spectrum parameters, the chemical shift (equal to the shift for SnO_2), quadrupole splitting (absent in this case, which means that all Sn bonds are equal), the effect probability and its temperature dependence (characteristic of tin with a coordination number of 6), warranted the conclusion that, in this yttric ferrite, tin is not directly bound with iron, but is connected with it through oxygen: Sn—O—Fe. Nevertheless, a considerable magnetic field – over 200 kOe at 77 °K – was observed at the nucleus of a diamagnetic tin atom as indicated by Zeeman splitting of the spectrum line into six components; at the Curie point it disappeared, as did the field on the iron nuclei (see Fig. 7c). Later measurements[39a] showed that the sign of the local magnetic field at the tin nucleus (similarly to that at the iron nuclei in the same octahedral sublattice) coincides with the sign of the imposed external magnetic field. Rather low values are obtained for the electrical conductivity of ferrite: 10^{-10} to 10^{-8} ohm^{-1} cm^{-1} (upper right-hand corner of Fig. 7d). The conductivity increases with decreasing field.

Thus, it was ascertained that the unpaired electron of iron polarizes the internal s electrons of tin at the expense of super-exchange interaction through two chemical bonds Fe—O and O—Sn. In other words, delocalization of the unpaired electron of iron was observed in an inorganic system having only σ bonds and it was found that this delocalization manifests itself by the polarizing exchange interaction between the unpaired electron and internal s shells.

IV. Examples of the Application of Gamma-Resonance Spectroscopy in Chemistry

Work on the development and the application of gamma-resonance spectroscopy in chemistry began in our laboratory some seven years ago. The results obtained in our first experiments, which were carried out mainly with organotin compounds, provided general substantiation of the applicability of gamma-resonance spectroscopy to the elucidation of chemical problems. For instance, the Mössbauer effect was observed in polymers and amorphous materials. It appeared that, due to optical branches of vibrational spectra, recoilless gamma-resonance was best displayed in systems consisting mostly of light atoms, *e.g.* H, C, N, O. Further, it was shown that it is possible to investigate the influence of chemical bonds in the immediate neighborhood of, and more distant from, the "Mössbauer atom". Finally, the asymmetric doublet structure in a quadrupole splitting for a polycrystalline specimen was investigated and interpreted.

Some applications of gamma-resonance spectroscopy in structural chemistry are illustrated by Fig. 8 and 9. The marked difference of the SnF_4 spectrum from the spectra of other tin halides (Fig. 8) and the study of data on chemical shift, quadrupole splitting, and the Mössbauer effect probability led to the conclusion that the SnF_4 structure is octahedral, that here the coordination number of tin is 6, and that the coplanar bonds

[39] *V. I. Goldanskii, V. A. Truchtanov, M. N. Deviševa,* and *V. F. Belov,* Ž. eksper. teoret. Fiz., Pis'ma v Redakciju *1,* 31 (1965); Physics Letters *15,* 317 (1965).

[39a] *V. I. Goldanskii, M. N. Devisheva, E. F. Makarov, G. V. Novikov,* and *V. A. Truchtanov,* Ž. eksper. teoret. Fiz., Pis'ma v Redakciju *4,* 63 (1966).

[40] *K. P. Belov* and *I. S. Lyubutin,* Ž. eksper. teoret. Fiz., Pis'ma v Redakciju *1,* 26 (1965).

between the tin and the four fluorine bridge atoms, which are responsible for formation of the inorganic polymer, are different from the bonds with the other two fluorine atoms. It is of interest that all six Sn–F bonds in salts of the K_2SnF_6 type become equivalent, and quadrupole splitting of the lines vanishes [41]. Tin coordination numbers of 5 and 6 were found from Mössbauer spectra for many organotin compounds.

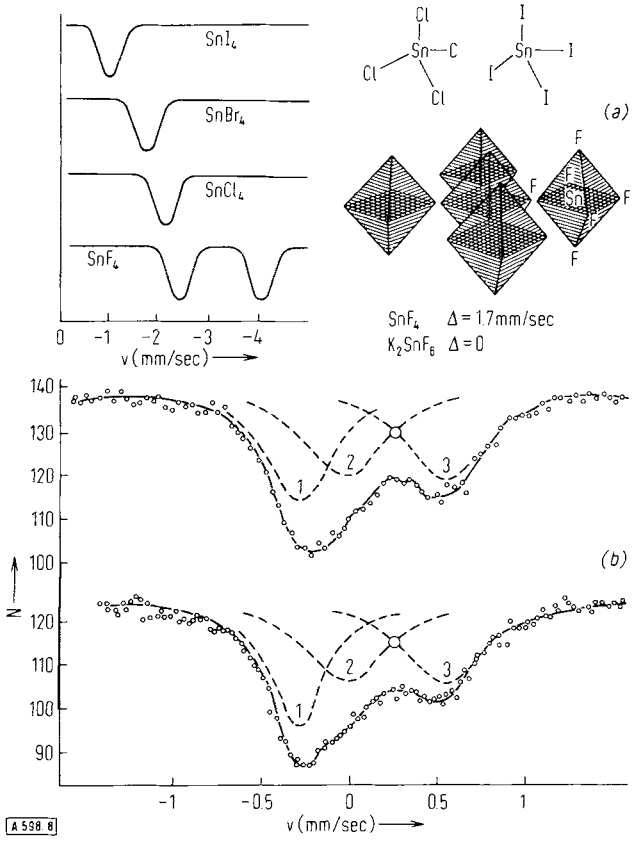

Fig. 8. Chemical gamma-resonance spectroscopy.

a) GR spectra of tin halides and their structures;

b) GR spectra of Prussian blue Fe(III) + $[Fe(CN)_6]^{4\ominus}$ (above) and Turnbull's blue Fe(II) + $[Fe(CN)_6]^{3\ominus}$ (below);
1: singlet $[Fe(CN)_6]^{3\ominus}$; 2,3: doublet Fe(III).

The structure of both Prussian blue and Turnbull blue is $[Fe(III)]_x\ [Fe(II)\ (CN)_6]_y$.

The spectra of two well-known iron complexes, *i.e.* Prussian blue and Turnbull blue, are shown in Fig. 8. It has been shown in a number of laboratories [5, 42–45] that the spectra of these two compounds are identical. As a rule (for an exception, see [45]) these spectra were regarded as superpositions of the $Fe^{3\oplus}$-doublet and the single line of the complex hexacyanoferrate(II) anion $[Fe(CN)_6]^{4\ominus}$. Thus, both Prussian blue and Turnbull blue turned out to be the same compound, and it is now considered that in these compounds the iron inside the complex occurs in the form of Fe(II), and in the external coordination sphere in the form of Fe(III).

The nuclear gamma-resonance spectra of xenon (^{129}Xe and ^{131}Xe) made it possible to ascertain the electronic structures of XeF_2 and XeF_4 [46–48] (see Fig. 9a). Quadrupole splittings that are identical in magnitude (but with opposite signs) must correspond to these two structures. Moreover, by using the radioactive iodine compound $K^{129}ICl_4$ as emitter of resonance gamma-quanta it was shown that a chlorine xenon compound $XeCl_4$, which was previously unknown, is formed in the process of β-decay of iodine (to ^{129}Xe); it was identified by its gamma-resonance spectrum (see Fig. 9b). In a similar way, β-decay of $K^{129}IO_3$ and $K^{129}IO_4$ gives rise to the formation of xenon oxides, XeO_3 and XeO_4.

The elucidation of the structure of iron dodecacarbonyl $Fe_3(CO)_{12}$ also serves as characteristic example

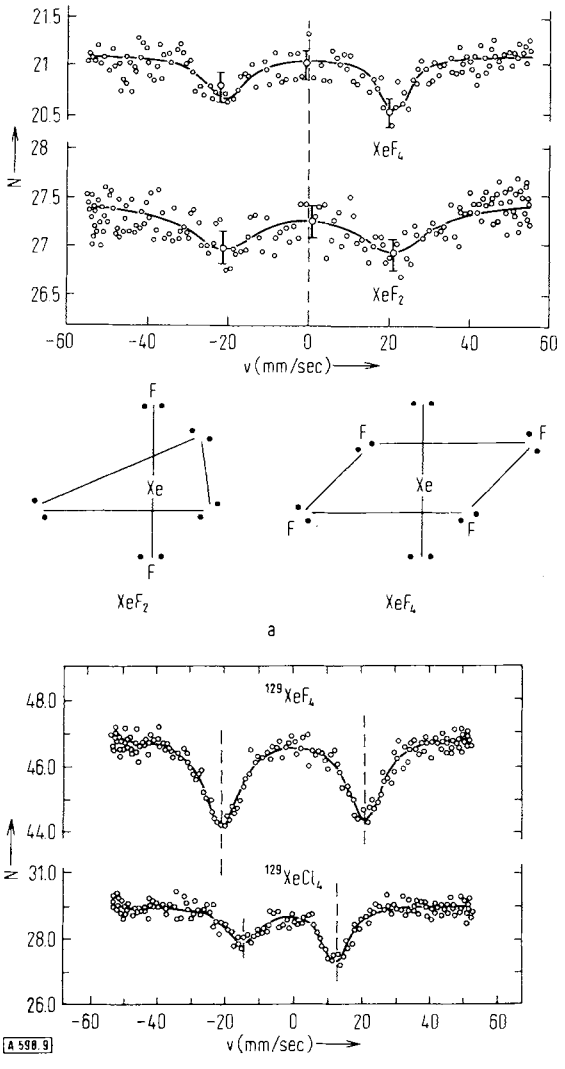

Fig. 9. Chemical gamma-resonance spectroscopy.

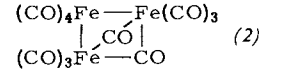
of the fruitful application of nuclear gamma-resonance in structural chemistry.



Three variants of the structure of iron dodecacarbonyl have been discussed previously in various papers (see, *e.g.*, the references [8, 9, 11]): the linear structures $(CO)_4Fe(CO)_2Fe(CO)_2Fe(CO)_4$ and $(CO)_3Fe(CO)_3Fe(CO)_3Fe(CO)_3$ designated as 4.2.2.4 and 3.3.3.3, and the cyclic one

(1)

all three having bridge bonds between the iron atoms *via* carbonyl groups.

X-ray structural analysis [49] resulted in selection of the cyclic structure *(1)*. However, all three iron atoms would be equivalent in this structure, whereas observations of the Mössbauer effect had shown a complex gamma-resonance spectrum of iron, shaped as a trident formed by superposition of the singlet and the quadrupole-split doublet. This spectrum rules out the above cyclic structure, and of the two linear variants it is more consistent with that of 3.3.3.3. However, this structure could not be allotted since it contradicted X-ray analysis indications. On the basis of a repeated X-ray analysis [50] the cyclic structure *(1)* was corrected – the structure of iron dodecacarbonyl is now assumed to be *(2)*.

(2)

Naturally, there are many cases in which a full interpretation of results requires complicated calculations, as for example in the use of the molecular orbital method. In this connection one might mention the various explanations of differences in ferrocene and ferricinium spectra [4, 51].

The application of gamma-resonance spectroscopy in chemical kinetics and physical chemistry of surface phenomena is illustrated by a number of examples in Figures 10 and 11. Curves describing the kinetics of oxidation of solid dibutyltin in air with formation of dibutyltin oxide [52] are shown in Fig. 10a; these curves were obtained by observation of variations in the intensity of nuclear gamma-resonance (NGR) spectra of initial compounds and reaction products as a function of time. The example that is of more common interest is that in which the tin atoms serve as observers in the characterization of the properties of dipolar aprotic solvents [53]. Dimethyl formamide and tetrahydrofuran are widely used as solvents in organic chemistry, and strongly affect the kinetics of nucleophilic heterolytic reactions. It appears that the quantitative aspect of the solvent properties may be defined from the increase in quadrupole splitting of the NGR spectra of solutions of polar compounds, such as dibutyltin dichloride (cf. Fig. 10b).

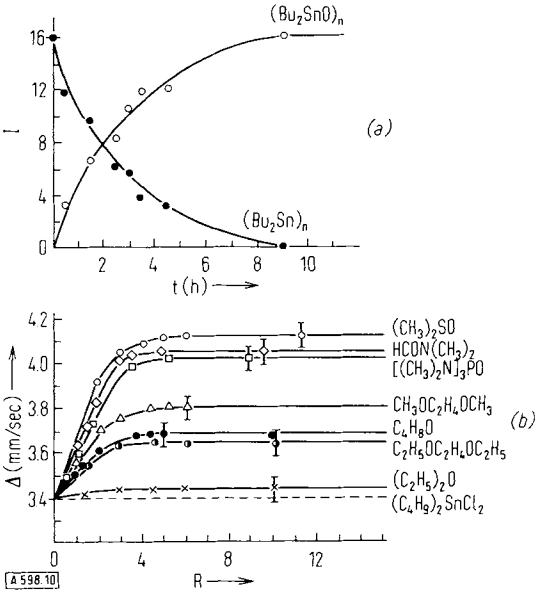


Fig. 10. Chemical gamma-resonance spectroscopy.

(a) Curves depicting kinetics of the decrease in the dibutyltin $(Bu_2Sn)_n$ content and increase in its oxidation product $(Bu_2SnO)_n$: obtained by analysis of GR spectra of tin (ordinate: intensity of Mössbauer effect in arbitrary units).

(b) Increasing quadrupole splitting of the GR-spectrum line of tin in dibutyltin dichloride, the latter dissolved in various dipolar aprotic solvents (abscissa: molar ratio of solvent to $(C_4H_9)_2SnCl_2$).

Indeed, both the increase in quadrupole splitting and the kinetic effects [53a, 53b] are of the same origin; they are caused by strong reactions of the solvents with the cationoid, but not with the anionoid parts of molecules. In contrast to the strongly solvated cations, the weakly solvated anions appear to be extremely reactive [53c, 53d].

Gamma-resonance spectra supply information both on the chemical state (chemical shifts, quadrupole splitting) and on the dynamics of surface atoms (asymmetry of quadrupole splitting). For example, the spectra of tin on a silicagel [54] surface shows two oxide forms – SnO and SnO_2. (The silica gel surface was prepared in the following way: (i) Ion exchange between $CaCl_2$ and the $H^{\oplus}$ ions of the silica gel OH groups, (ii) ion exchange between $SnCl_2$ and $Ca^{2\oplus}$.) On the basis of the stronger temperature dependence of the Mössbauer effect probability f' for the adsorbate SnO_2 (Fig. 11a), it may be inferred that the oxide SnO is chemisorbed while the dioxide SnO_2 is attached to the surface by van der Waals forces only. square amplitudes of thermal vibrations along the surface (0.07 Å) and normal to it (0.13 Å) were established from the quadrupole splitting asymmetry of SnO. In the case of SnO_2 it is possible to distinguish two factors of the Mössbauer effect probability, namely the role of atomic vibrations inside the molecule and that of molecular vibrations on the surface of the silica gel.

(b): GR spectra of iron in mordenite before adsorption (I and II; at 93 °K and 293 °K) and after adsorption of hexane (III; 93 °K).

The gamma-resonance spectra of synthetic zeolites have also been obtained[55]. At present, zeolites attract general attention as efficient separating and drying agents for mixtures. For the investigation of the structures and the adsorption properties of faujasite (Y) and mordenite (M), the sodium in these compounds was replaced by iron, which was highly enriched in ^{57}Fe. The basic structural unit of these zeolites is an octahedron consisting of silicon-oxygen and aluminum-oxygen tetrahedrons. The octahedrons are connected with one another *via* oxygen bridges forming the channels which form the internal surface of zeolites. The spectra given in Fig. 11b confirmed the suggestion[56] that two types of adsorption centers exist, localized and non-localized. It was found that only Fe(III) ions had been localized before adsorption, while localization of Fe(II) was induced only by filling of zeolite channels with various adsorbed compounds (for example, hexane). Accordingly, a doublet in the gamma-resonance spectrum of trivalent iron was observed before adsorption whilst after adsorption another doublet arising from Fe(II) with much larger quadrupole splitting appeared.

Spectroscopy has proved to be of immense value in the elucidation of problems in polymer science.

tra[58] of soluble polyferrocenes and insoluble polyferrocenes, *i.e.* of linear polymers *(3)* whose chains involve only one of the two cyclopentadienyl rings bonded to each iron atom, and polymers in which both cyclopentadienyl rings are involved in a continuous three-dimensional network. The spectrum of such an insoluble polymer *(4)* (Fig. 12b) consists of two doublets; the cross-linked regions exhibit a weaker quadrupole splitting and a relatively high Mössbauer effect probability. At room temperature, gamma-resonance is observed only for these cross-linked regions. The spectra may therefore be used to determine directly the extent of cross-linking in polyferrocene, and moreover provide information about the removal of electrons to the conduction levels of the cross-linked regions – such knowledge is important in the description of the properties of organic semiconductors.

Very curious results were obtained in the study of radiation damage in polyethylene, to which stabilizers, such as dibutyltin dimaleate, had been added. The strong, Co-γ-radiation-induced change of the chemical shift in the NGR spectra of tin in this compound (Fig. 13a) shows the detachment of two butyl radicals, tetravalent tin being converted to the divalent species. Obviously it is this reaction that is responsible for the effect of organotin stabilizers as inhibitors of oxidative aging of polymers[59].

A number of papers on kinetics of chemical conversions (*e.g.* solid-phase polymerization[60]) contain reports of sudden accelerations of reactions in the vicinity of a melting point or other phase transitions in the solid state. Such accelerations are assumed to be connected with an increase in the mobility of atoms in a solid under these conditions. In this connection, great interest attaches to the temperature dependence of the Mössbauer effect probability for different iron salts in ice[61]. It may be seen from Fig. 13, that within a certain temperature range close to −90 °C, the recoil-less nuclear-gamma resonance of iron atoms in $Fe(ClO_4)_2$ and $FeCl_2$ simply disappears, which is a direct indication of the sharp increase in mobility of the iron atoms in ice near the point of its phase transition.

This result is similar to that obtained later in the study of ferroelectrics for a second-order phase transition (cf. Section III).

(b): Temperature dependence of the Mössbauer effect probability f' for iron in frozen aqueous solutions of $Fe(ClO_4)_2$ and $FeCl_2$ within the range of −196 °C to −40 °C (the phase transition point for ice is close to −90 °C).

V. Nuclear Gamma-Resonance as a Method of Chemical Analysis

First of all let us consider a specialized but highly promising application of the Mössbauer effect in trace analysis[62,63]. Since gamma resonance is observed only for certain isotopes of certain elements (for example, ^{57}Fe), a new technique suggests itself for the study of the kinetics and mechanism of complicated reactions, and the structures of many chemical compounds. To this end it is necessary to study the dependence of the nuclear gamma-resonance spectrum upon the chemical state of the Mössbauer isotope in the system.

Even the first attempts to combine the Mössbauer effect with the tracer technique disclosed electron exchange between Fe(II) and Fe(III) ions in solid salts at

78 °K [62]. Assignment of the first of the two possible structures *(5)* and *(6)* to ferricinium ferrichloride thus became possible [63].

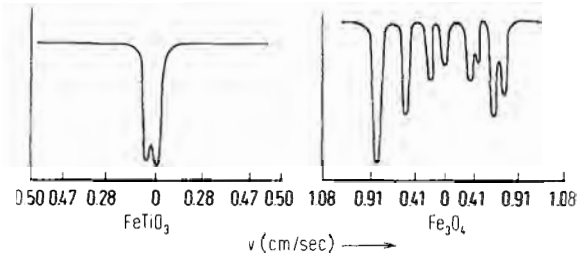

Fig. 14. Analytic applications of gamma-resonance spectroscopy. GR spectra of two iron minerals – ilmenite $FeTiO_3$ and magnetite Fe_3O_4.

Figure 14 shows the Mössbauer spectra of two minerals – ilmenite ($FeTiO_3$) and magnetite – at room temperature [64]. Magnetic splitting of the resonance line is observed for magnetite but not for ilmenite. Thus, it is possible to distinguish between the two minerals solely on the basis of the scattering of gamma-quanta by their surfaces. A given ore can be rapidly classified as iron (Fe:Ti > 10) or titanium (Fe:Ti < 10) ore, by determining the ilmenite-magnetite ratio in this way.

There are indications in scientific literature [65,65a] that the Mössbauer effect has been proposed for use in distant analysis (from a spacecraft) of the mineral composition of the surfaces of the moon and of Mars.

Since 1962 Soviet scientists have been working on various designs of gamma-resonance devices for determining the tin content (in the form of cassiterite (SnO_2)) of ores and minerals. From 1963 to 1965 these devices were tested under field conditions for different tin deposits, and in the summer of 1965 our device (MAK-1) was accepted for serial manufacturing. Figure 15 shows the principles of its operation both for absorption and for scattering of gamma-quanta by the objects tested. A picture of the MAK-1 portable gamma-resonance tin detector weighing about 3.5 kg is also shown in Figure 15.

Instead of delivering the ore to the laboratory for chemical investigation, it is sufficient to determine whether or not the counting rate for gamma-quanta changes with a slight movement of the resonance source. In a few minutes the tin content is known as accurately as can be determined by chemical analysis. Geologists and economists claim that every such instrument saves over 7000 roubles a year.

VI. Some Applications of Gamma-Resonance Spectroscopy in Biology

Application of the Mössbauer effect in biology [66, 66a] is favored at present mainly because iron – one of the principal elements showing this effect – is a component of hemoglobin and a number of ferments (see *e.g.* [71]). Moreover, it is present in all native nucleic acids, in which it evidently plays an essential, though not yet established, biological role.

The tobacco mosaic virus contains merely 0.01 wt.-% iron. However, removal of this very small amount of iron deprives the virus of its infectious properties and causes decomposition of the RNA molecule into smaller subunits, as has been shown by sedimentation measurements. Reintroduction of iron regenerates the RNA and the infectious nature of the virus is reestablished [67]. Before elucidating the role of iron in this system, it was necessary to ascertain the nature of its bonding in nucleic acids. By comparison of the spectrum of $FeCl_3$ and those of its complexes with nitrogeneous bases such as guanine and guanosine, with sugars such as ribose and deoxyribose and finally, with nucleic acids such as RNA and DNA, (Fig. 16a) it was demonstrated [68, 69] that incorporation of iron into RNA and DNA takes place *via* formation of coordinate bonds between Fe(III) ions and sugars. The latter act as electron donors in RNA and reduce the iron to Fe(II); in DNA they do not display donor properties. It is quite possible that these data might help to explain the essential difference in the biological roles of DNA and RNA.

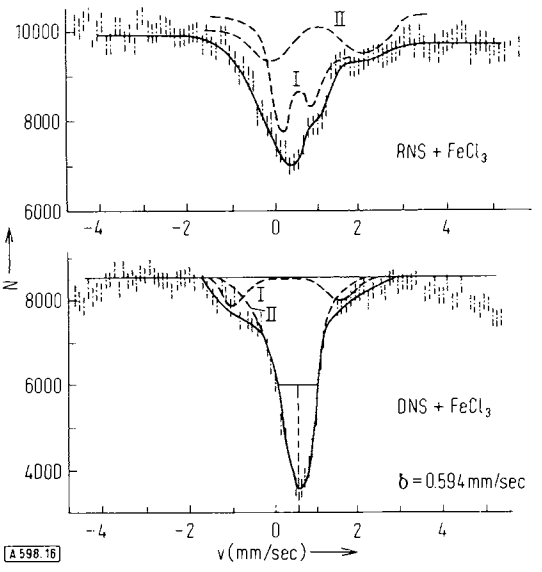

Fig. 16. Gamma-resonance spectroscopy in biology.

GR spectra of iron bound to RNA and to DNA. In case of RNA the complexity of the spectrum is caused by the two valence states of iron: (I) $Fe^{3\oplus}$ coordinated with ribose and (II) $Fe^{2\oplus}$ coordinated with ribose; in the case of DNA the spectrum represents superposition of the singlet due to $Fe^{3\oplus}$ coordinated with deoxyribose and that due to $Fe^{3\oplus}$ coordinated with bases.

A gamma-resonance spectrum[70] has recently been obtained of a living object, the hydrogeneous bacteria *Hydrogenomonas Z-1* grown in a ferric chloride medium that had been enriched in ^{57}Fe. This spectrum exhibits components due to both major iron valence states, *i.e.* Fe(II) and Fe(III) are apparently present in the cytochrome system of these bacteria. A change in the valence state of iron during the fixation of nitrogen by azobacteria has recently been observed and investigated[71].

Interesting research in biomechanics has been conducted by *Hillman et al.*[72]: A miniature ^{57}Co source (^{57}Fe served as absorber) was attached to the ear tympanum and the latter made to vibrated under the influence of acoustic oscillations. Since the oscillation frequency (10^3–10^4 sec^{-1}) was preset, and the tympanum velocity (of the order of 10^{-4} cm/sec) could be determined by the Doppler shift of the absorption maximum in the gamma-resonance spectrum, it was possible to ascertain the amplitude of oscillation of several Ångström at an accuracy of 1–2 Å. There are a number of analogous applications of the Mössbauer effect in engineering where one wishes to measure and control *e.g.* speeds, shifts, and accelerations. Pressure measurements can be based on the dependence of both chemical shifts and of Mössbauer effect probability on compression of matter; changes in component population of the hyperfine structures of gamma-resonance spectra, namely when the magnitude of kT becomes commensurable with the difference in energies of individual HFS lines ($kT \lesssim 10^{-5}$ eV, *i.e.* $T \lesssim 0.1\,^{\circ}K$), allow precise measurement of very low temperatures.

Physical Causes of Aging in Plastics

BY H. A. STUART [*]

A number of physical changes that take place in a polymer below the glass transition temperature without the action of a medium are first described, and are then explained on the basis of changes in supramolecular order. Pure stress crazing with the characteristic self-limitation of craze growth is then considered. Models are developed to explain stress crazing under the influence of a wetting medium. Attempts to reduce stress crazing are then treated and the article closes with a discussion of the influence of morphological structure on crazing and cracking.

I. Introduction

A large amount of experimental data on the chemical causes of aging, *i.e.* corrosion, of plastics has been published [1] and a systematic account has been given by *Kern* [2]. The physicochemical causes of aging, *e.g.* loss of plasticizer by diffusion, evaporation, or extraction have also been discussed recently in a review by *Voigt* [3].

In the examination of the physical causes of aging, it is convenient to distinguish between processes that take place with no outside agency, *i.e.* purely thermodynamic processes, and those that are due to external agents. The most common sign of aging is the occurrence of internal stresses, and hence the tendency toward crazing, cracking, and embrittlement, which may be due *e.g.* to crystallization or to changes in the supramolecular or morphological order also in a noncrystalline material. Other possible causes are plasticizer migration and the evaporation of small molecules such as monomer or water.

Both external and internal stresses, particularly in the presence of swelling wetting media, also leads to surface cracking and fissuring of the material (crazing). Naturally, any cracking also assists chemical attack, *e.g.* by oxygen, and so accelerates aging of the material. The present report will be deliberately confined to physical causes of aging, to which very little study has so far been devoted, although in practice combinations of the various aging effects are encountered.

Aging in metals is mainly due to electrochemical or purely chemical processes, though physical factors (*e.g.* mechanical stresses in stress-crack corrosion) may also be involved. In high polymers, physical factors and particularly the supramolecular order (see below) and the mobility of the molecules have a much greater influence, not only on the properties of the material, but also on the physical and chemical processes responsible for aging. This is due to the long-chain, anisotropic structure of the macromolecules. The van der Waals' forces between the chains of a polymer are much weaker than the valence forces acting in the chain direction. Consequently, mechanical stresses can lead to slipping of the chains relative to one another, plastic flow, and crazing without the need for rupture of the main polymer chain.

In a noncrystalline material or in the noncrystalline regions of a semicrystalline material, the packing of the macromolecules is rather disordered and loose. Consequently, transport and rate processes, particularly diffusion processes, and hence also any chemical reactions, take place mainly in the noncrystalline regions. If the substance is cooled below its glass transition temperature, the movement of the chain segments, *i.e.* the microbrownian motion, is frozen in and the substance becomes vitreous and hard, or even brittle. Once the microbrownian motion has stopped, the substance becomes progressively less able to reach its thermodynamic equilibrium state.

Insofar as polymers crystallize, the coiling and entanglement of the chains kinetically inhibit the formation of states of supramolecular order, *e.g.* crystallization, and are thus partly responsible for the many morphological structures of high polymers. Thus we know of very finely crystalline substances, such as the crystalline-amorphous system described by *Abbitz* and *Gerngross* [4], spherulites of widely varying structures and degrees of order, lamellar single crystals, and regions in which the chains are parallel (for further details see [4] and [5]). Owing to kinetic inhibition, a bulk polymer material never achieves complete crystallization either on cooling from the melt or on precipitation from solution, or even on subsequent

annealing. Thus it is characteristic of macromolecular materials that they are always removed to some extent from the thermodynamic equilibrium state. Their molecular order and hence their properties tend to change continuously in one direction, *i.e.* the materials tend to "age".

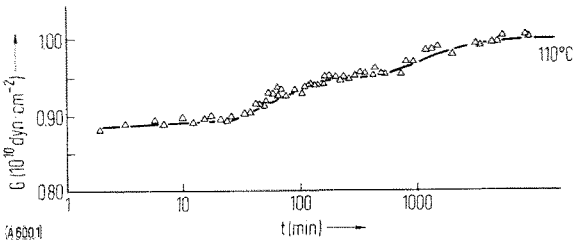

Fig. 1. Shear modulus of the polycarbonate of bisphenol A below the glass transition temperature as a function of annealing time.

II. Internal Thermodynamic Causes of Aging

It is generally known that changes in the crystallization state mainly influence the mechanical properties of a material (*e.g.* hardening or embrittlement). It is not so well known that similar phenomena can also occur in noncrystalline substances, such as amorphous polyethylene terephthalate, polymethyl methacrylate, polycarbonate, and polystyrene, on storage or after prolonged use. Since these processes can take place far below the glass transition temperature, they cannot be due to crystallization, but must involve an improvement in the short-range order characteristic of the amorphous state.

The completely disordered amorphous state can never be reached in liquids or melts, or even in somewhat compressed gases above the critical temperature. Even the close-packed spherical or rod-shaped molecules of a liquid exhibit a characteristic short-range order, *e.g.* approximately hexagonal close packing or a substantially parallel arrangement over very small regions. Since this statistical order extends only to the immediate surroundings of any given molecule (in the case of small molecules it has disappeared within a few intermolecular distances), it is known as short-range order. In substances consisting of chain molecules, there is always a certain amount of parallel arrangement of adjacent chain segments; the extent to which this occurs increases with the extent to which the chain segments are in the *trans* or zig-zag form as opposed to the *cis* and *gauche* forms. Since the width of X-ray reflections increases with decreasing dimensions of the crystallites, a substance having minute crystallites or crystal nuclei with an edge length of about 10 Å, gives, like an ordinary liquid or chain molecules in the melt or in the glassy state, only an amorphous halo. These systems are amorphous to X-rays, and will be referred to here simply as "amorphous", though it should be understood that this merely means that details of the short-range order at present defy investigation by X-ray methods. In my opinion, however, it is probable that information about the packing of the molecules in the noncrystalline regions can be obtained by accurate intensity measurements on the halo.

For some years we have been conducting experiments designed to measure and interpret structural changes in the amorphous region [6, 7]. Thus the increase in the shear modulus as a function of time at elevated temperatures was measured for the polycarbonate from bisphenol A, which is particularly suitable because of its high glass transition temperature (≈ 150 °C). When the polycarbonate is annealed *e.g.* at 110 °C (cf. Fig.1), the modulus increases in two stages. If it is then cooled to 20 °C, the modulus no longer returns to its old, room-temperature value, but remains constant between room temperature and the annealing temperature, *i.e.* the material has become stable in one of its mechanical properties. We might also say that it has been "artificially aged" to a final state that depends on the annealing temperature. The modulus returns to its original value only when the polycarbonate is heated for a short time at about 15 °C above its glass transition temperature and then quenched to 20 °C.

This effect is also exhibited by other high polymers, such as noncrystalline polyethylene terephthalate and polymethyl methacrylate. Similar phenomena are observed when the density or the rate of swelling is determined (i) at room temperature, (ii) after annealing below the glass transition temperature, and finally (iii) after heating above the glass transition temperature [7].

Investigations with an electron-microscope gave some very surprising results [8]. Figure 2 shows the surface replica of a polycarbonate film that had been etched with fast argon ions [9] after having been annealed in accordance with the program indicated in the figure. After annealing at 110 °C, the grain structure is coarser [a], and this difference disappears again when

[9] For details see, *e.g. L. Reimer*: Elektronenmikroskopische Untersuchungs- und Präparationsmethoden, Springer, Berlin 1967.

[a] Grain structures have recently also been directly detected by *Geil* [10] in amorphous, extremely thin, quenched polyethylene terephthalate films by electron microscopy with a transmitted beam.

[10] *P. H. Geil* and *G. S. Y. Yeh*, Lecture Meeting Amer. physic. Soc., March 27–30, 1967, Chicago; Bull. Amer. physic. Soc., in press.

the material is subsequently annealed above the glass transition temperature ($\approx$ 150 °C). These phenomena are obviously due to a substantially reversible change in the morphological structure of an amorphous substance. When etched with ions, the amount of material removed from the surface depends on the density of the region, so that regional differences in density become recognizable. Thus annealing below the glass transition temperature evidently leads to a change in the packing density on the submicroscopic level.

A theoretical treatment of the modulus curves at various temperatures shows that the two stages correspond to two activated rate processes having somewhat different activation energies.

This means that the change in molecular order in the glassy state takes place in two stages, and can be reversed by heating for a short time above the glass transition temperature. Crystallization begins only at much higher temperatures, *i.e.* the phenomena in question do not involve precrystallization or nucleation. The effect is most readily explained by changes in the conformations of the chain molecules. Suppose that the temperature-dependent degree of coiling of the chain molecules in the melt or just above the glass transition temperature depends on an equilibrium between *trans* and *gauche* conformations [b] along the chain. If the polymer is cooled below the glass transition temperature, the ratio of these conformations present in the melt is "frozen in". This ratio can be brought closer to the equilibrium value by annealing. As is shown by the increase in density, this leads to better packing, an increase in the parallelism of the chains, and an increase in the order of the short-range order regions with respect to one another, *i.e.* to an increase in the grain size. The modulus increases, and the rate of swelling decreases [6, 7].

Geymeyer [11] and *Hendus* [12] recently found that a plasticized commercial PVC (suspension polymer Vinoflex 531) that is 55 % syndyotactic and random, *i.e.* practically atactic, contained lamellae of folded chain molecules such as have hitherto been found only in high polymers that crystallize well; *Hendus* also detected a low-angle X-ray scattering giving the same period. It has been further known for some time that spherulites, which are admittedly very poorly formed, occur in PVC [13, 14].

All the observations mentioned show that morphological structures, which can change with time and temperature, occur not only in crystallizable materials, where they have been known for a long time, but also in typically amorphous substances, such as quenched PET (polyethylene terephthalate) and PC (polycarbonate) or in atactic PMA (polymethyl methacrylate) and PVC below the glass transition temperatures. This explains certain aging phenomena that were previously incomprehensible, such as gradual exbrittlement without crystallization.

[b] An extended chain would contain only *trans* conformations.

III. External Factors Affecting Aging

1. Stress Crazing

a) Pure Stress Crazing

A well-known and feared phenomenon is the formation of cracks on the surfaces, *i.e.* crazing, of materials that are subjected to mechanical stress in the presence of a wetting agent. If chemical reactions with gases, vapors, or liquids play any part in the crack formation, the process is known as stress-crack corrosion. This case will not be considered here. The limiting case of "pure stress crazing", *i.e.* without the simultaneous influence of the environment hardly ever occurs in practice, since even small quantities of moisture or carbon dioxide in the air affect the process.

Nevertheless, we have studied this limiting case in some detail [15–17] in order to obtain a better insight into the processes involved in crazing. The crazing stress, the number of crazes, the rate of crack growth, and the induction time were measured under vacuum for amorphous 120 micron polyethylene terephthalate film (Hostaphan, produced by Messrs. Kalle). These quantities are defined as follows:

The crazing stress is the critical stress at which the first crazes become visible to the naked eye; it increases appreciably with the rate of stretching of the film. A certain induction time is therefore required for a weak spot or defect [c] to develop into a visible crack. The crazing stress, like the tensile strength, decreases rapidly with rising temperature. Furthermore, as the temperature is raised, the increasing mobility of the chains, and hence the decreasing relaxation time, in amorphous materials leads to disappearance of crack formation (*i.e.* the 'number of cracks', or number of visible cracks per cm^2, consequently tends toward zero) with increasing proximity to the glass transition temperature.

For any given stress and at a constant temperature, a plot of the crack number against time tends toward a limiting value, which increases rapidly with increasing stress. This is evidently because at a given stress, visible cracks can develop only from weak spots whose notch number [d] lies above a certain minimum value.

[15] *H. A. Stuart, D. Jeschke*, and *G. Markowski*, Materialprüfung *6*, 77 (1964).

[16] *G. Markowski, H. A. Stuart*, and *D. Jeschke*, Materialprüfung *6*, 236 (1964).

[17] *H. A. Stuart, G. Markowski*, and *D. Jeschke*, Kunststoffe *54*, 618 (1964).

[c] The defect may even be a submicroscopic crack. Any inhomogeneity can lead to a crack or to rupture.

[d] The notch number is the ratio of the maximum stress occurring at a defect, *i.e.* the "notch stress", to the macroscopic stress. The notch number was originally defined and calculated for a crack oriented at right angles to the tensile stress.

Another important observation is that the length of the cracks on the surface always tends toward a limiting value; thus the growth of the cracks is accompanied by a reinforcing mechanism, which is evidently due to substantially reversible orientation of the molecular chains. Thus three stages can be distinguished in the crazing process: (a) conversion of the defect into a visible crack, (b) the growth phase, and (c) the reinforcement or termination phase.

As can be seen from Figure 3, the rate of crack growth $\Delta l/\Delta t$ and the ultimate crack length decrease as the induction time increases. This has also been observed by other authors [18], and is evidently related to the structure of the original defect; the greater the notch number of the defect, the shorter is the induction time, and the greater is the rate of growth and the ultimate crack length.

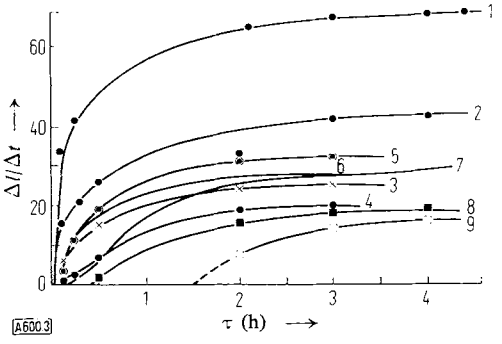

Fig. 3. Induction times τ and rates of crack growth $\Delta l/\Delta t$ for individual cracks in polyethylene terephthalate in air under constant stress. The figures 1 to 9 on the curves denote measurements on different cracks.

It is important to note that the cracks formed in vacuum or in an inert medium are largely reversible [18–20]. If an unstressed Hostaphan film covered with surface cracks is heated to 10 to 15 °C above its glass transition temperature, the cracks (provided that they are not longer than 10 μ) can no longer be recognized under the optical microscope after only a few minutes. However, this does not mean that they have completely disappeared, but only that they have become submicroscopic, since they again become visible on application of a tensile load. Moreover, the "cracks" observed on polycarbonate films in the presence of air are not true cracks, but are partly filled with oriented polymeric material [21]. As a result of the flow processes, the walls of the cracks are evidently joined by stretched fibrous material. This also explains the reversibility of crack formation.

b) Environmental Stress Crazing

If one disregards chemical reactions, crack formation depends mainly on three properties of a medium (apart from temperature, time, and the distribution of the stresses in the surface) *i.e.* the wetting, the rate of diffusion or of swelling, and the maximum degree of swelling, *i.e.* the equilibrium degree of swelling. Crazing can be caused only by wetting and moderately swelling liquids and by vapors that penetrate into the material. Comparison of such results with those obtained in vacuo shows several differences, even in the case of media that do not induce crystallization (*e.g.* methanol):

1. The crazing stress decreases; 2. the number of crazes is generally decreased by one to three orders of magnitude; 3. the rate of crack growth increases considerably. The cracks generally spread out over the entire surface and are much wider and deeper. Thus there is no self-limitation of crack growth. Crack formation under the action of a wetting and swelling medium involves both irreversible and reversible processes. This can be seen from the fact that when the material is heated above the glass transition temperature, the cracks disappear to a large extent, but never completely.

Considerable assistance in the explanation of crazing can be obtained *e.g.* from the curve of the crazing stress of stretched Hostaphan film at constant strain velocity as a function of the time of action of liquid methanol and methanol vapor (see Fig. 4).

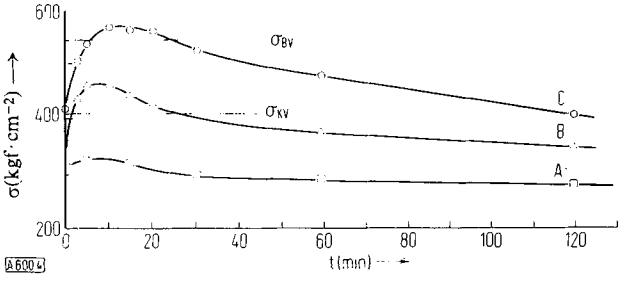

Fig. 4. Crazing stress as a function of the time of action in the presence of liquid methanol (curve A) and of methanol vapor (curve B: 150 mm Hg; curve C: 50 mm Hg) [16].

At very short times of action, the crazing stress is considerably lower than the value found in vacuum (σ_{KV}) (adverse effect of methanol). After a longer period of action, however, the properties appear to improve; for example, at a CH_3OH vapor pressure of 50 mm Hg (curve C), the crazing stress even rises above the value found for the tensile strength under vacuum (σ_{BV}). When the time of action is still further increased, however, the improvement is reversed by the progressive swelling of the material, and the crazing stress and the tensile strength decrease. The number of cracks after short times of action is also characteristically lower by a factor of 100 than in dry air [e]. In the course of time, *i.e.* with increasing swelling, the crack number again increases, but always remains much lower than in vacuum or in dry air.

[e] The decrease in the number of cracks under the influence of a wetting and swelling medium may seem surprising at first, but can be explained as follows: The higher the rate of crack growth and the wider the cracks become, the more rapidly will the stresses in the surface be relaxed in comparison with pure stress crazing. This is particularly pronounced when cracks have already formed over the entire width of the film. In this case the external stress in the crack profile decreases from the bottom of the crack toward zero at the surface of the film. Consequently, since cracks always originate at the surface of the film, new cracks, can no longer be formed. One could also say that the surface areas between cracks are no longer affected by external stresses ("islands" on a stressed surface).

[18] *O. K. Spurr jr.* and *W. D. Niegisch*, J. appl. Polymer Sci. *6*, 585 (1962).
[19] *S. B. Newmann* and *J. Wollock*, J. Res. nat. Bur. Standards *58*, 339 (1957).

[21] *R. P. Kambour*, Polymer *5*, 143 (1964); Nature (London) *195*, 1299 (1962).

Thus when a wetting medium is allowed to act on a polymer surface subjected to external or internal stress, at least three effects come into play. Though these effects frequently cannot be distinguished experimentally, except by detailed measurements, we shall distinguish them in the following discussion as the instantaneous effect (effect I), the healing effect (effect II), and the swelling effect (effect III).

c) Models of Surface Crack Formation

α) Instantaneous Increase in the Notch Stress at a Defect (Instantaneous Effect or Effect I)

The fact that the energy required to extend a crack is lowered by a wetting medium can be formally expressed by an additional stress that leads to an increase in the notch stress. This additional stress will be referred to as the wetting medium stress [f].

The rapidly arising differences in the concentration of swelling agent in the immediate vicinity of the base of a crack and the resulting difference in the degree of swelling can also lead immediately to additional internal stresses, which have not so far been directly measured, and which we shall call "swelling stresses". The more slowly the surface layer swells, the smaller are the swelling stresses. However, if these stresses are very high, the application of an external load can lead to immediate rupture, or at least to intensified surface crack formation, which can be caused even by internal stresses. If the penetrating swelling agent also induces crystallization of the polymer, crack formation will be further promoted by the shrinkage stresses. If the wetting medium is allowed to act for a long time, the instantaneous increase in the notch stress [d] is accompanied by that of effect III (see Section III.1.c.γ). However, the surface crack formation or the rupture usually takes place so rapidly that no swelling of the surface layer has taken place even at a depth of only a few microns.

Since the instantaneous effect arises only in the presence of very small, possibly even invisible cracks, and better still from defects, the material can obviously be made more resistant to crack formation by healing of surface cracks and defects (*e.g.* by heating, polishing, or irradiation).

β) Diffusion within the Region of a Defect with Stress Relaxation in Submicroscopic Regions (Healing Effect or Effect II)

If the wetting agent eventually penetrates into deeper zones of a weak spot, plasticization takes place in submicroscopic regions. Under the influence of internal or external stresses, this leads to "microflow", and hence to relaxation of the stresses in the vicinity of the defect, *i.e.* to lowering of the notch number or to healing of the weak spot. However, this is true only if the external stress and the wetting-medium stress are not too high, since the weak spot otherwise develops into cracks, which then grow further.

If the material contains amorphous but stressed regions as well as crystalline regions, the diffusion of the swelling agents will proceed preferentially in the non-crystalline zones, and will again lead to the dissipation of internal stresses.

It is clear that these healing effects, which take time, occur only in certain stress ranges and only with some swelling agents. Effect II cannot occur with swelling agents that penetrate very strongly and very rapidly.

γ) Diffusion into the Interior (Swelling Effect or Effect III)

If the molecules of the swelling agent eventually penetrate into the interior of the polymer between the long chain molecules, macroscopic softening takes place, and the material becomes more plastic. At the same time, the kinetic inhibition in the widening of cracks and the activation energies decrease. This favorable influence on the crack formation and crack widening is eliminated only when the temperature is raised sufficiently far above the glass transition temperature, *i.e.* when all stresses relax sufficiently rapidly.

Effects I, II, and III are certainly not sufficient to explain the stress-crazing complex, and the effects cannot always be separated from one another. Thus according to *Charles* and *Hillig* [22], the development of a notch into a crack also depends on whether the action of the wetting medium makes the notch base sharper or rounder (*e.g.* on slow swelling, or on microflow under stress (effect II)) [g]; if it becomes rounder, the notch number decreases.

It can be seen, therefore, that no definite relationship can be expected between the parameters of crack formation and a single physical constant of a swelling agent. Attempted further quantitative studies have so far been unsuccessful [17].

2) Attempts to Improve Crazing Properties

a) Temporary Swelling Under Stress

If a Hostaphan film is wetted for about 5 min with liquid methanol and then evacuated for 24 hours at 50 °C, the crazing stress and the crack number return to the values found before wetting. Thus the number and distribution of defects in the surface have not changed. When partial swelling is carried out under an external stress, the crack number decreases [17] by about two orders of magnitude, so that there is a

[f] The term "wetting stress" has already been reserved in the literature for another purpose.

[22] *R. J. Charles* and *W. B. Hillig*, Symposium sur la résistance mecanique du verre, Florence 1961. Union Scientific Continental du Verre, Charleroi 1962, p. 511.

[g] If the glass transition temperature of a mechanically stressed and swollen surface is below the experimental temperature, surface and interfacial tensions will cause smoothing of the surface. Rounding-off is probably important in the etching or dissolving-away of the surface of rock salt by water. Under water, the strength of the rock salt almost reaches its theoretical value, *i.e.* 500 times its normal value (Joffé effect) [23].

[23] *A. Joffé*, Trans. Faraday Soc. *24*, 65 (1928).

considerable permanent improvement in the quality of the material. Thus where the surfaces have internal stresses, as in the case of injection-molded articles, the quality can be improved simply by swelling for a short time followed by drying.

It is known that the quality can also be improved by heating slightly above the glass transition temperature; however, internal stresses are evidently again necessary. The quality of films that are substantially free from stresses can be improved by heating only if an external stress is also applied. Annealing in the presence of a weak swelling agent (*e.g.* in the form of a vapor), either with or without external stresses, should lead both to the relaxation of internal stresses in the surface and to the elimination of defects.

b) Wetting with Long-Chain Molecules

When polymer films are wetted with long-chain silicones, the crazing stress becomes higher than for the free film in air. The crack number decreases by three orders of magnitude or more (see Table 1). This

Table 1. Improvement of crazing quality by wetting with long polymethylsiloxane chains.

Wetting medium	Tensile strength (kgf cm^{-2})	Crazing stress (kgf cm^{-2})	Crack number N_R [*]
Air	630—650	490—510	$\approx 10^3$
Octamethyltrisiloxane	560—580	360—380	15—20
Silicone oil 50 cSt	580—600	520—540	0.2—1
Silicone oil 240 cSt	600—620	570—590	0.2—0.6
Silicone oil 100000 cSt	640—660	570—590	0.2—0.6

[*] Number of cracks per cm^2.

effect, which is strongly dependent on the molecular weight of the silicone, cannot be explained by diffusion within the region of a defect or by microflow, but is probably due to the fact that the strongly wetting and very mobile silicone chains cover the film surface with a molecular layer and probably also fill out holes or submicroscopic cracks, and so "bridge" the weak spots. This hypothesis is supported by the observation that the rate of crack growth remains the same as that in air, *i.e.* the spreading of cracks is not facilitated by penetrating molecules of the wetting liquid. This *coating* effect disappears only when a more strongly wetting or swelling liquid such as methanol is applied after the silicone.

IV. Morphological Structure, Diffusion, Swelling, and Crack Formation

1. Morphological Structure and Crack Formation

It has been known for some time that for a given degree of crystallinity, a polymer containing spherulites is more brittle than a finely crystalline polymer [24].

[24] *E.g. H. A. Stuart* in: Physik der Hochpolymeren. Springer Verlag, Berlin 1956, Vol. IV, p. 626.

Fracture along the radial fibers of the spherulites and the decrease in dielectric strength as compared with a material containing no spherulites indicate that molecular or capillary cracks must exist between the spherulites. Figure 5 shows [17] the free surface of a 1 mm isotactic polypropylene film; the melt was heated to 220 °C and kept at 120 °C for 3 hours to allow crystallization, and the material was then cooled. Shrinkage during crystallization led to distinct cracks along the radii and along the boundaries of the spherulites [25]. These cracks became larger on cooling, so that the shrinkage due to crystallization could be distinguished from the shrinkage due to cooling.

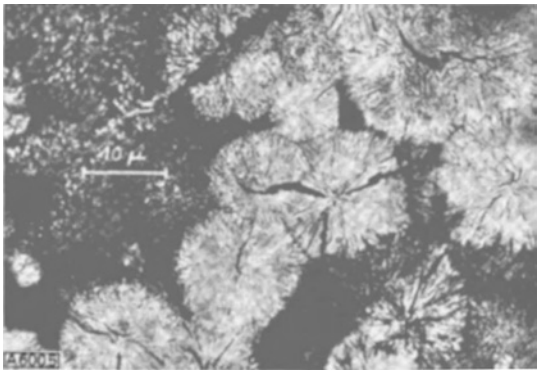

Fig. 5. Crack formation caused by crystallization of isotactic polypropylene.

Figure 6 shows the crack formation caused by the annealing of a polypropylene film that has been kept at 130 °C for more than 60 hours [26]. According to *Inoue* [26], the large cracks between the spherulites are due to oxidative degradation in the regions of low order between the spherulites (cf. also *Kavafian*'s experiments below). However, since the author himself found an increase in density, *i.e.* an increase in crystallinity within the spherulites, shrinkage must also have made an important contribution.

Fig. 6. Crack formation caused by annealing a polypropylene film for 60 hours at 130 °C [26].

On the basis of such observations, it might be concluded that materials containing spherulites are generally poorer in quality. However, the situation is

[25] *S. Van Schooten*, J. appl. Polymer Sci. *9*, 122 (1960).
[26] *M. Inoue*, J. Polymer Sci. *55*, 443 (1961).

not quite so simple as this, since according to *Reding* and *Walter*[27] the order within the spherulites is very important. Thus it is found that both branched and very high molecular weight polyethylenes are very resistant to stress cracking. Both branched and very long chains evidently prevent the attainment of a high degree of order inside the spherulites. Electron micrographs show that the spherulites in a high molecular weight polyethylene are still in a poorly ordered state after annealing. Ethylene-propylene block copolymers are also extremely resistant to crack formation, even after prolonged annealing[27]. The formation of large and well ordered spherulites is prevented in this case by the "elastomeric" chain segments, which are not incorporated into lattice zones. Thus to avoid crack formation, it is necessary to avoid a high degree of order within the spherulites and the formation of large spherulites.

2. Morphological Structure, Swelling, and Chemical Reactivity

Since the supramolecular order strongly influences diffusion and swelling processes, it is possible to develop details of the morphological structure and very fine, possibly even invisible cracks, *i.e.* to magnify them and make them visible, by means of a swelling agent. Figure 7 shows a highly ordered spherulite in a polyethylene sebacate film in transmitted polarized light. Its ring structure is due to bundles of single-crystalline lamellae which are twisted regularly along the radius. After treatment with xylene for a short time at room temperature, examination in transmitted unpolarized light reveals deep cracks, from which the period of the spherulite rings can still be recognized. Small cracks, which are shorter than the ring period and which are themselves arranged in rings, have also been formed (see Fig. 8).

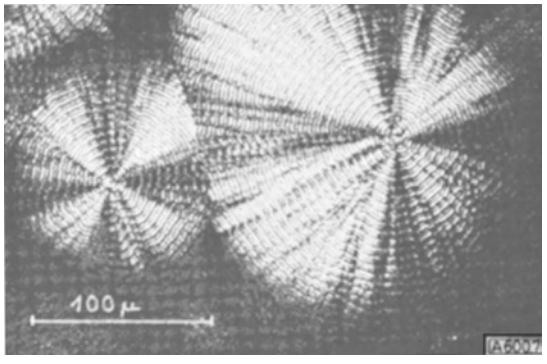

Fig. 7. Polyethylene sebacate spherulite with ring structure, photographed in transmitted polarized light [17].

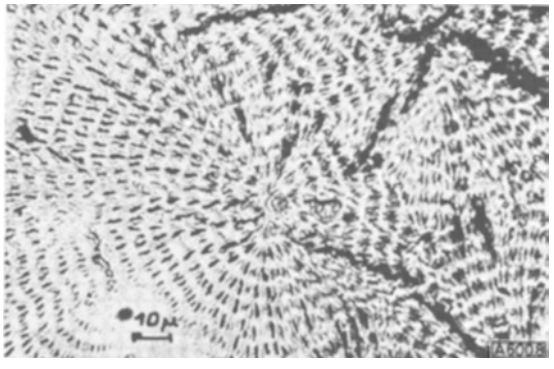

Fig. 8. The spherulite shown in Figure 7 after treatment with xylene [17].

Any orientation of the chains leads to reduced transverse strength, and hence to a greater tendency toward crack formation, *i.e.* toward preferential diffusion and swelling between the parallel, extended molecular chains or bundles of molecular chains. This is very clearly recognizable in a stretched film of amorphous polycarbonate from bisphenol A; the swelling agent, was eugenol, which dissolves the amorphous polycarbonate to a small extent, but at the same time induces spherulitic crystallization.

The stretched films were stuck to a cover glass with an epoxy resin and the projecting portions were cut off. The film was then exposed to the eugenol from the edge, and crack formation was followed under the microscope. Crack formation took place only from the edges perpendicular to the stretching direction, the cracks running parallel to the stretching direction. If the film is stuck on obliquely, the cracks also run obliquely into the interior, again exactly parallel to the stretching direction.

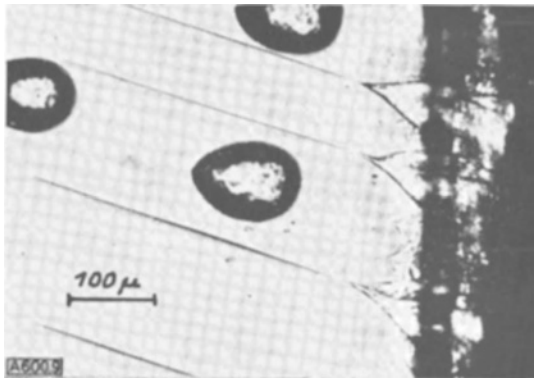

Fig. 9. Crack formation in a stretched amorphous polycarbonate film wetted with eugenol [17]. An irregular turbidity due to spherulitic crystallization and to the crystallization of the polycarbonate that first went into solution is seen at the edges of the film and in the eugenol itself.

The effects of chemical processes on aging vary in intensity according to the morphological structure. Thus *Kavafian*[28] has shown that tough specimens of polyethylene become completely embrittled on annealing in air at 100 °C for only 48 hours. New specimens prepared by melting and recrystallization of these brittle samples had practically the same properties as the original material, in agreement with the fact that viscometric and spectroscopic measurements show that only very slight chemical degradation of the chains has taken place. *Kavafian* considers that the attack by oxygen takes place mainly in the looser packed regions between the spherulites. Transport processes of every type, particularly diffusion, are greatly facilitated in these regions. Thus chemical reactions such as oxidation, which are practically

[27] *F. P. Reding* and *E. R. Walter*, J. Polymer Sci. *38*, 141 (1951).

[28] *G. Kavafian*, J. Polymer Sci. *24*, 499 (1957).

impossible in a perfect crystal zone, can take place in interposed amorphous regions and on internal surfaces. The temperature-dependence of the rate of a chemical reaction in high molecular weight solids will therefore depend partly on changes in molecular order and on internal crack formation with temperature and time. Consequently the temperature-dependence of the overall reaction rate can become considerably greater than in solution.

In many cases, it is impossible to make quantitative predictions, simply because of the unknown crack formation and the possibility of additional diffusion. This should always be borne in mind when information gained for artificially accelerated aging is applied to aging processes in practice.

Potential and Charge Distribution at Semiconductor-electrolyte Interfaces

BY R. MEMMING AND G. SCHWANDT [*]

The present article deals with the basic concepts of charge and potential distribution at semiconductor-electrolyte interfaces. The authors use examples to show how external polarization and the variation of the electrolyte composition can change the potential drop across the space-charge region in the semiconductor and in the Helmholtz double layer at the interface. The article also contains a detailed discussion of the effects exerted by surface properties and by injection of carries on the distribution of charge and potential.

Introduction

Problems connected with semiconductor-electrolyte interfaces were approached originally from two different branches, from electrochemistry and solid state physics. Semiconductor electrodes found electrochemical applications a long time ago, *e.g.* in semiconducting oxide electrodes in batteries. However, the electrical properties of semiconductor electrodes were then virtually unknown, and therefore systematic studies of the electrode processes were not possible. Only the preparation of high-purity single crystals of semiconductors gave a new impetus to research in this field. The basic electrochemical processes have been described by *Gerischer* [1] in a review article.

Surface effects are of great importance in solid state physics, because they exert a great influence on the electrical properties of many semiconductor devices. The properties of clean surfaces produced by cleaving single crystals in high vacuum have been investigated, and the electrical properties of the surfaces could be altered by the adsorption of gases or the formation of surface films. Furthermore, certain conditions can be created on the surface of the semiconductors by bringing these into contact with electrolytes. *Harten* [4] has lately discussed in a review article the electrical properties of such "wet" surfaces, particularly from the viewpoint of semiconductor physics, and has compared the distribution of charge and potential at the semiconductor-electrolyte interface with the corresponding distribution in a semiconductor-vacuum system.

The present article is devoted to a discussion of the charge and potential distribution mainly from the electrochemical viewpoint, and particularly to the description of the typical properties of semiconductor electrodes as distinct from the properties of metal electrodes. The three parts of this article deal respectively with the basic theoretical concepts of the distribution of charge and potential, the principal methods of measurement, and experimental results. Reactions at semiconductor electrodes will be discussed only in so far as they play a part in the distribution of charge and potential.

1. Theory

1.1. General Considerations

A double layer is formed at the semiconductor-electrolyte interface in the same way as at the metal-electrolyte interface. A double layer consists of opposite charges in the two phases and aligned dipoles at the interface. This results in a potential difference (Galvani potential) between the two phases whose interiors contain no charge. The corresponding charges

[1] *H. Gerischer* in *P. Delahay*: Advances in Electrochemistry and Electrochemical Engineering. Vol. I, Interscience, New York 1961.

are electrons on the metal or the semiconductor surface and ions in the electrolyte. The distance between these two charges is mainly determined by the radius of the solvation shell of the ions. Therefore, the double layer, which is also known as the Helmholtz layer, can be considered as a charged capacitor. On the assumption that the charges are uniformly distributed over the surface, the capacitance of this condenser should be constant; however, this picture can only be applied in the case of concentrated electrolyte solutions, otherwise the capacity varies with the electrolyte concentration. *Gouy*[2] and *Chapman*[3] have improved this model by regarding the charge of the condenser on the side of the electrolyte not as a continuous surface charge, but as a space charge (Gouy-Chapman layer) for which the well-known Poisson equation holds.

1.2. Space-charge Region in Semiconductors

Metal electrodes and semiconductor electrodes do not differ in the Helmholtz double layer and the Gouy-Chapman layer; the main difference between them is that the concentration of mobile charge carriers is much lower in semiconductors than in metals. As in dilute electrolytes, the charges in semiconductors are not confined to the surface, but extend over a certain region below the surface, and thus form a space charge. The relationship between the space charge density $\rho(x)$ and the potential at the surface φ is given by the Poisson equation:

$$\Delta\varphi = (d^2\varphi)/(dx^2) = -(\rho(x))/(\varepsilon\varepsilon_0) \qquad (1)$$

where Δ is the Laplace operator, ε is the dielectric constant, ε_0 is the influence constant, and x is a distance normal to the surface.

The space charge density ρ is given by the total number of mobile and non-mobile charges, *i.e.* electrons $n(x)$ and holes $p(x)$ on the one hand, and ionized donors n_D and acceptors n_A on the other. The following formula, where e is the unit charge, holds in the case of semiconductors with homogeneous doping:

$$\rho(x) = e(n_D - n_A - n(x) + p(x)) \qquad (2a)$$

The charge is zero in the inside of the bulk (*i.e.* $\rho = 0$), and the number of electrons and holes is given by the doping of the crystal: $n(x) = n_o$ and $p(x) = p_o$. In this case, we have

$$\rho(x) = 0 = e(n_D - n_A - n_o + p_o) \qquad (2b)$$

The concentration of electrons in the conduction band and of the holes in the valence band can be calculated using the energy gap model of semiconductors. Non-degenerate semiconductors – the only type to be discussed – are characterized by a Boltzmann distribution of the electrons and the holes. The following formula shows how the electron concentration in the conduction band depends on the Fermi potential E_F:

$$n = N_c \exp[-(E_e - E_F)/(kT)] \quad (E_c \gg E_F) \qquad (3a)$$

(N_c is the density of states in the conduction band, E_c is the lowest energy level in the conduction band, k is the Boltzmann constant, and T is the temperature).

The closer the Fermi level to the conduction band, the greater the number of electrons in the latter. An analogous formula applies to the concentration of holes:

$$p = N_v \exp[-(E_F - E_v)/(kT)] \qquad (3b)$$

(N_v is the density of states in the valence band and E_v is the highest energy level in this band).

Thermodynamic equilibrium between electrons and holes prevails inside the semiconductor, *i.e.*

$$n_o \cdot p_o = n_i^2$$

(where n_i is the intrinsic number of electrons).

The distribution of the potentials in the space-charge region below the surface can in principle be calculated from eqs. (1)–(3). The set of equations does not admit a closed solution, and a qualitative picture of the potential distribution in the space-charge region is obtained as described below.

In the equilibrium state, the Fermi level is the same inside the semiconductor and on its surface (Fig. 1). If the electron concentration on the surface and in the space-charge region is lower than in the interior, then the distance between the Fermi level and the bottom of the conduction band is greater. This leads to upward bending of the energy bands (Fig. 1).

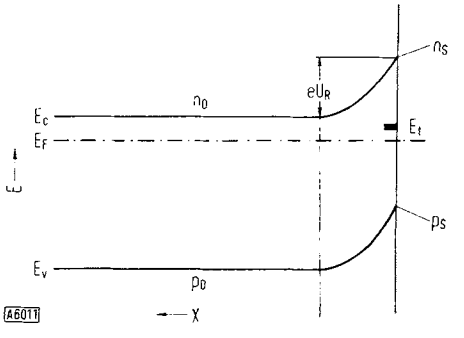

Fig. 1. Energy gap model of the semiconductor's surface.
E_c - bottom of the conduction band; E_v - top of the valence band; E_F - Fermi level; n_o and p_o - density of electrons and holes in the bulk; n_s and p_s - density of electrons and holes at the surface of the semiconductor; U_R - band bending at the surface; E_t - surface state: E - energy of electrons; x - vertical distance from the surface.

The use of eq. (3a) gives the following relationship between the electron density at the surface n_s and in the bulk n_o:

$$n_s = n_o \exp(-eU_R)/(kT) \qquad (4a)$$

where U_R is the band bending at the surface. An analogous relationship holds for the hole concentrations:

$$p_s = p_o \exp(eU_R)/(kT) \qquad (4b)$$

[2] *G. Gouy*, J. Physique [4], 9, 457 (1910).
[3] *D. L. Chapman*, Philos. Mag. Ser. 6. 25, 475 (1913).

Thermodynamic equilibrium normally prevails also in the space charge region, *i.e.*

$$n_s p_s = n_o p_o = n_i^2 \tag{5}$$

The upward bending of bands in an n-type semiconductor leads to an exhaustion layer ($n_s < n_o$) or an inversion layer ($p_s > n_s$), whereas if $n_s > n_o$, then the energy bands are bent downwards and an accumulation layer is formed.

1.3. Surface States

The charges on the semiconductor side of the interface need not all be distributed in the space-charge region; they may also be trapped in surface states. These are energy states E_t lying at the surface within the forbidden zone of the energy gap model (see Fig. 1). The surface states may arise *e.g.* by the interruption of the periodic structure of the lattice at the surface, or from the adsorption of impurity atoms or ions. The position of these states with respect to the Fermi level E_F will decide whether or not they will be occupied by electrons: if they are above E_F, they will not be occupied by electrons (though they may be occupied by holes), if they are below the Fermi level, on the other hand, then the surface states will be filled with electrons. By changing the band bending, *e.g.* by applying an external voltage, one can shift the surface states across the Fermi level, and thus change their charge.

1.4. Distribution of Potential

The charge distribution at the semiconductor-electrolyte interface shows a certain symmetry in that there are two opposite surface charges at an atomic distance (Helmholtz double layer), followed by the space-charge regions, beyond which extend the neutral bulks of the two phases. The corresponding charge and potential distributions are shown in Fig. 2.

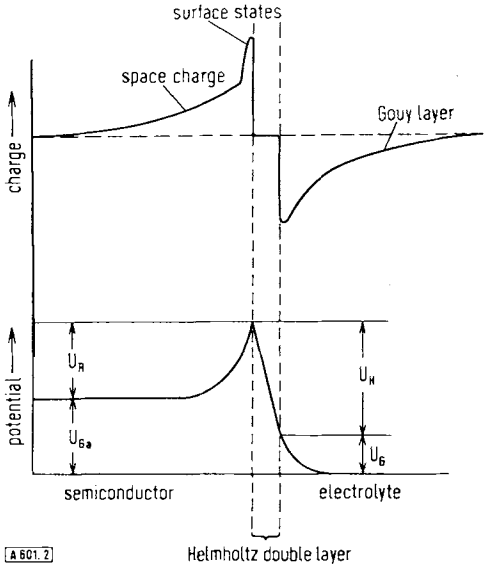

Fig. 2. Distribution of charge and potential around the interface between a semiconductor and an electrolyte.
U_R - potential drop across the space charge (band bending);
U_{Ga} - Galvani potential; U_H - potential drop across the Helmholtz double layer; U_G - potential drop across the Gouy layer.

The charge in the surface states is taken to be positive here. Since the density of these states is generally low and they are located only at the surface no remarkable potential drop occurs across the first atomic layers of the semiconductor. The Galvani potential U_{Ga} between the two phases is thus composed of three terms, namely the potential drop U_R across the space charge region in the semiconductor, the potential drop U_G across the Gouy layer, and the potential drop U_H across the Helmholtz double layer, *i.e.*

$$U_{Ga} = U_R + U_G + U_H \tag{6}$$

As with metal-electrolyte interfaces, the Galvani potential itself is not measurable. It can be determined except for an additive constant, when the electrode potential U_E is measured against a standard electrode such as the calomel electrode. Therefore, changes in the Galvani potential can be reliably determined. It holds that

$$\Delta U_E = \Delta U_{Ga} = \Delta U_R + \Delta U_G + \Delta U_H \tag{7}$$

or

$$U_E = U_R + U_G + U_H + \text{const.}$$

The constant contains the sum of all the Galvani potentials at all other phase boundaries of the electric circuit, and thus U_E is identical with the EMF of the galvanic cell.

It should be mentioned that the potential distribution shown in Fig. 2 is not quite satisfactory. Solids (metals or semiconductors) and electrolytes are treated as continua in the space-charge region. The potential is thus a "macro-potential" composed of the "micro-potentials" of the individual atoms. In the atomic dimensions of the Helmholtz double layer, a corresponding averaging is no longer permissible. The various definitions of potential have been discussed by *Harten*[4] and will not be dealt with here. In any case, they play no part in the measurement of the changes in the Galvani potential in a given system, since only potentials of the same definition are being compared. We shall deal in the following only with measurements of this type.

2. Methods of Measurement

Whereas only changes in the potential drop U_H can be measured in the Helmholtz layer, the potential drop U_R across the space-charge layer in the semiconductor can be determined as an absolute value. This can be done by measuring either the surface conductivity or the capacitance. The theoretical relationship between these and the band bending U_R can be derived as follows: The number of excess electrons ΔN and holes ΔP in the whole space charge region are defined respectively by

[4] *H. U. Harten* in: Festkörperprobleme III. Vieweg, Braunschweig 1964.

$$\Delta N = \int_0^l [n(x)-n_0]\,dx \text{ and } \Delta P = \int_0^l [p(x)-p_0]dx \qquad (8)$$

(where l is the thickness of the space-charge region).

The variations in the concentrations of electrons and holes in the space-charge region of an intrinsic semiconductor are shown in Fig. 3a. The hatched areas correspond to the excess or the missing charge carriers ΔN and ΔP. The attending potential-dependence

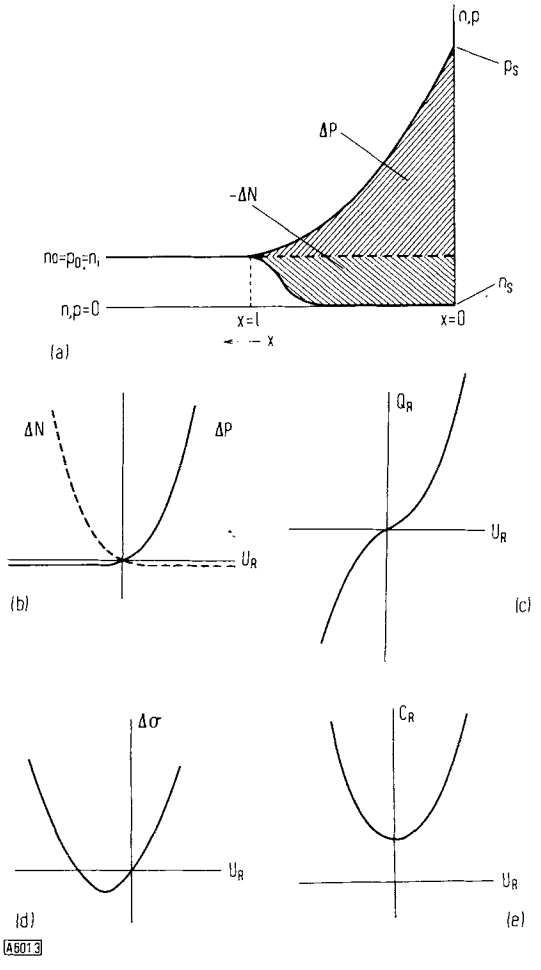

Fig. 3. a) Variation in the concentration of charges (n,p) in a p-conducting space-charge layer ($U_R > 0$) — Schematic representation; the hatched areas denote the excess charges. — b) Excess charge densities ΔN and ΔP as a function of the band bending U_R. — c) Surface density of the space charge Q_R as a function of the potential drop across the space region U_R. — d) Surface conductivity $\Delta\sigma$ as a function of the band bending U_R. — e) Space-charge capacity C_R as a function of the band bending U_R.

is illustrated in Fig. 3b. If the bands are flat ($U_R = 0$) up to the surface in an intrinsic semiconductor ($n_0 = p_0 = n_i$), then by definition $\Delta N = \Delta P = 0$. In the case of a p-conducting surface (upward band bending, $U_R > 0$), p_s increases exponentially with U_R according to eq. (4b) and ΔP also rises rapidly in a corresponding manner. On the other hand, ΔN becomes negative, though it cannot reach high values, since n_s tends to zero. These roles of ΔN and ΔP are reversed on n-conducting surfaces. The surface charge density Q_R in the space-charge region is given by

$$Q_R = e(\Delta P - \Delta N) \qquad (9)$$

(see Fig. 3c).

The change in the carrier concentration in the space-charge region alters also the conductivity parallel to the surface. The surface conductivity $\Delta\sigma$ is defined by

$$\Delta\sigma = e\,(\mu_n\,\Delta N + \mu_p \Delta P) \qquad (10)$$

(where μ is the mobility of electrons or holes).

The surface conductivity $\Delta\sigma$ is related to the measurable conductance ΔG of the space-charge region *via* a geometric factor. The dependence of the surface conductivity on the potential follows directly from Fig. 3b and eq. (10), and is illustrated in Fig. 3d. The minimum of the curve is not necessarily at $U_R = 0$, since electrons and holes usually differ in their mobility [5–7]. The accurate values of the excess charges ΔN and ΔP can be determined from the Poisson equation.

A similar connection may be found between the space charge capacity and the band bending U_R. This capacity is made up of two components, namely the Helmholtz capacity C_H and the space-charge capacity C_R. A differential capacity can be defined for the space-charge layer in exactly the same way as for the Helmholtz double layer. The opposite charge to the space charge is located in the electrolyte. The space-charge capacity is defined as follows:

$$C_R = \mathrm{d}\,Q_R/\mathrm{d}U_R \qquad (11a)$$

The charge per unit surface area (Q_R) of the space-charge layer is given by eq. 9, and is shown in Fig. 3c as a function of the band bending U_R. The slope of this s-shaped curve corresponds to the capacity C_R. When there is no space-charge layer (*i.e.* $U_R = 0$), the charge curve shows a turning point and the capacity C_R goes through a minimum (Fig. 3e). According to *Bohnenkamp* and *Engell* [8], the quantitative relationship between C_R and U_R for an intrinsic semiconductor ($n_o = p_o$) is as follows:

$$C_R = C_{min} \exp\,(e\,U_R)/(2\,kT) \qquad (11b)$$

Similar equations may be derived for doped (n- or p-type) semiconductors. This results in a small change in the shape of the curve for the U_R-dependence of the surface conductivity and the capacity.

As mentioned above, the potential-dependence of the surface conductivity can be directly determined from conductivity measurements [9]. The measurement of the space-charge capacity C_R is more difficult, since the equivalent circuit diagram contains some other RC terms as well. In the equivalent circuit diagram (see Fig. 4), the space-charge capacity is in series with the Helmholtz capacity C_H (the latter is generally much greater than C_R [*]) and with a series

[*] The space charge in the Gouy layer is neglected in the equivalent circuit diagram as well as in the investigations. This layer is suppressed in practice by increasing the concentration of electrolyte by the addition of a conducting salt.

resistance which basically represents the bulk resistance of the system. Parallel to this, there is a complex resistance Z_P, basically corresponding to the Faraday impedance. The equivalent circuit diagram should therefore be analysed in every case. This diagram generally reduces at high frequencies to one containing only C_R and R_S.

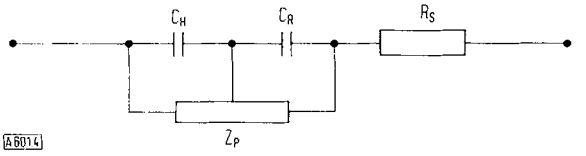

Fig. 4. Equivalent circuit diagram for the semiconductor-electrolyte interface.

The simplest of the many established methods uses an a-c bridge. However, this is not really suitable, because the potential-dependence of the space-charge capacity C_R must be measured within a few seconds so as to avoid any possible changes of the surface coverage. One uses therefore pulse techniques [10], or records the phase angle with an oscilloscope [11, 12]. A difficulty is introduced by the fact that the a-c voltage used must have a small amplitude ($\ll kT/e$), since the capacity itself depends on the voltage. The individual methods will not be described here in detail.

Applying an a-c field, the charge in the space-charge region is altered at a certain frequency. Since charges Q_o are also located in surface states, these too can be influenced by the a-c field, and can contribute to the total capacity.

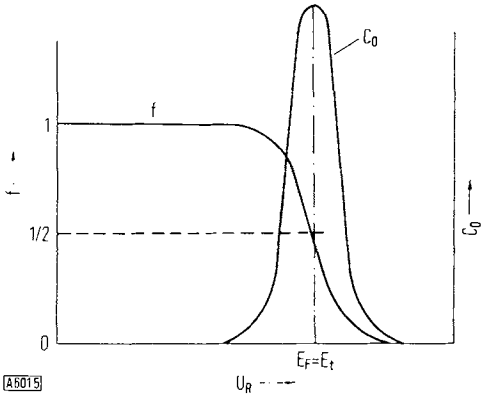

Fig. 5. Fermi function f and the capacity of the centers C_o (in arbitrary units) as a function of the band bending U_R.

As with space-charge capacity, we define a pseudo-capacity for the surface states:

$$C_o = (\mathrm{d}\, Q_o)/(\mathrm{d}\, U_R) \qquad (12)$$

The charge per unit area Q_o in the surface states is determined by the density of states N_t and their probability f of being filled by an electron:

$$Q_o = e\, N_t f \qquad (13)$$

Differentiation with respect to U_R gives the capacity C_o of the surfaces states, while f is given by the Fermi function whose dependence on U_R is shown qualitatively in Fig. 5. At a certain value of the band bending U_R, the energy of the surface state E_t coincides with the Fermi level E_F. The Fermi function has a turning point at this value, as shown in Fig. 5. It is here that the change ΔQ_o produced in the charge by a small a-c voltage is the greatest, and thus the capacity C_o reaches its maximum. Since the change in the charge of the surface states and the space charge region is of the same sign when the band bending is varied, the pseudo-capacity C_o in the equivalent circuit diagram is parallel to the space-charge capacity C_R. In the presence of surface states, therefore, an additional capacity must appear in the measurement of the space-charge capacity C_R.

3. Experimental Results

3.1. Space Charge and Surface States

Bohnenkamp and *Engell* [8] were the first to observe a minimum in the capacitance of a germanium electrode, and it was some years later that quantitative results were published about the potential distribution at germanium-electrolyte phase boundaries [13, 10]. Some data obtained by capacity and surface conductivity measurements are shown in Figs. 6a and 6b.

The experimental points are plotted against the electrode potential U_E (lower scale), and the theoretical curve features as a function of the band bending U_R (upper scale). The difference between the two potentials, which cannot be obtained by any theory, was determined by displacing the scales with respect to each other. The theoretical values are in addition multiplied by a factor of 1.3 corresponding to a linear

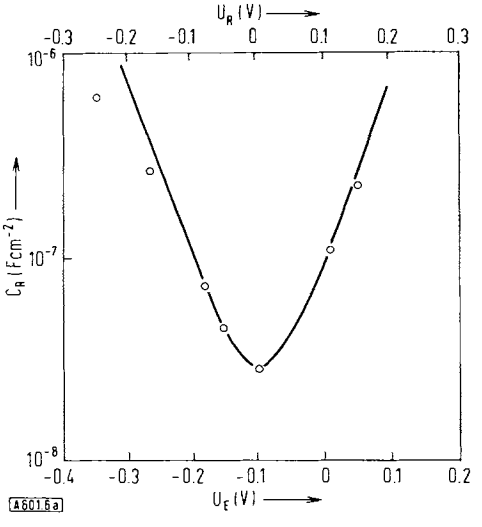

Fig. 6a. Space-charge capacity C_R as a function of the electrode potential U_E of a p-type germanium electrode (49 ohm. cm), as measured against a saturated calomel electrode. Solid line: theoretical capacity values calculated with the aid of the band bending U_R (upper scale); open circles: experimental values (a roughness factor of 1.3 was taken into account) (lower scale) [11].

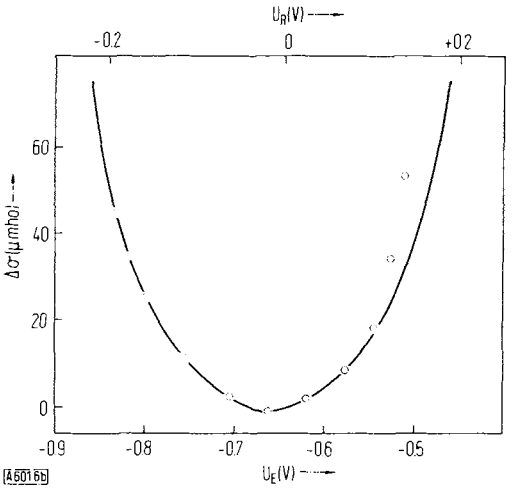

Fig. 6b. Surface conductivity $\Delta\sigma$ as a function of the electrode potential U_E of a germanium electrode (intrinsic), as measured against a saturated calomel electrode [13].

displacement on a logarithmic scale. This roughness factor is regarded as a correction for the roughness of the surface in contact with the electrolyte.

The agreement between theory and experiment means that the band bending U_R follows exactly the change in the electrode potential ΔU_E produced by an external voltage. Thus, in accordance with eq. (7), $\Delta U_E = \Delta U_R$. However, this result was obtained with a germanium electrode only when it was anodically polarized before the measurement, and when the potential change required for the measurement was rapidly achieved (within 10 sec). This suggests that otherwise chemical changes, too, occur at the interface (see below). Under the specified conditions, therefore, the potential drop U_H across the Helmholtz layer remains unchanged ($\Delta U_H = 0$). It has been found also with other electrodes (*e.g.* silicon [9,14] and zinc oxide [15]) that the external voltage is fully taken up by the space charge in the semiconductor.

The measurement of the interfacial capacity of germanium has led to another important result. The good agreement between the measurements and the theoretical values calculated for the space charge indicates that no surface states (*i.e.* fewer than $10^9/cm^2$) are present after anodic polarization. Using a term of *Brattain* and *Boddy*, one can describe the surface as "perfect". However, this is not a general property of semiconductor electrodes, as shown by the observations that surface states are present in silicon after anodic or cathodic polarization [9,14]. It has been found in the case of germanium [16,17] that the addition of copper, silver, or gold ions (10^{-7} M) raises the capacity in a certain potential region (see Fig. 7), which means that these ions give rise to surface states (about $10^{11}/cm^2$).

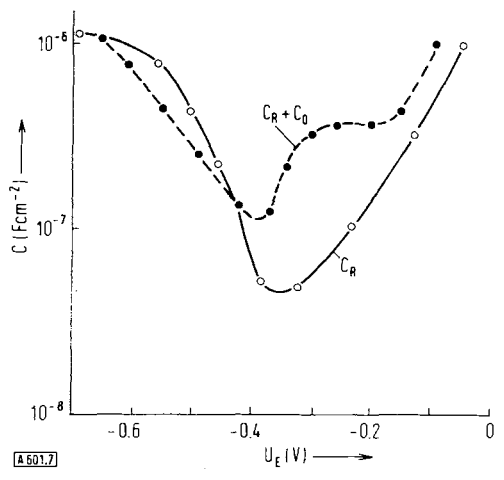

Fig. 7. Interfacial capacity as a function of the electrode potential of a p-type germanium electrode (45 ohm.cm) at pH 8 in a 0.1 M solution of Na_2SO_4 [18].

Solid curve: clean surface; dashed curve: after addition of cupric ions in a concentration of 10^{-7} M.

The properties of Cu, Ag, and Au impurity centers have been investigated in detail, particularly as regards their chemical nature. Since these elements are more electropositive than germanium, they readily deposit on the surface. This circumstance was used in the first attempt at explaining the formation of surface states at the interphase. Later investigations [18] have shown however, that below pH 4 surface states are no longer present, although these metals are still deposited (at rest potential). It seems therefore that the mechanism is much more complicated. Thus, only little is yet known of the actual chemical nature of the impurity centers. The formation of the surface states will be re-encountered in Section 3.4.2. in connection with other investigations.

3.2. Helmholtz Double Layer

The potential distribution at a germanium electrode was also investigated using electrolytes of various pH values. After anodic polarization and during a rather high sweeping rate, the band bending was only varied by the external voltage whereas the position of the capacity curve and the surface conductivity curve on the electrode potential (U_E) scale depends on the pH value of the electrolyte. Since the electrode potential is determined by the potential drop across the space-charge layer and across the Helmholtz double layer (we ignore the additive constant here), the above result suggests that the potential drop U_H across the Helmholtz double layer varies with the pH of the electrolytic solution.

A quantitative connection between U_H and the pH is established experimentally in the following way: In the case of an intrinsic semiconductor, the space charge in the semiconductor vanishes ($U_R = 0$) where the surface conductivity curve and the capacity curve reach their minimum. At this point, the electrode

[18] *R. Memming*, Surface Sci. *2*, 436 (1964).

potential U_E depends only on the potential drop across the Helmholtz double layer, and thus on the pH of the medium, *i.e.*

$$U_{E\,min} = U_H\,(pH) + \text{const.}\quad (U_R = 0) \qquad (14)$$

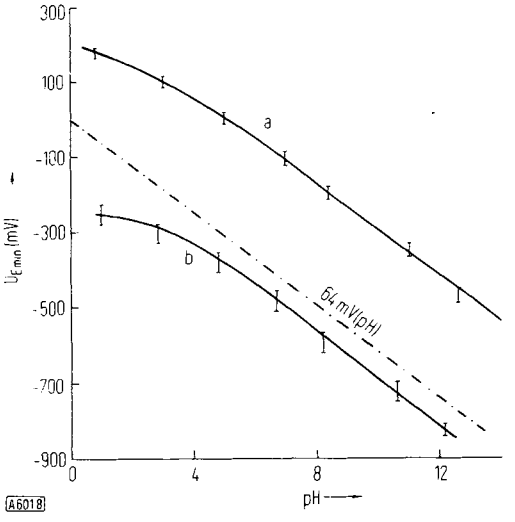

Fig. 8. pH-Dependence of the electrode potential at minimum capacity (on the standard hydrogen electrode scale) after a) anodic and b) cathodic polarization, measured on the <111> surface of germanium at 50 °C [19]. At pH > 4, the slope of the curves is 64 mV/pH.

The pH-dependence of the electrode potential has been determined by several authors [13, 19, 20]; curve (a) in Fig. 8 representing the results of *Gerischer* and *Mindt*. At pH > 4, the slope of this curve is 64 mV/pH, which means that the potential drop across the Helmholtz double layer must be fairly large, since it can be varied by a few hundred millivolts. *Gerischer* [19] has explained this by assuming that a dissociation double layer is present. It follows from the mechanism of the anodic dissolution of germanium [21] that the surface after anodic polarization is covered with OH groups. The dissociation on a <111> surface is then as follows:

$$\diagdown\!\!\diagup\!\!\text{Ge–OH} + OH^{\ominus} \rightleftharpoons \diagdown\!\!\diagup\!\!\text{Ge–O}^{\ominus} + H_2O \qquad (15)$$

and the equilibrium condition is given by

$$\mu_{Ge-OH} + RT \ln x_{Ge-OH} =$$
$$\mu_{Ge-O^{\ominus}} + RT \ln x_{Ge-O^{\ominus}} - F\,\Delta U_H + \mu_H + 2.3\,RT\text{pH} \qquad (16)$$

(where x_i is the mole fraction and μ_i is the chemical potential).

For electrostatic reasons, the proportion of $Ge-O^{\ominus}$ groups on the surface must be small, so that x_{Ge-OH} is practically 1. We thus obtain in the following form the pH-dependence that has also been found experimentally:

$$\Delta U_H = (RT/F)\,\text{pH} + \text{const.} \qquad (17)$$

[19] *M. Hoffmann-Perez* and *H. Gerischer*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *65*, 771 (1961).

[20] *P. J. Boddy* and *W. H. Brattain*, J. electrochem. Soc. *110*, 570 (1963).

[21] *F. Beck* and *H. Gerischer*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *63*, 500 (1959).

All these investigations discussed above have been carried out after anodic polarization. The potential drop across the Helmholtz double layer depends also on the polarization. If the germanium surface at a given pH is subjected not to anodic but to cathodic polarization, the capacity curve was observed in a more cathodic potential range (see Fig. 9a). The capacity minimum (no space charge layer, $U_R = 0$), therefore also appears at a different electrode potential. It follows therefore that, after cathodic polarization, the potential drop across the Helmholtz double layer assumes a different value.

It emerges from the current-voltage characteristic of the phase boundary [22] that, when U_E is changed externally in the cathodic direction, the surface coverage with OH groups is replaced by a surface coverage with hydrogen groups (see Fig. 9b) [12].

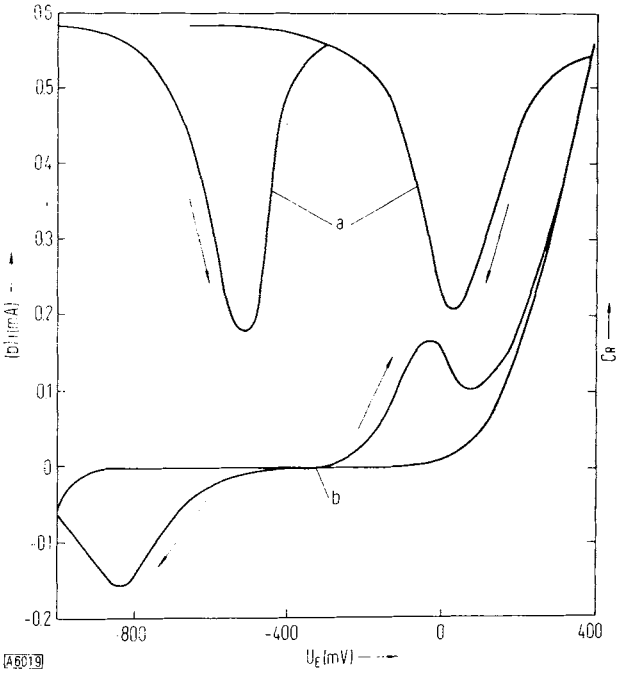

Fig. 9. a) Space-charge capacity C_R as a function of the electrode potential U_E after anodic (right) and cathodic (left) polarization of an n-type germanium electrode (15 ohm.cm), measured on the <111> surface against a saturated calomel electrode in a 0.01 N solution of H_2SO_4 (since only the position of the C_R - minimum is of interest here, the absolute values of C_R were not determined). — b) Current-voltage characteristic of an n-type germanium electrode (15 ohm.cm) (<111> plane), measured against a saturated calomel electrode, in a 0.01 N solution of H_2SO_4 [36].

Cathodic polarization is thus followed by the formation of a new Helmholtz double layer that is characteristic of hydride surfaces. This of course results in a change in the potential drop U_H across this double layer. The pH-dependence of the capacity minimum is similar to that after anodic polarization (cf. curves (a) and (b) in Fig. 8). Accordingly, there is a dissociation double layer also for hydride surfaces, the dissociation equilibrium being expressed as follows:

$$\diagdown\!\!\diagup\!\!\text{Ge–H} + OH^{\ominus} \rightleftharpoons \diagdown\!\!\diagup\!\!\text{Ge}^{\ominus} + H_2O \qquad (18)$$

[22] *H. Gobrecht*, *O. Meinhardt*, and *M. Lerche*, Ber. Bunsenges. physik. Chem. *67*, 486 (1963).

Investigations on silicon [14] have shown that the potential distribution across the Helmholtz double layer must again depend on the pH, but quantitative measurements are difficult, because the silicon electrode is covered with a silicon dioxide layer in aqueous solutions, with the exception of hydrofluoric acid.

In contrast to silicon, the picture concerning the potential distribution inside the Helmholtz double layer in germanium can be further refined [12]. Figure 8 shows that it is only at pH > 4 that the position of the capacity minimum is a linear function of the pH. At very low pH values, the position of the capacity minimum and the potential drop across the Helmholtz double layer are virtually independent of the pH. This is readily explained by the fact that the dissociation equilibrium in eq. (15) and that in eq. (18) are fully displaced to the left at such pH values. This does not mean that the potential drop disappears in the Helmholtz layer, since – as Fig. 9a shows – there is a great difference between the position of the capacity minimum of a hydroxide surface (*ca.* −500 mV) and that of a hydride surface (*ca.* +30 mV).

This behavior can be explained only by assuming that the two types of surface differ in their electrical moment. The Helmholtz double layer on the surface of germanium is therefore composed of two parts, namely a dissociation double layer and a dipole layer which lies inside the surface compound.

3.3. Application to Investigations of Reaction Kinetics

The distribution of potential at the semiconductor-electrolyte interphase is of interest in connection with electrochemical reactions at such electrodes. This will be shown by two examples.

Example 1. p-Type silicon is electrochemically dissolved in hydrofluoric acid when subjected to anodic polarization. The current-voltage characteristic (Tafel slope) plotted in a semilogarithmic coordinate system has a slope of $dU_E/d \log i = 60$ mV/decade [23]. Knowing the number of carriers (Z) participating in the rate determining step, one can calculate from the above value of the slope the transition factor α. In the present case, the value $\alpha Z = 1$ emerges from the equation:

$$\alpha Z = \frac{2.3\,RT}{F} \cdot \frac{1}{d\,U_E/d \log i} \qquad (19)$$

(where R is the universal gas constant and F is the Faraday constant).

On the assumption that $Z = 1$, *i.e.* that only one charge is involved in the rate-determining step, the transition factor itself has a value of one, which does not occur in practice in the case of metal electrodes. It should be added that this factor can be one only when the Helmholtz layer does not take up an external voltage. This is possible in semiconductors (silicon in this example), since the applied voltage can be taken up completely by the space-charge region in the semiconductor. This can be easily shown by measuring the interfacial capacity (see Fig. 10).

Measurements at the silicon-hydrofluoric acid interface have in fact shown that the potential drop across the Helmholtz layer does not change in anodic polarization [14], that is to say,

[23] *R. Memming* and *G. Schwandt*, Surface Sci. *4*, 109 (1966).

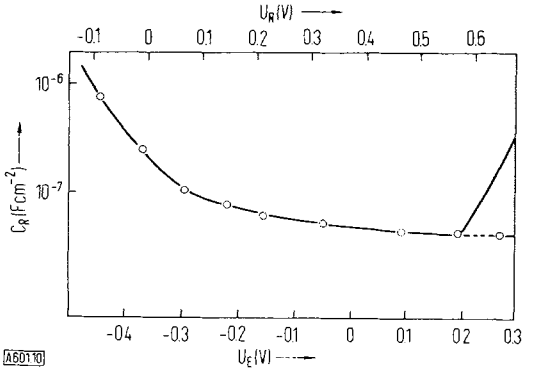

Fig. 10. Interfacial capacity C_R as a function of the electrode potential U_E of an n-type silicon electrode (1 ohm.cm) in 10 M hydrofluoric acid (measured on the saturated calomel electrode scale) [14].

Solid line: theoretical values (upper scale U_R); ○ - experimental values.

$\alpha = 1$. A further consequence of this result is: The concentration of holes at the surface is increased in accordance with eq. (4b) *i.e.* $p_s = p_o \exp (eU_R)/(kT)$ by a change in the band bending caused by the anodic polarization (this effect is shown as the upward bending of the energy bands). Since the external voltage appears only across the space-charge region, one can put $U_R = U_E + \text{const.}$ Substitution of this in eq. 4b gives

$$p_s = p_o \exp (e\,U_R)/(kT) = p_o \exp [e(U + \text{const.})]/(kT) \qquad (20)$$

Since the anodic dissolution current follows the same exponential law (eq. 10) it therefore increases in proportion to the hole concentration at the surface.

Example 2. As mentioned above, the surface of germanium subjected to cathodic polarization becomes coated with hydride groups instead of hydroxyl groups. This is indicated in the current-voltage curve (Fig. 9b) by the fact that a potential change in the cathodic direction is accompanied by a maximum in the cathode current [12, 22]. An anodic current maximum appears in the other sweeping direction. *Gerischer* and *Mindt* [24] have found that the reaction involved proceeds in two steps, one over the conduction band, and the other over the valence band [*]:

$$\text{Ge–OH} + \text{H}^{\oplus} + \text{e}^{\ominus} \rightleftharpoons \text{Ge}^{\bullet} + \text{H}_2\text{O} \qquad (21a)$$

$$\text{Ge}^{\bullet} + \text{H}^{\oplus} \rightleftharpoons \text{Ge–H} + \text{p}^{\oplus} \qquad (21b)$$

(where $e^{\ominus}$ is an electron in the conduction band and $p^{\oplus}$ is a hole in the valence band).

The authors assume that the reaction proceeds *via* an intermediate state represented by a surface radical. As shown before, the corresponding change of the potential drop ΔU_H in the Helmholtz layer is found from capacity measurements (Fig. 9a).

If H_2O_2 is added to the solution, an additional cathodic current (reduction of H_2O_2) can be expected. *Gerischer* and *Mindt* [25] have found however that the reduction of hydrogen peroxide (high redox potential) occurs only at that potential at which the hydroxide surface is changed into hydride surface. This leads to the assumption that the reduction occurs at the germanium radical by an electrochemical process:

$$\text{Ge}^{\bullet} + \text{H}^{\oplus} + \text{H}_2\text{O}_2 + \text{e}^{\ominus} \rightleftharpoons \text{Ge–OH} + \text{H}_2\text{O} \qquad (22)$$

[24] *H. Gerischer*, *A. Mauerer*, and *W. Mindt*, Surface Sci. *4*, 431 (1966).

[*] Electrochemical reactions basically involve either the conduction band or the valence band, depending on various factors which will not be discussed here.

[25] *H. Gerischer* and *W. Mindt*, Surface Sci. *4*, 440 (1966).

or that the following chemical reaction takes place:

$$\text{Ge–H} + H_2O_2 \rightarrow \text{Ge–OH} + H_2O \qquad (23)$$

This means that the hydroxide surface is re-formed continually in a cyclic process. The proof of this assumption is again based on the potential distribution[25]. Thus, a capacity curve typical of hydride formation is obtained after cathodic polarization without added H_2O_2 (see Fig. 9a), whereas the same polarization in the presence of H_2O_2 leads to a capacity minimum whose position is characteristic of a hydroxide surface (see the curve on the right in Fig. 9a). We shall return to this reaction mechanism in a different context.

3.4. Influence of Injection Processes on the Distribution of Charge and Potential

After the above description of the basic results pertaining to the potential distribution, an effect typical of semiconductor electrodes will now be discussed. The concentration of carriers is much smaller in semiconductors than in metals and the carriers in semiconductors are not only electrons in the conduction band, but also holes in the valence band. The number of carriers, particularly of the minority carriers (*e.g.* holes in an n-type semiconductor) is relatively small, but it can be increased by optical excitation or the injection of carriers during an electrochemical reaction. The following is a description of how the distribution of potential and the charge at the interphase is changed by these processes.

3.4.1. Surface Photovoltaic Effect

When a semiconductor electrode is exposed to light, the electrode potential U_E will assume a value different from that in the dark. The direction of this shift depends on the doping of the semiconductor. It has been found that the rest potential generally becomes cathodic in an n-type sample and anodic in a p-type sample. This difference indicates that the shift in the electrode potential is due to a change in the potential drop U_R across the space-charge region of the semiconductor, *i.e.* it is due to a change in the band bending. The cause of this effect is illustrated in Fig.11.

It will be assumed that the energy bands in the original state curve upward at the surface, *i.e.* that the space charge is positive (the corresponding negative charge is in the electrolyte). The optical excitation of electrons from the valence to the conduction band leaves behind holes in the valence band (Fig. 11a). The electron-hole pairs are separated by the electric field across the space-charge layer, and the electrons are drawn to the interior of the crystal, while the holes are drawn to the surface. The result is that the field is lowered and thus the band bending becomes smaller.

As shown before, this reduction in the positive space charge (change of the band bending downward in Fig. 1) is equivalent to a shift in the electrode potential in the cathodic direction. If the energy bands are bent downward in the dark (negative space charge), then the illumination causes a change of the band bending in the opposite direction, *i.e.*

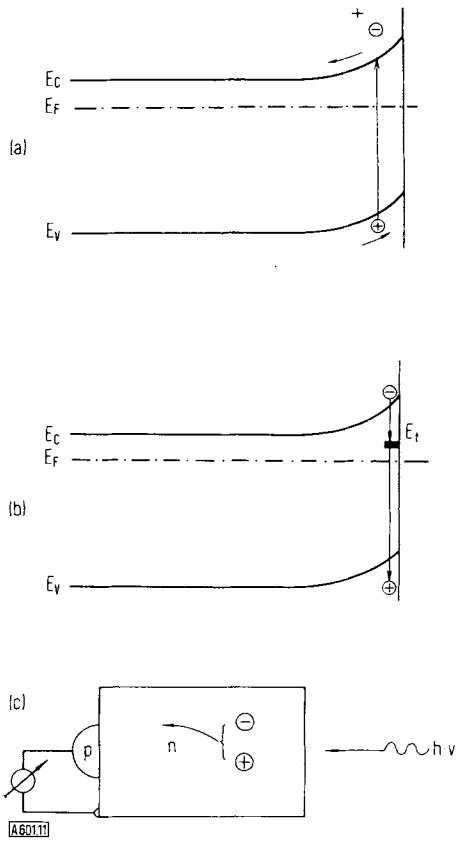

Fig. 11. (a) Energy gap model of a semiconductor illustrating the production of electron-hole pairs at the surface. — (b) Energy gap model of a semiconductor illustrating surface recombination *via* surface states. — (c) Semiconductor electrode with p-n junction on the reverse side of the electrode for detecting injected electron-hole pairs (schematic representation).

the photovoltaic effect has the opposite sign. It has already been seen that the type of band bending prevailing before illumination can be identified *e.g.* by measuring the interfacial capacity.

Brattain and *Boddy*[26] have investigated on germanium electrodes the quantitative relationship between the light-induced change in the electrode potential ΔU_E^L (and the change in the band bending ΔU_R^L) and the original band bending U_R. The variation of the photovoltage ΔU_R^L (change in the band bending) with the band bending U_R in the absence of light is given by the Poisson equation. Assuming that the concentration change is small ($dp = dn \ll n_o$, p_o) just outside of the space-charge region (between the bulk and the space-charge region), we find that the following equation holds for this variation:

$$\frac{d\,U_R^L}{dp} = \frac{1 - \exp(eU_R)/(kT)}{p_o + n_o \exp(eU_R)/(kT)} \cdot \frac{kT}{e} \qquad (24)$$

One can measure primarily only the light-induced change in the electrode potential ΔU_E^L (under galvanostatic conditions). The various band bendings in the dark are adjusted by an external voltage (see Fig. 12)[26], and determined by measuring the interfacial capacity. The experimental values satisfy eq. (24), which proves that $\Delta U_E^L = \Delta U_R^L$.

[26] *W. H. Brattain* and *P. J. Boddy*, Conf. On Clean Surfaces, New York Academy of Sci., Vol. *101*, Art. 3, 683 (1963).

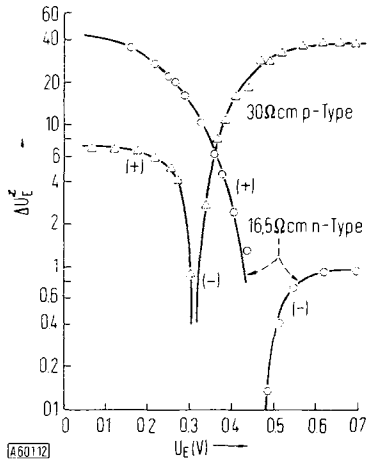

Fig. 12. Photovoltage ΔU_E^L (in arbitrary units) as a function of the electrode potential U_E (measured against a saturated calomel electrode) of p-type germanium (30 ohm.cm) and n-type germanium (16.5 ohm. cm) [26].

Similar investigations have been carried out on the variation of the photovoltage ΔU_E^L with the number of the injected carriers, particularly in the case of Ge, Si, GaP[27], and CdS[28]. Experiment again agrees well with theory in the case of germanium, but the relationships appear to be more complicated with other semiconductors examined.

The same effect can take place when carriers are not created by light, but are injected instead in electrochemical reactions. To produce electron-hole pairs in this manner, two reactions must in fact proceed simultaneously in opposite directions, *i.e.* in the anodic and the cathodic direction.The anodic process is mostly the electrochemical dissolution of the semiconductor electrode. If for example the atoms of the semiconductor go into solution with a valence of one, the equation of the reaction is as follows:

$$A + \lambda p^{\oplus} \xrightarrow{j^+} A^{\oplus} + (1-\lambda)e^{\ominus} \qquad (25)$$

(where λ is the distribution factor; if the reaction proceeds wholly *via* the valence band for example, then $\lambda = 1$).

This dissolution process is thought to involve both energy bands, *i.e.* $(1-\lambda)e^{\ominus}$ electrons are given off into the conduction band and $\lambda p^{\oplus}$ holes are extracted from the valence band. This means that the holes are neutralized by the liberation of electrons into the valence band. The corresponding anode current is given by j^+. When an oxidizing agent is introduced into the solution, it is reduced in a cathodic process. We shall assume that this reduction involves only valence-band electrons, in accordance with equation:

$$Ox \xrightarrow{j^-} Red + Zp^{\oplus} \qquad (26)$$

i.e. holes are injected into the valence band.

At equilibrium, the anode current j^+ is equal in magnitude to the cathode current j^-, *i.e.*

$$j^+ = j^- = j_{corr}. \qquad (27)$$

The partial currents are proportional to the charges transferred in unit time. However, λj_{corr} of holes injected in the reduction are consumed in the dissolution, so that $(1-\lambda)j_{corr}$ holes will be left behind. At the same time, however, $(1-\lambda)j_{corr}$ electrons are injected during the dissolution process, in accordance with eq. (25). These two reactions thus give rise to an equal number of electrons and holes, *i.e.* electron-hole pairs at the surface. The current corresponding to the pair production is given as

$$jp = (1-\lambda)j_{corr}. \qquad (28)$$

This pair production must exceed the thermal pair production i_s if it is to have an effective influence on the band bending.

This "electrochemical photovoltaic effect" was first detected by *Beck* and *Gerischer*[29] on germanium. A very large change (of several hundred millivolts) in the electrode potential (*i.e.* in the band bending) has been found to result from this pair formation in semiconductors with a wide band gap (*e.g.* GaP), in which the thermal pair production is insignificant[27].

3.4.2. Recombination Processes *via* Surface States

It has been shown in connection with the charge distribution inside the space-charge region that charge can also be stored in surface levels. Another property of such centers is that electron-hole pairs produced by light excitation or electrochemical reactions can recombine *via* such surface states (Fig. 11).

The mechanism of recombination *via* a lattice imperfection has been treated theoretically by *Shockley* and *Read*[30], and extended to surface processes by *Stevenson* and *Keyes*[31] and *Koc*[32]. The rate of recombination R' is proportional to the density of centers N_t and the change in the concentration Δn_o ($= \Delta p_o$) at the boundary between the interior of the crystal and the space-charge region. It depends furthermore on the position of the surface level with respect to the Fermi level, *i.e.* on the band bending. To obtain a magnitude characteristic of the surface recombination and independent of the change in the concentration Δn, the surface recombination velocity s is defined as

$$s = R'/\Delta n = N_t f(U_R) \qquad (29)$$

where s has the dimensions of velocity. The function $f(U_R)$ will not be discussed; suffice it to say here that s has about its maximum when the center passes through the Fermi level in the change of the band bending.

Recombination in surface levels is important in the investigations of the carrier injection. It affects the surface photovoltaic effect, and must also be considered in connection with the injection of minority carriers occurring in electrochemical processes at semiconductor electrodes. Furthermore, the measurement of the surface recombination can also be of use in the analysis of the surface states. This offers a further possibility of finding out something about the chemical nature of these states. This will be illustrated below by an example, but a method used for investigating the recombination process will first be described briefly.

The light-induced electron-hole pairs diffuse into the interior of the crystal provided that they do not recombine *via* traps. If there is a p-n junction on the reverse side of the electrode, then the electron-hole pairs are separated in the internal field of this junction. When the p-n junction is short-circuited (Fig.11c) *e.g.* by an ampere meter, then the corresponding short-circuit current is a direct measure of the number of the arriving electron-hole pairs[*]. At strong surface recombination at the semiconductor-electrolyte interface, only relatively few electron-hole pairs diffuse to the p-n junction, *i.e.* the corresponding short-circuit current i_K is small. A more accurate treatment[33] gives the following relationship for i_K

$$i_K \approx 1/s \qquad (30)$$

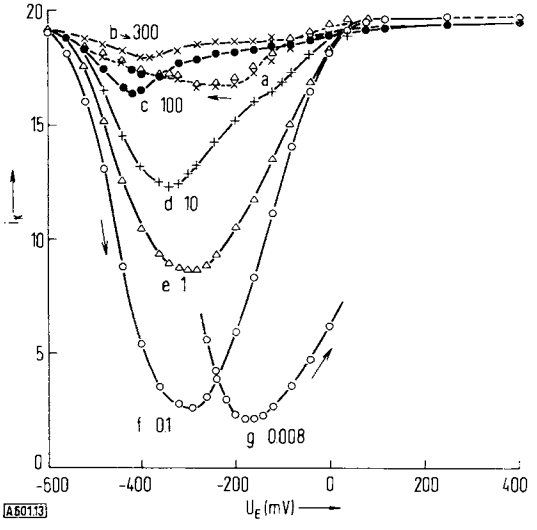

Fig. 13. Short-circuit current i_K as a measure of the surface recombination s ($s \approx 1/i_K$), determined as a function of the electrode potential U_E (on the saturated calomel electrode scale) of an n-type germanium electrode (15 ohm.cm) with a <111> surface in a 0.01 N solution of H_2SO_4 [36]. (a) After anodic polarization. — (b) - (g) after cathodic polarization. With curves (a)-(f), the sweeping time τ in the measurement was 1 sec, for (g) 2 msec; the polarization times t_k are given by the curves in sec.

provided that the depth of penetration of the light is sufficiently small. Fig. 13 shows the curve of recombination measured by this method as a function of the electrode potential.

In principle, the energy of the recombination center can be determined from such curves, but this will not be discussed here. It is sufficient to point out that the minimum short-circuit current $i_{k,\,min}$ (or the maximum of recombination) is a measure of the number of the recombination centers:

$$i_{k\,min} \approx 1/s_{max} \approx 1/N_t \qquad (31)$$

Germanium will again be used as an example. The recombination curves shown in Fig. 13 were measured under the following conditions: After anodic polarization (curve a), the short-circuit current has no minimum, *i.e.* there are practically no centers present. This was to be expected, since the centers were undetectable also in the capacity measurements (Fig. 9a). The same result was obtained after fairly prolonged cathodic polarization, during which the hydroxyl groups on the surface were replaced by hydride groups, this result indicating that the hydride surface, too, was practically perfect[36]. Surface recombination occurred only after a shorter duration of cathodic polarization (curves c–g in Fig. 13). At longer polarization times, the number of recombination centers was found to decrease (the sweeping time τ in the measurement was much smaller than t_k).

Capacity measurements have shown that the time in which the centers are present is exactly the same as is needed for the changing of a hydroxide surface to a hydride surface. It seems feasible to assume on the basis of eq. (21) that the recombination centers are identical with $\equiv$Ge$^\bullet$ surface radicals postulated as intermediate state. As mentioned before the addition of H_2O_2 to the electrolyte changes the hydride surface back to the hydroxide surface in a cyclic process. Thus, radicals are continuously re-formed [see eqs. (21)–(23)], so that they are present at a certain concentration in the stationary state[37]. As proved experimentally the recombination centers show the same behavior; even after a very long cathodic polarization, the recombination is as high as found without H_2O_2 after very short polarization times (curve f, Fig. 13).

Comparison between the experimentally observed kinetic properties of the centers and the theoretical properties of the radicals suggests that the surface states are identical in this case with the radicals. Capacity measurements show that the number of surface states or radicals amounts only to about 0.01 % of the total surface coverage.

It has been suspected before that surface states are brought about by surface atoms with unpaired electrons. Though such proposals remain largely hypothetical, the electric and electrochemical investigations of germanium electrodes give an excellent insight into the nature of surface states.

Cyclopentadienylgold(I) and Cyclopentadienyl-(triphenylphosphine)gold(I) [1]

By *R. Hüttel, U. Raffay*, and *H. Reinheimer* [*]

Pure cyclopentadienyl-metal compounds involving elements of the first sub-group have not been described hitherto. Only (triethylphosphine)cyclopentadienylcopper(I) is known [2].

We have now synthesized cyclopentadienylgold(I). The success of the method depends on preparing solutions of AuCl in organic solvents in which it is normally insoluble. This may be accomplished by means of a loose addition of a cyclic olefin. Dicyclopentadienylgold(I) chloride [3] and *trans,trans, cis*-1,5,9-cyclododecatrienegold(I) chloride [3] are soluble in tetrahydrofuran (THF) and on treatment with cyclopentadienylsodium afford the desired C_5H_5Au.

About 1 g of the olefin-gold(I) chloride is dissolved in 100 ml of THF/ether (1:4) and treated at −60 °C under nitrogen with a solution of C_5H_5Na (3 molar equiv.) in THF. A yellow precipitate is at once formed but dissolves in the excess of C_5H_5Na solution to give a colorless solution. The yellow substance separates again on addition of dry ice. After centrifugation at −30 °C the precipitate is washed three times with 96 % alcohol and twice with ether and then taken up in n-pentane. All solvents are precooled to −70 °C. On evaporation of the pentane under vacuum at −30 °C there remains a powdery, yellow insoluble substance whose elemental composition corresponds to the formula C_5H_5Au.

The substance is sensitive to heat and friction. It is stable for about an hour at room temperature but often deflagrates on gentle warming.

The same compound was obtained by treating the olefin-gold(I) chloride with cyclopentadiene (Cp) and triethylamine but was then not analytically pure.

Since the insolubility and instability of C_5H_5Au prevent its closer study, the soluble and more stable cyclopentadienyl-(triphenylphosphine)gold(I) was prepared.

About 1 g of (triphenylphosphine)gold(I) chloride [4] was made into a slurry in 20 ml of ether and treated at −30 °C under nitrogen with an excess of C_5H_5Na solution in ether (5×10^{-3} mole/liter). The temperature was slowly raised to 0 °C and the mixture was stirred for an hour. The whole was poured into 200 ml of ice-water with vigorous stirring and then filtered. The residue was washed first with water, then with cold acetone, and finally with ether. For purification it was dissolved in THF/acetone at 0 °C and treated dropwise with ice-water. Colorless rhombohedral crystals of the composition $C_{23}H_{20}AuP$ were obtained; they decompose above 100 °C.

The same compound was detected by NMR spectroscopy in the products of the following reactions:

C_5H_5Au + triphenylphosphine (TPP)
TPP·AuCl + Cp + triethylamine
TPP·AuCl + Cp + KOH
TPP·AuCl + Cp + $NaOCH_3$.

The IR spectrum (KBr disc) of cyclopentadienyl(triphenylphosphine)gold(I) (TPP·AuC_5H_5) contains the following bands in addition to those that occur in the spectrum of TPP·AuCl:

642 w, 734 s, 803 s, 922 w–m, 970 m, 998 m, 1404 m (cm^{-1})[5]

An ionic cyclopentadienyl-metal bond is excluded because there are two bands in the region around 1000 cm^{-1} [6]; it is questionable whether a π bond of the ferrocene type is present because the intense bands at about 1100 cm^{-1} are missing [6]. The only remaining possibility is a σ bond.

The UV spectrum of TPP·AuC_5H_5 resembles the spectra of σ-cyclopentadienyl(triethylphosphine)copper(I) and di(cyclopentadienyl)mercury(II) [2]. Its maximum lies at 236.6 nm (ε = 33400 in dioxane); TPP and TPP·AuCl give no maximum near this wavelength.

Only a few ^1H–NMR measurements of σ-cyclopentadienyl-metal compounds are available [7]. For TPP·AuC_5H_5 we find only one sharp signal (τ = 3.7) [8] for the protons on the five-membered ring, corresponding to a σ-bonded cyclopentadienyl ligand undergoing rapid exchange of the carbon-metal bond [9].

The NMR spectrum of (methylcyclopentadienyl)-TPP-gold(I), which we have so far obtained only in solution – by treating TPP·AuCl with methylcyclopentadienylsodium or with methylcyclopentadiene + $NaOCH_3$ – shows three signals, namely at τ = 3.9, 4.15, and 7.7 (2:2:3). This indicates that in this instance the metal is σ-bonded to the carbon atom carrying the CH_3 group [10].

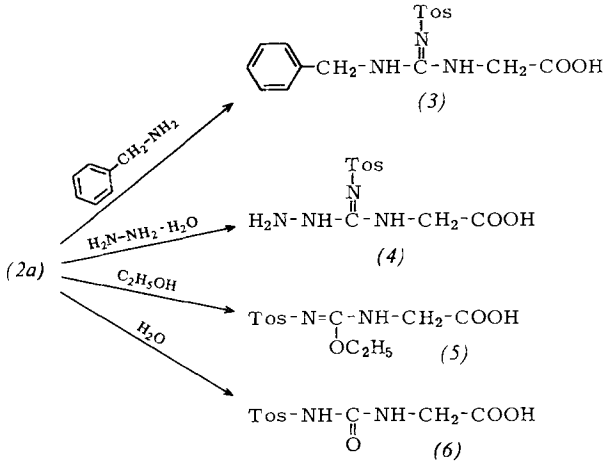
N-[(Methylthio)-*N*-tosylformimidoyl]amino Acids [1]

By *J. Gante* [*]

Heating the sodium salts of the amino acids *(1a)–(1d)* with *S,S*-dimethyl *N*-tosyldithiocarbonimidate [2] (molar ratio 1:1) in boiling ethanol/water (2:1) for five to six hours and then adding an equivalent amount of 1 N HCl gives the hitherto unknown *N*-[(methylthio)-*N*-tosylformimidoyl]-amino acids *(2a)–(2d)*. In the case of *(1d)* (L-glutamic acid the disodium salt is used.



(1) *(2)*

Tos = *p*-toluenesulfonyl

	R	Yield (%)	M.p. (°C)	Optical rotation
(2a)	$-H$	76	173–175	
(2b) DL-Form	$-CH_3$	61	135–136	
(2c) DL-Form	$-CH_2-C_6H_5$	85	168–170	
(2d) L-Form	$-CH_2-CH_2-COOH$	64	151–153	$[\alpha]_D^{25} = -24.4°$ (c = 1, ethanol)

Compounds *(2a)–(2d)* are colorless, crystalline substances that react weakly acidic and dissolve readily in ethanol but only slightly in water; they can be readily recrystallized from mixtures of these two solvents from which they often separate first as oils.

These compounds are susceptible to aminolysis, ethanolysis, and hydrolysis. Thus *(2a)* (as the sodium salt) reacts with an excess of benzylamine in boiling ethanol/water (3:1) within 8 h to give *N*-(*N*^{1}-benzyl-*N*^{2}-tosylamidino)glycine *(3)* (yield 41 %, m.p. 196–198 °C), and with an excess of hydrazine hydrate on six hours' heating with water under reflux to give *N*-(hydrazino-*N*-tosylformimidoyl)glycine *(4)* (yield 50 %, m.p. 146–147 °C).

When the sodium salt of *(2a)* (obtained by adding an equivalent amount of 1 N $NaOC_2H_5$) is heated for 30 h in boiling ethanol, ethanolysis occurs to yield *N*-(ethoxy-*N*-tosylformimidoyl)glycine *(5)* (yield 28 %, m.p. 166–168 °C). When, however, double the amount (100 % excess) of sodium ethoxide is used and the mixture is boiled for 15 h, *N*-(tosylcarbamoyl)glycine *(6)* (yield 22 %, m.p. 187–188 °C) is obtained, probably under the hydrolytic influence of small amounts of water present in the ethanol.

Synthesis of Asymmetric *O,O,O,O*-Tetraalkyl Dithiopyrophosphates

By *L. Almasi* and *L. Paskucz* [*]

We have found a simple process for preparing asymmetrical *O,O,O,O*-tetraalkyl dithiopyrophosphates *(3)* that have powerful anticholinesterase activity. This method affords a 95 % yield and avoids the high-vacuum distillation necessary for purification in all previous preparations of these compounds [1–3]. *O,O*-Dialkyl *S*-morpholinodithiophosphate *(1)* is treated with a dialkyl phosphite *(2)* in a stream of anhydrous HCl [4].

(3d)	i-C_4H_9	C_2H_5	1.4870	1.1302	96.54 96.33	95

[a] Values in the literature: For *(3a)* n_D^{20} = 1.5008 [1], 1.4964 [3], n_D^{25} = 1.4969 [2]; for *(3b)* n_D^{20} = 1.4920 [3].

The elemental compositions, molecular refractions, and IR spectra (maxima at 555, 653, and 1270 cm^{-1}, which correspond to P–O–P, P=S, and P=O groups) prove the purity and structure of the compounds *(3a)–(3d)*.

Experimental:

The thioamide *(1)* (0.04 mole) in anhydrous ether (100 ml) is treated at room temperature with an equivalent amount of *(2)* in a two-necked flask fitted with a $CaCl_2$ tube and a tube for introduction of gas. A stream of anhydrous hydrogen chloride is passed into the ice-cooled solution. After saturation of the solution with HCl, the precipitated morpholine hydrochloride is filtered off and the etheral solution is concentrated (at 10 mm) to half its volume, treated with 50 ml of petroleum ether, and washed successively with 20 ml of water, 20 ml of sodium hydrogen carbonate solution, and 20 ml of water. The organic layer is dried for 2 h over anhydrous $MgSO_4$, and the solvent is removed at room temperature (1 mm, 1 h). The residue *(3)* is a colorless liquid.

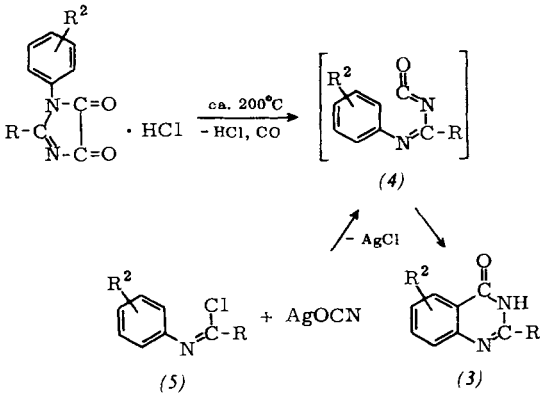
α-Iminoalkyl Isocyanates

By *L. I. Samaraj, V. A. Bondar,* and *G. I. Derkatsch* [*]

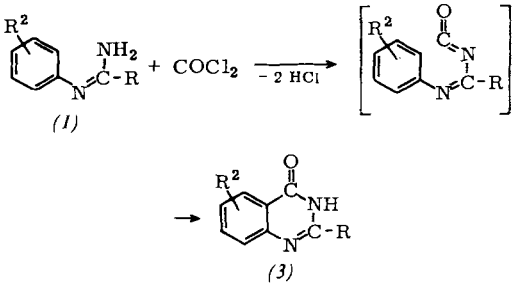
We recently ascertained that amidines *(1)* react very readily with oxalyl dichloride to give imidazoline-4,5-dione hydrochlorides *(2)* [1,2].



(1) *(2)*

R = Alkyl, Aryl

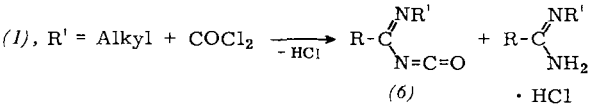
R' = H, Alkyl, Aryl



The products *(2)*, R' = aryl, lose HCl and CO when heated and are converted into 4-quinazolones *(3)*. These are formed by way of iminoalkyl isocyanates *(4)* as intermediates.

(4) *(5)* *(3)*

The same 4-quinazolones are obtained on treatment of the *N*-(chloroalkylidene)anilines *(5)* with silver cyanate.



N-Arylamidines *(1)*, R' = aryl, react with phosgene in hot inert solvents (benzene, toluene, xylene, chlorobenzene, *etc.*) (80–110 °C), again yielding 4-quinazolones *(3)* in almost quantitative yields [3].

(1) *(3)*

This reaction permits the one-stage preparation of 4-quinazolones containing various substituents in the benzene ring.

On the other hand, *N*-alkylamidines *(1)*, R' = alkyl, react with phosgene under the same conditions to give iminoalkyl isocyanates *(6)*. These products are relatively stable; they are colorless liquids with a powerful odor, with the exception of *(6d)* which is odorless. Reaction of the iminoalkyl isocyanates with amines or alcohols gives substituted ureas or urethanes, respectively. The compounds *(6)* react very slowly with water; their IR spectra are in accord with the structures assigned.

A New Fragmentation in the Adamantane Series

By *F. N. Stepanov* and *V. D. Sukhoverkhov* [*]

We recently reported [1] the preparation of 1-bromo-3-(bromomethyl)adamantane *(1)*, which was later synthesized also from 3,7-bismethylenebicyclo[3.3.1]nonane *(2)* by *Stetter* and *Gärtner* [2].

We have now found that, unlike 1-bromoadamantane, the dibromide *(1)* reacts readily with magnesium in ether. The main product is a resinous mass that we have not investigated in detail. The reaction takes a different course when the dibromide *(1)* is treated with zinc in dimethylformamide. In the latter case, two bromine atoms are removed and 3,7-bismethylenebicyclo[3.3.1]nonane *(2)* is obtained. The reaction is thus the reverse of the synthesis of *(1)* from the hydrocarbon *(2)* and bromine [2].

(1) *(2)*

A mixture of dibromide *(1)* (10 g), Na_2CO_3 (6.5 g), NaI (0.3 g), zinc dust (5 g), and dimethylformamide (10 ml) is boiled for 5 h. After dilution with water the hydrocarbon formed is distilled off in steam. Yield 3.6 g (75 %), m.p. 78–79 °C (from methanol) (lit. [2], m.p. 75 °C).

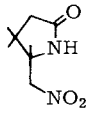
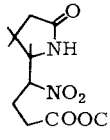
rac.-Dicyano-(1,2,2,7,7,12,12-heptamethylcorrin)-cobalt(III) [**]

By *I. Felner, A. Fischli, A. Wick, M. Pesaro, D. Bormann, E. L. Winnacker,* and *A. Eschenmoser* [*]

In our earlier work on the synthesis of corrin complexes the enamide *(1)* served as precursor of ring C of nickel(II) and cobalt(III) complexes of *rac.*-7,7,12,12,19-pentamethylcor-



rin[1]. Since that time, methods have been developed which permit use of this readily accessible enamide as precursor, not only of ring C, but also of rings A and B[2] of correspondingly methylated corrin derivatives. We now report the preparation of the (A)–(D) intermediate *(8)*. Corrin(III)-cobalt complexes of type *(10)* are now readily accessible by two-stage condensation of this compound with the component *(2)* used previously[1].



The impulse to work out the reaction sequence *(1)* → *(3)* → *(8)* was provided by the observation that nitromethane reacts readily and almost quantitatively with the enamide *(1)* in the presence of potassium t-butoxide. The product *(3)* doubtless arises by nucleophilic addition of deprotonated nitromethane to the *N*-acylketimine tautomer of the enamide[***]. The mixture of diastereoisomers *(4a,b)* formed on Michael addition of *(3)* to methyl acrylate is the result of thermodynamic control; they are separable by fractional crystallization and equilibrate to the same mixture of diastereoisomers under the conditions of the addition. Since the corresponding diastereoisomeric dilactams are very readily separated by virtue of their differing solubilities, the mixture *(4a,b)* is directly submitted to catalytic hydrogenation for preparative purposes. The series of steps *(5a)* → *(8)* carried out with the lower-melting dilactam isomer *(5a)* reflects types of reaction that were worked out earlier[1a,c]. The structural selectivity of the condensation step *(6)* → *(7)* is explained on steric grounds; the structure of the product *(7)* is unambiguously proved by the mass spectrum. As usual with compounds of this type[1], the (A–D) intermediate *(8)* exists in solution as a 1:1 mixture of the two isomers with the diastereoisomeric arrangement of substituents on the double bond.

Assignment of the *anti*-configuration[3] to the lower-melting dilactam isomer *(5a)* is for the moment unproved. The assignment was originally[4] made on the basis of IR-spectroscopic comparison with known *anti*- and *syn*-dilactams of the same type[1a,c]; it is supported in particular by the fact that the dicyanocobalt(III) complex *(9)* derived from the lower-melting lactam *(5a)* can be cyclized to a dicyano-(corrin)cobalt(III) complex whose UV, IR, and NMR spectroscopic data correspond to those of authentic 1,19-*anti*-dicyano(corrin)cobalt(III) complexes[1b,c]. The condensation *(8)* + *(2)* and subsequent complex formation to give *(9)*, the cyclization to *(10a)*, and hydrolytic removal of the cyano groups from the chromophore, yielding the corrin complex *(10b)* named in the title, parallel results obtained previously [1b,c] in the tetramethyl and pentamethyl series.

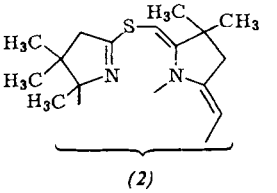
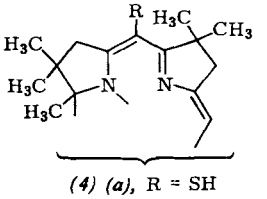
A Synthetic Route to Metal-free Corrins [**]

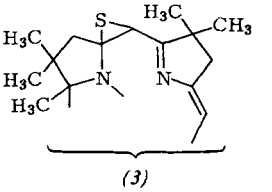


By *A. Fischli* and *A. Eschenmoser* [*]

Cobalt-free corrinoid compounds have recently been isolated from photosynthesizing bacteria [1]. However, it has not yet been possible to remove the cobalt solvolytically or reductively from cobalt-corrin complexes of either natural or synthetic origin whilst still retaining the ligand system [2]. The final cyclizing step in the route used by us hitherto for the synthesis of corrin complexes [3] requires the template effect of metal ions such as cobalt(III) and nickel(II). These metals form robust planar complexes with the polydentate ligand system to be cyclized and cannot be removed later [4]. We now describe a modified method of cyclization whereby the synthesis of metal-free corrins becomes possible: our example is *rac.*-15-cyano-1,2,2,7,7,12,12-heptamethylcorrin hydrochloride *(9)*.



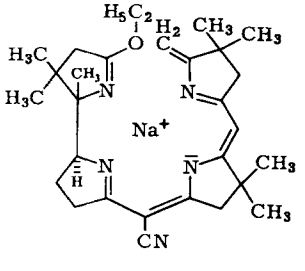
The process rests on a new type of condensation for formation of vinylogous amidine systems that was developed in our laboratory in another connection [6]. Formulae *(1)–(4)* illustrate the concept for the present case.



(1)

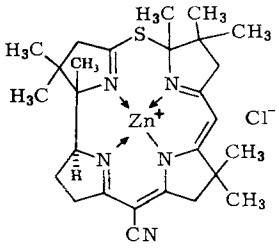
(2)

(4) (a), R = SH
(b), R = H



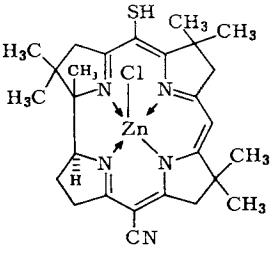
(3)

The two condensation centers C-4 and C-5 [cf. *(1)*] are first linked by a sulfur bridge [cf. *(2)*] and the bridged system is then either isomerized to *(4a)* by way of the hypothetical



intermediate of type *(3)* or desulfurized to *(4b)*. In contrast to base-induced cyclization by the imino-ester procedure [7], the sulfur bridging does not require fixation of the ligand system into a robust metal complex but can be carried out on the labile zinc(II) complex; the zinc ion can be removed from the cyclized corrin complex very easily by acidolysis. Experimental details are given in the reaction scheme *(5)* → *(9)*. The attempt to convert the tetracyclic condensation product *(5)* [8] by acid-catalysed reaction with hydrogen sulfide into the corresponding thiolactam derivative of type *(1)* and to isolate the latter as zinc complex gave the crystalline macrocyclic isomer *(6)* whose structure was recognized from, in particular, the NMR spectrum (eight methyl groups, one vinyl proton). The series of operations, a) oxidation with benzoyl peroxide in the presence of trifluoroacetic acid at room temperature, b) warming with trifluoroacetic acid in dimethylformamide in the presence of ethylenediaminetetraacetic acid, and c) re-formation of the complex with zinc(II) perchlorate and finally chromatography on silica gel, all effected without isolation of the intermediate products, yielded 15-cyano-1,2,2,7,7,12,12-heptamethyl-5-mercaptocorrinzinc(II) *(7)* together with smaller amounts of the already desulfurized complex *(8)*; the complex *(7)* was crystallized as its chloride. We assume that the trifluoroacetic acid equilibrates the reactant *(6)* with the corresponding open thiolactam [cf. *(1)*], and that this is oxidized by dibenzoyl peroxide [9] to the *O*-benzoyl-*S*-oxide in which the sulfur bridge to the methylidene group of ring B is formed. It is treatment b) that causes formation of the corrin chromophore (UV spectrum!), it being remarkable that intermediate decomplexing of the ligand system seems to be necessary for this reaction [11]. The product *(7)* can be converted by acid-catalysed desulfurization with triphenylphosphine into the zinc(II)-corrin complex *(8)*, and the latter can be decomplexed by treatment with trifluoroacetic acid in acetonitrile to yield *rac.*-15-cyano-1,2,2,7,7,12,12-heptamethylcorrin *(9)*, the reactions occurring very smoothly. Compound *(9)* was crystallized as the hydrochloride.

The structure of the metal-free corrin derivative is shown unambigously by the NMR and mass-spectroscopic results (cf. scheme). The UV spectrum in ethanol corresponds in structure and relative intensity of the absorption bands to that of the natural cobalt-free corrin derivatives measured by *Toohey* [1] for aqueous solutions at pH = 7; the hypsochromic position of the absorption maxima in the spectrum of *(9)*, ascribable to the differing substitution of the chromophore, accords with previous observations [3,8] in the series of natural and synthetic dicyanocobaltcorrin(III) complexes. The free corrin ligand corresponding to the hydrochloride *(9)* is a moderately strong base; the pK^*_{MCS} [12], determined in dimethylcellosolve-water (4:1 w/w) is 8.6 (pK^*_{MCS} of piperidine = 9.7). Treatment of the hydrochloride *(9)* with an excess of $Co(II)(ClO_4)_2 \cdot (DMF)_6$ in acetonitrile (2 h at room temperature), re-oxidation with air in a mixture of 1 N aqueous hydrochloric acid and acetonitrile (15 min at room temperature), and finally treatment with aqueous potassium cyanide afforded crystalline *rac.*-dicyano-(15-cyano-1,2,2,-7,7,12,12-heptamethylcorrin)cobalt(III) [8] in more than 90 % yield [13].



Spectroscopic and structural characterization of the mono- and di-protonated derivatives of *(9)*, as well as other questions arising from the above results, are currently under investigation.

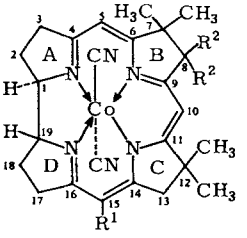
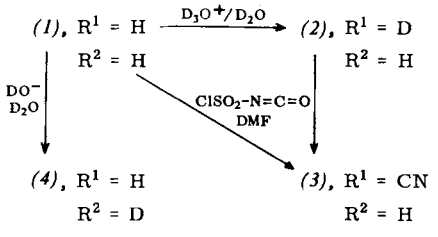
Reactivity of Ligands in Synthetic Cobalt(III)- and Nickel(II)-corrin Complexes [**]



By *D. Bormann, A. Fischli, R. Keese*, and *A. Eschenmoser* [*]

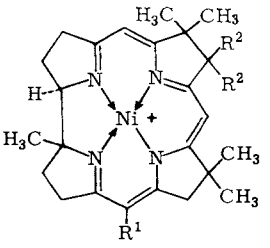


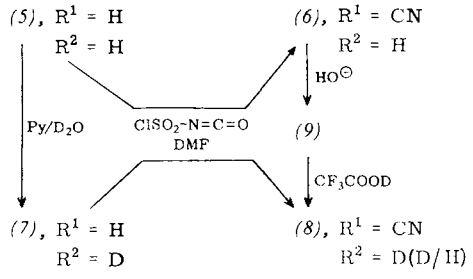
In investigations carried out so far, electrophilic substitution on the ligand chromophore of the synthetic corrin complexes *rac.*-dicyano-(7,7,12,12-tetramethylcorrin)cobalt(III) *(1)* [1] and *rac.*-7,7,12,12,19-pentamethylcorrinnickel(II) chloride *(5)* [2] occurs preferentially at position 15. In a basic medium, the periphery of the ligand system can be selectively deprotonated at position 8. These statements are based on the following findings.

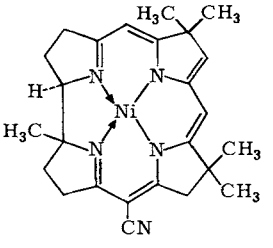
Reaction of the cobalt complex *(1)* with three equivalents of chlorosulfonyl isocyanate at room temperature for 15 min and subsequent treatment of the reaction mixture with dimethylformamide for 15 min at room temperature (*Lohaus* and *Graf*'s method of cyanation [3]) gave an 80–90 % yield of the monocyano complex *(3)*. The structure of this complex is certain because it is an intermediate in the total synthesis of *(1)* [4].

In the NMR spectrum of the cobalt complex *(1)* (in $CDCl_3$), the signals of the three vinyl protons appear as singlets at 5.40, 5.44, and 5.56 ppm. The last of these signals is broadened (tripletoid) as a result of spin-spin coupling of the corresponding vinyl proton with the protons of the

neighboring allyl methylene groups, whose signal occurs as a broadened singlet at 2.84 ppm[5]. All three vinyl positions are completely deuterated in the mixture *t*-BuOD-D_2O(1:1)–CF_3COOD (pD *ca.* 2; room temperature; 5 days), the four allylic methylene groups being unaffected.







In the NMR spectrum of the trideuterio complex the methylene signal at 2.84 appears as a sharp singlet. According to the mass spectrum[6], the product of partial deuteration (*p*D *ca.* 3; room temperature; 24 h) contains 38 %, 40 %, 17 %, and 4 % of the D_0, D_1, D_2, and D_3 components respectively; most of the loss in intensity in the NMR spectrum is due to the tripletoid vinyl-proton signal at 5.56 ppm. The complex *(3)* obtained on reaction of this product with chlorosulfonyl isocyanate and dimethylformamide (yield 86 %) contains the components D_0 (79 %), D_1 (17 %), and D_2 (4 %)[6]. This leads to the conclusion that acid-catalysed deuteration of the chromophore system occurs most rapidly at position 15, and that in the NMR spectrum of the cobalt complex *(1)* the tripletoid signal at 5.56 ppm is to be assigned to the vinyl proton at position 15, and the signal at 2.84 ppm to the proton of the methylene group in ring C (position 13). A sharp doublet at 2.91/2.93 ppm can now be assigned to the protons of the allylic methylene group of ring B (position 8), and can, as a near-singlet AB signal system, be clearly distinguished from the broad multiplet at 3.1 ppm of the allylic methylene protons of rings A and D.

Base-catalysed partial deuteration of the dicyanocobalt(III) complex *(1)* in the system *t*-BuOD–D_2O(1:1)–NaOD-KCN ($c_{(1)}$ = 0.071 mole/l; pD *ca.* 12; 7 h; 31 °C; under N_2) leads to the dideuterio complex *(4)*, *i.e.* to selective disappearance of the signal at 2.91/2.93 ppm in the NMR spectrum; the structure and intensities of the remaining NMR signals are unchanged (within experimental error). The reaction, followed in several experiments by NMR spectroscopy, is first order with respect to *(1)* (half-life 99 ± *ca.* 5 min) and is independent of the cyanide concentration from 0.13 to 0.70 mole/l.

Cyanation of the 7,7,12,12,19-pentamethylcorrinnickel(II) cation *(5)*[2] by chlorosulfonyl isocyanate occurs as in the cobalt series and affords a yield of over 90 % of the cyano nickel complex *(6)*, a complex which is known from its total synthesis[2]. With this positively charged complex ion, deuteration of the allylic methylene group of ring B [cf. *(7)*] takes place even in the presence of a weak base; keeping the compound for 15 h in pentadeuteriopyridine-D_2O (1:1) ($c_{(5)}$ = 0.014 mole/l; 31 °C; under N_2) brings about selective disappearance of the methylene-singlet signal at 3.18 ppm in the NMR spectrum[7]. However, the structure and intensities of the two weakly coupled signals at 3.02 ppm (methylene protons of ring C, position 13) and 6.10 ppm (vinyl proton in position 15) are substantially unchanged; assignment of these signals is based

(9)

on the evidence provided for the cobalt complex *(1)* that the vinylic-allylic spin-spin coupling observable for one of the three vinyl protons refers to the proton at position 15. This is also in accord with the theoretically predicted correlation[8] between spin-spin coupling constants and π-bond order in vinyl-allyl systems. According to the results of X-ray structure analyses of various corrin complexes[9] the 5,6- and 14,15-bonds have the highest π-bond order of the (C,C)-π-bonds of the corrin chromophore.

In our earlier investigations[1b,2] a neutral complex formed on deprotonation of the 15-cyano nickel(II) complex *(6)* was isolated in crystalline form and was characterized. Findings recorded below show that this complex has structure *(9)*. Thus, with a cyano group at position 15 it is also the methylene group in ring B that is preferentially deprotonated by base. In the NMR spectrum of the 15-cyano nickel(II) complex *(6)* in trifluoroacetic acid the signals of the two allylic methylene groups in rings B and C appear as singlets at 3.27 and 3.37, respectively. The complexes *(6)* and *(9)* in trifluoroacetic acid[10] give identical NMR spectra, but in the spectrum of complex *(9)* in deuteriotrifluoroacetic acid the signal at 3.27 is broadened and its intensity is reduced by half. This signal is absent from the spectrum of the 15-cyano-8,8-dideuterio complex *(8)* (in trifluoroacetic acid) that is obtained by treating the 8,8-dideuterio complex *(7)* with chlorosulfonyl isocyanate-DMF.

Neither the preference of electrophilic substitutions for position 15 (or 5) nor the selectivity in base-induced deprotonation at position 8 of the corrin ligand system can be convincingly predicted or interpreted on the basis of qualitative resonance structure formalism. The experimental findings, however, agree qualitatively with the atom localization energies A^- (positions 5 or 15 and 10) and A^+ (positions 4, 9, and 14) calculated by the HMO method[11]. The dominance of position 15 over the electronically equivalent position 5, observed particularly in the reactions with chlorosulfonyl isocyanate, is presumably to be ascribed to steric shielding of position 5 by the neighboring *gem*-methyl groups in ring B. To what extent the steric non-equivalence of positions

10 and 15 causes the difference in reactivity of these two centers remains to be clarified by further experiments.

The results now reported indicate new possibilities for selective structural modification of the corrin ligand system and contribute to a better understanding of previous results on the oxidation and dehydrogenation of ring B of vitamin B_{12} [12].

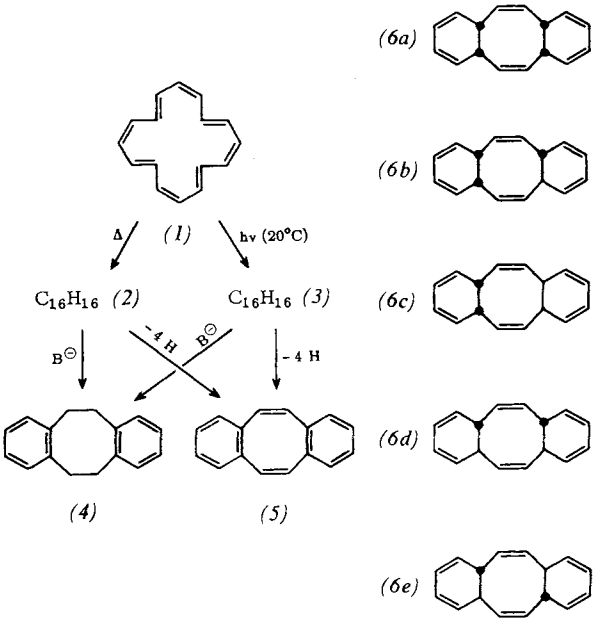
Thermal and Photochemical Behavior of a [16]Annulene



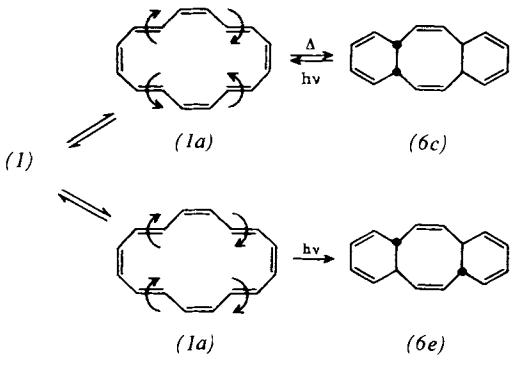
By *G. Schröder, W. Martin*, and *J. F. M. Oth* [*]

[16]Annulene *(1)* can be synthesized on the gram scale [3] by photolysis of the cyclooctatetraene dimer of m.p. 53 °C [1,2]. Both heat and UV light cause characteristic changes in this annulene. When warmed [4] in various solvents (benzene, ether, acetone, or CS_2) the compound rearranges to give a yield of over 90 % of an oil $C_{16}H_{16}$ *(2)* [5] which appears homogeneous on thin-layer chromatography (silica gel; cyclohexane, benzene, or CS_2).

In the UV region [6] the product *(2)* absorbs at λ_{max} = 261 nm (ε = 4900). The NMR spectrum [6] is unusually complex and shows twelve olefinic (τ = 4.0–5.1) and four aliphatic protons (τ = 5.8–7.5). No unambiguous result has so far been obtained from catalytic hydrogenation over Pd/C. The product is very sensitive to both oxygen and acids.

A solution of the annulene *(1)* in ether at 0 °C is unchanged on irradiation even for rather long periods (several days). However, at 20 °C a photoisomer $C_{16}H_{16}$ *(3)* [5] of m.p. 92 °C is obtained. When 2 g of *(1)* in 350 ml of ether is irradiated with a Philips high-pressure lamp HPK 125 W for 30 h, 0.8 g of pure *(3)* can be isolated. Its UV spectrum [6] shows several shoulders and a main band at 261 nm (ε = 8500) that is flanked by side bands. The NMR spectrum [6] discloses twelve olefinic (multiplet around τ = 4.45) and four aliphatic protons (pseudosinglet at τ = 6.8). Catalytic hydrogenation over Pd/C affords $C_{16}H_{28}$ [5].

On treatment with $KOC(CH_3)_3$ in dimethyl sulfoxide, both *(2)* and *(3)* yield 5,6,11,12-tetrahydrodibenzo[*a*,*e*]cyclooctatetraene *(4)* [5,7], and on dehydrogenation with chloranil yield dibenzo[*a*,*e*]cyclooctatetraene *(5)* [5,7] (yield in both cases, 60–70 %).



Compounds *(2)* and *(3)* are thus 4a,6a,10a,12a-tetrahydrodibenzo[*a*,*e*]cyclooctatetraene *(6)* and can differ only in their stereochemistry. Five isomers, *(6a)–(6e)*, are possible.

Which stereoisomers are we dealing with? – The products *(2)* and *(3)*, being 1,3-cyclohexadiene systems, should form Diels-Alder adducts. A diadduct $C_{28}H_{28}O_8$ [5], m.p. 232 °C (yield > 90 %), is formed surprisingly easily from *(3)* and dimethyl acetylenedicarboxylate (ADE) at 30–40 °C. A monoadduct $C_{22}H_{22}O_4$ [5], m.p. 93–94 °C, is obtained only when very dilute solutions and a several-fold excess of *(3)* [*e.g.* *(3)* 5.1 g, ADE 1.3 g, benzene 130 ml] at 65 °C are used [yields around 48 % calc. on the amount of *(3)* that reacts]. In the NMR spectra of the mono- and the di-adduct, the methyl protons of the ester groups give two singlets of equal intensity at τ = 6.2, which are separated by *ca.* 1.2 Hz. This results enables us to exclude the stereoisomers *(6a)*, *(6b)*, and *(6c)*. The methyl protons of the ADE adducts of *(6a)* and *(6c)* would be expected to give rise to one singlet, and those of the adduct of *(6b)* to give several singlets. Thus for the photoisomer *(3)* the decision lies between *(6d)* and *(6e)*. This is aided by the observation that formation of the diadduct is preferred to that of the monoadduct, a fact that is in accord only with the all-*trans*-configuration of the bridgehead protons as in *(6e)*. The photoisomer *(3)* is therefore *(6e)*.

The thermal isomer *(2)* does not react with ADE in a readily interpretable manner. This negative finding can be accommodated only by formula *(6c)* [8]. Consideration of models shows that the action radii of the two H atoms lying above the plane in the conformation with planar six-membered rings penetrate the π-orbitals of the other six-membered ring. The molecule will thus avoid this high-energy conformation which, however, is essential for a Diels-Alder reaction.

The behavior of [16]annulene on being warmed and on UV irradiation can be coordinated and understood on the basis of the Woodward-Hoffmann rule[9].

Structure *(1)* shows great conformational mobility[11]. Equilibration of *(1)* with *(1a)* is immediately understandable. The electrocyclic reactions of the two cisoid triene systems of *(1a)* are disrotatory in the thermal reaction and conrotatory in the photochemical reaction. The molecule undergoes two electrocyclic reactions in going from *(1a)* to *(6c)* or from *(1a)* to *(6e)*, and there are two possibilities for the second step: it can be in the same or in the opposite sense relative to the first. The opposing sense is dominant. However, we cannot yet decide whether the electrocyclic reactions of [16]annulene induced thermally or photochemically are synchronous or asynchronous.

Preparation of Carbonyl and Fluorocarbonyl Pseudohalides in Molten Salts

By *W. Verbeek* and *W. Sundermeyer*[*]

When carbonyl fluoride is passed into a melt of lithium chloride and potassium chloride containing *ca.* 10 wt.-% of dissolved potassium cyanate at 400 °C, carbonyl diisocyanate *(1)*[1] and fluorocarbonyl isocyanate *(2)*[2], in the wt. ratio 78:22, are obtained in quantitative yield (calculated on the COF_2 consumed).

$$COF_2 + 2\,KOCN \rightarrow OC(NCO)_2 + 2\,KF \quad (1)$$

$$COF_2 + KOCN \rightarrow FCO(NCO) + KF \quad (2)$$

With lower concentrations of potassium cyanate the proportion of *(2)* becomes higher.

Compound *(1)* is a colorless liquid (m.p. −50.5 °C, b.p. 104 °C). It was identified by elemental analysis, IR spectrometry[11], and mass spectrometry. Alongside the molecular ion at $m/e = 112$, fragments occur at $m/e = 70$ (OCNCO), 42 (NCO), and 28 (CO). At room temperature, pure *(1)* polymerizes within a few days to a white crystalline solid, which is reconverted quantitatively into monomeric *(1)* when heated in a high vacuum to above 150 °C.

When carbonyl fluoride is passed into an equimolar potassium thiocyanate/sodium thiocyanate melt at *ca.* 140 °C, fluorocarbonyl isothiocyanate *(3)*[3] is obtained in 20 % yield.

$$COF_2 + KSCN \rightarrow FCO(NCS) + KF \quad (3)$$

Decomposition products are also formed, which are apparently derived from the carbonyl isothiocyanate that is formed as intermediate. *(3)* is a colorless liquid (m.p. −74 °C, b.p. 65.6 °C), which becomes yellow on storage. The compound was identified by elemental analysis and by mass spectrometry [m/e = 105 (molecular ion), 73 FCO(NC), 47 COF, 28 CO]. Its IR spectrum contains bands at 2049 (vs), 1961 (vs), 1848 (vs), 1232 (vs), 1010 (vs), 759 (m), 689 (m), and 635 (m) cm^{-1} [3a]. The vapor pressure curve accords with the equation

$$\log p = -17.697/T + 7.89$$

(Trouton constant 25.7). The ^{19}F–NMR spectrum includes a signal at −16.3 ppm (referred to $CFCl_3$ as external standard, −40 °C).

Compound *(3)* was also obtained, in quantitative yield, by treatment of trimethylsilyl isothiocyanate with carbonyl fluoride at 50 °C in an autoclave.

$$(CH_3)_3SiNCS + COF_2 \rightarrow FCO(NCS) + (CH_3)_3SiF \quad (3)$$

When carbonyl fluoride is passed into a lithium chloride/potassium chloride melt (LiCl:KCl = 58:42 mole-%) containing 10 wt.-% of dissolved potassium cyanide at 400 °C, a small yield of carbonyl dicyanide *(4)*[4] is obtained.

$$COF_2 + 2\,KCN \rightarrow OC(CN)_2 + 2\,KF \quad (4)$$

The expected fluorocarbonyl cyanide *(5)*[5] was, however, obtainable only by reaction of trimethylsilyl cyanide with carbonyl fluoride.

$$(CH_3)_3SiCN + COF_2 \rightarrow FCO(CN) + (CH_3)_3SiF \quad (5)$$

Reaction in an autoclave at room temperature gives only a 26 % yield. Compound *(5)* is a colorless liquid (m.p. −85 °C, b.p. −14.4 °C). The molecular weight was deduced by Dumas' method and from the mass spectrum. The ^{19}F–NMR spectrum includes a signal at −47.5 ppm (referred to $CFCl_3$ as external standard, −40 °C). The IR spectrum contains

bands at 2232 (s), 1852 (vs), 1156 (vs), 822 (m), 728 (m), and 547 (m) cm^{-1} [3a]. The vapor pressure curve accords with the equation

$$\log p = -1464/T + 8.54$$

(Trouton constant 25.9).

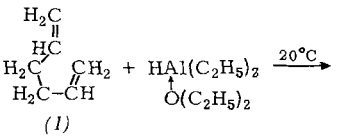
Diethyl-(5-hexenyl)aluminum-Ether [1]

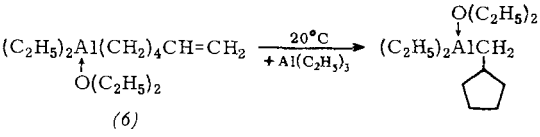
By *R. Rienäcker* and *G. F. Göthel* [*]

On reaction of dialkylhydridoaluminum with 1,5-hexadiene *(1)*, *Ziegler* and *Gellert* [2] obtained the dialkyl(cyclopentylmethyl)aluminum *(3)* and methylenecyclopentane *(4)*. This cyclization can be regarded as an intramolecular analogue of the dimerization of α-olefins [3]. The dialkyl-(5-hexenyl)aluminum postulated as first intermediate has not been detected previously.

(1) *(2)*



(3) *(4)*



We have found that even at low temperatures ring closure is very much faster than addition of dialkylhydridoaluminum to the terminal double bonds. Thus on reaction of diethylhydridoaluminum *(5)* with an excess of *(1)* at 0 °C (experiment a) and hydrolysis, we found, alongside unchanged *(1)*, methylcyclopentane as almost the sole C_6 hydrocarbon.

If, however, the reaction is carried out with the ether adduct of *(5)* at 20 °C, no ring closure occurs and diethyl-(5-hexenyl)aluminum-ether *(6)* can be isolated (experiment b). The IR spectrum of this product shows intense absorption at 1638 cm^{-1} ($\nu_{C=C}$), which is not present in the IR spectrum of the product from experiment a. Obviously, intramolecular cyclization is prevented or strongly hindered when a lone pair of electrons of ether fills the vacancy in the octet of the aluminum in diethyl-(5-hexenyl)aluminum.

In a third experiment (experiment c) the product *(6)* was converted quantitatively into *(3)* (R = ethyl) by addition of catalytic amounts of $Al(C_2H_5)_3$ at room temperature (slight evolution of heat) (IR spectrum: no vinyl absorption). The ring closure occurs after exchange of ether molecules between *(3)* and $Al(C_2H_5)_3$.

(1)

(6)

Composition of the C_6 hydrocarbons of the hydrolysed products, without consideration of the excess of *(1)*. Gas-chromatographic analysis (mol.-%).

Experiment	a	b	c
n-Hexane	1.9	6.2	6.3
1-Hexene	4.1	92.7	0.2
Methylcyclopentane	94.0	1.1	93.5

Oxidation [4] of *(6)* by air at room temperature and subsequent hydrolysis afforded 5-hexen-1-ol, b.p. 60 °C/10 mm, n_D^{20} = 1.4355 (n_D^{20} = 1.4355 [5]). Similarly, from *(3)* we obtained cyclopentylmethanol, b.p. 87 °C/36 mm, n_D^{20} = 1.4578 (n_D^{20} = 1.4552 [6]).

Transannular 1,4-Hydrogen Bridges in Thiepanols [1]

By *R. Borsdorf, H. Kasper*, and *H.-D. Repp* [*]

According to *Lüttringhaus et al.* [2] an intramolecular hydrogen bridge between the OH group and the sulfur of thianols (thiacyclohexanols) is formed only when the substituents are in the 1,3-position. We have found that in thiepanols (thiacycloheptanols) a hydrogen bridge between the sulfur and the OH group is formed also if these are in the 1,4-position.

(1) *(2)* *(3)* *(4)* *(5)*

(a), R = H; *(b)*, R = CH_3; *(c)*, R = $CH(CH_3)_2$

We obtained mixtures of 4-alkylthiepan-3-ones *(2)* and 3-alkylthiepan-4-ones *(3)* on ring expansion[3] of thian-3-one *(1)* by diazo-methane, -ethane, or -isobutane. These products were separated by distillation through a spinning-band column. Reduction with $LiAlH_4$ led to the alcohols *(4)* and *(5)*. When R = CH_3 or $CH(CH_3)_2$ the reduction gave mixtures of *cis-trans*-alcohols from which the pure *cis*-isomers were isolated by chromatography on silica gel with benzene/ethyl acetate.

The IR spectra of compounds *(4a)* and *(5a)* in CCl_4 ($<10^{-2}$ mole/l) each contained two ν_{O-H} bands – *(4a)* at 3623 and 3489 cm^{-1}, *(5a)* at 3623 and 3496 cm^{-1}, which shows that in both cases an equilibrium must be set up between a transannular-associated (lower frequency) and a non-associated conformation (higher frequency).

In *cis-(4b)*, *cis-(5b)*, *cis-(4c)*, and *cis-(5c)* the proportion of transannular-associated conformation is greater than in *(4a)* and *(5a)*. Thus the pseudoaxial position of the OH groups, which according to considerations of a model is necessary for transannular association, is favored by the alkyl group in the *cis*-position to the neighboring hydroxyl group.

Synthesis of Tetramethylcyclobutadienenickel(II) Bromide with a New Nickel(0) Complex

By *G. Henrici-Olivé* and *S. Olivé*[*]

Transition metal salts such as VCl_3, $CrCl_3$, $NiBr_2$, and $PtCl_4$ can be reduced in tetrahydrofuran (THF) with lithium naphthalide (LiNp). On slow addition of the metal salt solution to the naphthalide[1,2], very stable, dark solutions of the corresponding reduced metals are obtained.

The high stability of these solutions can be interpreted on the assumption of complex formation of the reduced metal with naphthalene, and hydrogen transfer from the hydrocarbon to the metal[2]. Such complexes can carry up to 6 negative charges. Results of deuterolysis and EPR evidence suggest structure *(1)*[2]. ($0 \leqslant n \leqslant 2$; S = solvent; m = number of solvent molecules required as ligands by the corresponding symmetry of the metal complex. $x \leqslant 6$ = number of negative charges. The greater the excess of naphthalide the higher the value of x.)

(1)

Although the stable solutions do not contain the metal in colloidal form, minor amounts of colloidal metal are formed as a by-product, particularly during the reduction of transition metals with high population of the d orbitals[2].

Several species *(1)* having different values of x may be present in equilibrium. If the excess of LiNp is small, the bisarene complex ($n = x = 0$) takes part in the equilibrium, as EPR measurements with vanadium[2] and chromium[2a] have shown.

In the complexes *(1)*, transition metals behave as highly reactive metal(0) species, as in the metal carbonyls. The reaction of the nickel complex with tetramethylcyclobutene dibromide (TCD) to give tetramethylcyclobutadienenickel(II) (TCNi) clearly demonstrates this similarity. *Criegee et al.* prepared the chloride[3] and bromide[4] of $(TCNi)^{2+}$ from $Ni(CO)_4$; prolonged heating of the reactants was required. With the complex *(1)*, however, the reaction took a few minutes at room temperature, giving TCNi in quantitative yield (referred to reacted nickel).

A solution of $NiBr_2$ in THF (concentration 1.2×10^{-2} mole/l) is added to a solution of LiNp in THF (concentration 7×10^{-2} mole/l, 5 % excess over the amount necessary for the reduction Ni(II) → Ni(0)). An excess of TCD is then added under argon. Within 10–15 minutes at room temperature, the color changes from brown-black to dark violet. Elimination of the solvent from the filtered solution and extraction of the residue with water lead to the isolation of the complex salt $TCNiBr_2$.

Visible and IR spectra[4] as well as precipitation of the complex cation with sodium dicyanoethylenedithiolate[3] established the identity of the compound. Recrystallization from chloroform-butanol (1:1) gave solvent-free fine needles[5]. X-ray analysis on single crystals afforded the following crystallographic data: $a = 16.2$ Å, $b = 8.5$ Å, $c = 17.5$ Å, $\beta = 108°$; volume of the unit cell = 2292 Å^3; space group $P2_1/n(C_{2h}^5$, No. 14); 8 molecules in the unit cell[**]. Thus the dibromide appears isomorphous with the dichloride as reported by *Dunitz et al.*[5].

Another reaction in which the reported complexes behave in a similar manner to the carbonyls is the initiation of radical polymerization[6].

Compared with the carbonyls, the Me(0) complexes have the advantage that they are easier and safer to handle as well as more reactive.

Nitrogen Fixation on New Transition Metal Complexes

By *G. Henrici-Olivé* and *S. Olivé*[*][**]

A number of the complexes that are obtained on reduction of a transition metal salt with lithium naphthalide (LiNp) in tetrahydrofuran (THF)[1–3] are capable of fixing and reducing molecular nitrogen. The ability to do this increases with the number of electrons carried by the complex (*i.e.* with increasing excess of LiNp) and, in favorable cases, results in the fixation of one N_2 molecule per molecule of metal complex. Since the number of electrons stored within the complex reaches a maximum of 6 per metal atom[2,3], it can be assumed that the nitrogen is present as N^{3-} in the complex:

$$N_2 + 6e \rightarrow 2\,N^{3-} \qquad (1)$$

The results of some fixation experiments are shown in Table 1 (20 °C, duration of reaction of N_2 with the complex in THF = 30 min).

Table 1. Nitrogen fixation on reduced transition metal salts in solution.

Salt	LiNp/ metal	N_2-pressure (atm)	NH_3/ metal
VCl_3	3	120	0.9
	5	120	1.2
	7	120	2.0
	10	1	0.9
$CrCl_3$	10	120	1.2
	10	1	0.4
$TiCl_4$ [a]	10	120	1.3
	15	120	1.7

[a] In toluene.

The solution of the metal salt was added to that of LiNp under N_2. After half an hour the reaction mixture was hydrolysed and analysed for ammonia according to reference [4]. At higher pressures, an ampoule containing the salt solution was broken (by the stirrer) in a solution of LiNp in an autoclave at the desired N_2 pressure No NH_3 was found in LiNp solution alone (120 atm, 24 h).

The mechanism of fixation and reduction indicated in eq. (1) finds support in the results of hydrolysis experiments. The electrons stored in the complex are consumed in decomposing water when the complex is hydrolysed. Thus the volume of hydrogen produced on hydrolysis gives an indication of the number of electrons available [2]. If the complexes are prepared under nitrogen the number of hydrogen atoms evolved on hydrolysis will be reduced by a quantity equal to the number of electrons that have been consumed in reducing the molecular nitrogen. This behavior is shown in Table 2. The ratio NH_3/metal in the last column was calculated according to equation (2), which follows from eq. (1):

$$NH_3/\text{metal} = 2\ (a-b)/3 \qquad (2)$$

Table 2. Hydrolysis of solutions of transition metals reduced under argon and under nitrogen.
LiNp/metal = 10; T = 20 °C; N_2-pressure = 1 atm.

Metal	H_2/metal under Ar = (*a*)	H_2/metal under N_2 = (*b*)	NH_3/metal (exp.)	NH_3/metal (calc.)
V	3.1	1.9	0.9	0.8
Cr	3.6	2.8	0.4	0.5
Ni	2.0	2.0		

It is worthy of note that Ni solutions, which under the given conditions did not fix any nitrogen, evolved the same amount of hydrogen when reduced under nitrogen as when reduced under argon.

Fixation of nitrogen under mild conditions by non-enzymatic systems which are based on transition metal salts and reducing agents such as Al-alkyls, Grignard compounds, or $LiAlH_4$ has been extensively investigated by *Volpin et al.* [4,5]. The highest yield was reported for the system bis(cyclopentadienyl)titanium dichloride/ethylmagnesium bromide, where 0.47 molecules of nitrogen per Ti atom were detected [5] after 31 hours at 150 atm nitrogen pressure.

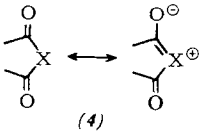
Preparation of Maleic Thioanhydride [**]

By *H.-D. Scharf* and *M. Verbeek* [*]

Attempts to prepare maleic thioanhydride *(3)* have hitherto failed [1]. We have now succeeded in finding a method for preparing this substance and for studying its properties [2].



(1) *(2)* *(3)*

Starting from the readily accessible 1,2,3,6-tetrahydrophthalic anhydride *(1)*, we prepared the hitherto unknown thio derivative *(2)* as follows: The anhydride and $Na_2S_x \cdot 9H_2O$ were triturated in a mortar and then poured into 10 % hydrochloric acid; the thioanhydride *(2)* was extracted with ether and isolated by vacuum distillation in 40 to 50 % yield with b.p. 81–83 °C/0.1 mm [3]. It solidified to colorless crystals which melt at 29 °C [3]. It is sparingly soluble in toluene, from which it recrystallizes at room temperature. On treatment with an aqueous suspension of mercury(II) oxide it is converted into the known *cis*-1,2,3,6-tetrahydrophthalic acid. In the IR spectrum of *(2)* (in $CHCl_3$), the carbonyl vibration is at 1710 cm^{-1}, being shifted by 70 cm^{-1} towards lower wavenumbers in comparison with *(1)*.

Thermal retro-diene fission of *(2)* in an electrically heated quartz tube (2.5 cm × 30 cm) at 430 to 450 °C with nitrogen as carrier gas (between 6.0 and 6.2 liter/h) leads to maleic thioanhydride *(3)* with *ca.* 50 % conversion and more than 90 % selectivity. The mixed product contains small amounts of decomposition products with, mainly, the thioanhydrides *(2)* and *(3)*, which are separated by distillation. The compound *(2)* recovered is used for further cleavage experiments.

The thioanhydride *(3)* boils at 72–74 °C/10 mm [3]; it solidifies to pale yellow, translucent crystals of m.p. 28 °C [3]. It becomes deep brownish-yellow in air and is sensitive to moisture. UV absorption (in n-hexane): 318 nm (ε = 620) and 230 nm (ε = 9300). NMR spectrum ($CDCl_3$, tetramethylsilane as internal standard): the signal of the two protons is at τ = 2.8 (maleic anhydride, τ = 2.85). IR spectrum ($CHCl_3$): *(3)* shows typical anhydride splitting ($\Delta\gamma$ = 40 cm^{-1}) of the carbonyl vibration at 1690 cm^{-1} (high intensity) and 1730 cm^{-1} (low intensity); these bands are both shifted by *ca.* 100 cm^{-1} to lower wavenumbers in comparison with maleic anhydride ($\Delta\gamma$ = 70 cm^{-1}) at 1780 cm^{-1} (high intensity) and 1850 cm^{-1} (low intensity) [4].

(4)

According to *Mirone* and *Chiorboli* [5] the fairly large splitting of the IR carbonyl bands of maleic anhydride is due to participation of polar limiting structures (cf. *(4)*). In *(3)*

participation of such polar resonance forms must therefore be small.

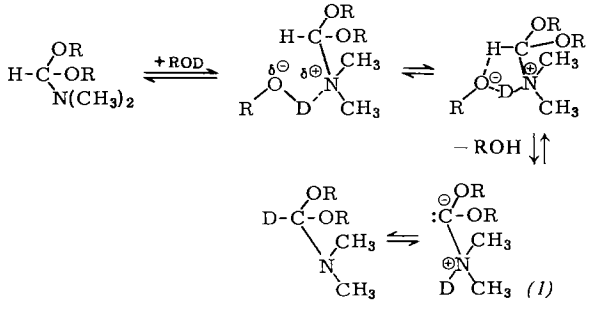
H/D Exchange in *N,N*-Dimethylformamide Acetals and Orthoformic Esters [**]



By *G. Simchen, S. Rebsdat,* and *W. Kantlehner* [*]

In connection with electrophilic substitution at the formyl-carbon atom of orthoformamides[1] we have studied the kinetic acidity of the formyl-hydrogen atom by means of H/D exchange reactions. It is known that the H atom of chloroform can be exchanged for deuterium within a few hours in the presence of bases[2], whereas analogous experiments with orthoformic esters were negative[3]. It was thus all the more surprising that, when dissolved in deuterioalcohols, most *N,N*-dialkylformamide acetals exchange their formyl proton for deuterium within a few minutes. The rate of exchange depends on the acidity of the alcohol used.

Overall velocity constants R^+ (sec^{-1}) [4] for H/D exchange between amide acetals and deuterated alcohols.

N,N-Dimethylformamide acetal	R in ROD	R^+
Dimethyl acetal	CH_3	1.63×10^{-2}
Diethyl acetal	C_2H_5	1.37×10^{-2}
Di-n-propyl acetal	n-C_3H_7	1.10×10^{-2}
Diisopropyl acetal	iso-C_3H_7	0.90×10^{-2}
Di-n-butyl acetal	n-C_4H_9	0.78×10^{-2}

The exchange reactions could be followed by NMR spectroscopy, using the diminishing CH-proton signal and the increasing intensity of the OH-proton signal of the alcohol formed. We assume that the exchange occurs by way of an ylide *(1)*.

(1)

We found that trimethyl orthoformate exchanges its formyl-hydrogen for deuterium if deuteriomethanol is allowed to react with the ester in the presence of deuterated sulfuric acid.

Synthesis and Properties of Diphenylphosphinous Amide

By *O. Schmitz-Du Mont, B. Ross,* and *H. Klieber* [*]

On ammonolysis of the triphenyl derivatives of arsenic, antimony, and bismuth in liquid ammonia in the presence of KNH_2 all the phenyl groups are removed as benzene to give $K[As(NH)_2]$, $K[Sb(NH)_2]$, and BiN, respectively[1]. Triphenylphosphine behaves differently. Even when it is heated in an autoclave at 130 °C, only one C_6H_5 group is eliminated as benzene, and the potassium salt *(1)* of diphenylphosphinous amide results:

$$P(C_6H_5)_3 + KNH_2 \rightarrow \underset{(1)}{(C_6H_5)_2PNHK} + C_6H_6$$

Treatment of *(1)* with NH_4Cl in liquid NH_3 affords the free amide *(2)*:

$$(C_6H_5)_2PNHK + NH_4Cl \rightarrow \underset{(2)}{(C_6H_5)_2PNH_2} + KCl + NH_3$$

This amide is also formed on ammonolysis of $(C_6H_5)_2PCl$ *(3)*[2]. It is obtained in a very pure state by reaction of *(3)* with a solution of KNH_2 in liquid NH_3:

$$\underset{(3)}{(C_6H_5)_2PCl} + KNH_2 \rightarrow \underset{(2)}{(C_6H_5)_2PNH_2} + KCl$$

Diphenylphosphinous amide *(2)* is an almost colorless oil (m.p. −54 °C), which is very soluble in liquid NH_3 and on cooling to −76 °C crystallizes in large needles. When warmed it eliminates NH_3 even below 100 °C, losing 0.5 mol. equiv. within 24 h at 150 °C with formation of tetraphenyldiphosphazane *(4)*[3]:

$$2\ \underset{(2)}{(C_6H_5)_2PNH_2} \rightarrow \underset{(4)}{(C_6H_5)_2P{-}NH{-}P(C_6H_5)_2} + NH_3$$

When recrystallized from benzene this product melts at 152 °C; it is difficulty soluble in liquid NH_3 but dissolves more readily on addition of KNH_2 indicating salt formation.

Hydrolysis of *(2)* in the presence of HNO_3 affords diphenylphosphinic acid $(C_6H_5)_2PO(OH)$.

Addition of R_3Ge and R_3Si Radicals to Multiple Bonds

By *K. Kühlein, W. P. Neumann*, and *H. P. Becker* [*]

Compounds $(R_3Ge)_2Hg$ *(1)*, which are quite stable thermally, react rapidly and exothermally with radical trapping agents even at room temperature, *e.g.* [1,2]:

$$[(C_2H_5)_3Ge]_2Hg + I_2 \xrightarrow{-Hg} 2\,(C_2H_5)_3GeI$$

$$+ \tfrac{1}{2}\,O_2 \xrightarrow{-Hg} (C_2H_5)_3Ge\text{-}O\text{-}Ge(C_2H_5)_3$$

$$+ BrCH_2\text{-}CH_2\text{-}Br \xrightarrow{-Hg} 2\,(C_2H_5)_3GeBr + H_2C{=}CH_2$$

It thus follows that induced decomposition is possible in which trialkylgermyl radicals occur as intermediates; this has been demonstrated by ESR spectroscopy [3].

We have now found that *(1)*, R = C_2H_5 [4], also reacts readily with compounds that contain C=C, C≡C, or N=N groups. The triethylgermyl groups always add to the unsaturated system with separation of Hg. Silyl compounds $[(CH_3)_3Si]_2Hg$ *(2)* react similarly [5,6]. Tables 1 and 2 present a selection of the compounds prepared.

We treated 10 mmoles of each compound listed in the tables with 10 mmoles of *(1)* or *(2)* under the conditions stated. The mercury was then syphoned off and the mixture was worked up by fractional distillation for distillable products and by crystallization from ethanol or acetonitrile for solid products. All the adducts were identified by C, H, N analyses and IR spectra, and most of them by hydrolysis with C_2H_5OH/H_2O (1:1) or by reaction with acyl chlorides.

Yields were generally very good. Polymerization and abstraction reactions competed, but with phenylacetylene only polymerization took place. Although only 1,2-addition normally occurred, with ethylenetetracarboxylic and 2-cyano-3-methylcrotonic ester we observed 1,4-addition to give the corresponding ketene acetals.

At least part of the additions occurs by way of radicals: ESR signals [3] were found during the four reactions with acetylenedicarboxylic and ethylenetetracarboxylic ester.

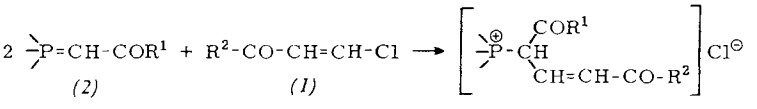
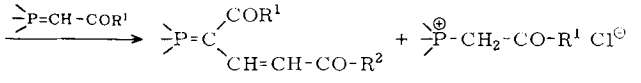
Reaction of Phosphorylides with 2-Chlorovinyl Ketones [1]

By *Elisabeth Werner* and *E. Zbiral* [*]



2-Chlorovinyl ketones *(1)* react readily with nucleophiles [2] thus:



$$R\text{-}CO\text{-}CH{=}CH\text{-}Cl + B^{\ominus} \rightarrow RCOCH{=}CH\text{-}B + Cl^{\ominus}$$

(1)

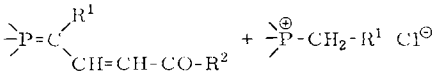
Both stabilized phosphorylides *(2)* and alkylphosphorylides *(4)* can be alkylated by compounds of type *(1)*. The phosphonium salt formed as intermediate at once reacts further with a second molecule of the ylide used, undergoing transylidation [3].

The small yields from the ylides *(3d)* and *(3e)* (R^1 = alkyl group) are probably attributable to the *O*-alkylation [4] that predominates.

(3)

	R^1	R^2	Yield (%)	M.p. (°C)
(3a)	$-OC_2H_5$	$-CH_3$	49.4	172–175 [a]
(3b)	$-OC_2H_5$	$-CH_2CH_3$	81.4	170–171 [a]
(3c)	$-OC_2H_5$	$-CH(CH_3)_2$	90.0	138–140 [b]
(3d)	$-CH_3$	$-CH_3$	18.2	174–176 [a]
(3e)	$-CH_3$	$-CH(CH_3)_2$	20.7	146–148 [b]

[a] From ethyl acetate/cyclohexane (1:1).



[b] From ether.

The compounds of type *(3)* are vinylogues of the diacylalkylidenephosphoranes prepared by *Horner* [5]. Whereas these no longer give salts, compounds *(3)* still dissolve in dilute HCl and can be precipitated therefrom. Hand in hand with this goes their ability to undergo a Wittig reaction with reactive aldehydes (*e.g.* phenylglyoxal).

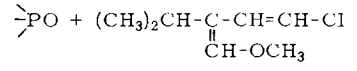
Reaction of alkylphosphorylides *(4)* with 2-chlorovinyl ketones has been successful when $R^1 = C_6H_5\text{-}S-$, C_6H_5-, $C_6H_5\text{-}CH_2-$, and $CH_3CH{=}CH-$.

(4) *(1)*

(5)

	R^1	R^2	Yield (%)	M.p. (°C) [a]
(5a)	$C_6H_5\text{-}S-$	CH_3CH_2-	25.8	188–189
(5b)	$C_6H_5\text{-}S-$	$(CH_3)_2CH-$	87.5	235–237
(5c)	$C_6H_5\text{-}S-$	C_6H_5-	66.3	218–220
(5d)	C_6H_5-	CH_3CH_2-	72.5	216–218
(5e)	C_6H_5-	$(CH_3)_2CH-$	87.0	227–229
(5f)	$C_6H_5CH_2-$	$(CH_3)_2CH-$	36.0	185–188
(5g)	$CH_3CH{=}CH-$	$(CH_3)_2CH-$	26.2	160–162 [b]

[a] All the compounds melt with decomposition and, except for *(5g)*, were recrystallized from acetonitrile.



[b] Recrystallized from cyclohexane.

The reaction leading to *(5g)* with α-alkylation is remarkable. In such cases reaction with an acid chloride occurs with γ-alkylation [6].

(Methoxymethylene)triphenylphosphorane *(6)* and 2-chlorovinyl isopropyl ketone do not give a phosphorylide under these conditions, but instead a Wittig reaction occurs:

(6)

The structures of the compounds recorded were proved by elemental analyses and IR and NMR spectra.

Compounds (3a)–(3e)

To the ylide *(2)*, dissolved in anhydrous benzene, the 2-chlorovinylketone [0.5 mole for each mole of *(2)*] is added and refluxed for 5–10 hours. After cooling to room temperature the phosphonium salt is filtered off, the solution is washed well with water, dried over Na_2SO_4, and evaporated. After wetting with ether the ylides *(3)* usually crystallize on scratching.

Compounds (5a)–(5g)

The ylide is prepared by adding the corresponding volume of an etheral C_6H_5Li solution to a well stirred suspension of phosphonium salt $(C_6H_5)_3\overset{\oplus}{P}\text{–}CH_2R_1X^{\ominus}$ in anhydrous ether. After the addition of β-chlorovinylketone in ethereal solution stirring is continued for 10–15 minutes at room temperature. Then the two to threefold quantity of benzene is added and the mixture refluxed for one hour. After cooling to room temperature the solution is shaken with water and any undissolved residues are filtered off. The organic layer is dried over Na_2SO_4 and evaporated. The compounds *(5)* crystallize on wetting with ether.

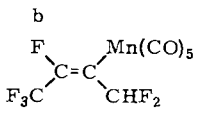
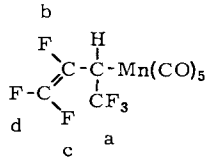
Formation of Fluoroorganocarbonylmanganese and -rhenium Complexes from Hexafluoro-1,3-butadiene and Pentacarbonylmanganese and -rhenium Hydrides

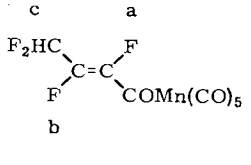


By *B. W. Tattershall, A. J. Rest, M. Green*, and *F. G. A. Stone*[*]

When tetrafluoroethylene reacts with carbonyl(transition metal) hydrides, the $F_2C{=}CF_2$ group is inserted into the metal-hydrogen bond forming, for example, $F_2HCCF_2Mn(CO)_5$[1], $(F_2HCCF_2)_2Fe(CO)_4$[2], and $F_2HCCF_2Co(CO)_4$[3].



Treatment of hexafluoro-1,3-butadiene with pentacarbonylrhenium hydride at room temperature affords a volatile white crystalline complex *(1a)*[4] (yield 45%), the proposed structure being in accord with the infrared (ν(CO), 2142(s), 2067(m), 2038(vs), 2008(vs); ν(C=C–Re), 1638(m) cm^{-1}), ^{19}F-NMR (multiplets at 102.6(F_a), 118.7(F_c), 138.2(F_d), and 159(F_b) ppm, with relative intensity 1:2:2:1; $J_{a,b}$ = 129.5 and J_{d-H} = 53.4 Hz), and ^{1}H-NMR (τ = 4.05; J_{H-d} = 53.4 Hz) spectra.



(1a), M = Re
(1b), M = Mn

(2)

(3)

(4)

In contrast, pentacarbonylmanganese hydride and hexafluoro-1,3-butadiene react rapidly at 0 °C to give several complexes with fluoroorganomanganese groups of a hitherto unknown type, as well as a mixture of *cis*- and *trans*-1,1,2,3,4,4-hexafluoro-2-butene. The nature of compounds *(1b)–(4)* was established by elemental analysis, mass spectrometry, and examination of their IR and NMR spectra: *(1b)*, yield 8%, ν(C=C–Mn) 1637(m) cm^{-1}; ^{19}F-NMR multiplets at 97.6(F_a), 118.6(F_c), 137.6(F_d), and 160.2(F_b) ppm, with relative intensity 1:2:2:1, J_{ab} = 126.5, J_{d-H} = 53.5 Hz; ^{1}H-NMR spectrum showed one band at τ = 4.06, J_{H-d} = 53.5 Hz.

(2), yield 15%, ν(C=C–Mn) 1648(sh), 1630(m) cm^{-1}; ^{19}F-NMR multiplets at 63.1(F_c), 81.4(F_b), and 93.5(F_a) ppm, with intensity 3:1:2, J_{a-H} = 60.0 Hz; ^{1}H-NMR showed a band at τ = 3.2, J_{H-a} = 60.0 Hz.

(3), yield 9%, ν(C=C–C–Mn) 1773(m) cm^{-1}; ^{19}F-NMR bands at 57.0(F_a), 107.1(F_d), 119.3(F_c), and 161.0(F_b) ppm, of intensity 3:1:1:1; ^{1}H-NMR showed a quartet split into a doublet of doublets at τ = 7.22.

(4), yield 13%, ν(C=C) 1674(m), ν(COMn) 1597(m) cm^{-1}; ^{19}F-NMR multiplets at 125.8(F_c), 144.5(F_a), and 170.9(F_b) ppm, with intensity 2:1:1, J_{ab} = 129.0, J_{cb} = 18.6, J_{c-H} = 51.8, and J_{b-H} = 14.6 Hz; ^{1}H-NMR spectrum showed one band at τ = 3.60, J_{H-c} = 51.8 and J_{H-b} = 14.6 Hz.

Complexes *(1a)* and *(1b)* correspond to a reaction involving 1,4-addition of the hydride to hexafluoro-1,3-butadiene, followed by a 1,3-fluorine shift:

$$F_2C{=}CF{-}CF{=}CF_2 + HMn(CO)_5 \rightarrow [F_2HC{-}CF{=}CF{-}CF_2{-}Mn(CO)_5] \rightarrow \textit{(1b)}$$
(5)

Evidence for the intermediacy of the insertion product *(5)* is provided by the isolation of 1,1,2,3,4,4-hexafluoro-2-butene, which could form by reaction of *(5)* with $HMn(CO)_5$[3]. Since the fluoroolefin is formed as a mixture of isomers, the 1,4-addition to give *(5)* cannot be stereospecific, and a cyclic concerted mechanism for the addition is unlikely. A two-stage process involving a resonance-stabilized allylic intermediate seems more probable.

Compound *(2)* appears to arise through 1,2-addition, followed by a 2,4-fluorine shift; while formation of *(3)* could involve 1,2-addition and then a hydride shift. It is suggested that the acyl complex *(4)* is produced by the capture by water of an allylic intermediate involved in the transformation of *(5)* to *(1b)*.

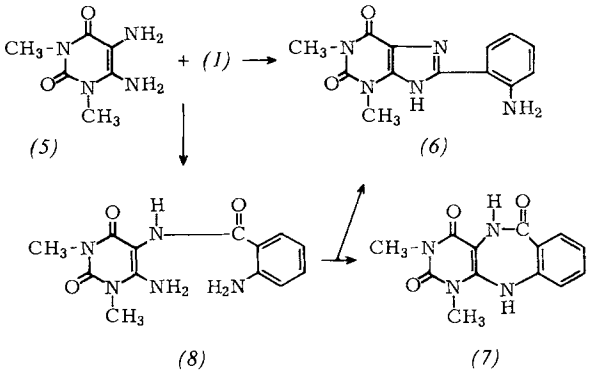
Condensed Imidazoles from *o*-Diamines and Isatoic Anhydrides

By *E. C. Taylor* and *F. Yoneda*[*]

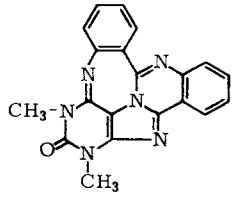
2-(*o*-Aminophenyl)benzimidazoles *(3)* and 6,7-dihydrobenzimidazo[1,2-*c*]quinazolin-6-ones *(4)* are formed when *o*-phenylenediamine *(1)* is heated with isatoic anhydrides *(2)* under gentle reflux for 20 minutes in sulfolane as solvent followed by cooling and dilution with water. *(3)* dissolves in boiling ethanol from which it is precipitated on dilution with water; it may be recrystallized from aqueous ethanol. *(4)* is purified by recrystallization from aqueous dimethylformamide.



(2) *(1)* *(3)* *(4)*

	R	R'	*(3)* M.p. (°C)	*(3)* Yield (%)	*(4)* M.p. (°C)	*(4)* Yield (%)
a	H	H	213 [1]	68	334 [3]	20
b	Cl	H	244 [2]	56	>340	30
c	NO_2	H	295 (decomp.)	39	>350	57
d	H	CH_3	213	95	—	0
e	Cl	CH_3	175	90	—	0
f	NO_2	CH_3	315 (decomp.)	85	—	0
g	H	C_2H_5	124	85	—	0
h	H	$CH_2C_6H_5$	188	88	—	0

A remarkable solvent effect was found when *(1)* and *(2a)* were heated under gentle reflux for 30 minutes in dimethyl sulfoxide; the major product was benzimidazolone (69%), with only a minor amount (17%) of *(4a)* formed.



Reaction of 1,3-dimethyl-4,5-diaminouracil *(5)* with *(1)* in sulfolane under the conditions described above gave a mixture of 8-(*o*-aminophenyl)theophyllin *(6)* (m.p. > 320 °C) and 1,3-dimethyl-11*H*-pyrimido[4,5-*b*][1,4]benzodiazepine - 2,4,6-(1*H*, 3 *H*, 5 *H*)-trione *(7)* (m.p. 260 °C), which could be separated by fractional crystallization from dimethylformamide. The compounds were obtained in yields of 17 % and 16 % respectively and were purified by recrystallization from alcohol or dimethylformamide. Compound *(7)*, a 'homo-alloxazine' in which the central ring of alloxazine has been expanded to seven members, is the first example of this ring system.

(5) *(6)* *(8)* *(7)*

Fusion of *(1)* and *(5)* at 220 °C for 1 hour gave 4-amino-5-(*o*-aminobenzamido)-1,3-dimethyluracil *(8)* (m.p. 296 °C) which was purified by recrystallization from aqueous dimethylformamide. On boiling with $POCl_3$, *(8)* was converted into *(6)*, and into a mixture of *(6)* and *(7)* by heating in sulfolane.

The novel hexacyclic purine derivative *(9)* (m.p. 285 °C) was formed by heating either *(5)* or *(6)* with anthranilic acid in polyphosphoric acid at 250–280 °C for 5 hours, followed by addition of water (yield 25 %; purification by recrystallization from dioxane). The composition and structure of *(9)* was ascertained by elemental analysis, molecular weight determination (by mass spectrometry), and from IR (no N–H absorption) and NMR spectra. An analogous pentacyclic product is obtained from *o*-phenylenediamine and anthranilic acid in polyphosphoric acid [2].

Addition of Isocyanides to Transition Metal Carbene Complexes

By *R. Aumann* and *E. O. Fischer* [*]

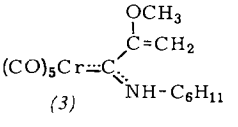
Methoxymethylcarbenepentacarbonylchromium(0) *(1)* can be readily obtained in good yields (>90 %) by the alkylation [1] of $Li[(CO)_5CrCOCH_3]$ [2] with $[(CH_3)_3O]BF_4$. It

reacts with isocyanides (at 0 °C in pentane) to form a new type of carbene complex *(2)*, in which the carbene carbon atom is incorporated in an aziridine system. The reaction proceeds by insertion of the isocyanide carbon atom into the original Cr-carbene bond.

Methoxymethylcarbenepentacarbonylchromium(0) (1):

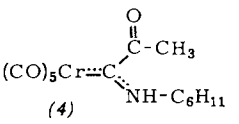
A suspension of 10 g (0.045 mole) of dry, finely powdered $Cr(CO)_6$ in 500 ml of water-free ether is prepared in a 1 liter round bottom flask fitted with a side arm for nitrogen introduction. 90 ml of a 0.5 M ethereal $LiCH_3$ solution is added slowly to the suspension from a measuring pipette. During the addition, the mixture is stirred vigorously with a magnetic stirrer; an intense yellow coloration develops as the $Cr(CO)_6$ goes into solution. When all the $LiCH_3$ has been added, the ether is removed in a water-pump vacuum and the residue is dissolved in *ca.* 100 ml of water. 6.71 g (0.045 mole) $[(CH_3)_3O]BF_4$ is added in small portions to this solution whereupon the carbene complex immediately separates as an oil. Completion of reaction is indicated by acid reaction of the aqueous solution; oxonium salt is added until such an acid reaction is manifest. Since the complex itself is decomposed by acid it must be extracted with pentane (*ca.* 200 ml) immediately after the reaction has reached completion. The pentane solution is filtered (through a G4 sintered disk loaded with freshly ignited Na_2SO_4) and evaporated to one third of its original volume. On cooling *ca.* 9.8 g (87 %) of the complex crystallizes out as long yellow needles. The yield can be increased by evaporation of the mother liquor and sublimation of the residue. After one recrystallization from pentane, the complex has m.p. 34 °C.

(2) is formed as odorless, yellow crystals [m.p. 65.5–66.5 °C (decomp.)], which in air are rapidly converted into a green, resinous material. The mass spectrum [3] of *(2)* shows a molecular ion at $m/e = 359$ and $[(CO)_nCr\cdot Ligand]^+$ (n = 5,4...0) ions in accordance with the expected fragmentation pattern of a $(CO)_5Cr$ complex.



The following reactions have been carried out in order to establish the presence of an aziridine structure:

i) Reaction of *(2)* with benzoyl peroxide at 0 °C to give the compound *(3)* [yellow crystals, m.p. 99.5–100 °C].

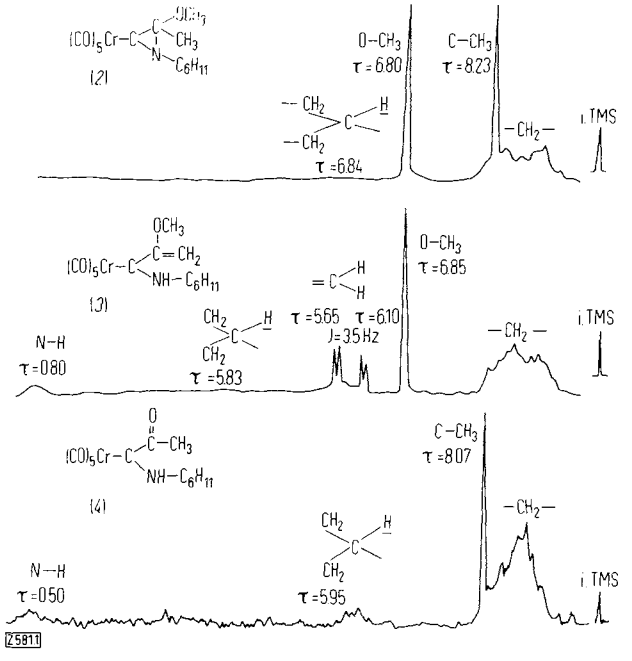


ii) Reaction of *(3)* with 2 N HCl in H_2O/THF at 20 °C to give *(4)* [yellow crystals, m.p. 114 °C (decomp.)].

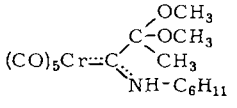
iii) Compound *(4)* heated at 80–100 °C in a high vacuum to give *(5)* [colorless crystals, m.p. 72 °C].

The compounds *(2)*, *(3)*, and *(4)*, which are obtained in almost quantitative yields, may be purified by recrystallization

(3)



(4)



(5)

from pentane or hexane after removal of the reaction medium. The compounds have been characterized by elemental analysis, and by their IR, ^{1}H-NMR (10 % solution in C_6D_6, see figure), and mass spectra.

The formation of the stable aminodimethoxyketal carbene complex *(6)* [yellow crystals, m.p. 109.5–110 °C] when *(2)* is

(6)

allowed to react with CH_3OH at 20 °C is further evidence for the presence of an aziridine structure in *(2)*.

In the presence of aqueous acid, *(6)* is converted into *(4)*.

Thermophilic and Mesophilic Aminopeptidases from *Bacillus stearothermophilus* [1]

By *H. Zuber* and *G. Roncari* [*]

We have isolated from several strains of *Bacillus stearothermophilus* [2], three aminopeptidases that differ in molecular weight, thermal stability, and substrate specificity. Aminopeptidase I (AP I) is thermostable and is therefore designated a thermophilic enzyme. The aminopeptidases II and III (AP II and III) are mesophilic enzymes and thermolabile. All three enzymes are metal enzymes. In their native forms they probably occur as Co^{2+} or Mn^{2+} enzymes since, after inactivation by EDTA, they are best reactivated by Co^{2+} and Mn^{2+} ($Co^{2+} = Mn^{2+} \gg Mg^{2+} > Ni^{2+} > Cd^{2+}$). Ca^{2+}, Zn^{2+}, and Fe^{2+} do not activate but (in concentrations of 0.001 to 0.05 M) inhibit them. The pH optimum for all three enzymes is at pH = 7.5 to 9. The substrate specificity (Table 2) is, in part, very different from the specificity of leucinaminepeptidase (LAP) [3] from pig's kidneys.

Table 1. Properties of aminopeptidases I–III

	AP I	AP II	AP III
Molecular weight [a]	*ca.* 150000	*ca.* 70000	*ca.* 80000
Michaelis constant K_m (60 °C, Leu-Gly) (mmoles/l)	95	37	4
Activation energy [b] (kcal/mole)	16.3	16.3	—
Optimum temperature (°C)	90	60	60
Thermal stability [c] (% of initial activity after 3 min	—	64	81
18 min	120	35	54
120 min at 80 °C)	120	0	0

[a] Determined by gel filtration, Sephadex G-200, 0.05 M Tris-HCl buffer, pH = 7.2, 10^{-3} M Co^{2+}.

[b] Determined by hydrolysis of a 0.0075–0.06 M Leu-Gly solution (AP I and AP II), or of a 0.0002–0.002 M Leu-Gly solution (AP III) (0.05 M Tris-HCl buffer, pH = 7.2, 10^{-3} M Co^{2+}; incubation time 10 min at 20, 40, 60, 80, 90 °C).

[c] Determined by hydrolysis of a 0.06 M Leu-Gly solution, 0.05 M Tris-HCl buffer, pH = 7.2, 10^{-3} M Co^{2+}. Incubation time 10 min at 65 °C (AP I) or 37 °C (AP II and III).

AP I has a specific activity of 1000 units mg^{-1} min^{-1}, where the unit is defined as hydrolysis of 1 μmole of substrate per min. The molecular activity is 150000 mole·(mole of enzyme)$^{-1}$·min^{-1}. Both these activities were determined by hydrolysis of a 0.045 M solution of Gly-Leu-Tyr in 0.05 M Tris-HCl buffer at pH 7.2 and 65 °C with 10^{-3} M Co^{2+}.

Table 2. Substrate specificities (substrate concentrations: 0.045M, 65 °C, 0.05 M Tris-HCl buffer, pH = 7.2, + 10^{-3} M Co^{2+}). The figures (except those in column C_1) denote % hydrolysis in 5 min.

Peptide	AP I	C_1 [a]	AP II	AP III
Leu-Gly	16	30	1.6	1.6
Gly-Leu	0.8	1.4	0.1	0.09
Leu amide	5	8.8	9	1.2
Leu-Gly-Gly	30	50	25	80
Gly-Leu-Tyr	36	77	8	18
Pro-Tyr-Lys	3.2	5.6	2.7	25
Glu-Ala-Ala	5.5	9.8	1.2	1.7
Lys-Tyr-Glu	1.5	2.6	1.3	24

[a] $C_1 = k_1/E$; k_1 = rate constant for first-order reaction; E = protein concentration (mg of N per ml) on the basis of a 15 % nitrogen content in the protein.

AP I was purified by repeated chromatography in 0.05 M Tris-HCl buffer (10^{-3} M Co^{2+}) on Sephadex G-150 and DEAE-Sephadex A-50, and AP II and AP III by repeated chromatography on Sephadex G-100 and DEAE-Sephadex. AP I, AP II, and AP III are homogeneous on polyacrylamide electrophoresis [4] (pH = 8.9, 45 min). Preliminary experiments with the ultracentrifuge gave: for AP I, $S_{20} = 2.80 \times 10^{-13}$ and $D_{20} = 1.8 \times 10^{-7} \pm 0.16$ (symmetrical band). It follows that AP I is highly hydrated in solution or is a very extended molecule. AP I is stable in 8 M urea solution, but it is inactivated by reagents such as formic acid or LiBr that break hydrogen bridges and is thereby split into fragments (gel electrophoresis).

All three enzymes are found even at the beginning of the log phase of the growth curve of the bacteria, and both in the cells and in the culture medium. The yield of enzymes is maxi-

mal at the end of the log phase and in the stationary phase (24–30 h). The amounts of AP I, AP II, and AP III present in *Bacillus stearothermophilus* vary according to the strain. Obligatory thermophilic strains (temperature optimum 55 °C, no growth at 37 °C) produce much AP I and AP II and little AP III, whereas obligatory mesophilic strains (temperature optimum 37 °C, no growth at 55 °C) contain much AP III and very little AP I or AP II. Facultative strains (growth at 37 °C and 55 °C) may contain the three aminopeptidases in comparable amounts.

For preparation of the crude enzyme mixture the bacteria were opened up by ultrasonic vibrations or in a sand mill. Treatment with lysozyme liberated only AP II and AP III; AP I seems to be more firmly bound to the cell membranes. The aminopeptidases were obtained from the culture medium by adsorption on DEAE-Sephadex (pH = 7.2) and elution with 1 M NaCl solution (0.05 M Tris-HCl buffer, pH = 7.2, 10^{-3} M Co^{2+}).

Synthesis of Hydridopentacyanoiridate Complexes

By *K. Krogmann* and *W. Binder* [*]

Suggestions that complexes of the type $[MH(CN)_5]^{3-}$ (M = Co, Rh, Ir) exist in solution [1,2] have been questioned [3] since, hitherto, such compounds have not been successfully isolated. We have now been able to prepare iridium compounds of this type by reaction of bis(1,3-cyclohexadiene)-iridium chloride [4], $Ir(C_6H_8)_2Cl$, or bis(2,3-dimethylbutadiene)iridium chloride, $Ir(C_6H_{10})_2Cl$, with excess KCN in CH_3OH:

$$Ir(C_6H_8)_2Cl + 5\,KCN + CH_3OH \rightarrow K_3[IrH(CN)_5] + KCl + KOCH_3 + 2\,C_6H_8.$$

$K_3[IrH(CN)_5]$ is a white, crystalline, diamagnetic compound, which is unaffected by air; it is very soluble in water and moderately soluble in CH_3OH. It reduces two equivalents of iodine per mole Ir. Aqueous solutions are stable at room temperature for many hours, after which a grey-white polymer begins to deposit. The free acid, which may be prepared from the potassium salt by cation exchange, contains three strongly acidic protons, which can be titrated. It may be isolated as white $(H_3O)_3[IrH(CN)_5]$. Addition of $AgNO_3$ solution leads to the precipitation of white, insoluble $Ag_3[IrH(CN)_5]$, which turns dark at the surface on standing.

No deuterium exchange was observed in a solution of $K_3[IrH(CN)_5]$ in D_2O, even after 7 days at 20 °C.

IR-spectra of $K_3[IrH(CN)_5]$ (in KBr, nujol, and Hostaflon) show bands at 2110 cm^{-1} (vs) [shoulder at 2127 and at 2152 cm^{-1}], and 2043 cm^{-1} (m) as C–N– and Ir–H– stretching frequencies. Further bands occur at 810 (s, shoulder at 855), 533 (s), 513 (s), 454 (w), 404 (s), 386 (s), 333 (w), and 302 cm^{-1} (w) [5]. We assume ν(Ir–H) to be at 2043, δ(Ir–H) at 810 cm^{-1}.

The UV-spectrum of the aqueous solution of $K_3[IrH(CN)_5]$ has an absorption maximum at 470 nm (ε = 540) and a shoulder at 364 nm (ε = 36) [6]. In D_2O, there is a ^1H–NMR signal at δ = +1730 Hz (reference signal: HDO) or τ = 23.9 ppm [5], as expected [2]. All known data confirm C_{4v} symmetry for the complex.

Preparation: 3.25 g (50.0 mmole) of KCN is dissolved in 200 ml of water-free CH_3OH and then 1.94 g (5.00 mmole) of $Ir(C_6H_8)_2Cl$ or 1.96 g of $Ir(C_6H_{10})_2Cl$ is added. The yellow color of the solution disappears within minutes. Olefin, together with CH_3OH, is driven off from the solution by distillation. Methanol must be added to the solution during the distillation until all the liberated olefin has been removed. Within 3 h the desired complex separates from the solution as a white, finely crystalline mass, which can be dried under vacuum (yield 85 %).

Identification of the Subsidiary Steroids from the Prothoracic Protective Gland System of *Dytiscus marginalis* [1,2]

By *H. Schildknecht* and *D. Hotz* [*]

The methanol-soluble part of the secretion from the prothoracic protective glands of *Dytiscus marginalis* contains cortexone as main component [3]. When this steroid is isolated as previously described [4], it contains as impurities substances whose molecular weights are shown by their mass spectra to be 316 and 314. If, however, the gland secretion is worked up by thin-layer chromatography [silica gel G and cyclohexane/ethyl acetate (1:1)], these subsidiary products are found to be enriched together in the zone immediately above that of cortexone. By repeated chromatography [5] this mixture can be separated into two components with absorption maxima at 283 and 240 nm.

(1)

(2)

Help with identification of these compounds was obtained from the circular dichroism of the less polar compound whose absorption maximum is at 240 nm. The position and fine structure of the maximum at 331 nm indicated a 3-oxo-Δ4-steroid [6], and indeed we found in the mass spectrum a peak at *m/e* = 124 characteristic of such a steroid [7]. Comparison with the mass spectrum of a steroid that we had isolated from the prothoracic protective glands of the water beetle *Acilius sulcatus* [5] enabled the *Dytiscus* steroid of *m/e* 316 to be identified as 20α-hydroxy-4-pregnen-3-one *(1)*.

Our assumption that, as with *Acilius sulcatus* and *Cybister lateralimarginalis* [8], the second subsidiary steroid would be the corresponding 6,7-dehydro compound was confirmed by

IR spectroscopy. However, this 20α-hydroxy-4,6-pregnadien-3-one (cybisterone) occurs in vanishingly small amounts compared with *(1)*.

Preparation of *N*-(Dichloromethylene)-chlorosulfonamide and -fluorosulfonamide [1]

By *H. W. Roesky* and *U. Biermann* [*]

Chlorosulfonyl isocyanate *(1)* [2] reacts with phosphorus pentachloride *(2)* to give *N*-(dichloromethylene)chlorosulfonamide *(3)*.

$$\underset{(1)}{ClSO_2\text{-}N{=}C{=}O} + \underset{(2)}{PCl_5} \longrightarrow \underset{(3)}{ClSO_2\text{-}N{=}C(Cl)Cl} + \underset{(4)}{POCl_3}$$

0.1 mole each of *(1)* and *(2)* are heated together in a sealed, thick-walled glass tube for 1.5 h at 210 °C. The tubes may be opened at room temperature without cooling. *(1)* and *(4)* are distilled off at atmospheric pressure, and *(3)* is then distilled off in a water-pump vacuum (b.p. 71–72 °C/15–16 mm, 32–33 °C/0.2 mm; yield 10 %). At this stage, the product *(3)* contains $(CNCl)_3$ as impurity; it is obtained pure by repeated distillation.

The mass spectrum contains, besides the molecular ion at *m/e* 195, peaks for the following fragments: SO_2NCCl_2 (160), SO_2Cl (99), $NCCl_2$ (96), SO_2 (64), NCCl (61), SO (48), and CCl (47). The IR spectrum (capillary film) in the NaCl and KBr regions contains bands at 1608, 1570, 1402, 1180, 940, 790, 627, 593, 550, and 530 cm^{-1}. These are provisionally assigned as follows: ν(C=N) 1608 and 1570 (because of Fermi splitting) ν_{as}(SO) 1402, ν_s(SO) 1180, ν_{as}(CCl) 940, ν_s(CCl) 790, ν(S–N) 627, ν(S–Cl) 593, and deformation vibrations. The compound *(3)* reacts with antimony trifluoride to afford *N*-(dichloromethylene)fluorosulfonamide *(5)*.

$$\underset{(3)}{} + SbF_3 \longrightarrow \underset{(5)}{FSO_2\text{-}N{=}C(Cl)Cl}$$

0.3 mole of *(3)* is heated with an excess of SbF_3 ($SbCl_5$ as catalyst) for 2 h at 60 °C and for a further 2 h at 85 °C. The mixture is then distilled in an oil-pump vacuum. The product *(5)* is collected in a cold trap (liquid nitrogen) and then refractionated. Crude yield, 0.2 mole; pure yield, 0.05 mole (b.p. 114–115 °C). Compound *(5)* can also be obtained from fluorosulfonyl isocyanate and phosphorus pentachloride in a sealed tube, the yield being 5 %.

The IR spectrum of *(5)* contains bands at 1615, 1440, 1220, 950, 850, 798, 628, 570, and 500 cm^{-1}. Provisional assignments are: ν(C=N) 1615, ν_{as}(SO) 1440, ν_s(SO) 1220, ν_{as}(C–Cl) 950, ν(SF) 850, ν_s(C–Cl) 798, ν(SN) 628, and deformation vibrations. The ^{19}F-NMR spectrum contains a signal at $\delta = -54.2$ ppm referred to CCl_3F as external standard. The mass spectrum shows, besides the molecular ion at *m/e* = 179, fragments FSO_2NCCl (144), SO_2F (83), SF (51), and SO (48).

Adsorption of Nitrogen on Iron

By *R. Brill, E.-L. Richter,* and *E. Ruch* [*]

In connection with investigations on the catalysis of NH_3 synthesis by iron, experiments on the adsorption of nitrogen on iron tips were performed by means of the field electron microscope. Fig. 1a shows the emission picture of the clean tip prepared by field evaporation in presence of hydrogen. The crystal is oriented with the axis of the tip perpendicular to 110. Fig. 1b shows the effect of physical adsorption of N_2 at the temperature of liquid nitrogen. The pattern shown in Fig. 1c was obtained after the tip with physically adsorbed N_2 had been heated, without field, for 3 seconds to a temperature of about 400 °C. It can easily be seen that the main change takes place at the 111 faces. Here the work function is remarkably large. (Some change also occurs at the 100 poles and in a circular zone around them. This circular zone probably represents a series of steps.)

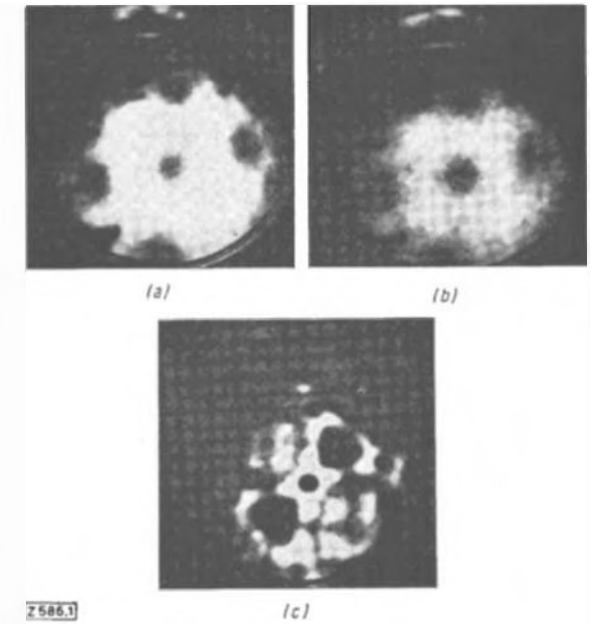

Fig. 1. Field electron microscope patterns. (a) A clean iron tip (longitudinal axis of iron tip perpendicular to the 110 face), (b) the same tip after adsorption of N_2 at 76 °K, and (c) after adsorption of N_2 and subsequent heating at *ca.* 400 °C for about 3 sec.

From these experimental results the following conclusions may be drawn:

1. N_2 is preferentially chemisorbed at the 111 face of iron.

2. The work function is increased by the adsorption of N_2.

3. The adsorption of N_2 diminishes the surface energy of the 111 face; consequently, this non-equilibrium face grows.

These facts can be understood on the basis of a theoretical model[1] which describes the possibility of binding the nitrogen molecule. According to this model the partner should be able to accept the four π electrons of an N_2 molecule without completely destroying the bonds they form between the nitrogen atoms. For this reason the partner should have empty orbitals of low energy that are transformed according to $e^{i\varphi}$ and $e^{-i\varphi}$ with regard to an at least threefold symmetry-axis. These orbitals should overlap with the π orbitals of the nitrogen molecule when oriented along this axis, and there should be no considerable repulsion between other electrons of the binding partners.

In an iron crystal, all iron atoms are surrounded by eight nearest neighbors at the corners of a cube; the 111 surface therefore appears to be a suitable binding partner for nitrogen molecules having their molecular axes perpendicular to this surface. As the iron atoms of the 111 plane occupy lattice points of a two-dimensional hexagonal lattice and the distance between these surface atoms is $2\sqrt{2}/3$ times the nearest-neighbor distance within the crystal, the iron atoms on the surface surround cavities of trigonal symmetry. It can be assumed that the surface atoms provide unoccupied atomic orbitals which can combine to give π orbitals with regard to the trigonal cavity axis. Thus the adsorption of nitrogen molecules at the cavities of the 111 surface can be explained. Since the assumed binding weakes the N_2 π bonds of the nitrogen molecules this may well represent the initiating step in the catalysis of the ammonia synthesis.

Dipotassium Diphenylhypophosphonate and Diphenyltetrathiohypophosphonate

By *E. Fluck* and *H. Binder*[*]

Hypophosphonic and tetrathiohypophosphonic acid and their derivatives were hitherto unknown.

We have now prepared the potassium salts of diphenylhypophosphonic acid *(1)* and diphenyltetrathiohypophosphonic acid *(2)* by reduction of phenylphosphonic anhydride *(3)* and phenyldithiophosphonic anhydride *(4)*, respectively, with elemental potassium.

(1) X = O
(2) X = S

Phenylphosphonic anhydride (14.0 g, 0.05 mole) is added to a solution of potassium (3.9 g, 0.1 g-atom) in 100 ml liquid ammonia, whereupon the blue color rapidly disappears. After removal of the solvent, the salt *(1)* can be extracted from the residue with 80 % ethanol. On concentration of the solution, *(1)* is precipitated as colorless needles that are readily soluble in water (yield 47.5 %). The ^{31}P-NMR spectrum contains one singlet, which proves the equivalence of the two phosphorus atoms. The chemical shift is $\delta_P = -5.2$ ppm (referred to 85 % aqueous H_3PO_4).

Reduction of phenyldithiophosphonic anhydride[1] is effected by adding it to a solution of potassium in the tris(dimethylamide) of phosphoric acid, *e.g.* 17.2 g (0.05 mole) of the anhydride to a solution of 3.9 g (0.1 g-atom) of potassium in 50 ml of $OP[N(CH_3)_3]_2$. Heat is evolved and within about 30 min the initially blue solution becomes colorless. After the amide has been distilled off in a vacuum a pale yellow product is found which can be recrystallized from 80 % ethanol. Yield 35 %. The chemical shift of the singlet in the ^{31}P-NMR spectrum occurs at $\delta_P = -95.2$ ppm.

The free acids can be obtained from the potassium salts by adding dilute HNO_3 to their aqueous solutions[2].

Preparation of Porphobilinogen from 5-Aminolevulic Acid by means of *Propionibacterium shermanii*

By *G. Bezold*, *G. Müller*, and *O. Müller*[*]

Porphobilinogen *(1)* can be prepared by chemical methods only with difficulty[1]. It is isolated from the urine of patients suffering from acute porphyria or from the urine of rabbits that have been treated with Sedormid or other compounds that induce porphyria[1]. A further method of obtaining porphobilinogen consists in enzymic treatment of 5-aminolevulic acid *(2)* with 5-aminolevulic acid dehydratase[1,2].

We have found that porphobilinogen *(1)* can be obtained from 5-aminolevulic acid *(2)* by fermentation with *Propionibacterium shermanii*. Porphobilinogen is isolated from the culture medium. Resting cells also yield porphobilinogen, and this has the advantage that the difficult isolation from the culture medium is not needed. The bacteria can be used for several batches; the yield is decreased slightly but only on the third incubation.

(2) *(1)*

When *P. shermanii* acts on 5-aminolevulic acid, products other than porphobilinogen are also found in the medium. We are studying whether these further compounds[3] are intermediates in the formation of porphyrin or in the biosynthesis of the corrin ring.

Experimental

A cobalt-free batch (4 liters) of *P. shermanii* is grown for three days under conditions described previously[4]. The moist bacterial mass (*ca.* 100 g) obtained on centrifugation is washed with tris[(hydroxymethyl)amino]methane/HCl buffer (pH = 8.2)[5] and suspended in 1500 ml of this buffer. A solution of 5-aminolevulic acid hydrochloride (820 mg) in water (100 ml), whose pH has been adjusted to 7 by NaOH, is added and the mixture is incubated for 1 h at 70 °C with stirring and passage of nitrogen. The solution is freed from bacteria by

centrifugation, adjusted to pH = 7.2 by dilute hydrochloric acid and placed on a column (10 cm in length, 4.5 cm in diameter) of DEAE-cellulose (DEAE-Sephadex A-25) whose chloride form has been washed with tris[(hydroxymethyl)-amino]methane/HCl buffer (pH = 7.2) until the eluate has pH = 7.2. The column is eluted with buffer until no more porphobilinogen is removed from it. The eluates are evaporated in a vacuum to *ca.* 1800 ml, then adjusted to pH = 4 by dilute hydrochloric acid and treated with 20 % mercury(II) acetate solution. The resulting precipitate is centrifuged off, washed with 1 % mercury(II) acetate solution, and suspended in *ca.* 3 ml. of water. H_2S is passed into the suspension to decompose the mercury compound. Then the precipitate is centrifuged off, nitrogen is passed into the liquid to remove H_2S, and the pH of the liquid is adjusted to pH = 4 by dilute hydrochloric acid. This precipitates crude porphobilinogen[6] which is centrifuged off after having been kept for 12 h in a refrigerator. Just sufficient 0.5 N ammonia is added to the centrifuge tube to dissolve the porphobilinogen, undissolved material is centrifuged off, the pH is adjusted carefully to 4 by glacial acetic acid for precipitation of the porphobilinogen, and the whole is left overnight in a refrigerator. The crystals are filtered off under suction and washed with ice-cold dilute acetic acid (pH = 4) and immediately thereafter with a little cold acetone. Drying in a vacuum desiccator gives 73 mg (12 %) of porphobilinogen.

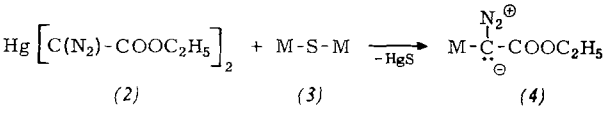
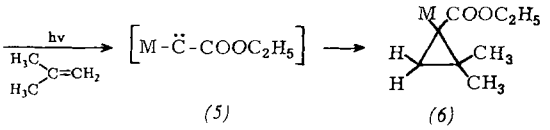
Triphenylstannyl- and Trimethylsilyl-ethoxycarbonylcarbene from Ethyl Diazo-(triphenylstannyl)- and -(trimethylsilyl)-acetate

By *U. Schöllkopf* and *N. Rieber*[*]



Unusual properties are to be expected for metalated carbenes because the empty or filled electron orbitals of the metal may interact with those of the carbene-carbon atom, giving the mesomeric limiting structures *(1a)* to *(1d)*. We have obtained



(1a) *(1b)* *(1c)* *(1d)*

M=Metal

the first metalated carbenes, namely, triphenylstannyl- and trimethylsilyl-ethoxycarbonylcarbene *(5)*, by photolysing ethyl diazo-(triphenylstannyl)- [$\nu(N_2)$ = 2080 cm^{-1}, $\nu(CO)$ = 1670 cm^{-1}] and -(trimethylsilyl)-acetate [$\nu(N_2)$ = 2090 cm^{-1}, $\nu(CO)$ = 1685 cm^{-1}] in isobutene (0.03 M or 0.3 M, respectively) until the solutions were decolorized[1]. This affords ethyl 2,2-dimethyl-1-(triphenylstannyl)cyclopropanecarboxylate *(6a)* (yield 35 %) and the corresponding trimethylsilyl ester *(6b)* (yield 49 %), respectively, [$\nu(CO)$ = 1710 cm^{-1} for *(6a)*, 1715 cm^{-1} for *(6b)*; NMR, AB spectrum of the cyclopropyl protons, τ = 8.7 (CCl_4), J_{AB} = 4.5 Hz for *(6a)*, τ = 9.0 (C_6D_6), J_{AB} = 4 Hz for *(6b)*]. The starting materials *(4a)* and *(4b)* were obtained (in yields of 80 and 95 %, respectively) by treating diethyl mercuribis(diazoacetate) *(2)*[2] in boiling benzene for 5 and 3 h, respectively, with rather more than one equivalent of bis(triphenylstannyl) or bis(trimethylsilyl) sulfide *(3)*. After filtration, the benzene solutions were evaporated (aspirator vacuum) in a rotary evaporator.

Sulfur and Selenium Adsorbate on Platinum Electrodes in Acid and Alkaline Electrolytes

By *H. Binder, A. Köhling*, and *G. Sandstede*[*]

Since the properties of catalysts are modified by adsorbates, it is of interest to find out the conditions under which adsorbed substances exist on the surface of catalysts. We have studied the adsorption of sulfur and of selenium on platinum by the

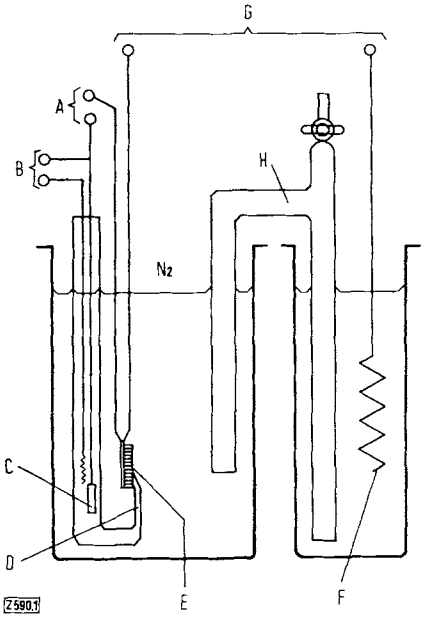

Fig. 1. Half-cell for potentiodynamic current density measurements. A: continuously increasing, or decreasing, reference voltage; B: electrolytic H_2-production for the H_2-reference electrode; C: H_2-reference electrode; D: capillary; E: measuring electrode; F: counter electrode; G: anodic or cathodic current flow caused by change of reference voltage.

triangular voltage sweep method. A continuously increasing voltage (against a reversible hydrogen reference electrode in the same electrolyte) was applied to a porous platinum electrode [1] (Raney platinum) in a half cell arrangement (Fig. 1).

The voltage was allowed to attain a prefixed value (*ca.* 1300mV) and was then continuously decreased. The resulting anodic or cathodic current flow was recorded as a function of the reference voltage (Fig. 2).

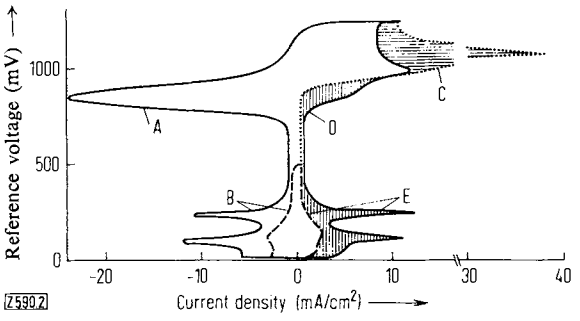

Fig. 2. Periodic current-voltage curve of a platinum electrode with (and without) selenium adsorbate, and potentiodynamic curve of the oxidation of selenium adsorbate.

——— without selenium adsorbate; with selenium adsorbate; ····· oxidation of the selenium adsorbate; electrolyte: 3 N H_2SO_4; 90 °C. Rate of change of reference voltage 40 mV/min.

A: Cathodic reduction of O-adsorbate; B: cathodic reduction (discharging) of H^+ ions during formation of H-adsorbate; C: anodic oxidation of Se-adsorbate; D: anodic oxidation of H_2O during formation of O-adsorbate; E: anodic oxidation of H-adsorbate.

In many acidic and alkaline electrolytes a monatomic hydrogen adsorbate, which is formed reversibly on the platinum surface, is present at 0 mV; at *ca.* 1300 mV a monatomic oxygen adsorbate is present. In acid electrolytes, oxygen adsorbate formation, which is caused by electron transfer from adsorbed water, begins at 800 mV. In alkaline electrolytes, oxygen adsorbate formation caused by electron transfer from adsorbed hydroxide ions begins at 550 mV. Reduction of oxygen adsorbate starts at a lower reference voltage than that at which it is formed.

Sulfur as well as selenium can be adsorbed on the platinum surface to form a complete monolayer, thus preventing hydrogen adsorption on the covered atoms. It is possible to determine the degree of coverage by comparing the quantities of charge (the area under the curves in the range 0 to 500 mV) necessary for the deposition or removal of hydrogen adsorbate layer with, and without, sulfur or selenium adsorbate (Fig. 2).

Sulfur is adsorbed when the electrode is placed in sulfur vapor, sulfur solution, carbon disulfide, hydrogen sulfide gas or sodium sulfide solution. It can also be deposited by cathodic reduction of sulfuric acid, sulfurous acid, or sulfite solution. Selenium can be adsorbed from a solution in concentrated sulfuric acid after slight dilution. Other elements may be deposited by similar methods.

The adsorbate layers may be oxidized anodically (Fig. 2). For a complete oxidation of sulfur it is necessary to keep the potential of the electrode at a value above 1200 mV for approximately one hour (selenium: several hours). The quantity of charge required for a complete oxidation of the sulfur or selenium adsorbate is approximately four times that necessary for oxidizing the displaced hydrogen. We conclude that on each surface platinum atom a sulfur or selenium atom is adsorbed which can be oxidized to SO_2 or SeO_2 respectively.

At 70 °C the sulfur adsorbate is stable up to a potential of about 650 mV [2]. This value surpasses the standard potential of oxidation of sulfur, in acid, by 200 mV. In potassium hydroxide solution oxidation sets in at about 450 mV (sulfur is not thermodynamically stable in alkaline media). Selenium is not oxidized below 900 mV in sulfuric acid (Fig. 2) (standard oxidation potential 740 mV). The simplest way of obtaining different coverages is the partial oxidation of a complete layer. It has recently been observed that adsorbates are not only responsible for inhibition of but also for acceleration of various reactions; the shift reaction and the decomposition as well as the anodic oxidation of carbon monoxide or formic acid at a platinum electrode, which are considerably accelerated by a partial coverage of the electrode surface with sulfur or selenium [2], may be cited as examples.

CONFERENCE REPORTS

Use of Viridic Acid as Coloring Matter for Foodstuffs

By *R. Burkhardt* [*]

One of the means by which chlorogenic acid can be detected on chromatograms is by its reaction with ammonia or ammonium carbonate. This reaction leads to the formation of viridic acid, which is an unstable green compound.

More than 100 years ago a housewife unknowingly used the formation of a stabilized viridic acid to color cakes. A crude green coffee bean was left overnight in egg white that had been separated from the yolk. Chlorogenic acid extracted from the coffee bean reacted with the egg white which provided the amino groups needed for the reaction, the optimal pH, and an oxidizing enzyme, and at the same time acted as protective colloid. Pure chlorogenic acid behaves in the same way; the resulting stabilized viridic acid, is firmly bound to the albumin and cannot be separated from it without destruction.

At present chlorophyll is the only natural coloring matter allowed to be added to foodstuffs. It is now proposed that the brilliant grass-green viridic acid compound should be used; this dye is unobjectionable and is not a foreign substance since (i) it contains the digestible egg white and (ii) chlorogenic acid is a substance that occurs in many vegetable foodstuffs.

Tin Content of Condensed Milk

By *W. Wodsak* [*]

Condensed milk is stored almost exclusively in tin-plate cans. The tin content of condensed milk samples that were not older than four weeks was at most 40 ppm and rose

only inappreciably during a further five months. In storage experiments lasting more than 2 years the tin content rose to 160 ppm in exceptional cases. It was higher, on the average, in condensed milk with 10% fat content than in that with 7.5%.

There have been no reports of poisoning by the tin present in condensed milk. Nevertheless the manufacturer should be instructed to state the date of filling on the cans so that it is possible to use only tins of recent date for feeding babies.

Recovery, in Aqueous Solution, of Nuclear Fuels of High Plutonium Content

By *F. Baumgärtner* [*]

In the future, fuel elements of high plutonium content will accumulate, especially as a result of the use of fast breeder reactors. The presence of such large amounts of plutonium will make chemical reprocessing of these fuel elements difficult in many respects. In the simultaneous extraction of uranium and plutonium the uranium strongly represses the extraction of plutonium, and critical concentrations of plutonium can result in the aqueous phase. In reductive separation of plutonium and uranium, decontamination of the uranium is made difficult by the presence of large quantities of plutonium; part of the plutonium becomes irreversibly bound in the organic phase owing to radiolysis of the organic extracting medium.

Measurements of the rate of material transfer for plutonium and uranium indicated the possibility of a rapid extraction procedure and this has been developed by means of a centrifugal separator, by use of which up to 120 kg of nuclear fuel can be worked up safely per hour. At the same time disturbance of the extraction by radiolysis is reduced to *ca.* 1/20. More than 99% separation of plutonium from uranium is possible when U(IV) is used as reducing agent.

The Fundamental Photographic Process in Silver Halide Crystals

By *W. F. Berg* [*]

The latent image state of silver halide crystals increases the rate of reduction of the silver halides to metallic silver in the developer. We are therefore dealing with a catalyst.

In analogy with visible photolysis of silver halides it is assumed that the latent image state involves accumulation of electrons and silver atoms, about whose degree of aggregation there is still speculation. Absorption of only four quanta suffices to produce this state.

The simplest interpretation is to consider formation of the latent image as the formation of a new solid phase. The most important features of this view are:

a) The latent image state is formed independently in individual microcrystals of an emulsion.

b) Its formation is a process involving several steps – several quanta are necessary.

c) Its formation involves a reverse process: regression.

d) The latent image is formed on the surface and in the interior of the crystals.

e) Crystallization nuclei, formed by chemical treatment or preillumination, play an important role.

f) Competition between nuclei of different effectivity is important. Often several nuclei occur in any one microcrystal; these then compete with one another for latent-image substance.

These simple concepts are sufficient to account for the majority of photographic effects, such as reciprocity failure and its temperature sensitivity.

Gurney and *Mott* assumed that absorption of light liberates mobile photoelectrons, which in some cases are captured. This leads to an electric field, which attracts the mobile silver ions in interstitial positions (Frenkel defects). An aggregate of silver atoms is formed in this way. The essential principle of the *Gurney-Mott* theory is the interplay of photelectrons and mobile silver ions.

Mitchell emphasized the role of structural defects and defect electrons. A requirement of this theory is that electrons and defect electrons must remain separated; *Mitchell* achieves this by the postulate of electric charge transfer at the centers where the charge carriers are captured. On capture of defect electrons, interstitial silver ions are produced that take part in forming the image. The natural sites for capture of electrons are apparently the crystal defects and the foreign nuclei adsorbed on them (*Mitchell*); the sites of capture of the defect electrons are point defects (*Malinowski*), which stabilize the defect electrons by charge transfer (*e.g.* $Cu^{+} \rightarrow Cu^{2+}$). Thus silver halide crystals containing suitable impurities would have an in-built mechanism for separation of electrons and defect electrons.

The essential constituents of our interpretation of the formation of the latent image are thus:

1. Formation of a new solid phase.

2. The *Gurney-Mott* principle: formation of this phase by movement of electrons and silver ions.

3. The *Mitchell* principle: separation of electrons from defect electrons and their stabilization by charge transfer.

4. Separation of these charge carriers by capture on centers of different kinds – electrons on crystal defects, and defect electrons an point defects amenable to charge transfer.

Surface Diffusion and Relaxation Times of Adsorbed Molecules

By *R. Haul* [*]

Information about the mobility of adsorbed molecules on the surface of solids has been obtained by three methods of investigation.

a) At low surface coverage (Θ = 0.1 to 0.001 of a monomolecular layer), determination of residence times from the transport process on molecular streaming of adsorbed gas through a single capillary. Examples: Ar, Kr, Xe on Pyrex glass [1].

b) At high surface coverage (Θ = 0.1 to 1.5), determination of surface diffusion coefficients D_S from measurements of the adsorption velocity in a large number of pores (Aerosil disk) by means of a vacuum sorption balance. Examples: Ar, N_2, and organic molecules. For benzene and cyclohexane between 15 and 55 °C the D_S values are of the same order as the diffusion coefficients in liquids (10^{-5} cm²/sec). At all temperatures there is a distinct maximum at about half a monomolecular layer. Examples, at 52 °C: benzene at Θ = 0.4, $D_S = 2.0\times10^{-5}$ cm²/sec; cyclohexane at Θ = 0.3, $D_S = 2.1\times10^{-5}$ cm²/sec. This is explained by the fact that the activation energy for surface diffusion at first diminishes rapidly (from 70 % of the adsorption energy at $\Theta \approx 0.1$ to about 40 % at Θ 0.5) and that D_S increases correspondingly (filling of energy holes). As the coverage increases further the probability of place exchange of the adsorbed molecules decreases and D_S becomes correspondingly lower.

c) Determination of relaxation times from measurements with a nuclear resonance impulse spectrometer on the same samples as were used for measurement of Ds. The spin-spin relaxation times for benzene in the temperature range studied lies between that of the liquid (T_2 about 50 sec) and of the solid state (T_2 about 10 μs); for benzene adsorbed on Aerosil (Θ = 0.68) at −60 °C, T_2 = 10 ms; at +100 °C, T_2 = 80 ms.

Structure, Preparation, and Properties of Cyclopolyphosphines

By *L. Maier* [*]

Although many cyclopolyphosphines containing aliphatic substituents have been prepared during recent years, among those with aromatic substituents only the phenyl derivative has been closely characterized [1]. Phenylcyclopolyphosphine, $(C_6H_5P)_x$, occurs in various forms, with melting points (A) 150 °C, (B) 190 °C, (C) 252–256 °C, and (D) 262–285 °C. It has been shown by X-ray structure analysis that form A is pentaphenylcyclopentaphosphine, in which the phosphorus atoms form an equilateral pentagon with approximate m symmetry. Form B occurs in at least four crystal modifications, all having the structure of hexaphenylcyclohexaphosphine with the phosphorus atoms forming a six-membered ring in the chair conformation. Forms C and D give the same Debye diagram and are highly crystalline [2], but their structures are not known.

Depending on the reaction conditions, treatment of $ClC_6H_4PCl_2$ with $ClC_6H_4PH_2$ gives three (chlorophenyl)-cyclopolyphosphines of formula $(ClC_6H_4P)_x$ with melting points (A, from ether) 191–193 °C, (B, from benzene) 194–198 °C, and (C, no solvent) 161–165 °C. Determination of the molecular weights in exaltone (cryoscopic) and benzene (osmometric) shows that the phosphorus rings are five-membered in form (A), six-membered in form (B), and four-membered in form (C).

So far, two forms of the *o*-tolyl compounds $(o\text{-}CH_3C_6H_4P)_x$ have been isolated, the melting points being (A) 290–299 °C and (C) 198–202 °C. Determination of the molecular weight in $CHBr_3$ indicates a five-membered phosphorus ring for form (A). Form (C) crystallizes in the tetragonal system, probably of space group $J\bar{4}$ with parameters $a = b = 12.89$, $c = 7.60$ Å; there are eight $o\text{-}CH_3C_6H_4P$ units in the unit cell. Although the possibility that C is monomeric or dimeric cannot yet be excluded, it is very probable that this form contains a four-membered phosphorus ring.

Experiments on the Scattering of Molecular Beams for the Study of Reactions of Potassium with Methyl Iodide, Hydrogen Bromide, and Bromine

By *J. P. Toennies* [*]

Theoretical and experimental developments have led to marked advances in the study of gas-phase reactions during the last few years. Particular interest attaches to work on the determination of reactive collision cross-sections (σ) by means of scattering experiments with crossed molecular beams. Reactive collision cross-sections are important for the theory of chemical reactions because they are dependent on the interaction potential $V(R)$ between all the atoms taking part in the reaction and are thus the only quantities that afford direct information about this potential. The relation between the potential and the cross-section is derived by classical calculations of trajectories. The cross-sections obtained from experiments on the scattering of molecular beams have made it possible, for the first time, to study the connection between the interaction potential and the reaction constants.

For experimental reasons, the scattering of molecular beams can at the present time only be used for study of those reactions involving at least one alkali atom (M). The exothermic reaction

$$K + CH_3I \rightarrow KI + CH_3 \qquad (\Delta E = -22 \text{ kcal/mole})$$

has been studied by the molecular beam method and has also been very recently subjected to intensive theoretical investigation by trajectory methods.

The angular distribution of the KI formed indicates that the reaction occurs mainly during the central collision in which the K atom is reflected backwards with capture of the I atom. The collision process can thus be described by the following diagram:

K	→	←	ICH_3	Before
KI	←	→	CH_3	After

The backward scattering observed indicates a short reaction time ($\tau < 10^{-12}$ sec), so that the reaction does not proceed by way of an activated complex as postulated by the Eyring theory. The velocity of the KI shows that most of the reaction energy is used for internal activation of the KI molecule. Similar results have been obtained for the reaction between K and HBr.

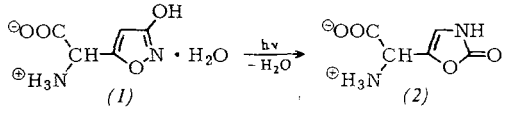
Bunker and *Karplus* and co-workers have carried out extensive trajectory calculations for the K + CH_3I reaction. They calculated reactive cross-sections for five potential models, of which one was shown to be satisfactory by comparing the experimental cross-section with the corresponding theoretical values; with this model the whole of the reaction energy becomes free when the distance between K and the I of CH_3I amounts to about 4 Å. In this way the first determination of the interaction potential for a reaction was made.

The potential model agrees well with the view that one electron

$K + ICH_3 \rightarrow K^{\oplus} + I^{\ominus}CH_3 \rightarrow KI + CH_3$

jumps from the potassium atom to the CH_3I. The strong attraction between the resulting ions explains why the reaction energy is liberated before the products are formed.

The electron-jump mechanism, which is also known for reactions in the liquid phase, was first used by *M. Polanyi* as early as the 1930's to explain the high velocities of reactions of the type $M + X_2$ observed in sodium flames. The results of molecular beam studies of this type of reaction agree well with the cross-section found by *Polanyi*. Molecular beam measurements also show that the products of this reaction are scattered forwards, as is to be expected from the large cross-section.



K	$\rightarrow$	$\leftarrow$	Br_2	Before
Br	$\leftarrow$	$\rightarrow$	KBr	After

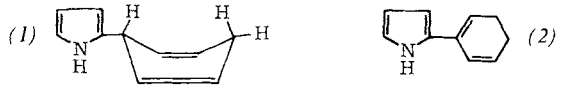
SELECTED ABSTRACTS

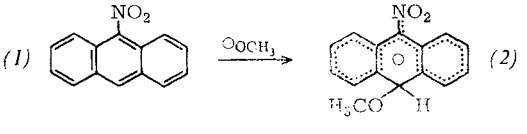


The formation of 2-oxazolones by photorearrangement of 3-hydroxyisoxazoles has been observed by *H. Göth, A. R. Gagneux, C. H. Eugster*, and *H. Schmid*. UV irradiation of aqueous solutions of ibotenic acid *(1)* from toadstools leads in 35% yield to muscazone *(2)*, an α-amino acid that has been

(1) *(2)*

isolated from *Amanita muscaria*. Similarly, UV irradiation of muscimol (5-aminomethyl-3-hydroxyisoxazolone), another active principle from *Amanita* leads to 5-aminomethyl-2-oxazolone (15%), together with 3-hydroxy-5-hydroxymethylisoxazole. 3-Hydroxyisoxazoles, *e.g.* 3-hydroxy-5-methylisoxazole, can be obtained from ethyl 3,3-bis(methoxy)butyrate by conversion into the hydroxamic acid and ring closure by heating under vacuum or with HCl gas in anhydrous methanol or glacial acetic acid. / Helv. chim. Acta *50*, 137 (1967) / –Ma. [Rd 653 IE]

A 1,4-photoaddition of pyrrole to benzene was observed by *M. Bellas, D. Bryce-Smith*, and *A. Gilbert*. UV irradiation of solutions of pyrrole in benzene at 25 °C under nitrogen led to a mixture of 1:1 adducts, about 95% of which consisted of a colorless compound having the constitution *(1)*, m.p. 15 °C. The compound is practically non-basic, and is not attacked by dilute mineral acids. On catalytic hydrogenation it gives 2-cyclohexylpyrrole and a trace of 2-phenylpyrrole. *(1)* is



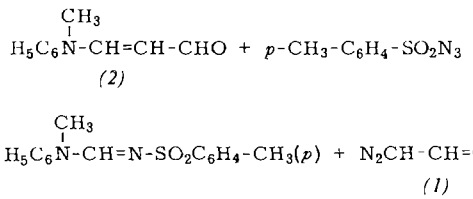
(1) *(2)*

rearranged by potassium t-butoxide into an unstable diene, probably *(2)*. The assumed constitution *(1)* is in agreement with the UV and NMR spectra. / Chem. Commun. *1967*, 263 / –Ma. [Rd 685 IE]

The Protein Sequenator described by *P. Edman* and *G. Begg* is an instrument for automatic amino-acid sequence analysis. It was used to automate the "Edman degradation", *i.e.* the reaction of the N-terminal amino acid of a peptide chain with phenyl isothiocyanate and conversion of the adduct into the peptide chain having one amino acid less and the 2-anilinothiazolin-5-one derivative of the amino acid removed. This is delivered to a fraction collector, converted outside the Sequenator into the 3-phenyl-2-thiohydantoin, and identified by thin-layer chromatography. One reaction cycle, *i.e.* the removal of one amino-acid residue from a peptide chain, involves 30 operations and takes 93.6 min. The average yield per cycle has so far been 98.5%; this permits about 100 cycles, and hence the sequence analysis of a protein consisting of 100 amino acid units. The reaction vessel, which is maintained at 50 °C thermostatically, consists of a glass beaker rotating at a constant speed of 1425 r.p.m., in which the reaction solution covers the wall in the form of a film. With this arrangement, the necessary technical operations such as dissolution, evaporation, vacuum drying, and extraction can be carried out in such a way that the protein always remains in the reaction vessel.

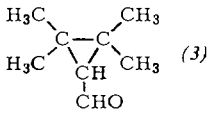
The Sequenator was used for the sequence analysis of humpback-whale apomyoglobin. 5.0 mg of protein were sufficient. The analysis was allowed to proceed for 60 cycles, and it was found that within this sequence of 60 amino acids, six were interchanged in relation to the sequence in sperm-whale myoglobin. / Europ. J. Biochem. *1*, 80 (1967) / –Hö. [Rd 683 IE]

A Meisenheimer complex *(2)* **containing only one nitro group** has been detected by *R. Foster, C. A. Fyfe, P. H. Emslie*, and *M. I. Foreman* by NMR spectroscopy. The addition of sodium methoxide to 9-nitroanthracene *(1)* in dimethyl sulfoxide yields a deep red solution (λ_{max} = 505 nm), and a band appears in the NMR spectrum at –4.96 ppm, whereas the absorption of the hydrogen in position 10 of *(1)* is situated at –8.92 ppm.



(1) *(2)*

The absorption of the protons in positions 1 and 8 is shifted from –8.2 ppm to –8.8 ppm, and the multiplet due to the remaining hydrogens is shifted from –7.75 to –7.16 ppm. Meisenheimer compounds from dinitrophenyl ether and methoxide and from trinitroaromatic compounds and acetonate (color carriers of the Janovski reaction) exhibit similar NMR-spectroscopic behavior. / Tetrahedron *23*, 227 (1967) / –Bu. [Rd 667 IE]



Diazoacetaldehyde *(1)* was synthesized by *Z. Arnold* by heating β-*N*-methylanilinoacrolein *(2)* with excess *p*-toluenesulfonyl azide at 70–80 °C under vacuum, whereupon diazoacetaldehyde *(1)* distilled off [pure *(1)* detonates violently when overheated!] (yield approx. 70%). *(1)* can be purified by vacuum distillation (bath temp. < 50 °C) or by extraction from aqueous solution with methylene chloride; it is a yellow liquid having b.p. 40 °C/10 mm, and is stable at

−70 °C. Decomposition of *(1)* in tetramethylethylene in the presence of copper acetylacetonate gives tetramethylcyclopropanecarbaldehyde *(3)* (yield 25 %); it is assumed that formylcarbene occurs as an intermediate.

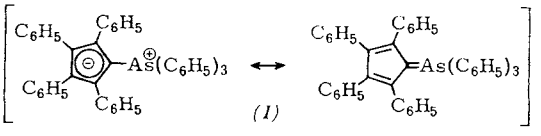
Derivatives of amphi-anthraquinone, a new quinone system, have been synthesized by *P. Boldt*. 3,7-Dihydroxy-2,6-anthraquinone *(1)*, which is obtained from 2,3,6,7-tetrahydroxyanthracene by dehydrogenation with 2,3-dichloro-5,6-dicyanobenzoquinone, is a pale yellow, very unstable compound.

(1), R = H
(2), R = CH_3

If positions 9 and 10 are screened by methyl groups, the stable, orange 3,7-dihydroxy-9,10-dimethyl-2,6-anthraquinone *(2)* is obtained. / Chem. Ber. *100*, 1270 (1967) / −Ma. [Rd 684 IE]

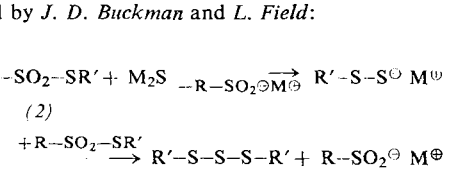


Metal carbonyls, such as $Fe(CO)_4 \cdot C_6H_5CN$, $Fe(CO)_5$, $Fe_2(CO)_9$, $W(CO)_6$, and $Mo(CO)_6$, catalyse (at concentrations of about 1 wt.-%) the conversion of isocyanates into carbodiimides. Thus bis(*o*-tolyl)carbodiimide was obtained in yields of 82.3 to 85.6 % when *o*-tolyl isocyanate was refluxed in the presence of such catalysts.

The reaction proceeds as follows:

$$M{=}C{=}O + RNCO \rightarrow M{=}C{=}NR + CO_2$$
$$M{=}C{=}NR + RNCO \rightarrow RN{=}C{=}NR + M{=}C{=}O$$

/ Tetrahedron Letters *1967*, 1731 / −Ma. [Rd 698 IE]



An arsene ylide has been obtained for the first time by *D. Lloyd* and *M. I. C. Singer* from a carbene and an arsine. When diazotetraphenylcyclopentadiene is heated in triphenylarsine, tetraphenylcyclopentadienylidene triphenylarsorane is formed *(1)* [m.p. 228–230 °C (decomp.), golden-yellow crystals (from nitromethane)]. This synthesis provides a new route to the formation of a C–As bond. *(1)* dissolves in perchloric acid to form triphenyl(tetraphenylcyclopentadienyl)arsonium

(1)

perchlorate. This compound and *(1)* are stable in air. *(1)* reacts only with difficulty with benzaldehyde to form 1,2,3,4,6-pentaphenylfulvene. / Chem. and Ind. *1967*, 510 / −Ma. [Rd 701 IE]

A new route to symmetrical trisulfides *(1)* *via* thiosulfonates has been found by *J. D. Buckman* and *L. Field*:

(2)

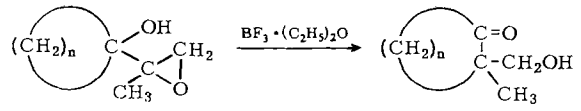
(1)

(a), R=R′=*p*-CH_3–C_6H_4; *(b)* R=*p*-CH_3–C_6H_4, R′=$C(CH_3)_3$ M=K or Na

In this way it is possible to obtain symmetrical trisulfides with a primary or tertiary alkyl group, or with an aryl group, in yields of 82–95 % and in a very pure state. The reaction of *(2a)* with potassium sulfide in methanol for 30 min at room temperature gives di-*p*-tolyl trisulfide *(1a)* (m.p. 81–82 °C) in 90 % yield. On the other hand, the reaction of t-butyl *p*-toluenethiosulfonate *(2b)* is better carried out in an ether-water mixture, since *(1b)* (b.p. 108–110 °C/20 mm Hg) is otherwise contaminated with tetrasulfide. / J. org. Chemistry *32*, 454 (1967) / −WG. [Rd 707 IE]

Thermodynamic data on the "mutarotation" of fructose, *i.e.* on the reaction

$$\beta\text{-fructopyranose } (F_6) \underset{k-}{\overset{k+}{\rightleftharpoons}} \beta\text{-fructofuranose } (F_5)$$



were determined by *F. Grønlund* and *B. Andersen* from the following information: initial concentrations of fructose, specific rotations α_F of the pure forms F_6 and F_5 (α_{F5} determined by *B. Andersen* and *H. Degn*, Acta chem. scand. *16*, 215 (1962) by enzymatic hydrolysis of cane sugar), time-dependence of the instantaneous rotation and its ultimate equilibrium value α_∞, and temperature-dependence of the

T (°C)	k_+ (min^{-1})	k_- (min^{-1})	$K = k_-/k_+$

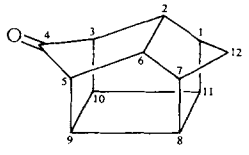
rate constants and equilibrium constants. E_A+($F_6 \rightarrow F_5$) = 17.2 kcal mole^{-1}; E_A-($F_5 \rightarrow F_6$) = 13.4 kcal mole^{-1}; ΔH^0 = 3.80 kcal mole^{-1}. / Acta chem. scand. *20*, 2663 (1966) / −Jg. [Rd 695 IE]



The reaction of monosaccharides with thiocyanic acid was studied by *J. C. Jochims*, *A. Seeliger*, and *G. Taigel*. D-Glucose, D-xylose, D-galactose, L-arabinose, and D-ribose react with HSCN in acidic solution to give 5-substituted 2-thioxo-6-hydroxyhexahydro-*cis*-furo[2,3-*d*]oxazoles *(1)*. D-Lyxose gives a pyranose. Fructose gave a mixture from which two compounds were isolated as the main products. A peracetylated thiourethane was obtained from D-mannose on warming with alcohol and acetylation. Compounds *(1)* cannot have more than one *endo* substituent for steric reasons. Consequently, mannose, gulose, and lyxose do not form hexahydro-*cis*-furo[2,3-*d*]oxazoles. / Chem. Ber. *100*, 845 (1967) / −Ma. [Rd 687 IE]

A ring expansion in 1-(isopropenyl) cycloalkanol epoxides *(1)* has been reported by *C. J. Cheer* and *C. R. Johnson*. Epoxides *(1)* are obtained from the olefin by oxidation with *m*-chloroperbenzoic acid in chloroform. The rearrangement to form the cyclic ketone *(2)* is effected in methylene chloride at

$-5\,^{\circ}C$ with boron trifluoride/ether as catalyst, or in boiling benzene with acid-washed aluminum (Merck). When BF_3/ether is used as catalyst, the yield of *(2)* falls from 63 % ($n = 3$) to 49 % ($n = 4$), and thence to 15 % ($n = 5$). / J. org. Chemistry *31*, 428 (1967) / –WG. [Rd 704 IE]

The "birdcage ketone" *(1)* (hexacyclo[5.4.1.0^{2,6}.0^{3,10}.0^{5,9}.0^{8,11}] dodecan-4-one) and some of its derivatives have been prepared by *R. J. Stedman* and *L. S. Miller*. The synthesis of *(1)* from 1,2,3,4,7,7-hexachloronorbornadiene and the ethylene ketal of tetrachlorocyclopentadienone or the last-named compound and vinyl chloride takes place in four or six steps respectively, *via* stereoselective Diels-Alder reactions, which are followed by photochemical processes.

(1)

The structure of *(1)*, m.p. 180–182 °C, is shown *inter alia* by IR, NMR, and mass spectra. / J. org. Chemistry *32*, 35 (1967) / –WG. [Rd 670 IE]

Oleic acid is the precursor of naturally occurring acetylenes in *Tricholoma grammopodium* cultures, as was indicated by radiochemical investigations carried out by *J. D. Bu'Lock* and *G. N. Smith*. All the radioactive products occurring in the following scheme could be chromatographically separated (as the methyl esters) and detected 7 days after the cultures had been fed with [10–^{14}C]-oleic acid *(1)*.

$CH_3-CH_2-CH_2-CH_2-CH_2-CH_2-CH_2-CH_2-{}^{14}CH{=}CH-(CH_2)_7-COOH$

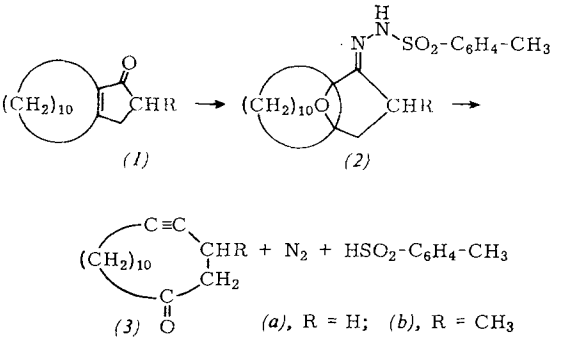
$\downarrow -2\,H$ *(1)*

$CH_3-CH_2-CH_2-CH_2-CH_2-CH{=}CH-CH_2-{}^{14}CH{=}CH-(CH_2)_7-COOH$

$\downarrow -2\,H$

$CH_3-CH_2-CH_2-CH_2-CH_2-C{\equiv}C-CH_2-{}^{14}CH{=}CH-(CH_2)_7-COOH$

$\downarrow -2\,H$



$CH_3-CH_2-CH_2-CH{=}CH-C{\equiv}C-CH_2-{}^{14}CH{=}CH-(CH_2)_7-COOH$

$\downarrow$

$CH_3-C{\equiv}C-C{\equiv}C-C{\equiv}C-CH{=}{}^{14}CH-CH_2OH$

These experiments provide the first experimental proof of the biogenetic path postulated some ten years ago for the dehydrogenation of fatty acids to form acetylenes; however, the detailed mechanism of the formation of the triple bond is still unknown. / J. chem. Soc. (London) C *1967*, 332 / –Bu. [Rd 671 IE]

A novel fragmentation of cyclic α,β-unsaturated carbonyl systems has been discovered by *A. Eschenmoser*, *D. Felix*, and *G. Ohloff*. The bicyclic ketone *(1a)* or *(1b)* is first epoxidized and then converted into the α,β-epoxy *p*-toluenesulfonylhydrazones *(2a)* or *(2b)*, which are stirred for 20 hours with two equivalents of sodium methoxide in dimethyl sulfoxide. As expected, this yields 4-cyclopentadecyn-1-one *(3a)* (m.p.

(a), R = H; *(b)*, R = CH_3

40 °C, 60–65 % yield) or *(3b)*. The structure of *(3a)* is evidenced, *inter alia*, by the formation of exaltone on catalytic hydrogenation; the structure of *(3b)* is established by hydrogenation to form racemic muscone. / Helv. chim. Acta *50*, 708 (1967) / –WG. [Rd 706 IE]

Trichlorovinylamines *(3)* are obtained, together with cyclopropane derivatives, on reaction of allylamines *(1)* with phenyltrichloromethylmercury, as was found by *W. E. Parham* and *J. R. Potoski*. The following reaction probably takes place:

$R_2N-CH_2-CH{=}C(CH_3)_2 + C_6H_5-Hg-CCl_3 \rightarrow$

(1)

$R_2\overset{\oplus}{N}-CH_2-CH{=}C(CH_3)_2$
$H_5C_6-\overset{\ominus}{Hg}-CCl_3 \rightarrow$

$R_2N-CCl_2-Hg-C_6H_5 + ClCH_2-CH{=}C(CH_3)_2$

(2)

$\downarrow$

$R_2N-\ddot{C}-Cl + C_6H_5HgCl$

$\downarrow +CCl_2$

$(C_6H_5HgCCl_3) \rightarrow R_2N-C{=}C(Cl)-Cl$ (Cl)

(3)

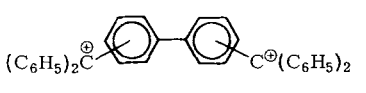
Other reaction products detected are isoprene, chloroform, and adducts of dichlorocarbene with isoprene and with *(2)*. As the basicity of the amine *(1)* increases, the yield of cyclopropane decreases, and the quantity of vinylamine *(3)* and chloroform increases. The reaction can proceed in this manner only if the allyl chain contains at least four carbon atoms. / J. org. Chemistry *32*, 278 (1967) / –WG. [Rd 705 IE]

Syntheses and rearrangements of hydrazonic acid azides have been reported by *A. F. Hegarty*, *J. B. Aylward*, and *F. L. Scott*. The hydrazonoyl bromides *(1)* not only react with

$R-C(Br){=}N-NHAr \rightarrow R-C(N_3){=}N-NHAr \rightarrow$

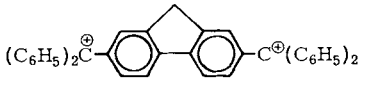
(1) *(2)*

$[R-N{=}C{=}N-NHAr] \rightarrow R-NH-C(=O)-NH-NHAr$



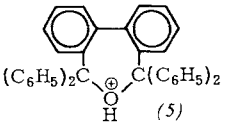
(3) *(4)*

R = C_6H_5, *p*-Cl–C_6H_2, *p*-$(CH_3)_3CH-C_6H_4$, *p*-$CH_3-C_6H_4$, *p*-Br–C_6H_4



Ar = *o*-Br–C_6H_4, *p*-$NO_2-C_6H_4$, *o*,*p*-$Br_2-C_6H_3$

H_2NNH_2 and HNO_2 to give tetrazoles, but also react readily and uniformly with the equivalent quantity of NaN_3 in a dioxane/water mixture (4:1) at 25 °C to give hydrazonic acid azides *(2)*. The isomeric tetrazoles cannot be obtained from *(2)* either by heating or by the action of alkali or excess NaN_3, whereas imidic acid azides undergo this reaction readily. The hydrazonic acid azides *(2)* rearrange in trifluoroacetic acid or acetic acid/sulfuric acid to give semicarbazides. There is considerable evidence to suggest that this rearrangement takes place *via* an *N*-aminocarbodiimide *(3)*. The retention of optically active residues R shows that the residue R is never free during the course of the rearrangement. / Tetrahedron Letters *1967*, 1259 / –Jg. [Rd 696 IE]



Dicarbenium ions of the biphenyl series, *(1)* to *(4)*, in aqueous H_2SO_4 following the synthesis of the corresponding dicarbinols have been studied by *H. Hart, Th. Sulzberg, R. H. Schwendeman*, and *R. H. Young*. (For data in the longest wavelength absorption and $pK_{R^{++}}$ values, see Table). The experimental longest wavelength absorption maxima μ_{max} are linearly related to the calculated (MO method; ω technique) Δm values (= energy difference between the highest occupied and lowest unoccupied MO's). Data for the tetraphenylxylyl dications were also plotted. It must be concluded that the central biphenyl grouping in *(2)* is twisted through > 20°; the extremely low $pK_{R^{++}}$ value of *(3)* is due to the formation of the stable 2,7-dihydrooxepinium ion.

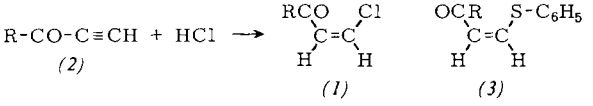
A new photochemical rearrangement of β,γ-unsaturated cyclic ketones is described by *J. R. Williams* and *H. Ziffer*. Irradiation of 1,2,3,4,5,6,7,8-octahydronaphthalen-2-one *(1)* (high-pressure mercury lamp, N_2, t-butanol) gave the bicyclic ketone *(2)* (60% yield), which could be converted in good yield into *(3)* by treatment with HBr in glacial acetic acid.

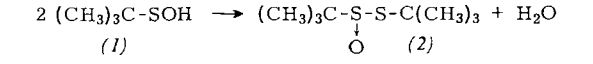


(1) *(4)*

(2) *(3)*

Reaction with alkali leads to reformation of *(2)*. The reaction may proceed *via (4)*. 17β-Hydroxyester-5(10)-en-3-one undergoes the same rearrangement. / Chem. Commun. *1967*, 194 / – Ma. [Rd 650 IE]

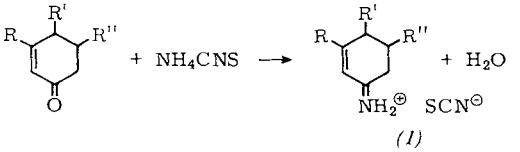
***cis*-(2-Chlorovinyl) ketones** *(1)*, unlike the *trans* compounds, have hitherto remained unknown. According to *D. Landini* and *F. Montanari*, they can be obtained by the addition of the stoichiometric quantitiy of HCl to ethynyl ketones *(2)* in dry chloroform at –40 °C in the presence of CuCl. The reaction is complete in 6–24 hours, and its course can be followed by IR spectroscopy. A small excess of acid or the use of high reaction temperatures leads to *cis* → *trans* isomerization. The ketones *(1)* can be converted into *cis*-phenylthiovinyl ketones *(3)* by reaction with thiophenolate ions in acetone/



(2) *(1)* *(3)*

water at 0 °C. The *trans*-sulfides are thermodynamically less stable than the *cis*-compounds, and can be converted into the latter by base catalysis. / Chem. Commun. *1967*, 180 / –Ma. [Rd 651 IE]

The existence of t-butylsulfenic acid *(1)*, the first aliphatic sulfenic acid, has been demonstrated by *J. Reid Shelton* and *E. Davis*. *(1)* is formed on partial thermolysis (80 °C) of di-t-butyl sulfoxide in various solvents. The final product is the thiosulfinate *(2)*. *(1)* was detected by NMR and IR spectroscopy and by its addition reaction with electrophilic olefins.



(1)

(1) *(2)*

Addition to ethyl acrylate gave ethyl β-t-butylsulfinylpropionate, while addition to methyl propiolate (with loss of isobutylene) led to bis(*trans*-methoxycarbonylvinyl) sulfoxide (diadduct) *(3)*. / J. Amer. chem. Soc. *89*, 718 (1967) / –Ma. [Rd 652 IE]

A new condensation reaction of α,β-unsaturated cyclic ketones with ammonium thiocyanate has been described by *G. Kabas*. Condensation of 3-substituted 2-cyclohexen-1-ones with NH_4CNS in a non-polar solvent with azeotropic removal of water, *e.g.* in boiling toluene, leads, *via* a heterogeneous reaction, to iminium thiocyanates *(1)*. Salts such as NaCl, Na_2SO_4, and Na phosphates increase the yield, probably by stabilization of *(1)*. The orange-yellow compounds are very readily soluble in polar solvents; the solutions can be kept for several days, but are hydrolysed by $NaHCO_3$, with reformation of the ketone. Examples: isophorone → 3,5,5-trimethyl-2-cyclohexene-1-iminium thiocyanate, 85% yield

(1)

3-phenyl-2-cyclohexen-1-one → 3-phenyl-2-cyclohexene-1-iminium thiocyanate, 81.5%. / J. org. Chemistry *32*, 218 (1967) / –Ma. [Rd 647 IE]

The polymerization of 4-azido-1-butyne by inner 1,3-dipolar addition to form a polyethylenetriazole *(1)* is described by *K. E. Johnson, J. A. Lovinger, C. O. Parker,* and *M. G. Baldwin.* 4-Azido-1-butyne could be prepared from 3-butynyl *p*-toluenesulfonate and NaN_3 in sulfolane/water (69% yield), and could be polymerized by bulk polymerization or precipitation polymerization from boiling benzene. The product

(1)

does not exhibit thermal decomposition below 320 °C. *(1)* contains a mixture of 1,4- and 1,5-substituted triazole rings. / Polymer Letters 4*B*, 977 (1966) / –Ma. [Rd 648 IE]

The arylation of aromatic and heterocyclic compounds by nitro compounds at high temperatures is described by *E. K. Fields* and *S. Meyerson.* The components are made to react for 2–30 sec in a continuous flow reactor packed with quartz pieces. Nitrobenzene/benzene (molar ratio 1:5) at 600 °C in a current of N_2 gives a mixture of 62% of biphenyl and 13.9% of terphenyl (total yield 85 mole-%). The phenylation of pyridine with nitrobenzene at 600 °C leads to a mixture of the 2-, 3-, and 4-isomers (63·6:26.3:10.1) in 72% yield. Thiophene/nitrobenzene gives a mixture of 2- and 3-phenylthiophene (75:25) in a yield of 60 mole-%. 3-Nitrobiphenyl and *m*-terphenyl (7:1) are obtained in 40% yield from *m*-dinitrobenzene and benzene at 450 °C. Arylations have also been carried out with trinitrobenzene, 1-nitronaphthalene, *m*-nitrobenzotrifluoride, and methyl *p*-nitrobenzoate. The reaction proceeds *via* free radicals. / J. Amer. chem. Soc. *89*, 724 (1967) / –Ma. [Rd 649 IE]

BOOK REVIEWS

Radioaktive Isotope in der organischen Chemie und Biochemie (Radioactive Isotopes in Organic Chemistry and Biochemistry). By *H.-R. Schütte.* Verlag Chemie. GmbH., Weinheim/Bergstr. 1966. 1st Edit., xi, 689 pages, (of which 417 pages form the tabular part), numerous figures and tables. DM 78.–.

This is an excellent book for the chemist, biologist, or physician who is using radioactive isotopes in practice, as well as for the advanced student who wishes to familiarize himself with the principles of the use of isotope techniques in organic chemistry and biochemistry. The author presents a very readily understandable introduction to this field, while the well-chosen examples of applications, the numerous references, and the comprehensive tables make the book a useful reference work.

Starting with a detailed chapter on the monitoring techniques of radioactive preparations, autoradiographic detection processes, and a short section on radiation protection and the equipment of isotope laboratories, two long chapters follow which deal with the preparation of labeled compounds and their many uses. Numerous examples of the use of labeled reagents in analysis, degradation methods for the determination of the activity distribution in labeled compounds, the investigation of reaction mechanisms, and in particular the successful use of radionuclides for the elucidation of biochemical processes are described concisely and clearly.

The second part of the work consists of several tables listing more than two thousand organic compounds labeled with radioactive carbon, phosphorus, sulfur, iodine, bromine, or chlorine, and whose preparations have already been described in the literature. The comprehensive list of references, which covers the literature up to the end of 1965, is an excellent source list for anyone who wishes to learn about the synthesis or use of labeled compounds. Though a somewhat more complete index would have been desirable, the book can be warmly recommended to all those who intend to use radioactive isotopes in organic chemistry and biochemistry.

A. Schwarz [NB 605 IE]

Fluorimetrie. Eine Anleitung zur Ausführung von quantitativen fluorimetrischen und spektrofluorimetrischen Messungen (Fluorimetry. An introduction to quantitative fluorimetric and spectrofluorimetric measurements). By *J. Eisenbrand.* Wissenschaftliche Verlagsgesellschaft mbH, Stuttgart 1966. 1st Edit., vii, 153 pp., 81 figures, linen DM 44.–.

Fluorescence methods have been in use for some time for the qualitative and quantitative analysis of many substances that either fluoresce themselves or can be converted by specific reactions into substances that fluoresce. They are particularly suitable for the analysis of small quantities of material, where they are inferior only to the much more costly radiochemical methods.

The present monograph deals with the methods and applications of such fluorescence measurements for analytical purposes. In addition to earlier instruments, a selection of commercial photoelectric fluorescence spectrometers is described, including a recent development in which the excitation is carried out with selected parts of the xenon continuum. The decrease in excitation intensity in comparison with excitation with mercury radiation is unimportant, owing to the sensitivity of modern radiation detectors, and is more than compensated for by the greater freedom of choice of the excitation conditions

As examples of the application of the methods, detailed analytical procedures, largely developed and proved in the author's laboratory, are given for various inorganic and organic substances. The groups of substances discussed include porphyrins, vitamins, optical brighteners, and scintillators. These more specialized methods are accompanied by general hints on the development of procedures. A short bibliography includes other monographs on fluorescence. However, this list does not contain the book on fluorescence analysis published a few years ago by *Udenfriend*, which is included only among the journal references.

The present monograph should be useful to anyone who uses fluorescence methods as analytical aids and prefers to use procedures that have already been developed.

Th. Förster [NB 589 IE]

Quantitative Bestimmung organischer funktioneller Gruppen (Quantitative determination of organic functional groups). By *R. Kaiser.* Volume 4 of the series "Methoden der Analyse der Chemie" (Analytical methods in chemistry). Akademische Verlagsgesellschaft. Frankfurt am Main 1966. 1st Edit., x, 445 pp., 33 figures, 11 tables, DM 58.–.

The classical methods of determining functional groups in organic compounds and their mixtures are today supplemented and frequently replaced by physical methods; satisfactory summaries of each approach are available. Undoubtedly a combination of the two routes will be needed to provide the optimum solution to analytical problems, some of which, in fact, can be solved only by such means. Supported by the

extensive experience of a large analytical laboratory, *R. Kaiser* gives an excellent survey of the quantitative determination of all important functional groups; both the above categories are considered in terms of their present development.

Following a survey of conventional systems, *Kaiser* proposes a new uniform system built up on "functional numbers". A functional number is defined as the numerical value of the concentration by weight of the key atom that is being determined in the form of the functional group. These data are explicit and facilitate establishment of the compositions of mixtures. Control methods and error determination are treated in detail, and equal care is devoted to the optimization of analytical procedures. Sampling errors are assigned their critical role: "90 % of all analytical errors are sampling errors". The combination of group determination with chromatographic methods of separation concludes the first part; the author's great experience in this field becomes obvious in this section.

In the second part the most frequently encountered functional groups are dealt with individually. In every case the qualitative detection (mostly in the UV, IR, and NMR spectrum) and the analytical behavior are given first and at least one proved standard method is described in detail together with an indication of its range of application and the most frequently encountered interference. The third part gives a survey of additional methods, mainly in the form of tables and references.

The presentation is clear and easy to understand. A lively style matches the book's good external appearance. The work should soon become an indispensable aid, both for the research chemist and for his colleagues in the control laboratory.

G. Hesse [NB 632 IE]

Handbuch der physiologisch- und pathologisch-chemischen Analyse, für Ärzte, Biologen und Chemiker (Handbook of Physiological and Pathological Chemical Analysis for Physicians, Biologists, and Chemists). By *Hoppe-Seyler/Thierfelder*, edited by *K. Lang* and *E. Lehnartz* with the assistance of *O. Hoffmann-Ostenhof* and *G. Siebert*. Vol. 6: Enzymes, Part B. Springer-Verlag, Berlin-Heidelberg-New York 1966. 10th Edit., xvi, 1282 pages, bound DM 424.– (subscription DM 339.20).

Appearing eighteen months after the publication of Part 6 A [*], the present Part 6 B contains the conclusion of the article on oxidoreductases, the contribution headed transferases and the beginning of the contribution on hydrolases. The assignment of the enzymes to these groups is somewhat confusing, since all the coenzyme A dependent enzymes are included under oxidoreductases, though only about 20% of the 50 or so enzymes discussed belong to this group; the others are hydrolases, transferases, lyases, isomerases, or ligases. A similar situation is found for the folic acid dependent enzymes and for the "phosphate-transferring enzymes", which is the description used for the pyrophosphorylases. As in the first Part, some of the topics receive a treatment such as might be expected in a monograph: coenzyme A enzymes (*O. Wieland*), transaminases (*Trautschold* and *Werle*), ribonucleases (*Siebert*), glycosidases (*Wallenfels* and *Diekmann*) and the "phosphate-transferring enzymes" (*Rohdewald*). In addition to analytical procedures, these chapters contain considerable additional information that cannot be found elsewhere in such a compact form. Other enzymes are dealt with more briefly with the main emphasis on the methods.

It is regrettable that in some cases the literature is covered only up to 1961 or 1962. It is to be hoped that the final Part, with the index for all three volumes will be published soon, so that greater use may be made of this work than is possible at present. The print and presentation are excellent.

H. Sund [NB 599 IE]

[*] Cf. Angew. Chem. *78*, 215 (1966); Angew. Chem. internat. Edit. *5*, 262 (1967).

Chemisch-physikalische Vitamin-Bestimmungsmethoden (Physicochemical methods for the determination of vitamins). By *G. Gstirner*. Ferdinand Enke Verlag, Stuttgart 1965. 5th revised Edit., xii, 426 pages, 26 figures, 20 tables, plastic DM 58.–; paper DM 53.50.

The present 5th edition of this well known work [*] has been thoroughly revised. It now includes methods for the elimination of interfering accessory compounds in order to increase the specificity and sensitivity of the processes. New entries include methods for the determination of vitamin B_{12} (cyanocobalamin), panthenol, and (valuable, though disputed from the strictly vitamin point of view) choline and rutin. New methods are also described for pyridoxine, *p*-aminobenzoic acid, and folic acid. The polarographic determination of some vitamins is also discussed for the first time.

Theoretical discussions are deliberately kept brief, without detriment to the book. This leaves room for detailed descriptions of the processes, generally in the words of the original publication. The selection seems rather narrow in places, but this is counterbalanced by the range of possible applications described. They relate to the testing and determination not only of pure vitamins, but also of natural products of all kinds, foods, fodder and pharmaceutical preparations (tablets, juices, solutions for injection, multivitamin preparations). Physiological-chemical methods for animal organs, tissues, urine, and blood, as well as clinical-chemical methods, are also included. The grouping of the procedures is simple and clear, and the critical evaluation of the various determination methods is particularly welcome.

The print, composition, and presentation leave nothing to be desired. The present edition, to an even greater extent than the earlier editions, will be a useful source of advice to those interested in the field and also to the food chemist.

J. Schormüller [NB 613 IE]

[*] Cf. Angew. Chem. *63*, 541 (1951).

Chemie-Lexikon (Encyclopedia of Chemistry). By *H. Römpp*, edited by *E. Ühlein* (4 Volumes). Franckh'sche Verlagshandlung, Kosmos-Verlag, Stuttgart 1966. Sixth Edit., 7408 columns of text, 452 columns of tables, and an English-language index. DM 390.–.

When *Hermann Römpp* died in 1964 many asked whether, and how, "Römpp" would live on. The new sixth edition of this chemical encyclopedia answers the question. Much of the manuscript of this edition is *Hermann Römpp*'s, completed by the new editor, Dr. *Erhard Ühlein*.

For the first time the encyclopedia comprises 4 volumes, with about 3900 pages containing 37,500 entries (over 25 % more than the fifth edition which was published in 1962). Entries such as "Antimatter," "Catenane", "Electrophoretic Coating", "Ionic Propellants", "Laser Crystals", "Desalination of Sea-water", "Rocket Fuels" and "Tranquilizers" are included, to name only a few that demonstrate the topicality of the work. The 37,500 entries hide nearly 49,000 literature references, 29,500 source references, 13,500 tradenames, and 1150 biographical sketches. It is difficult to think of a problem that is not answered in "Römpp".

A 182-page English index of the entries is a novelty. It is placed at the end of the fourth volume and not only facilitates the use of the encyclopedia by English-speaking readers, but extends the scope of the work to that of an English-German chemical dictionary. To help the German-speaking reader to find the English equivalent of an entry this is given at the end of each description. There is no doubt that this extension was an excellent idea.

It is unnecessary to recommend "Rompp". Without exaggeration it may be stated that the work never leaves its user in the lurch. Its information is reliable, well balanced, and despite its brevity sufficiently detailed to provide more than just preliminary data. Further details are easily ob-

tained with the aid of the cited literature. "Römpp" does not just have a place in every library – it is a miniature library in its own right.

H. Grünewald [NB 646 IE]

Technisches Taschenwörterbuch (Pocket Technical Dictionary), English-German, German-English. By *H. G. Freeman.* Max Hueber Verlag, Munich 1965. 285/297 pp., soft cover, DM 9.80 each volume.

When one reads in the foreword to a dictionary that "Nearly every engineer needs – rightly and properly – to consult a technical dictionary from time to time. Such dictionaries .... should not confront the user with a crossword puzzle in every 7 out of 8 renderings", then one is dealing either with a very good dictionary, or else with a very self-confident author. After looking through these two volumes, the reviewer has gained the impression that the latter alternative is the more likely. Or is it not, perhaps, a "crossword puzzle" to find – without any distinction being drawn – "waste, refuse; decrease, drop" for "Abfall", or "outlet, discharge; outflow; expiration" for "Ablauf"? The engineer seeking to satisfy his "right and proper" needs will be disappointed, for a list of such puzzles would run right through the alphabet.

A good solution has been found to the problem of composite words: to avoid long lists of similarly formed words, the author in each case quotes only the first part of such words, illustrating its use with a few examples. This enables both volumes to remain compact at no cost to the information contained.

It is difficult to discern precisely for whom the dictionary is intended. The vocabulary extends to practically all branches of industrial technology (the list of subjects covered by the dictionary contains over 90 entries). Translations of some 13000 terms are given, so that there is some justification for the claim made in the foreword, that the user will seldom be at a loss. However, even the author should not believe that the user will *never* be at a loss, although he offers this as a modest alternative to "seldom".

H. Grünewald [NB 582 IE]

Rodd's Chemistry of Carbon Compounds. Edited by *S. Coffey.* Vol. 1. Part D: Dihydric Alcohols, Their Oxidation Products and Derivatives. Elsevier Publishing Company, Amsterdam-London-New York 1965. 2nd Edit., xvi, 418 pages, 32 tables, bound Dfl. 65.–, subscription Dfl. 55.–.

The fourth part of the seven-part first volume of the 2nd edition of Rodd (the 1st Edition [*] had only two parts) has now been published, shortly after the appearance of the earlier parts. Six well-arranged chapters deal with the preparation, properties, and reactions of acyclic compounds containing two functional groups (on different carbon atoms). Six authors discuss the following classes of compounds: glycols and glycol ethers, their sulfur analogues, nitro- and amino-alcohols, diamines (*E. S. Waight*); hydroxyaldehydes and -ketones and dicarbonyl compounds (*E. S. Waight*); monohydroxymonocarboxylic acids and their derivatives (*D. St. C. Black, G. M. Blackburn, G. A. R. Johnston*); amino acids and their derivatives, peptides, hydrazo and azo acids (*I. E. Davies*); keto acids (*D. St. C Black, G. M. Blackburn, G. A. R. Johnston*); dicarboxylid acids and their derivatives (*J. Oldham*).

The chapters on keto acids, dicarboxylic acids, and amino acids are much larger than in the first edition owing to the rapid expansion of these fields. The arrangement of individual sections is on a mechanistic basis, *e.g.* the description of diazo esters as nucleophilic and electrophilic reagents and as carbene generators, or according to preparation, *e.g.* in the preparation of peptides (by amino or carboxyl activation or by dehydrating agents). This gives a very clear presentation of the extensive material covered. The consistent application should be encouraged whenever possible in subsequent volumes. This volume with numerous references, which also include early publications as well as reviews (mostly up to 1963), is a valuable source of information which no organic chemistry laboratory should lack. Print and presentation are excellent.

K. Hafner [NB 609 IE]

[*] Cf. Angew. Chem. *78*, 397, 398 (1966); Angew. Chem. internat. Edit. *5*, 433, 434 (1966).

The Acridines. Their Preparation, Physical, Chemical, and Biological Properties, and Uses. By *A. Albert.* Edward Arnold (Publishers) Ltd., London 1966. 2nd Edit., xii, 604 pages, numerous figures and tables, 168 s.

Because of the inclusion of many new results in the acridine field, the 2nd edition of this book is almost twice as large as the first edition (1951). The grouping of the material is the same as in the previous edition, the preparation, the physical, chemical, and biological properties, and the many uses of the acridines being discussed in five sections. It should be mentioned that the C atoms and the N atoms of the acridine ring are numbered in accordance with the IUPAC recommendations, with the result that earlier confusion with regard to the positions of substituents has now been eliminated.

The first eight chapters deal from the practical angle with the methods of synthesis known up to September 1965. The most successful of these methods are naturally discussed at greatest length, and an added note gives advice about the most suitable methods for individual cases, fine purification, and the manipulation of the acridines. The next few chapters are devoted to special properties, such as surface activity, dipole moments, association and ionization, redox potentials, and absorption, fluorescence, and phosphorescence spectra. The relationship between the electron distribution and the physical and chemical properties of the compounds are discussed, and reference is made to the possibility of prediction of the properties of as yet unknown acridines.

The largest section deals with the chemical properties of acridine as well as of fused-ring and substituted acridines. Special attention is given to the amino-substituted acridines, with are used as medications and dyes A new feature of this section is a short chapter on the photochemistry of the acridines, which has recently been intensively studied. The photoproducts lead over to the acridanes, which are also discussed, together with the hydroacridines, acridones, thioacridones, and selenoacridones.

Like the first edition, the present edition contains an up-to-date comparison of physical, chemical, and biological properties. In addition to the use of the acridines in clinical medicine, the topics discussed include the interaction of these substances with nucleic acids and the relationship between their physical and chemical properties and their bactericidal, carcinogenic, and anticarcinogenic effects.

The final part of the book deals with the use of acridines as pigments and dyes, corrosion inhibitors, biochemical reagents, fuel cells, and microscopic and photographic reagents. Numerous figures and tables make the book very readable, and a great deal of information is presented in this way.

The fact that the present-day production of acridine-based medications amounts to more than 500 tons per year testifies to the considerable extension of the chemistry of acridine and its derivatives. This is particularly clear from the new edition of the book, which has not only organic chemists, but also physical chemists as well as physicians and biologists as potential readers. The book is strongly recommended to anyone who wishes a survey of the present situation in this field.

V. Zanker [NB 612 IE]

Organic Stereochemistry. By *G. Hallas*, McGraw-Hill Publishing Company Ltd., London-New York-Toronto-Sydney 1965. 1st Edit., xi, 244 pages, numerous figures, paper 28s.

The author intends this book as an introduction to static stereochemistry for students. A short historical introduction is followed by a discussion first of the optical isomers resulting from the presence of an asymmetric C atom, and then of other types of optical isomers. A special chapter is devoted to the definition and determination of relative and absolute configuration. This is followed by sections on "geometrical isomers" and methods for the determination of their configuration, and on the stereochemistry of cyclic compounds, allenes, and systems containing nitrogen. The monograph closes with a short collection of problems.

The subject matter is presented in a pleasing and readily understandable form, and the examples are drawn both from "classical" and from modern stereochemistry. Comprehension is greatly assisted by clear tables and short legends to each of the very numerous reaction schemes. The original literature is not cited, but a list of important monographs and reviews is given at the end of each chapter. References to reaction mechanisms are confined to the most important. The dynamic aspects of organic stereochemistry are almost completely ignored. The problems for practice vary considerably in difficulty, and suffer from frequent repetition, since they are taken from the courses of several universities.

There are very few printing errors (*e.g.* Fig. 5.10 is identical with Fig. 5.9). All the steric formulae are neat and correct. Despite the fact that it is confined to static problems, this book provides an excellent introduction to the principles of stereochemistry, and can be recommended to all those who wish to obtain a short review of this subject.

G. Snatzke [NB 604 IE]

Nonclassical Ions. By *P. D. Bartlett*. W. A. Benjamin, New York-Amsterdam 1965. 1st. Edit. xiv, 559 pp., many illustrations. $ 12.00.

Few questions of organic chemistry have given rise to so much discussion and so many well thought out experiments as the question concerning the existence of nonclassical ions. Developments have now reached a stage at which it is possible for only a small circle to follow competently a discussion or even to make contributions to this field. For these reasons the appearance of a book about nonclassical ions is more than well timed.

The present work consists of a collection of 75 publications concerning nonclassical ions. The publications, which are arranged in chronological order, are each introduced by a commentary dealing with the significance of the subject matter with respect to the existence of nonclassical ions. Each publication is reproduced complete (including the experimental part).

Thus instead of a review, or a justification of a particular viewpoint, the author offers the reader an opportunity to form his own opinion as to this controversy, which is now almost 30 years old. It is the declared purpose of the book to present 'how we know what we know, and why we hold our present opinions' in this special field. The author leaves it to the reader to examine the validity of the interpretation. However, the reviewer doubts whether research students, for whom this book is primarily intended, are capable of such critical reading.

The overall picture of a logical and consistent development, which is presented to the reader is an adequate justification of the choice of publications made. The book begins with the work carried out by *Roberts* and *Kimball* on bromonium ions (1937) and is concluded by the NMR investigations conducted by *Saunders*, *Schleyer*, and *Olah* (1964). A number of later publications (up to August 1965) is cited, without commentary, in the appendix.

Although the author does not conceal his own ideas regarding the more controversial points when he deals with them in the various commentaries, the final evaluation of the results is, however, left to the reader. The commentaries will thus scarcely help the biased reader to lose his prejudices, or the non-critical reader to form his own opinion. In spite of this fact, the value of the book lies in the commentaries, which occupy *ca.* 50 pages, and by virtue of which the book becomes more than a collection of reprints. Questions are posed and relationships are demonstrated which go beyond the bounds of the individual publications and render "Nonclassical Ions" stimulating reading material.

The value of the book is further enhanced by a complete author index. It is, however, regrettable that some of the publications have been reduced in size to such a degree that they are difficult to read. *W. R. Roth* [NB 622 IE]

Nitrenes and the Decomposition of Carbonylazides

BY W. LWOWSKI[*]

Gratefully dedicated to Professor Karl Freudenberg

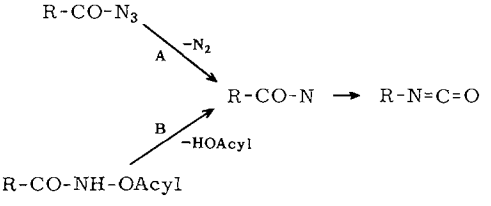
The decomposition of organic carbonylazides can lead to the formation of nitrenes. Ethoxycarbonylnitrene is formed in the photolytic and thermal decomposition of ethyl azidoformate and by α-elimination from N-(p-nitrobenzenesulfonyloxy)urethan. Both of the possible electronic states of this nitrene take part in intermolecular reactions. Pure singlet nitrene is formed by α-elimination from the urethan and on thermal decomposition of ethyl azidoformate, but changes so rapidly into the triplet form that the reactions of both forms are observed. Singlet ethoxycarbonylnitrene undergoes selective and stereospecific insertion into C–H bonds and adds stereospecifically to olefins. Triplet ethoxycarbonylnitrene, however, does not undergo insertion into C–H bonds, and adds to olefins with complete loss of the geometric configuration. By following quantitatively the stereospecificity of the addition reaction and by selective interception of the triplet and singlet forms of the nitrene, it can be shown that the photolysis of ethyl azidoformate leads directly to nitrene of which one third is in the triplet state. In the decomposition of aryl- and alkylcarbonylazides (acid azides), the removal of nitrogen is accompanied by a synchronous rearrangement to isocyanates (Curtius rearrangement). In this system, nitrenes are obtained only by photolysis. They add to double bonds and undergo very selective insertion into C–H bonds, but do not rearrange at a measurable rate to isocyanates. The photolytic Curtius rearrangement is also a concerted reaction.

1. Introduction

Interest in the study of electron-deficient, uncharged intermediates has increased greatly in the past 15 years. A great deal of work is being carried out in particular on the carbenes, but their nitrogen analogues have also attracted increasing attention. These compounds contain a nitrogen atom having only six electrons in its valence shell. Two of these electrons form the bond with the single ligand, while the other four can be arranged in two ways, *i.e.* as two pairs of electrons on a nitrogen atom with a low-energy empty orbital (singlet nitrene) or as one electron pair plus two electrons with parallel spins (triplet nitrene). In the triplet state, one of the three low-energy orbitals that are not used for bonding is occupied by a pair of electrons, and the other two contain one electron each.

The terms "singlet" and "triplet" are borrowed from spectroscopy, but the two electronic states must not be confused with the spectroscopic states. The very short-lived spectroscopic states have the geometric configuration of the ground state (Franck-Condon principle). The long-lived states of *e.g.* the nitrenes or carbenes, on the other hand, assume the energetically most favorable conformation, which can differ very appreciably from that of the ground state. States separated from the ground state by forbidden transitions can be sufficiently long-lived to enter into intermolecular reactions before crossing to the electronic ground state.

In the study of the mechanisms of potential nitrene reactions, therefore, one is concerned, not only with the questions of whether a nitrene is in fact present and how it behaves chemically, but also with the



[*] Prof. W. Lwowski

Las Cruces, N.M. 88001 (U.S.A.)

question of the electronic state of the reacting nitrene. It is possible (and does in fact happen; see below) that two different electronic states of a nitrene enter into intermolecular reactions, in which they behave quite differently.

Unfortunately, there is as yet no agreement on nomenclature. Molecules R–N are described as azenes, azylenes, imenes, imines, imidogen derivatives, and nitrenes [1,2]. These names are all open to objections [1,2]. The name "nitrene" is used in the present article because of the analogy with "carbene".

It is not intended to present a survey of the entire nitrene field, which has been the subject of recent reviews [1–3]. Instead, the present article will deal with some aspects of the chemistry of the carbonylnitrenes, R–CO–N, connected with our investigations on the decomposition of carbonylazides.

The carbonylazides (acid azides) were discovered by *Curtius* [4,5], who also observed their rearrangement [6] to isocyanates on thermal decomposition. As early as 1896, *Stieglitz* [7] explained the Curtius rearrangement (path A) as involving a nitrene intermediate, similar to *Tiemann*'s formulation [8] of the Lossen rearrangement (path B).

Curtius later coined the term "rigid azides" [9] for azides that do not rearrange, but form "short-lived intermediates R–N<", which react intermolecularly. Thus *Curtius* wrote that sulfonylazides form the residues Ar–SO_2–N<, which exhibit "unmistakable analogies" to the residues R–CH<, which are nowadays known as carbenes [10]. Though *Stieglitz*'s views on the mechanism of the Curtius rearrangement appear to be incorrect (Section 6), it is obvious that *Tiemann*, *Stieglitz*, and *Curtius* had a clear conception of carbenes and nitrenes as early as seventy years ago. They simply lacked the means of proving conclusively the existence of these species. Moreover, at that time there was no theoretical foundation for an understanding of the reactivity of the nitrenes.

The first nitrene whose existence was verified by physical methods was NH. This nitrene can be prepared by the decomposition of hydrazoic acid, and can be detected spectroscopically in the gas phase. Some of its reactions have been elucidated (for reviews see [2,11]).

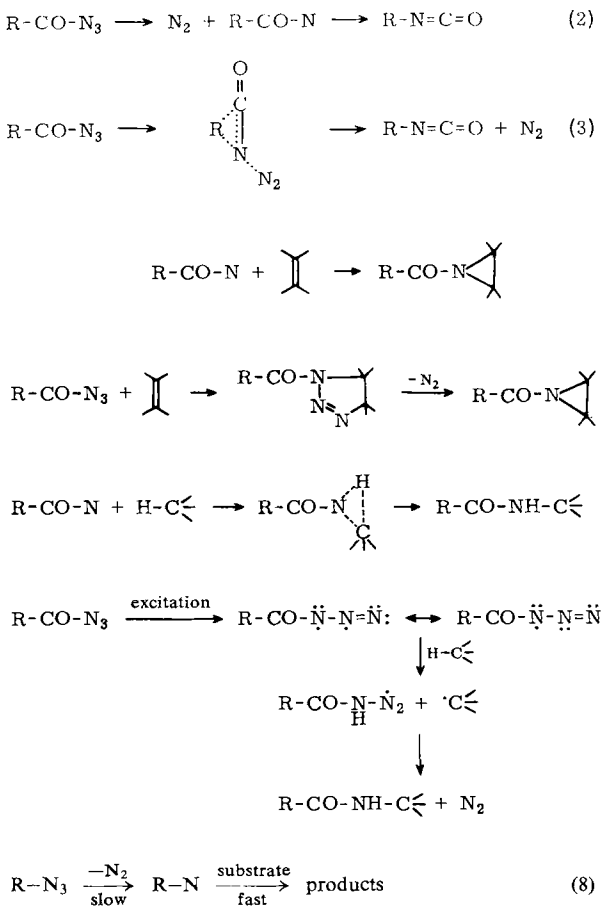
2. Reactions of Nitrenes and Azides

The assumption that the first step in the decomposition of an azide is the removal of nitrogen appears satisfactory, since the great heat of formation of the nitrogen molecule and its suitability as a leaving group (*e.g.* in the decomposition of the diazonium salts) are well known.

(1)

However, this does not mean that the activation energy for the process (1) must necessarily be low and that the nitrene hypothesis may be accepted without question for all azide decompositions. In fact, for all the azide decompositions that can be explained on the basis of nitrenes, it is also possible to offer other reasonable mechanisms. This can be illustrated by nitrene and azide mechanisms for the formation of rearrangement, addition, and insertion products (see eq. (2)–(7) on facing page).

In fact, the heat-induced Curtius rearrangement appears to proceed *via* an azide mechanism (eq. (3)) and not *via* a nitrene (eq. (2)) (see Section 6). With reference to the formation of aziridines from olefins and decomposing azides (eq. (4), (5)), it has been known for a long time that triazolines can be prepared by addition of azides, and that they can decompose to form nitrogen and aziridines [12].



The nitrene mechanism (6) seems particularly attractive for insertion reactions; however, evidence favoring the azide mechanism (7) can also be produced. Thus one would expect that a radical pair such as that in (7) can dissociate, the nitrogen radical then yielding nitrogen and R–CO–NH_2 by abstraction of another H atom. Amide (or amine in the case of alkylazides R′–N_3) is in fact always found as a by-product.

Similar arguments can also be advanced in every other case for the distinction between azide and nitrene mechanisms, *i.e.* the reaction mechanism cannot be deduced entirely from the nature of the products.

Kinetic measurements provide further evidence concening the thermal decomposition of azides. It may be assumed that the reactions of a nitrene will be faster than its formation (see eq. (8)).

The solvent used as the substrate participates only indirectly (by solvation) in the formation of the nitrene, and should have only a relatively small in-

(3)

(4)

(5)

(6)

(7)

(8)

fluence on the rate or temperature of the decomposition of the azide. However, the solvent (substrate) is involved in an azide reaction, and its chemical nature must have a decisive influence on the rate of the reaction.

Waters and *Walker*[13] observed two types of kinetic behavior in the thermal decomposition of some aryl- and alkylazides in various solvents. In one group of solvents the rate of decomposition (at 132 °C) is independent of the nature of the solvent (mineral oil, tetrachloroethylene, *etc.*); the authors conclude that the reaction proceeds by a nitrene mechanism in these solvents. In other solvents (benzene, indene, styrene) the rate of decomposition (again at 132 °C) is higher, and is determined by the solvent, indicating that an azide mechanism is involved. For example, the ratio of the rates of decomposition of phenylazide in mineral oil and in indene is 1:225. Indene evidently reacts directly with the azide. *D. S. Breslow*[14] studied the thermolysis of a number of azidoformates in aliphatic and aromatic solvents as well as in ketones and alcohols. The very slight differences in the rate of decomposition indicate a nitrene mechanism.

Strictly speaking, the procedure described shows only that the solvent is not involved in the rate-determining step. It tells us nothing about the nature of the intermediate, which could be a valence tautomer of the azide or of the nitrene rather than a nitrene. Unfortunately, the procedure cannot be applied to photolytic decompositions, in which the rate of decomposition of the azide is determined by the light flux and the quantum yield.

The existence of a number of nitrenes has been demonstrated by physical methods. The triplet state of the simplest member of the series, NH, can be identified by its optical absorption spectrum[2], and the disappearance of NH in mixtures with ethylene has been followed spectroscopically[15]. Most of the available data relate to triplet nitrenes at very low temperatures, particularly ESR measurements in glasses between 4 and 80 °K[16].

Though measurements of this type show the existence of nitrenes under the conditions in question, they do not answer questions about the chemical properties of nitrenes, and tell us nothing about the mechanisms by which azides decompose at room temperature and in liquid solutions. Moreover, the measurements provide information only about the electronic ground state of the nitrenes observed. It is quite possible, however, that a nitrene is formed in a higher electronic state, *e.g.* the lowest singlet, and enters into chemical reactions in this state before it has a chance to cross to the electronic ground state. It will be shown in Section 4.1 that this is in fact what happens to ethoxycarbonylnitrene.

3. Ethoxycarbonylnitrene

The photolytic[17,18] or thermal[18,19] decomposition of ethyl azidoformate[20] in various solvents yields products whose formation can be explained by the

assumption of a nitrene intermediate, RO–CO–N, or by azide mechanisms. A number of reactions of this type are shown in Scheme 1.

Scheme 1. Decomposition of ethyl azidoformate in hydrocarbons [17, 18, 21–23, 27], olefins [17, 18], alcohols]24, 25], benzene [21, 26, 28], amines [26, 29], and nitriles [30, 31].

To settle the question of the existence of ethoxycarbonylnitrene as an intermediate in the reactions in Scheme 1, we prepared the nitrene by an independent route [21, 32]. *N*-(*p*-Nitrobenzenesulfonyloxy)urethan *(1)* can be converted even by weak bases into its anion *(2)*, which splits off a *p*-nitrobenzenesulfonate ion in a first-order reaction. The half-life of the reaction (in dichloromethane at room temperature) is about 7 seconds [33]. The other fragment formed is ethoxycarbonylnitrene. In the presence of the solvents indicated in Scheme 1, the same products are formed as from ethyl azidoformate.

The following quantitative comparison of the C–H insertion products confirms our belief in a common intermediate in the decomposition of *(2)* and of ethyl azidoformate.

Insertion into the C–H bonds of 2-methylbutane gives four isomeric products *(3)–(6)*. Division of the ratios of the quantities (determined by gas chromatography) by the number of hydrogen atoms of each type gives the relative reactivities, which are shown in Table 1. The two methyl groups on C-2 in 2-methylbutane have the same reactivity. Despite somewhat different reaction conditions, the figures differ only slightly. We regard this as confirmation of a common reactive intermediate, which must be ethoxycarbonylnitrene.

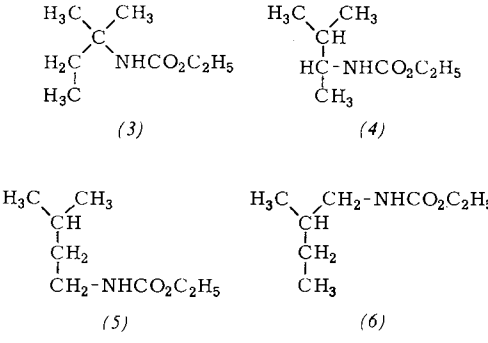

Table 1 also contains data on the thermolysis of ethyl azidoformate in 2-methylbutane, which were determined independently by *D. S. Breslow* [23], and which agree well with our results. The differences in the numerical values for nitrenes prepared by different methods are probably due to the fact that the very different leaving groups (N_2 and $^{\ominus}O_3S–C_6H_4–NO_2$) in the photolysis and in the α-elimination are still located in the neighborhood of the nitrene. The difference in the values for the photolysis and the thermolysis of the azidoformate is probably due mainly to the difference in the reaction temperatures (30 °C and 100 °C respectively).

Table 1. Relative reactivities of ethoxycarbonylnitrene with tertiary (3°), secondary (2°), and primary (1°) C–H bonds.

Hydrocarbon and solvent	Nitrene source: Azide photolysis 3°:2°:1°	Azide thermolysis 3°:2°:1°	α-Elimination 3°:2°:1°
100% 2-Methylbutane	37 9 1	30 [23] 10 [23] 1	27 11 1
38 mole-% 2-Methylbutane in dichloromethane	36 10 1	— — —	25 8 1
100% 3-Methylhexane [34]	16 5.3 1	17 6 1	— — —
27 mole-% 3-Methylhexane in dichloromethane [34]	14 5.2 1	18 6.6 1	13.5 4.7 1

Similarly, good agreement was found in the mixtures obtained with cyclohexene [18, 21, 32] and with nitriles [30]. Such a marked agreement cannot be coincidence, and it must therefore be accepted as certain that the decomposition of ethyl azidoformate and α-elimination reactions of *(1)* proceed *via* a common intermediate.

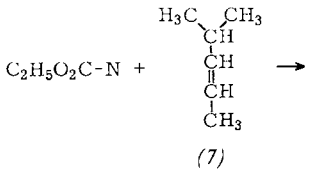
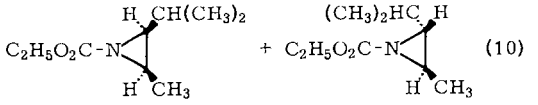
4. Singlet and Triplet Ethoxycarbonylnitrene

4.1. Addition to C=C Double Bonds



Following the detection of ethoxycarbonylnitrene as a reactant, there arose the question of its electronic state at the moment of reaction. *Wasserman* [35] recently showed by spin-resonance measurements at the temperature of liquid helium that the ground state of ethoxycarbonylnitrene is the triplet. However, it may be assumed that the nitrene is formed in the singlet state, particularly in α-elimination from *(1)* and in the thermolysis of azides. Spontaneous spin reversal is practically unknown in reactions of this type, though it is not impossible on the grounds of any natural law. Nothing is known about the lifetime of the nitrene in the singlet state, except that it is quite capable of entering into intermolecular reactions in solution (see below).

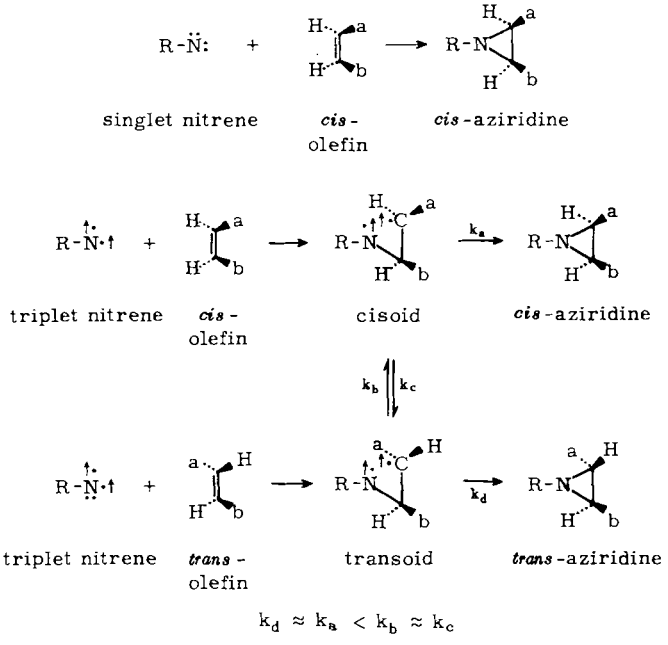
Attempts to determine the spin state of ethoxycarbonylnitrene spectroscopically and at the same time to follow its reactions in the gaseous state by flash photolysis have so far been unsuccessful [36]. In the absence of a reaction partner, the nitrene (presumably as the triplet) decomposed, with a life time of between 3×10^{-7} and 10^{-5} sec, to alkoxy and isocyanate radicals.



The problem was finally solved by a method developed by *Skell* for carbenes [37], which proved very successful [38] in spite of many critical arguments, though theoretical details still remain to be clarified [39].

Skell has postulated that singlet carbenes add to C=C double bonds in a single step, and hence stereospecifically. Triplet carbenes, on the other hand, should first react with the olefin to form an open-chain diradical, the ring closure of which proceeds more slowly than rotation about the former C=C double bond. This free rotation leads to the establishment of an equilibrium between conformers, and finally to the formation of a mixture of geometrically isomeric cyclopropanes. In the extreme case, the composition of this mixture depends only on the position of the equilibrium between the conformers, and not on the nature (*cis* or *trans*) of the starting olefin. Scheme 2 shows the application of *Skell*'s method to nitrenes.

We had observed that the addition of ethoxycarbonylnitrene to *cis*- and *trans*-4-methyl-2-pentene is only partly stereospecific. Both ethyl *cis*- and *trans*-2-isopropyl-3-methylaziridine-1-carboxylate are formed in both cases. The main product is the aziridine whose configuration corresponds to that of the olefin used. If the nitrene is prepared by α-elimination in dichloromethane solution containing 33 mole-% of *cis*-olefin *(7)*, the total aziridine yield [based on *(1)*] is 57 %, of



(7)

(8), cis *(9), trans*

which 92 % is *(8)* and 8 % is *(9)*. *Hafner* [40] found a similar situation in the photolysis of methyl azidoformate in *cis*- and *trans*-2-butene. If it is assumed that all the nitrene is formed in the singlet state and that *Skell*'s method is applicable, the formation of

$k_d \approx k_a < k_b \approx k_c$

Scheme 2. Application of *Skell*'s method to the addition of singlet and triplet nitrenes to *cis*- and *trans*-olefins.

products resulting from nonstereospecific reactions can be explained by the additional assumption that part of the singlet nitrene changes into triplet nitrene before adding to the olefin. This (hypothetical) transition should be a first-order reaction and the addition to the olefin a second-order reaction; this hypothesis can be checked by the use of different olefin concentrations. The lower the olefin concentration, the greater should be the quantity of nonstereospecifically formed aziridine. This is the case, as can be seen from Table 2 [41].

The values can be quantitatively explained by a simple kinetic model, which is shown in Scheme 3. According to this model the precursor P [ethyl azidoformate or *(1)*] forms only singlet nitrene, which then enters into competing reactions leading either to triplet nitrene

(unimolecular) or to stereospecific combination with the olefin and formation of aziridine (bimolecular). The triplet nitrene adds on nonstereospecifically to the olefin or is consumed in side reactions. Since all the triplet nitrene is formed from the singlet nitrene, side reactions of the singlet nitrene do not affect the distribution between the paths k_3 and k_4.

Scheme 3. Possible reactions between nitrene and olefin.

The stereospecific path (k_3) leads to the formation of *(8)* from *cis-(7)* and *(9)* from *trans-(7)*. In the reaction of the triplet nitrene (k_4), the same mixture of *(8)* and *(9)* is formed both from *cis*- and from *trans-(7)*. The composition of the mixture of aziridines depends only on the position of the equilibrium between the conformers of the open-chain diradical intermediate (cf. Scheme 2). In our case the mixture consists of 80 % of *trans*-aziridine *(9)* and 20 % of *cis*-aziridine *(8)* [42]. If it is assumed that k_1 is much smaller than k_3, and that k_2 and k_3 are of a similar order of magnitude, a steady state assumption for the concentration of the triplet nitrene leads to the following relationship (eq. (11)) [42].

$$T/S = k_2\,(k_3\,[\text{olefin}] + k_5/k_4)^{-1} \qquad (11)$$

where T is the yield of aziridine mixture (80 % *trans* + 20 % *cis*) formed by nonstereospecific reaction; S is the yield of stereospecifically formed aziridine; for k_2, k_3, k_4, and k_5 see Scheme 3.

[42] *J. S. McConaghy* and *W. Lwowski*, J. Amer. chem. Soc. *89*, 2357 (1967).

Figure 1 shows the results of the experiments with the nitrenes produced by α-elimination. As required by Scheme 3, a straight line is obtained if k_5/k_4 is taken to be 0.015. The slope of the line is 0.036 ± 0.004. This indicates that the addition of the singlet nitrene to 4-methyl-2-pentene is about 30 times as fast as the singlet-triplet transition, *i.e.* $k_3/k_2 = 30$. (Note however that k_3 is a second-order rate constant, whereas k_2 is a first-order constant.)

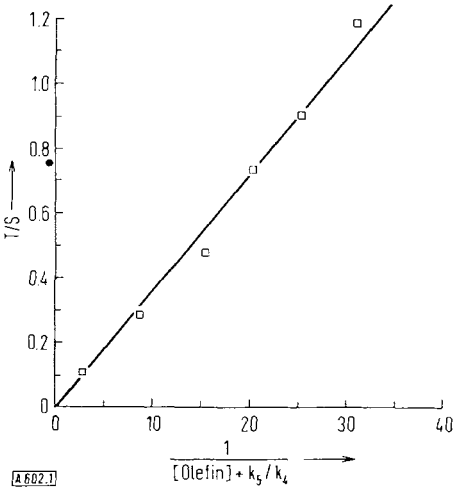

Fig. 1. Experimental results of the addition of the ethoxycarbonylnitrene obtained by α-elimination to the 4-methyl-2-pentenes. For explanations see eq. (11).

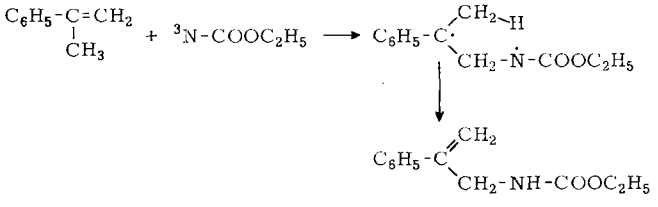
The thermolysis of ethyl azidoformate in dichloromethane solutions of *cis*- and *trans*-4-methyl-2-pentene gives similar results. Corresponding to the higher temperature, k_2/k_3 is greater, *i.e.* 0.08 instead of 0.036. The straight line for the data obtained in the thermolysis of azide, like the line in Figure 1, passes through the origin. This means that both the α-elimination and the thermal decomposition of ethyl azidoformate [43] yield only singlet nitrene, and that the triplet nitrene is formed from singlet nitrene.

The photolysis of ethyl azidoformate with light of wavelength 2537 Å [43], on the other hand, leads directly to a mixture of about $^1/_3$ triplet and $^2/_3$ singlet nitrene. A plot similar to that in Figure 1 gives a straight line that does not pass through the origin, but intersects the ordinate at $T/S = 0.44$. This corresponds to a triplet component of 0.44/1.44 = 30.5 % in the nitrene formed. At 12 °C, the slope of the line is 0.035. The mathematical evaluation of the photolytic reactions is basically the same as for the thermal reaction and for the α-elimination, but owing to the complete absorption of light it is necessary to use expressions other than k_1, and the fact that triplet nitrene is formed directly requires that a steady state condition also be applied to the singlet nitrene concentration.



The quantitative agreement of the experimental data with the requirements of Scheme 3 does not in itself conclusively prove the correctness of our assumptions concerning the electronic states of the nitrenes and the mechanisms of their reactions. Other reaction mechanisms could fit in with the same kinetic laws, and intermediates other than singlet and triplet nitrene could add stereospecifically or non-stereospecifically to olefins. However, our ideas are supported by independent observations:

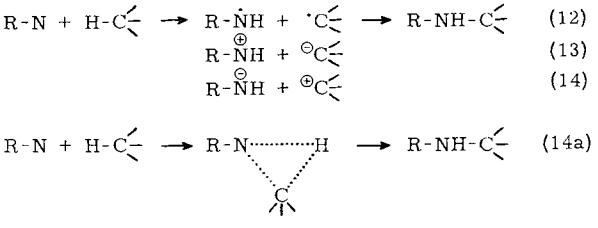
Both the triplet nitrene and the singlet nitrene can be intercepted by reactions in which only one of the two types of nitrene takes part. *Skell* assumes a diradical

[43] *J. S. McConaghy* and *W. Lwowski*, J. Amer. chem. Soc. *89*, 4450 (1967).

intermediate for the triplet reaction in his scheme for carbenes, which has been applied here to nitrenes (Scheme 2). The rate of formation of this intermediate should be greater for more strongly stabilized radicals, since this stabilization should already be reflected in the transition state leading to the diradical.

The triplet nitrene can be intercepted with α-methylstyrene. The reaction of a solution containing 3.3 mole-% of *cis*-4-methyl-2-pentene in dichloromethane [production of nitrene by α-elimination from *(1)*] gives absolute yields of 25 % of ethyl *cis*-2-isopropyl-3-methylaziridine-1-carboxylate and 13 % of the *trans* isomer. When 3.3 mole-% of α-methylstyrene is added to the reaction mixture, only a trace of the *trans*-substituted aziridine is formed, while the yield of *cis*-aziridine falls to 16 %. The reaction is thus almost completely stereospecific. When 1.5 mole-% each of *cis*-4-methyl-2-pentene and α-methylstyrene are used, the aziridine mixture obtained contains only 2.1 % of the *trans* compound, as opposed to 43 % of the *trans* compound in the absence of the triplet interceptor. It can be calculated from these results that triplet ethoxycarbonylnitrene reacts 86 times as rapidly with α-methylstyrene as with *cis*-4-methyl-2-pentene. The nature of the reaction product supports the assumption of a diradical intermediate[42]; thus α-methylstyrene gives, not an aziridine, but ethyl *N*-(2-phenyl-2-propenyl)carbamate *(10)*.

(10)



Singlet ethoxycarbonylnitrene can also be selectively intercepted. It undergoes very rapid insertion into C–H bonds, a reaction that has not so far been observed with triplet ethoxycarbonylnitrene[44]. If ethoxycarbonylnitrene produced by photolysis is allowed to react with cyclohexene (0.2 and 100 mole-% in dichloromethane), the ratio of the yield of aziridine to the yield of insertion products (insertion into the 4-position and the more active 3-position of cyclohexene) is 58:1 and 5:1 respectively[45]. The failure of triplet ethoxycarbonylnitrene to undergo insertion into C–H bonds is also confirmed by the experiments with 3-methylhexane (see Section 4.2).

When ethyl azidoformate is photolysed in cyclohexane, a large part of the singlet nitrene is intercepted as cyclohexylurethan. The directly formed triplet nitrene remains, and can add nonstereospecifically to added *cis*-4-methyl-2-pentene At an olefin concentration of 5 %, this gives a 33 % yield of an aziridine mixture consisting of 54.5 % of *trans*-substituted and 44.5 % of *cis*-substituted aziridine. On the other hand, if the nitrene is formed by α-elimination (again in 5 % *cis*-olefin + 95 % cyclohexane), the total yield of aziridines is 15 %, of which 30 % are *trans* compound and 70 % *cis*. With dichloromethane as the solvent, a 43 % yield of an aziridine mixture containing 26 % of *trans* compound would be expected. Cyclohexane evidently intercepts only the singlet nitrene; the triplet nitrene produced by photolysis remains and leads to the formation of a large quantity of *trans*-aziridine and to higher yields. It is possible to calculate from these data the proportion of triplet nitrene formed directly during photolysis. The calculation gives a result of 31 %, which agrees almost exactly with the value (30.5 %) obtained from the experiments in olefin-dichloromethane solutions.

The mechanism of the direct photochemical formation of triplet nitrene has not yet been elucidated. However, experiments on the acetophenone sensitized decomposition of ethyl azidoformate indicate that the triplet azide is not the precursor of the triplet nitrene[18].

4.2. Insertion into C—H Bonds

The insertion of nitrenes into C–H bonds may in principle proceed in one or two steps. In one-step processes, the atoms involved may assume electric charges in the transition state (eq. (13), (14)), or they may remain entirely or substantially uncharged (eq. (12), eq. (14a), cf. eq. (6)).

In a two-step reaction, insertion on asymmetric carbon atoms should lead to at least partial loss of optical activity.

Smolinsky[46] found that in intramolecular insertions with formation of five-membered rings (2-ethyl-2-methylindoline and 4-ethyl-4-methyloxazolidin-2-one), the optical activity is at least partly retained. It was later shown[47] that 4-ethyl-4-methyloxazolidin-2-one is formed with almost complete retention of configuration. We[48] have studied an intermolecular insertion reaction because various substrate concentrations can be used in such a system, and it is therefore possible to search for insertion reactions of triplet nitrene. As was mentioned in Section 3, ethoxycarbonylnitrene and 3-methylhexane react to form all the possible insertion products. Starting with optically active 3-methylhexane, we separated the ethyl *N*-(1-ethyl-1-methylbutyl)carbamate *(11)* by gas chromatography, and found that this product is formed

[44] However, triplet cyanonitrene reacts with C–H bonds: *A. G. Anastassiou*, J. Amer. chem. Soc. *88*, 2322 (1966).

[46] *G. Smolinsky* and *B. I. Feuer*, J. Amer. chem. Soc. *86*, 3085 (1964).

[47] *S. I. Yamada*, *S. Terashima*, and *K. Achiwa*, Chem. pharmac. Bull. (Tokyo) *13*, 751 (1965).

[48] *W. Lwowski* and *J. Simson*, Abstracts, 153th Meeting Amer. chem. Soc., April 1967, Report O 163; *J. Simson*, Dissertation, Yale University 1967.

with complete retention of configuration. The absolute configurations of the starting material [49] and of the product [48] are known.

S(+) *R*(+)(*11*)

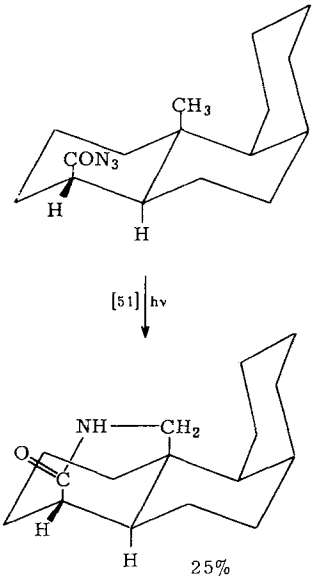
The optical purity of *(11)* is independent of the experimental conditions, as can be seen from Table 3.

Table 3. Stereospecificity of the insertion of ethoxycarbonylnitrene into the tertiary C–H bond of 3-methylhexane.

Method of nitrene production	3-Methylhexane in CH_2Cl_2 (mole-%)	Observed rotation value *(11)* (°)	Retention of configuration (%)
α-elimination	1.2	+ 1.67	98 ± 7
azide thermolysis	100	+ 1.69	99 ± 5
azide photolysis	1.2	+ 1.74	102 ± 3
azide photolysis	26.8	+ 1.71	100 ± 6
azide photolysis	100	+ 1.67	97 ± 5

Since the proportion of triplet nitrene must be very much higher at low substrate concentrations (1.2 mole-%) than in pure substrate, whereas the rotation value remains unchanged, it must be concluded that the triplet nitrene either inserts with retention of configuration or does not take part in the reaction at all. Since the yield of insertion product decreases very rapidly with decreasing substrate concentration, we feel (taking earlier results [45] into account) that triplet nitrene does not take part in the reaction [44].

It may therefore be concluded that the insertion of ethoxycarbonylnitrene into the C–H bonds of simple hydrocarbons is a one-step process. However, the one-step singlet mechanism need not apply to all C–H bonds. It is known [2] that nitrenes can remove hydrogen atoms from other molecules. If this led to the formation of a radical pair with a low activation energy of combination, a two-step insertion mechanism such as that found for cyanonitrenes [44] could occur [27].



The nature and size of the charge distribution in the transition state of a one-step insertion are not fully known. The marked preference for tertiary rather than secondary and primary C–H bonds (Table 1) is compatible both with a positive charge and with "radical character" of the carbon atom involved. In experiments with norbornane, whose C-1 and C-4 atoms accept positive charges only with difficulty, smooth insertion into these positions has been observed. The average reactivity of all the other C–H bonds in norbornane (per C–H bond) is only about 1.7 times as great as that of the C–H bonds on C-1 and C-4 [50]. Thus these carbon atoms do not assume a strong positive charge.

5. Other Carbonylnitrenes

Ethoxycarbonylnitrene can be prepared particularly easily and in various ways, since the starting materials exhibit only a small tendency to undergo the Curtius or Lossen rearrangements [25]. Alkyl- and arylcarbonyl azides rearrange readily to isocyanates. Nitrenes are formed from these azides only on photolysis, and not on thermal decomposition (see below). *Edwards* [51] first observed intramolecular insertion into C–H bonds in his work on atisine and in the decomposition of acid azides [51,52]. These cyclizations are valuable in preparative work [53,54].

On photolysis of benzoyl azide in dimethyl sulfoxide, dioxane/water, or acetic acid, *Horner* [55,56] found products that can be attributed to intermolecular reactions of benzoylnitrene:

Products resulting from further reaction of phenyl isocyanate were also formed.

When acetyl azide was photolysed in benzonitrile and in phenylacetylene, *Huisgen* [57] obtained 2-methyl-5-phenyl-1,3,4-oxadiazole and 2-methyl-5-phenyl-1,3-oxazole respectively, *i.e.* the formal products of 1,3-cycloaddition of acetylnitrene to the triple bonds of the solvents.

[56] *L. Horner*, *G. Bauer*, and *J. Dörges*, Chem. Ber. *98*, 2631 (1965).

[57] *R. Huisgen* and *J.-P. Anselme*, Chem. Ber. *98*, 2998 (1965).

While trying to find a model system for the study of the mechanism of the photolytic Curtius rearrangement [58], we observed the cyclizations of photolytically produced (with light of wavelength 2537 Å) alkylcarbonylnitrenes indicated in Table 4. In agreement with *Edwards'* results [51,52], δ-lactams are formed in preference to γ-lactams [59].

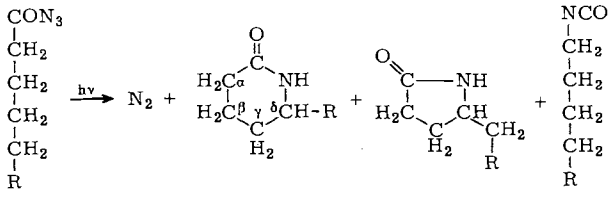

Table 4. Photolysis of n-alkanecarboxylic azides in dichloromethane and cyclohexane.

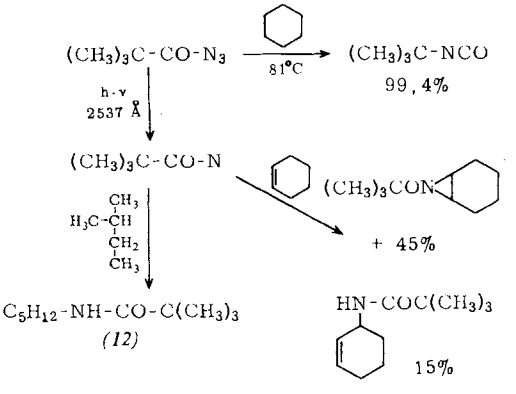
Starting material $R-CON_3$ where R =	Photolysis in dichloromethane: Yield of intramolecularly formed products	Photolysis in cyclohexane: Yield of intramolecularly formed products	Yield of *N*-cyclohexyl-n-alkanecarboxamide
C_3H_7	3.5 % 2-Pyrrolidinone	1 % 2-Pyrrolidinone	8.1 %
C_4H_9	23.5 % 5-Methyl-2-pyrrolidinone	7.8 % 5-Methyl-2-pyrrolidinone	4.7 %
C_5H_{11}	Total 33.5 %: 10.8 % 5-Ethyl-2-pyrrolidinone 22.7 % 6-Methyl-2-piperidinone	Total 15.8: 5.1 % γ-Lactam 11.5 % δ-Lactam	1.9 %
C_7H_{15}	Total 32.0 %: 11 % 5-Butyl-2-pyrrolidinone 21 % 6-Propyl-2-piperidinone	Total 16.0: 5.5 % γ-Lactam 11.5 % δ-Lactam	1.4 %



The preferential formation of the six-membered lactams agrees with the assumed three-membered ring transition state in insertions into C–H bonds (eq. (6)). The transition state for the formation of the δ-lactam would be a six-membered ring with a fused three-membered ring. The assumption of a linear transition state for the insertion (–N.....H.....C–) requires a distorted seven-membered ring with three atoms arranged in a line for the formation of the δ-lactam; this is probably a much less favorable arrangement.

6. Pivaloylnitrene and the Mechanism of the Curtius Rearrangement

Edwards [52], *Horner* [56], *Huisgen* [57], and we [60] observed that (unrearranged) nitrene products are obtained only on photolysis, and not on thermolysis, of alkane- and arenecarboxylic azides. No nitrene products can be found on thermolysis, in spite of careful searches, whereas they are often formed in large quantities on photolysis. This shows that no nitrenes are formed during the thermal Curtius rearrangement; the reaction evidently proceeds in a single step with simultaneous removal of the nitrogen and migration of the alkyl or aryl group. Thus the Stieglitz formulation *(2)* [7] is invalid at least for the thermal rearrangement, and it must be assumed that the reaction proceeds as indicated in eq. (3). In the photolytic reaction, on the other hand, it seemed a reasonable assumption that the first step is the formation of a carbonylnitrene R–CO–N, which partly rearranges into isocyanate and partly forms nitrene products R–CO–NXY resulting from intramolecular and intermolecular reaction.

On photolysis of pivaloyl azide, pivaloylnitrene is formed in a yield of at least 47 %. The nitrene adds to the double bond of cyclohexene and undergoes insertion into C–H bonds [59,60]. Four isomers of *(12)* are obtained from 2-methylbutane in an overall yield of 25 %.

The photolysis of pivaloyl azide in cyclohexane gives *N*-cyclohexylpivalamide in 20 % yield, and 0.5 % of pivalamide. The quantity of gas evolved is always greater than would correspond to the theoretical yield of nitrogen. Analysis showed that isobutylene is also formed. (The isobutylene was determined as its mercuric nitrate complex [61].) For example, photolysis in

neopentane gives a 13 % yield of isobutylene. Thus if the pivaloylnitrene is not intercepted in some other way, it appears to decompose into isobutylene and isocyanic acid. The isocyanic acid, together with part of the isobutylene, forms a polymeric oil, whose IR spectrum shows C–H absorption (at 2994 cm^{-1}) as well as O–H or N–H (broad, about 3290 cm^{-1}) and carbonyl absorptions (broad, about 1686 cm^{-1}). Including the oil and t-butyl isocyanate, the total yields were always greater than 90 %, based on the pivaloyl azide used [59].

The selectivity of the insertion of pivaloylnitrene into C–H bonds is greater than that of ethoxycarbonylnitrene, and is 160:9:1 for the tertiary, secondary, and primary C–H bonds in 2-methylbutane [60].

[58] *L. Horner, E. Spietschka,* and *A. Gross,* Liebigs Ann. Chem. *573,* 17 (1951).

[59] *S. Linke* and *W. Lwowski,* unpublished.

[60] *W. Lwowski* and *G.T.Tisue,* J. Amer. chem. Soc. *87,* 4022 (1965).

[61] *G. Denigès,* C. R. hebd. Séances Acad. Sci. *126,* 1043 (1898); *C.D. Hurd* and *A.R. Goldsby,* J. Amer. chem. Soc. *56,* 1815 (1934); *C. E. Starr* and *T. Lane,* Analytic. Chem. *21,* 572 (1949).

The yield of t-butyl isocyanate (on photolysis with light of wavelength 2537 Å at −10 °C) is always 39–42 %. This provides a clue to the mechanism of the rearrangement.

If pivaloylnitrene were the precursor of the isocyanate, the quantity of isocyanate obtained should decrease with increasing ability of the solvent to intercept nitrenes. In neopentane (which contains only unreactive primary C–H bonds), only 0.2 % of *N*-neopentylpivalamide is obtained, together with 0.7 % of pivalamide, 40 % of t-butyl isocyanate, 13.5 % of isobutylene, and polymeric oil. In cyclopentane, which contains the much more reactive secondary C–H bonds, 13 % of insertion product, 41 % of isocyanate, and 0.5 % of pivalamide are obtained, together with isobutylene and polymer. In cyclohexene, in which the addition and insertion products are formed in a total yield of 47 %, the isocyanate is formed in 41 % yield. Thus the isocyanate cannot have been formed from the nitrene, but must be formed directly from excited pivaloyl azide. The photolytic Curtius rearrangement is therefore also a concerted reaction.

It is interesting to note that pivaloylnitrene does not rearrange into isocyanate. On paper, there appears to be nothing to prevent such a rearrangement, and it might be assumed that such a reactive intermediate would react intramolecularly much more readily than intermolecularly. Nevertheless, the life of pivaloylnitrene must be appreciable (extending over many collisions), since it would otherwise be impossible to explain its high selectivity coupled with relatively good yields (*e.g.* in insertion into C–H bonds).

Our understanding of the finer details of the chemical behavior of nitrenes (and of electron-deficient intermediates in general) is still incomplete. Further theoretical and experimental effort will be necessary before it will be possible to make reliable predictions about the behavior of such intermediates.

I am very grateful to my co-workers for their untiring efforts and for the numerous contributions they have made to the planning of new experiments. Our work would not have been possible without the generous financial support of the National Institutes of Health and the National Science Foundation (U.S.A.).

Syntheses with Ketones, Sulfur, and Ammonia or Amines at Room Temperature [***]

BY F. ASINGER AND H. OFFERMANNS [*]

A large number of preparatively interesting compounds have become readily available by the simultaneous action of sulfur and ammonia or amines on ketones. Direct syntheses of Δ^3-thiazolines, Δ^3-imidazoline-5-thiones, 5,6-dihydro-4H-1,4-thiazines, and the 1,2,3,4,5,6-hexathiocane system from ketones, sulfur, and ammonia or amines, and further possibilities for the synthesis of these heterocyclic systems have been proposed. Other heterocycles containing N or N and S (thiazoles, thiophenes, thiazolidines, tetrahydrothiazolo[2,3-c]-1,4-thiazines, thiomorpholines, 4-amino-2H-imidazoles, etc.) are readily obtainable by further reactions of these compounds. Hydrolysis of the Δ^3-thiazolines yields α-mercapto ketones, which are the starting materials for other syntheses. Most of the syntheses described proceed at room temperature and at normal pressure.

1. Introduction

Elementary sulfur, or even sulfur in the polysulfide form, is often used instead of oxygen for dehydrogenations (abstraction of hydrogen with formation of hydrogen sulfide) or oxidations (introduction of mercapto, thioxo, or dithio acid functions, or subsequently of carbonyl or carboxyl groups) of organic compounds [1,2].

The action of sulfur alone or sulfur in the presence of basic additives (alkalis, amines) at high temperatures on organic compounds such as paraffins, cycloparaffins, olefins, alkylaromatic compounds, nitrated aromatic compounds, aryl alkyl ketones, *etc.* has been extensively studied [1,2] and is of industrial interest in many cases, *e.g.* for the preparation of carbon disulfide, thiophenes, dicarboxylic acids (terephthalic acid), *p*-aminobenzaldehyde, and sulfur dyes, as well as in vulcanization. On the other hand, no investigations on the reactions of organic compounds with elementary sulfur under mild conditions were reported for a long time.

In 1956, one of the present authors [3] discovered a novel synthesis in which Δ^3-thiazolines are formed by the action of elementary sulfur and gaseous ammonia on ketones at room temperature and at normal pressure.

In this synthesis, an intermediate α-mercapto ketone formed by a thiolation instantaneously and irreversibly condenses with ketone and ammonia to form the Δ^3-thiazoline. The first step in this reaction (thiolation = sulfhydrylation = base-catalysed replacement of an H atom α to the carbonyl group by a mercapto group) was described in 1962 by *W. A. Pryor* [2] as "the only known sulfur oxidation at a carbon atom that has an appreciable rate at 25 °C".

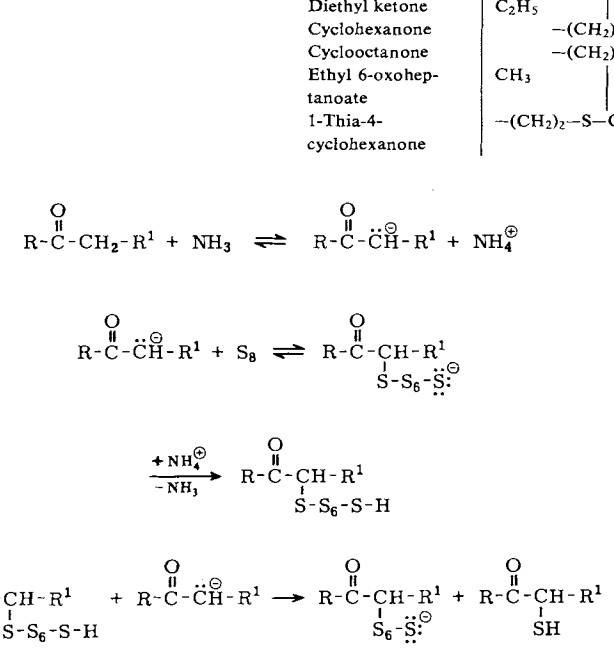
This showed the possibility of studying the action of sulfur on suitable systems under mild conditions.

The formation of the Δ^3-thiazoline takes place in two steps.



(a)

(b)

The first step (a), an α-thiolation, is an amine-catalysed ionic reaction induced by a carbanion (cf. [2], p. 154ff.) (R^2 = H).

The second step (ring formation) (b) may also be regarded as an α-aminoalkylation of an SH acid and subsequent stabilization by ring closure with elimination of water (cf. [4], p. 28ff.) (variant of the Mannich condensation).

A study of the two steps showed that both the thiolation reaction and the ring closure reaction are capable of generalization and can be applied to other systems. The result is a very powerful preparative tool [5].

2. Δ^3-Thiazolines (Action of Sulfur and Ammonia on Ketones)

2.1. Syntheses

The action of elementary sulfur and gaseous ammonia on aliphatic, alicyclic, mixed aliphatic-alicyclic, and heterocyclic ketones having at least one H atom α to the carbonyl group, and which may also contain functional groups, leads at room temperature and normal pressure to substituted Δ^3-thiazolines *(1a)*, generally in excellent yields [3, 6]. The reaction is very widely applicable [5, 6] (for examples see Table 1).

The optimum conditions are as follows. An excess of ammonia is passed into a well-stirred suspension of the ketone

Table 1. Δ^3-Thiazolines *(1a)* prepared by the action of sulfur and ammonia on ketones (selection).

Ketone	R	R^1	R^2	Yield (%)	M.p. (°C)	B.p. (°C/mm)	Ref.
Diethyl ketone	C_2H_5	H	CH_3	85	–	96/12	[11]
Cyclohexanone	$-(CH_2)_4-$		H	80	81.5–82	162/15	[12]
Cyclooctanone	$-(CH_2)_6-$		H	62	–	150–152/0.5	[13]
Ethyl 6-oxoheptanoate	CH_3	H	$(CH_2)_3-CO_2C_2H_5$	80	–	140/10^{-4}	[14]
1-Thia-4-cyclohexanone	$-(CH_2)_2-S-CH_2-$		H	85	115	–	[13]

(1 mole) and sulfur (0.5 g-atom) at room temperature. After a short incubation period, the reaction mixture turns brown. The reaction is generally complete after 3–4 hours. To obtain optimum yields, the conditions must be varied to suit the ketone. In many cases it is advisable to carry out the reaction in anhydrous benzene (in the case of methyl isopropyl ketone) [7], in pyridine at 60 °C (7-tridecanone) [8], in dimethylformamide at 60 °C (aryl methyl ketones) [9], or in methanol (*N*-methyl- and *N*-benzylpiperidone) [10]. In some cases (*e.g.* with acetophenone and its derivatives) it is desirable to vary the proportions.

However, the synthesis also has its limitations. Cyclopentanone gives ill-defined resinous products. It has not so far been possible to prepare Δ^3-thiazolines from camphor, stearone, and isophorone [6]. Keto acids and their esters give Δ^3-thiazolines only when the keto group and the carboxyl group are so far

apart that they no longer influence each other (*e.g.* 6-oxohexanecarboxylic acid and its esters [14]).

The reaction of aldehydes with sulfur and ammonia is complicated. Under the conditions used for ketones, Δ^3-thiazolines are obtained only in poor yields (maximum 10 %) from aldehydes; 2,3,5-trialkylated pyridines are also formed (yields 20–35 %) [14a].

Acetone reacts in a complicated manner with sulfur and ammonia [15, 15a].

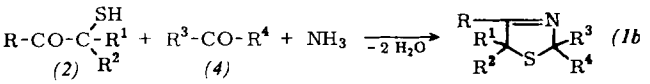
Asymmetric ketones with at least one thiolatable H atom in each of the positions α to the carbonyl group give two isomeric α-mercapto ketones on thiolation; the ring-closure step consequently gives two isomeric Δ^3-thiazolines.

Investigations on asymmetric ketones have shown that the thiolation direction (expressed in the ratio of the isomeric Δ^3-thiazolines, which was determined by fractional precipitation of the picrates and, more recently, by gas-chromatographic analysis [16]) is very strongly dependent on the temperature:

20 °C : $CH_2 \gg CH > CH_3$

80 °C : $CH_2 > CH_3 > CH$

The addition of bases or solvents causes only a slight change in the isomer ratio (cf. [17], which contains further references).



The ketone plays a double role in the synthesis of Δ^3-thiazolines. On the one hand it is thiolated to form the α-mercapto ketone, while it also functions as the oxo component for the irreversible ring closure in the second step. The substituents on the Δ^3-thiazoline are determined by the choice of ketone. Extensive variation (particularly with respect to the substituents in position 2) is possible in the synthesis from practically any α-mercapto oxo compounds (α-mercapto aldehydes, α-mercapto ketones), ammonia, and ketones, aldehydes or carbonyl compounds having functional substituents [6] (resynthesis).

A small selection of the Δ^3-thiazolines (total ≈ 180) prepared by us in this way is given in Table 2.

The α-mercapto oxo compounds are obtainable from α-halogeno carbonyl compounds and sodium hydrogen sulfide in alcoholic solution [18]. It is also possible to prepare an α-mercapto oxo compound by hydrolysis of one Δ^3-thiazoline [19] and to convert it into another Δ^3-thiazoline by reaction with any oxo component.

The condensation of α-mercapto aldehydes and ketones with carbonyl compounds and ammonia (α-amino-

alkylation of an SH acid with subsequent stabilization by cyclization) is capable of generalization, and can be applied to special acyloins and to α-amino ketones.

The reaction of acyloins with oxo compounds and ammonia leads to Δ^3-oxazolines [20], while α-amino ketones give Δ^3-imidazolines [21].

The analogous ring closure reaction with β-mercapto oxo compounds leads to Δ^3-dihydro-1,3-thiazines [22, 22a], while 2,3,4,5-tetrahydropyrimidines [23] can be obtained from β-amino ketones.

The action of elementary sulfur on α-mercapto ketones in the presence of traces of ammonia or amine leads *via* a vigorous reaction to almost quantitative formation of α,α′-diketo disulfides, with liberation of hydrogen sulfide [24]. The reaction is a special case of the amine-catalysed dehydrogenation of thiols to disulfides by elementary sulfur, which was discovered by *McMillan* and *King* [25]. It is reversible if the α-mercapto oxo compound is removed from the equilibrium by other reactions.

Thus the action of hydrogen sulfide and ammonia on a mixture of α,α′-diketo disulfides and oxo components

gives Δ^3-thiazolines in excellent yields (modified resynthesis) [24, 33–36].

This process has proved particularly useful when the tendency toward desulfurization, *i.e.* the elimination of sulfur with reformation of the ketone or else the formation of epiminodithiane, is so strong in the presence of ammonia (see below) that resynthesis fails. Good yields of thiazoline are also obtained in these cases if *S*-acetylated α-mercapto ketones are used; on reaction of these compounds with ammonia and carbonyl compounds, one mole of acetamide is formed per mole of Δ^3-thiazoline [26].

$$\underset{(5)}{R\text{-}CO\text{-}CR^1R^2\text{-}S\text{-}CO\text{-}CH_3} + NH_3 + \underset{(4)}{R^3\text{-}CO\text{-}R^4} \longrightarrow \underset{(1b)}{\text{thiazoline}}$$

The *S*-acetylated α-mercapto ketones are obtained by acetylation of monomeric or even dimeric α-mercapto ketones with acetic anhydride in pyridine or by reaction of α-halogeno ketones with sodium acetothiolate [26].

Δ^3-Thiazolines can also be synthesized by the reaction of alkylidene vinylamines *(6)* (which can be prepared from secondary aliphatic aldehydes and ammonia) [27] with sulfur.

$$\underset{(6)}{\text{alkylidene vinylamine}} + S \longrightarrow \underset{(1c)}{\text{thiazoline}}$$

The α-thiolation of the condensation product of 2 moles of aldehyde and 1 mole of ammonia (= enazomethine) is followed by an intramolecular cycloaddition of the thiol to the olefinic double bond with formation of the stable Δ^3-thiazoline ring system. This possibility was first described in 1959 [28] und was recently re-examined by us [29]. We studied it in detail for the case of isobutylidene-β β-dimethylvinylamine and applied it to other alkylidenevinylamines. By the addition of solvents and special amines, it is possible [29] to lower the reaction temperature from 140 °C to 65 °C, and even to 20 °C and to double the yield to 80 % (see Table 3).

2.2. Properties and Reactions

The alkyl-substituted Δ^3-thiazolines are colorless liquids having a musty odor. As the molecular weight increases, the odor becomes similar to that of terpene and finally almost completely disappears. The Δ^3-thiazoline formed from cyclohexanone is an exception in that it is crystalline and almost odorless [12], while the Δ^3-thiazoline derived from cycloheptanone [35] and that formed by the reaction of α-mercaptocyclopentanone with cyclopentanone and ammonia [35] are again liquid. Δ^3-Thiazolines with aromatic substituents are frequently obtained in the crystalline form.

The compounds can in many cases be characterized in the form of the picrates which melt between 90 and 150 °C.

The hydrochlorides are directly obtainable only in exceptional cases. In other cases they can be obtained *via* the hydrochlorides of the thiazolidine-4-carbonitriles by elimination of HCN (see below). Some Δ^3-thiazolines form stable adducts with BF_3 [29]. The Δ^3-thiazolines are insoluble in water but soluble in alcohols, chlorinated hydrocarbons, ether, benzene, and petroleum ether.

The principal reactions of the Δ^3-thiazolines are shown in Scheme 1.

Attempts to reduce Δ^3-thiazolines with sodium and alcohol, sodium in liquid ammonia, or aluminum in the presence of potassium hydroxide solution or moist ether did not yield uniform results. On the other hand, the Δ^3-thiazolines are very smoothly hydrogenated with lithium tetrahydridoaluminate; this reaction results, not only in the hydrogenation of the azomethine bond, but also in hydrogenolytic ring cleavage between

Scheme 1. Reactions of the Δ^3-thiazolines *(1)*.

S and C-2 with formation of *N*-substituted cysteamines *(7)* [37].

Δ^3-Thiazolines are generally stable and can be stored for long periods without deteriorating. However, those derived from cycloaliphatic ketones are converted into Δ^3-thiazoline *S*-oxides *(8)* by air [13].

2,2-Pentamethylene-4,5-tetramethylene-Δ^3-thiazoline and the Δ^3-thiazolines derived from alkylcyclohexanones are suitable for use as antioxidants for polyolefins [38]. The superiority of their properties as compared with those of other compounds containing sulfur is due to the ease with which these thiazolines autoxidize to form *S*-oxides.

The Δ^3-thiazolines obtained from primary or secondary α-mercapto ketones or aldehydes, aldehydes, and ammonia, which contain C–H bonds in positions 2 and 5, can be smoothly dehydrogenated to thiazoles *(9)*, preferably by heating with sulfur at about 130 °C [39–41]. $FeCl_3$, $K_3[Fe(CN)_6]$, K_2Cr_2O, and hydrogen peroxide are less suitable than sulfur powder for this novel thiazole synthesis. The yields are about 80 %.

sulfur and ammonia [9] can be pyrolysed by heating at about 250 °C for 5 to 15 hours, the products being 2,4-diarylthiophenes *(10)* [9]. The yield when Ar = C_6H_5 is 56 %.

(10)

Anhydrous hydrogen cyanide adds readily to the azomethine bond of many Δ^3-thiazolines at room temperature [42]. The resulting thiazolidine-4-carbonitriles *(11)* are more or less stable, depending on their purity and on the nature and number of substituents in positions 2 and 4; however, they are always stable in the form of their hydrochlorides. No relationship could be found between structure and stability. Thiazolidine-4-carbonitriles that are not quite pure decompose much more rapidly.

Scheme 2. Reactions of thiazolidine-4-carbonitriles, illustrated for the case of 2,2,5,5-tetramethylthiazolidine-4-carbonitrile [42, 42a].

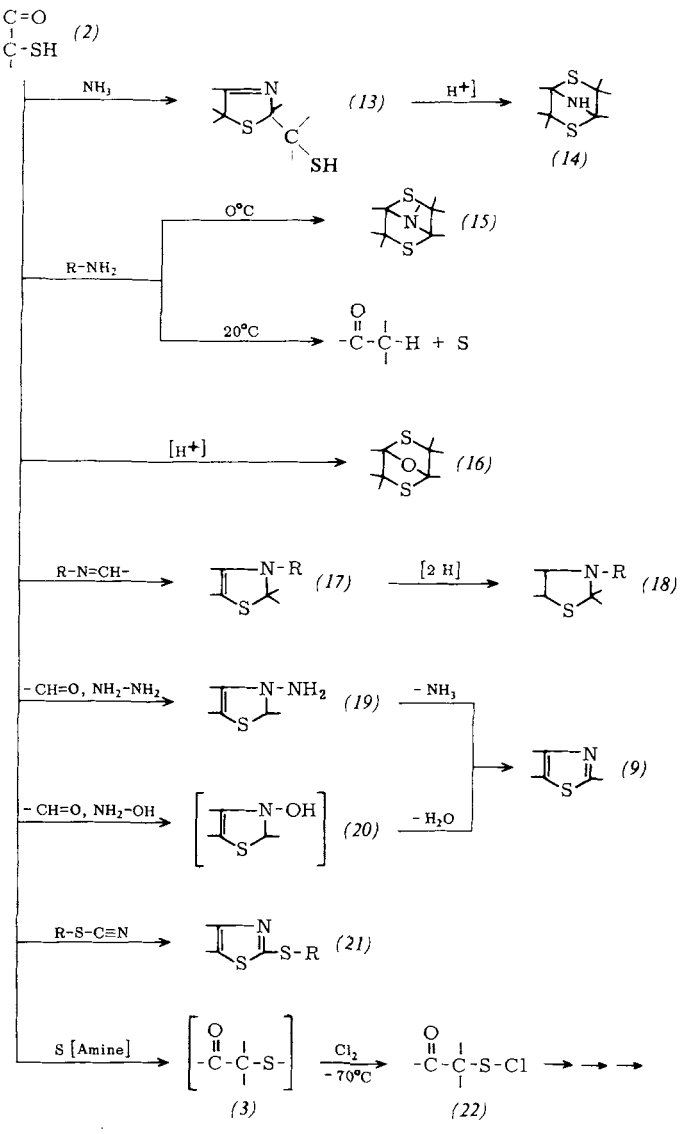
[42a] *F. Asinger, H. Offermanns*, and *M. Ghyczy*, unpublished.

The reactions of the thiazolidine-4-carbonitriles may be illustrated for the case of 2,2,5,5-tetramethylthiazolidine-4-carbonitrile *(11a)*, (see Scheme 2), which is particularly important for the preparation of penicillamine and its derivatives *(12a)–(12d)*.



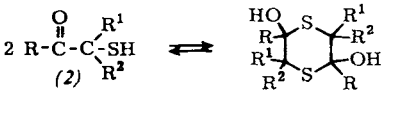
A general property of the Δ^3-thiazolines is their ability to undergo hydrolysis by aqueous acids with formation of α-mercapto ketones or aldehydes, oxo compounds, and ammonium salts (reversal of ring formation)[19].

The rate of hydrolysis is strongly dependent on the nature, number, and position of the substituents on the thiazoline ring. The time taken to reach a degree of hydrolysis of 50 % is *e.g.* between 10 min and 85 hours for methyl-substituted Δ^3-thiazolines. A substituent in position 2 has an accelerating influence; a substituent on C-4, on the other hand, strongly inhibits hydrolysis, an effect that can be intensified by additional substitution on C-5. Two substituents on the same C atom intensify the effect in the same direction. It is possible on the one hand to prepare Δ^3-thiazolines that are practically no longer hydrolysable, and which form stable hydrochlorides (which are otherwise obtainable only by the elimination of HCN from 4-cyanothiazolidine hydrochlorides[42]). On the other hand, it is also possible to prepare readily hydrolysable Δ^3-thiazolines whose acid hydrolysis provides a favorable route to α-mercapto ketones, which is superior in most cases to the other methods of preparation, *e.g. via* α-halogeno ketones, thioesters, or Bunte salts.

The hydrolysis is best carried out with dilute acetic acid, the low dissociation of which suppresses the troublesome formation of epoxydithiane from the α-mercapto ketone.

If the rate of hydrolysis is too low and self-condensation with ammonium acetate (see below) takes place, the hydrolysis is carried out with dilute hydrochloric acid and the α-mercapto ketone is removed by steam distillation.

The convenient 2-stage process[19] for the preparation of α-mercapto ketones by formation and hydrolysis of Δ^3-thiazolines, which proceeds in excellent yields without the use of high temperatures or pressures, led us to study in detail the behavior of the reactive 1,3-bifunctional α-mercapto ketones.



Scheme 3. Reactions of the α-mercapto ketones.

3. Syntheses with α-Mercapto Ketones

The reactions of the α-mercapto ketones are shown in Scheme 3.

The lower α-mercapto ketones *(2)* are generally liquid (exception: α-mercaptoacetone, m.p. 75–76 °C[43]) and have an extremely unpleasant odor. They frequently exhibit a double molecular weight, so that an equilibrium with a dithiane form must be assumed.

(For the association behavior of α-mercapto ketones in CCl_4, see[44].)

Under the influence of mineral acids, many α-mercapto ketones form 2,5-epoxy-1,4-dithianes *(16)*. This reaction can be troublesome in the preparation of α-mercapto ketones by hydrolysis of Δ^3-thiazolines.

In the presence of ammonia, α-mercapto ketones in general undergo self-condensation to form 2-mercaptoalkyl-Δ^3-thiazolines *(13)*, which exist in acidic media as 2,5-epimino-1,4-dithianes *(14)* (intramolecular addition of SH to the azomethine group). *N*-Substituted epiminodithianes *(15)* are formed when primary amines or carbonyl reagents such as phenylhydrazine, hydroxylamine, and semicarbazone are allowed to react with α-mercapto ketones at low temperatures. The action of primary amines on α-mercapto ketones at or above room temperature yields ketones and sulfur (in the form of alkylammonium polysulfides). In this desulfurization reaction[11] (cf.[17]), which is the reverse of the α-thiolation, the positionally isomeric ketones are formed as well as the expected ketone. Thus the desulfurization of 2-mercapto-3-pentanone leads to both 2-pentanone and 3-pentanone, while that of α-mercaptobutyrophenone yields all three positionally isomeric 1-phenylbutanones[45]. This desulfurization reaction is very important to the interpretation of the Willgerodt-Kindler reaction. Pure secondary amines desulfurize α-mercapto ketones only to a small extent; tertiary amines react with α-mercapto ketones only above 70 °C, to form hydrogen sulfide and non-uniform polymeric products[45a]. The desulfurizing action of ammonia has so far been ob-

served only with 1-mercapto-1-phenylpropanone, since the rapid formation of epimonodithiane occurs in other cases [40].

If primary amines are allowed to act, not on α-mercapto ketones alone (except tertiary), but on a mixture of the ketone and an aliphatic aldehyde at about 0 °C, epiminodithiane formation and desulfurization are completely suppressed, and Δ^4-thiazolines *(17)* are formed by an exothermic reaction [46].

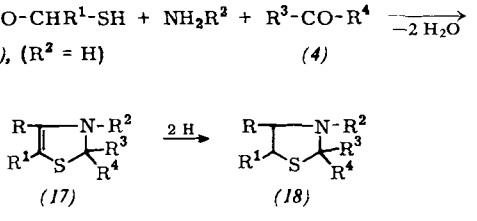
Instead of starting with an aldehyde and an amine, aldimines may be allowed to react directly with α-mercapto ketones [47]. Ketimines and the components of ketimines, *i.e.* ketones and primary amines, do not react with α-mercapto ketones to form Δ^4-thiazolines. The result is desulfurization, together with other reactions that have not yet been clarified. (An exception is cyclohexanone.) The reaction of α-mercapto ketones with cyclohexanone and primary amines or directly with *N*-alkylketimines of cyclohexanone leads smoothly to the corresponding Δ^4-thiazolines.

α-Mercapto ketones can also react with aldehydes (or cyclohexanone) and esters of α-amino acids (or their hydrochlorides), or with the Schiff bases formed by these components, to form esters of Δ^4-thiazolin-3-ylacetic acids [47a].

The Δ^4-thiazolines *(17)*, which are colorless to yellow liquids, are generally less stable than Δ^3-thiazolines. They have a fixed enamine structure, and so can be hydrogenated to thiazolidines *(18)* by formic acid at 50–60 °C [48]; this offers a new route to the thiazolidines. Some examples of the synthesis and hydrogenation of Δ^4-thiazolines are given in Table 5.

The reaction of primary or secondary α-mercapto ketones with aldehydes and hydrazine leads to 3-amino-Δ^4-thiazolines *(19)* [48], which lose ammonia to form thiazoles *(9)* on treatment with acids. Whereas Δ^3- and Δ^4-thiazolines are decomposed again by mineral acids, *i.e.* their formation is reversed, the hydrolysis is suppressed in this case in favor of thiazole formation.

The reaction of α-mercapto ketones with aldoximes leads to the formation of thiazoles and water [48]. The postulated intermediate 3-hydroxy-Δ^4-thiazoline *(20)* has not been isolated. The last two reactions are new thiazole syntheses. Certain α-mercapto ketones react with both aliphatic and aromatic thiocyanates to give *S*-substituted 2-mercaptothiazoles *(21)* [49].



As was mentioned earlier, α-mercapto ketones can be smoothly oxidized with sulfur in the presence of catalytic quantities of amine or ammonia to give α,α'-dioxo sulfides *(3)* [24] (modified McMillan-King reaction).

α,α'-Dioxo disulfides react readily with stoichiometric quantities of liquid chlorine in methylene chloride at −70 to −80 °C to form β-oxo sulfenyl chlorides *(22)*, which cannot be isolated as such. Their existence was shown by secondary reactions, *e.g.* with triethyl phosphite [50].

Tertiary β-oxosulfenyl chlorides react with ammonia or amines to give moderate yields of β,β'-dioxosulfenylimides or β-oxosulfenylamides which can be isolated [50,51].

Primary β-oxosulfenyl chlorides react with secondary amines with dehydrogenative rearrangement and formation of α-oxothioamides. The yield of α-oxothioamide is considerably increased by the addition of sulfur [52,53].

Table 5. Δ^4-Thiazolines *(17)* prepared from primary or secondary α-mercapto ketones, oxocomponents, and primary amines (or from α-mercapto ketones and aldimines) [46,47] and thiazolidines *(18)* prepared by hydrogenation of the corresponding Δ^4-thiazolines *(17)* with formic acid [48] (selection).

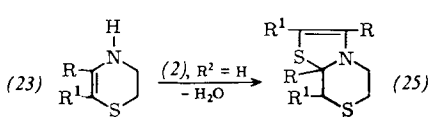
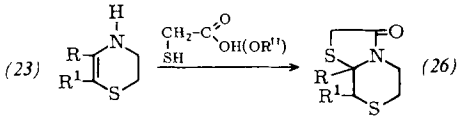
4. 5,6-Dihydro-4*H*-1,4-thiazines, 5,6,8,8a-Tetrahydrothiazolo[2,3-*c*]-1,4-thiazines, and Thiomorpholines (Action of Sulfur and Ethylenimine on Ketones)



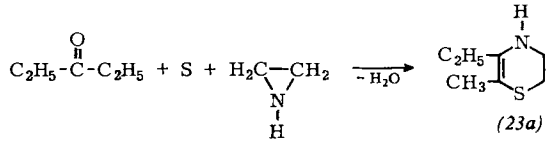
The action of ethylene on primary or secondary α-mercapto ketones (special case of the action of a secondary amine on α-mercapto ketones) leads to a new class of substances, *i.e.* the 5,6-dihydro-4*H*-1,4-thiazines *(23)* [54,55] [*].

The equilibrium between the azomethine and the enamine forms lies completely on the enamine side. 5,6-Dihydro-4*H*-1,4-thiazines can be acetylated at the nitrogen and can react with phenyl isocyanate; their reduction with formic acid (cf. [56]) yields thiomorpholines *(24)* [54,55]. The 5,6-dihydro-4*H*-1,4-thiazines are also characterized by the ease of addition of an excess of α-mercapto ketone. This leads smoothly to 5,6,8,8a-tetrahydrothiazolo[2,3-*c*]-1,4-thiazines *(25)* [54, 55], which can be reduced by formic acid to the perhydrogenated products.



Further investigations on the simultaneous formation of the compounds *(23)* and *(25)* have shown that the preferential formation of one form or the other does not depend mainly on the molar ratio of α-mercapto ketone to ethylenimine, as might at first be assumed; the reaction temperature is a much more important factor. If the α-mercapto ketone is added dropwise to boiling ethylenimine, the temperature (which is initially determined by the boiling point of ethylenimine) being gradually raised to 70–75 °C, *(23)* is obtained in 95 % yield. On the other hand, if the reaction is carried out at −20 °C, *(25)* is obtained in 80 % yield. The results are given in Table 6 for the reaction of 2-mercapto-3-pentanone with ethylenimine [54] (for further examples see [54,55]).

Table 6. Temperature-dependence of the reaction of ethylenimine (1.3 mole) with 2-mercapto-3-pentanone (1 mole) (R = C_2H_5, R^1 = CH_3)



Temp. (°C)	Yield of (%)	
	(23a)	*(25a)*
60 → 75	95	–
60	86	4
40	78	12
20	50	36
0	21	66
−20	10	78

5,6-Dihydro-4*H*-1,4-thiazines can also be prepared from α-bromo ketones and cysteaminesodium. This reaction also serves as structural evidence. The problems involved in the reaction of tertiary α-mercapto ketones with ethylenimine and the reaction of propylenimine with α-mercapto ketones will not be discussed here [55].

5,6-Dihydro-4*H*-1,4-thiazines react with α-mercapto carboxylic acids or their esters to form 5,6,8,8a-tetrahydro-3-oxothiazolidine[2,3-*c*]-1,4-thiazines *(26)* [57].

As was shown in the case of 3-ethyl-2-methyl-5,6-dihydro-4*H*-1,4-thiazine *(23a)*, the dihydro-1,4-thiazines are also directly obtainable from ketones, sulfur, and ethylenimine [58]. *(23a)* is formed in a yield of about 80 %.

When elementary selenium is used in the reaction instead of sulfur [59], 3-ethyl-2-methyl-5,6-dihydro-4*H*-1,4-selenazine is formed in a yield of more than 50 %. So far as we know, this is the first direct selenation of a CH acid.

Unlike the selenazines, Δ³-selenazolines cannot be prepared either directly from ketone, selenium, and ammonia or *via* α-hydroseleno ketones (the reaction of α-halogeno ketones with sodium hydrogen selenide leads to deposition of selenium and resinification) [59]. At present we are investigating whether the thiazine and selenazine synthesis is as generally applicable as the action of sulfur and ammonia on ketones.

5. Δ³-Imidazoline-5-thiones (Action of Sulfur and Ammonia on Methyl Ketones)

5.1. Syntheses

Methyl ketones occupy a special place in the synthesis of Δ³-thiazolines. Methyl ketones having at least one H atom in the other α position preferentially give

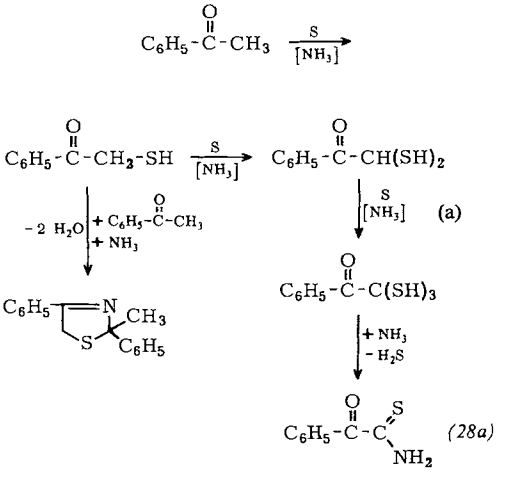
[59] *F. Asinger* and *H. Berding,* unpublished.

the Δ^3-thiazoline, which is not formed by thiolation of the methyl group. Methyl ketones in which only the methyl group is available for thiolation have proved inert under the standard conditions of the Δ^3-thiazoline synthesis (acetophenone [34, 60], pinacolone [61]). Acetophenone gives only 11 % of 2-methyl-2,4-diphenyl-Δ^3-thiazoline together with 4 % of a yellow crystalline compound $C_{16}H_{14}N_2S$ [34, 52, 60, 61] (see below).

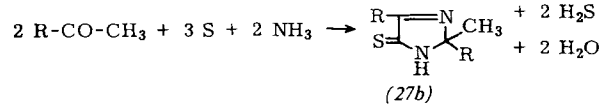
Since similar yellow crystalline compounds are also formed in the reactions of other methyl ketones (methyl isopropyl ketone, methyl neopentyl ketone, methyl cyclohexyl ketone) with sulfur and ammonia, this behavior seemed to be a pecularity of the methyl ketones. Acetophenone was of particular interest, since it is the classic ketone for the Willgerodt and Willgerodt-Kindler reactions, and we hoped to obtain an understanding of these reactions.



The yellow crystalline compound formed in a 4 % yield from acetophenone, sulfur, and ammonia under standard conditions was identified by degradation reactions and comparison synthesis as 2-methyl-2,4-diphenyl-Δ^3-imidazoline-5-thione *(27c)* [62].

(27c)

The yield of *(27c)* can be increased to more than 90 % if 8 g-atoms of sulfur are used per mole of acetophenone (though only 1.5 g-atoms are theoretically required), the reaction being carried out in methanol and ammonia being passed into the mixture for about 24 hours at 20 °C and normal pressure [52] (see Table 7).



The reaction is applicable to many other methyl aryl ketones. The yields obtained with methyl heteroaryl ketones are considerably lower. With aliphatic methyl ketones, Δ^3-thiazoline formation generally predominates; however, even in this case formation of Δ^3-imidazoline-5-thiones can be made the principal reaction by the addition of one mole of piperidine per mole of ketone.

Like the Δ^3-thiazoline formation, the formation of Δ^3-imidazoline-5-thiones can be broken down into two steps (illustrated for acetophenone):

(a) formation of phenylglyoxylic thionamide; (b) ring closure.

Table 7. 2,2,4-Trisubstituted Δ^3-imidazoline-5-thiones *(27b)* prepared from methyl ketones, sulfur, and ammonia (molar ratio ketone: sulfur = 1:8; 24 hours at 20 °C) (selection).

[a] Addition of 1 mole of piperidine per mole of ketone.

The formation of phenylglyoxylic thionamide *(28a)* is due to multiple thiolation of the acetophenone [66]. This explains the high sulfur requirement in the reaction. The final result is the oxidative replacement of all the H atoms of the methyl group in acetophenone by SH groups. It is not yet possible to decide whether this substitution takes place simultaneously

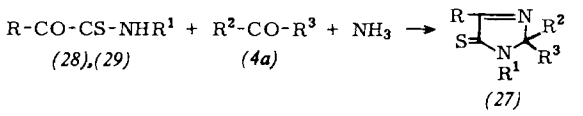
(to the trimercapto ketone stage) or stepwise *via* the dimercapto compound, the thioaldehyde, or the products of their further reaction with ammonia (aminomercapto compound, α-oxoaldimine); however, this is of no importance to the interpretation of the course of the reaction. Those cases in which the ketimine formation is allowed to precede the α-thiolation in order to increase the acidity of the α-CH group will not be discussed here (see, however, [66, 67]).



The second step (b) as in the Δ^3-thiazoline formation, involves the α-aminoalkylation of an N–H acid compound (cf. [4], p. 64) and subsequent stabilization by ring closure with elimination of water.

(28a) *(27c)*

Since we have been able to develop efficient syntheses both for *N*-unsubstituted *(28)* and for *N*-monosubstituted *(29)* α-oxothionamides, many Δ^3-imidazoline-5-thiones *(27)*, particularly with a substituent (of almost any type) in position 2, are now available by reaction of these α-oxothionamides with ketones and ammonia (see Table 8).

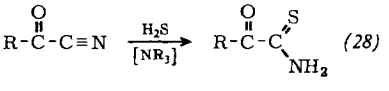


Table 8. Δ^3-Imidazoline-5-thiones prepared from α-oxothionamides, ketones, and ammonia (selection) [65, 69].

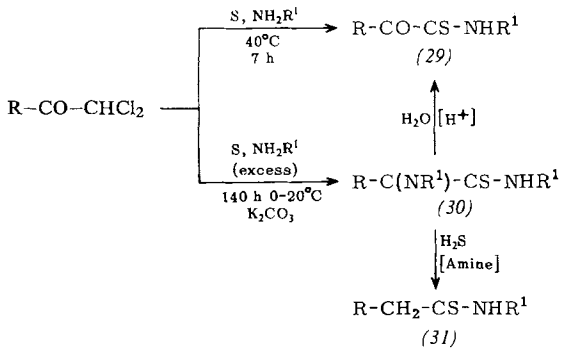
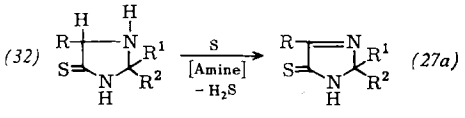
N-Unsubstituted α-oxothionamides *(28)* are obtained by base-catalysed (triethylamine) addition of H_2S to acyl or aroyl cyanides, in accordance with the equation:



(28)

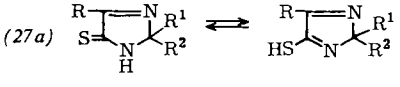
This reaction must be carried out in nonpolar solvents such as n-heptane or ether [68, 69].



We were also able to prepare *N*-monosubstituted α-oxothionamides *(29)* readily by the action of primary amines and sulfur in boiling ether on α-oxodichloro compounds of the type R–CO–$CHCl_2$ (R = alkyl or aryl) [69], the residue R^1 depending on the amine used.

Under different conditions [70] (increase in the quantity of amine, addition of potash, and increase in the reaction time to 140 hours, the reaction temperature being lowered to 20 °C), the reaction leads to yields of more than 70 % of α-ketiminothionamides *(30)*, which can be quantitatively converted into α-oxothionamides *(29)* by hydrolysis with dilute acetic acid.

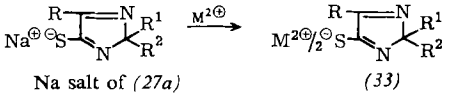
The ketiminothionamides can be converted into the Willgerodt-Kindler products *(31)* by the introduction of hydrogen sulfide even at room temperature [70].



Another method for the synthesis of Δ^3-imidazoline-5-thiones *(27a)* is the dehydrogenation of imidazolidine-4-thiones *(32)* by heating with sulfur in the presence of catalytic quantities of amine [62, 71].

(32) *(27a)*

5.2. Reactions



The intensely yellow, highly crystalline, and very stable Δ^3-imidazoline-5-thiones are cyclic thionamides. They are tautomeric with mercapto-2*H*-imidazoles.

(27a)

The position of the equilibrium depends on the basicity of the reaction medium, and it is possible to prepare derivatives both of the thionamide and of the thiolimine form. The reactions can be illustrated by the case of 2-methyl-2,4-diaryl-Δ^3-imidazoline-5-thiones *(27b)* and *(27c)*.

Solutions of the Δ^3-imidazoline-5-thiones in dilute NaOH form salts with bivalent metal ions [72].

yields are obtained with $NaBH_4$. Reduction with $LiAlH_4$ in ether at 35 °C leads to ring cleavage and removal of the sulfur as hydrogen sulfide, with formation of a mixture of two structurally isomeric diamines [72].

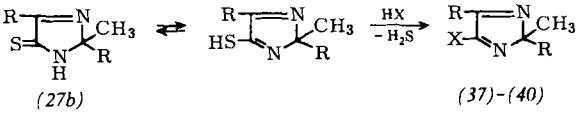
The oxidation reactions are shown in Scheme 4 [72]. They lead to products in which exocyclic sulfur remains on the ring, but in a higher oxidation state, or is replaced by oxygen.

Scheme 4. Action of oxidizing agents on Δ^3-imidazoline-5-thione.

Electrophilic substitution is possible either on the N of the thionamide form or on the S of the thiolimine form, depending on the reaction medium and the attacking agent [64, 72].

Benzoylation yields an N^1-benzoyl derivative of the thionamide form (together with a little *S*-benzoyl compound); acetylation with acetic anhydride follows a similar course (yield 70 %). Substitution with electrophilic reagents in aqueous alkaline media leads to thiolimine derivatives. Methylation with dimethyl sulfate gives the 4-methylmercapto compound in a yield of 83 %. Benzoylation in the presence of pyridine leads to the *S*-benzoyl compound. The corresponding thiolimine derivatives are also formed on benzylation and on reaction with chloroacetic acid or with α-bromoacetophenone.

The 4-mercapto group of the thiolimine form can be smoothly replaced by nucleophilic substitution [72].



Reaction with PbO in methanol in the presence of ammonia leads to the 4-methoxy-2*H*-imidazole *(37a)* [64]. Sulfuryl chloride reacts to give a 4-chloro-2*H*-imidazole *(38a)* [72]; this is a novel cyclic imide chloride, which can enter into many reactions. The reaction with ammonia [73] (at 80 °C in ethylene glycol) or with primary or secondary amines [74] provides a simple route to 4-amino- or 4-alkylamino-2*H*-imidazoles *(39)–(40)*.

Derivatives of the thiolimine form are listed in Table 9.

The 4-amino- and alkylamino-2*H*-imidazoles *(39)* to *(40)* are nearly all colorless, highly crystalline substances. They can be converted back into the Δ^3-imidazoline-5-thiones by the introduction of hydrogen sulfide.

The reaction of the Δ^3-imidazoline-5-thiones *(27)*, as well as of the bis(2*H*-imidazol-4-yl) disulfides *(36)* (cf. Scheme 4) with sulfuryl chloride in the presence of MgO (or better, CaO) leads to good yields of 4-chloro-2*H*-imidazoles *(38a)*. The reaction of the 4-chloro-2*H*-imidazoles *(38a)* with aromatic amines

Table 9. Derivatives *(37)* to *(40)* of the tautomeric thiolimine form of the Δ^3-imidazoline-5-thiones *(27b)*.

yield 4-arylamino-2*H*-imidazoles that are not obtainable by direct reaction of the Δ^3-imidazoline-5-thiones [74]. Similarly, 5-selenoxo-Δ^3-imidazolines, which cannot be directly prepared by the action of selenium and ammonia on methyl ketones [59], can be synthesized by the reaction of *(38a)* with hydrogen selenide.

6. 8-Alkylamino-8-aryl-1,2,3,4,5,6-hexathiocane-7-thiones (Action of Sulfur and Primary Amines on Methyl Aryl Ketones)

Acetophenone and ring-substituted acetophenones react even at room temperature with primary aliphatic amines to form *N*-alkylketimines *(41)* of the acetophenones [66, 75, 76].

(41)

Quantitative IR measurements [66, 76] have shown that this reaction is strongly dependent on the polarity of the solvent, the substituents on the phenyl nucleus, and the catalyst. The acetophenone imines can be readily synthesized from acetophenone and primary amines with acid catalysis (glacial acetic acid).

Apart from the catalytic effect of acids (glacial acetic acid, *p*-toluenesulfonic acid, *etc.*), dehydrating agents (K_2CO_3), and polar solvents (CH_3OH), the favorable influence of catalytic quantities of elementary sulfur on the ketimine formation is particularly interesting.

Acetophenone reacts with n-butylamine at room temperature in the presence of elementary sulfur (0.25 g-atom per mole of ketone) to give a 44 % yield of the *N*-(n-butyl)ketimine of acetophenone. When the quantity of sulfur is increased to 0.5 g-atom per mole of

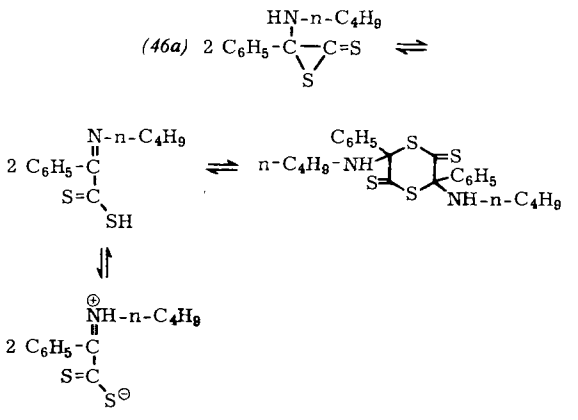
[76] *F. Asinger* and *H. Offermanns,* unpublished.

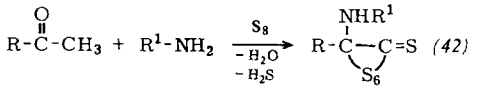
ketone, the yield of ketimine falls to 26 %[75]. A further increase in the quantity of sulfur (molar ratio ketone : amine : sulfur = 1:2:8; CH_3OH as solvent) gives a yellow crystalline product $C_{12}H_{15}NS_7$ in 20 % yield[77]. If acetophenone imine is used instead of acetophenone (molar ratio imine : amine : sulfur = 1:2:8), the compound $C_{12}H_{15}NS_7$ is formed in 65 % yield[77]. The yellow crystalline compound formed from acetophenone, n-butylamine, and sulfur is 8-n-butylamino-8-phenyl-1,2,3,4,5,6-hexathiocane-7-thione *(42a)*[77]. No compounds of this class had previously been known.

The degradation reactions of *(42a)* are shown in Scheme 5.



Scheme 5. Degradation reactions of the 8-alkylamino-8-phenyl-1,2,3,4,5,6-hexathiocane-7-thiones, illustrated by the case of the 8-n-butylamino product *(42a)* [77].

The hydrogenation of *(42a)* with Raney nickel, which is accompanied by removal of sulfur, yields *N*-n-butyl-(α-methylbenzyl)amine *(43a)*. The reduction of *(42a)* with hydrogen sulfide in the presence of amine leads to bis-(α-methylbenzyl)polysulfides *(44a)*, which can be reduced with $LiAlH_4$ to 1-phenylethylthiol *(45a)*.



When sodium methoxide is allowed to act on *(42a)* at room temperature, 5 g-equivalents of sulfur separate out with formation of a new crystalline compound $C_{12}H_{15}NS_2$ *(46a)*, which can be converted back into *(42a)* by reaction with sulfur in the presence of amine.

The compound $C_{12}H_{15}NS_2$ is assigned the 3-n-butylamino-3-phenylthiirane-2-thione structure *(46a)*. The reactions of this thiirane can be readily explained if a number of tautomeric equilibria are taken into account.

The yields of hexathiocane (20 % with n-butylamine as the amine component) can be considerably improved if the molar ratio of ketone : amine : sulfur is changed from 1:2:8 to 1:7:10 and the reaction time reduced from 80 to 18 hours[76]. The hexathiocanes prepared under optimum conditions are listed in Table 10.

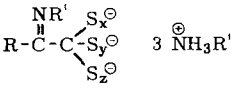


Table 10. 8-Alkylamino-8-aryl-1,2,3,4,5,6-hexathiocane-7-thiones *(42)* prepared by the reaction of aryl methyl ketones (0.1 mole) with primary amines (0.7 mole) and sulfur (1.0 g-atom) in methanol (50 ml) at room temperature; reaction time 18 hours [76,78] (selection).

R	R^1	M.p. (°C)	Yield (%)
C_6H_5	CH_3	145—146	73
C_6H_5	C_2H_5	139	82
C_6H_5	n-C_4H_9	109—110	80
C_6H_5	Cyclohexyl	145	63
4-Pyridyl	n-C_4H_9	139—139.5	65

The first step in the hexathiocane formation is the formation of the *N*-alkylketimine of the methyl aryl ketone. This results in a considerable increase in the acidity of the α C—H group[79].

In the presence of a large excess of primary amine (thiophilic reagent), the S_8 rings are cleaved into sulfane chains, which then add on to the carbanions formed by the basic action of the amine. The result is triple thiolation.

The sulfane chain, which has exactly the "right" chain length (x, y, or z = 6) after partial degradation, adds to the azomethine bond to form the hexathiocane ring. Further degradation of the remaining sulfane

[79] *V. E. Haury, E. Cerrito,* and *S. A. Balard,* US-Pat. 2418173 (April 1, 1947); Chem. Abstr. *41,* 4510d (1947); *V. E. Haury* and *S. A. Balard,* French Pat. 951655 (Aug. 7, 1947); Chem. Zbl. *1950,* II 1876; *J. Mosjew, A. Inasinski, K. Kubiczek,* and *J. Zawrjkraj,* Roczn. Chem. *34,* 1169 (1960); Chem. Abstr. *55,* 15387 a-d (1961).

chains and reaction with $\overset{\oplus}{N}H_3R$ leads to the formation of the 8-alkylamino-8-aryl-1,2,3,4,5,6-hexathiocane-7-thione. No pentathiepane, tetrathiane, or trithiolane rings were found.

Reaction of ketimines of acetophenone, not with excess primary amine and a large quantity of sulfur in methanol at room temperature (hexathiocane yield >80 %), but with the stoichiometric quantity of sulfur in the presence of tertiary amine in DMF, preferably at 65 °C, the formation of hexathiocane is completely

Scheme 6.

suppressed, and the Willgerodt-Kindler product (*N*-monosubstituted arylacetic thionamide) *(31)* is formed in a yield of more than 80 %[76].

The formation of the Willgerodt-Kindler product from the ketimine is assumed to proceed as shown in Scheme 6[76].

The reactions of the ketimine, on the one hand to form the hexathiocanethione *(42)* and on the other to form the Willgerodt-Kindler product *(31)*, show that there is a close connection between the base-catalysed thiolation reaction (of preparative interest for the synthesis of new heterocycles) and the original Willgerodt and Willgerodt-Kindler reaction, though it is not yet possible to collect all the existing knowledge of the thermal and base-catalysed action of sulfur on organic systems in a common scheme.

Hydration of C=N Bonds in Heteroaromatic Substances[**]

BY A. ALBERT[*]

Many aromatic N-heterocycles add water across the C=N double bond. Methods are described for recognizing this phenomenon and for diagnosis of the site of attack. These methods are extended to the determination of (a) the ionization constants of unstable states (whether hydrated or anhydrous), (b) the ratio of hydrated to anhydrous forms at equilibrium, and (c) the rate constants of hydration. The features that stabilize hydration in a molecule are discussed. The literature through 1965 and 1966 is reviewed with special reference to the emergence of new principles, such as di-hydration and the shifting of hydration within a molecule.

1. Introduction

In 1952, we became convinced that quinazoline, and some of the pteridines, had ultraviolet spectra and ionization constants that were absolutely incompatible with the orthodox formulation of these molecules. By 1955, we had eliminated the more obvious explanations, such as ring-opening, and decided that water was being added across the C=N bond of at least one ionic species in each case[1,2]. For example, quinazoline has a stable anhydrous neutral species *(1)*, but the cation is stable only as the hydrated form *(2)*. This means that as soon as the cation corresponding to *(1)* is formed (by the addition of dilute acid), it is rapidly hydrated to *(2)*. Again the anion of 6-hydroxypteridine *(3)*, when made neutral, quickly becomes hydrated to *(4)*.

Before reviewing recent work on the hydration of heteroaromatic molecules, it is necessary first to summarize the principal methods which we have found to be most reliable for studying the phenomena of C=N hydration.

2. Diagnosis and Location of Covalent Hydration

It should be clear that obstinate retention of water in an analytical specimen is no evidence of covalent hydration. This is very often due to water of crystallization, held by lattice forces and not by covalent bonds. Covalent hydration is often unrecognized in elementary analysis because the hydrated ionic species is seldom subjected to analysis (this was the fate of quinazoline before 1961).

The four most useful indications of covalent hydration have proved to be: anomalous ionization constants (measured as pK_a values), anomalous ultraviolet spectra, anomalous infrared spectra, and anomalous nuclear magnetic resonance spectra. Of these, the first two are the most valuable, at least early in the investigation, because they can be used in a swamping excess of water, thus taking advantage of the mass action effect and also reproducing biological conditions.

The principal anomalies of ionization constants caused by covalent hydration are (a) bases are usually strengthened and (b) acids weakened; these results would be expected for the deletion of a double bond. The change is marked; the anomalous constant differs about one thousand-fold from the norm, which can be that of a *C*-methyl derivative, or else a calculated value[3]. Sometimes an anomalous value can be detected in a table of pK_a values; otherwise the anomaly is found when the pK_a is measured, using one of the simple procedures in a manual[4]. If the hydration is slow, hysteresis should be seen during potentiometric titration.

In UV spectra, the usual anomaly caused by covalent hydration is a large shift of the absorption to shorter wavelengths, which is consonant with the deletion of a double bond. (Normally the long-wavelength peak in the spectrum of a substance does not shift more than 10 nm when an ion is formed from the neutral species.) Further, according to the R. Norman Jones rule[5] the UV spectrum of the anion of a hydroxy derivative should be identical with that of the neutral species of the corresponding primary amine. If hydration is suspected in the neutral species, the spectra obtained in water and hexane should be compared: the latter often shows less or none of the anomaly depending on how strongly the water is held. If hydration is suspected in the cation, the spectrum in dilute mineral acid should be compared with that in a more concentrated acid where the thermodynamic activity of the water is much less[6,7].

The IR spectra should show lack of the vibrations ascribable to $-NH_2$ and $-CHO$, which would arise from ring-opening (the $-CHO$ group can also be sought with *p*-nitrophenylhydrazine which is effective at a pH as high as 3.8).

Suitable NMR spectra cannot usually be obtained for the neutral species, which are seldom soluble enough in water; and other solvents have not the same likelihood of permitting full hydration. NMR spectra of anions and cations should show an aliphatic-type peak upfield, at about $\tau = 4$, if hydration has occurred.

The most reliable method for locating the site of hydration is to examine the homologue which has a methyl group attached to that carbon atom which is thought to carry the hydroxyl group. If the location is correct, all the anomalies mentioned above will disappear. Thus in Fig. 1, it is seen that the UV

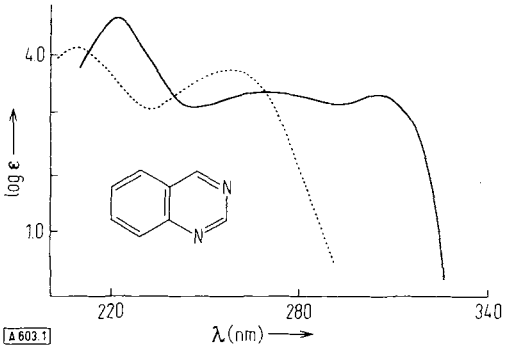

Fig. 1. UV spectra of quinazoline in water, ——: neutral species; ·····: cation.

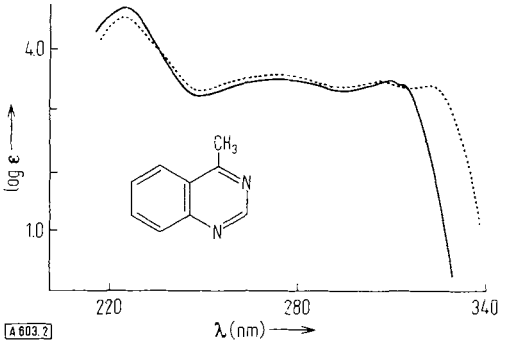

Fig. 2. UV spectra of 4-methylquinazoline in water, ——: neutral species, ·····: cation.

spectrum of quinazoline has moved, anomalously, to shorter wavelengths for the cation, whereas Fig. 2 shows that the spectrum of the cation of 4-methylquinazoline is normal. This indicates that quinazoline is hydrated in the 4-position, a conclusion which other tests confirm [7]. Another useful method is to oxidize the hydroxy group gently to a carbonyl group and to compare the product with substances of known constitution[2]. Hydrogen peroxide in 1 N sulfuric acid, potassium permanganate, and alkaline potassium ferricyanide have proved suitable if used at room temperature. NMR spectroscopy and comparison of the UV spectrum with UV spectra of known dihydro derivatives are further methods which can be used for locating the site of hydration.

3. Equilibrium Methods and Kinetic Methods

Figure 3 shows the equilibria involved in hydration processes. The relevant ionization equilibria are twofold: (a) between A and $AH^{\oplus}$ (the anhydrous

[3] *J. Clark* and *D. D. Perrin*, Quart. Rev. (chem. Soc., London) *18*, 295 (1964); *G. B. Barlin* and *D. D. Perrin*, *ibid. 20*, 75 (1966).

[6] Sulfuric acid (50% w/w) has been successfully used for this purpose [7]; a useful alternative, free from any danger of forming a dication is anhydrous dichloroacetic acid with a Hammett acidity function (H_0) of -0.9 [7].

[7] *A. Albert*, *W. L. F. Armarego*, and *E. Spinner*, J. chem. Soc. (London) *1961*, 2689,5267.

neutral species and the anhydrous cation) and (b) between B and $BH^{\oplus}$ (the corresponding hydrated pair). These equilibria are instantaneous (perhaps 10^{-6} seconds). There are also time-dependent equilibria between A and B, and between $AH^{\oplus}$ and $BH^{\oplus}$ with half-times of 0.01 to 4000 seconds. It is usually found that A and $BH^{\oplus}$ are stable species, whilst B and $AH^{\oplus}$

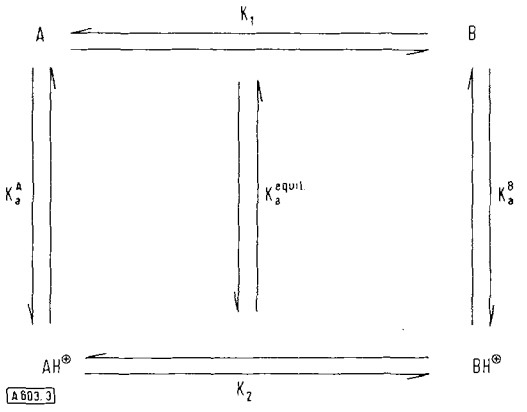

Fig. 3. The equilibria in covalent hydration: A, anhydrous form. B, hydrated form. $AH^{\oplus}$, cation of anhydrous form. $BH^{\oplus}$, cation of hydrated form.

are unstable (*i.e.* they rapidly lose and gain water, respectively). By the use of *Chance*'s rapid-reaction apparatus (Fig. 4) [8] it is possible to obtain UV spectra of the unstable species and to calculate the four equilibrium constants shown on the periphery of Fig. 3. If a conventional apparatus is used for determining pK_a values, the observations are spread over 20 minutes or more and a different ionization constant is obtained, namely $K_a^{equil.}$, which is a composite of

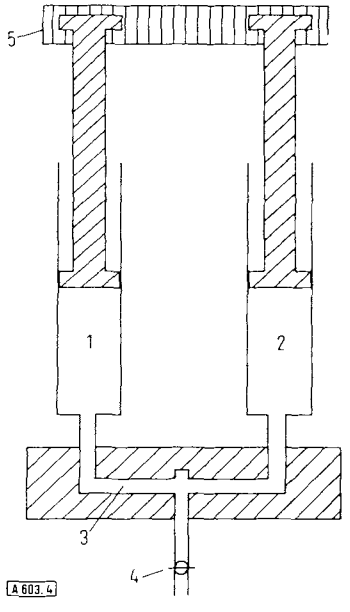

Fig. 4. Diagram of the *Britton Chance* [8,9] mixing apparatus for studying rapid reactions. 1,2: storage vessels; 3: mixing chamber; 4: tap; 5: handle for pressing down piston.

the values K_a^A, K_a^B, K_1, and K_2 Although $K_a^{equil.}$ is not a pure constant, it has a use as we shall see later. The mixing apparatus shown in Fig. 4 (for details of construction see ref. [9]) is suitable for reactions whose half-times are not less than one second.

The left-hand cylinder 1 of the mixing apparatus is filled with an equilibrated solution of one ionic species (say, the neutral species) and into cylinder 2 is put a buffered solution at a pH suitable for the liberation of a different ionic species (say, the cation). The outflow from the mixing apparatus is allowed to fall into an ultraviolet spectrophotometer cell 3, the bottom of which is fitted with a tap. To obtain the spectrum of the unstable species, it is only necessary to leave open the tap of the spectrophotometer cell, and let the automatic instrument record the spectrum while the pistons of the mixing apparatus are steadily pushed down (by means of the handle 5). To obtain the pK_a of the unstable species, a series of buffers are, in turn, placed in the cylinder 2, and the variation in optical density measured. The values obtained at different pH values are plotted as shown in Fig. 5a [10]. The pK_a value is obtained from this graph by drawing a vertical line through the point where there is the least increment in pH per unit change in density; the point where it intercepts the pH axis is the pK_a. More accurate values of pK_a are obtained by averaging individual values calculated directly from the data and corresponding to various sections of the curve. When the rate of change is too great to obtain reliable points for a plot such as that shown in Fig. 5, the required result can still be obtained, but not so quickly, by recording density changes with time for one buffer solution. The resulting straight-line plot of these values (see Fig. 5b), if back-extrapolated to zero time, gives one of the necessary density values from which to calculate the pK_a.

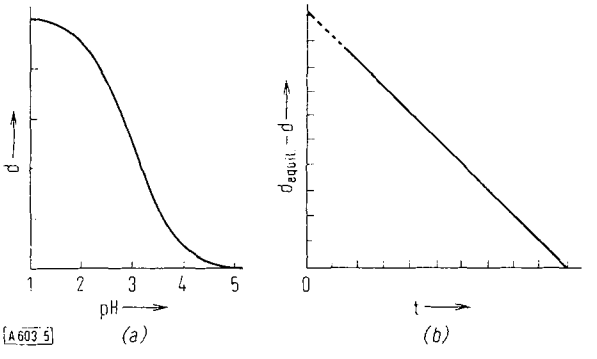

Fig. 5. (a) Plot of optical density against pH for a continuously flowing mixture (for determination of ionization constant of an unstable ionic species). (b) Plot of optical density against time for a stationary mixture.

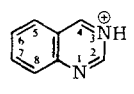
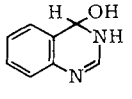
The graphical representation shown in Fig. 5b has also been used to study the kinetics of these reactions [9,11], which were found to be first-order (at any constant pH), and catalysed by both acid and alkali. The half-times for the reactions are obtained from the equation:

$$t_{1/2} = 0.301/K_{obs} \qquad (1)$$

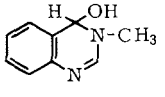
where K_{obs} is the observed velocity constant obtained by the use of logarithms to the base 10. Microscopic velocity constants (for the hydration and also for the



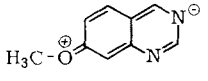
[10] These measurements are made at a single wavelength chosen from knowledge of the UV spectrum of the unstable species, *e.g.* 230 nm is suitable for the anhydrous cation of quinazoline, which necessarily has almost the same spectrum as that of 4-methylquinazoline (see Fig. 2).



[11] *Y. Inoue* and *D. D. Perrin*, J. chem. Soc. (London) *1963*, 2648, 3936, 4803, 5166.



dehydration, exclusively) are then calculated, and plots of these constants against pH enable rate-pH profiles to be plotted. The hydration and dehydration rate curves for a single compound have different pH maxima, and intersect at low pH values [11].



Because many ionization constants for anhydrous species are low, and hence have to be measured in a region where hydrogen-ion catalysis is very fast, an auxiliary apparatus was needed, one capable of handling $t_{1/2}$ values as low as 0.03 second. A quartz capillary tube served as the optical cell. A beam of monochromatic light was passed through cylindrical quartz lenses, placed both in front of and behind this cell, and made to fall on a photomultiplier tube. The output of the latter was applied, in a single sweep, to a cathode-ray oscilloscope. The tracings were then recorded by rapid-repeat photography. No more than 3 milliseconds elapsed between the time of mixing the reagents (mechanical drive was used on pistons) and the arrival of the mixture in the observation cell [12].

With the help of this new apparatus the pK_a of anhydrous quinazoline was measured [12], *i.e.* for the equilibrium *(1)* ⇌ *(5)*, and found to be 1.95, whereas that of hydrated quinazoline, *i.e.* for the equilibrium *(2)* ⇌ *(6)*, was 7.77. The latter value was suitably obtained with the original apparatus because the rate is not too fast between pH 4 and 10 [7]. These two pK_a values (1.95 and 7.77) are very different from the previously accepted pK_a of quinazoline, 3.51, which is only an equilibrium value. The value 1.95 for anhydrous quinazoline agrees well with a value calculated from the pK_a (2.52) of 4-methylquinazoline (known to be largely anhydrous) by substracting the usual 0.7 increment due to an α-methyl group. The value 7.77 for hydrated quinazoline is also reasonable because 4-hydroxy-3-methyl-3,4-dihydroquinazoline *(7)*, which does not lose methanol, has a pK_a value of 7.64. All these ionization constants were determined at 20 °C, in water [7].

(5) 

(6)

(7) 

(8)

In those cases where the cation is highly hydrated, such as quinazoline, it is easy to calculate the ratio of hydrated to anhydrous molecules in the neutral species, at equilibrium, by equation (2):

$$\frac{[B]}{[A]} = \frac{K_a^B}{K_a^{equil.} - K_a^B} \quad (2)$$

$$K_a^B = \frac{[H^{\oplus}] \cdot [B]}{[BH^{\oplus}]} \quad (3)$$

$$K_a^{equil.} = \frac{[H^{\oplus}]\,([A] + [B])}{[AH^{\oplus}] + [BH^{\oplus}]} \quad (4)$$

Equation (2) is derived directly from equations (3) and (4) after rejection of the term $[AH^{\oplus}]$ (rejected because no appreciable proportion of anhydrous cation is present). Some of the ratios obtained in this way for neutral species are given in Table 1. It can be seen that the degree of hydration is small but increases as the number of doubly bound nitrogen atoms increases. By constructing analogous equations, the ratio of anhydrous to hydrated cations can also be calculated [9].

Table 1. Ratio of hydrated (B) to anhydrous neutral species (A) in some azanaphthalenes (at equilibrium, in water at 20 °C).

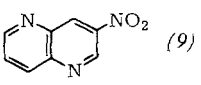
Azanaphthalene	[B] : [A]
1,3-Di- (quinazoline)	1:10000
1.3,5-Tri-	1:200
1,3,7-Tri-	1:50
1,3,8-Tri-	1:500
1,3,5,8-Tetra- (pteridine)	1:4

A *C*-methyl group represses hydration only when it is attached to that carbon atom which is to be hydroxylated, an effect which is largely steric but partly electronic (see Section 7). However, a powerfully mesomeric (+M) group can exert a strong repressive effect from a distance. Thus a methoxy, amino-, or hydroxy group inserted in the 7-position of quinazoline, as in *(8)*, lowers hydration of the cation from 100 to 22 per cent [13].

4. Causes of Hydration

Until 1965, the only heteroaromatic substances known to hydrate covalently were polyazanaphthalenes, so that most of the original work on the causes of hydration was carried out using these substances. Table 1 shows that the hydration of neutral species increases as the number of ring-nitrogen atoms rises (cations are hydrated more strongly than neutral species but also observe this order). It seems that one feature necessary for hydration is the presence of an electron-withdrawing center, one so powerful that the π-electron layer (on the persistence of which normal aromatic stability depends) is depleted. As a result, a highly polarized double bond becomes isolated from Kekulé-type conjugation, and reactions typical of such a bond can take place. A doubly bonded nitrogen atom has the electron-withdrawing force of a nitro group. The presence of several doubly bonded nitrogen atoms in one nucleus can weaken its aromatic character, especially if they are placed 1,3 to one another so that their separate effects are completely additive. We have found that many nucleophilic reagents, such as methanol, malononitrile, and acetylacetone can easily be added to the 3,4 double bond of 2-hydroxypteridine [14] and 2-aminopteridine [15].

However, water is a weaker nucleophile than these substances and is not likely to be strongly bound unless some other force operates. Resonance has been found to supply the extra influence that makes the hydrated

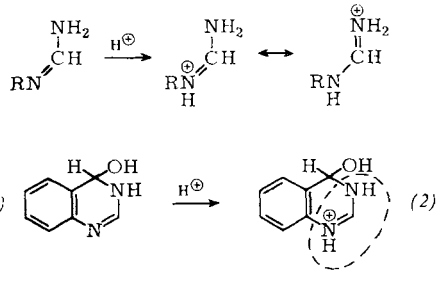


[12] *J. Bunting* and *D. D. Perrin*, J. chem. Soc. (London) *B 1966*, 433, 436.

[13] *W. L. F. Armarego*, J. chem. Soc. (London) *1962*, 561.

[14] *A. Albert* and *C. F Howell*, J. chem. Soc. (London) *1962*, 1591.

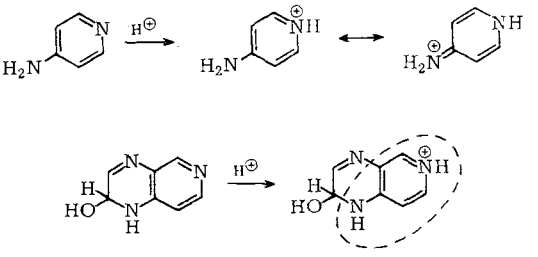
[15] *A. Albert* and *J. J. McCormack*, J. chem. Soc. (London) *C 1966*, 1117.



forms stable. Thus, water cannot be added to the 4-nitroisoquinoline cation whereas the quinazoline cation is fully hydrated. Again 3-nitro-1,5-naphthyridine *(9)* does not undergo hydration, but 1,3,5-

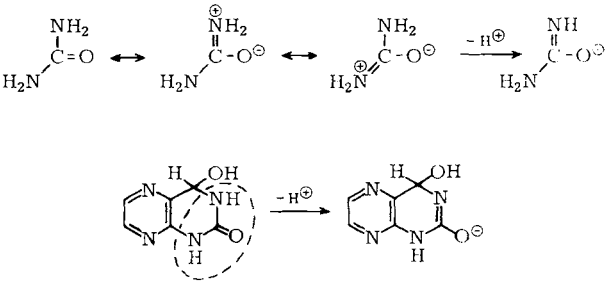
(9)

triazanaphthalene does so. No hydration could be detected in quinoline, isoquinoline, cinnoline, phthalazine, or quinoxaline.



The stabilization of the cation of quinazoline in the hydrated state is ascribed to the amidinium-type resonance which is possible only in this state. This resonance, well-known in the aliphatic amidines, is much more strongly developed in the cations than in the neutral species because the latter have a separation of charge which is destabilizing [16]. The highly basic character of amidines is a result of this resonance. Scheme 1 shows how the amidinium resonance is present in the hydrated quinazoline cation and how it is responsible for stability in such a compound; this applies also to higher azalogues of quinazoline and many of their derivatives. The guanidine-type resonance found in 2-aminoquinazoline is an obvious extension of this.

Scheme 1. The amidinium cation as a model for the stabilization of the quinazoline cation *(2)*.



The 4-aminopyridinium-type resonance, one of the most interesting stabilizers of hydration, is a vinylogous amidinium resonance. The far greater resonance possible in the cation (as compared to the neutral species) of 4-aminopyridine makes the substance ten thousand times stronger a base than pyridine [17]. The stability of the 4-aminopyridinium resonance depends on the equality in energy of a *p*-quinonoidal conjugation and a benzenoid conjugation. The simplest hydrating azanaphthalene with this conjugation is 1,4,6-triazanaphthalene (see Scheme 2). 6-Hydroxypteridine also is stabilized as the hydrate because of this resonance. A 2-aminopyridinium resonance is also known, but it is weaker and, for the present purposes, of only borderline interest. The amidine anion type of resonance, which stabilizes the anion of pteridine, will be discussed later.

The urea-type resonance, yet another stabilizing influence, is significant mainly in the neutral species. It

Scheme 2. The 4-aminopyridinium cation as a model for the stabilization of various azanaphthalene cations as hydrates.

is almost ineffective in the anionic species because one of the two possible canonical forms would have to carry the negative charge on the nitrogen atom, and hence would not be equivalent to that carrying the charge on the much more electro-negative oxygen atom. In Scheme 3, the urea resonance is illustrated and an example is given of a substance, 2-hydroxypteridine, whose hydrate (it is hydrated in the neutral species only) owes its stability to this type of resonance.

Scheme 3. The urea molecule as a model for the stabilization of 2-hydroxypteridine (neutral species) as hydrate.

5. Recent Results from Other Systems

Attempts have been made to elicit hydration in the purine *(10)* series, both to extend the phenomenon beyond the azanaphthalene series and also to obtain substances with which the supposed activity of hydrated purines as enzyme substrates [18] could be tested. Since published tables of ionization constants and UV spectra of the known purines revealed no anomalies, it was decided to prepare purines with an electron-attracting substituent in the 8-position (both with and without a hydroxy group in the 2-position).

Although purines of this type would be among the most likely to show evidence of hydration, none was found to hydrate [19]. However, the cation of 8-azapurine *(11)* was strongly hydrated, as were the cations of its 2-amino, 2-hydroxy, and 2-mercapto derivatives. This hydration was detected by the use of ionization constants and UV spectroscopy. The hydrating hydroxyl group was found to enter the 6-position; this was evidenced by the facts that (a) 6-hydroxy-8-azapurine was produced on gentle oxidation and (b) a methyl

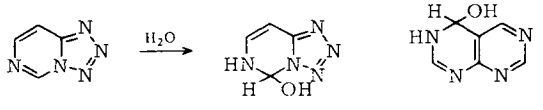
group in the 6-position (but not in 2-) restored normal pK_a and UV values [20]. An additional, and surprising, finding was that a methyl group in the 9-position prevented the cation from hydrating. This may be

(10) 

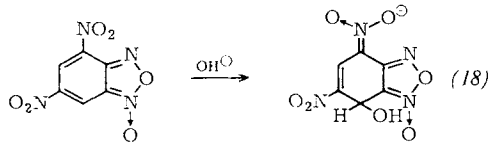
 (11)

ascribed to the antagonistic inductive effect of this group on the 8-nitrogen atom [21]. NMR spectroscopic studies of the azapurines also led to the same conclusions; equilibrium ratios and kinetics were also determined using the rapid-reaction apparatus [12].



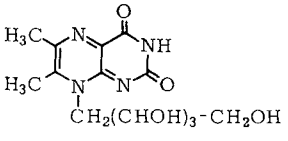
The first example of hydration in a single-ring heteroaromatic substance is the hydrated 5-nitropyrimidine cation [22]. In general, single-ring nuclei do not become hydrated because by doing so they would lose all benzenenoid resonance. However, the 5-nitropyridinium ion has access to the *p*-nitroaniline-type resonance *(12)* ↔ *(13)*. In spite of a general electronic

(12) (13)



resemblance, this stabilization is not possible in 1,3,5-triazine which is immediately hydrolysed to formamide by cold water [23].

It has recently been found that the neutral species of tetrazolo[1,5-*c*]pyrimidine *(14)* absorbs atmospheric moisture to form 5-hydroxy-5,6-dihydrotetrazolo-[1,5-*c*]pyrimidine *(15)*, a reaction that is not easily reversible [24]. Hydration, *e.g.* to *(16)*, has also been detected in various derivatives of pyrimido[4,5-*d*]-pyrimidine [25].



(14) (15) (16)

In spite of the frequency with which the pyrimidine ring occurs in hydrated compounds, its presence is not necessary for hydration as is shown by the ready hydration of 1,4,5- and 1,4,6-triazanaphthalenes [26] and of 3-nitro- and 8-nitro-1,6-naphthyridine [27] (cf. also 1,4,5,8-tetraazanaphthalene, below). It has now been shown that 4,6-dinitrobenzofuroxan *(17)*, usually considered to be a heteroaromatic compound, is converted into the hydrated anion *(18)* by alkali [28].

(17)  (18)

6. Recent Results for the 8-Substituted Pteridines

Ever since the time that *Masuda* [29] showed that 6,7-dimethyl-8-ribityllumazine *(19)* is an intermediate in the biosynthesis of the vitamin riboflavine, difficulties have been encountered in reconciling the UV spectrum of this important intermediate with the spectra of other 6,7,8-trialkyllumazines and the 3,6,7,8-tetra-alkyllumazines. Not only did the spectra of the neutral

 (19)

species of the models not agree with those of the intermediates but also they showed a surprising, variable hypsochromic shift when made alkaline [30]. When ionization constants were determined as a preliminary to confining the UV spectra to a single ionic species, it was found that these constants, too, differed widely among homologues [31]. These apparent contradictions were finally explained by studies of covalent hydration. First an account will be given of 8-alkylpteridines with only one polar substituent.

As early as 1956, *Brown* and *Mason* had indicated that 6,7,8-trimethyl-4-pteridone *(20)* (which is an acid of pK_a 9.5 and which shows hypsochromy in alkali) gives the anion *(21)* by 3,7-hydration followed by loss of a proton [2]. This work was recently followed up by *Jacobsen* who applied the complete range of diagnostic aids, including the rapid-reaction technique [32].

He studied 8-methylpteridines containing one oxo, thioxo, or imino substituent in the 2- or in the 4-position. In most cases it is impossible to obtain derivatives void of methyl groups in the 6- and 7-positions because such derivatives polymerize. The neutral species, *e.g.* 6,7,8-trimethyl-2-methylimino-2,8-dihydropteridine *(22)*, is analytically free from water

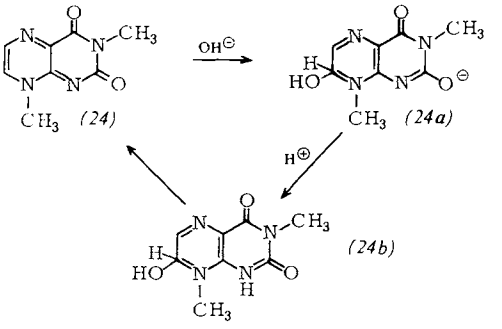
(22)

and gives the same UV spectrum in cyclohexane as in water, with a prominent peak at 350 nm. The anhydrous cation, formed by adding acid, has a similar spectrum in water (λ_{max} = 336 nm), which changes completely within 20 minutes. Peaks appear at lower wavelength, although not more than 75 per cent diminution in the height of the original peaks occurs at equilibrium. It was established that the cation *(23)* is hydrated to *(23b)* [*(23a)*:*(23b)* = 1:3]. The mixture of cations is shown in Scheme 4, together with the resonances that give almost equal stabilization to both. If this mixture of cations is made alkaline, the anhydrous neutral species is totally regenerated within 20 minutes. The UV spectrum of the anhydrous cation in a cyclohexane solution of dichloroacetic acid remains stable (at 336 nm) indefinitely. Ring opening was carefully excluded in this study.

(23a)



(23b)

Scheme 4. The two resonances that stabilize the 2-methylimino-6,7,8-trimethylpteridinium cation almost equally well in the anhydrous and hydrated states.

That the hydroxyl group has actually entered the 7-position, in spite of the steric hindrance offered by the methyl group, can be shown by oxidation with potassium permanganate in acetic acid at 20 °C. This reagent removes the methane, and affords 6,8-dimethyl-2-methylamino-7,8-dihydro-7-pteridone. The reaction was shown to be quite general for diagnosing the position of hydration in azanaphthalenes [32]; it is reminiscent of the oxidation of 1-methylcyclohexanol to cyclohexanone with potassium permanganate in water at room temperature [33].

W. Pfleiderer et al. of Stuttgart and our group in Canberra collaborated in a study of the hydrating properties of 28 examples of the 8-alkyllumazines [34]. The first series of investigations were carried out with lumazines in which the ionizable hydrogen atom on N-3 was replaced by a methyl group. It was found that 3,8-dimethyllumazine *(24)* (examined with or without further methyl groups in the 6- and 7-position) shows no anomalies of pK_a or UV spectra as the neutral species or cation. Alkali produces a mono-anion (p$K_a^{equil.}$ 10.4) which must necessarily come from a hydrated form. It has a lower UV maximum at shorter wavelengths, corresponding to the loss of a double bond (Scheme 5). A hydrated mono-anion of

Scheme 5. The anhydrous neutral species *(24)*, the hydrated neutral species *(24b)* and the hydrated anion *(24a)* of 3,8-dimethyllumazine. [*24*], λ_{max} = 394 nm; *(24a)*, λ_{max} = 306 nm; *(24b)*, λ_{max} = 308 nm].

this type had already, if not quite correctly (see below), been suggested for 8-methyllumazine [35]. Its relation to the anion (pK_a 11.2) which pteridine forms in alkali should be noted [1, 36]; this anion is stabilized by the resonance *(25)* ↔ *(26)*. In 3,8-dimethyllumazine, the electronegative oxygen accepts the negative charge more easily than does the nitrogen atom in the anion of pteridine.

When an alkaline solution of 3,8-dimethyllumazine is neutralized, an unstable form of the neutral species *(24b)* is produced; it has a UV maximum at 308 nm, an indication that it is the hydrated neutral species corresponding to the hydrated anion *(24a)*. On standing at room temperature, *(24b)* is soon converted into the anhydrous neutral species *(24)* (the starting material). Studies made with rapid reaction apparatus showed that, at equilibrium, there were 5360 molecules of the anhydrous neutral species to each one of the hydrated neutral species. That the anion was not dihydrated was confirmed by NMR spectroscopy.

Experiments were now directed to an investigation of 8-alkyllumazines, with a hydrogen atom on N-3. Here again the neutral species and cation presented no anomalies, but the spectra of solutions in alkali were wildly sensitive to small changes in the nature of alkyl groups in the 6-, 7-, or 8-positions. This variation was traced to the formation of equilibrium mixtures of two mono-anions (one of them hydrated) and a di-anion. According to its NMR and UV spectra, this di-anion corresponds to the mono-anion *(24a)*, but the pK_a (12.4) is higher (pK_a of *(24a)* = 6.7) because of the opera-

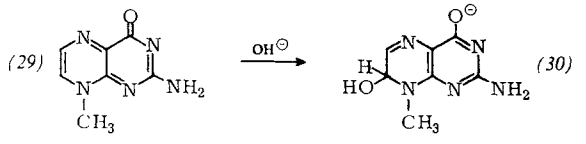
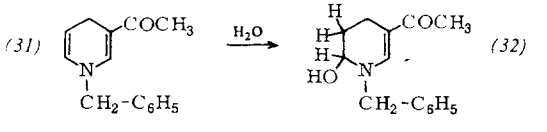
tion of Coulomb's Law. The two mono-anions of 8-methyllumazine exist in roughly equal proportions at equilibrium; each anion is stabilized by an effective resonance (see Scheme 6). The anhydrous anion (a reasonably strong acid of pK_a 10.1) can be obtained and its rate of hydration recorded by slightly basifying a solution of the neutral species in the rapid-reaction apparatus. The hydrated anions (pK_a values 6.4 and 12.4) are obtained in a similar manner by slightly lowering the pH of solutions of the di-anion [34].

Scheme 6. Resonance structures that stabilize the two mono-anions of 8-methyllumazine equally well in the anhydrous and hydrated states.



The proportion of hydrate in the neutral species of 8-methyllumazine was found to be 1 part in 5700. The presence of two methyl groups in the 6- and 7-positions decreases the hydration, whereas two isopropyl groups raises it to 1 in 86. These 6- and 7- isopropyl groups must interfere with each other's rotations, so that the normally flat pyrazine ring becomes distorted. This steric strain is relieved by hydration. Two phenyl-groups give rise to a similar, but slighter, effect [34]. Similar 6,7-steric effects have also been noted by *Jacobsen* [32]. Kinetic studies show that the neutral species of 6,7-diisopropyl-8-methyllumazine becomes hydrated about 20 000 times more slowly than the neutral species of 8-methyllumazine, although the former contains a higher proportion of hydrate when equilibrium is finally attained.

Lumazines with a β-hydroxyethyl group on N-8, of which the riboflavine precursor *(19)* is an example, were shown to be in equilibrium, not with a hydrate, but with a form in which the β-hydroxy group has attacked the 7-position, as in *(27)*. These substances give spectra similar to the hydrates, even though they are themselves anhydrous. The attack of the β-hydroxyethyl group on the 7-position is about 2000 times faster than the attack of water molecules on 8-methyl analogues. These β-hydroxyethyl compounds are much more stable to opening of the pyrazine ring on prolonged exposure to alkali than their analogues without the β-hydroxy group. The ring-opening products, *e.g. (28)*, are characterized as absorbing at 360 nm and can be identified by the dependence of ring-opening and -closing on the ionic strength of buffer solutions [34].

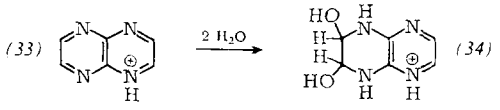


It can now be said that the problems posed by the riboflavine precursor *(19)* and the other 8-alkyllumazines have at last been solved.

The cations of the 8-alkyl-2-aminopteridin-4-ones, *e.g. (29)*, are stronger bases than the cations of the lumazines and, like them, are anhydrous. The neutral species are, in general, anhydrous; but a hydrated neutral species can be made by acidifying the anion *(30)*, which is necessarily hydrated, because the 2-aminopteridin-4-ones, unlike the lumazines, have no mobile hydrogen atom on the nitrogen. As with 8-alkyllumazines, the hydrated species show a UV peak at about 300 nm and the anhydrous species a peak at about 400 nm. The kinetics of hydration indicate first-order reactions, which are catalysed by both hydrogen ions and hydroxide ions. The kinetics of ring-opening and -closing of some 6,7-dimethyl derivatives (neutral species) have also been studied [37] and show salt catalysis.

7. Recent Results for Multiple Hydration and Shifting Hydration

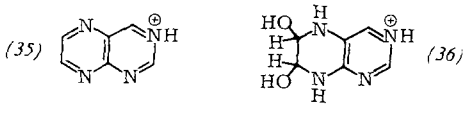
In most of the examples discussed so far, only one molecule of water is added; but the hydration process need not stop there. Because monohydration gives the ring system an electron-releasing (–NH–) group, the drain on the π-electrons of the molecule is halted, and further hydration is not likely to occur in the remaining heteroaromatic ring. However, the ring that has already been hydrated now contains a highly polarized double bond which, while partly stabilized by conjugation with the heteroaromatic ring system, may be sufficiently activated to take up a second molecule of water. This is not surprising, for ethylenic (in contrast to aromatic) heterocycles readily form hydrates. For example, 3-acetyl-1-benzyl-1,4-dihydropyridine *(31)*, in dilute acid at 25 °C, adds water to give the crystalline 5,6-hydrate *(32)*, which can be isolated in 93 per cent yield [38].



It has recently been found that the cation of 1,4,5,8-tetraazanaphthalene *(33)* can form a dihydrate *(34)* in this way. In anhydrous [D]-trifluoroacetic acid, the NMR-spectrum of the cation consists of only one peak – a sharp singlet at $\tau = 0.51$ (33 °C; 60 MHz), which can be ascribed to the four equivalent aromatic protons. A solution of the cation in 1 N DCl (in D_2O), on the other hand, shows two sharp singlets of equal intensity, one at $\tau = 2.48$ (aromatic protons) and one at $\tau = 4.63$ (aliphatic protons), *i.e.* a spectrum, which

[37] *W. Pfleiderer, J. Bunting, D. D. Perrin,* and *G. Nübel,* Chem. Ber. in press.

[38] *A. G. Anderson* and *G. Berkelhammer,* J. Amer. chem. Soc. *80,* 992 (1958).



must arise from a symmetrical (time averaged) species. This dihydrate is stabilized by 2-aminopyridinium resonance. Gentle oxidation with acidic hydrogen peroxide gave 2,3-dihydroxy-1,4,5,8-tetraazanaphthalene [39].

The introduction of methyl groups hinders this hydration. Thus the cation of 2,3,6-trimethyl-1,4,5,8-tetraazanaphthalene [40] is not hydrated in aqueous solutions; in D_2O, H-7 shows a sharp NMR signal at $\tau = 0.78$. Similarly the cation of 1,4,6-triazanaphthalene was found to be dihydrated in the pyrazine ring, whereas that of 1,4,5-triazanaphthalene is almost anhydrous. These dihydrates are quickly converted by alkali into the anhydrous neutral species [39].

A few examples are known of a time-dependent intramolecular shift in the position of hydration of a substance. Thus the neutral species of 2,6-dihydroxypteridine initially takes up water in the 3,4-position, but after a lapse of about an hour, it is found to be hydrated exclusively in the 7,8-position. The 3,4-position has only a small affinity for water, but a low energy barrier, so that water is added there by a kinetic process. On the other hand, the 7,8-position has a high affinity for water but a high energy barrier, so that water is eventually transferred there by a thermodynamically controlled process [41]. It is noteworthy that both hydrates retain one heteroaromatic ring.

Recently it has been found that the cation *(35)* of pteridine transfers water in this way. The NMR spectrum of the neutral species of pteridine shows peaks for all four protons in the region $\tau = 0.2$ to 0.7. Acidifying a solution in D_2O with DCl to pH 2 quickly produces the 3,4-hydrate, in which the signal for H-4 has moved upfield to $\tau = 3.2$. Gentle oxidation at this stage gives 4-hydroxypteridine. If the acidic solution of *(35)* is allowed to stand at 33 °C, new peaks appear and the spectrum may be interpreted as being that of an equilibrium mixture of 3,4-monohydrate and 5,6,7,8-dihydrate *(36)* [42]. The UV spectrum of *(36)* is almost identical with that of the 5,6,7,8-tetrahydropteridine cation.

The near equivalence of the two resonances (4-aminopyridinium stabilization of 7,8-hydration, and amidinium stabilization of 3,4-hydration) in the pteridine cation prompted an investigation of the effect of substituents on this delicately balanced system. Only three other substances could be found in which 5,6,7,8-dihydration was preceded by 3,4-hydration, namely: 2-methyl-, 7-methyl-, and 2-amino-4-methylpteridine (note that 6,7-dimethyl-, 2-amino-, 2-amino-6-methyl-, and 2-amino-7-methyl-pteridine remain stably hydrated in the 3,4-position). Five cases of apparently direct 5,6,7,8-dihydration were also found: 4-methyl-, 2-methoxy-, 2-chloro-, 2-methylthio-, and 4-methylthio-pteridine. However, a detailed survey showed that the majority of pteridine cations are subject neither to dihydration nor to shifting hydration [42].

Two recent investigations have extended our understanding of 3,4-hydration of quinazoline and have more general significance. Although electron-attracting groups ($-NO_2$ or $-CF_3$) in the benzene ring of quinazoline assist hydration by their inductive (−I) effect [13], it has now been shown that this kind of substituent in the 2-position antagonizes hydration. This is to be expected because hydration requires a 3,4-double bond that is polarized as in *(37)*. When a −I substituent in the 2-position attracts an electron from N-3, the polarization conducive to hydration is diminished [43].

The effect of a 4-methyl group in preventing hydration of the quinazoline cation has usually been interpreted as being principally steric, acting in cooperation with a smaller inductive component. A kinetic study of 4-carbamoylquinazoline shows that this substituent exerts its steric effect by slowing the attainment of equilibrium (from less than a second to several hours). But since this molecule eventually becomes 3,4-hydrated, it is concluded that the inductive effect (−I) favors hydration. This suggests that the +I effect of the methyl group plays a more important part than had been thought in maintaining the cation of 4-methylquinazoline anhydrous at equilibrium [44]. The previous emphasis on the steric role of this methyl group was derived from the finding that 4-chloro- and 4-sulfo-quinazoline have anhydrous cations; but these could not be observed for more than a few minutes because of hydrolysis.

It has recently been shown that the mono-cation of 2-hydroxypteridine, when placed in strong alkali, forms the di-anion *(38)*; 6-hydroxypteridine also forms a di-anion. (The pK_a values and UV spectra of both have been recorded [45].) The anhydrous basic pK_a values of thirteen quinazolines and four triazanaphthalenes have been determined for the first time [12] by means of the fast-reaction oscilloscope apparatus. From the results, the anhydrous pK_a of pteridine was calculatedas −1.1. Such a negative value is, as yet, inaccessible experimentally because of the strong catalytic effect of the hydrogen ion at low pH values.

8. Conclusion

The phenomenon of covalent hydration is not limited to heteroaromatic substances. That it is commonplace in heterocycles with olefinic double bonds was hinted in Section 7. The hydration of ethylene and the dehydration of ethanol involve such high energy barriers that they cannot be studied by the methods outlined in Sections 2 and 3. However these or similar methods have been employed for studying the hydration of aldehydes (to methylene glycols)[46], and the hydration equilibria of the aminotriphenylmethane dyes shown in Scheme 7[47]. These studies were carried out at room temperature and show interesting parallels with the results obtained for heteroaromatics.

Scheme 7. The hydration equilibria of amino triphenylmethane dyes.

The widespread occurrence of covalent hydration, which depends on a very small energy barrier, should encourage investigators in all fields of chemistry to look for this phenomenon in their own work.

The Concept of Hard and Soft Acids and Bases as Applied to Multi-Center Chemical Reactions[**]

BY B. SAVILLE [*]

Many chemical bonds of differing types and strengths have recently been regarded by Pearson[1] as representing partnerships between (Lewis) acids and (Lewis) bases. Most acceptor molecules or ions (acids) can be placed in one or other of two categories, graphically termed "Hard" and "Soft". There are also two broad categories of donor molecules or ions (bases) which can also be termed Hard and Soft. On the whole, strong chemical bonds are partnerships between either a Hard base and a Hard acid or a Soft base and Soft acid, whereas weaker bond types most usually result in cases of either Hard base-Soft acid or Soft base-Hard acid interactions. The present paper shows how this concept of acidity and basicity can be applied in the interpretation of multi-center chemical reactions involving interconnected acid-base relationships. In particular, four-center substitutions and additions involving cooperative attack by nucleophiles and electrophiles at various chemical bonds have been examined, and a conclusion is reached that especially reactive patterns of reactants can be developed if the substrates contain bonds between either a hard acid and a soft base, or a soft acid and a hard base. Indeed, the arguments can be elaborated to provide two distinct Rules which should be of interest in the interpretation of metal-ion assisted reactions and in the design of novel syntheses.

1. Introduction

In 1963 *Pearson* published a notable paper[1] on the concept of hard and soft acids and bases. In essence, the idea that *Pearson* succeeded in conveying so convincingly is that practically any type of chemical bond one cares to choose (be it either a strong σ or π bond of an organic molecule, a ligand-metal interaction, a bond between charge-transfer complex partners, or even a solvation bond) can be thought of as an acid bound to a base, this being true as long as one is prepared to adopt the view that there are two general classes of acids and two general classes of bases.

Pearson brought out powerfully the generalization that some bases, which can be termed hard, tend to form their strongest bonds with a fairly definite class of acids which he also called hard. On the other hand, hard bases interact rather weakly with a second class of acids which were termed soft. However, the latter

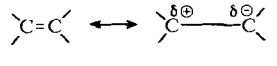
[**] Presented in part as lectures at Imperial College (London), Geneva (Cyanamid European Research Institute), and St. Andrews (Scotland).

[1] *R. G. Pearson*, J. Amer. chem. Soc. *85*, 3553 (1963); Science (Washington) *151*, 172 (1966).

form their strongest bonds with bases drawn from a second class, also labeled soft. The soft bases generally (but not always) fail to give strong bonds with hard acids.

acids		bases
hard	⇆	hard
soft	⇆	soft

How can one determine whether a molecule or an ion is hard or soft?



At an international symposium on this subject [2] it was generally agreed that hardness has to do with bonds which have high ionic character, whereas softness relates more directly to the current picture of covalent bonds. Thus, factors such as small atomic radius, high effective nuclear charge, low polarizability, and low ease of oxidation confer hard character. We find among hard acids the proton, cations of small size (Li^+, Be^{2+}), and cations or molecules in which substituents induce a high positive charge on the central atom (Mg^{2+}, Fe^{3+}, Co^{3+}, Th^{4+}, BF_3, $AlCl_3$, SiF_4).

These species give strong bonds with a restricted range of hard bases which are drawn from N, O, and F as donor atoms. It is interesting that carbanionoid systems ($R_3C^{\ominus}$ or $R_2C^{\delta\ominus}$), also containing a first row element, are not very hard as bases, especially in cases where the 2p electron density is low, as in an olefin. Indeed, saturated carbon as a base seems to be of hard-soft borderline character but falling, on the whole, into the wider group of soft bases.

Outstanding examples of soft bases are the hydride ion and ions derived from P(III), As(III), S(II), Se(II) (Cl(I)), Br(I), I(I), which form bonds of greater covalent character with soft acids.

Soft acids are usually characterized by low positive charge, large size, filled outer orbitals, and high polarizability and include derivatives of saturated C(IV), O(II) (surprisingly), S(II), P(III), Cl, Br, I (as cations or atoms) Hg(I), Hg(II), Ag(I), $B(Alk)_3$, Pt(II), Pt(IV), Pd(IV), as well as some electron-deficient π systems such as those in polynitroaromatics and tetrahalogenoquinones. A complete list and some explanation of these class divisions is provided in *Pearson*'s paper [1].

Although $R_3C^{\ominus}$ is not a very hard base it can still bond well with hard acid centers on account of its high charge density; nevertheless, a polarized olefin

is most decidedly a soft base [3]. A carbon radical is soft both as an acid and a base, whereas a carbonium ion must be regarded as a hard acid. Saturated carbon centers as acids (*e.g.* in nucleophilic substitutions) are definitely soft. Carbonyl and thiocarbonyl carbon centers which, as $>C^{\oplus}-O^{\ominus}$ and $>C^{\oplus}-S^{\ominus}$, resemble carbonium centers are hard like the proton [4,5], whereas aromatic carbon both as a donor and acceptor tends to be soft.

It will be seen that the above statements are in accord with the following well-known distinctions in simple organic reactions:

(i) It is much easier to make a soft acid such as Br^+ or Ag^+ react with an olefin than to convert the latter into a carbonium ion with a proton source (hard acid).

(ii) Carbon radicals add to soft oxygen π bonds or attack halogen compounds (soft acids) with great ease, or combine with themselves, but abstract hydrogen (hard acid) from activated methylene groups only slowly.

(iii) The t-butyl cation $(CH_3)_3C^{\oplus}$ in aqueous solution reacts preferentially with hard solvent molecules but not with added soft thio nucleophiles (bases), such as $S{=}C(NH_2)_2$ or $S_2O_3^{2\ominus}$.

(iv) The reagents generally used in attacking carbonyl groups, eliminating water, or displacing attached basic groups are $HO^{\ominus}$, $RO^{\ominus}$, $HOO^{\ominus}$, and a wide range of reagents containing amino groups; the latter are hard bases. Iodide ion and thiolate ions (soft bases) are less suitable reagents.

We shall now see how usefully the concept can be applied to aspects of chemical reactivity. We shall be concerned not only with equilibrium situations, but also with kinetic aspects – indeed, with hardness and softness seen in regard to the rate of interaction of acidic and basic centers. In the majority of situations it seems that the hard-soft disctinctions based on equilibrium properties may be applied to rate processes, but, as *Pearson* points out, acids and bases tend to exhibit soft character more in kinetic investigations than in equilibrium investigations [1]. This follows from the fact that bonds are longer in transition state configurations. Softness can in part be due to overlap between diffuse orbitals and thus can contribute to bonding at an earlier point along a reaction coordinate.

Notwithstanding such possible complications, the author is of the opinion that the concept may find major application when reactions are considered in which two or more pairs of atoms are at some stage involved in bond making and bond breaking processes, *i.e.* in the field of multi-center reactions. This article is devoted to developing a general picture of four-center reactions.

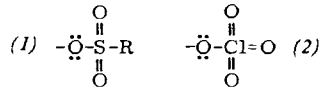
2. Four-Center Substitutions and Additions

Bimolecular nucleophilic substitution can be represented as follows:

$$Z{:} + A{-}X \rightarrow [Z{-}A]^{\oplus}\,[{:}X]^{\ominus} \qquad (1)$$

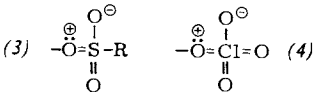
where Z: is a nucleophile which always carries an unshared pair of outer-shell electrons on the attacking atom; A is the electrophilic center, *i.e.* one which, after departure of the nucleophilic leaving group :X,

[2] For a summary of papers, see Chem. and Engng. News *43*, No. 22, p. 90 (1965).



[3] *J. Chatt*, J. inorg. Nuclear Chem. *8*, 515 (1958).

[4] *J. O. Edwards* and *R. G. Pearson*, J. Amer. chem. Soc. *84*, 16 (1962).



[5] *R. G. Pearson, D. N. Edgington*, and *F. Basolo*, J. Amer. chem. Soc. *84*, 3233 (1962).

can present a vacant orbital to the electron-pair of Z: for bonding purposes. Thus, as reaction proceeds, the center A changes its partnership with :X for a more satisfactory one with Z:.

Let us consider now the factors that influence the bimolecular substitution system. Clearly, the incipient development of a strong bond between Z: and A (particularly if this strength is maintained at the strained-bond lengths in transition states) will be of key importance in determining reaction rate, and may be of dominant importance if the new Z–A bond is nearly completely formed before the old A–X bond breaks. On the other hand, if in the transition state considerable stretching of the A–X bond has already occurred, the electron pair of the A–X σ bond begins to reside on X. The easier the pair can be accommodated on X the more rapidly will substitution proceed. Generally, the bonding pair of A–X is finally delocalized and stabilized if X is an electron-deficient π system spread over atoms of high effective positive charge. Thus *(1)* and *(2)* are two of the best leaving-groups because of the charge spreading contributions of the type *(3)* and *(4)*. By contrast, –ÖH and –ÖR

(1) *(2)*

(3) *(4)*

are much poorer leaving groups because the 2p electron pairs reside firmly on one oxygen atom.

The interaction of the developing species $[:X]^{\ominus}$ with the solvent can also be a stabilizing factor; however, the effect is complicated since it is often impossible to arrange for a solvent to bond well with $[:X]^{\ominus}$ and not with :Z. *Pearson*[1] has discussed *Parker*'s view[6] that solvation reduces basicity of small (hard) anions whilst having little effect on basicity of large (soft) anions. Selective assistance of substitutions is therefore possible on this basis.

A greatly increased driving force for substitution (1) above can be provided by increasing the effective charge of the nucleophilic atom in the leaving group, a condition that can be achieved if :X carries at least two pairs of free p electrons. In this case, A–X (more correctly A–Ẍ) can coordinate with an added electrophilic acceptor molecule or ion E.

$$A\text{–}\ddot{X} + E \rightleftharpoons \underset{(5)}{A\text{–}\overset{\oplus}{X}\text{–}\overset{\ominus}{E}} \qquad (2)$$

A new reactive substrate *(5)* will develop in which X carries a higher effective nuclear charge than it does in A–Ẍ bond. The higher charge will now assist X in accepting and stabilizing the electron pair of the A–X bond in $A\text{–}X^{\oplus}\text{–}E^{\ominus}$ which we wish to break.

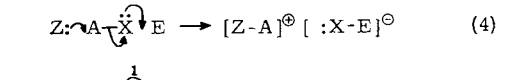
[6] *A. J. Parker*, Quart. Rev. (Chem. Soc., London) *14*, 163 (1962); *J. Miller* and *A. J. Parker*, J. Amer. chem. Soc. *83*, 117 (1961).

Adding the electrophile E thus causes a rate-enhancement of substitution (1). The rate constant k_{Ass} for the four-center electrophilic substitution (3),

(3)

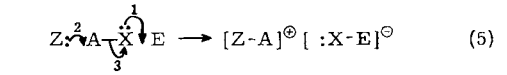
should be greater than the second-order rate constant, k, of the normal substitution (1). Also, if reaction (1) were reversible, the final equilibrium position would be displaced well to the right in the presence of E. The species E would also serve to reduce the nucleophilicity of $[:X]^{\ominus}$.

This rather general statement is based on accepted orders of leaving group activity ($R_2O^{\oplus}$, $RHO^{\oplus}- \gg$ RÖ–, $R_3N^{\oplus}- \gg R_2\ddot{N}-$, $R_2{}^{\oplus}S- \gg R\ddot{S}$) given in textbooks dealing with reaction mechanisms[7].



Although the above theme of electrophilic assistance of a bimolecular substitution has been developed having regard to a process in whose transition state considerable A–Ẍ bond stretching has occurred, it should be applicable also to the case where formation of a Z–A bond is well developed before the A–Ẍ bond begins to break. This follows from the idea that for Z–A bond formation to precede A–Ẍ bond breaking an initial vacant orbital must be available in A to receive the nucleophile Z:. However, if X carries an electron pair this will be involved in π bonding with the vacant orbital of A; thus the effect of adding E would be to uncouple the π bond, leaving the orbital on A vacant and ready to receive Z: more easily than before.

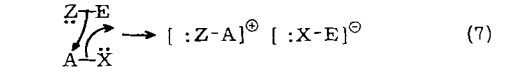
We therefore come to visualize a general form of four-center reaction (4) involving the cooperative action of a nucleophile (Z:) and an electrophile (E) on a substrate (A–Ẍ)[*].



The arrows can be numbered to indicate the timing of the covalency changes. Equation (5) represents an electrophilically assisted nucleophilic substitution.

A nucleophilically assisted electrophilic substitution, in which the need for an unshared electron-pair on X is removed but in which a vacant orbital on A is mandatory, is depicted in eq. (6).

There will also be situations in which Z: and E are neighboring atoms or groups in the same molecule (eq. (7)).



(4)

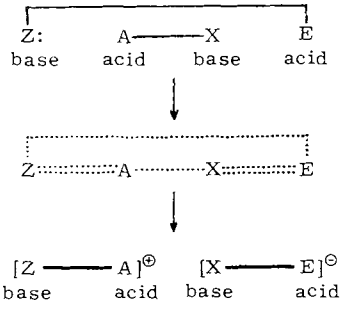
(5)

(6)

(7)

(8)

[7] *C.K.Ingold*: Structure and Mechanism in Organic Chemistry. Bell and Sons, London 1953, p. 338ff. *E. S. Gould*: Mechanism and Structure in Organic Chemistry. Holt, Rinehart and Winston, New York 1959, p. 261.

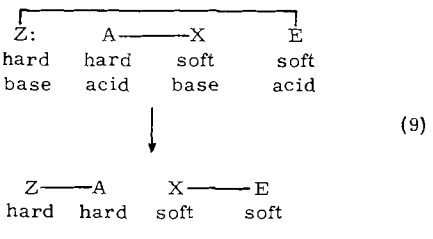


[*] *R. E. Dessy* [83] has approached the subject of multicenter substitutions from the standpoint of the conventional electrophilic substitution but has arrived at much the same picture.

These pictures of four-center substitutions in which A–X σ bonds become broken can be easily extended to the case of electrophilically assisted nucleophilic additions to π electron systems, in which π bonds are opened rather than σ bonds. Thus, if we consider A=X′ as substrate in place of A–Ẍ, then a four-center process can be written as eq. (8).

The rate of this process should again be greater than that of the corresponding process in the absence of the electrophile, E.

3. Two Rules Concerning Choice of Reactants



The above four-center reactions can be regarded as (i) formation of acid-base pairs and (ii) destruction of other pairs in the reactants (Scheme 1).

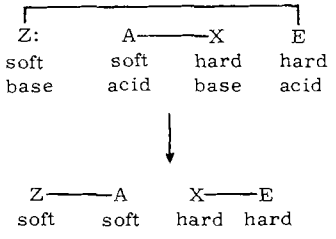
Scheme 1. —— denotes original acid-base pairs of reactants; ····· acid-base pairs being destroyed; ::::::: developing acid-base pairs; —— *final acid-base interactions of the products.*

How can the concept of hard and soft acids and bases be applied to the choice of reactants in four-center reactions? We believe that in order for reactions to proceed easily to afford thermodynamically well-stabilized products, the acid-base pairs[*] of the products Z–A and Ẍ–E must be bonded much more firmly than the acid-base pairs Z–E and A–Ẍ[**] present in the reactants. This condition will be best fulfilled when the substrate bond A–Ẍ possesses hard-soft dissymmetry, *i.e.* when A is hard and Ẍ is soft (1st case) or when A is soft and Ẍ is hard (2nd case).

For the first case, bearing in mind that it is important that Z–A, when developed, should be a strong bond it will be appropriate to make Z: a hard base. Also, as Ẍ is to bond strongly with E the latter should be a soft acid. A rational four-center reaction pattern can be written:

(9)

[*] From this point we omit overall charges in our representations of acid-base partnerships.



[**] Alternatively, here read the A = X′ π bond in the case of substrates undergoing nucleophilic addition.

It is only when the A–X bond possesses hard-soft dissymmetry that is it possible for the preferred Z: and E reagents to have a low mutual interaction energy, as required by the earlier deduction.

Equation (9) can now be formulated as the "first rule" for reagent choice in achieving particularly easy four-center substitutions. This is stated as follows:

If the electrophilic center A of a substrate A–Ẍ is a hard acid, then Ẍ should be a soft base. A–Ẍ will then react most easily with a nucleophile Z:, which is a hard base, together with an electrophile E, which is a soft acid.

In the second case of a substrate possessing hard-soft dissymmetry a second, complementary rule can be derived (eq. (10)).

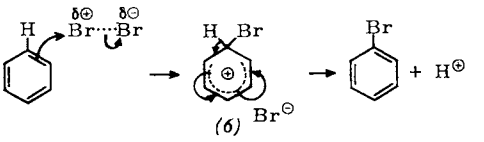
(10)

Here, the weak Z——E and A——X bonds of the reactants are replaced by strong Z–A (soft-soft) and X–E (hard-hard) bonds in the products.

The above rules should apply equally well to the variants of four-center substitution (equations (4)–(7)) and also to four-center assisted nucleophilic additions eq. (8). (In the latter case, one has to decide whether the atoms terminating an opened π bond are hard or soft.)

If A–X is initially either a hard-hard or soft-soft partnership, Z: and E must be either both hard or both soft. In other words, Z: and E are no longer co-operative reagents, and one cannot expect easy forward reactions under such conditions.

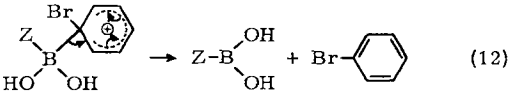
It is now of interest to consider a selection of known four-center reactions to see if reagents used in these cases do indeed conform to the rules proposed above. To begin, we shall consider the first rule and note that here the electrophilic center is to be a hard acid. Examples of hard acid centers include those based on boron, carbon in R–CO- and R–CS–, phosphorus in R_2PO–, sulfur in R–SO_2– Al(III), Si(IV), Sn(IV), and of course $H^{\oplus}$.



These provide a wide range of substrates when coupled to soft leaving-group centers Ẍ, such as RS–, R_2P–, halide, $H^{\ominus}$, and $R_3C^{\ominus}$.

4. Examples of the Operation of the First Rule

4.1. Cleavage of Aryl-Boron Bonds



In the bromination of an aromatic compound it is generally assumed that the π electron system of the benzene ring attacks a bromine molecule (suitably activated in the sense $Br^{\delta\oplus}\cdots Br^{\delta\ominus}$) to provide an

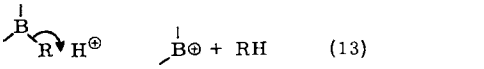
intermediate *(6)* which then loses a proton in affording the observed substitution product:

(11)

It appears that a similar mechanism applies in the reaction of bromine with aryl-boron bonds. The ease of this process should be considerably enhanced if the vacant orbital on boron is first filled by the electrons of a suitable nucleophilic base (Z) to provide a four-center transition state, for example in the cleavage of benzeneboronic acid by means of bromine.

(12)

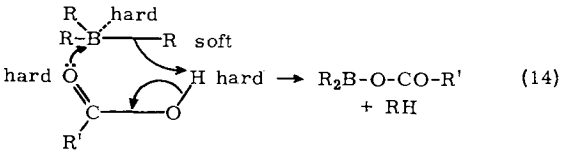
In acetic acid, the rate of this reaction is proportional to the product of concentration of substrate, bromine, and the added bases $OAc^{\ominus}$, or H_2O [8]. As the first rule predicts, the hard boron center responds to hard oxygenated bases, but not at all to soft $Br^{\ominus}$ species.



Clearly, also, the soft aromatic leaving group bonds well with the soft electrophilic $Br^{\oplus}$ center. Thus it seems that equation (12) furnishes excellent confirmation of the first rule:

Z:	A	X	E
oxygen	boron	benzene	bromine
base	center [*]	nucleus	(electrophilic acid)
hard	hard	soft	soft

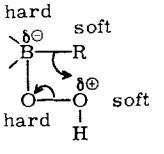
If the first rule is to be useful, it must provide predictive information. It is therefore suggested that hypohalous acids, peracids, mercuric acetate, or bromine fluoride, *i.e.* reagents which all combine a soft electrophilic acid (E) [$Hal^{\delta\oplus}$, $HO^{\delta\oplus}$, $Hg^{\oplus}X$, $Br^{\delta\oplus}$] with a hard nucleophilic base [$HO^{\delta\ominus}$, $RCOO^{\delta\ominus}$, $F^{\ominus}$], would also be effective in cleaving aryl-boron bonds [**].



4.2. Cleavage of Boron Alkyls

The hydrolysis of trialkyl borons, even when catalysed by strong mineral acids, is remarkably slow [9,10]. This can be ascribed to the difficulty in producing the unusual "boronium" state (two vacant 2p orbitals on boron) demanded by the protolysis mechanism (eq. (13)).

(13)



Even though the developing electron-deficiency at boron in such a process could be offset by prior coordination with a base, the bases available in solutions of strong mineral acids will be weak and relatively ineffectual. On the other hand, conventionally weak acids such as propionic acid, which supply a relatively potent hard carboxylate base, are far better reagents for the protolysis of boron alkyls [11–13]. The reaction can be visualized as a four-center substitution:

(14)

However, equation (14) does not conform with the requirements of the first rule; the hard proton has to be changed for a soft acid center *e.g.*, Hal^{+}, RS^{+}, or $HO^{\oplus}$ if rate enhancement is to occur. Indeed, perbenzoic acid (possessing the soft, electrophilic OH center) reacts with tri-n-butylborane at 0 °C in chloroform [1,17,57].

The use of alkaline hydrogen peroxide [14,15] as a general reagent for cleaving organoboranes is a similar example. The hard, electron-dense, oxygen base of hydroperoxide anion can coordinate with the vacant boron orbital to give an intermediate *(7)* (cf. [16]),

(7)

in which the soft alkyl group has enhanced nucleophilicity and, moreover, finds itself in close proximity to a soft electrophilic $OH^{\delta\oplus}$ center. Other reagents which could be suggested for the cleavages of boron alkyls, on the basis of the first rule, are hypochlorite ion and chloramine [*].

[*] Boron is a hard center in BF_3 (cf. $BF_4^{\ominus}$) but a soft one in BH_3 (cf. $BH_4^{\ominus}$) and BPh_3 (cf. $BPh_4^{\ominus}$). Hard ligands, such as $OH^{\ominus}$, confer hardness to boron.

[**] *A. D. Ainley* and *F. Challenger* (J. chem. Soc. (London) *1930*, 2171) have shown that hypoiodite ion, neutral hydrogen peroxide, and aqueous mercuric bromide are effective in cleaving aryl-boron bonds. Zinc and cadmium halides also serve as hydrolysis catalysts.

[17] *J. R. Johnson* and *M. G. Van Campen jr.*, J. Amer. chem. Soc. *60*, 121 (1938).

[*] Chloramine indeed cleaves trialkylboranes (*H. C. Brown*, *W. R. Heydkamp*, *E. Breuer*, and *W. S. Murphy*, J. Amer. chem. Soc. *86*, 3565 (1964) but in the opposite sense to the first rule, to afford alkylamines. *N*-chlorodialkylamines R_2NCl, however, give alkyl chlorides with trialkylboranes (*J. G. Sharefkin* and *H. D. Banks*, J. org. Chemistry *30*, 4313 (1965)). It is conceivable, in *Brown*'s reaction, that the alkyl attachments confer sufficient soft character on boron to attract soft $Cl^{\ominus}$. The $-NH_2$ group is left positively polarized and soft enough to attack the alkyl group.

$Cl-\!\!-\!\!-O^{\ominus}$ $Cl-\!\!-\!\!-\ddot{N}H_2$

soft hard soft hard

H. C. Brown[15a] has also described the reaction of silver, gold, and platinum oxides with triethylboron to furnish noble metal alkyls in accordance with the first rule.

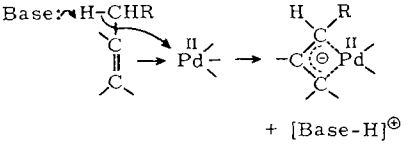
In the intermediate *(7)* the leaving group R (alkyl) carries no lone pairs. On the other hand the center A (boron) has a vacant orbital. It thus seems that bond formation between boron and oxygen occurs first, and is followed by bond formation between R and OH; finally breakage of the R–B and O–O bonds takes place. The reactions are best thought of as nucleophilically assisted electrophilic substitutions.

4.3. Four-Center Systems in the Cleavage of Hydrogen Compounds

This field is less rich than might have been supposed because the conventionally weak acids (in which proton-transfer rates might be measurably slow) are often of the type $H^{\oplus}$ (hard acid) joined to a hard base, and are therefore not examples of an A–X substrate according to the first rule. Conversely, protons joined to soft-base centers (*e.g.* $Hal^{\ominus}$) give strong acids in the conventional sense in which proton transfer is too fast to study. However, we can consider thiols (eq. (15)), selenols, and phosphines as intermediate types.

$$\overset{\text{hard}}{\text{base}}\!\!\rightsquigarrow\!H\!\!\frown\!\!SR \longrightarrow [\text{base-H}]^{\oplus}\ SR^{\ominus} \qquad (15)$$

It would be of interest to know whether the forward dissociation rates of RSH, RSeH, and R_2PH can be enhanced by the presence of a suitable soft acid such as Ag(I), Hg(II), or I_2. The fact that equilibria are pushed well to the right in the presence of such agents forms the basis of analytical methods[18]. When the proton (A) is bonded to a very potent soft base (X) such as $H^{\ominus}$ and $R^{\ominus}$, proton transfer becomes slow and the system is suited to detailed kinetic studies. We ought then particularly to see the operation of the first rule in the nucleophilic cleavage of the hydrogen molecule, and in the cleavage of CH bonds in olefins and paraffins.



4.3.1. Cleavage of the Hydrogen Molecule

Halpern[19,20] has described an important form of homogeneous activation of molecular hydrogen (eq. (16)).

$$\text{Base:}\!\rightsquigarrow\!H\!\frown\!H\!\rightarrow\!M \longrightarrow [\text{Base-H}]^{\oplus}\,[\text{H-M}]^{\ominus} \qquad (16)$$

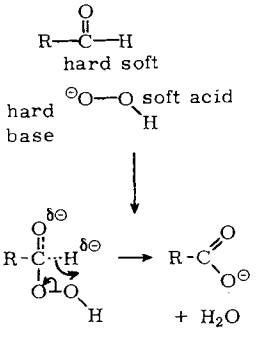
Here the preferred bases appear to be of the hard category (carboxylate ions, pyridine derivatives) and the entity M is a soft metal cation, notably Ag(I), Hg(I), or Hg(II), Cu(I), and Pt(II). A large range of reagent combinations were tested but only the above types were found to be effective. The pattern is seen to be completely consistent with the first rule. It is interesting to note that $F^{\ominus}$ (a very hard base according to *Pearson*) is particularly effective in promoting the silver ion-assisted heterolysis of the hydrogen molecule[21].

The author is unaware of an example that demonstrates the assisted ionisation of a paraffin in the sense $H\!\frown\!CR_3$. Recently, evidence has appeared that olefins form complexes with palladium-group metal centers according to eq. (17)[22].

(17)

The very soft palladium center can be thought of as assisting H–C ionization by supplying, within the initial π complex, a soft coordination position ready to acquire the electrons of the CH bond.

4.4. Cleavage of Bonds to Carbonyl Centers: Acyl Derivatives of Soft Bases



Pearson has firmly classified the carbonyl group as hard both on kinetic and equilibrium behavior[1]. In the well-known stable carbonyl[*] compounds (*e.g.* carboxylic acids, esters, and amides) the carbonyl center is bonded to hard basic groups (OH, OR, NHR, NR_2). Their reactions cannot be predicted in terms of the first rule. The acid fluorides RCOF may also be placed in this category.

However, in derivatives such as RCO–H, RCO–SH, RCO–SR, RCO–SeR, RCO–PR_2, and RCO–Hal (Cl, Br, I) the hard carbonyl center $R-CO^{\oplus}$ is bonded to the soft bases $H^{\ominus}$, $SH^{\ominus}$, *etc.*

Hence these acyl compounds should participate in four-center reactions and respond particularly to a combination of a hard nucleophilic base and a soft electrophilic acid.

4.4.1. Reactions of Aldehydes

In the Baeyer-Villiger oxidation[23] aldehydes are oxidized with alkaline hydrogen peroxide:

(18)

[18] *B. Saville*, Analyst *86*, 29 (1961).

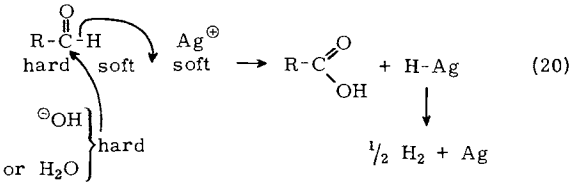
[22] *R. Hüttel*, *J. Kratzer*, and *M. Bechter*, Chem. Ber. *94*, 766 (1961); *G.W. Parshall* and *G. Wilkinson*, Inorg. Chem. *1*, 896 (1962).

[*] We here use carbonyl not in the sense of a derivative of carbon monoxide but rather to refer to the carbon center of R–CO–X.

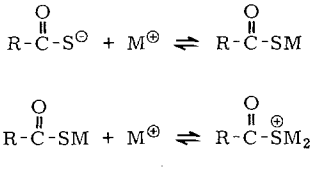
[23] *C. H. Hassall*, Org. Reactions *9*, 73 (1957).



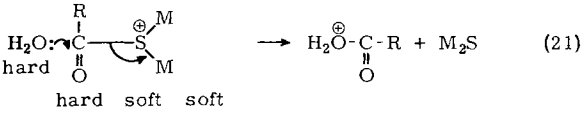
A hard oxyanion attacks carbonyl and the leaving soft hydride ion is removed by a sterically well-placed soft electrophilic O(II) center.

In distinction to this process, no report has been made of the conceptually similar reaction (19). Aldehyde-carboxylic exchange does not occur because the electrophilic R'CO center

(19)

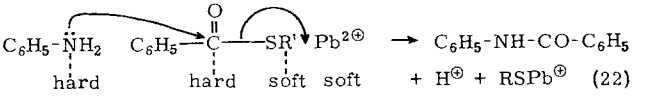


is hard and will therefore not bond easily with the potential hydride ion. Another example of the oxidation of aldehydes (conforming to the first rule) is the silver ion-assisted reaction in aqueous alkali [24–26].



(20)

4.4.2. Thioacids and Thioesters

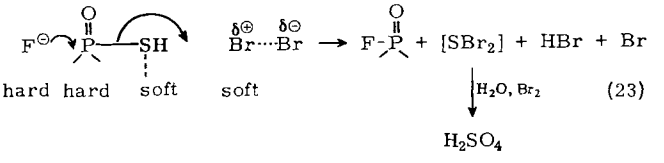


Thioacetic acid, and particularly thioacetamide, precipitate certain soft heavy-metal cations [27–30] as their sulfides. Since the hydrolysis of the carbonyl-sulfur bond is quite slow in the absence of heavy cations [31], and yet precipitation of the heavy metal sulfides can occur nearly instantaneously, it appears that the soft metal electrophile can actively assist hydrolysis (see eq. (21)), in accordance with predictions of the first rule.

(21)

It should be possible to add a hard base nucleophile to the above kind of reaction system in order to provide new acylation products at increased rates. In this regard it is known that thiolesters not only undergo hydrolysis assisted by the soft acids Ag^+, Hg^{2+}, and Pb^{2+}, but also undergo a faster, metal ion-assisted reaction with aniline or with amino groups of amino acids to afford amides in good yield [32, 33]:

(22)

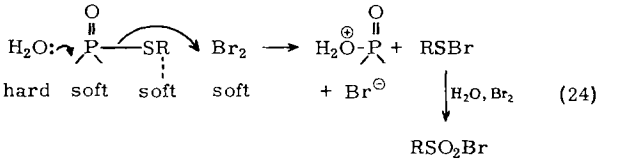


$R'SH$ = $HOCH_2-C(CH_3)_2-CHOH-CO-NH-(CH_2)_2-CO-NH-(CH_2)_2-SH$

(Pantetheine)

4.5. Phosphoryl and Sulfonyl Compounds

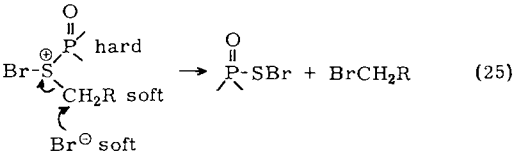
In reactions similar to that above, >P(O)–S bonds can be rapidly cleaved as follows:



(a) A solution of fluoride ions in aqueous bromine [34] converts a phosphorothioic acid into a phosphorofluoridate instantly, whilst in the absence of fluoride

(23)

ions overall oxidative hydrolytic decomposition to a phosphoric acid and sulfate occurs with near equal ease (eq. (23)).



(b) Aqueous bromine or chlorine converts thiophosphate esters into acids and alkanesulfonyl halides [35,36]:

(24)

and mechanistically similar examples occur with thiolesters *etc.* [37].

In this reaction, the formation of alkyl bromides as well as sulfonyl bromides can be ascribed to high concentrations of bromide ions developing in preparative-scale reactions. The bromide ions (soft) prefer to attack the soft alkyl groups of the presumed *S*-bromosulfonium intermediate in preference to the hard phosphonyl center

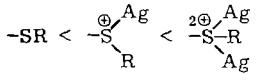
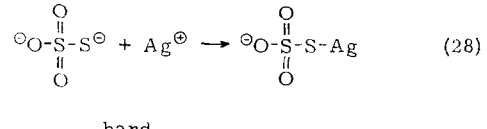
(26)



(27)

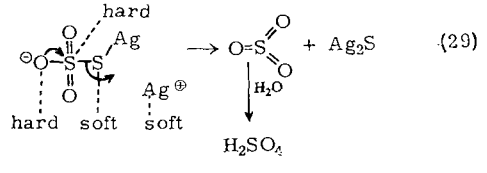
(c) A solution of fluoride and silver ions in water reacts with *O,S*-diethylethylthiophosphonate [38] rapidly giving the products of hydrolysis and substitution by fluoride ion (see equations (26) and (27)).

In the case of reactions (26) and (27), which proceed in accordance with the first rule, a detailed kinetic analysis [38] has revealed that the electrophile ($Ag^{\oplus}$)-modified substrate (that is susceptible to rapid attack by hard H_2O or $F^{\ominus}$ reagents) probably contains two silver ions per molecule (see also [39]).



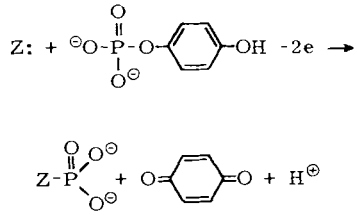
This contrasts with monoprotonation of oxygen or nitrogen derivatives in proton catalysed hydrolyses of esters or amides. The coordination of more than one silver ion to one atom of sulfur is most plausibly explained by the postulate that, in a silver-sulfur bond, metal to ligand electronic feed-back involving $d_{\pi}-d_{\pi}$ bonding has the effect of leaving the positivity of the sulfur atom only slightly enhanced. The sulfur is then able to use its remaining pair of 3p electrons to coordinate with yet another heavy-metal ion until high positive charge on sulfur precludes further coordination, and, moreover, produces a good leaving group (from the phosphonyl center).

Thus the leaving-group activities may be written:



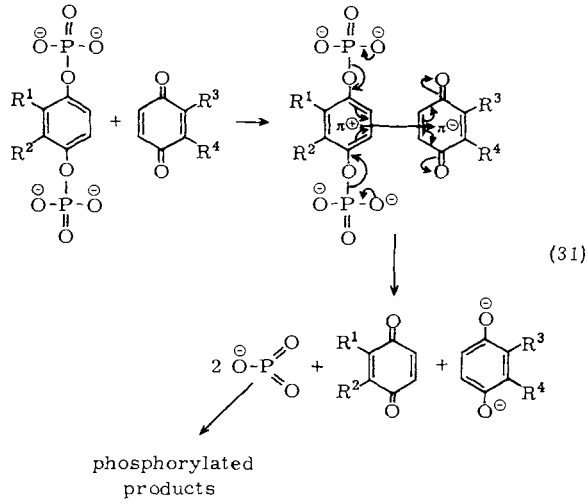
It may well be that this kind of multi-coordination is general for soft polarizable bases interacting with soft acids (being formally analogous to the multiplicity of oxidation numbers often characteristic of soft bases), so that many reactions in which assistance derives from soft leaving group/soft acid interaction will be of high kinetic order referred to the assisting acid. Recent work by *Schwarzenbach* and *Schellenberg* [40] on the binding of thio ligands to the methylmercuric cation is in accord with this picture, as is the recognition of species such as $Ag_3I^{2\oplus}$, $Ag_3S^{\oplus}$, 6 $AgNO_3 \cdot AgC \equiv CAg$ [41–43].

Similar activation of cleavage of bonds between sulfur(II) and sulfonyl sulfur – a hard acid center – has been observed in polythionate and thiosulfate chemistry [44]. Thus, in strong aqueous solutions of silver or mercury salts, thiosulfate ion breaks down readily according to eq. (28) and (29).



(28)

(29)



(d) Phosphorylations of biological importance are often geared to redox processes, and phosphorylated hydroquinone derivatives of the vitamin K, ubiquinone, and the vitamin E groups are known to be important intermediates [45–47].

Model studies [45] have shown the activation of *O*-phosphorylated quinols by oxidizing agents (air, Br_2, or Ce^{4+} ions) in the sense:

(30)

Hard nucleophiles (*e.g.* ADP, water, or inorganic phosphate) attack the hard phosphoryl center whilst the *p*-dihydroxyaryl system (a soft leaving group) is removed because of interaction with oxidizing agents, all of which can be regarded as soft electrophiles. It has been suggested [45] that certain *O,O'*-diphosphorylated quinols can become active phosphorylating agents in the presence of quinones. In this case the soft-soft interaction of partners in a charge-transfer complex, as envisaged by *Pearson* [1], becomes the driving force of assisted phosphorylation as depicted by eq. (31).

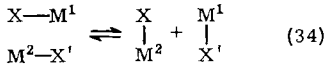
Hadler [48] has argued differently and suggests the intermediacy of enol phosphates in biological phosphorylations (eq. (32)).

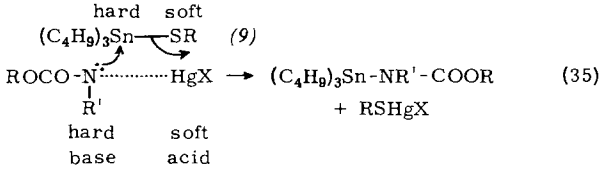
(32)

(8)



However, the oxidative activation of molecules such as *(8)* follows the same general pattern as that proposed in eq. (31).

(33)



4.6. Other Examples of Substitutions Assisted According to the First Rule

The organometallic field contains numerous examples of exchange reactions of the type (34).

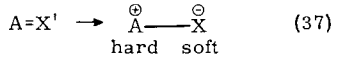
(34)

Clearly, the preferred equilibrium positions in these cases should be predictable from the first rule. Equation (35) represents a relevant reaction of organotin compounds [49].

(35)

(9)

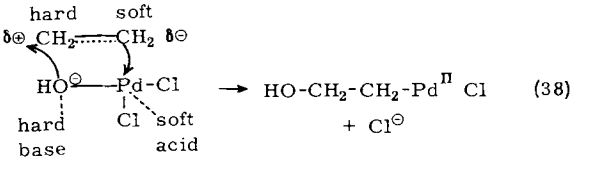
Sn(IV) is usually regarded as a hard base [1]; however, we do not know the extent to which the three soft butyl groups confer softness on the tin center. Presumably, electron-attracting substituents on tin facilitate the above type of reaction. One can thus understand why *N*-halogenoamides also react with compounds such as *(9)* to furnish tin amides and sulfenyl halides. A further example of a multi-center reaction in organotin chemistry [51] is the decomposition of trialkyltin hydrides by acids in dimethylsulfoxide in the presence of basic substances [51] (eq. (36)).



(36)

The activity of the assisting base is related roughly to its position in the spectrochemical series, which in turn is an approximate measure of hardness. According to the first rule, soft metal cations should be more effective than the proton as the electrophile in the above type of reaction.

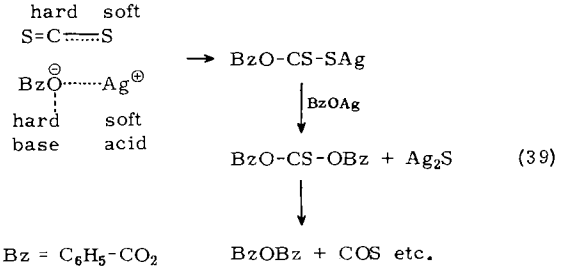
4.7. Assisted Nucleophilic Additions



When, as in eq. (37), a π bond can be opened to provide a positively charged hard-acid center with a vacant orbital and simultaneously a negatively charged soft-base center, it is to be expected that such an

(37)

opening might best be brought about by the combined action of a hard nucleophile (Z:) and a soft electrophile (E).



Olefins, $R^1R^2C{=}CR^3R^4$, where neither of the pairs R^1R^2 or R^3R^4 markedly stabilize the carbonium center, and thiocarbonyl compounds such as carbon disulfide, are therefore substrates to be considered in this regard. The reaction of alcoholic mercuric acetate solutions with olefins, and the oxidation of ethylene to a hydroxyethyl ligand under the action of $PdCl_2$ complexes [20,50], are good examples of such opening of olefinic π bonds.

(38)

The reaction of silver carboxylates with carbon disulphide gives acid anhydrides [52] (eq. (39)).

Finally, certain trialkylaluminums, trialkyl borons, and dialkylphosphines are spontaneously inflamma-

(39)

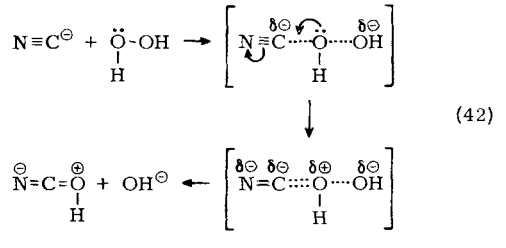
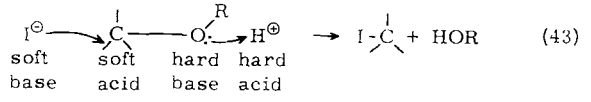
ble[53,54] (eq. (40) and (41)). Could this be a consequence of easy concerted acid-base activity?



5. Examples of the Operation of the Second Rule

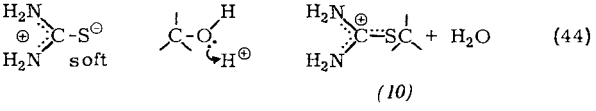
The saturated carbon center R_3C is a good example of a soft electrophilic center A of a substrate A–$\ddot{X}$ whose reactions should be interpretable in the light of the second rule. This center responds very directly to softness in the attacking nucleophile in the case of simple S_N2 displacements[4,55,56].

As other examples of a soft A center we have bivalent oxygen (as in peroxides and hypohalites)[4,57,58], sulfur[4,59,60], and probably trivalent nitrogen[61,62] in the rare cases of N attached to good leaving groups. The reason for the softness of these atoms as acids has not been made clear but may well concern the overlap of filled 2p or 3p orbitals on the oxygen or sulfur atom with empty p or d orbitals of the approaching soft nucleophile, a π-bonding effect which can strengthen the new bond both in the transition state and the final state (see, *e.g.*, eq. (42)).



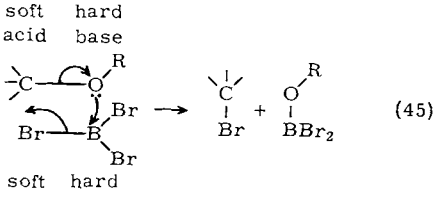
Softness in the case of saturated carbon is more difficult to rationalize; however, since most saturated carbon centers possess at least one C–H bond it is possible that in the transition state the σ electrons of this bond are somewhat delocalized across to the vacant orbital of the approaching soft nucleophile – in a manner similar to the current picture of hyperconjugation involving vacant carbon 2p orbitals.

Positive halogen compounds can also usefully be regarded as A–$\ddot{X}$ derivatives in which A is a soft-acid halogen atom.



5.1. Cleavage of Carbon-Oxygen Bonds

The simple ethers are typical substrates involving soft saturated carbon and hard basic oxygen as leaving groups. The classical method, due to *Zeisel*[63,64], of cleaving ethers provides a good example of the operation of the second rule (see eq. (43)).



It is significant that if a weak hard nucleophile such as $HSO_4^{\ominus}$, is used in place of $I^{\ominus}$ or $Br^{\ominus}$ (soft) a much slower cleavage takes place[64]. Also, replacement of the hard ether oxygen atom by a soft sulfur atom (thus violating the conditions of the second rule) gives an almost unreactive system[65].

The reaction of halogen acids with n-alkanols to yield alkyl halides, and the reaction of thiourea with n-alkanols and mineral acids (eq. (44))[66] likewise obey the second rule.

(10)

A more recent reagent for the cleavage of ethers is boron tribromide[67,68], in which a hard boron center (E) is present in the same molecule as an incipient soft nucleophilic bromide ion (Z). With this reagent, cleavage (eq. (45)) may occur at temperatures as low as $-60\,^{\circ}C$. Violation of the second rule pattern by changing from BBr_3 to BF_3 (F is hard) leads to nonreactive addition compounds, at least one of which can be distilled unchanged[69]. The many examples given

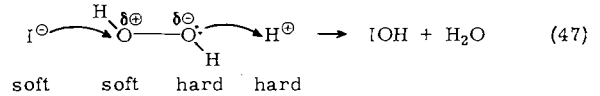
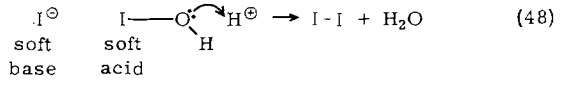
in *Gerrard*'s papers on the reaction of alcohols with boron halides involving carbon-oxygen bond cleavage would similarly fit into the second category of four-center assisted substitutions [70, 71].

Further examples of a saturated carbon center joined to a hard oxygen undergoing reactions according to the second rule appear in the chemistry of phosphate esters. Lord *Todd* and his co-workers [72, 73] noted that lithium chloride is a valuable reagent for the dealkylation of phosphate and pyrophosphate esters (eq. (46)).



(46)

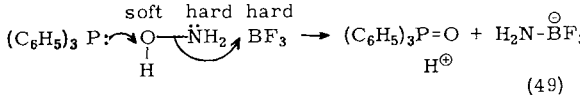
Since $Cl^{\ominus}$ is not an outstandingly potent soft nucleophile it seems possible that the lithium ion (which *Pearson* clearly classifies as hard [1]) may render electrophilic assistance.



Lithium salts are frequently used in studies of salt effects in organic reactions. The question now occurs whether catalysis by salts, in appropriate cases, should be re-interpreted to include specific electrophilic assistance, in addition to ion-atmosphere effects.

5.2. Substitutions at Oxygen and Sulfur Atoms

Substitutions at O and S centers tend to require soft nucleophilic reagents (Z:) [57, 58] and hence we should again expect to find examples of assistance by hard acids when the leaving-group is hard, as required by the second rule. Such a case is exemplified by the acid-catalysed reaction of hydrogen peroxide with iodide ion [74, 75] (eq. (47) and (48)).

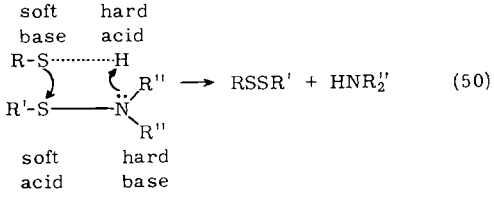


(47)

(48)

Indeed, practically every known proton-catalysed reaction of hydrogen peroxide involves attack by a soft nucleophile on oxygen (*e.g.* epoxidation of olefins, oxidation of sulfides to sulfoxides and sulfones). Iodide ion attack on hydrogen peroxide is also strongly catalysed by molybdic acid [76], and, although the mechanism is unknown, the reaction classifies this acid as hard.

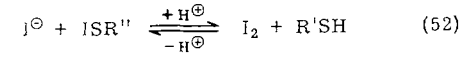
Outside these examples, however, little use seems to have been made of behavior conforming to the second rule in connection with the cleavage of O–O or O–N bonds. It is here considered that soft nucleophiles such as RSR′, R_3P:, and R_3As: used in conjunction with BX_3, SnX_4, or AlX_3 could become interesting reagents; for example, equation (49) represents a proposed cleavage of hydroxylamine. (This reaction is



(49)

similar in principle to the reaction of sulfurous acid [$HO\ddot{S}O_2^{\ominus}$: soft, $H^{\oplus}$: hard] with hydroxylamine [77] [*].)

For substitutions at bivalent sulfur centers, the second rule demands that those centers be attached to hard leaving groups. Hence the sulfenic acids and esters (RS–OH, RS–OR′) and sulfenamides (RS–NR′R″) are suitable substrates. The sulfenic esters readily react with soft base/hard acid combinations (*e.g.* HX [X = Hal], HSR) as also do the sulfenamides [78, 79].



Thiols, as well as hydrogen sulfide, generally react with sulfenamides according to equation (50), and with halogen acids according to equations (51) and (52) [78].

(50)

Dialkylphosphites and sulfenamides also react by the same principle [80], as also do thiosulfuric acid and sulfenamides [80a].

(51)

(52)

The soft base and hard acid (Z: and E) requirements of the reagents for assistance under the second rule can sometimes be provided through the opening of a suitable π bond. For example, π bond opening of a C=S bond in carbon disulfide leads to the state

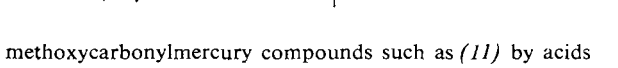
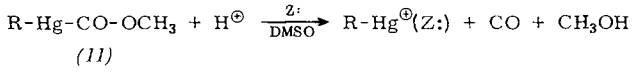
$S{=}C^{\oplus}{-}S^{\ominus}$ in which $C^{\oplus}$ is a hard acid and $S^{\ominus}$ is a soft base. Hence certain "insertion" reactions of carbon disulfide can be interpreted; an example [81] is given in equation (53).

(53)



An analogous reaction takes place with tervalent phosphorus [82] (eq. (54)), thus indicating that P(III) in its rather unusual role of an electrophilic center is soft.

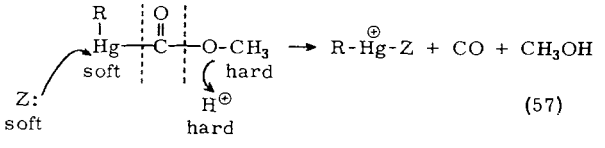
(54)



5.3. The Reaction of Methoxycarbonylmercury Complexes

Dessy discovered an analogue of the α-elimination mechanism [83] (equation (55)) which involves the decomposition of

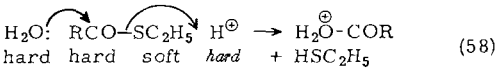
(55)



methoxycarbonylmercury compounds such as *(11)* by acids in the presence of anionic and neutral "assistors" (equation (56)). The "assistor"-bases are of the polarizable soft type

(56)

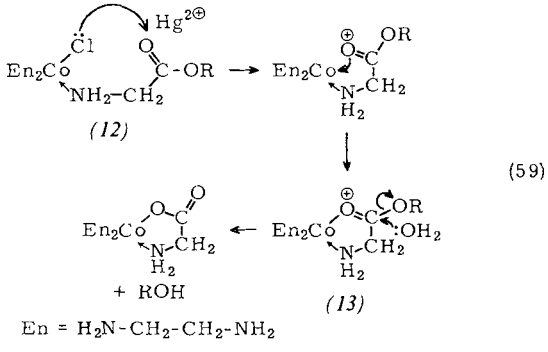
(11)



(RSH, $I^{\ominus}$, $Br^{\ominus}$, *etc.*). This pseudo-four-center substitution conforms well with the requirements of the second rule.

(57)

6. Final Remarks



How may the "Rules" outlined be best applied in practice? If a given reagent assembly being used in a four-center reaction does not conform to the patterns of the first or second rules it should be of interest to study the effect of changing the assembly to conform with one or other of these cooperative patterns. As a final illustration it is noted that the hydrolysis of a thiol ester is weakly catalysed by protons (see equation (58)). In this case the hard proton does not

(58)

"match" with the soft SC_2H_5 group. However, if the catalysing proton is changed for a soft acid, such as silver ion, then the thiol ester is hydrolysed far more rapidly.

It is hoped that the principles arrived at here may further prove useful in interpreting metal-ion assisted reactions of biochemical (*e.g.* enzymic processes) and industrial (*e.g.* heterogeneous metal catalysis) importance. In concluding this section mention may be made of the elegant use of the hard-soft principle by *D. H. Busch* [84] in his studies of the cobalt-complex assisted hydrolysis of glycine esters (eq. (59)).

(59)

The chloro derivative *(12)* is stable until a chloride ion is removed by Hg^{2+} ions (soft base interacting with soft acid). This leaves a hard vacant acid center on Co^{3+} that can coordinate with the hard oxygen atom of the glycine moiety thereby leaving a hard carboxyl carbon center in *(13)*. This compound is now suitably activated for attack by a hard water molecule.

The Author acknowledges with sincere thanks the encouraging interest shown in these ideas by Professor R. F. Hudson (in particular), by his colleagues Dr. A. A. Watson and Mr. G. M. C. Higgins, and by Professors R. G. Pearson, Sir Ronald Nyholm, F. R. S., G. Wilkinson, F. R. S., and J. I. G. Cadogan.

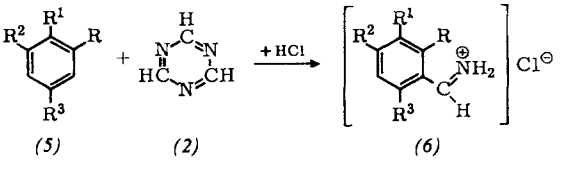
Gattermann Aldehyde Syntheses with *s*-Triazine in Place of Hydrogen Cyanide[1]

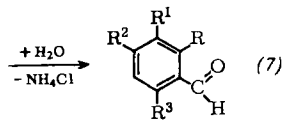
By *A. Kreutzberger*[*]

In syntheses of polymethine dyes by treatment of *s*-triazine *(2)* with quaternary five- or six-membered heterocycles[2], aldimines have been postulated – but not isolated – as intermediates[3].

We have succeeded in preparing the hydrochlorides of such aldimines in the furan and pyrrole series by treating *(2)* with 2-methylfuran *(1a)* or the pyrrole derivatives *(1b)* to *(1d)*. The reaction takes place at room temperature when anhydrous hydrogen chloride is passed into a solution of *(2)* and one of the compounds *(1a)* to *(1d)*. In order to prepare the aldehyde *(4)*, the aldimine hydrochloride *(3)* is hydrolysed by water or dilute acids or bases without prior isolation.



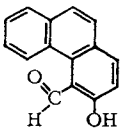
(1) *(2)* *(3)*



(4)

	X	R	R^1	Solvent	*(4)*, b.p. (°C/mm) or m.p. (°C)	Yield (%)	IR bands (cm^{-1})
(a)	O	CH_3	H	$(C_2H_5)_2O$	72–73/12	56	$\nu_{C=O}$ 1710, 1680
(b)	NH	CH_3	CH_3	$(C_2H_5)_2O/HCCl_3$ (5:7)	90–91	86	ν_{N-H} 3450
(c)	NCH_3	H	H	$HCCl_3$	71–72/12	31	$\nu_{C=O}$ 1670
(d)	NC_4H_9	H	H	$(C_2H_5)_2O$	85–86/6	66	$\nu_{C=O}$ 1660

Reactive aromatic compounds including those of the carbocyclic series, such as phloroglucinol *(5a)* and orcinol *(5b)*, undergo this aldehyde synthesis without a Friedel-Crafts catalyst. Even in cases where the Gattermann synthesis with hydrogen cyanide depends on the presence of aluminum chloride, as with pyrogallol *(5c)*, the synthesis can be effected with *s*-triazine without a catalyst. However, phenol ethers and aromatic compounds lacking an activating substituent undergo the aldehyde synthesis with *(2)* only at elevated temperature and then only in the presence of a Friedel-Crafts catalyst.



(5) *(2)* *(6)*

(7)

	R	R^1	R^2	R^3	Solvent	Temp. (°C)	Catalyst	*(7)*, m.p. (°C) or b.p. (°C/mm)	Yield (%)
(a)	OH	H	OH	OH	$(C_2H_5)_2O$	25	–	292–295 (decomp.)	77
(b)	OH	H	OH	CH_3	$(C_2H_5)_2O$	25	–	179–180	86
(c)	OH	OH	OH	H	$(C_2H_5)_2O$	25	–	158–159	61
(d)	H	H	OCH_3	H	Anisole	40	$AlCl_3$	137–138/18	67
(e)	H	H	OC_6H_5	H	Benzene	40	$AlCl_3$	158–159/4	78
(f)	H	H	H	H	Benzene	100	$AlCl_3$	86–87/40	31

The Gattermann aldehyde synthesis with *(2)* can also be effected with condensed aromatic ring systems. Thus 3-hydroxyphenanthrene-4-carbaldehyde *(8)* can be prepared in 64% yield by the action of *(2)* on 3-phenanthrol in benzene at 45 °C in the presence of $AlCl_3$.

Fluorothiocarbonyl Isothiocyanate

By *A. Haas* and *W. Klug*[*]

The presumed bifunctional behavior of Cl–CO–SCl *(1)* in its reaction with silver pseudohalides[1] led us to study whether the C–Cl bond in chlorofluorothiocarbonyl S=CClF *(2)* is susceptible to attack by silver salts. In this compound, as in compound *(1)*, the carbon is sp^2 hybridized.

There was no reaction when compound *(2)* was treated with silver cyanate at room temperature; similarly, reaction of *(1)* with AgCNO involves replacement of only the Cl atom attached to sulfur by a NCO group.

However, when *(2)* is treated with AgSCN (molar ratio 1:1.15) in a bomb tube at –25 °C, fluorothiocarbonyl isothiocyanate S=CF–NCS *(3)* is obtained in 50 to 60% yield (calculated on the amount of *(2)* used). This product is an orange liquid of b.p. 35 °C/40 mm and has an extremely pungent odor. At room temperature it slowly becomes red, and at higher temperatures it decomposes rapidly to dark solids. It was characterized by elemental analysis and by IR, ^{19}N–NMR, and mass spectra.

The IR spectrum measured in the NaCl and KBr regions shows strong absorptions at 1208, 1298, and 1972 cm^{-1} and bands of medium strength at 511, 843, 930, 956, 2043, 2395, 2500, 2633, and 2930 cm^{-1}.

The ^{19}F-NMR spectrum at 30 °C contains one very broad signal, which becomes narrower with decrease in the temperature. At −60 °C the chemical shift amounts to −55.1 ppm referred to CCl_3F as internal standard.

The mass spectrum of *(3)* contains the typical fragments SC−NCS (*m/e* = 102), CNCS (70), SCF (63), CS (44), and FC (31), as well as the molecule ion at *m/e* = 121.

An equimolar mixture of *(3)* and chlorine reacts at −70 °C in a bomb tube in an extremely short time, the color becoming paler and the chlorine being consumed quantitatively. Elemental analysis and the IR, ^{19}F-NMR, and mass spectra of the yellow liquid product showed that FCl(SCN)C−SCl *(4)* is formed quantitatively in this reaction; this compound boils at 53 °C/10 mm and has the typical odor of sulfenyl chlorides. The IR spectrum contains a strong absorption band at 1958 cm^{-1} and bands of medium strength at 530, 575, 811, 1040, and 1165 cm^{-1}. The ^{19}F-NMR spectrum of *(4)* at 30 °C contains a single signal with chemical shift +44.7 ppm referred to CCl_3F as internal standard. The mass spectrum shows, *inter alia*, fragments FCl(S)C−NCS (*m/e* = 156), FClC−NCS (124), F(S)C−NCS (121), and SCClF (98).

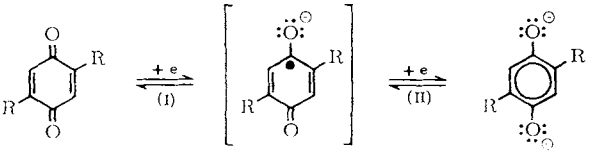
Half-wave Reduction Potentials of 2,5-Bis(trimethylsilyl)- and 2,5-Di-t-butyl-1,4-benzoquinone [**]



By *H. Bock* and *H. Alt* [*]

The interpretation of d-orbital effects [1] is made difficult in the case of phosphorus-nitrogen compounds according to the oxidation state and coordination number of phosphorus by the presence of free electron pairs, positive charges, or partial double bonds. However, the d-π and d-π* interactions and their differences can be investigated by comparing silicon-substituted π-electron systems with the corresponding alkyl derivatives using suitable methods of measurement [2]. Thus the half-wave reduction potentials $E_{1/2}$ are related to the eigenvalues of the lowest unoccupied levels of π-electron systems into which the electron is inserted on reduction [3]. The prerequisite of a reversible redox equilibrium is fulfilled for alkylated *p*-benzoquinones [4].

The 2,5-bis(trimethylsilyl)-1,4-benzoquinone *(5)* needed for comparison with the 2,5-di-t-butyl derivative was obtained as follows: *(1)* is converted with trimethylchlorosilane/pyridine in boiling toluene into the ether *(2)* (m.p. 58–59 °C) which reacts with sodium/trimethylchlorosilane in boiling toluene to form *(3)* (m.p. 121 °C). Cleavage of the O−SiR_3 bonds with 4 M sodium methoxide in methanol at 20 °C leads after neutralization with diluted acetic acid to *(4)* (m.p. 183 to 186 °C), which can be oxidized with silver(I) oxide in benzene at 20 °C to *(5)*.

The 2,5-bis(trimethylsilyl)-1,4-benzoquinone (n→π*: ν^m = 19999 cm^{-1}; ε_m = 25 l $mole^{-1}$ cm^{-1}) is orange in contrast to the yellow 2,5-di-t-butyl compound (n→π*: ν_m = 21900 cm^{-1}; ε_m = 36 l $mole^{-1}$ cm^{-1}); it melts a 188 °C and gives two NMR singlets at τ = 3.24 and 9.77 in the required ratio 2:18. The half-wave reduction potentials for the two steps (I) and (II) in acetonitrile were measured with tetra-n-butylammonium iodide as conducting electrolyte against the constant [5] mercury anode.

R	$E_{1/2}^{(I)}$ (V)	$E_{1/2}^{(II)}$ (V)
H	+0.04	−0.47
$C(CH_3)_3$	−0.15	−0.71
$Si(CH_3)_3$	+0.04	−0.51

The results show that the silicon-substituted quinone and semiquinone have higher oxidation potentials than the alkyl derivatives, *i.e.* they are stronger electron-acceptors. This is inexplicable if one assumes exclusively an inductive effect ($+I_{SiR_3} > +I_{CR_3}$) [6] and indicates an additional d-π* interaction between the vacant 3d levels of the silicon and the lowest unoccupied or singly occupied molecular orbitals of the *p*-benzoquinone π-system.

This type of model, already postulated several times [7], for the Si−C_{sp^2} bond, which requires $Si_d \leftarrow C_\pi$ back-donation of electrons alongside the $^{\delta+}Si \rightarrow C^{\delta-}$ inductively polarized σ skeleton, is in accord with the results of further polarographic measurements on silyl- and alkyl-butadienes, -styrenes, -naphthalenes, and -phenyl ketones [2].

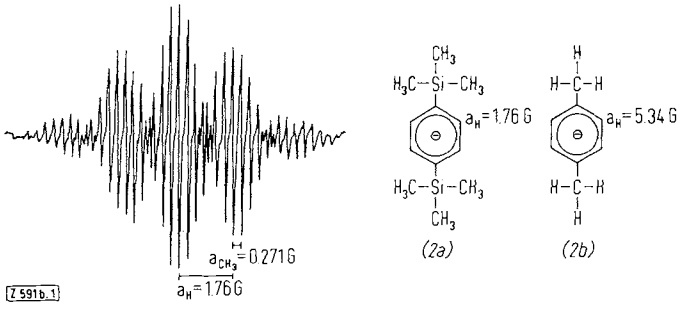
UV and ESR Studies of *p*-Bis(trimethylsilyl)- and *p*-Dialkylbenzenes [**]

By *H. Alt, H. Bock, F. Gerson*, and *J. Heinzer* [*]

A notable feature of the UV spectrum of *p*-bis(trimethylsilyl)benzene *(1a)*, when compared with the UV spectrum of *p*-di-t-butylbenzene, is that the ^1L_a band ($^1B_{1u} \leftarrow {}^1A_{1g}$)

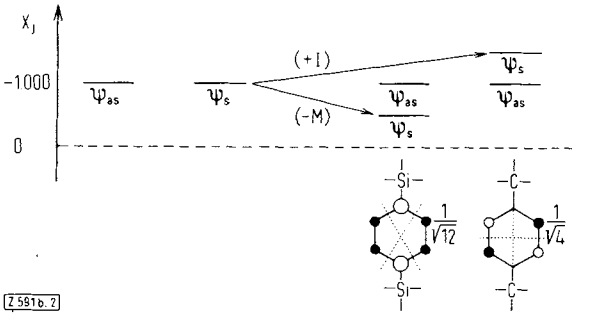
which is polarized along the substituent axis is shifted bathochromically and considerably intensified.



(1a), R = $Si(CH_3)_3$
(1b), R = $C(CH_3)_3$

	^1L_b		^1L_a	
	ν_m (cm^{-1})	ε_m (l $mole^{-1}$ cm^{-1})	ν_m (cm^{-1})	ε_m (l $mole^{-1}$ cm^{-1})
(1a)	36250	390		
	37050	480	43500	14700 (shoulder)
	37900	460	44250	16850
	38750	340		
(1b)	36900	310		
	38000	340	45850	8850
	39050	240	46950	9400
	40000	160		

The difference in ^1L_a transition energies amounts to 2700 cm^{-1} = 7.7 kcal/mole and can be interpreted as the difference between the d-π^* and d-π interactions in *(1a)* if the varying inductive effects are neglected.



In general[1], electron spin resonance measurements for radical anions permit conclusions to be drawn about the unoccupied non-bonding or antibonding states of the original neutral molecule and thus about the electronic effects of substituents. For instance, from a comparison of the ESR spectra of silyl- and alkyl-substituted benzene[2] and biphenyl radical anions[3] it was concluded that a $Si_d \rightarrow C_\pi$ back-donation of electrons counteracts the inductive $^{\delta+}Si \rightarrow C^{\delta-}$ polarization[4]. In the case of *p*-bis(trimethylsilyl)benzene *(1a)* such a –M effect of the R_3Si groups, which is already indicated by differences in the electron spectra of *(1a)* and *(1b)*, should be demonstrable for the monoanion *(2a)* by ESR spectroscopy. For biphenyl derivatives[3] interpretation is made difficult by twisting effects, and for monosubstituted benzene derivatives[2] splitting of the initially degenerate antibonding e_{2u} orbitals ψ_s and ψ_{as} may be too small to exclude vibrationally induced mixing with energy-richer states; but *p*-disubstituted benzene derivatives are planar and show a considerable energy difference between ψ_s and ψ_{as} orbitals[5]. Owing to participation of unoccupied Si-3d states in the π-system of the benzene radical anions the ψ_s molecular orbital that takes up the unpaired electron should thus be more strongly depressed, in this way increasing the stability of the radical. In accordance with expectation, a solution of *p*-di-t-butylbenzene *(1b)* in potassium/1,2-dimethoxyethane at –70 °C shows the ESR signal of only the solvated electron, whereas the ESR spectrum of the *p*-bis(trimethylsilyl)benzene radical anion *(2a)* (Fig. 1) can be observed up to more than 0 °C.

Z 591b. 1

Fig. 1. ESR spectrum of *p*-bis(trimethylsilyl)benzene, measured in K-1,2-dimethoxyethane at –70 °C. Coupling constants of the ring protons of *p*-disilyl- and *p*-dialkyl-benzene.

As can be calculated from the simple 5-group spectrum the coupling constants of the four equivalent nuclear protons of *(2a)* amount to 1.76 gauss, whereas those of the *p*-xylene radical anion *(2b)*[6] selected as reference substance amount to 5.34 gauss. These values can be reproduced quantitatively by use of the McConnell equation $a_H = Q \cdot \rho_H$ with a *Q* value of 21.2 gauss and Hückel spin densities $(c_{J\mu})^2$ of 1/12 and 1/4, respectively; this proves the occupation of ψ_s in *(2a)* as required by the –M effect of the R_3Si group, and the occupation of ψ_{as} of *(2b)* as required by the +I effect of the H_3C group. The d-π^* splitting thus demonstrated for the radical anion *(2a)* follows – although different electron interactions have to be considered – for the neutral *p*-bis(trimethylsilyl)benzene *(1a)* from the electron spectra too.

Z 591b. 2

Fig. 2. MO scheme of inductive and mesomeric substituent effects on the antibonding molecular orbitals (e_{2u}) of *p*-disubstituted benzene derivatives. Hückel coefficients c_{J2} of the symmetrical (s) and the antisymmetrical (as) molecular orbitals.

However, experimental verification of a d-π interaction in *p*-bis(trimethylsilyl)benzene encounters difficulties. Attempts to determine approximately the ionization potentials of *(1a)* and *(1b)* from the longer-wavelength band of the charge-transfer complexes failed because this band was always overlapped by the shorter-wavelength band of the charge transfer complex to give a single band of large half-width. The –M effect of R_3Si groups in the ground state can, however, be proved by means of charge-transfer complexes of mono- or di-substituted benzene and naphthalene derivatives[7].

Substituent Effects of β-Trimethylsilyl Groups in Bis-, Tetrakis-, and Hexakis-(trimethylsilyl)-*p*-xylenes [**]

By *H. Bock* and *H. Alt* [*]

An interaction between unoccupied Si-3d orbitals and antibonding states of neighboring π-electron systems can be demonstrated by comparing the UV and ESR spectra of

R_3Si- and R_3C-substituted benzene derivatives[1]. For the substituents R_3Si-CH_2- and R_3C-CH_2-[2] it remains to be decided whether the group R_3Si exerts a–M effect in spite of the insulating action of the CH_2 group or whether it acts mainly inductively.

α,α′-Poly(trimethylsilyl)-*p*-xylenes were chosen as model compounds, since, in order to increase the desired effect, up to six R_3Si groups can be introduced in the β-positions to the aromatic system by *in-situ* Grignard reactions[3]:

(1)

Experimental: 0.2 mole of α,α,α,α′,α′,α′-hexachloro-*p*-xylene was added dropwise to 2.4 moles each of trimethylsilyl chloride and magnesium (100 % excess) in tetrahydrofuran. After the strongly exothermic reaction had ceased, the mixture was heated for 2 days under reflux, then hydrolysed cautiously with 1 N HCl. The ether phase was concentrated and chromatographed on Al_2O_3 (neutral, activity grade I) with benzene, and the crude product was recrystallized from 2-butanol and purified by sublimation (yield 3 %). α,α,α′,α′-Tetrakis(trimethylsilyl)-*p*-xylene *(2)* was obtained in 2 % yield analogously from the tetrabromo derivative.

The structures of the new compounds follow from molecular weight determinations and ^1H–NMR spectra [*(1)*, singlets in the ratio 4:54 at τ = 2.85 and 9.79; *(2)*, singlets in the ratio 4:2:36 at τ = 3.27, 8.65, and 10.05; tetramethylsilane as internal standard]. The dumbbell-shaped compound *(1)* sublimes at 280 °C and liquifies in a closed tube only at 332 °C, whereas the tetrakis(trimethylsilyl) derivative *(2)* melts at 125 °C.

of the donor, it is possible to correlate these maxima with the energies of the highest bonding states of the donor[5].

It can be seen that the TCNE complex of trimethylsilylbenzene absorbs at shorter wavelength than does that of t-butylbenzene, a finding that can be ascribed to a d-π interaction[1,6] opposing the +I effect of the R_3Si group. If, however, the $C(CH_3)_3$ group of neopentylbenzene is replaced by $Si(CH_3)_3$, one of the two CT bands lying at longer wavelength[7] is shifted so strongly bathochromically that two distinctly separated CT maxima can be observed for the benzyltrimethylsilane/TCNE complex, in contrast to complexes of all other monoalkylbenzenes. This CT doublet is derived from the considerable splitting of the degenerate e_{1g} molecular orbitals of the benzene ψ_s and ψ_{as} by the

	46950	9400						
^1B	> 50000		[49250] [b]	48700	49400	63800	48100	37150
			50250	54500				

[a] In n-hexane. Dimensions of ε: l mol^{-1} cm^{-1}. [b] Shoulder.

The absorption bands of the α,α′-poly(trimethylsilyl)-*p*-xylenes *(1)*, *(2)*, and *(3)*[4] lie at unexpectedly long wavelengths in comparison with those of the hexamethyl compound *(4)*[1] (see Table).

According to Pariser-Pople-Parr calculations, energies for the ^1L_b, ^1L_a, and $^1B_{a,b}$ transitions are in general lowered by simulated positive inductive effects at centers 1 and 4 of the benzene ring; yet, in the absence of conjugative interactions, the bathochromic shifts listed in the Table – for the ^1L_a band maxima up to 6650 cm^{-1} = 19 kcal/mole – correspond to a considerable +I effect of the β R_3Si groups. That this is actually true can be demonstrated by the charge-transfer maxima ν_{CT}^{max} of the tetracyanoethylene (TCNE) complexes of the compounds listed in Fig. 1: for any one acceptor, an approximately constant equilibrium distance between the components of the complex, and a high ionization potential

$-CH_2Si(CH_3)_3$ group and establishes the presence of a notable +I effect of β R_3Si groups, as previously postulated from electronic spectra. For bis(trimethylsilyl)-*p*-xylene *(3)* the position of band II ($c_{as,1} = c_{as,4} = 0$) remains approximately constant but its distance Δν from band I increases to twice the value for the mono(trimethylsilyl) compound. Within the framework of the HMO theory, this additivity of the perturbations indicates an exclusively inductive influence on the ground state by R_3Si-CH_2 substituents where the R_3Si group is insulated from the π-electron system by a tetrahedral C atom.

Thus, for aromatic compounds in which a R_3Si group is directly attached to a ring carbon atom, an inductive polarization $^{\delta+}Si-C^{\delta-}$ should also strongly lower the transition energy of the CT band I. In fact, however, the CT bands[7] of trimethylsilylbenzene lie at shorter wavelengths than do

those of other monoalkylbenzenes, which again indicates a considerable conjugative $Si_d \leftarrow C_\pi$ electron back-donation [1,6] to the Si/C_{sp^2} bond.

[7] Substituted benzenes should in general show two CT bands due to removal of the degeneracy of the e_{1g} orbitals. The half-band widths for trimethylsilyl- ($\Delta\nu_{1/2} = 6050\ cm^{-1}$) and for t-butyl-benzene ($\Delta\nu_{1/2} = 6750\ cm^{-1}$) are greater than that for benzene ($\Delta\nu_{1/2} = 5800\ cm^{-1}$) and indicate overlapping of the two expected CT bands, the position of the maximum being determined largely by the more intense, longer-wavelength, substituent-dependent CT absorption.

Synthesis of Dicarboxylic Acids by the Willgerodt-Kindler Reaction

By *H. Feichtinger* and *W. Konkol* [*]

Carboxylic acids and their derivatives are accessible by the Willgerodt-Kindler reaction [1]. Oxalic and malonic acids can also be obtained in this way from vinyl and propenyl ethers [2] *i.e.* from compounds containing two functional groups.

Ring cleavage under the conditions of this reaction appeared to us as a possibility for synthesis of dicarboxylic acids, and their derivatives, containing acid groups that are widely separated from one another. We have now found the first example of this principle: 2,3-Dihydro-4*H*-pyran-2-carbaldehyde *(1)* reacts under the usual conditions (5 h at 160 °C in pyridine) to yield adipdiamide *(2)* directly in 25–30 % yield.

(1) *(2)*

Adipic acid monoamide (5–10 %) and small amounts of oxidative degradation products, such as glutardiamide (6–8 % and succindiamide (1–2 %), were also detected.

We can contribute the following findings towards elucidation of the reaction mechanism. Under the conditions stated, 2-hydroxyhexanedial *(3)* [3] affords very little diamide *(2)*. The cyclic trimeric aldimine *(4)* [4] of 2-formyl-2,3-dihydropyran obtained from the aldehyde *(1)* and aqueous ammonia, as well as the 2-hydroxythiohexanedial *(5)* of formula $(C_6H_{10}O_2S)_x$ (m.p. 133–143 °C), give lower yields of adipdiamide than are obtained from *(1)*. Thus occurrence of compounds *(3)* to *(5)* as intermediates is unlikely.

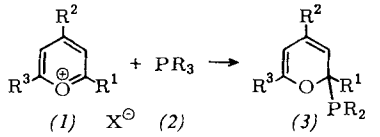
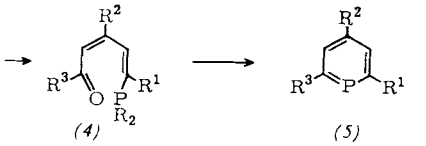
Preparation of Phosphorin Derivatives from Pyrylium Salts and Phosphine



By *G. Märkl, F. Lieb,* and *A. Merz* [*]

For steric reasons, the synthesis of phosphorins from pyrylium salts *(1)* and tris(hydroxymethyl)phosphine *(2a)* [1] or tris(trimethylsilyl)phosphine *(2b)* [2] is limited to the 2,4,6-triaryl and tri-t-butyl derivatives [3]. Nucleophilic attack by *(2a)* or *(2b)*, which could occur at either C-2 or C-4 of *(1)*, is rendered irreversible by the loss of formaldehyde or $X–Si(CH_3)_3$; α-pyrans *(3)* or their γ-isomers are formed.

If R^2 is smaller than R^1 and R^3, the phosphines *(2a)* and *(2b)* react with *(1)* exclusively at C-4: 2,6-diphenylpyrylium perchlorate is quantitatively dimerized to 2,2',6,6'-tetraphenyldipyrylene, m.p. 313 °C [4]. Compound *(1)*, $R^2 = CH_3$, $R^1 = R^3 = C_6H_5$, does not give a phosphorin.



If R in *(2a)* or *(2b)* is larger than, or equal in size to, R^1 and R^3 and if these are smaller than R^2, then nucleophilic attack occurs preferentially at C-2. In contrast to the reaction of 2,4,6-triarylpyrylium salts (in which R is smaller than $R^1–R^3$), the α-pyran *(3a)* or *(3b)* appears to open, yielding the ketone that is isomeric with *(4)* by virtue of containing a *trans*-phosphine group. Compound *(1)*, $R^2 = CH_3$, $R^1 = R^3 = C_6H_5$, does not react to give *(5)*.

These difficulties would be overcome if one could make the phosphine *(2c)* react with *(1)*. Nucleophilic attack on *(1)* would then be reversible, and the smaller steric requirements of PH_3 should then always favor the opening of the α-pyran ring *(3c)* to give *(4c)* which is required for ring closure. The low nucleophilicity of PH_3, however, made this reaction unlikely. 2,4,6-Triphenylpyrylium salts do in fact react with phosphine but the compound *(5)*, $R^1 = R^2 = R_3 = C_6H_5$, could not be detected in the complex mixture of products, even when ethyldicyclohexylamine was used as auxiliary base.

The primary phosphine *(4c)* must be assumed to be an intermediate in the synthesis and, like primary and secondary phosphines in general[5], should be able to react with the carbonyl group under proton catalysis. In fact, the pyrylium salt *(1)*, $R^1 = R^2 = R^3 = C_6H_5$, reacts smoothly with phosphine in 1-butanol at 120—130 °C within 48 h yielding 2,4,6-triphenylphosphorin without side reactions. As shown in the table, 2- and 4-methylphosphorins could thus be prepared for the first time. Phosphabenzenes substituted by alkyl groups are thus accessible without limitation.

2-Methyl-4,6-diphenylphosphorin:

A suspension of 2.1 g (6.3 mmoles) of 2-methyl-4,6-diphenylpyrylium fluoroborate in 50 ml n-butanol and 2.6 g (16 mmoles) phosphonium iodide are heated for 24 h at 110—120 °C. After removal of the solvent, the residue is taken up in benzene; the benzene solution is washed several times with water, dried over $CaCl_2$ and finally concentrated. The residue crystallizes from a cold ethanol solution on scratching. Colorless crystals (m.p. 79—81 °C, yield 945 mg) are obtained on recrystallization from a little ethanol.

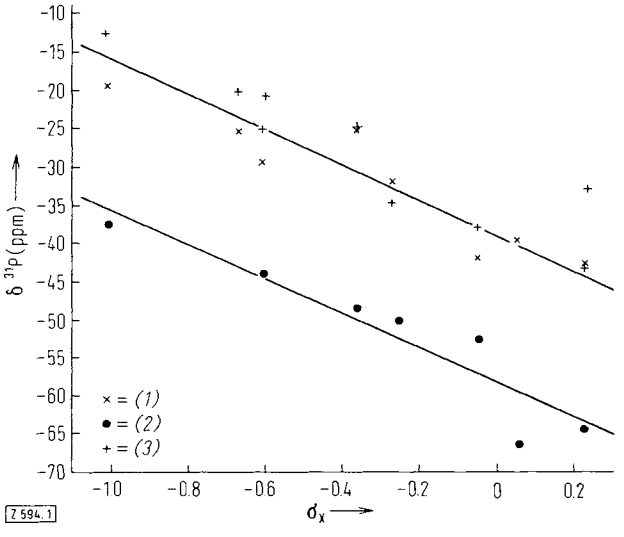
Linear Relation between Chemical Shifts of the ^{31}P Resonance and Hammett Constants [1]

By *A. Schmidpeter* and *H. Brecht* [*]

It is still uncertain how the influence of substituents on the chemical shift of the ^{31}P resonance of tetracovalent phosphorus should be interpreted. We are therefore studying possible relations between the shift $\delta^{31}P$ and values that characterize a known substituent effect. For several series of phosphinyl derivatives we found $\delta^{31}P$ to lie in the same order as the Hammett constants $\sigma_{(para)}$ [3] of the substituents, the shielding increasing with increasing efficiency of the substituent as electron donor.



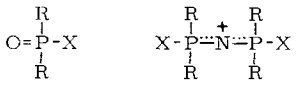


Fig. 1. Relation between chemical shifts $\delta^{31}P$ and Hammett constants σ_X for compounds *(1)* to *(3)*.

Table 1. Experimental values of the chemical shifts $\delta^{31}P$ (figures in ppm referred to 85 % H_3PO_4; negative values denote shifts to lower field strengths) for compounds *(1)* to *(3)*, together with the values calculated according to the equations given in the text.

X	σ_X	δ(1) exp.	δ(3) exp.	δ(1), (3) calc.	δ(2) exp.	δ(2) calc.
$-O^{\ominus}$	−1.0	−19.5 [a]	−12.7 [c]	−15.5	−37.5 [c]	−35.3
$-NH_2$	−0.660	−25.5 [5]	−20.3 [8]	−23.6		−43.1
$-N(CH_3)_2$	−0.600	−29.6 [b]	−25.4 [d]	−25.1	−44.1 [11]	−44.5
$-NHCH_3$	−0.592		−20.9 [b]	−25.2		−44.8
−OH	−0.357	−25.5 [b]	−25.1 [e]	−30.8	−48.6 [6]	−50.1
$-OCH_3$	−0.268	−32.2 [b]	−35.0 [b]	−33.0		−52.3
$-OC_2H_5$	−0.250			−33.8	−50.3 [12]	−52.7
$-S^{\ominus}$	[g]		−35.6 [9]			
$-SCH_3$	−0.047	−42.3 [b]	−38.4 [2]	−38.2	−52.7 [11] [f]	−57.4
−F	+0.062	−40.0 [7]		−40.8	−66.3 [7]	−60.3
−Cl	+0.226	−42.7 [6]	−43.3 [9,10]	−44.7	−64.3 [13]	−64.8
−Br	+0.232		−33.2 [9] [b]	−44.9		−64.9

Our own, hitherto unpublished, measurements: [a] in ethylene glycol (−23.6 was given in [5]); [b] in CH_2Cl_2; [c] in CH_3OH; [d] in $C_6H_5NO_2$; [e] tetra-*P*-phenylimidodiphosphinic acid in glacial acetic acid; [f] value for $(CH_3)_2PO(SC_3H_7)$; [g] unknown.

If the shifts measured for all available diphenylphosphinyl derivatives *(1)* are plotted against σ_X, a linear relation is obtained (Fig. 1). The same is true for the tetra-*P*-phenylimidodiphosphinyl derivatives *(3)*, which are formally derived from *(1)* when O is replaced by $N^+/2$.

(1) R = C_6H_5 *(3)* R = C_6H_5
(2) R = CH_3

For both *(1)* and *(3)* the relation

$$\delta_{(1),(3)}\ (\text{ppm}) = -39.4 - 23.8\ \sigma_X$$

holds approximately (correlation coefficient = −0.96). The shifts calculated in this way are compared with the experimental values in Table 1; further, plotting the shifts for the dimethylphosphinyl derivatives *(2)* against σ_X (Fig. 1) gives a parallel line:

$$\delta_{(2)}\ (\text{ppm}) = -58.4 - 23.2\ \sigma_X$$

(correlation coefficient = −0.94). The difference of 19.0 ppm in the position where the axis is cut is in agreement with the average shift of 10.8 ppm found previously [4] for replacement of one methyl by a phenyl group in phosphinyl chlorides. This value is not, however, generally valid, as was previously assumed.

The relation found between $\delta^{31}P$ and σ_X is remarkable in that the influence of a substituent on the shift should certainly not be characterized solely by the Hammett constant. Clearly, in the examples given above, other changes must have a small influence compared to the increase in diamagnetic shielding that results from increased electron density. The large deviation observed for *(3)*, X = Br, can be ascribed to an anisotropy effect of the substituent.

Phosphine oxides *(1)* and *(2)* in which X is an organic group cannot be included in the above considerations. Their shifts are always to higher field strengths than are calculated from the equations given.

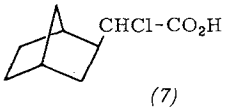
Synthesis of α-Chloro-1-adamantaneacetic Acids and α-Chloro-2-norbornaneacetic Acid by means of Trichloroethylene

By *K. Bott* [*]

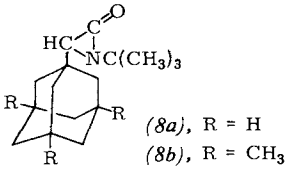
The method of carboxylic-acid synthesis by means of 1,1-dichloroethylene [1] can be applied to trichloroethylene *(2)*. However, at the high temperatures (80–115 °C) required, only the carbonium ions from the adamantane and norbornane series are sufficiently stable in concentrated sulfuric acid to permit addition to *(2)*.

(1) *(3)*



(5) *(6)*

R^1	R^2	R^3	X	Yield (%) *(3)*	Yield (%) *(6)*	*(3)*, m.p. (°C)	CH_3 ester of *(6)* b.p. (°C/mm)
H	H	H	Br	20	65 [a]	141–142	174–176/0.5
CH_3	H	H	Br	26	55 [a]	118–119	174–176/0.4
CH_3	CH_3	H	Br	28	37 [a]	130–131	160–162/0.1
CH_3	CH_3	Br	Br	—	88		160–162/0.1
CH_3	CH_3	CH_3	Br	94	—	175–176	
H	H	CH_2CO_2H	H	86	—	162–164	
CH_3	CH_3	CH_2CO_2H	OAc	95	—	209–211	
CH_3	CH_3	CH_2CO_2H	H	86	—	209–211	



[a] In the calculation of the yields no attention was paid to loss of *(1)* by hydride exchange [route (a)]. The actual yields in the synthesis are thus higher than those given.

The primary products, α-chloro-1-adamantaneacetic acids *(3)* with hydrogen atoms at the bridgehead position, lead (a) by hydride transfer from *(3)* to *(4)* or (b) on oxidation by sulfuric acid to new carbonium ions *(5)* which react in a further synthetic step to give α,α'-dichloro-1,3-adamantanediacetic acids *(6)*. The mixture of *(3)* and *(6)* obtained can be separated into its components by esterification with methanol and subsequent fractional distillation. Heating the 1-adamantaneacetic acids with *(2)* and sulfuric acid gives α-chloro-1,3-adamantanediacetic acids.

Treating norbornene with *(2)* affords α-chloro-2-*exo*-norbornaneacetic acid *(7)*, m.p. 46–50 °C, in 66 % yield.

(7)

(8a), R = H
(8b), R = CH_3

In aqueous sodium hydroxide, even at 90 °C, α-chloro-1-adamantaneacetic acids exchange the chlorine atom for hydroxyl. The reaction presumably goes through an α-lactone stage since the rate of hydrolysis is independent of the hydroxide ion concentration. Also, like the t-butylamides of α-bromocarboxylic acids [2], t-butylamides of *(3)* are con-

verted into the stable α-lactams *(8a)* (m.p. 58–59 °) and *(8b)* (m.p. 85–86 °) by potassium t-butoxide. The IR spectra (KBr discs) contain the absorption maxima for carbonyl groups at 1820 cm^{-1} characteristic of aziridinones.

Preparation of α-Chloro-3,5,7-trimethyl-1-adamantaneacetic Acid:

A mixture of 1-bromo-3,5,7-trimethyladamantane (30 g) and trichloroethylene (90 g) is added dropwise over 4 h, with stirring, to 90 % sulfuric acid (240 ml) at 103–106 °C. Stirring is continued for a further 2 h at the stated temperature, then the mixture is cooled and hydrolysed with crushed ice. The product that separates can be freed from the neutral fraction by dissolution in dilute aqueous sodium hydroxide and extraction with ether. Acidification of the alkaline layer with dilute hydrochloric acid precipitates the carboxylic acid (29.5 g; m.p. 173–175 °C). The product melts at 175–176 °C after recrystallization from cyclohexane.

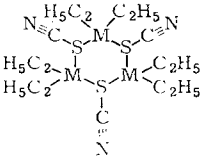
Diethylmetal Thiocyanates of Aluminum, Gallium, and Indium



By *K. Dehnicke* [*]

Reaction of equivalent amounts of triethyl-aluminum, -gallium, and -indium with thiocyanogen occurs exothermally and quantitatively according to the equation:

$$M(C_2H_5)_3 + (SCN)_2 \rightarrow (C_2H_5)_2MSCN + C_2H_5SCN$$

When the solvent and ethyl thiocyanate are distilled off, there remain the diethylmetal thiocyanates (M = Al, Ga, or In) as yellow hygroscopic oils that are very reactive and are sensitive to oxygen. Whereas the compounds with M = Al or In decompose at 180 °C on distillation in a vacuum, diethylgallium thiocyanate distils without decomposition at 145 °C/10^{-3} mm. When pure, the gallium compound is inert to water. When kept for some time in the cold the indium compound forms crystals having m.p. 51 °C.

Cryoscopic determination of the molecular weight in benzene shows that the diethylmetal thiocyanates are trimeric. The IR spectra indicate planar six-membered metal-sulfur

(M = Al, Ga, In)

rings (symmetry D_{3h}). Evidence for this is the high-frequency CN stretching vibration, which corresponds to a C≡N triple bond, the long-wave absorption due to the CS stretching vibration, which corresponds to a C–S bond [1], and the strictly single occurrence of these bands, which is to be found, for point group D_{3h}, only with antisymmetrical vibrations (class E′) whereas for a non-planar six-membered ring (symmetry C_{3v}) the symmetrical vibrations (class A_1) must also appear. The diethylmetal thiocyanates are thus analogous to the diethylmetal azides $[(C_2H_5)_2MN_3]_3$ (M = Al [2] or Ga [3]).

Heating $[(C_2H_5)_2AlSCN]_3$ at 180 °C in a vacuum yields ethylaluminum dithiocyanate as a pale yellow crystalline powder that is insoluble in benzene:

$$2\ (C_2H_5)_2AlSCN \rightarrow C_2H_5Al(SCN)_2 + Al(C_2H_5)_3$$

This reaction is explosive at 210 °C. According to the solubility relations and the IR spectrum, the dithiocyanate is to be regarded as a coordination polymer in which the aluminum atoms are linked through the sulfur atoms of the SCN groups. Characteristic IR bands are at 2050 cm^{-1} (s, νCN), 619 cm^{-1} (s, νCS), 601 cm^{-1} (vs, νCS, νAl–C), 458 cm^{-1} (vs, δSCN), and 393 cm^{-1} (vs, δSCN).

Table 1. Characteristic IR absorptions of the compounds $[(C_2H_5)_2MSCN]_3$.

Class	Vibration	M = Al	M = Ga [a]	M = In [a]

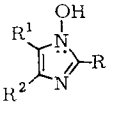
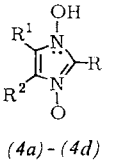
N-Oxides of Imidazolyls

By *K. Volkamer*, *H. Baumgärtel*, and *H. Zimmermann* [*]



During our work on imidazolyls [1] we took an interest in the *N*-oxides of these radicals and their ESR spectra. Imidazolyl *N*-oxides *(1)* and *N,N′*-dioxides *(2)* are to be considered as dehydrogenation products of imidazol-1-ol *(3)* and its *N*-oxide *(4)*.



(1a)-(1b)

(2a)-(2d)

(3a)-(3b)

(4a)-(4d)

	R	R^1	R^2
(a)	C_6H_5	2,2′-Biphenylylene	
(b)	C_6H_5	C_6H_5	C_6H_5
(c)	CH_3	CH_3	CH_3
(d)	C_6H_5	CH_3	CH_3

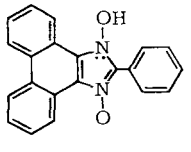
The radicals *(1a)* and *(2a)–(2c)* are formed on treatment of the alkali salts of *(3a)* and *(4a)–(4c)* with halogen in polar organic solvents, and *(2c)–(2d)* by dehydrogenation of *(4c)–(4d)* with lead dioxide. Short-lived radicals *(1a)* and *(2a)–(2b)* were detected at room temperature by ESR spectroscopy when a streaming technique was used.

The spectrum of *(1a)* shows three equidistant lines in the intensity ratio 1:1:1, corresponding to coupling of the radical electron with the nitrogen nucleus of the NO group. Coupling constants and g factors are, in benzonitrile, J_N = 3.59 gauss and g = 2.0059.

In contrast to the formation of *(1a)*, that of *(1b)* could not be effected by treatment of the alkali salt with halogen. On dehydrogenation of *(3b)* with lead dioxide in dioxane a radical was formed, which gave an ESR spectrum with seven equidistant lines having an intensity ratio 1:1:2:1:2:1:1. The fine structure can be interpreted as due to coupling of the unpaired electron with two non-equivalent nitrogen nuclei. J_{N1} = 7.98; J_{N2} = 3.99 gauss; g = 2.0062 (in dioxane). On oxidizing lophine with *p*-nitroperbenzoic acid, *Rassat et al.*[2], also obtained a radical whose ESR spectrum contains a signal with seven lines (intensity ratio 1:1:2:1:2:1:1); they ascribed structure *(1b)* to this signal. J_{N1} = 8.4 gauss; J_{N2} = 4.2 gauss (in methylene chloride). In contrast to *(1a)*, the radical obtained by dehydrogenation of *(3b)* with lead dioxide has an unusually long life. Although its ESR spectrum is compatible with structure *(1b)*, it seems to us that identification of the radical *(1b)* is not beyond question.

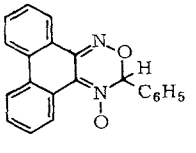
Imidazolyl *N,N'*-dioxide *(2a)* gives an ESR spectrum with five equidistant lines in the intensity ratio 1:2:3:2:1, corresponding to coupling of the unpaired electron with the equivalent nitrogen nuclei of the two NO groups. J_N = 3.89 gauss, g = 2.007; λ_{max} = 613 nm (in dimethylformamide).

(2a) is the most stable radical of the series under study. Its decomposition, as followed by ESR spectroscopy, can be described by the equation $(dc/dt) = -kc^{2.5}$ (c = radical concentration) where $k = 3.6\times10^3$ $l^{1.5}$ mole$^{-1.5}$ sec^{-1}.



The ESR spectrum of *(2b)* is similar to that of *(2a)* in number of lines and intensity ratios. J_N = 3.61 gauss, g = 2.0071; λ_{max} = 548 nm (in dimethylformamide).

The ESR spectrum of *(2c)* consists of twelve equidistant lines (intensities in the ratios 1:3:5:7:9:11:11:9:7:5:3:1). The multiplet can be interpreted as due to coupling of the radical electron with the two equivalent nitrogen nuclei and the three equivalent protons of the 2-methyl group. J_N = 6.92 gauss, J_H = 3.46 gauss, g = 2.0067 (in dioxane).



Replacing the 2-methyl group of *(2c)* by phenyl gives the radical *(2d)* whose ESR spectrum, as expected, also contains five lines at equal distance with intensity ratios 1:2:3:2:1, corresponding to coupling of the radical electron with the two nitrogen nuclei. J_N = 7.24 gauss, g = 2.0068 (in dioxane).

The imidazol-ols *(3a)* and *(3b)* used as starting materials were prepared by condensing phenanthraquinone monoxime or benzil monoxime, respectively, with concentrated ammonia solution and benzaldehyde in ethanol. *(3a)*: colorless crystals, m.p. 232–235 °C (solidifies, after melting, to a substance of m.p. 285–290 °C). *(3b)*: colorless crystals, m.p. 240–241 °C (decomp.).

Imidazol-1-ol *N*-oxides *(4c)* and *(4d)* were prepared as described in the literature[3,4]. *(4b)* was synthesized by *Bodendorf* and *Towliati*[5], and similarly but independently by us, by condensation of benzil α-monoxime and α-benzaldoxime. *(4b)*: colorless crystals, m.p. 231–232 °C (decomp.).

(4a)

(5)

We obtained compound *(4a)* by condensing phenanthraquinone dioxime and benzaldehyde at 5–10 °C in ethanol that was saturated with hydrogen chloride. Colorless crystals, m.p. 188–189 °C (decomp.); at 60–65 °C the isomer *(5)* is formed as main product alongside *(4a)*. *(5)*: yellow crystals, m.p. 184–185 °C.

The structures of compounds *(3a)*, *(3b)*, *(4a)*, *(4b)*, and *(5)* were proved by the IR, NMR, and mass spectra, as well as by reduction with hydrogen and Raney nickel in ethanol. This reduction gave the corresponding imidazoles from *(3a)* and *(3b)* and *(4a)* and *(4b)* with consumption of one and two molecular equivalents, respectively, of hydrogen. Benzyl alcohol and 9,10-phenanthrenediamine were formed from *(5)* on consumption of four molecular equivalents of hydrogen.

Ring Contraction on Oxidation of Phenyl-substituted Resorcinols

By *H. Güsten, G. Kirsch*, and *D. Schulte-Frohlinde*[*]

Oxidation of 2,4,5,6-tetraphenylresorcinol *(1)* in benzene with alkaline $K_3[Fe(CN)_6]$ solution affords deep red crystals of tetraphenylcyclopentadienone (tetracyclone) *(2)* in 47% yield.

(1) *(2)*

The tetracyclone was identified by elemental composition, molecular weight, mixed melting point, UV spectrum (512 nm, ε = 1300; 342 nm, ε = 6700 in benzene)[1], and IR spectrum (C=O band at 1718 cm^{-1})[2]. The 100 MHz NMR spectrum in $CDCl_3$ at 30 °C contains a sharp singlet at τ = 2.76 and two groups of multiplets centered at approximately τ = 2.81 and 3.04[3]. The CO evolved can be detected by means of an aqueous $PdCl_2$ solution. The oxidation has also been effected with PbO_2 and tetrachloro-*o*-benzoquinone[4], but yields are poorer.

Oxidation of 2,4,6-triphenylresorcinol gives 2,3,5-triphenylcyclopentadienone, and that of 2,4-diphenylnaphthoresorcinol gives 2,3-diphenyl-1-indenone.

The deeply colored solutions obtained on oxidation give strong ESR signals.

Experimental: A solution of tetraphenylresorcinol (1 g, 2.4 mmoles) in benzene (80 ml) is added dropwise to solution of $K_3[Fe(CN)_6]$ (4 g, 12 mmoles) and KOH (0.6 g) in water (15 ml) at room temperature and with vigorous stirring. The deep-red benzene solution is separated off after 3 h, washed with water, and, after drying, chromatographed on an Al_2O_3

(II, standard) column. Deep-red crystals of *(2)* are obtained; m.p. 217–218 °C (from petroleum ether), yield 0.44 g (47 %).

Oligonucleotide Syntheses by means of 2,2,2-Trichloroethyl Phosphorodichoridate [1]

By *F. Eckstein* and *I. Rizk* [*]

Although phenyl phosphorodichloridate has proved useful in phosphatide chemistry for the preparation of unsymmetrical phosphoric acid esters, monoesters of phosphorodichloridic acid have been applied successfully in nucleotide chemistry only for the synthesis of symmetrical esters, *e.g.* diuridine 5′→5′-phosphate [2].

We have found that the 2,2,2-trichloroethyl phosphorodichloridate *(1)* [3] can be used for the step-wise preparation of oligonucleotides with the desired 3′ → 5′-linkage. 5′-Tritylthymidine (1 equiv.) in chloroform was added dropwise over a period of 6 h, with stirring, to a solution of *(1)* (1.2 equiv.) and pyridine (2.5 equiv.) in chloroform. The mixture was stirred for a further 24 h. The tritylthymidine was thus phosphorylated to 5′-tritylthymidine 3′-[2,2,2-trichloroethyl phosphorochloridate] *(2)* which was neither characterized nor isolated; bis(5′-tritylthymidine-3′) tris(2-chloroethyl) phosphate was formed only in traces. The solution was evaporated with exclusion of moisture and the resulting residue was dissolved in anhydrous pyridine. This solution was treated with 3′-*O*-acetylthymidine (0.7 equiv.) and, after the mixture had been kept for 48 h at room temperature, the pyridine was evaporated off and the reaction mixture was separated by preparative thin-layer chromatography (Merck Kieselgel PF 254, chloroform/methanol = 93:7). The triester *(3a)* [4], m.p. 127–130 °C, was obtained in 56 % yield (calculated on acetylthymidine).

(3b)	0.43		

[a] On Merck DC-Fertigplatten Kieselgel F_{254}, chloroform/methanol = 93:7.

Removing the trityl group by treatment with 80 % acetic acid at 100 °C for 15 min affords *(3b)*. If *(3b)* is used in place of 3′-*O*-acetylthymidine in the reaction described, the product *(4)* [4] is obtained in 40 % yield after the same working up procedure.

We also tried to prepare a tetranucleotide from two dinucleotides in this way. Removing the acetyl group from *(3a)* (12 % ammonia solution, 1 h, room temperature) gives *(3c)* in quantitative yield. The triester is not hydrolysed under these conditions. Compound *(3c)* is phosphorylated by *(1)* to give *(3d)*, in a similar manner to that described for *(3a)*. After evaporation of the solution, the residue is taken up in anhydrous pyridine, and a solution of *(3b)* in pyridine is added. The mixture is kept for 12 h at 50 °C, then worked up by preparative thin-layer chromatography. Compound *(5)* is thus obtained in poor yield (3 %).

Removal of the trichloroethyl groups (Zn dust in 80 % acetic acid, 10 min, room temperature), the trityl (80 % acetic acid, 100 °C, 15 min), and the acetyl groups (concentrated ammonia solution, 2 h, room temperature) from compounds *(3a)*, *(4)*, and *(5)*, gives the nucleotides TpT, TpTpT, and TpTpTpT, respectively, in about 80 % yield. We were able to degrade these products by means of phosphodiesterase from spleen to thymidine and thymidine 3′-phosphoric acid in the expected proportions.

New High-temperature Initiators [1]

By *Ch. Rüchardt* and *G. Hamprecht* [*]

t-Butyl α-acyloxypercarboxylates *(2)* have been obtained from acid chlorides *(1)* and t-butyl hydroperoxide in pyridine. They belong to a new class of active low-temperature initiators [2]. We have now found that 2,5,5-trisubstituted 2-t-alkylperoxy-1,3-dioxolan-4-ones *(3)* are formed from the same components *(1)* and t-alkyl hydroperoxides under certain conditions [3]. These are more stable than most of the known peroxides [*e.g.* *(3)*, $R^1 = CH_3$, $R^2 = C_2H_5$, R^3 = iso-C_3H_7: $t_{1/2}$ = 40 min in decalin at 172 °C] and form a new class of readily accessible, very reactive, high-temperature initiators. A new type of neighboring group participation of the α-acyloxy group during the acylation [4] is responsible for the ring closure.

R^1	R^2	R^3	Base	(3), Yield[a]
CH_3	CH_3	CH_3	Pyridine	0
CH_3	CH_3	CH_3	2,6-Lutidine	100
CH_3	C_2H_5	CH_3	Pyridine	20
CH_3	C_2H_5	CH_3	None	100
C_2H_5	C_2H_5	CH_3	Pyridine	100 [b]
C_2H_5	C_2H_5	CH_3	2,6-Lutidine	100
CH_3	iso-C_3H_7	CH_3	Pyridine	80
C_2H_5	C_2H_5	C_2H_5	Pyridine	70
C_2H_5	C_2H_5	C_6H_5	Pyridine	40
$-(CH_2)_4-$		CH_3	$NaOH/H_2O$	100
$-(CH_2)_5-$		CH_3	Pyridine	72
$-(CH_2)_5-$		CH_3	2,6-Lutidine	100 [c]
CH_3	C_2H_5	p-$CH_3O-C_6H_4-CH_2-$	None	100

[a] Given as % of *(3)* in the mixture of *(2)* and *(3)*; total yields were usually greater than 60%.

[b] Same result with t-pentyl hydroperoxide.

[c] Same result with aqueous sodium hydroxide as base.

If in *(1)* neither R^1 nor R^2 is hydrogen, then ring closure is favored by increase in size of R^1 and R^2, by a smaller group R^3, and by a bulky base (*e.g.* 2,6-lutidine or triethylamine). The ring closure is kinetically controlled. *(1)*, $R^1 = R^3 = CH_3$, $R^2 = C_2H_5$, and *(1)*, $R^1 = R^2 = CH_3$, $R^3 = S\text{-}C_6H_4\text{-}CH_2$, in absence of a base, give *(3)* almost exclusively.

Acid chlorides *(1)* in which R^1 or R^2 is hydrogen, even with the bulky base ethyldiisopropylamine, afford only a little *(3)*. On the other hand, even in the absence of base, *O*-acetyllactoyl chloride *(1)*, $R^1 = H$, $R^2 = R^3 = CH_3$, and *O*-acetylglycoloyl chloride *(1)*, $R^1 = R^2 = H$, $R^3 = CH_3$, give *(3)* almost exclusively[5].

The composition and the active-oxygen content of the oily peroxides were determined. The dioxolane derivatives *(3)* can be quantitatively and qualitatively analysed by means of the carbonyl bands near 1800 cm^{-1} [*(2)*, C=O at 1735 and 1775 cm^{-1}] and the NMR signal of the methyl group R^3 at $\tau = 8.33$ [*(2)*, $R^3 = CH_3$, $\tau = 7.96$].

Experimental: 4.11 g (25.0 mmole) of α-acetoxyisobutyryl chloride in 15 ml of petrol ether (b.p. 40 °C) or methylene chloride was added dropwise over 15 min to a stirred solution of 3.22 g (30.0 mmole) of 2,6-lutidine and 3.60 g (40.0 mmole) of t-butyl hydroperoxide in 45 ml of the same solvent at 0 °C. After having been stirred for two hours the solution was filtered and subsequently washed neutral with dilute sulfuric acid, aqueous sodium bicarbonate, and water and dried over magnesium sulfate. It was quickly chromatographed on a 10 cm column of neutral Al_2O_3 (activity I) in order to remove residual hydroperoxide and was then concentrated in vacuum. 3.31 g (60%) of colorless, oily 2,5,5-trimethyl-2-t-butylperoxy-1,3-dioxolan-4-one (3 $R_1=R_2=R_3=CH_3$) was isolated having $n_D^{20} = 1.4189$ and containing 7.2% active oxygen (calc. 7.3%); IR spectrum showed C=O band at 1808 cm^{-1}; molecular weight (osmometric) = 243 (calc. 232). The same material was obtained when no base was present and the HCl formed was removed in a stream of nitrogen.

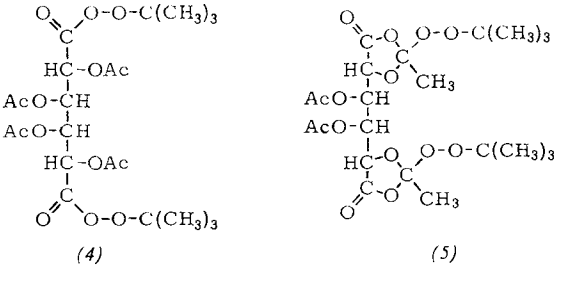
Isomeric Peroxy Esters of Sugar Carboxylic Acids

By *Manfred Schulz* and *P. Berlin*[*]

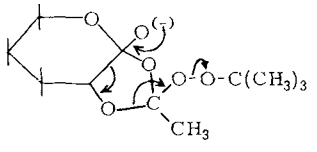


Reaction of penta-*O*-acetyl-D-gluconoyl chloride *(1)* with t-butyl hydroperoxide gives two isomeric peroxy esters. In the presence of bases such as 2,4,6-collidine, pyridine, or triethylamine in benzene at room temperature, t-butyl 2,3,4,5,6-penta-*O*-acetyl-D-peroxygluconate *(2)* is formed in 80% yield. M.p. 70–72 °C, $[\alpha]_D^{22} = +6.53°$ ($c = 3.5$ in $CHCl_3$), IR band of the perester-carbonyl at 1779 cm^{-1}.

However, in the absence of a base, reaction of the acid chloride *(1)* with t-butyl hydroperoxide gives exclusively the isomeric "anomalous perester" *(3)*[1]. 2-t-Butylperoxy-2-methyl-5-(D-*arabino*-1,2,3,4-tetracetoxybutyl)-1,3-dioxolan-4-one *(3)* is isolated in 90% yield after *(1)* has been heated with an excess of t-butyl hydroperoxide at *ca.* 70 °C for 4 h; it has m.p. 162–163 °C and $[\alpha]_D^{22} = -8.0°$ ($c = 3.7$ in $CHCl_3$). Ring closure to the 1,3-dioxolanone system, which occurs here under acid conditions, is caused by neighboring group participation of the α-acetyl group of *(1)*[2].

The structure of *(3)* was proved by elemental analysis, IR spectrum (acetyl-carbonyl 1747 cm^{-1}, dioxolanone-carbonyl 1813 cm^{-1}), and NMR data (t-butyl protons, $\tau = 8.77$; acetyl-CH_3 protons, $\tau = 7.94$; CH_3 protons of the methyl group on the dioxolanone ring, $\tau = 8.30$).

Reaction of tetra-*O*-acetylmucoyl dichloride with t-butyl hydroperoxide in the presence of pyridine gives the bisperoxy ester *(4)*, m.p. 126 °C (decomp.), in 91% yield. Warming the acid chloride with an excess of t-butyl hydro-



peroxide *without* a base gives exclusively *(5)*, m.p. 211 to 213 °C (90 % yield).

Treatment of *(2)* or *(3)* with methanolic 0.01 N $NaOCH_3$ solution causes a sugar degradation by a new type of perester degradation. The anomalous peroxy ester *(3)* is completely decomposed within 5 h at room temperature, yielding 70 % of D-arabinose (crystalline, paper-chromatographically pure), 66 % of carbon dioxide, t-butyl alcohol, and methyl acetate, with 30 % of methyl D-gluconate as by-product (percentages calculated with respect to compound *(3)*). Complete decomposition of the normal peroxy ester *(2)* requires more energetic conditions: after 8 hours' warming at 60 °C, D-arabinose was isolated in 51 % yield.

The diperoxy compounds *(4)* and *(5)* are not degraded with C–C cleavage by sodium methoxide solution; only transesterification and deacetylation occur, yielding dimethyl mucate (90 %).

We interpret the decomposition of *(3)* as fragmentation[3] of an intermediate pyranoid compound *(6)*. Presumably, *(2)* also decomposes by way of a cyclic intermediate.

Stereochemistry of the Cycloaddition of Sulfonyl Isocyanates and *N*-Sulfinylsulfonamides to Enol Ethers [1]

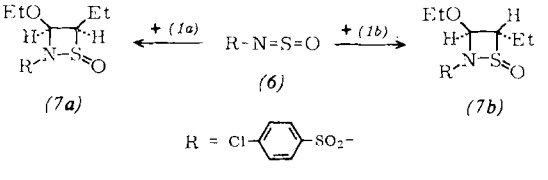
By *F. Effenberger* and *G. Kiefer* [*]

4-Alkoxyazetidin-2-ones *(3)* are formed on cycloaddition of sulfonyl isocyanates to enol ethers under mild conditions[2]. We have now studied the stereochemistry of this reaction in order to decide between a synchronous mechanism, as proposed by *Huisgen et al.*[3] for the cycloaddition of ketenes to enol ethers, and a two-stage reaction involving an intermediate compound of type *(4)*.

The *cis*- and *trans*-1-butenyl ethyl ethers *(1a)* and *(1b)*, which are separable by preparative gas chromatography, were treated separately in $DCCl_3$ with *p*-tosyl isocyanate *(2)* in the molar proportions 1:1, and the progress of the reaction was followed by NMR spectroscopy (Table).

One minute after the reactants had been mixed the signals of *(1a)* (H_A = doublet at τ = 4.18, H_B = quadruplet at τ = 5.74; J_{AB} = 6.3 Hz) and *(1b)* (H_A = doublet at τ = 3.82, H_B = 2 triplets at τ = 5.32; J_{AB} = 12.6 Hz) had disappeared, whence it is concluded that there is very rapid reaction with *(2)*.

Reaction of *(2)*



with *(1a)*			with *(1b)*		
Reaction time (min)	*(3a)* (%)	*(3b)* (%)	Reaction time (min)	*(3a)* (%)	*(3b)* (%)
1	95	—	1	10	90
3	90	10			
7	80	20	5	15	85
10.5	75	25			
18	65	36			
23	54	46	24	20	80
62	30	70	63	23	77
1440	27	73	1440	27	73

The proportions of the β-lactams *(3a)* and *(3b)* formed (see table) can be obtained from the newly appearing resonance signals of the proton H_A in *(3a)* or *(3b)* with an accuracy of about ± 4 %. *(3a)*: H_A gives a doublet at τ = 4.5, J_{AB} 5.3 Hz; *(3b)*: H_A gives a doublet at τ = 4.81, J_{AB} = 2 Hz. The structures *(3a)* and *(3b)* are assigned on the basis of the coupling constants J_{AB}[4].

From the table it can be seen that *(1a)* reacts stereospecifically with *(2)* and that *(1b)* reacts stereoselectively, but that after somewhat more than an hour an equilibrium mixture containing 27 % of *(3a)* and 73 % of *(3b)* is formed from either pure *(1a)* or pure *(1b)*. The isomerization *(3a)* ⇄ *(3b)* is formulated as occurring by way of a resonance-stabilized polar intermediate *(4)*.

When kept for several days in $DCCl_3$ the equilibrium mixture of *(3a)* and *(3b)* rearranges to the thermodynamically more stable compound *(5)*, the compound *(4)* being again assumed as intermediate.

Enol ethers combine with *N*-sulfinylsulfonamides to give 1,2-thiazetidine 1-oxides *(7)*[5]. NMR spectroscopic studies conducted during this cycloaddition in $DCCl_3$ show a stereospecific reaction of both *(1a)* and *(1b)*. The products *(7a)* and *(7b)* do not isomerize and do not rearrange on long storage in $DCCl_3$.

(7a) *(6)* *(7b)*

The results show that in the reaction of enol ethers with polar reagents the kinetically controlled cycloaddition occurs largely synchronously. Quite possibly, different bond lengths are to be considered for the transition state[6]. Depending on the ring strain, isomerization and removal of a proton occur,

both under thermodynamical control, to give a stable substitution product.

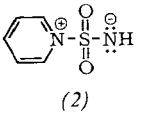
Derivatives of Imidobissulfamide [1]

By *R. Appel* and *R. Helwerth* [*]

Sulfimide, $HNSO_2$, has been assumed to be a reactive intermediate in the reaction of sulfamoyl chloride with nitrogenous bases. Hitherto, however, it has been isolated only as the pyridinium salts of the oligomers, tri- and tetra-sulfimide [2]. *Atkins* and *Burgess* [3] proved the formation of *N*-substituted derivatives of sulfimide, $RNSO_2$ (*N*-sulfonylamines), on treatment of *N*-substituted sulfamoyl chlorides with tertiary amines at −78 °C.



We have found that sulfamoyl(trialkylammonio)sulfonyl imides *(1)* are formed when a solution of sulfamoyl chloride in acetonitrile is treated at −40 °C with tertiary nitrogenous bases such as trimethyl- or triethyl-amine or pyridine in the molar ratio 2:3. They are nitrogen analogues of the mesylsulfenamine adducts recently described by *Opitz* and *Bücher* [4].

$$2\ H_2NSO_2Cl + 3\ NR_3 \longrightarrow H_2N\text{-}SO_2\text{-}\ddot{\underset{\ddot{}}{N}}^{\ominus}\text{-}SO_2\text{-}\overset{\oplus}{N}R_3 \quad (1)$$
$$+$$
$$2\left[HNR_3\right]^{\oplus}Cl^{\ominus}$$

	R	M.p. (°C)	Yield (%)
(1a)	CH_3	154–156	90
(1b)	C_2H_5	94–96	47
(1c)	$NR_3 = C_5H_5N$	Rearrangement above 105 °C	68

The compounds *(1)* are precipitated, sometimes with the amine hydrochlorides, from which they can be separated readily by utilizing their poor solubility in cold water.

When sulfamoyl chloride is treated with pyridine below −80 °C, a very reactive intermediate (m.p. 57–65 °C) can be isolated, which dissolves in water to an acid solution. Within a few seconds this clear solution deposits the neutral compound *(1c)*. Slow heating of the reactive intermediate affords first this product *(1c)*, which, when further heated, resolidifies and is converted into the known pyridinium salts of tri- and tetra-sulfimide [2]. Further experiments are to be performed to decide whether the reactive intermediate is the pyridine adduct *(2)* of monomeric $HNSO_2$, which is isoelectronic with the known pyridine-SO_3 adduct *(3)*.

(2)

(3)

The structure of compounds *(1a)* to *(1c)* follows from their elemental analysis, IR and ^1H–NMR spectra, and the lack of conductivity of freshly prepared solutions.

The behavior of the compounds is similar to that of the SO_3-amine adducts, *e.g.* stronger bases replace weaker ones from their linkage to the S atom. With liquid ammonia they give a quantitative yield of the NH_4^+ salt of imidobissulfamide, which was identified by conversion into free imidobissulfamide *(7a)* [5].

The action of primary or secondary amines on compounds *(1a)* to *(1c)* provides a synthesis of trialkylammonium salts of monosubstituted *(4)* and asymmetrically di-*N*-substituted imidobissulfamides *(5)*. They can be converted by ion-exchangers or by treatment of their silver salts with the calculated amounts of hydrochloric acid into the free, hitherto unknown asymmetrically substituted imidobissulfamides *(6)* and *(7)* in yields exceeding 90 %.

$$H_2N\text{-}SO_2\text{-}\ddot{\underset{\ddot{}}{N}}^{\ominus}\text{-}SO_2\text{-}\overset{\oplus}{N}R_3 + HNR_2' \longrightarrow [H_2N\text{-}SO_2\text{-}\ddot{\underset{\ddot{}}{N}}\text{-}SO_2\text{-}NR_2']^{\ominus}[HNR_3]^{\oplus} \quad (4)$$

$$H_2NR' \longrightarrow [H_2N\text{-}SO_2\text{-}\ddot{\underset{\ddot{}}{N}}\text{-}SO_2\text{-}NHR']^{\ominus}[HNR_3]^{\oplus} \quad (5)$$

$H_2N\text{-}SO_2\text{-}NH\text{-}SO_2\text{-}NR_2'$ *(6)*

$H_2N\text{-}SO_2\text{-}NH\text{-}SO_2\text{-}NHR'$ *(7)*

	R'	M.p. (°C)
(6a)	C_2H_5	Liquid
(6b)	NR'_2 = piperidine	110–111
(7a)	H	167–168
(7b)	C_6H_{11}	124–125
(7c)	C_6H_5	154–155
(7d)	iso-C_3H_7	97–100

Compounds *(6)* and *(7)* dissolve readily in water, giving strongly acid solutions. Sulfate ions can be detected therein only after addition of sodium nitrite. These well-crystalline materials are stable in air.

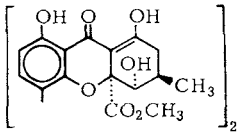
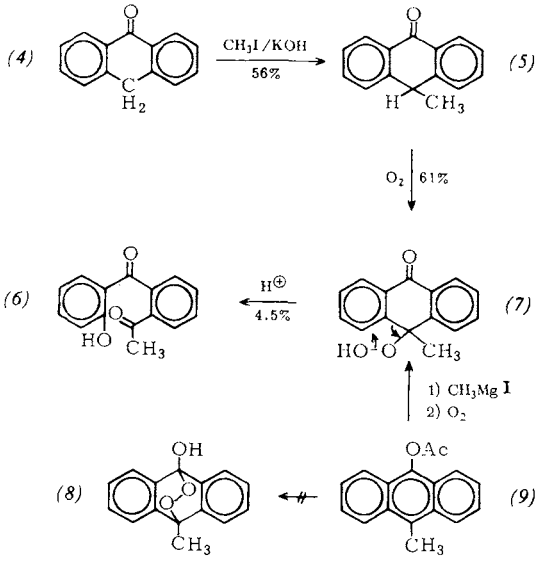
Model Reactions for Biological Ring Opening of Anthraquinones [1]

By *B. Franck, V. Radtke*, and *U. Zeidler* [*]



Although the biosynthesis of more than 100 natural anthraquinone pigments is largely clarified [3,4], very little is known about their biological degradation. This must begin with an oxidative opening of the quinonoid ring. We have previously reported the detection of such a ring opening as a metabolic reaction [2]. It was shown by feeding experiments with radioactively labeled precursors that ergochromes [5], *e.g.* secalonic acid A *(3)*, are formed from emodin *(1)* by way of the acid *(2)*. We have now found a reaction sequence that may serve to explain this oxidative ring opening *(1)* → *(2)* that was previously unknown in anthraquinone chemistry.

(1)



(2)

(3)

We first ascertained that 19 systematically selected hydroxyanthraquinones, including emodin *(1)*, were stable to peracids (perbenzoic acid, peracetic acid, and trifluoroperacetic acid) which seemed most likely to effect ring opening, whereas benzophenone was cleaved smoothly thereby. Thus it is unlikely that anthraquinones themselves are liable to biological ring opening. Anthrones *(4)*, on the other hand, which are biogenetic precursors or reduction products of anthraquinones, can be considered as starting products for the ring cleavage.

10-Methylanthrone *(5)*, which was prepared from anthrone *(4)*, gave on reaction with O_2/azobisisobutyronitrile in benzene the hitherto unrecorded 10-methylanthronyl hydroperoxide *(7)* [m.p. 159–161 °C (decomp.)]. This was rearranged by CH_3CO_2H/4 N H_2SO_4 (4:3), with ring opening, to 2-acetyl-2′-hydroxybenzophenone *(6)* (m.p. 108 °C); an approximately equal yield of anthraquinone, formed by elimination of methanol, was also obtained. The structure of *(6)* was confirmed by elemental analysis, UV spectrum in CH_3OH (λ_{max} = 253, 328 nm), IR spectrum in KBr ($\nu_{C=O}$, chelated = 1635, $\nu_{C=O}$ = 1685 cm^{-1}), and mass spectrum [*m/e* = 240 ($M^{\ominus}$, 100%) 197 (M − CH_3CO), 147 (M − C_6H_4OH), 121 (M − C_6H_4CO–CH_3)]. The proton-catalysed rearrangement of *(7)* is analogous to the rearrangement of cumyl hydroperoxide and may follow the same mechanistic route. Attempts by *Money*[6] and by us to effect this ring opening with anthrone *(4)* or anthranol in place of *(5)* failed because of the instability of the corresponding hydroperoxides.

10-Methylanthronyl hydroperoxide *(7)* was obtained, not only by autoxidation of 10-methylanthrone *(5)*, but also by another route which was stated by *Julian, Cole*, and *Diemer*[7] to lead to 9,10-epidioxy-10-methylanthranol *(8)*. The action of CH_3MgI on 10-methylanthryl acetate *(9)* and subsequent autoxidation gave a product $C_{15}H_{12}O_3$ that agreed in m.p. and other properties with the hydroperoxide *(7)* and with the material previously described as *(8)*[7]. There is no doubt that its structure is that of *(7)*[8], as is shown by, *inter alia*, its anthrone-like UV spectrum in cyclohexane (λ_{max} = 219, 271 nm) and its IR spectrum in KBr ($\nu_{C=O}$ = 1640 cm^{-1}); further, mass and NMR spectra support structure *(7)*.

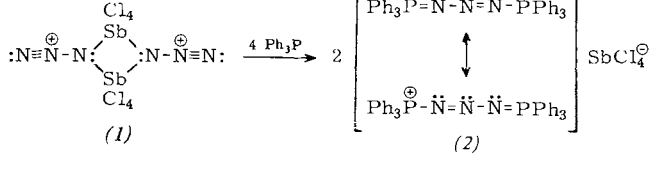
Bis(triphenylphosphine)triazenium Tetrachloroantimonate(III) [1]

By *N. Wiberg* and *K. H. Schmid*[*]

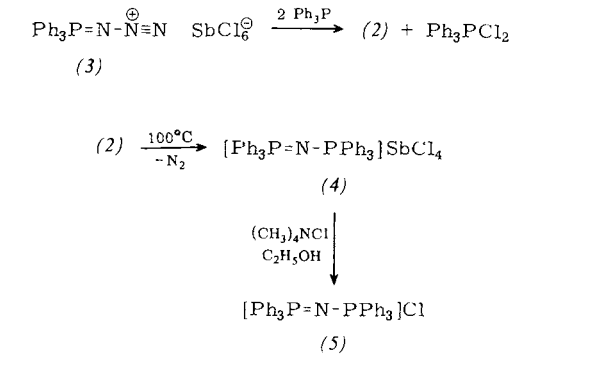


Antimony azide tetrachloride *(1)* contains[2] *N*-diazenium groups. An ability to add bases is typical of diazenium groups attached to carbon. In order to see whether this ability is possessed by azenium groups bonded to nitrogen we treated the salt *(1)* with triphenylphosphine.

This reaction, however, did not lead to the adduct containing the group $\overset{\oplus}{N}=N-N=PPh_3$. The adduct is probably formed as intermediate but at once decomposes to other products. The course of the reaction is determined by the redox reaction:

$$Sb(V) + P(III) \rightarrow Sb(III) + P(V)$$

When *(1)* is treated in benzene with PPh_3 in the molar ratio 1:4 (2 h at 20 °C), the antimony is reduced, the phosphorus is oxidized, and a quantitative yield of bis(triphenylphosphine)-triazenium tetrachloroantimonate(III) *(2)* is obtained as insoluble product[3].



The cation *(2)*, an aza vinylogue of the known cation $Ph_3PNPPh_3^+$[4], is the first example of a compound containing a PNNNP group. The salt *(2)* forms yellow crystals,

(1) (2)

which melt at 90 °C with decomposition and are insoluble in apolar solvents but soluble in CH_2Cl_2. The charge on the cation is spread equally over the PNNNP group, since only one signal appears in the ^{31}P–NMR spectrum.

The structure given is supported, not only by the composition, molecular weight, solubility relations, and IR and ^{31}P–NMR spectra, but also by the following facts: (i) Compound *(2)* can also be prepared from *(3)*[5] and triphenylphosphine, and (ii) *(2)* is converted quantitatively at 100 °C, with evolution of nitrogen, into the compound *(4)* (m.p. 168 to 169 °C) which can then be transformed into the known chloride *(5)* (m.p. 268 °C; lit.[4], m.p. 269–271 °C).

Treatment of tellurium azide trichloride, $TeCl_3N_3$[6], with Ph_3P in CH_2Cl_2 apparently causes simultaneous formation and thermal decomposition of the cation *(2)*, since the reaction occurs quantitatively, even at room temperature, in accord with the equation:

$$2\ Cl_3TeN_3 + 4\ Ph_3P \rightarrow [Ph_3P{=}N{-}PPh_3]_2TeCl_6 + 2\ N_2 + Te$$

Decomposition of the cation *(2)* may be catalysed by the tellurium produced.

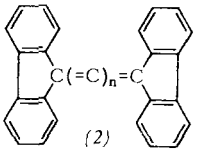
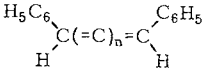
UV-Absorption of α,α,ω,ω-Tetraphenylcumulenes with Coplanar Benzene Rings [1]



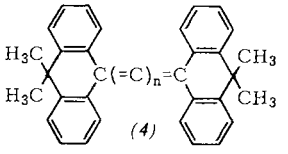
By *H. Fischer* and *W. D. Hell*[*]

Cumulenes containing an odd number of cumulated double bonds mostly give very intense long-wave bands in their UV spectra and are thus suitable for a study of the influence of substituents on the spectrum. If the positions of the longest-wavelength bands for tetraphenylcumulenes *(1)* and bis-biphenylenecumulenes *(2)* are calculated by HMO methods (all $\alpha_i = 0$, all β_{ik} for bonded centres $= \beta$) it transpires that corresponding compounds of the two series should differ only slightly from one another. Experimentally, however, cumulenes of type *(2)* absorb at longer wavelengths, by *ca.* 60 nm (2000 to 3000 cm^{-1}), than do the corresponding cumulenes of type *(1)*[2]. This discrepancy is apparently due to a non-planar arrangement of the geminal benzene rings of *(1)*. Cumulenes in which the positions of the phenyl groups are exactly known would therefore be of interest.



In the series of α,ω-diphenylcumulenes *(3)* the spectrum of 1,6-diphenylhexapentaene is known[3]. Starting from 9,9-dimethyl-10-anthrone[4], we have prepared the butatriene, hexapentaene, and octaheptaene of the series *(4)* by standard methods[2]. In these cumulenes the geminal "benzene" rings should be essentially coplanar.

(1)



(2)

(3)

n = 2, 4, 6

(4)

Table 1.

n in *(4)*	M.p. (°C)	Color of soln. in $CHCl_3$	λ_{max} (mμ) [log ε] in $CHCl_3$
2	260	Orange-yellow	481 [4.68], 295 [4.46], 284 [4.49]
4	>360 (dec.)	Red-violet	555 [5.04], 520 [4.68], 437 [3.78], 382 [3.96], 311 [4.43], 293 [4.45]
6 [a]		Blue	610 [5.2], 560 [4.7], 472 [4.6]

[a] Not yet isolated in crystalline form; extinction estimated.

As expected, the cumulenes *(4)* absorb at appreciably longer wavelengths than do the corresponding cumulenes *(1)*. The non-planarity of the benzene rings in *(1)* can be taken into account in the HMO calculations by reducing the resonance integrals for the bonds from the benzene rings to the cumulene chain. The best results are obtained by taking a resonance integral of 0.85 β for these bonds. Table 2 shows a comparison of the positions of the longest-wavelength UV bands for the cumulenes *(1)* to *(4)* as calculated by HMO methods (least squares refinement) with the values found experimentally. The deviations are within reasonable limits.

Table 2. Comparison of the calculated and experimental values (in eV) of the positions of the longest-wavelength UV bands for the cumulenes *(1)* to *(4)*.

n	*(1)*		*(2)*		*(3)*		*(4)*	
	HMO	exp.	HMO	exp.	HMO	exp.	HMO	exp.
2	2.95	2.95	2.52	2.58	3.28		2.64	2.58
4	2.53	2.55	2.24	2.27	2.76	2.75	2.31	2.23
6	2.24	2.22	2.03	2.09	2.41		2.07	2.04

If the resonance integral is set proportional to the cosine of the angle formed by the two neighboring π-orbitals then the benzene rings of the cumulenes *(1)* would have to be twisted out of plane by about 30°. On the basis of dipole moment measurements for 1,1-diphenylethylene, *Coates* and *Sutton*[5] also deduced an angle of twist of 30°; and a similar result was obtained from MO calculations for 1,1-diarylethylenes by *Simonetta* and *Carrà*[6].

It is remarkable that introduction of conjugation between the benzene rings [transition from the cumulenes *(4)* to *(2)*] leads to a small hypsochromic shift of the longest-wavelength

band (cf. Table 2). This result is not intelligible within the framework of the HMO theory.

Chemical Shifts of NMR Signals of the Acetyl Protons of β-Penta-*O*-acetylglucose

By *K. Heyns*, *W.-P. Trautwein*, and *F. Garrido Espinosa* [*]

The NMR signals of the acetoxyl groups of acetylated carbohydrates are often used for configurational and conformational analysis [1], a use that depends on the fact that the methyl protons of equatorial acetoxyl groups in general absorb at higher field than do such axial groups. Whereas this rule has proved its value for countless partially or completely acetylated pyranoses [2], halogeno sugars [3], amino hexoses [4], and inositols [5], there are only a few, and partially contradictory, indications as to how to assign the individual signals within each of these groups. It is sometimes assumed that acetoxyl groups on the primary C atom 6 of hexopyranoses absorb at highest field [1,6] and that acetoxyl groups above the plane of the ring are less shielded than those under the pyranose ring [7,8].

We have studied, by NMR spectroscopy, 2,3,4,6-, 1,3,4,6-, 1,2,3,6-, and 1,2,3,4-tetra-*O*-acetyl-β-D-glucopyranose that have been acetylated on the unsubstituted OH group by hexadeuterioacetic anhydride in pyridine. Whereas the NMR spectrum of unlabeled β-penta-*O*-acetylglucose shows four

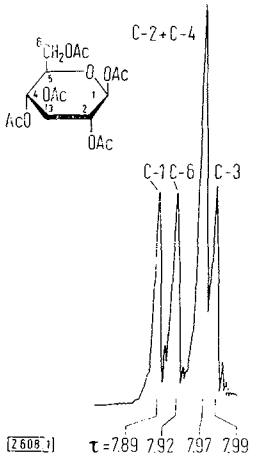

Fig. 1. ^{1}H—NMR spectrum of 1,2,3,4-penta-*O*-acetyl-β-D-glucose at 100 MHz in $CDCl_3$.

signals for the acetyl protons (one of these signals has double intensity), the spectra of all the labeled compounds lack one line, namely, that of the trideuterioacetyl group (Fig. 1). By selective labeling of individual acetyl groups it is possible to assign each line in the spectrum to a definite acetyl group. It was thus shown that the two signals at lowest field refer to groups on C-1 and C-6, whereas the line of relative intensity 2 is caused by the groups on C-2 and C-4; the signal at highest field was present in all the spectra and thus is to be ascribed to the group on C-3.

Occurrence of Cyclododecasulfur in Sulfur Melts

By *M. Schmidt* and *H.-D. Block* [*]

The physical properties of liquid sulfur have long been the subject of study [1], but it was only the theoretical propositions by *Powell* and *Eyring* [2], *Gee* [3], and in particular *Tobolsky* and *Eisenberg* [4] that made it possible to interpret satisfactorily its unusual behavior over the whole liquid range. Fundamental to the theory that is currently recognized is the assumption of temperature-dependent equilibria between cyclooctasulfur and catenaoctasulfur as "monomers" and of polycatenaoctasulfur as "polymer".

We now report experiments which throw doubt on this principle and at least necessitate refinement of, if not a change in, the theoretical interpretation. Working up sulfur that has been melted at 120 °C, 140 °C, 165 °C, 190 °C, 220 °C, 290 °C, 340 °C, 350 °C, or 370 °C and then brought quickly to the solid state by cooling in air, cold water, or liquid air leads in each case, reproducibly, to crystalline cyclododecasulfur [5], S_{12}, even if only in a "yield" of *ca.* 0.1 %. The sulfur used as starting material was free from S_{12}, as also from S_6 and S_8 that are formed by chain-building on decomposition of thiosulfate by acid [6]. Slow cooling of the melt (during 10 hours) leads, however, to pure S_8. This result shows that in sulfur melts there are also S_{12} rings in the equilibrium mixture alongside S_8, and it is certain that only a small part of the S_{12} rings survive transition, on cooling, into the S_8 rings that constitute the only thermodynamically stable form. It is, however, also probable that other, hitherto unisolated, rings S_x ($x < 12$ and in particular $x > 12$ – perhaps even $x \gg 12$) are present in the equilibrium of the melt, as previously postulated by *Krebs* [7]. It remains an open question to what extent the S_{12} content, already shown to be present slightly above the melting point, is responsible for the decrease of the "ideal" to the "natural" melting point.

Experimental Example: 20 g of sulfur is heated at 200 °C for 10 min. The vessel is cooled with tap water and the sulfur is divided as finely as possible and stirred for 12 hours with

100 ml of pure CS_2 at room temperature. The clear yellow solution, obtained by filtration from insoluble polymer, is concentrated to 20 ml in a vacuum and then cooled at −30 °C for 12 h. The mother liquor is decanted from precipitated sulfur, and the latter is treated dropwise, with careful shaking, with sufficient pure CS_2 (*ca.* 10 ml) to dissolve all the yellow S_8 and leave behind only the characteristic four-cornered platelets of S_{12}. After decantation of the solution, these platelets are washed with 1 ml of CS_2 and the remaining suspension of crystals is finally dried on filter paper. In this way 20 mg of S_{12} ("yield" *ca.* 0.1 %) of S_{12} is isolated, having m.p. 140–142 °C (146–148 °C after recrystallization from benzene).

Photodimerization of Uracil Sensitized by Acetone

By *C. H. Krauch, D. M. Krämer, P. Chandra, P. Mildner, H. Feller*, and *A. Wacker* [*]

When a 10^{-3} M solution of uracil in acetone/water (1:3) is irradiated with light of wavelength 315 nm (1×10^6 erg/mm^2), four products are formed quantitatively, of which we have identified one as the *syn* head-to-head dimer of uracil by means of its R_F value [1]. Use of more than 50 % acetone as solvent during the irradiation leads to addition of about 5 % of acetone. This photosensitized dimerization of uracil may be more useful for molecular-biological studies than is the dimerization by UV light [2], since in the latter the uracil also adds water at the 5,6-double bond [3]. When cytosine is irradiated in aqueous acetone, a change in the molecule (including addition of acetone) can be observed only after radiation doses that have caused total reaction of uracil. Acetone-sensitized photodimerization of thymine has already been reported [4].

The effect of the reaction on the template activity of nucleic acids is shown by the following observations. When poly-A, poly-C, and poly-U [5] (1 mg/ml) in 23 % acetone are irradiated with light of wavelength 315 nm (3×10^5 erg/mm^2, grating monochromator, Bausch and Lomb, Rochester, USA; mercury high-pressure lamp HBO 200, Osram), the extinction at λ_{max} falls by 1 % for poly-A, by 6 % for poly-C, and by 61 % for poly-U. In cell-free protein synthesis (the reaction mixture contained, after *Nirenberg* and *Matthaei* [6], 80 μg/ml of poly-U or 120 μg/ml of poly-A or poly-C; specific activity of the [^{14}C]-amino acids = 3.6 mCi/mmole), the irradiation affects only the phenylalanine incorporation that is poly-U-dependent, this being inhibited to the extent of more than 80 %. If homopolynucleotides are used as templates for the synthesis of RNA with a polymerase from *Micrococcus lysodeikticus* [7], then again it is only the poly-U-dependent incorporation of AMP that is inhibited (by about 40 %). Thus photodimerization of uracil sensitized by acetone provides a further, mild method of specifically altering nucleic acids by photochemical methods.

Synthesis of a Catena Compound by the Semistatistical Principle

By *A. Lüttringhaus* and *G. Isele* [*]

Cyclization of the dinitrile *(1)* [1] by Ziegler's method [2] affords the isomers *(2)* and *(3)* as viscous oils that are separable chromatographically on silica gel but give identical IR and NMR spectra. Since these products also give identical mass spectra (the same molecular ion and similar fragments), they are stereomers or topological isomers [3], differing only in that the macrocycles of *(2)* are intraannularly, and of *(3)* extraannularly, combined by the N atom.

The total yield from the cyclization amounted to 57 %. Of this, 5–8 % consisted of *(2)* and 92–95 % of *(3)*. Proof that only *(2)* is a pre-catena compound was provided by cleavage of the nitrogen-phenyl bond by way of the *o*-quinone according to the pattern established by *Schill* [4]. Compound *(3)* was cleaved into compounds *(4)* and *(5)*, but compound *(2)* was converted into the catena-compound *(6)*. The product *(6)* was shown to be homogeneous by thin-layer chromatography; its IR spectrum contains the expected CO frequencies at 1780 (phenolic acetyl groups), 1720 (keto group), and 1650 cm^{-1} (*N*-acetyl).

The mass spectrum of *(6)* is completely analogous to that of the catena-compound *(7)* prepared by *Schill* [4] by "planned" synthesis. Compound *(7)* is a homologue of *(6)*, having a heterocyclic ring smaller by 2×5 CH_2 groups; its mass spectrum was analysed by *Vetter* and *Schill* [5]. The mass spectrum of *(6)* shows the molecular ion at *m/e* = 1161; then follow, with increasing intensity, fragments at *m/e* = 1119, 1077, and 1035 (base peak) corresponding to stepwise removal of three molecules of ketene from the three *O*-acetyl groups; in the region *m/e* = 600 to 990 the mass spectrum is empty; below *m/e* = 600, the fragments of the separated rings appear, as is to be expected for a catenane of this structural type [5]. Thus the catena structure of *(6)* is proved too by the mass-spectrometric evidence.

This synthesis of *(6)* demonstrates unequivocally for the first time that, provided the steric stipulations are satisfactorily met, catenanes can be synthesized by a predominantly "statistical" method, which is simpler than the multi-step, strictly "planned" *Schill* principle[4] involving intermediate double linking of the two macrocycles. Further, our preliminary experiments indicate that the relative amounts of the stereomers *(2)* and *(3)* can be altered in favor of *(2)* by thermal equilibration of the conformers of *(1)* before the cyclization, so that the yield of *(6)* can also be increased.

Cyclization of (1) to (2) and (3):

Before the cyclization, the nitrile was heated in dioxane under nitrogen for 200 h at 100 °C. The dinitrile *(1)* (5.2 g) in anhydrous ether (250 ml) was added dropwise, with stirring, during 60 h to a boiling solution of Na-methylanilide in ether (0.66 M solution); after a further 5 h, water was added and the ethereal phase was separated. Ether, methylaniline, and ethylbenzene[2] were driven off in a vacuum and the residue was dissolved in propionic acid (20 ml) and treated with 50 % sulfuric acid (100 ml). The mixture was boiled under reflux in a nitrogen atmosphere for 9 h. Water was then added to the mixture and the whole was extracted with ether. After removal of the ether, the residue was dissolved in acetone (250 ml); dimethyl sulfate (10 ml) and potassium carbonate (20 g) were added, and the mixture was boiled, with stirring, under nitrogen for 5 h. The excess of dimethyl sulfate was hydrolysed, and the cyclization product was extracted into ether. The ethereal solution was washed with water and bicarbonate solution, dried with Na_2SO_4, and evaporated. The residue was chromatographed in benzene on a short column of neutral aluminum oxide. 3.2 g of eluate were obtained. The products *(2)* and *(3)* were separated by repeated chromatography on a SiO_2 column (55 cm long, 4 cm in diameter) with benzene.

Cleavage of (2) to (6), and (3) to (4) and (5):

Compound *(3)* (500 mg) was treated with HBr-saturated glacial acetic acid (50 ml), propionic acid (20 ml), and 48 % hydrobromic acid (10 ml) and boiled for 12 h under nitrogen. Water was added to the mixture and the whole extracted with ether. The ethereal solution was then washed with water and bicarbonate solution and finally evaporated. Further working up was analogous to that described by *Schill*[4]. The two separated rings *(4)* and *(5)* were obtained.

In the same way compound *(2)* (90 mg) afforded a product that was purified by chromatography on SiO_2 with ethyl acetate/benzene (7:3). The catenane *(6)* (60 mg) was obtained as a colorless oil.

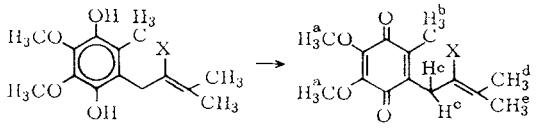
Fluoro-coenzyme Q_1 (Fluoroubiquinone-5) [**]

By *H. Schumacher* and *H. Machleidt* [*]

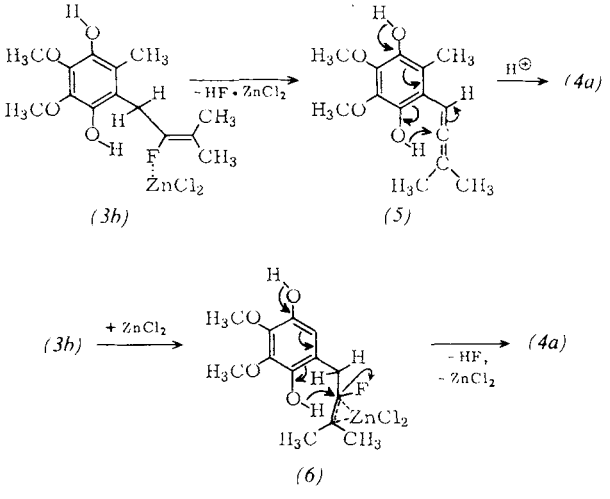


Ubiquinones (coenzyme Q)[1] are obtained on electrophilic substitution of *(1)* with isoprenols in the presence of Lewis acids and subsequent oxidation[2,3]. Homogeneous coenzyme Q_1 *(4a)* is obtained as a red oil, $\lambda_{max} = 274$ nm, $\log \varepsilon = 4.07$ (in CH_3OH), by treating *(1)* (0.51 g)[4] with 3-methyl-2-buten-1-ol *(2a)* (0.86 g) in anhydrous ether (75 ml) in the presence of anhydrous zinc chloride (12 g)[3] for 20 h with stirring under nitrogen, then distilling off the ether in a vacuum, partitioning the residue between petroleum ether/methanol/water (4:3:1), drying the petroleum ether layer, chromatographing it on Al_2O_3 (neutral, activity grade IV) with petroleum ether/ether (98 : 2), and treating the product with MnO_2[5]. 269 mg (39 %) of *(4a)* was obtained which was homogeneous on thin-layer chromatography on Kieselgel G with cyclohexane/ethyl acetate (8:2). A small amount (40 mg), of 2,3-dimethoxy-6-methyl-1,4-benzoquinone (coenzyme Q_0), arising from unreacted *(1)*, was also isolated from the products; it was characterized by $\lambda_{max} = 264$ nm, $\log \varepsilon = 4.14$ (in CH_3OH), and m.p. 54–57 °C.

Reaction of 2-fluoro-3-methyl-2-buten-1-ol *(2b)*[6] (2.40 g) with *(1)* (2.42 g) in anhydrous ether (90 ml) in the presence of $ZnCl_2$ (5.50 g), treatment of products as above, and preparative thin-layer chromatography on Kieselgel G with cyclohexane/ethyl acetate (8:2) gave coenzyme Q_1 *(4a)*

(1)

(2a), X = H
(2b), X = F
(2c), X = Cl



(3a), X = H
(3b), X = F
(3c), X = Cl

(4a), X = H
(4b), X = F
(4c), X = Cl

(95 mg) and fluoro-coenzyme Q_1 *(4b)* (53 mg). The latter is a red oil with λ_{max} = 272 nm, log ε = 4.08 (in CH_3OH); a better yield (20 %) of *(4b)* was obtained by condensing *(1)* (210 mg) with *(2b)* (500 mg) in anhydrous ether (15 ml) containing $AlCl_3$ (1.5 g) for 4 h. The ^1H–NMR spectrum of *(4b)* (60 MHz, in CCl_4) showed 6 H-a at 4.00 ppm, 3 H-b at 2.06 ppm (singlet), 2 H-c at 3.45 ppm (doublet, J = 22 Hz), 3 H-d at 1.78 ppm (doublet, J = 2.5 Hz), and 3 H-e at 1.62 ppm (doublet, J = 3.5 Hz).

Following a reaction under N_2 by thin-layer chromatography showed that formation of *(4a)* and *(3b)* begins about 5 min after the start and that the amount of *(4a)* increases during the reaction at the expense of *(3b)*. Oxidation of the sample gives compounds *(4a)* and *(4b)* and coenzyme Q_0. The coenzyme Q_1 *(4a)* that accompanies *(4b)* must arise by an intramolecular redox reaction *(3b)* → *(4a)* + HF. An intermolecular redox reaction *(1)* + *(3b)* → *(3a)* + Q_0 + HF or 2 *(3b)* → *(3a)* + *(4b)* + HF yields coenzyme Q_0 or *(4b)* directly and not only after oxidation of the sample.

The product *(4a)* can be formed from *(3b)* by an elimination-addition mechanism[7] by way of *(5)* or by an addition-elimination mechanism[8] by way of *(6)*.

(3b) (5) (6)

A solution of ethyl 2-chloro-3-methyl-2-butenoate (2.0 g) in anhydrous ether (5 ml) at −78 °C was added dropwise to a suspension of $LiAlH_4$ (500 mg) in anhydrous ether (45 ml). After 12 h at −50 °C the mixture was decomposed with saturated NH_4Cl solution and the products were subjected to the usual purification procedure to give 2-chloro-3-methyl-2-buten-1-ol *(2c)* (910 mg), b.p. 72 °C/11 mm. Condensing this product (400 mg) with *(1)* (350 mg) in anhydrous ether (20 ml) for 6 h in the presence of $AlCl_3$ (1.5 g), and working up as described for *(1)* → *(4a)*, gave coenzyme Q_0 (220 mg) and chloro-coenzyme Q_1 *(4c)* (31 mg). The latter product is a red oil with λ_{max} = 272 nm, log ε = 4.14 (in CH_3OH), whose ^1H–NMR spectrum shows signals due to 6 H-a at 4.00 ppm, 3 H-b at 1.83 ppm (singlet), 2 H-c at 3.58 ppm (singlet), 3 H-d at 2.08 ppm (singlet), 3 H-e at 1.98 (singlet). Chloro-coenzyme Q_1 *(4c)* is more stable than the fluoro compound *(4b)*. Compound *(4a)* could not be detected among the products from this reaction.

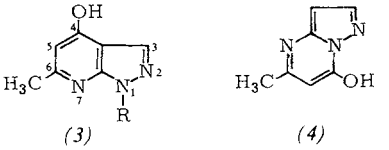
Pyrazolo[3,4-*b*]pyridines [1]



By *H. Dorn* and *A. Zubek* [*]

Pyrazolo[3,4-*b*]pyridines *(3)* are a new type of potential purine antagonists. The only members of this series known hitherto have an OH group on C-3[2] or a phenyl group on N-1 or N-2 [3] and are thus uninteresting as antimetabolites. These bicyclic compounds can be obtained in 80–90 % yield from 3-aminopyrazole *(1a)*, 5-amino-1-methylpyrazole *(1b)*, or 5-amino-1-benzylpyrazole *(1c)* (m.p. 70–72 °C) by reaction with a β-keto ester such as acetoacetic ester. Thus are obtained: 5-methylpyrazolo[1,5-*a*]pyrimidin-7-ol *(4)*[4] from *(1a)*; 1,6-dimethyl- *(3b)* (m.p. 270–272 °C) and 1-benzyl-6-methyl-pyrazolo[3,4-*b*]pyridin-4-ol *(3c)* (m.p. 227 to 288 °C) from *(1b)* and *(1c)*[5] respectively. We proved the positions of the substituents in *(3b)* and *(3c)* by a second synthesis, namely, cyclization of *(2b)* and *(2c)* in boiling ethylene glycol.

(1) (2)

(a), R = -H
(b), R = $-CH_3$
(c), R = $-CH_2C_6H_5$
(d), R = $-COCH_3$

(3) (4)

Hydrogenolytic debenzylation of *(3c)* in glacial acetic acid (Pd-charcoal) gave, surprisingly, 1-acetyl-6-methylpyrazolo-[3,4-*b*]pyridin-4-ol *(3d)* (m.p. 236–239 °C, needles from ethanol). The IR spectrum of *(3d)* in KBr showed, not only an intense, broad carbonyl band, ν(CO) = 1655 cm^{-1} (to be ascribed to the tautomeric 4-pyridone structure), but also a carbonyl absorption band for N–CO–CH_3 at 1749 cm^{-1}. The ^{1}H–NMR spectrum [in $(CD_3)_2SO$] contains a doublet for the 6-CH_3 group at τ = 7.69 and a singlet for N–CO–CH_3 at τ = 7.33; however, the NMR spectrum of *(3d)* in D_2O containing NaOD is exactly the same as that of *(3a)*, *i.e.* there is extremely rapid deuterium exchange at the *N*-acetyl group. Acidifying an alkaline solution of *(3d)* precipitates 6-methyl-1*H*-pyrazolo[3,4-*b*]pyridin-4-ol *(3a)* (m.p. 319 to 322 °C), which we were also able to obtain, in 95 % yield, directly from *(3c)*. This was achieved by treatment of *(3c)* with sodium in liquid ammonia. Compound *(3a)* is converted by $POCl_3$ into 4-chloro-6-methyl-1*H*-pyrazolo[3,4-*b*]pyridine (m.p. 154–156 °C). The IR spectrum (ν(CO) in KBr = 1650 cm^{-1}) shows that in the solid state *(3a)* exists mainly in the tautomeric 4-pyridone form.

[5] *(1c)* was formed in 90 % yield on hydrolysis and decarboxylation of ethyl 5-amino-1-benzylpyrazole-4-carboxylate (m.p. 110 °C), which was obtained from benzylhydrazine and ethyl 2-cyano-3-ethoxyacrylate in boiling ethanol.

Difluorothiophosphoryl Fluorosulfate [1]

By *Max Lustig* [*]

Phosphoryl fluorosulfate, $PO(OSO_2F)_3$, is the first compound reported with a fluorosulfate group attached to a phosphorus atom. This compound decomposes slowly to the lower fluorosulfates, $POF(OSO_2F)_2$ and POF_2OSO_2F [2] at temperatures above 100 °C. Difluorothiophosphoryl fluorosulfate, PSF_2OSO_2F, a colorless compound that is unstable at ambient temperature, has been synthesized in our laboratory.

The highest yield of this compound can be achieved by the slow addition of peroxydisulfuryl difluoride, $S_2O_6F_2$, (0.33 mmoles) to difluorothiophosphoryl bromide (0.57 mmole) in a 50 ml. Pyrex bulb at −45 °C. After the addition was completed the reaction mixture was allowed to stand for 1/2 h and then allowed to warm slowly to room temperature. Analysis revealed that the product mixture contained PSF_2OSO_2F (0.46 mmoles or 81 % yield), POF_3 (0.04 mmoles), SO_2 (0.09 mmoles) and PSF_3 (0.01 mmole) as well as unreacted PSF_2Br (0.03 mmole). A small quantity of a yellow solid remained in the reaction vessel. Purification is accomplished by passing the reaction mixture through cold traps maintained at −95 and −119 °C; the PSF_2OSO_2F is retained in the latter.

Immediately after purification of a sample of PSF_2OSO_2F, the molecular weight was determined (vapor density method) and found to be 197.1 (Calcd: 200.1). The ^{19}F-NMR spectrum showed resonances at φ = −47.5 [5], assigned to the fluorine bonded to the sulfur atom, and at φ = 27.6 and 57.7 (J_{P-F_2} = 1240 Hz) both of which are assigned to the fluorines attached to the phosphorus. The measurements are relative to CCl_3F as an internal standard. The area ratio of the two higher field resonances to that at low field was found to be 1.8:1.0. The low-field resonance is divided into a multiplet due to coupling with both the phosphorus and the fluorines attached to the phosphorus. However, both the high-field resonances are split into doublets (J_{F-F_2} = 4 Hz). The ^{31}P-NMR spectrum showed a triplet centered at −165 Hz (relative to H_3PO_4 used as an internal standard) where J_{P-F_2} = 1221 Hz. The NMR spectrum of POF_2OSO_2F is similar [2]. The mass spectrum shows major absorptions [reported as mass number (species) and relative abundance] as follows: 32(S^{++}) 24.4, 47(PO^+) 7.4, 48(SO^+) 4.6, 50(PF^+) 8.4, 64(SO_2^+) 28.4, 67(SOF^+) 31.2, 69(PF_2^+) 100, 80(SO_3^+) 8.5, 82(PSF^+) 3.1, 83(SOF_2^+) 78.5, 98($PSFO^+$) 9.5, 101(PSF_2^+) 37.9, 117(PSF_2O^+) 7.4, and 200($PSF_2OSO_2F^+$) 17.3. The infrared spectrum shows the following major absorptions (cm^{-1}): 1493(s), S=O asym. str., and 1250(s), S=O sym. str. [3]; at 985(vs) and 943(vs, broad) in the P–F and P–O str. region [2,4]; 862(s), S–F str. [3]; 788 (ms), S–O str., and at *ca.* 671 (m, broad), P=S str.

A pure sample of PSF_2OSO_2F was placed into an infrared gas cell at 10 mm pressure and periodically monitored. After 3 h nearly half the sample remained, after 7 h it was barely observable and after 24 h it had completely decomposed according to both infrared and mass spectral evidence. The gaseous decomposition products are SO_2 and POF_3, present in *ca.* 2:1 molar ratio, along with a small quantity of $S_2O_5F_2$. A yellow solid was also formed.

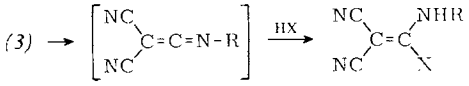
Degradation of 2-Azidoethylene-1,1-dicarbonitriles [1]

By *K. Friedrich* [*]



Acylmalononitriles *(1)*, R = H [2], CH_3 [3], or C_6H_5 [4], can be converted into the 2,2-dicyanovinyl chlorides *(2)* by phosphorus pentachloride, or, as their sodium salts, by phosphorus oxychloride. The reactivity of compounds *(2)* is comparable with that of carboxylic acid chlorides, in accord with the principle that structural elements =O and $=C(CN)_2$ are analogous in organic compounds [5]. For instance, 2-azidoethylene-1,1-dicarbonitriles *(3)* are obtained smoothly

	R	B.p. (°C/mm) M.p. (°C)	Yield (%)
(2)	H	83/18	70
	CH_3	92/15	62
	C_6H_5	126/0.1 74–75	55
(3)	H	79–80 (decomp.)	71
	CH_3	Oil	68
	C_6H_5	80 (decomp.)	79

from *(2)* by means of sodium azide in acetone-water (2 : 1 v/v) at 0–5 °C.

The azides *(3)* decompose slowly at 20 °C, and rapidly when warmed to 60–70 °C, with loss of one mol. equiv. of nitrogen. In inert solvents such as ether, benzene, or dimethoxyethane decomposition gives polymeric products. An indication of the course of the reaction is obtained by carrying out the decomposition in dimethoxyethane in the presence of compounds of the type HX such as ethanol, hydrogen chloride, or, if R = C_6H_5, also aniline[**]. Under such conditions, the 2-aminoethylene-1,1-dicarbonitriles *(5)* are obtained as decomposition products. When R = H, the intermediate *(4)* can be isolated as its tetramethyl-ammonium salt if the reaction is carried out in acetone-water; *(4)* is the tautomer of methanetricarbonitrile[6]. It may be concluded that, on evolution of the nitrogen, the group R migrates to the N atom that remains attached, with formation of the 2-imino-ethylene-1,1-dicarbonitriles *(4)*, which then react with HX to give *(5)*. The reaction thus corresponds to the Curtius degradation of carbonyl azides, the dicyanovinyl group here corresponding to the carbonyl group.

NH···S Hydrogen Bonds and the Structure of the Anions in Ammonium Diamidothiophosphate and in Diammonium Amidothiophosphate

By *D. Mootz, W. Look, G. Sassmannshausen*, and *J. Goldmann*[*]

The crystal structures of ammonium diamidothiophosphate *(1)*, $NH_4[POS(NH_2)_2]$, and of diammonium amidothiophosphate *(2)*, $(NH_4)_2[PO_2S(NH_2)]$, have been determined from three-dimensional photographic X-ray-reflection data[1]. The salt *(1)* crystallizes in the monoclinic system with the space group $P2_1$, and the salt *(2)* in the triclinic form belonging to space group $P\bar{1}$. Both contain two formula units in the unit cell.

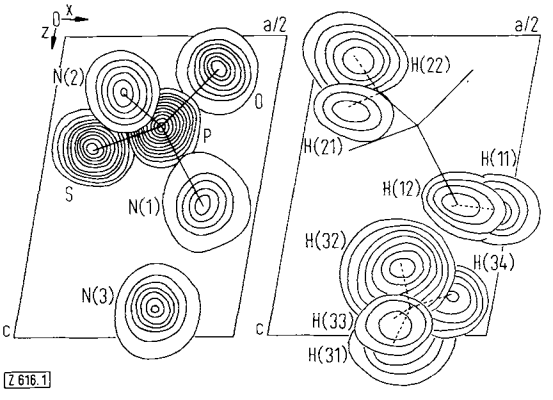

Fig. 1. Left: electron density distribution in $NH_4[POS(NH_2)_2]$ *(1)*. — Right: the maxima corresponding to hydrogen atoms in *(1)*.

The structures were determined from the Patterson functions and were refined by the method of least squares. The *R* factors attained were 0.063 for *(1)* (688 independently observed data) and 0.101 for *(2)* (1087 data). Refinement for *(2)* is not yet complete.

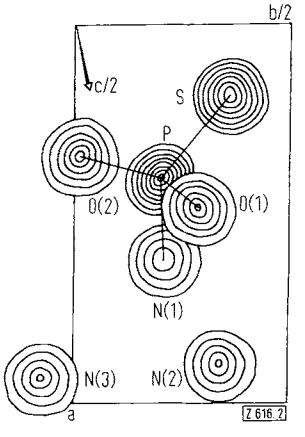

Fig. 2. Electron density distribution in $(NH_4)_2[POS(NH_2)]$ *(2)*.

The left-hand part of Fig. 1 shows the electron density function for *(1)* and on the right the maxima of a Fourier difference synthesis corresponding to the hydrogen atoms. The electron density function for *(2)* is shown in Fig. 2. The bond lengths and bond angles in the anions are listed in the Table; standard deviations amount to 0.004 to 0.008 Å and 0.3 to 0.5 °. The bond lengths for *(1)* are corrected for thermal vibrations.

As a result of additional d_π-p_π bond contributions[2], all the P–X bonds are shorter than pure single bonds. Analogous results have been obtained for other compounds of this type.

Analysis of the interatomic distances and angles showed that in both compounds the sulfur atom participates, by means

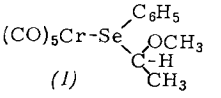
Addition-Rearrangement Reactions of Transition Metal-Carbene Complexes with Selenophenol



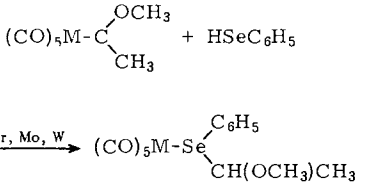
By *E. O. Fischer* and *V. Kiener* [*]

Pentacarbonyl[methoxy(methyl)carbene]chromium reacts with thiophenol with nucleophilic replacement of the OCH_3 on the carbene-carbon atom by the SC_6H_5 group, yielding the brown $(CO)_5CrC(SC_6H_5)CH_3$ [1]. However, on treating the pentacarbonyl[methoxy(methyl)carbene] complexes of chromium, molybdenum, and tungsten [2] with the stronger nucleophile selenophenol, in hexane with exclusion of air, we observed a new type of addition reaction, which yielded brownish - yellow $C_{14}H_{12}CrO_6Se$ (m.p. 74 °C), brown $C_{14}H_{12}MoO_6Se$, and greenish-yellow $C_{14}H_{12}WO_6Se$ (m.p. 85 °C). Table 1 gives the positions and the most plausible assignments of the NMR signals of the three diamagnetic $C_{14}H_{12}MO_6Se$ complexes [3]. The coupling constants J_{CH_3-CH} are 6 Hz in all cases.

Table 1. ^1H—NMR signals measured in $CDCl_3$ with tetramethylsilane as internal standard. Chemical shifts in τ. Relative intensities in parentheses. (D = doublet, S = singlet, Q = quartet, M = multiplet.)

	M = Cr	M = Mo	M = W
$-CH_3$	8.40 (3)D	8.42 (3)D	8.43 (3)D
$-OCH_3$	6.45 (3)S	6.47 (3)S	6.48 (3)S
—CH	4.80 (1)Q	4.85 (1)Q	4.88 (1)Q
$-C_6H_5$	2.37 (5)M	2.35 (5)M	2.60 (5)M

From the NMR data we conclude that the groups $-C_6H_5$ and $-CH(OCH_3)CH_3$ are present. In addition to the molecular peak at $m/e = 406$ and 408, the mass spectrum [4] of $C_{14}H_{12}CrO_6Se$ (Atlas CH4, 50 eV) contains fragments at $m/e =$ 266 and 268 $[CrSe(C_6H_5)-CH(OCH_3)CH_3]^+$, 207 and 209 $[CrSeC_6H_5]^+$ as well as 214 and 216 $[Se(C_6H_5)-CH(OCH_3)CH_3]^+$ which evidence a Cr-Se bond and thus also the structure *(1)*.



(1)

The complexes have a pseudooctahedral configuration and their IR spectra contain four ν_{CO} bands (Table 2), as is to be expected for lowering of the symmetry by the selenium ligands.

Table 2. Positions of the ν_{CO} vibrations of the compounds $C_{14}H_{12}MO_6Se$ in n-hexane (cm^{-1}).

M = Cr	M = Mo	M = W
2070	2078	2078
1990	1990	1980
1948	1951	1940
1934	1935	1932

The selenium ligand, which had become coordinated to the metal atom by nucleophilic replacement of the carbene-carbon atom and proton migration, is replaced by pyridine, with formation of yellow pentacarbonylpyridinechromium(0). Because of the similarity of their spectra, the structures of $C_{14}H_{12}MoO_6Se$ and $C_{14}H_{12}WO_6Se$ are assumed to be analogous to *(1)*. We thus formulate the reactions of the three metalcarbene complexes with selenophenol as:

If pentacarbonyl[methoxy(methyl)carbene]chromium is allowed to react with selenophenol in ethanol, a dark red oil is obtained from which ruby-red crystals are precipitated on treatment with concentrated aqueous KOH. Elemental analyses and IR and NMR spectra indicate a compound $[(CO)_5Cr-Se(C_6H_5)-Cr(CO)_5]^-K^+$.

Structure and Mode of Action of Aldolases

By *B. L. Horecker*[*]

Fructose diphosphate aldolase from rabbit muscle has a molecular weight of 160000 and appears to be built up according to the $\alpha_2\beta_2$ principle from four sub-units of equal molecular weight. The function of the various sub-units is not yet known. The active center of the enzyme contains an active lysine residue that forms a Schiff base with the substrate dihydroxyacetone phosphate. Reduction of this intermediate with sodium borohydride enables the active center to be labeled. A peptide containing this center could be isolated; it proved strongly hydrophobic in character. The fact that the corresponding peptide from rabbit-liver aldolase has a similar primary structure carrying numerous analogous amino-acid substituents provides evidence for the genetically independent origin of the two enzymes.

Investigations with reagents for the specific rearrangement of individual amino acids evidence further essential amino acids alongside the active lysine.

N-Ethylmaleimide reacts with sulfhydryl groups.The presence of the substrate inhibits this reaction and, consequently, the deactivation of the enzyme. The sulfhydryl groups may be oxidized to disulfides by *o*-phenanthroline. Since this reaction is also inhibited by the substrate, the sulfhydryl group must lie in the active center. Reaction with acetylimidazole provided evidence for the presence of essential tyrosine residues, and essential histidine residues were shown to be present by photooxidation. The properties of the aldolase that has been modified by acetylation or by photooxidation resemble those of transaldolase and, like the latter, such modified aldolases do not promote proton exchange between the substrate and water.

On the basis of the above and other observations, the following possible steps are discussed for the reaction of aldolases: 1. Formation of a Schiff base. 2. Reaction of the 6-phosphate group of the fructose diphosphate with a positively charged group in the active center, during which a negatively charged group is released. The latter abstracts a proton from the OH group on C-4 and thus initiates the aldol cleavage. 3. The resulting Schiff base carbanion reacts with a proton of the water *via* the histidine residue.

The aldol cleavage of fructose 6-phosphate with transaldolase is promoted by a histidine residue at the active center. This group retains the proton as long as the Schiff base structure remains intact.

Demixing Phenomena in High Polymers and Their Technical Importance

By *H. Gerrens*[*]

Incompatibility between two polymers is the rule, compatibility the exception. In the chemical technology of high polymers, demixing phenomena are sometimes avoided and sometimes consciously utilized. Precipitation polymerization begins with a homogeneous starting mixture, from which the polymer is precipitated during the polymerization. The precipitation is either achieved by adding a precipitant to the monomer (example: copolymerization of styrene and acrylonitrile) or it arises by insolubility of the polymer in the monomer (example: bulk polymerization of vinyl chloride). In discontinuous copolymerization it is only with azeotropic mixtures[1] that the copolymer has the same composition as the starting mixture. In all other mixtures the composition of the copolymer changes during the course of the reaction and inhomogeneous copolymers are formed which tend to demix. Azeotropic mixtures very seldom contain more than two different monomers, although recently some have been found with three, four, or five different monomers.

Block copolymers occasionally demix to give ordered structures, some even showing Bragg reflections in visible light. Block and graft copolymers often cause a better compatibility of the corresponding homopolymers, which in principle results from intimate distribution of the two phases in each other: the copolymers act, as it were, as emulsifiers of a polymeric oil-in-oil emulsion. Almost all high-impact polystyrenes and ABS polymers are to be considered as such emulsions, consisting of a soft rubber and a hard polystyrene or poly(styrene/acrylonitrile) phase. The properties of such shock-resistant masses depend on which of the two components forms the coherent phase of the emulsion. When, *e.g.*, high-impact polystyrene is manufactured by polymerization of styrene in presence of polybutadiene dissolved in styrene, it is the polybutadiene that first forms the coherent phase; but as reaction continues, the volume of the polystyrene phase progressively increases and this leads to phase reversal so that the coherent phase then consists of polystyrene.

[1] A monomer mixture is termed azeotropic when the copolymer formed from it has the same composition as the monomer mixture over the whole range of conversion.

Chemistry of Sulfur Ylides

By *A. Hochrainer*[*]

Individual sulfur ylides have been known for a long time, but it is only in recent years that their chemistry has been intensively studied[1,2]. Sulfonium ylides *(1)* are formed from oxosulfonium ylides *(2)*:

(1a) *(1b)* *(2a)* *(2b)*

Sulfur ylides can be prepared in four general ways:

1. From the corresponding sulfonium salts and a base.

2. By direct condensation of CH-acidic compounds with sulfoxides (only with very strongly CH-acidic compounds; owing to electron delocalization in the carbanion of the ylide this yields particularly stable ylides).

3. By rearrangement of an ylide already present (particularly by replacement of one or both of the hydrogen atoms on the carbanion [R^1 and R^2 in *(1)* or *(2)*]).

4. By a few special processes, of which some appear capable of generalization, *e.g.*, reaction of diazo compounds with sulfides (yielding sulfonium ylides) or with sulfoxides (yielding oxosulfonium ylides)[3].

Many sulfur ylides have only limited stability: depending on the structure of the ylide various types of rearrangement or decomposition may occur:

a) Hofmann elimination (either normal *trans*-elimination or α',β-elimination).

b) Stevens rearrangement.

c) Sommelet rearrangement.

d) Decomposition to sulfide or sulfoxide and carbene; the carbene may dimerize, polymerize, or attack other molecules.

These complications can be avoided by attaching strong electron acceptors to the anionic carbon of the ylide (whereby, however, the reactivity is decreased) or by substituting the ylide-sulfur only by phenyl or methyl groups.

Reaction of sulfur ylides (i) with acylating agents leads to new ylides [if R^1 or R^2 in *(1)* or *(2)* is H], (ii) with nitroso compounds to nitrones[4], (iii) with Schiff bases to aziridines[5] and products of further reaction[6], and (iv) with α,β-unsaturated oxo compounds to oxiranes[1,2] in contrast to the phosphorylide Wittig reactions which afford olefins.

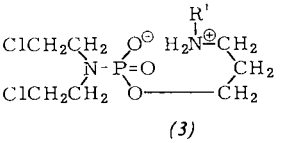
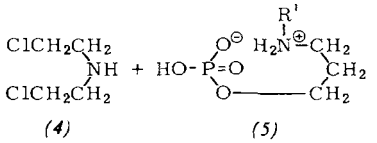
General Meeting of the Gesellschaft Deutscher Chemiker 1967

This year's General Meeting was held in Berlin (Germany) from 18th to 23rd September in conjunction with the centenary celebration of the Deutsche Chemische Gesellschaft. A selection of abstracts of the lectures and the discussions that took place on this occasion is given below. Only works that have not yet been published or presented for publication are included. The abstracts are listed in the alphabetical order of authors' names.

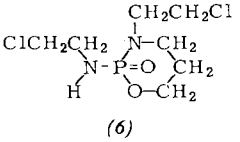


The Change in the Properties of Cyclic *N*-Lost Phosphoramidate on Substitution on the Ring Nitrogen

By *H. Arnold*[*]



The introduction of substituents R′ on the ring nitrogen of the *N*-Lost-phosphoramidate *(1)* to give *(2)* affects the susceptibility of the molecule to hydrolysis in various ways, depending on the size and nature of the substituent.



(1): R = H
(2): R = R′

(3)

(4) *(5)*

(6)

Solutions of the compounds *(2)* in ether are allowed to react with molar quantities of H_2O and HCl at 37.5 °C. If R′ = CH_3, the zwitterion *(3)* is formed. If R′ = C_2H_5, no hydrolysis takes place; when R′ = CH_2CH_2Cl, the molecule is cleaved at two points to form *(4)* and *(5)*. The compound *(6)*, which is isomeric with *(1)*, is also cleaved at two points to give the chloroethylamine salt of the acid *(5)*.

Compound *(1)* is a latent cytostatic[1], which is inactive *in vitro*, but is converted by metabolic enzymes *in vivo* into products having a strong cytostatic action. This activation involves ring cleavage of *(1)* with liberation of a hydroxyl function of the phosphoric acid (formation of an anion). In view of this structural change leading to alkylation, the rate of hydrolysis of *(3)* (R′ = CH_2CH_2Cl) and *(6)* was studied in comparison with that of *(1)* on the basis of the kinetics of chlorine ionization in neutral aqueous solution and with the aid of paper chromatography. The new *N*-chloroethyl derivatives *(3)* (R′ = CH_2CH_2Cl) and *(6)* exhibited interesting cytostatic properties in animal experiments. Since *(6)* contains no *N,N*-bis(chloroethyl)amine group, and so is not a nitrogen mustard, this compound embodies a new cytostatic principle with latent action.

Radiochemical Investigation of the Fission of the Bismuth Nucleus with High-Energy Protons [1]

By *K. Bächmann*[*] and *J. B. Cumming*[**]

Thin bismuth targets were bombarded with 2.2 GeV protons (Cosmotron, Brookhaven) and the recoil products were caught in thin Mylar films; the differential range curves for ^{128}Ba, ^{131}Ba, ^{100}Pd, ^{101}Pd, ^{103}Pd, ^{109}Pd, ^{112}Pd, ^{82}Sr, ^{83}Sr, ^{89}Sr, ^{91}Sr, ^{61}Cu, ^{64}Cu, and ^{67}Cu could be determined by measurement of activity at angles of 15°, 19°, and 165° to the direction of the proton beam. The range curves were converted into energy curves by means of a range-energy relation. The angular distributions were also measured for these nuclides.

The energies of the neutron-deficient fragments are only about half as great as those of the neutron-excess fragments. The energy distribution curves of the neutron-poor nuclides are broader and asymmetric. This result leads to the conclusion that neutron-excess and neutron-deficient products are formed in different ways.

This conclusion is supported by the angular distributions. Neutron-deficient nuclides exhibit isotropic distribution in the moving system, whereas neutron-excess nuclides exhibit a maximum angle of 90° to the direction of the proton beam.

Analysis of these results by Monte Carlo calculations based on the two-step model[2] showed that this model (contrary to earlier belief) is also applicable to neutron-deficient

nuclides and that fragmentation cannot be proved. The neutron-deficient products are probably formed after the evaporation of many small particles from highly excited primary nuclei, whereas the neutron-excess products are formed from primary nuclei in a low state of excitation by a process comparable to low-energy fission.

Compound Formation in Ternary Metal(II)oxide, Phosphorus(V)Oxide, and Boron(III) Oxide Systems

By *H. Bauer*[*]

Though many mineral and synthetic borate silicates are known, borate phosphates were unknown until recently. We have systematically investigated compound formation in systems of the type $MO/P_2O_5/B_2O_3$[1].

The systems with M = Mg, Mn, Co, Ni, Zn, and Cd were found to contain $6MO \cdot P_2O_5 \cdot B_2O_3$, which are best prepared by thermal reaction of orthophosphate $3MO \cdot P_2O_5$ with orthoborate $3MO \cdot B_2O_3$ (molar ratio 1:1), slightly below the melting point of the compound formed. The compounds are isostructural and crystallize in the hexagonal system with lattice constants between $a_0 = 8.42$ and $c_0 = 12.40$ Å for the nickel compound and $a_0 = 8.82$ and $c_0 = 13.23$ Å for the cadmium compound.

Several compounds exist in the systems with M = Ca, Sr, and Ba:

1) Isostructural compounds $2\,MO \cdot P_2O_5 \cdot B_2O_3$, which crystallize in the hexagonal system[2].

2) Compounds of orthophosphate and orthoborate with a homogeneity range extending from a molar ratio of 1:1 toward the borate side; the powder diagrams are very similar to those of the above-mentioned compounds $6\,MO \cdot P_2O_5 \cdot B_2O$.

3) Phases with a larger homogeneity range and an apatite structure[3].

In the system $PbO/P_2O_5/B_2O_3$ we found $2\,PbO \cdot P_2O_5 \cdot B_2O_3$, which is isostructural with the compounds named under 1), and a phase having an apatite structure, as well as $2PbO \cdot P_2O_5 \cdot 1/3B_2O_3$ and $8PbO \cdot P_2O_5 \cdot B_2O_3$ ($6\,PbO \cdot P_2O_5 \cdot B_2O_3$ could not be obtained).

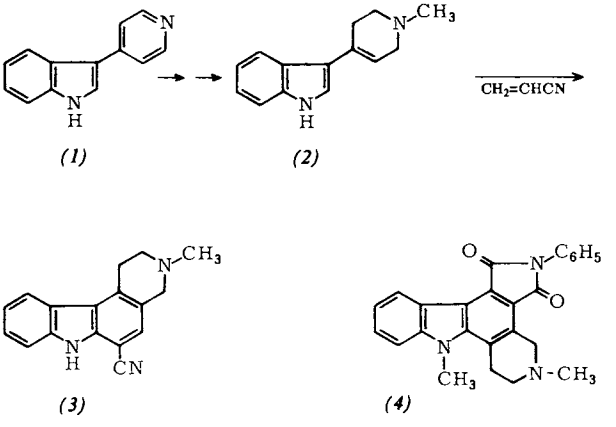
Some Aromatic Complexes of the Transuranium Elements

By *F. Bäumgartner, E. O. Fischer, B. Kanellakopulos*, and *P. Laubereau*[*]

The following aromatic complexes of the transuranium elements have so far been obtained: $Np(C_5H_5)_3Cl$; $Pu(C_5H_5)_3$ and $Am(C_5H_5)_3$.

These are all sublimable, benzene-soluble substances, which are sensitive to oxygen. The plutonium compound is pyrophoric. The complexes can be synthesized by double decomposition of the corresponding chlorides with $Be(C_5H_5)_2$ in the melt at 70 °C.

The magnetic susceptibilities were measured from 4.2 °K upward.



IR spectrometric studies indicate that, in contrast to the behavior of the corresponding lanthanide compounds, the ionic bond character increases with increasing atomic number.

Electrophoretic Painting on the Rotating Disk Electrode

By *F. Beck*[*]

Electrophoretic painting is widely used nowadays. An anionic binder is very often deposited on an iron electrode from aqueous solution or dispersion. The binder particles are transported from the interior of the bath by convection, and in the diffusion layer in front of the electrode by transport and diffusion. During electrolysis, the binder anions $P^{n\ominus}$ coagulate and their charge disappears. It remains to determine whether the charge is transferred directly to the anode or whether it is indirectly neutralized by the cations such as H^+ or Fe^{2+} formed in secondary electrolytic processes.

The Lewitsch rotating disk electrode has proved a valuable aid to the investigation of the primary processes in electrophoretic painting. Films are deposited on Fe and Pt anodes under galvanostatic conditions ($j = 1-6$ mA/cm²) from an aqueous solution of an acrylate-based model binder with an acrylic acid content of 10%. The start of deposition can be recognized by a sharp increase in voltage.

When the rotation speed exceeds a certain limit n_{lim}, no further deposition is observed. The limiting speed increases with the square of the current density j. The value of n_{lim} decreases with increasing degree of neutralization; this can be quantitatively interpreted by the diffusion of free amine. The critical hydrogen ion concentration is calculated to be about 10^{-4} mole/l. The values of n_{lim} pass through a maximum as the content of organic solvents is increased. The increase in n_{lim} is due to a decrease in the dissociation constant of the polyacid, and the decrease to the increasing solubility of the polyacid in the solvent. If the acrylic acid content of the binder is increased, n_{lim} decreases because of the increasing solubility of the binder in water. n_{lim} increases rapidly at low and high binder concentrations. The addition of foreign electrolytes leads to a decrease in the limiting speed, since the more mobile foreign anion reduces the transport of the polymeric anion in the boundary layer.

The very long induction periods required close to the limiting speed are explained by nucleation processes and viscosity increases in the diffusion layer.

The experimental results are in agreement with the view[1] that the binder coagulates in an acidic boundary layer in front of the anode. Protons are injected at the phase boundary by electrolytic processes such as the decomposition of water.

Isotope Concentration by Countercurrent Electrolysis at High Electrolyte Concentrations with the Aid of Separating Columns having Capillary Properties[1]

By *B. A. Bilal* and *K. Wagener*[*]

In separations by countercurrent electrolysis, the relationship between the total separation factor Q of a separating column, the elementary separation factor $1 + \varepsilon$ of the process, and the number of theoretical plates n in the column is given by

$$Q = (1 + \varepsilon)^n$$

A high separation factor in the separation of isotopes is therefore achieved by increasing the elementary effect ε (in this case the relative difference in the rate of migration of the ions $\Delta u/\bar{u}$) and by increasing the number of plates n.

The use of high electrolyte concentrations offers a possibility of significantly increasing the elementary effect. Complex-formation equilibria in the homogeneous phase can sometimes lead to large isotope effects between two chemical states of the element in question, which differ in charge, and can therefore be utilized for isotope separation by ion migration.

In a separating column with a given maximum cooling performance N_{max}, the field strength E to be applied must be reduced with increasing specific conductivity $\varkappa$ of the electrolyte in accordance with the equation

$$E_{max} = (N_{max}/\varkappa)^{1/2}$$

Consequently, a lower flow speed (v_L) along the column must be used in order to maintain the steady state condition

$$E \cdot \bar{u} + v_L = 0$$

required for the countercurrent electrolysis. ($\bar{u}$ = mean mobility of the two isotopes.)

For a column of length X, the relationship

$$n = X\, v_L/D_{eff}$$

(D_{eff} = effective diffusion coefficient of the ions in the solution in the longitudinal direction of the column).

is valid in the ultimate separation state. This relationship shows that the use of high electrolyte concentrations results in an unavoidable decrease in the number of theoretical plates. This disadvantage was overcome by development of columns with a high specific cooling power, in which the separation takes place in capillaries. In these columns the number of theoretical plates was increased, not only by the use of higher flow rates, but also by the fact that smaller values of D_{eff} were obtained in the capillary spaces.

We developed two types of column. In the first the separating space takes the form of a thread of liquid inside a capillary, while in the second (to increase the throughput) it is a capillary layer of liquid between two externally cooled parallel plates, arranged vertically and open at the top.

Using these two types of column we obtained a fast separation of ^7Li in 0.5 N CH_3COOLi solution. The ε value calculated from the slope of the concentration curve is an order of magnitude higher than that in a 0.05 N CH_3COOLi solution.

Stable Triarylhydrazyls Containing no Nitro Groups

By *D. Braun* and *G. Peschk*[*]

Triarylhydrazyls containing nitro groups, such as α,α-diphenyl-β-picrylhydrazyl *(1)*, are among the most stable nitrogen radicals known. On the other hand, apart from the unstable triphenylhydrazyl, which exists mainly as the dimer, triarylhydrazyls containing no nitro groups were unknown until now.

Stable triarylhydrazyls can also be obtained when ester groups are incorporated instead of the nitro groups in *(1)*. Trimethyl 2-(2,2-diphenylhydrazino)trimesate is prepared by reaction of an excess of α,α-diphenylhydrazine with trimethyl 2-fluorotrimesate in ether (lemon-yellow crystals, m.p. 155–156 °C). When a solution of this product in benzene is shaken for several hours with a tenfold excess of active lead dioxide in the absence of air, the hydrazyl *(2)* is obtained as a black crystalline substance (m.p. 152 °C) having a metallic luster. A solution of the radical in benzene gives an ESR spectrum with 7 lines.

Hydrazyls with no nitrogroups are of particular interest as free-radical interceptors and as inhibitors for radical-initiated polymerization reactions. Unlike *(1)*, they contain no retarding substituents, which make it impossible in inhibition experiments to distinguish between a reaction involving the radical function of the molecule and one involving the nitro groups. For example, the free-radical polymerization of styrene is completely inhibited in the induction period by *(2)* [but not by *(1)*] until all the hydrazyl radicals have been consumed. The subsequent polymerization is no longer

(1) R = NO_2
(2) R = $COOCH_3$

influenced by *(2)*, whereas *(1)* or some other polynitro compound strongly retards the polymerization after the induction period.

Stable Nitroaryllithium Compounds

By *P. Buck* and *G. Köbrich* [*]

Halogen-metal exchange on nitrobromoaromatic compounds proceeds satisfactorily only at low temperatures (about −100 °C) and in THF. Higher temperatures and less polar solvents favor the oxidation of the lithium compound by the nitro group. Owing to the purely inductive promotion of the halogen-metal exchange by the nitro group, the best yields of nitroaryllithium compounds are obtained with *o*-substituted nitrobromoaromatic compounds, *e.g.* 97% of *o*-nitrophenyllithium from *o*-nitrobromobenzene and phenyllithium, and 92% of 2-methyl-6-nitrophenyllithium from 2-bromo-3-nitrotoluene.

With a bromine *m* or *p* to the nitro group, halogen-metal exchange is suppressed considerably in favor of the redox reaction. No lithium compound can be detected (by carboxylation) in the reaction product obtained from *p*-nitrobromobenzene.

A further competitive reaction in the case of di- and trinitroaromatic compounds is addition to the aromatic ring, but up to 25% of 2,4-dinitrobenzoic acid can still be obtained (after carboxylation) from 2,4-dinitrobromobenzene and a maximum of 9% of 2,4,6-trinitrobenzoic acid from picryl bromide. If the nitro groups are prevented from becoming coplanar with one another and with the ring, halogen-metal exchange is promoted (see Table for yields of the carboxylic acids formed).

	R^1	R^3	R^3	R^4	R^5	Yield (%)
(1)	NO_2	H	NO_2	CH_3	H	63–77
(2)	NO_2	CH_3	NO_2	H	H	82–85
(3)	H	NO_2	CH_3	NO_2	H	41
(4)	NO_2	H	H	H	NO_2	61–67
(5)	NO_2	Br	H	Br	NO_2	63
(6)	NO_2	Br	NO_2	Br	NO_2	80–85

The reaction of *(6)* with an excess of phenyllithium yields 1,3,5-trinitro-2,4,6-trilithiumbenzene together with 2,4,6-trinitro-3,5-dilithiumbiphenyl.

Nitroaryllithium compounds are stable only at low temperatures. They dimerize on warming and can be converted in good yields into 2,2′-dinitrobiphenyl derivatives after oxidation with methyl chloroformate. The linkage point is the carbon atom that formerly carried the metal.

Structural Analysis of Polymers in Solution

By *H.-J. Cantow* [*]

Various columns (one for use on the microscale) were developed to permit the continuous fractionation of polymers on the basis of differences in solubility. The change in the quality of the solvent with time is achieved by temperature programming, working with *one* critical solvent. The polymer concentration in the eluate is recorded refractometrically [1]. The columns may be combined with a continuously recording apparatus for the measurement of the scattered light so that the molecular weight distribution curve is recorded simultaneously with the separation process. In a pseudo-ideal solvent, the molecular weight can be measured directly by means of a special optical-electronic arrangement, even when intraparticle interference occurs [1].

In the case of copolymers, the mass concentration can be determined refractometrically and the chemical composition of the system UV-spectroscopically. Gel-permeation chromatographic studies [2] have been carried out on block copolymers of the type A–B–A and the corresponding homopolymers (styrene-butadiene system).

The significance of the turbidimetric titration in the determination of the molecular-weight distribution and the chemical heterogeneity of polymers is discussed. Dissolution titration [3] is superior to conventional precipitation titration, since time-dependent retardation effects are practically eliminated.

First attempts to obtain turbidity curves in a temperature gradient using a critical solvent showed that the process, which has a good separating efficiency, is suitable for use as a fast method [4]. The turbidity gradient that is rapidly established may be related to the molecular-weight distribution.

The sequence-length distribution in copolymers, particularly in the methyl methacrylate-methacrylic acid system, was investigated by high-resolution nuclear magnetic resonance spectroscopy. Combined studies on polymers obtained by copolymerization and by partial hydrolysis of polymethyl methacrylates facilitate the interpretation of the spectra, in which the resonances due to 'chemical' sequences and those due to 'configurative' sequences overlap [5].

Finally, the incompatibility of polymers was studied by measurement of the light scattering from ternary polymer-polymer-solvent systems and by determination of the turbidity point of such systems. If one polymer and the solvent are isorefractive components, the second virial coefficient of the osmotic pressure of the other polymer is a measure of the incompatibility of the two polymers. The dependence of the Θ point on the molecular weight of the polymer that is isorefractive with the solvent is discussed, as well as its temperature-dependence. The turbidity point determinations permit the prediction of the compatibility limits (of polystyrene and polymethyl methacrylate in the case in question), even in the solid state. [6]

Measurement of Heats of Adsorption on the Surfaces of Single Crystals with the Field Electron Microscope

By *M. Drechsler* [*]

Heats of adsorption on the surfaces of single crystals can be experimentally determined with the aid of the Clausius-Clapeyron equation if the pressure, temperature, and emission current are measured with a special field electron microscope, as has been shown by a preliminary measurement [1].

The method has been improved to permit more accurate and systematic measurement. 1. The electrons emitted from the surface of a single crystal are now stopped down and measured directly, 2. the partial pressure in the adsorption equilibrium between 10^{-5} and 10^{-8} mm Hg is determined with a mass spectrometer, and 3. an improved ultrahigh vacuum technique is used, the partial pressure of the impurities being less than 2×10^{-11} mm Hg. For hydrogen on tungsten, the differential heat of adsorption on several faces of the single crystal has been determined as a function of the degree of coverage. The value *e.g.* for the (122) face is 15 kcal/mole for a coverage $\theta = 0.1$ and for the (001) face a value was obtained of 4 kcal/mole at a coverage of $\theta = 0.8$.

Spectrophotometric Studies on the Hydrolysis and Complex Formation of the Plutonyl and Neptunyl Ions

By *S. H. Eberle*, *J. B. Schäfer*, and *W. Robel*[*]

The absorption spectra of pentavalent neptunium and of hexavalent plutonium both show an extremely sharp and intense line such as is rarely found for other elements. The extinction of this line changes on complex formation or chelation and on hydrolysis, *i.e.* when the central atom forms coordinate bonds; in many cases new absorption maxima also appear. This phenomenon was used to follow quantitatively the reaction of the two transuranium ions with aliphatic α-hydroxycarboxylic acids and pyridinecarboxylic acids.

Extinction measurements with variation of the pH value of the solution demonstrate the formation of the compounds $Pu^{VI}O_2L^+$, $Pu^{VI}O_2L_2$ and $Np^{V}O_2L$ (L = anion of the acid). In the series of acids $C_nH_{2n}(OH)COOH$, the stability increases with increasing chain length; the chelates with pyridine-α-carboxylic acid are still more stable. The course of hydrolysis is also recognizable from the spectrum; it begins at pH = 7 for the neptunyl(v) ion and at pH = 4 for the plutonyl(vi) ion. The results were evaluated quantitatively by least-squares calculations on a computer. The principles of measurement and evaluation appear to be generally applicable to the study of the complex formation of both ions.

The Binding of Water in Crystalline Zeolites

By *G. Ebert*, *W. Matron*, and *F. H. Müller*[*]

In dielectric studies on Linde molecular sieves (LMS) 3A, 4A, and 13X[1] between 300 Hz and 400 kHz, −190 to +90 °C, and 0 to 215 mg of water/g of LMS, three Debye-type dispersion regions[2] were found. The behavior described by us as a β-relaxation process occurs between 300 Hz and 400 kHz in LMS 3A at −60 to +20 °C. The α process is observed at temperatures about 100 °C higher. The β mechanism appears in a very similar manner with LMS 4A and 13X. It is largely independent of the crystal structure and of the water content. The ε′- or ε″-ω curves[3] simply undergo a parallel displacement toward the frequency axis with increasing water content (at the same temperature). The Cole arcs are largely independent of temperature in the β process. For example, between −60 and −20 °C one obtains a single circular arc, the center of which (in contrast to the results for ice and liquid water) lies far below the abscissa, thus indicating a broad relaxation time distribution. The activation energy for 4A and 13X, unlike that of γ-Al_2O_3 or silica gel, increases rapidly with the water content.

We assume that the β process is due to transport of water molecules between the cages. This process is hindered as more water is added, since the additional H_2O molecules, owing to the small size of the cages (maximum 13 Å), couple the H_2O molecules present with the cage wall, with the result that their mobility is energetically and sterically hindered. The largest cages can accommodate 28 H_2O molecules. On the other hand, the clusters of liquid, unadsorbed water contain > 100 H_2O molecules. The transfer of H_2O molecules between the cages is greatly restricted by the very narrow pores (2.5, 4.2, and 8 to 9 Å for LMS 3A, 4A, and 13X, respectively).

In the case of LMS 3A, the activation energy is constant (15 kcal/mole) up to a water content of about 100 mg/g, and only then begins to increase. This is evidently due to the $K^{\oplus}$ present in LMS 3A.

In the α process, ε′ and ε″ increase rapidly with the water content. This relaxation region is probably connected with interchange of sites by ion pairs. The γ process seems to result from the re-orientation of mobile H_2O molecules in the interior of the cages.

As expected no dielectric hysteresis of the ε′- and ε″-temperature curves was observed, such as is found with γ-Al_2O_3 which has much larger cavities.

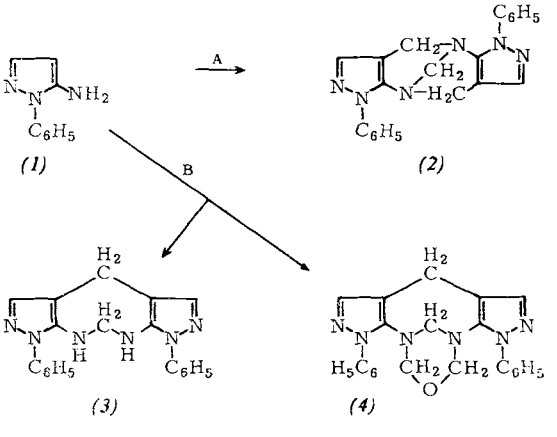
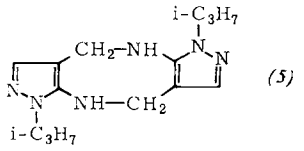
[1] These molecular sieves are zeolites pretreated at 300 °C. Manufacturer: Union Carbide Corporation.



[2] We term these α-, β-, and γ-process, the α-process being the slowest and the γ-process the fastest.

[3] ε′, ε″, and ω are the real and the imaginary part of the complex dielectric constants and the circular frequency.



Reactions of Heterocyclic Amines with Formaldehyde

By *K. Eichenberger*, *F. A. Stuber*, and *P. Schmidt*[*]

The reaction of 1-phenyl-5-aminopyrazole *(1)* with paraformaldehyde in sulfuric acid yields a polycyclic ring system *(2)* of the Tröger base type (path A). If the reaction is carried out in formic acid and formalin, *(3)* and *(4)* are formed (path B).

If the phenyl group is replaced by an isopropyl group, the isopropyl derivative corresponding to *(3)* is formed in formic acid and formalin, whereas with paraformaldehyde in sulfuric acid, the bis-fused eight-membered ring *(5)* is obtained along with the isopropyl compound corresponding to *(2)* as by-product.

(5)

The structures of the compounds obtained were established mainly by NMR spectroscopy.

The Gas-Chromatographic and Spectrophotometric Investigation of Essences

By *H. Farnow* and *E. Klein*[*]

The IR spectra of the juniper oils of *J. communis, phoenica,* and *macropoda* show characteristic differences in some band intensities, which permit the identification of the only one that is of interest in the production of essences, *i.e.* that of *J. communis*. The gas-chromatographic examination of the monoterpene fraction of these oils (58% for *J. communis*, 88% for *J. phoenica*, and 65% for *J. macropoda*) leads to the same result.

Oil of anise, which is obtained from the fruit of the evergreen tree *Illicum verum* Hooker f., consists of about 90% of *trans*-anethole, about 5% of limonene, about 1% of linalool, and about 20 other substances. The IR spectrum differs from that of anethole only in the presence of three weak bands.

For the gas-chromatographic examination of oil of anise, the components that boil before the anethole were distilled off. The distillate was then finely fractionated under vacuum in a packed column 120 cm high, with constant gas-chromatographic control. If individual components still could not be isolated, a preparative gas chromatograph was used. The maxima in the first gas chromatogram could be assigned after the isolated substances had been identified.

The gas chromatograms and IR spectra of Italian and Californian lemon oils are so similar that they are insufficient as a criterion of source. The UV spectrum is useful in this case. The extinction of a solution of 0.25 g of oil in 100 ml of 96% alcohol is measured between 400 and 270 nm. The CD value (distance between the maximum at 315 nm and the tangents to the branches of the curve at about 370 and 285 nm) is found from the curve; the values are about 0.60 extinction units for Italian lemon oils and 0.30 for Californian oils. The absorption at 315 nm is mainly due to citraptene, a coumarin derivative.

The components of essences belong to many classes of substances, and their number is usually large. Several methods are now available for taking into account the characteristic properties of the components in the evaluation of gas chromatograms: determination of area factors; construction of a calibration curve; and the use of an internal standard. The first two procedures presuppose that every component of the mixture is known, that it can be detected quantitatively, and that it is available in a sufficiently pure state. These conditions are generally not satisfied in multicomponent mixtures. The use of an internal standard fails because of the large number of components present.

The investigation of two test mixtures of terpene hydrocarbons and of terpene hydrocarbons with derivatives containing oxygen gave relative errors of 0 to ± 50%. The reproducibility was generally good.

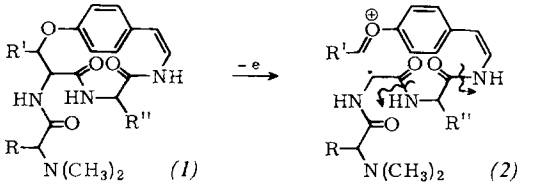
Mass-Spectrometric Determination of the Structure of Peptide Alkaloids from Rhamnaceae

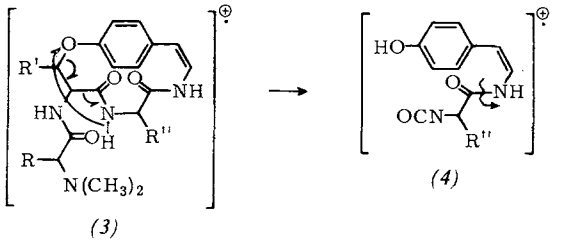
By *H.-W. Fehlhaber*[*]



The fragmentation of peptide alkaloids of the type *(1)* on electron impact is substantially independent of the nature of the amino acid residues R, R′, and R″. The most important degradation reactions are a)–d).

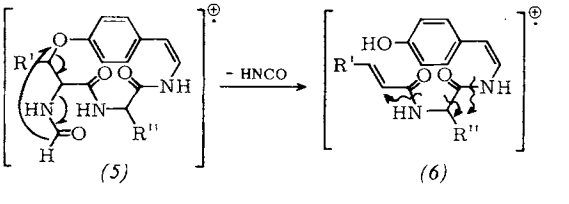
a) Cleavage of the C–C bonds adjacent to the dimethylamino group leads to the ions $[M-R]^{\oplus}$ and $R-CH=\overset{\oplus}{N}(CH_3)_2$ (= *m/e* [57 + R]).

b) The cleavage of the 14-membered ring in accordance with *(2)* and subsequent cleavage at the amide groups with concomitant hydrogen shift lead to the fragment-ions



$R'-CH=\overset{\oplus}{O}-C_6H_4-CH=CH-NH-CO-CH(R'')-NH_2$ (= *m/e* [203 + R′ + R″]) and

$R'-CH=\overset{\oplus}{O}-C_6H_4-CH=CH-NH_2$ (= *m/e* [147 + R′]).



(1) (2)

c) The ring can also be cleaved, *e.g.* as formulated in *(3)*, by the typical decomposition accompanied by a hydrogen shift observed for phenol ethers, giving the fragment-ion *(4)* (*m/e* [217 + R″]). The fragment $[HO-C_6H_4-CH=CH-NH_2]^{\oplus}$ (= *m/e* 135) is also formed.

(3) (4)

d) Stepwise degradation of the side chain yields ions *(5)* (= *m/e* [287 + R′ + R″]) and *(6)* (= *m/e* [244 + R′ + R″]). *(6)* decomposes further into $R'-CH=CH-C\equiv O^{\oplus}$ (= *m/e* [54 + R′]), R′–CH=CH–CO–NH=CHR″ (= *m/e* [82 + R′ + R″]), and R′–CH=CH–CO–NH–CH(R″)–$C\equiv O^{\oplus}$ (= *m/e* [110 + R′ + R″]).

(5) (6)

The number of fragments is sufficiently large to permit a fast and definite assignment of the basic skeleton and the determination of the amino acid residues R, R′, and R″ for compounds of the type *(1)*. The method has so far been successfully used for six alkaloids.

Anodic Behavior of Nickel in Aqueous Solution

By *E. Flechsig* [*]

Current density-potential curves were measured potentiostatically on nickel surfaces; the course of the curve depends much more strongly on the preparation of the surface than was formerly thought. This may explain the lack of agreement among published results. In particular, the occurrence of several current density maxima at potentials below the passivation potential and the puzzling acceleration of the dissolution of nickel by sulfate ions [1] must be attributed to oxide or Beilby layers formed on the surface during processing. Such layers dissolve only with great difficulty or not at all in acidic solution, as is shown by optical and electron-microscope studies.

For clean surfaces, the anodic dissolution of the metal, like the deposition of hydrogen, can be represented as a Tafel slope. It can be concluded that the rate-determining step in the dissolution of nickel is a charge transfer reaction. The highest current density that could be reached below the passivation potential was about 400 mA/cm³ at 25 °C and pH = 0.3, *i.e.* appreciably higher than the values reported so far. This corresponds to the values obtained for iron under comparable conditions. Passivation of the nickel took place over a narrow range of potentials and proceeded very rapidly. The potential of the steep decrease in current density and the current density maximum were pH-dependent, whereas the Tafel slope was not. At 25 °C, the passivation potential changes by 90 mV/pH unit; the value accepted until now was 58 mV/pH unit. It must be concluded from these results that earlier views concerning the passivation mechanism are not entirely correct. The following reaction is proposed as the decisive process in the formation of a passive layer:

$$Ni + 2\,H_2O \rightleftharpoons HNiO_2^- + 3\,H^+ + 2\,e$$

The $HNiO_2^-$ ions, as a monatomic adsorption layer, could strongly hinder the dissolution of the nickel.

Kinetics of the Extraction of Plutonium(IV) and of Uranium(VI) in the Purex Process

By *L. Finsterwalder* and *F. Baumgärtner* [*]

The most important reprocessing technique for irradiated nuclear fuel elements is liquid-liquid extraction with tributyl phosphate in the Purex process. Using the drop method, we tried to get a better understanding of the processes involved in the mass transfer of Pu(IV) and U(VI) across the boundary between the organic and the aqueous phases.

In the drop method, which was first used by *J. M. Coulsan* and *S. J. Skinner,* and was later improved by *W. Nitsch,* the rate of transfer of material from a stationary phase into the drops of the other phase is measured.

At 25 °C we obtained reaction orders of 1.28, 1.16, and 1.03 for the transfer of uranium from an aqueous solution which was 3 N in HNO_3 into an organic phase containing 20, 10, and 5 wt-%, respectively, of TBP. A reaction order of 1.0 was obtained for plutonium, The rate of transfer of Pu(IV) and U(VI) was found to vary linearly with the nitrate concentration.

The transfer rates into the organic phase decrease in the order U, Pu, HNO_3, while for back-extraction into the aqueous phase they increase in the order U, Pu, HNO_3. This explains the displacement effects of the three substances.

New Peroxotungstates

By *J. Fuchs* and *J. Kurzidim* [*]

The peroxotungstates $b_2O{\cdot}WO_3{\cdot}4O_{act}{\cdot}aq$ *(1)* (b = monovalent cation, aq = water) and $b_2O{\cdot}2WO_3{\cdot}4O_{act}{\cdot}aq$ *(2)*, which can be obtained from aqueous solution, are already known. The question of whether salts of peroxidized polytungstic acids can also be prepared has until now been strongly disputed.

Other peroxotungstates have now been prepared by hydrolysis of tetramethyl tungstate(VI) in ethanol with 85% hydrogen peroxide in the presence of bases. They have the analytical composition $b_2O{\cdot}WO_3{\cdot}2O_{act}{\cdot}aq$ *(3)*, $3b_2O{\cdot}6WO_3{\cdot}10O_{act}{\cdot}aq$ *(4)*, $5b_2O{\cdot}12WO_3{\cdot}20O_{act}{\cdot}aq$ *(5)*, and $b_2O{\cdot}4WO_3{\cdot}4O_{act}{\cdot}aq$ *(6)*.

Potassium hydroxide, ammonia, piperidine, pyridine, quinoline, diethylamine, and triethylamine are examples of bases used. The type of compound formed in all cases depends on the concentration of the reaction components, the temperature, the p*K* value of the base, and possibly the steric structure of the base.

The IR spectra of compound types *(4)–(6)* are very similar in the region of the W–O vibrations; it may therefore be concluded that the structures of their polyanions are very similar. Results of ultracentrifugation indicate that aqueous solutions of the potassium salts of the types *(4)* and *(5)* contain hexameric anions. Proton magnetic resonance measurements show that the salts of these types contain both water of crystallization and OH (possibly O–OH) groups.

According to these findings, the following formulations are probably correct for *(4)–(6)*: $b_6[H_2W_6O_{32}]{\cdot}n\,H_2O$ *(4)*; $b_5[H_3W_6O_{32}]{\cdot}n\,H_2O$ *(5)*; and $b_3[H_5W_6O_{28}]{\cdot}n\,H_2O$ *(6)*.

Annealing of $K_5[H_3W_6O_{32}]{\cdot}9H_2O$ at temperatures up to 200 °C yields the peroxide-free potassium paratungstate B (intermediate of the potassium paratungstate A and Z), which was recently obtained for the first time by *K. F. Jahr, J. Fuchs,* and *E. P. Flindt* by hydrolysis of esters of tungstic acid in the presence of potassium acetate.

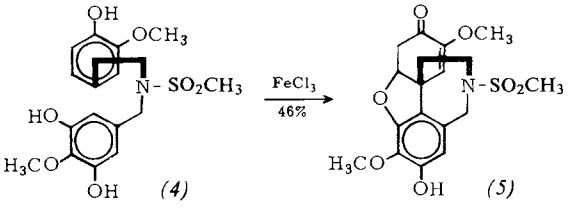
Synthesis of Alkaloid Skeletons by Biogenetic-type Ring Closure

By *B. Franck, H. I. Lubs,* and *G. Dunkelmann* [*]



Morphine and galanthamine are the principal members of two important groups of alkaloids, whose skeletons are formed in the plant cell by oxidative condensation of phenolic precursors. The biosynthesis has now been successfully imitated on the preparative scale by prevention of polymerization and of side reactions on the nitrogen. Thus the oxidation of reticuline *(1)*, the biosynthetic precursor of the morphine alkaloids, with MnO_2/thin-layer silica gel 1:3 in $CHCl_3$ led for the first time to the isolation of a morphinan derivative *(2)* as the crystalline monoacetate (m.p. 203 °C). Like morphine, *(2)* can undergo proton-catalysed rearrangement into an apomorphine derivative *(3)*.

The additional adsorption surface presented in the form of the silica gel during the oxidation keeps the concentration of reticuline molecules on the MnO_2 particles low, thus substan-

tially preventing intermolecular condensation. This two-dimensional or heterogeneous variant of the Ziegler dilution principle also plays a part in enzymatic reactions.

The *N*-benzylphenylethylamine derivative *(4)*, in which the nitrogen is protected by a methylsulfonyl group, undergoes double ring closure on oxidation with aqueous $FeCl_3$ to give a 46% yield of the crystalline condensation product *(5)* (m.p. 239 °C) having the complete galanthamine ring skeleton.

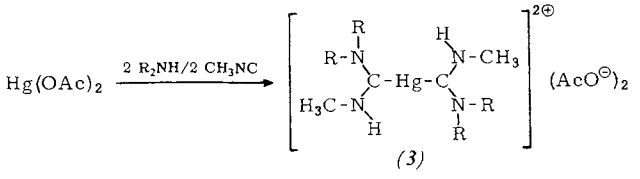
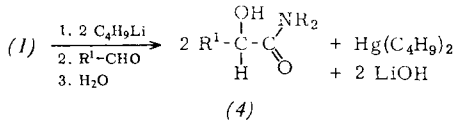
Synthesis and Reactions of Stable Mercury-Carbene Complexes

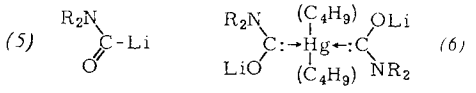


By *U. Schöllkopf* and *F. Gerhart* [*]

Stable carbene-metal complexes[1] have until now always been prepared from metal π-carbonyls. We have now examined the possibility of preparing carbene complexes from σ-carbonylmetal compounds.



Bis(dialkylcarbamoyl)mercury compounds *(1)* [2], which can be prepared from mercury acetate, secondary amines, and CO, give stable adducts with strong protonic acids (100% H_2SO_4, 100% $HClO_4$) or with trialkyloxonium fluoroborates *(2)* [3].



When $R^1 \neq R^2$, three stable, isolable isomers are obtained. Adducts *(3)* of diaminocarbenes are obtained directly from mercury acetate, secondary amines, and methyl isocyanide.

We attempted to prepare anionic carbene adducts from *(1)* and two moles of n-butyllithium. The reaction at −78 °C in tetrahydrofuran yields intensely yellow solutions, which readily give carbamoyl adducts such as *(4)* on treatment with acid chlorides, aldehydes, and ketones [4].

It is not yet possible to decide whether free carbamoyllithium *(5)* or a dialkylaminolithiumoxycarbene complex *(6)* functions as the reactive species.

(5) or *(6)* is the only known reagent suitable for the direct nucleophilic introduction of a carbonyl group into polar substrates [5].

Behavior of Lactones Under Pressures of 20–24 kbar: A Model Reaction for the Formation of Petroleum

By *W. Glet* and *F. Korte* [*]

γ-Butyrolactone can be homopolymerized at 20–24 kbar [1] to give a polyester [2]. On the other hand, the polymerization of the more stable [3] alkyl-substituted γ- and δ-lactones at 20–24 kbar and 150–200 °C generally proceeds with elimination of water and carbon dioxide to form highly branched hydrocarbons. The ease with which the reaction takes place increases with the proximity of the alkyl group to the ring oxygen atom. Thus δ-caprolactone is simply decarboxylated, whereas the reaction of β-methyl-δ-valerolactone results mainly in polyester formation, together with slight decarboxylation. Both cases presumably involve competitive reactions. The decarboxylation may be favored because it is irreversible. However, the deciding factor is probably the nature of the lactone ring cleavage. Alkyl cleavage leads to decarboxylation, whereas acyl cleavage leads to polyester formation. The ring cleavage is influenced by the substituents, the strength of the influence depending on their position [4,5].

α,α-Dimethyl-δ-valerolactone gives polyester only, while α,α-dimethyl-γ-butyrolactone does not react at all. α-Methyl-γ-butyrolactone, on the other hand, is decarboxylated. It may be concluded from this behavior that decarboxylation cannot take place if the α position is blocked.

The proposed reaction scheme

is supported by the following observations:

1) The first step is supported by the fact that decarboxylation is favored by bases and inhibited by acids.

2) According to the scheme, an ω-hydroxy-α-acyllactone *(1)* is formed as an intermediate. α-Acyllactones give first poly-β-oxo acids, which are rapidly decarboxylated under normal pressure to form polyketones. Water is not formed from α-acyllactones when the OH group in *(1)* is not present. It is therefore possible that carbon dioxide is split off only at normal pressure, since water appears to play an important part in the removal of CO_2 at very high pressures.

α-Acyllactones exhibit a greater tendency toward alkyl cleavage than alkyllactones[4,5]. This facilitates the subsequent steps in the reaction and explains the relatively high reactivity of the α-acyllactones.

3) It is possible to prepare a polycondensation product from acetone that is very similar to those obtained from lactones. This is as might be expected from a comparison with the penultimate step of the scheme when $R^1 = R^2 = H$.

So far as we know, this is the first demonstration that carboxylic acids can be converted into hydrocarbons by pressures of 20–24 kbar at temperatures below 200 °C. Since petroleum does not appear to have reached temperatures higher than 200 °C during its formation[6], pressure could have played a part in its formation. The reaction of the lactones could be regarded as a model reaction for the formation of bituminous substances.

Investigations on the Biosynthesis of D-Apiose

By *H. Grisebach, H. Sandermann,* and *T. Tisue*[*]

Our investigations on the biosynthesis of D-apiose (3-*C*-hydroxymethyl-D-*erythro*-tetrose) in parsley with ^{14}C- and T-labeled precursors have shown that this sugar is formed from D-glucose by intramolecular rearrangement with expulsion of C-3; the C-6 of the glucose is lost[1]. An intermediate in this biosynthesis is D-glucuronic acid (possibly in the nucleotideactivated form), since this acid is specifically incorporated into the D-apiose of the glycoside apiin with loss of C-6[2].

In the transition D-glucose → D-apiose, an H atom migrates from the C-4 of glucose to the C-3′ of the apiose, as was shown with tritium-labeled glucose[1]. D-Apiose was detected in parsley in the UDP sugar fraction.

Incubation of ^{14}C–UDP-D-glucuronic acid with a protein fraction of acetone-dried powder from parsley, on addition of NaF or NaF + NAD, gave a new radioactive compound, from which radioactive D-apiose was obtained by hydrolysis.

Enzyme-Catalysed Changes in the Volatile Components of Peas

By *W. Grosch*[*]

Young freeze-dried green peas were extracted with water; after rough filtration, the extract was centrifuged at 17500 g and the supernatant liquid was freeze-dried. When the supernatant [dissolved in a phosphate buffer, pH = 6.5] was incubated aerobically at 15 °C with lipids isolated from peas[1], the typical aroma of peas in storage was evolved. The aroma that developed in the first hour gradually gave way to an unpleasant odor.

The following four fractions were vaporized under vacuum from the lipids emulsified in the buffer:

1. the compounds dissolved in the lipids; 2. the compounds formed during a 'blank incubation' (*i.e.* in the absence of supernatant); 3. the compounds adhering to the supernatant added to the emulsion; and 4. the compounds formed during incubation of the lipids for two hours with the supernatant. The third and fourth fractions were extracted with ether/pentane (2:1 v/v) and the extracts were analysed by gas chromatography and mass spectrometry. It was deduced from the results that hexanal, 2-heptenal, 2,4-heptadienal, pentanol, and 2-penten-1-ol (?) are formed in high concentrations and 2-pentenal, 2-hexenal, 3-pentanone, 3-octanone, 2-pentylfuran, and hexanol in low concentrations during the incubation at 15 °C.

Whitfield and *Shipton*[2] believe that the enzyme lipoxygenase (EC 1.13.1.13) is involved in the formation of carbonyl compounds during the storage of unblanched peas at −17.5 °C. Dialysis and precipitation with ammonium sulfate yielded a protein fraction[3] from freeze-dried peas in which the lipogenase and peroxidase activities (based on the dry weight) were 30 and 5 times as high, respectively, as in the peas themselves, and incubated the lipids aerobically for two hours at 15 °C with this preparation. The carbonyl compounds formed were isolated as the 2,4-dinitrophenylhydrazones and analysed. Result (in % of the total carbonyl compounds): n-alkanals C_2 (13), C_3(19), C_4(1), C_5(3), C_6(22), C_9(3); n-2-alkenals C_4(1.5), C_5(4.5), C_6(1.5), C_7(10), C_8(3), C_{9-11}(< 1); n-2,4-alkadienals C_7(3), C_9(< 1), C_{10}(2); acetone (6); unidentified (7).

According to *Bengtsson* and *Bosund*[1], 50% of the fatty acids of pea lipids consists of linoleic acid. Linoleic acid was therefore incubated with the enzyme preparation. Analysis of the volatile carbonyl compounds showed (%): n-alkanals

$C_5(5)$, $C_6(65)$, $C_9(11)$; n-2-alkenals $C_6(< 1)$, $C_7(9)$, $C_8(3.5)$; n-2,4-alkadienals $C_9(1)$, $C_{10}(4)$.

Gas-Chromatographic Investigation of Lemon Oils

By *H. Günther*[*]

A total of 19 commercial lemon oils were studied gas-chromatographically (gas chromatograph Perkin-Elmer 116, Überlingen). The substances found are: α-pinene, β-pinene, limonene, γ-terpinene, citronellal, α(?)-terpineol, neral, and geranial (= citral), neryl acetate, geranyl acetate, and β-bisabolene. Myrcene, geraniol, bergamotene, and caryophyllene are also present (but in some cases were not separated from the above substances). The substances could be quantitatively estimated by manual measurement of the areas (though cutting out and weighing of a photocopy[1] should be more accurate[2]), by planimetry, or by means of an integrator. However, it is advisable to construct calibration curves for each substance, since the detector deflections are not the same for all substances, and since the curves obtained are often nonlinear or are linear only up to a certain concentration[3]. The nature of the substances should be verified by IR spectra, since the substances may undergo partial or complete decomposition on the metal of the gas chromatograph. The substances must be obtained on preparative columns in quantities of 0.5 to 1 g and then examined in the IR instrument either between two KBr disks or between two NaCl windows. The usual method of admixture with two different columns can be regarded only as a provisional identification.

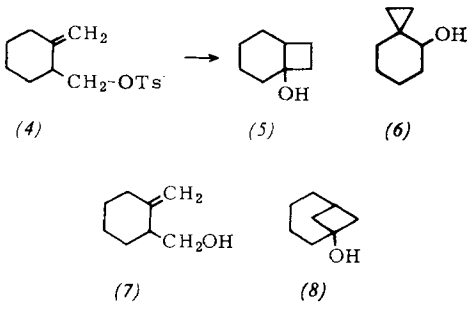
Rearrangements of Cyclic Homoallyl Compounds

By *M. Hanack*, *H. Schneider-Bernlöhr*, *H.-J. Schneider*, and *R. Hüttinger*[*]



Cyclic homoallyl derivatives *(1)* (X = OTs, NH_2) rearrange during carbenium ion reactions to form cyclopropane spiro compounds *(2)*, Z = OH, OCOR, and condensed cyclobutane compounds *(3)*, Z = OH, OCOR.

This isomerization, which was first observed with the cyclohexenylethyl system *(1)*, $n = 4$, has now been applied to larger rings. Cycloheptenyl-, cyclooctenyl-, and cyclononenylethyl compounds also form cyclopropane spiro compounds *(2)*, $n = 5$–7, and condensed cyclobutane derivatives *(3)*, $n = 5$–7. The systems *(2)*–*(3)*, which are partly known only as hydrocarbons, are obtainable on the preparative scale in this way.

(1) *(2)* *(3)*

Systems having both the double bond and the C atom carrying the functional group outside the ring also tend toward substantial rearrangements in carbenium ion reactions. For example, the hydrolysis of 2-methylenecyclohexylmethyl *p*-toluenesulfonate *(4)* yields a mixture of the alcohols *(5)*, *(6)*, and *(7)*, and another component, which is assigned the structure *(8)*.

Kinetics of the Oxidation of a Silver-Cadmium Alloy containing 51 Atom-% of Cd. A Contribution to the Hedvall Effect

By *K. Hardel*[*]

A Hedvall effect, *i.e.* the increased reactivity of a solid during a crystallographic transition is not to be expected if the reactants are separated by a layer of reaction product, and diffusion through this layer is the rate-determining process. A Hedvall effect is feasible, on the other hand, if in addition to this diffusion the counterdiffusion of another type of ion through the lattice of one of the reactants is rate-determining; the rate of the reaction then also depends on the structure of this reactant.

This situation can be realized in the internal oxidation of some alloys. The oxidation of the powdered silver-cadmium alloy containing 51 atom-% of Cd was therefore studied thermogravimetrically and with the aid of photomicrographs in oxygen at 1 atm and between 350 and 450 °C, *i.e.* above and below the transition point for the transition from the ζ-phase into the β-phase (430 °C).

Two reaction mechanisms were found to apply. In one range the linear law is valid and in a subsequent region the parabolic law is obeyed; in the latter the rate of oxidation is determined by the diffusion of oxygen through the inner oxidation zone and by the counterdiffusion of cadmium from the interior of the alloy. The rate constant of the parabolic time law changes steadily throughout the temperature range studied; the rate constant of the linear time law, on the other hand, decreases suddenly at the transition point. No abnormal increase in reactivity was observed at the transition point in either reaction and thus no Hedvall effect could be detected. The increase in the rate of oxidation of an alloy of the same composition in the vicinity of the transition point at 430 °C as reported by *Hedvall* and *Rosén*[1] is simply the result of the superposition of the reaction for which the linear time law is valid on the diffusion-controlled reaction.

Curium Oxides[1]

By *H. O. Haug*[*]

In the thermal decomposition of curium dioxide (see Fig. 1), a phase $CmO_{1.71}$ was formed at 650 °C in oxygen. The strong lines of the X-ray powder photographs were characteristic of the fluorite lattice, while additional weak lines showed a strong similarity to the lines of the rhombohedral oxides $PrO_{1.71}$ and $TbO_{1.71}$. As the temperature was raised (in air), the $CmO_{1.7}$ lost oxygen ('$CmO_{1.7-x}$ phase') and the lattice constants increased. Above 800 °C, two phases appeared in the powder diagrams: $CmO_{1.7-x}$ and monoclinic Cm_2O_3 (B form). Only the stronger lines of the $CmO_{1.7-x}$ phase, *i.e.* those characteristic of the fluorite lattice, could be observed. The higher the temperature to which the samples were heated, the greater was the quantity of monoclinic Cm_2O_3 formed, until at 1100–1200 °C only very small quantities of $CmO_{1.7-x}$ remained. The lattice constants of the monoclinic Cm_2O_3 phase remained constant between 800 and 1200 °C.

Cycli-alkylation with 1,4-Dihalo Compounds as a Convenient Way of Preparing Polycyclic Hydroaromatic Compounds

By *D. Hausigk*[*]

Partially hydrogenated aromatic hydrocarbons such as tetralin, symmetrical octahydrophenanthrene, and symmetrical octahydroanthracene react with 1,4-dichlorobutane in the presence of catalytic amounts of $AlCl_3$, and the reaction leads to an enlarged molecule. Thus, dodecahydrotriphenylene is formed from tetralin *via* the intermediates of the octahydro derivatives of phenanthrene and anthracene. Other partially hydrogenated hydrocarbons that still contain one aromatic ring with replaceable hydrogen atoms (*e.g.* hydroindene, decahydropyrene, and hexahydrofluorene) similarly react with 1,4-dichlorobutane, and the reaction leads to the incorporation of further ring systems. With aromatic hydrocarbons themselves (except benzene), the reaction proceeds in widely differing ways.

Some alkyl-substituted benzenes (except methyl-substituted ones) similarly give dodecahydrotriphenylene with 1,4-dichlorobutane under the cleaving action of $AlCl_3$.

Using 1,2-bis(bromomethyl)cyclohexane as an alkylating agent, one obtains from the partially hydrogenated aromatic compounds enlarged hydroaromatic compounds always comprising two condensed rings. Thus octahydrophenanthrene gives hexadecahydrodibenzo[a,c]anthracene. The resulting rings are *trans* to each other.

All polycyclic hydroaromatic compounds obtained by cycli-alkylation can be readily dehydrogenated into the corresponding aromatic hydrocarbons; the latter can therefore be prepared by this method easily and in good yields.

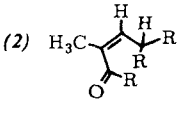
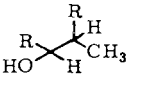
Etherification of Phorbol

By *G. Kreibich* and *E. Hecker*[*]



Phorbol is a tetracyclic polyfunctional diterpene[1]. Its diesters with one short-chain and one long-chain fatty acid exhibit strongly inflammatory properties. Phorbol is sensitive to heat, to acids, and to alkalis, and reduces Fehling's solution and Tollens' reagent[1–4].

The hydroxyl groups on C-20 and C-13 can be etherified in ether with diazomethane in the presence of aluminum isopropoxide[5]. With diazoethane, it is also possible to ethylate the secondary hydroxyl group on C-12. Rather surprisingly, the tertiary hydroxyl group on C-4 can be methylated with methyl iodide and silver oxide in dimethylformamide[6] if the hydroxyl groups on C-12, C-13, and C-20 are protected by acetate groups. When ethyl acetate is used as the solvent for this reaction, only the primary hydroxyl group is etherified if the cyclopropane hydroxyl group is protected. If the hydroxyl group on C-13 is free, the cyclopropane ring is oxidatively cleaved.



The partial structures *(2)* and *(3)*, which were verified by nuclear magnetic resonance spectrometry, were at first assumed to be joined to a secondary acyloin, since phorbol and its esters give positive Fehling and Tollens reactions[4,7]. However, it can be shown with ether derivatives of phorbol that the free hydroxyl group on the cyclopropane ring is alone responsible for the reducing properties. Independently of us[8], a similar reaction was recently observed with simple tertiary cyclopropanols. As is shown by the UV and circular dichroism data obtained for phorbol derivatives having the tertiary hydroxyl group on C-4 etherified or esterified this group is in the α position with respect to the carbonyl group. Phorbol therefore contains a tertiary acyloin grouping.

The Separation Efficiency in Gel Chromatography

By *W. Heitz*[*]

The efficiency of gel chromatography depends on the spread of the gaussian concentration profile of a substance during elution. This spread determines what substances can be

separated if their difference in elution volume is given and what details are still recognizable in the molecular-weight distribution.

A measure of the separation efficiency is the number of theoretical plates n or the height of the theoretical plate H:

$$n = \left(\frac{v_E}{\sigma}\right)^2 \text{ and } H = l/n$$

v_E = elution volume, σ = mean deviation (distance from the point of inflection to the perpendicular at the maximum), l = length of column.

Polyvinyl acetate gels and polystyrene gels with crosslinking-agent contents of 1 to 30 mole-% and particle sizes of 0.015 to 1 mm were used; the diffusion coefficient of the test substances was between 5×10^{-6} and 3×10^{-5} cm²/sec; the elution velocity was 2 cm/h to 2 m/h.

The separation efficiency of gel chromatography can be expressed in a general form with the aid of reduced quantities (*van Deemter, Giddings*)

$$h = a + b/\nu + c\nu$$

$$h = H/d_p,\ \nu = v \cdot d_p/D$$

d_p = particle diameter of the gel; v = elution velocity; D = diffusion coefficient; a,b,c = constants.

The constant a describes the regularity of packing, and is approximately 2 for good packing.

b is accounted for by diffusion broadening. The influence of the second term decreases with increasing flow rate; the reduced separation efficiency at high flow rates can thus be approximately represented by a linear relation. A minimum occurs at low reduced rates, *i.e.* there is an optimum elution velocity in gel chromatography. This optimum elution velocity depends on the substance: the diffusion coefficient is the normalizing factor.

c results from the lack of equilibration.

For gels with low crosslinking densities, the reduced separation efficiency can be represented by a single series of curves, which is independent of the above experimental parameters and the chemical nature of the gel. Diffusion in the gel is increasingly hindered with increasing crosslinking density. The curves obtained depend on the substance, but are independent of the particle size of the gel. It is estimated from the experimental data that values of the number of theoretical plates as high as 10^5 may be realized.

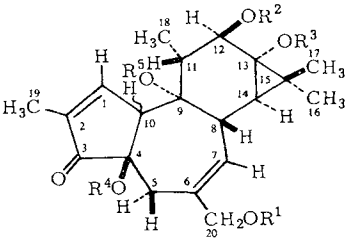
Circular Dichroism in Phorbol Derivatives

By *H. Bartsch* and *E. Hecker*[*]



Oxidation of the secondary hydroxyl group on C-12 of phorbol 13,20-diacetate *(1)* with CrO_3/pyridine yields a diketone (phorbolone). The carbonyl group on C-3 can be selectively reduced with $NaBH_4$ in THF/isopropanol. This gives a monoketone that is isomeric with phorbol, and which is called neophorbol 13,20-diacetate[1]. If phorbol 13,20-diacetate has the formula first suggested[2], the diketone should contain α-carbonyl groups. However, the CD curve of phorbolone in the range 280–380 nm is made up additively from the curves of the monoketones. If the compound were an α- or β-diketone, *i.e.* if the carbonyl groups in this case were both situated in the same ring, electronic interaction of the chromophores would make an additive curve impossible[4]. The carbonyl group in position 3 and the hydroxyl group on C-12 are therefore clearly seen to be situated in different rings. By comparison of the dichroisms of various phorbol acetates and ethers with the values for unesterified and unetherified derivatives, it was possible to detect a tertiary acyloin grouping of the sequence C-3,4[3] [as in *(4)*][1]. The vicinal effects of an axial α-acetoxy group occur only in *(2)*. *(2)* and *(3)* also show a sign reversal of the R-band of the enone, which consists of a positive and a negative component in the case of *(3)*.

The magnitude of the dichroic absorption of neophorbol 13,20-diacetate permits the application of the rule for α,β-cyclopropyl ketones[4]. This gives an α three-membered ring for the absolute configuration of neophorbol, and hence also for phorbol (the conformation of the six-membered ring is the same in both compounds)[1]. X-ray analysis, on the other hand, gives the mirror image with a β three-membered ring[5].

The first restriction of the general validity of the α,β-cyclopropyl ketone rule is therefore shown by neophorbol 13,20-diacetate, an α,β-cyclopropyl ketone with a tertiary acetoxyl group on the three-membered ring.

Another unusual feature is the occurrence of a third CD band at 272 nm in phorbol derivatives. This anomaly is rigidly associated with the *trans*-fusion of the 5-membered ring and with the presence of the tertiary OH group on C-4.

It is not yet possible to explain this behavior.

Determination of Partial Structures of Phorbol by Cleavage with Periodate and with Lead Tetraacetate

By *M. Gschwendt* and *E. Hecker*[*]

Several observations indicate that phorbol contains a tertiary acyloin group on C-3/C-4[1]. This grouping can be detected by reduction to the secondary-tertiary glycol with $NaBH_4$ and cleavage of the glycol with sodium periodate to give a keto aldehyde. Reduction of the keto aldehyde with $NaBH_4$ gives a primary-secondary alcohol, in which the sequence C-10, C-4, C-5 [cf. *(1)*] is given by NMR measurements with spin decoupling (for further partial formulae deduced earlier, see[2]).

Oxidation with lead tetraacetate or sodium periodate results in cleavage of the cyclopropane ring. Bisdehydrophorbol *(3)*,

tiglophorbol[**], phorbolactone hemiacetal, and hydroxyphorbolactone hemiacetal[4] are formed from the resulting carbenium ion *(2)*.

(3) is found to be a key substance for the detection of the linkage of C-12 with C-13. The carbonyl group in bisdehydrophorbol *(3)* was reduced with $LiAlH_4$ to a secondary hydroxyl group, and the coupling of the new H-13 with H-12 was detected by nuclear magnetic double resonance measurements. The partial structure *(4)* deduced from this, together with the partial structure *(5)*, gives the structure of phorbol *(6)*.

The relative configurations of all the centers of asymmetry in phorbol except C-10 can be determined from the structures of its oxidation products and their NMR data. A half-chair conformation can be deduced for the bicyclo[4.1.0]heptane partial structure of phorbol (X-ray structure analysis, see reference[5].)

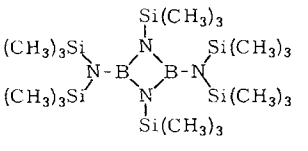
Petroporphyrins from Bitiminous Shales

By *W. Heller*[*]

Porphyrins and porphyrin-metal complexes have been obtained by very careful extraction from Swabian and North German Posidonia shale (Lias epsilon) and from the bituminous shales of the limiting bitumen horizon (Anis/Ladin) of Monte San Giorgio (Ticino, Switzerland). The material must be very finely ground and then extracted in stages in a Soxhlet apparatus so that it is finally free from porphyrins. We extracted successively with ether, hexane, chloroform, dioxane, benzene, pyridine, and DMSO. The porphyrins are almost quantitatively extracted in the ether. After further prepurification on aluminum oxide and Dowex, free porphyrins as well as porphyrin-metal complexes were found in the extracts.

Porphyrins both of acidic and of basic degradation occur in the shales. However, each shale zone contains only one type of degradation products.

Only an extremely small percentage of the metal complexes are of a physiological nature; the nonphysiological (V and Cu) complexes predominate. Chlorophyll degradation products that still contain Mg are not found either in the shales of Monte San Giorgio or in the Posidonia shales. This is probably because Mg is very readily replaced by V or Cu, even in chlorophyll. Thus the only physiological porphyrin-metal complexes found are the Fe complexes which may be derived from the hemin series. (The formation of the V and Cu complexes is a secondary process involving the degradation products.)



Moreover, nearly all the synthetic precursors of hemin and of chlorophyll, *e.g.* δ-aminolevulinic acid, uroporphyrin, coproporphyrin, and protoporphyrin, could be quantitatively detected in the bituminous shales. Porphobilinogen was also present in traces.

Crystal and Molecular Structures of Hexakis-(trimethylsilyl)-2,4-diamino-1,3,2,4-diazadiboretidine

By *H. Hess*[*]

Hexakis(trimethylsilyl)-2,4-diamino-1,3,2,4-diazadiboretidine *(1)*[1] was investigated by X-ray methods.

(1)

The compound crystallizes in the monoclinic system, space group $P2_1/a$, with $a = 22.11$, $b = 14.96$, $c = 10.93$ Å, $\beta = 108.6°$, and 4 molecules in the unit cell. The structural determination is based on 3500 reflection values, which were obtained with the aid of an automatic diffractometer and partly also by photometrization of integrated Weissenberg photographs. Three-dimensional Patterson and Fourier syn-

theses were used for the structural determination. The structure was refined by the method of least squares, first with isotropic, and later also with anisotropic temperature factors. The weighted R value is at present 10.6 %; the hydrogen atoms are not taken into account.

The proposed structure[1] could be confirmed. The four-membered ring is planar, within the limits of accuracy of the determinations, and the substituents on the N atoms are also arranged in a plane. The Si atoms attached to the exocyclic N atoms lie, not in the plane of the four-membered ring, but perpendicular to it. This can be attributed to steric factors. The following average bond lengths were found: B–N (endocyclic) 1.47, B–N (exocyclic) 1.43, N–Si 1.75, Si–C 1.88 Å. The shortness of the exocyclic B–N bond is surprising since the substituents on the B and N atoms are arranged perpendicularly to one another.

Acidolysis of Organolead Compounds

By *F. Huber, H. Horn* and *V. Bade*[*]

The action of acidic compounds HX on tetraorganoplumbanes PbR_4 proceeds in two steps.

$$PbR_4 + HX \rightarrow R_3PbX + RH \quad (1)$$

$$R_3PbX + HX \rightarrow R_2PbX_2 + RH \quad (2)$$

In all the cases studied (by acid titration, conductivity and / or gas volume measurements), both reactions are second order and proceed as competing consecutive reactions. In the reaction of aryl compounds ($R = C_6H_5$, $CH_3OC_6H_4$, *etc.*), the rates of both *(1)* and *(2)* are higher than in the reaction of alkyl compounds. For example, in reaction *(1)* (X = Cl, solvent CH_3OH) the reactivity increases with R in the order $n\text{-}C_4H_9 \approx n\text{-}C_3H_7 < C_2H_5 < CH_3 \ll C_6H_5 < CH_3OC_6H_4$.

The important question of the isolability of R_3PbX and/or R_2PbX_2 depends appreciably on the ratio of the rate constants k_1/k_2, and hence naturally on the reaction time and temperature. In establishing general rules for the preparation of R_3PbX and R_2PbX_2 by acidolysis of PbR_4 ($RPbX_3$ cannot be obtained by acidolysis), special attention must be paid to the group-specific properties and the acidity of HX, the influence of R, the polarity of the solvent, and the coordination-chemical effects. An S_E2 mechanism is suggested for *(1)*; for *(2)*, however, an S_N2 initiated multi-center reaction is proposed.

Preparative Isolation of ^{242}Cm in the 100 Ci Range

By *G. Höhlein* and *H.-J. Born*[*]

A process for the isolation of ^{242}Cm in the 100 Ci range was developed and tested. The separation apparatus for the mechanical and chemical processing of a 200 mg sample of ^{241}Am irradiated in a high-flux reactor is remote-controlled and is continuously monitored by means of a gamma spectroscope.

The curium is separated from americium, plutonium, and the fission products on cation exchangers. The trivalent actinides and lanthanides are first absorbed on an exchanger column, and ^{103}Ru and ^{95}Zr, ^{95}Nb, and tetravalent $^{238,242}Pu$ are eluted as sulfato and oxalato complexes. ^{91}Y, ^{140}Ce, trivalent $^{238,242}Pu$, ^{241}Am, and ^{242}Cm are then separated on a larger column by an automatic pH-gradient elution technique with α-hydroxyisobutyric acid as the eluent. 91.6% of the ^{242}Cm is isolated with a purity of 98.5%. Pu is eluted after the Ce, indicating that Pu(III) has a weaker tendency toward complex formation with α-hydroxyisobutyric acid.

The influence of the weight ratios and the pH gradient on the effective number of plates and on the separation factor was studied by means of the elution curve. The effective number of plates in a column can be appreciably increased with respect to tracer and carrier quantities by the introduction of a gradient.

The elution of Am and Cm in a weight ratio of 8:1 showed that, despite its high specific α activity (10 mg of ^{242}Cm = 33.16 Ci), ^{242}Cm can be eluted on the mg scale on sulfonated polystyrene resins (AG 50 X 8, 200–400 mesh) without appreciable disturbance of the separation by the α-radiolytic decomposition of the cation exchanger. On absorption of pure ^{242}Cm on the mg scale, on the other hand, the resin is spontaneously decomposed because of the high energy density (16 Wh/ml of resin volume).

Separation of Uranium and Plutonium by the Fractional Sublimation of the Chlorides

By *B. Kanellakopulos* and *H. Parthey*[*]

The separation of plutonium from uranium and fission products by the fractional sublimation of the chlorides was investigated. The preparation of uranium chloride characterized by the highest possible uniformity is essential for a good separation starting with the oxides. By heating the gaseous reaction products and annealing the condensates, we obtained predominantly UCl_4 in addition to $PuCl_3$. The reaction temperature, the temperature gradient, and the total pressure are important in the separation. Chlorination was carried out with a Cl_2–CCl_4–Ar mixture. There are two ways of volatilizing plutonium: (a) plutonium is eleminated as gaseous $PuCl_3$ in accordance with the vapor pressure of the solid at the temperature used and (b) plutonium is removed as $PuCl_4$, which is a gaseous component of the equilibrium

$$PuCl_3\,(s) + Cl_2\,(g) \rightleftarrows PuCl_4\,(g)$$

at elevated chlorine pressures and temperatures. At low chlorine pressures and temperatures, it decomposes without kinetic inhibition.

At a suitable temperature, uranium tetrachloride can be selectively sublimed off during chlorination, while $PuCl_3$ is left behind or is hardly formed. It is possible, moreover, to carry out a rapid selective chlorination at higher temperatures and to decompose the mixture of chlorides by fractional sublimation under reduced pressure. Separation factors of 300–600 can be reached in a single sublimation step.

The Solid-State Chemistry of Neptunium Oxide

By *C. Keller*[*]

Many ternary oxides and oxide phases of tetravalent, pentavalent, and hexavalent neptunium can be prepared by reaction in the solid state or by hydrothermal synthesis. The compounds of tetravalent neptunium are very similar to the analogous oxometalates of the other tetravalent actinides. Typical examples are $BaNpO_3$ (cubic perovskite type), NpP_2O_7 (cubic α-ThP_2O_7 type), $NpTi_2O_6$ (monoclinic brannerite type), α-$NpSiO_4$ (tetragonal zircon structure), $NpO_{0.25}NbO_3$ (tetragonal defect perovskite type), and $NpNb_3O_{10}$ (hexagonal $UTa_3O_{10.67}$ structure). Whereas NpO_2 cannot be further oxidized in oxygen at high temperatures, pentavalent and hexavalent neptunium compounds such as Li_3NpO_4 and Na_3NpO_4 with Np(v) and $Na_2Np_2O_7$, $\alpha+\beta$-Na_2NpO_4, $\alpha+\beta$-Na_4NpO_5, $CaNpO_4$, or $BaNpO_6$ with Np(vi) are obtained in the presence of alkali metal and alkaline earth metal oxides. These are very similar to the uranium compounds having the same formula, but are less stable thermally.

Under inert and under oxidizing conditions, NpO_2 forms extended oxide phases with rare earth (RE) oxides. These phases contain two definite ternary oxides: $(Np^{V}_{0.5}, RE^{III}_{0.5})O_2$ with a fluorite structure and statistical distribution of the metal ions, and $NpO_3{\cdot}6REO_{0.5}$ with a hexagonal $UO_3{\cdot}6REO_{0.5}$ structure. In contrast to the uranium compound, the 1:6-Np(vi)–RE compound exists only as a stoichiometric compound. Whereas the solubility of $REO_{1.5}$(Lu,Tm,Ho) in NpO_{2+x} can be up to 60 mole-% between 1100 and 1700 °C, a maximum of 2–3 mole-% of NpO_{2x} dissolves in $REO_{1.5}$.

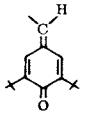
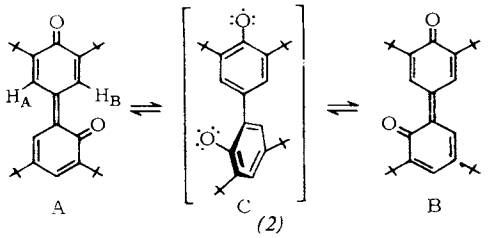
Detection of Intramolecular Mobility in Quinoid Systems by NMR Spectroscopy

By *H. Kessler*[*]



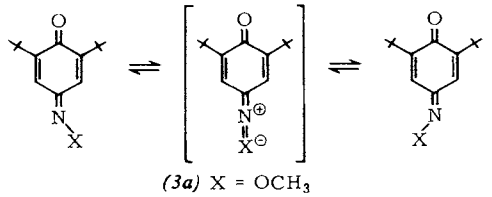
The isomerization at CC and CN double bonds in quinoid systems of the type *(1)–(3)* was studied by NMR spectroscopy.

The nuclear resonance spectra of the quinonemethides *(1a)–(1e)* exhibit no temperature-dependence up to 180 °C. The free energy of activation of the *cis-trans* isomerization is thus > 26 kcal/mole. In the case of the *o,p*-diphenoquinone *(2)*, the coalescence of the signals for the quinoid protons H_A and H_B at 155 °C ($\Delta\nu_{AB}$ = 44 Hz) gives a free energy of activation (for A ⇌ B) of 21 kcal/mole. A biradical transition state C is assumed.



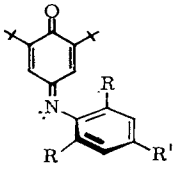
I

(1a) X = C_6H_5
(1b) X = OCH_3
(1c) X = $PO(Oi\text{-}C_3H_7)_2$
(1d) X =



(1e) X = CN

A C B



(2)

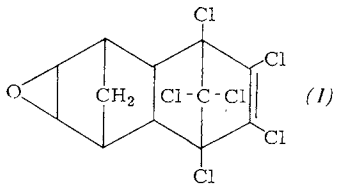
(3a) X = OCH_3
(3b) X = $SO_2C_6H_5$

The isomerization about the CN double bond requires more than 23 kcal/mole for *(3a)*; $\Delta G^{\ddagger}$ = 17.1 kcal/mole for *(3b)*, at 44 °C, and 18–23 kcal/mole for *(3c)*, depending on substitution.

When the substituents R and R′ in *(3c)* are varied, $\Delta G^{\ddagger}$ at 100 °C decreases with increasing size of R.

(3c), X = 2,6-R-4-R′-C_6H_2

R = R′	H	CH_3	C_2H_5	i-C_3H_7	t-C_4H_9
$\Delta G^{\ddagger}$ 100 °C [kcal/mol]	21.7	20.1	20.0	19.8	18.6



On the basis of the electronic effects of the substituents, the values would be expected to vary in the opposite direction. This was shown by systematic variation of R′ in compounds of the type *(3c)* (R = H). The rates of isomerization as found by NMR spectroscopy can be correlated with the Hammett σ_p values ($\rho = +1.5 \pm 0.3$ at 100 °C). The isomerization is therefore hindered by electron-repelling substituents. The increasing ease of reaction with increasing size of R in *(3c)* is therefore due to steric factors. It can be deduced from this that the isomerization in quinoneanilines proceeds, not by rotation about the CN bond, but by inversion (folding in the bond plane on the nitrogen.)

Metabolic Fate of Endrin, Dihydroheptachlor, and Heptachlor

By *W. Klein, F. Korte, N. Poonavalla, I. Weisgerber, R. Kaul, W. Müller,* and *A. Djirsarai*[*]

Endrin *(1)*: Experiments in which this insecticide labeled with ^{14}C was administered orally or intravenously to male and female rats in doses of 16–200 µg/kg of body-weight showed that the biological half-live of endrin is 3–6 days. When the labeled compound was given to rats in a daily dose of 8 µg, a steady state of storage was reached in about six days. It was found to be stored mainly in the fatty tissues.

(I)

When [14C]-endrin is administered orally, *ca.* 25 % is eliminated unchanged in the first day through the alimentary canal. After this, and after intravenous injection, two hydrophilic metabolites are excreted, mainly with the feces. The chief metabolite is chromatographically identical with the keto rearrangement product of endrin.

Experiments on mosquito larvae (*Aedes aegypti*) have shown that up to 80 % of the administered [14C]-endrin is eleminated in the form of hydrophilic metabolites. In the first hour after the exposure of the larvae, up to 20 % of the substance is converted. An increase in the concentration of the insecticide in the nutrient solution by a factor of 10 accelerates the metabolism by about 10 %.

Four weeks after treating varieties of cabbage with 14C-endrin, we recovered 5–25 % of the radioactivity, according to the conditions of life of the plants. About 40 % of the original amount evaporates from the plant surfaces, and 35–55 % is eliminated by transpiration. Almost only endrin was found on the surface of the leaves, while the leaves themselves contained 7 % of their radioactivity in the form of metabolites, the corresponding values being 26, 40, and 51 % for the stem, the root, and the soil, respectively. As regards the total radioactivity measured in the various parts, there is a decrease in the concentration from the leaves to the roots. Blank tests have shown that the conversion products are metabolites of the living plant.

Experiments with *Aspergillus flavus* have shown that a dose of 55 µg of endrin is metabolized to an extent of 22 % by 170 g of fungus mycelium within 3 weeks.

β-Dihydroheptachlor: This insecticide is metabolized to an extent of about 5 % in 15 days by fungi (*A. flavus*, *Penicillium urticae*, and soil microorganisms).

Heptachlor: After the intravenous injection of 14C-heptachlor into rabbits and rats, the compound is converted quantitatively into two metabolites, namely into the *exo*-epoxide and into a substance that is chromatographically identical with the 5-*exo*-hydroxy-3,4-*exo*-epoxy derivative of heptachlor.

Photochemical Formation of Titanium Peroxide

By *H. Knoll* and *U. Kühnhold*[*]

Very pure TiO_2·aq prepared by hydrolysis of $Ti(C_2H_5O)_4$ irreversibly turns yellow on exposure to UV light of wavelength 365 nm after recrystallization to anatase (by heating below 450 °C). Samples prepared between 110 and 150 °C in a bomb tube and anatase-brookite mixtures (about 60 % of brookite) recrystallized at 40 °C are particularly sensitive to light. Anatase that contains anions such as $Cl^{\ominus}$, $F^{\ominus}$, $SO_4^{2\ominus}$, or $PO_4^{3\ominus}$ as well as pure, well crystallized anatase and rutile are insensitive. Discolored preparations absorb in the long-wave part of the absorption edge of TiO_2·aq. Measurement of the diffuse reflection against unexposed TiO_2·aq as standard gives a band having a maximum at 395–405 nm, similar to that of acido-titanium peroxide complexes in solution.

The absorption of oxygen during the photoreaction can be detected in the tensio-eudiometer. From the positive result of the Riesenfeld-Liebhafsky test, it is concluded that a peroxide bond is present. The formation of the colored compound is associated with the presence of mobile surface water. Preparations that have been substantially freed from adsorbed water by pumping (25 °C) discolor only slightly on illumination. When the sample is re-wetted, the absorption band re-appears in its original intensity on illumination.

The sensitivity to light is independent of the partial pressure of the oxygen between $p_{O_2} = 100$ and $p_{O_2} = 30$ mm Hg (peroxide formation range). After the adsorbed water has been released between 30 and 10 mm Hg, strong photosorption of oxygen is observed. Photolysis suddenly begins at 4 mm Hg, with an increase in pressure and blue coloration of the TiO_2. The dependence of the photoreaction on the wavelength of the incident light is determined by monochromatic illumination between 280 and 500 nm. Maximum discoloration takes place at $\lambda = 360$–370 nm. The intensity gradually decreases toward shorter wavelengths. Between 370 and 420 nm (the long-wave limit of the effect), the decrease follows the course of the absorption of unexposed TiO_2·aq. Graphic differentiation (in 5 nm steps) over the active range gives a point of inflection at 380 nm only.

From the result of the experiment, it is concluded that a surface compound similar to $H_4[TiO_3 \cdot O_2 \cdot aq]$ is formed. The time-dependence of the reaction can be described by the differential equation for second-order reactions, with $k = 2.3 \times 10^{-4}$ (25 °C). It is not yet possible to give any data on the individual reaction steps. There is no evidence that the active electrons are excited out of defects. The absorption edge can therefore be interpreted at present only as a valence band/conduction band transition of the electrons in anatase. The photochemical activity is then determined only by the surface state of the titanium dioxide. The blocking of peroxide formation by anions suggests the possible participation of surface OH in the photochemical reaction.

Investigation of the Preparative Uses, Kinetics, and Energetics of Photosensitized Processes at Low Temperatures

By *E. Koch*[*]

Photosensitized processes are possible even at −150 °C in suitable solvents. Thus O_2-transfers onto numerous dienes and olefins in dilute solution are diffusion-controlled; between +30 and −130 °C and with an adequate oxygen supply, they follow a simple kinetic scheme in which two competing processes and a preliminary diffusion step have to be taken into account. The evaluation of the O_2-absorption curves from numerous experiments with several acceptors, sensitizers (rose bengal, tetrachlorofluorescein, eosin, tetrachloroeosin, methylene blue, hematoporphyrin, binaphthylenethiophene), and solvents at various temperatures permits the absolute calculation of rate constants and activation energies. Since these values show a strong dependence on the sensitizer, the acceptor must react, not with excited oxygen, but with its adduct with the sensitizer. This adduct has a maximum life of 10^{-6} to 10^{-8} sec in methanol, depending on the sensitizer.

The course of the photosensitized O_2-transfers could also be followed thermochemically in a specially developed 'photocalorimeter'. During irradiation, the quantity of heat produced was accurately compensated by a Peltier element at +20 °C. The extent of Peltier cooling required showed that the formation of the peroxides from furan, 2-methylfuran, α-terpinene, cyclohexadiene, and trimethylethylene is exothermic (30 to 70 kcal/mole).

In many cases the peroxides formed are unstable and can be isolated only transiently by working-up at low temperatures;

this was so for furan and many substituted furans, dimethylfulvene, and cyclopentadiene. Malealdehyde acid pseudoesters are formed from furan itself above −40 °C, while substituted furans in alcoholic solvents are partly converted into 2-alkoxy-5-hydroperoxydihydrofurans. Transformations of this type can be followed particularly easily by differential thermal analysis. In the case of photochemical reactions that have not yet been studied in detail, this method can provide valuable preliminary information on the stability of the primary products obtained at low temperatures. In conjunction with a photocalorimetric study, therefore, the heats of formation of the primary products can be determined in two ways:

1) From the heats of formation of the starting materials and the energy liberated on irradiation and 2) from the heat of formation of the end products and the energy liberated on decomposition of the primary products.

Both methods give a heat of formation of about −80 kcal/mole for the ozonide-like epidioxyfuran, which is stable below −80 °C.

Liquid-Liquid Extraction of Tetravalent and Hexavalent Actinide Nitrates by a Long-chain Trialkylmethylammonium Nitrate [1]

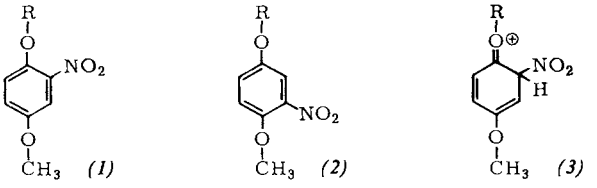
By *G. Koch* [*]

During a search for new extractants for the aqueous reprocessing of spent nuclear fuels, tricaprylmethylammonium nitrate (TCMAN) (Aliquat-336®, nitrate form; 'capryl' = mainly n-octyl and n-decyl) was studied. Tetravalent actinides are extremely efficiently extracted from nitric acid solution. The order of extraction is Pu(IV) > Np(IV) > U(IV) > Th(IV). The partition coefficients exhibit a maximum between 2 and 4 M aqueous HNO_3; the values for a 0.5 M TCMAN solution in Solvesso-100® are between 1.7×10^4 (Pu(IV)) and 4.2×10^2 (Th(IV)). Hexavalent actinides are efficiently extracted; the partition coefficients exhibit a maximum at 6–7 M aqueous HNO_3, and under the same conditions as above have the maximum values 28 for Pu(VI) and 11 for U(VI).

Back-extraction from the organic phase with dilute HNO_3 is possible in the case of the hexavalent actinides and of thorium, whereas for Pu(IV) and Np(IV), the use of foreign acids (*e.g.* CH_3COOH, H_2SO_4) or conversion into an unextractable valence state (Pu(III), Np(V)) is necessary.

Spectroscopic studies show that the tetravalent actinides are extracted as hexanitrato complexes $[M(NO_3)_6]^{2\ominus}$ and the hexavalent actinides as trinitrato complexes $[MO_2(NO_3)_3]^{\ominus}$. The nitrate ions act as bidentate ligands, so that the coordination numbers of hexavalent and of tetravalent actinides are 8 and 12 respectively. Deviations from 'ideal' behavior in the plot of the partition coefficient against the extractant concentration can be used to calculate the activity coefficients of the organic extractant.

Advantages over the Purex process (extraction of U + Pu with tributyl phosphate) are that TCMAN extracts the more valuable metal (Pu(IV)) better than the less valuable (U(VI)) and that the U/Pu separation is possible without the use of a reducing agent (selective back-extraction of the uranium with dilute HNO_3). Disadvantages are the poorer hydrodynamic behavior of TCMAN solutions, which leads to longer residence times in the extraction apparatus, the stronger tendency toward emulsification and three-phase formation, the unavoidable use of (expensive) aromatic diluents, and the increased extraction of fission product ruthenium. The prospects for the replacement of the Purex process by extraction with quaternary ammonium nitrates appear poor at present. Better prospects exist in the isolation of neptunium from uranium product solutions or from highly radioactive waste solutions.



[*] Dr. G. Koch

[1] This work was carried out as part of the joint program of EURATOM and the Gesellschaft für Kernforschung m.b.H., Karlsruhe, in the field of fast reactors.

Some Chain-Length Effects of Paraffins

By *F. Korte, H. Schumacher, M. Haag,* and *R. Adatia* [*]

To determine the influence of the chain length of paraffins on electrophilic aromatic substitution, the nitration of unsymmetric alkyl methyl hydroquinone diethers was studied. The nitration leads to the isomers *(1)* and *(2)*, whose concentration ratio was determined as a function of the chain length

(1) *(2)* *(3)*

(R = C_1–C_{16}), the branching and substitution of the chain, the solvent and nitrating agent, and the temperature. The isomer ratio *(1)*/*(2)* increases with increasing chain length (*(1)*/*(2)* = 1.54 for R = C_2H_5, and 1.81 for R = n-$C_{16}H_{33}$).

The hydrogen-bridge-bonded solvents used at first were replaced by nonpolar solvents (sulfolane, n-hexane), and the nitrating agent was varied (HNO_3, NO_2BF_4, CH_3CONO_3). The isomer ratio still depends on the chain length.

If one considers the limiting resonance structures and the transition states in the electrophilic nitration of alkyl methyl hydroquinone diethers, the resonance-stabilized state *(3)* should decide the course of the reaction. We attempted to explain the increase in resonance stabilization of the oxonium structure *(3)* with increasing chain length. The change in the isomer ratio per C atom is greatest on going from the dimethyl to the methyl ethyl hydroquinone ether. Steric control of the reaction is unlikely, since the alkyl group approaches the *ortho* position on rotation, and does not influence the *meta* positions.

Steric hindrance should increase with the introduction of isopropyl or t-butyl groups instead of n-alkyl groups, but the extent of *ortho* substitution is found to increase with increasing dipole moment.

The IR spectra show that inhibition of rotation occurs only in derivatives with very long chains (C_{16}). The reaction is evidently directed primarily by the polarizability of the alkyl chain. The electronic control of the reaction is particularly obvious in the nitration of hydroquinone diethers containing electronegatively substituted alkyl groups [chain substituents = Cl, Br, F]. The expected inversion of the isomer ratio is found even with as few as six saturated C atoms between the substituent and the oxonium oxygen. The same results are obtained on bromination as on nitration.

The experiments described show that straight and branched paraffin chains can give rise to a charge density on an electron acceptor that increases with increasing length or with increasing branching; this influences the aromatic system, and is thus responsible for the course of certain reactions. In addition to this, Mössbauer measurements of some iron complexes of fatty acids show that the charge density on the

iron atom increases with increasing chain length. The results can be interpreted by means of a rod model [1], according to which primary carbanions are more stable than secondary and tertiary carbanions.

Fragmentation of Bicyclic Keto-*p*-toluenesulfonates

By *W. Kraus* and *W. Rothenwöhrer* [*]

Solvolysis of 8-ketobicyclo[3.2.1]oct-2-yl and 9-ketobicyclo-[3.3.1]non-2-yl *endo-p*-toluenesulfonates in anhydrous glacial acetic acid yields only the acetates. On the other hand, solvolysis of the 8-ketobicyclooctyl *p*-toluenesulfonate in 80% aqueous formic acid and hydrolysis in water/acetone (1:4) leads to fragmentation and formation of 4-cycloheptenyl-1-carboxylic acid only. The 9-ketobicyclononyl *p*-toluenesulfonate does not fragment under these conditions. This decreasing tendency toward fragmentation with increasing ring size is attributed to the decrease in ring strain. A synchronous mechanism in which the carbonyl group is nucleophilically attacked by water is proposed. Simultaneous ring cleavage and release of the *p*-toluenesulfonate group lead to the fragmentation product.

Reduction of the two keto-*p*-toluenesulfonates with $LiAlH_4$ in ether is also accompanied by fragmentation. The overwhelmingly predominant product obtained from 8-ketobicyclo[3.2.1]oct-2-yl *p*-toluenesulfonate is 4-cycloheptenylmethanol, which is formed together with small quantities of *syn*- and *anti*-bicyclo[3.2.1]octan-8-ol; 9-ketobicyclo[3.3.1]-non-2-yl *p*-toluenesulfonate gives 35% of 4-cyclooctenylmethanol and 65% of bicyclo[3.3.1]nonan-9-ol. The tendency toward fragmentation again decreases with increasing ring size. The extremely high rate of this new reaction, which is described as 'reductive fragmentation', indicates a synchronous mechanism [1].

When the *p*-toluenesulfonates of the corresponding ethyleneketals are reduced with $LiAlH_4$, the bicyclo[3.2.1]octane derivative undergoes fragmentation to form 4-cycloheptenyl aldehyde acetal. Similar behavior is observed with the ethyleneketal of 2-keto-1-methylbicyclo[2.2.2]oct-4-yl *p*-toluenesulfonate. In the ketal of 9-ketobicyclo[3.3.1]non-2-yl *p*-toluenesulfonate, on the other hand, only the *p*-toluenesulfonate group is reductively removed. Since the carbonyl group cannot take part in the reactions of these compounds, an ionic multi-step mechanism must be assumed.

Syntheses and Reactions of Cyclic Amine Oxides with Activated Methylene Groups [**]

By *R. Kreher* [*]

Amine oxides [1] are most easily obtained by oxidation of tertiary amines with H_2O_2. The thermolysis of *N*-(β-phenylethyl)dialkylamine *N*-oxides containing a β-methylene group activated by the phenyl residue generally proceeds in accordance with the scheme of the Cope elimination with loss of styrene, and is a convenient method for the preparation of *N*,*N*-dialkylhydroxylamines. Dehydrogenation of these products with mercury(II) oxide yields nitrones [2]. This route has been used for the preparation of *e.g.* 4,7-(3′-cyclobuteno)-4,7,8,9-tetrahydro-1*H*-isoindolenine *N*-oxide [3] and 5*H*-dibenzo[*ce*]azepine *N*-oxide [4] as 5-membered and 7-membered cyclic nitrones.

N-Alkyl-Δ^3-pyrroline *N*-oxides, in which the cyclic α-methylene groups are activated by a CC double bond, undergo Cope-type elimination to only a small extent on thermolysis, with elimination of alkene and formation of the *N*-hydroxy-Δ^3-pyrroline. The main reaction is elimination of water to form *N*-alkylpyrroles, which are practically the only products formed on acetolysis (reaction of the amine oxides with acetic anhydride at 0 °C) [1,5]. The acetolysis of *N*-alkylisoindoline *N*-oxides, which follows a similar course, provides a convenient route to the *N*-alkylisoindoles [6]. Reaction with dialkyl acetylenedicarboxylates at room temperature gives 1:2 adducts, which are also formed from the *N*-alkylisoindoline *N*-oxides and a very large excess of acetylenedicarboxylate *via* *N*-alkylisoindole intermediates [7].

Pt^{3+} Compounds

By *K. Krogmann* [*]

The Pt^{3+} compounds discussed here can be described as adducts of halogen-amine complexes of Pt^{2+} and Pt^{4+}. Structures of this type consist of chains in which halogen atoms (X) form bridges between Pt^{2+} and Pt^{4+}.

The substances studied were compounds of the type $enPtX_3 = [enPtX_2]\cdot[enPtX_4]$ (X = Cl, Br, I) and mixed-halogen variants thereof. All these compounds crystallize in the orthorhombic system, space group Ccmc (D_{2h}^{17}).

	a	*b*	*c*
$enPtCl_3$	5.52 Å	13.52 Å	9.77 Å
$enPtBr_3$	5.66 Å	13.97 Å	10.28 Å
$enPtI_3$	5.95 Å	14.54 Å	11.12 Å

The compounds are very sparingly soluble in water and are dark colored (red to black). The Pt–X....Pt chains are parallel to one another; Pt atoms in different oxidation states cannot be distinguished crystallographically.

Compounds having the composition $enPtX_2Z$ can form isomeric chains if the distribution of the halogen atoms is regular:

a) Z as the bridge atoms, X as side atoms;

b) X as the bridge atom and as the side atom on Pt(1), Z as side atoms on Pt(2);

c) X as the bridge atom, X and Z as side atoms on Pt(1) as well as on Pt(2).

Isomers of the types a) and b) can be distinguished IR spectroscopically by the fact that the Pt–X and Pt–Z stretching vibrations have different frequencies according to whether X (or Z) is a bridge atom or a side atom. For example, the isomer a) $enPtCl_2(Br)$ gives $\nu(Pt-Cl) = 325$, $\nu(Pt-Br) = 227$ cm^{-1}; the isomer b) $enPtBr_2Cl$ gives $\nu(Pt-Cl) = 341$ and 321, $\nu(Pt-Br) = 230$ cm^{-1}.

Isomers of type a), with different bridge atoms and similar side atoms, *e.g.* $enPtBr_2(Cl)$, $enPtBr_2(Br)$, and $enPtBr_2(I)$, have practically identical values for *b* and *c*, while the distance *a* between chains varies. However, the last is not constant for a given bridge atom, but depends on the side atoms: for $enPtCl_2(Cl)$ and $enPtBr_2(Cl)$, $a = 5.52$ and 5.64 Å respectively; for $enPtCl_2(Br)$ and $enPtBr_2(Br)$, $a = 5.58$ and 5.66 Å respectively.

The isomeric compounds of types a) and b) were obtained as follows: a) $enPtX_2$ dissolved in DMF is treated with a highly diluted aqueous solution of K_2PtZ_6.

$$2enPtX_2 + PtZ_6^{2\ominus} \longrightarrow [enPtX_2] \cdot [enPtX_2Z_2] + PtZ_4^{2\ominus}$$

(with Z in *trans* positions as bridge atoms).

b) $enPtX_2 + enPtZ_4 \longrightarrow [enPtX_2] \cdot [enPtZ_4]$

Determination of Some Excitation Functions for Deuteron Reactions with ^{141}Pr

By *J. Lange* and *H. Münzel*[*]

The excitation functions of the (d,3n), (d,2n), and (d,p) reactions for the target nuclide ^{141}Pr were measured at energies up to 50 MeV. The samples were irradiated with the internal beam of the Karlsruhe isochronous cyclotron. The deuteron flux was determined by means of an aluminum monitor. Contrary to the usual practice, a homogeneous mixture of the target substance and the monitor (chemical compound) was used. The excitation functions studied were discussed.

In these investigations the half-lives of the nuclides ^{140}Nd, ^{141}Nd, and ^{142}Pr were re-determined. The values obtained were 3.37 ± 0.02 d, 2.60 ± 0.12 h, and 19.09 ± 0.07 h, respectively. Furthermore, an isomeric state of ^{139}Nd with a half-life of 29.7 min was discovered.

Isolation and Properties of a Crystalline β-Glucosidase from *Aspergillus wentii*

By *G. Legler*[*]

One of the six β-glucosidases shown to be present in *Aspergillus wentii* was isolated in an electrophoretically uniform, crystalline state by ammonium sulfate precipitation and column chromatography on CM- and DEAE-cellulose. The molecular weight as determined by gel filtration was 165000 to 170000. The enzyme is very slightly soluble in water at pH = 4.0 (about 0.2 mg/ml), but readily soluble at pH > 4.5 and in the presence of neutral salts. The thermal stability in the weakly acidic range is relatively high; the half-life of the inactivation in glycine/HCl (pH = 3.5) at 66.5 °C is 90 min.

The enzyme is specific for β-D-glucopyranosides, aliphatic glucosides being rather more weakly bound by the enzyme and also somewhat more slowly hydrolysed than the aromatic compounds. One exception is cellobiose, which is cleaved very rapidly. The rate of cleavage of phenyl-β-D-6-deoxyglucopyranoside was 1/10 and that of *p*-nitrophenyl-β-D-xylopyranoside 1/200 of the value for the corresponding glucosides.

The pH-dependence of the hydrolysis follows a sigmoid course, which can be explained by participation of a group that dissociates as an acid with $pK_A = 5.4$, and is active in the protonated form. Strong substrate inhibition is observed with *p*-nitrophenyl- and to a smaller extent with phenyl-β-D-glucopyranoside. *p*-Nitrophenyl-β-D-thioglucoside and D-gluconic acid 6-lactone act as competitive inhibitors with $K_i = 3 \times 10^{-4}$ M and 1.3×10^{-5} M respectively. The enzyme is rapidly and irreversibly inactivated by 10^{-4} M Condurit B epoxide[1] ($t_{1/2} = 22$ min at 25 °C and pH = 3.5), the rate of inactivation being strongly reduced by competitive inhibitors. The enzyme activity is not affected by heavy metal salts and *N*-ethylmaleimide.

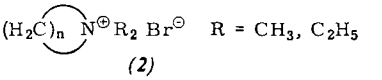
Nuclear Quadrupole Interaction and Molecular Structure

By *J. M. Lehn*[*]



The ^1H- and ^{14}N–NMR spectra of substances containing nitrogen depend on the field gradient and on the molecular movements. The stronger the quadrupole interaction ($e^2qQ/\hbar$) and the longer the correlation time τ_K of the molecular movements, the smaller is the quadrupole relaxation time T_q of the ^{14}N nucleus. If the ^1H and ^{14}N nuclei are coupled by spin-spin interaction, the form of the ^1H line will depend on T_q. A triplet is observed when T_q is long (^{14}N has a spin $I = 1$), and a singlet when T_q is short; broadened lines are obtained in intermediate cases. T_q can be calculated from the form of the ^1H line and from the widths of the ^{14}N resonance lines.

Small molecules, locally symmetrical (in the vicinity of the ^{14}N nucleus) have long quadrupole relaxation times T_q. This value is affected by the electronic structure, symmetry, and correlation time of a molecule.

When *n* in the substances *(1)*[1] and *(2)*[2] is large, the electric symmetry on the ^{14}N is high, and T_q is long (^1H triplet; narrow ^{14}N line); when *n* is small, the field gradient becomes greater and T_q becomes shorter (^1H singlet; broad ^{14}N resonance).

$$(C_2H_5)_3\overset{\oplus}{N}-(CH_2)_n-\overset{\oplus}{N}(C_2H_5)_3 \; 2\,Br^{\ominus}$$

(1)

(2)

These predictions are confirmed by the ^1H and ^{14}N spectra

The broad lines observed for the proton on C-2 or C-3 in nitrogen containing heterocycles (pyridine, thiazole, isothiazole, oxazole, isoxazole, *etc.*) can be attributed to the incomplete elimination of a $^{14}N-^1H$ coupling.

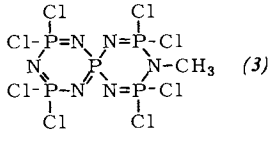
Substitution in Trimeric Phosphorus Nitride Chloride: The Formation of a Spirane Compound

By *W. Lehr*[*]



Double substitution of the chlorine atoms on the planar ring of trimeric phosphorus nitride chloride by a suitable bifunctional substituent leads to the formation of a new ring. It is still uncertain whether an ansa compound or a spirane compound is formed.

A more reliable route to a spirane compound starts with a geminally substituted compound. The diamide *(1)* was converted into the compound *(2)*, which has two geminal side chains.

(1) *(2)*

Ring closure with heptamethyldisilazane instead of with methylamine, which is too reactive, leads to the spirane compound *(3)* (2,2,4,4,8,8,10,10-octachloro-9-methyl-2,4,6,8,10-pentaphospha-1,3,5,7,9,11-hexazaspiro[5.5]undeca 1,3,5,7,10-pentaene) (m.p. 226 °C, decomp.), in which both rings contain only phosphorus and nitrogen atoms.

Quasibinary Phase Diagrams of the Systems Rare Earth Metal (Ho, Tm, Lu) Oxide / Actinide (Th, U, Np, Pu) Dioxide

By *L. Leitner, H. Engerer, U. Sriyotha,* and *C. Keller*[*]

Samples of definite composition obtained by mixed hydroxide precipitation were calcined under oxidizing, inert, and reducing conditions. The resulting oxide phases and their lattice constants were then determined. The actinide dioxides, which crystallize in a fluorite lattice, take up different quantities (up to 72 mole-%) of the rare earth metal oxides, which crystallize in a C-type lattice (Mn_2O_3 structure). The fluorite phases always have a fully occupied cation lattice, whereas the anion lattice (at least in the systems with ThO_2) exhibits vacancies. In the systems $UO_2/REO_{1.5}$, $NpO_2/REO_{1.5}$, and $PuO_2/REO_{1.5}$, these anion vacancies are partly filled under oxidizing conditions, with simultaneous oxidation of the actinide metal to valence states higher than +4. The solubility of the actinide dioxide in the rare earth metal oxide is significantly lower (maximum 30 mole-%). The solubility and its temperature-dependence are definite functions of the radii of the cations. As the difference between the radii increases, the oxide phase becomes narrower; *e.g.* 35 mole-% of $HoO_{1.5}$, 15.5 mole-% of $TmO_{1.5}$, or 11 mole-% of $LuO_{1.5}$ dissolve in ThO_2 at 1550 °C.

The phase diagrams of the systems $ThO_2/REO_{1.5}$ and $UO_2/REO_{1.5}$ (in a current of hydrogen) have a two-phase region between the fluorite phase and the C-type phase. Whereas pure NpO_2 is not oxidized by oxygen at high temperatures, oxidation of tetravalent neptunium is observed in the system $NpO_2/REO_{1.5}$. The $NpO_2/REO_{1.5}$ systems are therefore similar to the $UO_2/REO_{1.5}$ systems (1 atm of O_2); a rhombohedral compound having the limiting composition $MO_3 \cdot 6REO_{1.5}$ (M = Np, U) also occurs in both systems together with the fluorite and C-type phases. In the $UO_2/REO_{1.5}$ system, this compound forms a rhombohedral phase between 72 and 85.7 mole-% of $REO_{1.5}$ in the mixed oxide. The analogous system with neptunium oxide exhibits no phase width of the compound $NpO_3 \cdot 6REO_{1.5}$. Moreover, the solubility of MO_{2+x} in the rare earth metal oxide is about 1 to 2 mole-% in both systems, *i.e.* significantly lower than that of MO_2 in $REO_{1.5}$.

Determination of ^{239}Pu in Unirradiated Nuclear Fuel Samples by γ-Spectroscopy

By *L. Lindner* and *A. von Baeckmann*[*]

Though only about 10^{-3}% of all disintegrations of ^{239}Pu result in the emission of a 380 keV γ quantum, such quanta can be used for the determination of ^{239}Pu in the gram and milligram range. No interference is to be expected from the other long-lived plutonium isotopes. The measurements were carried out with an NaI(Tl) scintillation counter fitted with a lead screen, in conjunction with a multi-channel analyser. The determination of ^{239}Pu in this apparatus is subject to interference from ^{237}U (333 keV), which is formed by decay of ^{241}Pu. However, this interference is negligible when the plutonium has a constant isotope composition and contains less than 1% of ^{241}Pu. Under these conditions the detection limit in pure plutonium solution is about 0.5 mg of ^{239}Pu. The interference due to secondary products of uranium is slight (< 0.2% of the intensity of ^{239}Pu for equal weights of uranium and ^{239}Pu). The same is true of the other secondary products of the long-lived plutonium isotopes.

The plutonium content of PuO_2–UO_2 pellets of definite geometry was determined both by wet chemical methods and by γ spectroscopy. The standard deviation between the two processes was 0.6% for about 80 pellets containing about 3 g of ^{239}Pu. This non-destructive and time-saving γ-spectroscopic method thus seems suitable for process control of the plutonium content in the production of nuclear fuels.

The Structure of Hexacyanobenzene

By *W. Littke*[*]

On crystallization from anhydrous acetonitrile or on fast sublimation in a high vacuum, hexacyanobenzene is obtained in the form of colorless octahedra. The crystals are isotropic to polarized light. Powder and single-crystal photographs with CuK_α radiation showed a primitive cubic unit cell ($a = 10.820 \pm 0.005$ Å) with four formula units per cell. The Weissenberg diagrams indicate the space group Pa3. It should be noted that only about ten organic compounds with such high symmetry are known.

Fine-structure analysis shows that the centers of gravity of the molecules are situated at the corners and in the face centers of the cubic cell. The hexacyanobenzene molecules at

the corners lie in the octahedral faces. Each molecule is so arranged that one cyano group from each of three adjacent molecules above the molecule in question and three below points exactly toward the center of the molecule, the groups from molecules above alternating with those from molecules below. These six groups tend to draw the π electrons back, so that the planarity of the benzene ring is substantially retained. This structural determination may be accepted as reliable since, R has now been reduced to 0.10.

Investigations on the Age and Place of Origin of Paintings by Neutron Activation Analysis

By *F. Lux*, *L. Braunstein*, and *R. Strauss*[*]

Neutron activation analysis can be used to examine the relationships between the contents of trace elements in the white lead of paintings and the age and place of origin of the paintings. The investigations are being carried out jointly with the Dörner-Institut at Munich.

The contents of Mn, Cu, Ba, Cr, Ag, and Sb in Dutch and Venetian pictures were determined. The white leads from these two sources were found to differ significantly in their Mn, Ag, and Sb contents[1]. A distribution of the trace element contents in the white lead that depended on the place of origin of the paintings was found in two Tiepolo paintings executed in Italy and in Würzburg. Differences between modern and old white leads can be used for the detection of forgeries. The differences found agree, as regards the Cu content, with the results obtained by *Houtman* and *Turkstra*[2].

In further work, Sn, Au, and Hg were also determined. Each sample for analysis is divided into a short-time irradiation sample (irradiation time 4 h; ^{56}Mn, ^{64}Cu, ^{139}Ba, ^{198}Au) and a long-time irradiation sample (irradiation time 400–500 h; ^{51}Cr, ^{110m}Ag, ^{113}Sn, ^{122}Sb, ^{203}Hg). The trace components are determined by combination of radiochemical separation and γ spectrometry.

The separation operations were carried out without determination of the yield. Model analyses gave standard deviations of $\pm$ 2.1 to $\pm$ 3.4 % for the determination of the trace components. On analysis of three white lead samples from different parts of the same picture, the largest difference between two values for the same trace component was 20%.

To check variations in the binder content of white lead, the lead content in the solution of the irradiated sample before the addition of the carrier was determined on 1/10 of the solution by inverse polarography (in a Teflon vessel). The standard deviation of the lead determination is $\pm$3.4% for 5×10^{-7} g of Pb and $\pm$2.4% for 5×10^{-6} g of Pb.

A selection of the works of painters who worked mainly in Southern Germany during the 17th and 18th centuries is now being studied. In addition to Dutch and Venetian white leads, other types were also found:

	Type of white lead	Sb content (ppm)	Ag content (ppm)
1		< 8	15–75
2a	(identical with Venetian white lead [1])	10–70	< 7
2b		10–70	10–30
2c	(identical with white lead from 2 *Rubens* paintings [1])	10–70	> 30
3a	(identical with *Tiepolo*'s Würzburg white lead [1])	> 70	< 5
3b	(identical with Dutch white lead [1])	> 70	8–50
3c	(identical with Dutch white lead [1])	> 70	> 50

Types 1 and 2c were used in southern Germany up to about 1640, 2a after 1615, 3c after 1640, and 2b after 1670. This time scale was also established for pictures by one painter: *Johann Heinrich Schönfeld* used white lead 2a in 1633 and 3c in 1681.

Pictures by *Peter Candid* and by *Johann Georg Fischer* have become distinguishable for the first time by the application of chemical methods. The paintings that have been shown by recent historical findings to be by *Fischer* were formerly attributed to *Candid*. Paintings by *Candid* contain white lead 2a, while the *Fischer* paintings formerly attributed to *Candid* contain white lead 1,2b, 2c, and 3b.

Measurement of Self-Diffusion Coefficients of Na by Heterogeneous Solid/Melt and Solid/Solid Isotope Exchange on Sodalite, Obsidian, and NaCl

By *W. Lutze* and *H. W. Levi*[*]

Studies on the exchange kinetics of silicate ion exchangers have so far generally been carried out with powdered material. The results could therefore be used for the calculation of diffusion coefficients only for small penetration depths (low conversions). We used samples having a definite shape and size, so that the complete exchange process could be measured and used for the calculation of diffusion coefficients. Moreover, the rate-determining step of the exchange (film or volume diffusion) could be determined on the same sample by an interruption test.

Spheres (diameter $\geqslant$ 0.4 mm; deviation from spherical shape $\leqslant$ 3%) of the materials in question were prepared with the aid of a slightly modified ball mill. The Na present in the substances was isotopically labeled by adsorption of ^{22}Na on the surface followed by heating for a sufficiently long time to ensure homogeneous distribution in the solid phase.

Na self-diffusion coefficients were first determined for natural sodalite and two natural volcanic glasses by isotope exchange with $NaNO_3$, NaBr, and NaCl melts and with ^{22}Na as a tracer. The sample spheres were repeatedly immersed in a salt melt, and the progress of exchange was followed by measurement of the residual radioactivity of the solid. The following functions $D_{Na}(T)$ were obtained from the experimental results:

Sodalite (Canada) $D = 1.2\times10^{-2} \exp(-1.18\ \mathrm{eV}/kT)\ \mathrm{cm^2\ sec^{-1}}$ (500–850 °C)

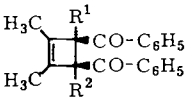
Obsidian I (Italy) $D = 2.9\times10^{-3} \exp(-0.80\ \mathrm{eV}/kT)\ \mathrm{cm^2\ sec^{-1}}$ (360–600 °C)

Obsidian II (Italy) $D = 9.2\times10^{-3} \exp(-0.78\ \mathrm{eV}/kT)\ \mathrm{cm^2\ sec^{-1}}$ (400–540 °C)

Exchange between two solid phases was investigated with radioactively labeled sodalite spheres in polycrystalline NaCl tablets. A sphere was embedded in NaCl powder and a tablet was made from this in a laboratory press at 15 t/cm^2. The tablets were heated at between 570 and 700 °C. The exchange process could again be followed by measurement of the residual activity in the sphere after separation of the phases by dissolution of the NaCl. The rate-determining step in this

case is diffusion in the NaCl. To evaluate the results, the second Fick law was solved under the appropriate boundary conditions. The self-diffusion coefficient of Na in polycrystalline NaCl was found to be:

$$D = 2.7 \exp(-1.75\ \mathrm{eV}/kT)\ \mathrm{cm^2\ sec^{-1}}\ (570\text{–}700\ ^\circ\mathrm{C})$$



Ion exchange processes could also be carried out in tablets of powdered sodalite and salts of cations other than Na. Thus Li-sodalite was formed within a few minutes with LiCl at 400 °C.

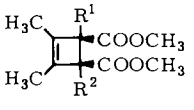
Reactions of Benzoylcyclobutenes

By *G. Maier* and *M. Wiessler*[*]



The cyclobutene derivatives *(1)*, *(2)*, and *(3)*, which are possible starting materials for the synthesis of derivatives of 3,4-diazabicyclo[4.2.0]octa-2,4,7-triene, exhibit unusual reactions under the action of bases, and when heated.

(1)

(2)

(3)

(a): $R^1 = R^2 = H$ *(b)*: $R^1 = H$, $R^2 = CH_3$ *(c)*: $R^1 = R^2 = CH_3$

With CH_3OH/CH_3ONa, *(1a)*, *(2a)*, and *(3a)* first rearrange to form *trans*-derivatives. In a stereoselective secondary reaction, *(1a)* adds a molecule of methanol across the 'unactivated' double bond of the four-membered ring. In *(1c)*, the addition takes place preferentially on the C=O double bond.

The compounds *(1)*, *(2)*, and *(3)* are converted by heating, and in some cases even at room temperature, conrotatorily into butadiene derivatives. The dibenzoylbutadienes formed from *(1)* give derivatives of furo[3,2-*b*]furan on heating. The esters *(2)* give esters of benzoylbutadienecarboxylic acid, which form pyrans by a Cope-type rearrangement involving the carbonyl double bond. The rate and direction of this secondary reactions can be influenced by the addition of SiO_2.

α-Aminoalkylation of White Phosphorus

By *L. Maier*[*]

The reaction of white phosphorus with *N*-hydroxymethyldialkylamines *(1)* leads mainly to three products: tris(dialkylaminomethyl)phosphine oxides *(4)*, bis(dialkylaminomethyl)phosphinic acids *(3)*, and dialkylaminomethylphosphonic acids *(2)*.

$$2\ P_4 + 20\ R_2NCH_2OH \rightarrow \underset{(1)}{} \quad \underset{(2)}{R_2NCH_2P(O)(OH)_2} +$$

$$2\ (R_2NCH_2)_2P(O)OH + 5\ (R_2NCH_2)_3P{=}O + 8\ H_2O$$
$$\underset{(3)}{} \qquad \underset{(4)}{}$$

The ratio *(2)*:*(3)*:*(4)* depends mainly on the ratio of the reactants, the pH, and the solvent. The highest yield of *(4)* is obtained at a ratio of $P_{white}:CH_2O:HNR_2 = 1:2.5:2.5$ in weakly basic to neutral media (water/alcohol). Tertiary phosphine oxides with $R_2N = (CH_3)_2N$, $(C_2H_5)_2N$, $(C_4H_9)_2N$, (cyclo-$C_6H_{11})_2N$, pyrrolidino, piperidino, and morpholino were prepared[1].

This new α-aminoalkylation appears to be confined to white phosphorus. Red phosphorus, arsenic, silicon, and tin do not react with *N*-hydroxymethyldialkylamines under these conditions.

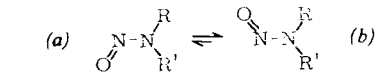
Electrochemical Reactions at Electrodes of Solid Hydrocarbons

By *W. Mehl*[*]

We used single crystalline aromatic hydrocarbons as electrodes in the investigation of oxidations and reductions. The oxidizing and reducing agents were 'simple' ions, in which rearrangements take place only in the outer solvation sphere during electron transfer. The charge transfer reaction was discussed on the basis of the Marcus theory of adiabatic electron transfers. According to this theory, electrons can pass from an ion to the electrode only if the solvation sheath of the ion is so arranged by thermal excitation that the difference between the energies of interaction of the oxidized and of the reduced forms of the ion with the solvation sheath corresponds to a permitted energy level for electrons in the surface of the electrode.

For quantitative estimates of the rate constants of fast reactions at electrodes of solid hydrocarbons, the reorientatio of the lattice polarization cannot be neglected in relation to the energy of rearrangement of the solvation sheath of the ions taking part in the charge transfer. The ratio of the exchange current for redox reactions measured at a metal electrode and the value measured at an anthracene electrode agreed satisfactorily with the predicted result.



The procedure is particularly suitable for use in the study of the electrochemical behavior of the excited states of aromatic compounds, whose reaction rates can be determined in the form of a limiting photo-current through the crystal. From the energy of the first excited singlet state and the electron affinity and ionization energy of the crystal, it is possible to predict a redox potential for 'simple' redox reactions at which a maximum of the photo-current is observed.

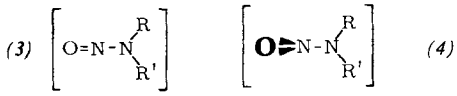
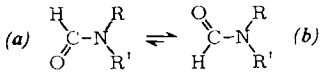
Separation and Equilibration of Conformeric Nitrosamines and Formamides



By *A. Mannschreck* and *H. Münsch*[*]



The conformers *(a)* and *(b)* of the nitrosamines have until now been detected only in equilibrium. In a few cases we have been able to separate *(a)* and *(b)* completely, or to a large extent, by fractional crystallization and preparative thin-layer chromatography at low temperatures. Some examples are *(1a)*, m.p. 62–63.5 °C, *(1b)*, m.p. 86.5–88 °C[1], *(2a)*

(1) R = CH_2-C_6H_5, R' = 2,6-$(CH_3)_2C_6H_3$
(2) R = CH_2-C_6H_5, R' = CH_2-$C(CH_3)_3$

and *(2b)*, m.p. 40–42 °C; *(2a)* melted at 15–21 °C and still contained 19% of *(2b)*. When one isomer is dissolved, the equilibrium *(a)* ⇋ *(b)* is established at a measurable rate at room temperature[2]. Equilibrations of this type at 36 ° C in CCl_4 gave half-lives of 5 to 100 min and free energies of activation of 22.3 to 24.2 kcal/mole, depending on R and R'. Feasible transition states for this reorientation of the nitroso group are the structures *(3)* and *(4)*, which correspond to a linear and an angular O–N–N system respectively.

(5) R = CH_2–C_6H_5, R' = 2,6-$(CH_3)_2C_6H_3$
(6) R = CH_2–C_6H_4 [*o*-$N(CH_3)_2$], R' = 2,4,6-$(CH_3)_3C_6H_2$

The only formamides that have so far been obtained in the pure state are *(5b)*, m.p. 76–79 °C, and *(6b)*, m.p. 66–69 °C. *(5a)* could not be separated; the sample of *(6a)*, m.p. 72 to 76 °C, that was isolated still contained 8% of *(6b)*. *Siddall*[3] concentrated one rotational isomer of each of two other formamides. The equilibrations in $CDCl_3$ at 35 °C gave half-lives of 17 min for *(5)* and 30 min for *(6)*, and free energies of activation of 22.6 to 23.7 kcal/mole[2]. This reorientation of the formyl group cannot proceed *via* a transition state analogous to *(3)*, with a linear O–C–N system. The transition state of the internal rotations in the formamides corresponds instead to the structure *(4)*.

The True Nature of the Transuranium Elements Reported by *O. Hahn, L. Meitner,* and *F. Strassmann*

By *H. Menke* and *G. Herrmann*[*]

Between 1934 and 1938, *O. Hahn, L. Meitner,* and *F. Strassmann* obtained a number of radionuclides by irradiation of uranium with slow neutrons. On the basis of the then current views on nuclear reactions and the position of the heaviest elements in the periodic system, these nuclides were thought from their chemical behavior to be transuranium elements[1].

After the discovery of nuclear fission, it was realized that these were fission products. The 66 h 'eka-iridium' was found to be a mixture of 67 h ^{99}Mo and 78 h ^{132}Te, from which 2.3 h ^{132}I, or 'eka-platinum', was formed[2].

To identify further components, ammonium diuranate samples that had been irradiated in the Mainz reactor were dissolved in 2 N hydrochloric acid, $PtCl_4$ was added, and platinum sulfide, with which the 'transuranium elements' had been isolated as a group, was precipitated from the solution. The fission products belonging to the hydrogen sulfide group were then isolated from this precipitate and their isotopes were identified by γ-spectroscopy; their contribution to the β activity of the sulfide precipitate was also measured.

Each of the 'transuranium' nuclides is simulated by a mixture: 16 min 'eka-rhenium' mainly by ^{101}Mo, ^{101}Tc, ^{104}Tc, ^{131}Sb, and ^{131g}Te; 59 min 'eka-osmium' by ^{133m}Te, ^{134}Te, ^{134}I, and ^{130g}Sb; and 5.7 h 'eka-osmium' by ^{129}Sb and ^{105}Ru. The iodine isotopes are secondary products from tellurium precursors. Complications are raised by the fact that several main components belong to mother-daughter pairs having similar half-lives, *i.e.* to the pairs molybdenum-technetium-101, antimony-tellurium-131, and tellurium-iodine-134.

	$_{93}$Eka-Rhenium	$_{94}$Eka-Osmium	$_{95}$Eka-Iridium	$_{96}$Eka-Platinum
$t_{1/2}$	2.2 min	59 min	66 h	2.5 h

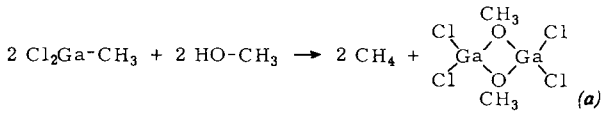
Structural Investigations on Polyolefins by means of Pyrolysis and Gas Chromatography

By *L. Michailov, P. Zugenmeier,* and *H. J. Cantow*[*]

Polyethylene samples obtained by various methods, and also ethylene-propylene copolymers, were pyrolysed in the carrier gas stream of a gas chromatograph. Simultaneous hydrogenation, achieved by using hydrogen as the carrier gas and introducing a hydrogenation catalyst, simplified the pyrograms. The experimental conditions were chosen to favor the formation and identification of fragments of as great a length as possible. This was achieved by a low pyrolysis temperature (680 °C), a low dead volume between the pyrolysis unit and the column inlet, and a linear temperature programming of the column. This enabled fragments with molecular weights > 700 to be separated.

Highly branched high-pressure polyethylene of low density and relatively linear Ziegler polyethylene of high density could be readily distinguished on the basis of the iso-compounds derived from the chain branching, and by the mass distribution of the straight chain fragments. The pyrograms of Ziegler and Phillips polyethylene samples also showed significant differences.



In the case of the ethylene-propylene copolymers, three pairs of products were discussed, having approximately the same overall composition but differing in the detailed structure of the polymer chains. In the sequence length distribution of the copolymers, even slight deviations showed up in the fragment distribution. A measure of the content of ethylene sequences capable of crystallization was obtained. The data from the pyrograms are supported by X-ray diffraction data. In addition, pyrograms can provide information on the sequence distribution in amorphous ethylene-propylene rubbers that cannot be obtained by other analytical methods.

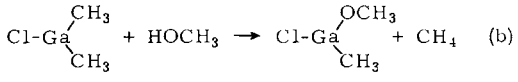
The Reaction of Alkylgallium Halides with Lower Aliphatic Alcohols



By *L. Mögele* [*]

Alkylgallium dihalides, $R-GaX_2$ ($R = CH_3$, C_2H_5; $X = Cl$, Br), react with lower aliphatic alcohols to give the hydrocarbon and the dimeric alkoxygallium dihalide [1] (eq. (a)).

(a)

However, dialkylgallium halides, R_2GaX, undergo solvolysis, even with an excess of alcohol and under severe reaction conditions, with substitution of only one alkyl group to give alkylalkoxygallium halides (eq. (b)). Unlike the alkoxygallium dihalides, which are crystallized at room temperature and are highly sensitive to moisture, the alkylalkoxygallium halides are highly viscous to waxy substances with no definite melting point, and are surprisingly stable towards hydrolysis. Studies by differential thermal analysis, osmometry, mass spectrometry, and nuclear magnetic resonance spectroscopy show that in the solid phase highly condensed systems are present in an isomeric equilibrium having a high rate of exchange; the tetrameric ring systems that are present in solution, split up into dimeric units in the vapor phase.

Dependence of the Kinetic Energy of some ^{239}Pu Fission Fragments on the Excitation Energy of the Fissioning Nucleus

By *G. Rohde* and *H. Münzel* [*]

The mean ranges of some fission products formed in the reactions $^{239}Pu(n_{th},f)$, $^{239}Pu(d_{20},f)$ and $^{239}Pu(d_{50},f)$ were determined by the 'thick target – thick catcher' method [1]. From the range and the irradation conditions, the kinetic energy of the primary fission fragments and the average excitation energy and nucleon number of the fissioning nucleus were calculated. The following conclusions were drawn from the results. The values of the total kinetic energy at a mass ratio of about 0.8 and 1.3 (asymmetric fission) are independent of the excitation energy of the fissioning nucleus. The value for the total kinetic energy in the symmetric fission range increases by 8 MeV as the excitation energy of the fissioning nucleus increases from 5 to 20 MeV, and then remains practically constant. This result may be interpreted on the basis of the hypothesis of two independent types of fission. The often used assumption about the distribution of the excitation energy of the fissioning nucleus among the primary fission fragments according to their nucleon numbers does not seem to apply. This could be estimated from the number of evaporated neutrons in the range of symmetric fission.

Induced Decomposition of Unsymmetrical Acyl Peroxides

By *W. P. Neumann, K. Rübsamen, Ra. Sommer*, and *U. Frommer* [*]

The decomposition of diacyl peroxides in dilute solutions is accelerated by several orders of magnitude if stannyl radicals $R_3Sn\cdot$ are present. These are produced in the reaction mixture from organotin hydrides. ^{18}O-labeling of the carbonyl groups permitted a synchronous mechanism (S_R2) to be demonstrated, in which the attack of the stannyl radical occurs at one of the peroxide oxygens, simultaneously with the breaking of the peroxide bridge [1].

In contrast to other radicals, the stannyl radical is nucleophilic. Its attack on the peroxide bridge is rendered easier (or, indeed, made possible in the first place) if electron-withdrawing groups create an electron deficiency at this point. This can be confirmed with unsymmetrical acyl peroxides

(1)

where $X = CN$, NO_2, Cl, H, OCH_3, OC_2H_5, *etc.* The more positive of the two bridge oxygens will be attacked preferentially by the stannyl radical.

The reaction rates were measured in dilute benzene solution and all the reaction products were determined qualitatively and quantitatively.

Experiments with trialkyltin deuterides enabled side reactions to be clarified, *e.g.* the cleavage of C–Sn bonds by acyloxy radicals and the cleavage of C–H bonds.

The unsymmetrical peroxides were prepared in good yield from the perbenzoates and an aliphatic carboxylic acid chloride ($R = CH_3$, C_2H_5, *etc.*).

Chemical Affinity and Structural Relationships Between Protein and Inorganic Components in Biogenous Mineralization

By *H. Newesely* [*]

The reactions involved in the calcification of hard biological substances have been largely clarified for the inorganic phase and for the protein component of the hard tissue by micromorphological, analytical, and structural investigations by several research groups.

Relationships were recognized between the crystal morphology (in the electron-microscopic range) and the structural type of the sparingly soluble calcium phosphates and the influence of accessory ions (F, Mg) on the reaction mechanisms. (Example: transformation of octacalcium phosphate/apatite; whitlockite.)

The attachment of the crystal component to the protein can be interpreted by metric similarities in the elementary dimensions (geometric factor, orientation properties) and by affinity relationships of the components (energy factor, H bonds >CO–NH.....O(F)).

We prepared substitution series in the calcium phosphate system (for example, $Ca_5(PO_4)_3OH$, $Ca_4H(PO_4)_3\cdot 2\,H_2O$, $CaHPO_4\cdot 2\,H_2O$ as well as model experiments with natural material) and studied the substances by X-ray and electron diffraction and by spectroscopy [1]. In dental enamel (keratin-

like organic matter, apatite crystals), there exist analogies of the lattice parameters that almost amounted to epitaxy relationships.

Epitaxy of Gallium Arsenide with Gallium Arsenide from Organogallium Compounds [1]

By *J. Nickl*[*]

An attempt was made for the first time to use halogen containing organogallium compounds as sources of Ga in the epitaxy of GaAs/GaAs. There was a danger that the organic ligands might be cracked to carbon (soot) at the overgrowth temperature and inhibit the monocrystalline growth. However, it was found that highly perfect monocrystalline GaAs layers can be produced with $GaCH_3Cl_2$ if the vaporized compound is heated with H_2 and arsenic at $\approx$ 1000 °C before layering.

With a flow rate of 1.5 cm/sec (700 °C) and a gas composition of $\approx$ 35–65 vol-% of H_2, $\approx$ 15–30 vol-% of arsenic, and 20–35 vol-% of $GaCH_3Cl_2$, the overgrowth rate on (111) is about 0.3–1 μm/min.

Only polycrystalline layers have so far been obtained with $Ga(CH_3)_2Cl$. At 350–700 °C and at low $GaCH_3Cl_2$ concentrations, GaAs whiskers are preferentially formed with falling temperature. Between 550 and 650 °C, the whiskers sometimes grow in two steps. In the first step a (111)-oriented whisker $\leqslant$ 1 μm thick is formed, and this thickens radially to 3–50 μm in the second step, giving rise to a six-pointed cross-section. The electrical properties, particularly the resistance as a function of temperature, were studied on highly perfect GaAs whiskers grown in one step.

Preparation and Properties of Titanium Silicides

By *J. Nickl*[*]

Attempts were made to grow single crystals of titanium silicides by transport reactions [1], by deposition from the gas phase, and in copper-rich melts. Titanium and silicon were also fused together without a crucible and zone-melted. The results are shown in the table, and may be summarized as follows:

1. $TiSi_2$, TiSi, and Ti_5Si_3 could each be prepared from the gas phase as polycrystalline layers; single crystals with a stoichiometric composition were obtained only in the case of $TiSi_2$.

2. TiSi was prepared for the first time in the monocrystalline form by a transport reaction with $TiSi_2 + Br_2$.

3. The Lebeau process [2] did not give $TiSi_2$ as described in the literature, but yielded, for the first time, a ternary (TiCuSi) [3] and quaternary E phase ($Ti_{0.5}Zr_{0.5}CuSi$) [4].

4. The graphite-like complex carbide Ti_3SiC_2 was prepared for the first time from the gas phase [5].

5. A crucible-free "drop-melt process" [6], in which the starting materials in the form of grains on a suspended drop of the melt are melted by high frequency methods, was developed for the preparation of titanium silicides from Ti + Si.

Compound	Form and properties sc = single crystal pc = polycrystalline	Preparation TR = transport reaction M = melt
$TiSi_2$	sc, $\approx$ 10 mm³ octahedron or needle-shaped, cryst., soluble in HF	$TiSi_2 + Br_2$ $Ti + Si + Br_2$ } TR; 1000→800 °C
	sc, $\approx$ 4 mm³ octahedron, dendritic cryst. and pc layers $\approx$ 0.01–3 mm	$TiCl_4 + SiCl_4 + H_2$ on heated graphite rods at 1000–1400 °C. sc at > 90 vol-% of H_2
	pc rods, always two-phase with $\leqslant$ 0.5% of the second phase; rods: diameter 5–8 mm	Ti + Si by 'drop-melt process'[6] followed by zone melting in high vacuum
TiSi	sc, platelets $\leqslant$ 3 mm² soluble in HF	TiCuSi + Br_2, TR 1000→750 °C
	pc layers, 0.01–1 mm	$TiCl_4 + SiCl_4 + H_2$ } gas phase deposition on graphite rods at $\leqslant$ 1000 °C
Ti_5Si_3	pc layers, 0.01–1 mm	$TiCl_4 + SiCl_4 + H_2$
TiCuSi E-phase	sc, column-shaped, dia. $\leqslant$ 1 mm, length $\leqslant$ 10 mm. Soluble only in HF + HNO_3. Dec. above 1000 °C into Ti_5Si_3 + Cu silicides. $\sigma = 1 \times 10^3\ \Omega^{-1}\ cm^{-1}$ paramagnetic $\chi = 2 \times 10^{-6}$	$TiSi_2 + CuO$ Ti + Si + Cu } fusion
$Ti_{0.5}Zr_{0.5}CuSi$ E-phase	sc, form and behavior toward acids as for TiCuSi	($TiSi_2 + ZrSi_2$ + Cu) melts.
Ti_3SiC_2	pc lamellae or slate-like crusts, graphite-like material[5], soluble only in HF + HF + HNO_3. Is slowly oxidized to anatase and amorphous silica in O_2 (1 atm at 300 °C)	$TiCl_4 + SiCl_4 + CCl_4 + H_2$ on heated graphite or titanium rods at 1000–1400 °C

Investigation of High Polymers by Pyrolysis

By *D. Noffz*[*]

A *Simon* pyrolysis apparatus combined with a gas chromatograph and a mass spectrograph was used for the investigation of the fragmentation products of homopolymers and copolymers. Examples of the results [1]:

1. The fragmentation products of polyvinyl chloride are mainly aromatic hydrocarbons (benzene, toluene, ethylbenzene, the xylenes, styrene, C_3-alkyl- and alkylenebenzenes,

azulene, indan and indene with their methyl derivatives, naphthalene and its methyl derivatives, biphenyl, fluorene, and higher hydrocarbons).

2. Polyvinylidene chloride gives mainly chlorohydrocarbons, together with chloroolefins: mono-, di-, and trichloro derivatives of C_4 and C_5 mono- and diolefins, mono-, di-, and trichlorobenzene, di- and trichloro derivatives of toluene, styrene, and indene, and polychlorophenylacetylenes.

3. The copolymer of vinyl chloride and vinylidene chloride yields the main components formed by the homopolymers, together with chloro compounds having degrees of chlorination intermediate between those of the fragments from the two homopolymers: chlorotoluene, mono- and dichloronaphthalene, chlorobiphenyl.

4. In addition to the homologues of benzene, polystyrene yields diphenylethane and diphenylpropane, as well as about 20 compounds having the composition $C_{16}H_{16}$ = dimeric styrene. However, the main products are not the 'true' dimers, *i.e.* the 1,3-diphenylbutenes, but 1-benzyl-2-methyl-3,4-benzocyclobutene, which is probably formed by cyclization from the 'true' dimers.

5. Polypropylene occupies a special place in this investigation, because of the influence of steric effects. Thus polypropylenes of different tacticities can be readily distinguished by pyrolysis. This is possible by separation of the diastereoisomeric olefins formed by pyrolysis.

Polymerization Reactions on Adsorption Layers of Solids

By *K. Nollen* and *K. Hamann*[*]

The adhesion of polymers to powdered solids, *e.g.* pigments or fillers, is of great importance for a number of technological properties of filled or pigmented plastics and paints. The adhesion of the macromolecules could be considerably increased if the solid, or reactive groups on its surface, could be incorporated into the macromolecule as a comonomer or as an initiator, since the bond between the surface of the solid and the macromolecule is chemical and is therefore very strong. Fillers and inorganic pigments do not generally possess such properties. However, if they are provided with firmly-adhering reactive adsorption layers, they will participate in many polymerization reactions.

Adsorption layers of this type are formed *e.g.* on inorganic oxide pigments by the adsorption of low molecular-weight polar compounds such as organic acids or amines. Though the molecules adsorbed directly on the surface are generally not bound chemically to the solid, they still adhere relatively strongly. If these adsorption layers have a suitable structure they can be used for initiation or as a 'comonomer', the polymer formed being firmly bonded to the pigment surface.

For example: sodium hydrogen oxalate adsorbed on several titanium dioxide pigments can initiate the polyaddition of epoxides; silicates on a wide range of powders act as initiators for the anionic copolymerization of phthalic anhydride and glycol carbonate to form polyesters. If the adsorption layer consists of polymerizable acids such as acrylic or methacrylic acid, vinyl compounds can be polymerized with these adsorption layers by a free-radical mechanism.

Organic powders, such as organic pigments, cannot generally be provided with firmly-adhering adsorption layers. However, initiating or polymerizable groups can be incorporated into the pigment, so that polymerizations become possible directly on the surface of the substances. For example, the copolymerization of phthalic anhydride and glycol carbonate can be initiated by the carboxylate and sulfonate groups of salt-like azo pigments. Since the initiator is incorporated into the resulting macromolecule in these reactions, the polymer adheres very firmly to the pigment surface.

Extraction of Macro-Quantities of Plutonium with Tributyl Phosphate in the Presence of Uranium[1]

By *W. Ochsenfeld*[*]

In the reprocessing of irradiated fuel elements of high plutonium content, such as those of fast breeder reactors, the behavior of macro-concentrations of plutonium in the presence of uranium is of interest in the extraction and separation. The data found for the partition of plutonium and of uranium between 20% tributyl phosphate in n-dodecane and aqueous nitric acid solutions show that each of the two elements influences the extraction of the other.

Of the essential steps in a possible flow scheme for the processing of a fuel containing 10% of PuO_2 + 90% of UO_2 only the separation of the plutonium from uranium is mentioned.

The reduction of Pu(IV) to Pu(III) by U(IV) and the instability of Pu(III) and U(IV) at the high plutonium concentrations present make the separation difficult. It is well known that Pu(III) is oxidized to Pu(IV) by nitric acid and its reaction products, as well as by air. Under countercurrent operation, the plutonium losses in the uranium product could be reduced to $< 0.2\%$ by an 8- to 10- fold stoichiometric excess of U(IV), aqueous solution stabilized with 0.2 M hydrazinium nitrate at acid concentrations lower than 2.5 N, and suitable flow conditions. The plutonium product need not be absolutely free from uranium, since it is made into a PuO_2/UO_2 mixed oxide in any case.

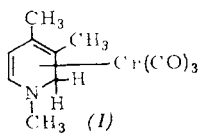
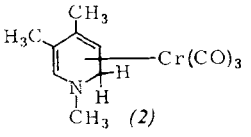
[1] This work was undertaken as part of the joint research program of EURATOM and the Gesellschaft für Kernforschung mbH., Karlsruhe, in the field of fast reactors.



Carbonylmetal π-Complexes of Dihydropyridine Derivatives

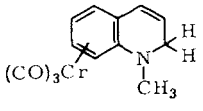
By *K. Öfele*[*]



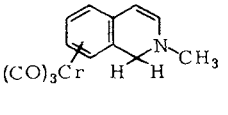
N-Methyldihydropyridines react with $Cr(CO)_6$ or $(CH_3CN)_3Cr(CO)_3$ to form red, sublimable *N*-methyldihydropyridinecarbonylchromiums(0). In these complexes, which, unlike the free dihydropyridines, are remarkably stable, the heterocyclic ring is evidently bonded to the metal *via* two C=C double bonds and the free electron pair on the nitrogen. These are therefore the first known complexes with a vinylamine group as a chelating ligand.

Tricarbonylchromium complexes have so far been obtained only from 1,2-dihydropyridine derivatives; *N*-methyl-1,2-dihydropyridine complexes are also obtained by rearrangement from *N*-methyl-1,4-dihydropyridines and $Cr(CO)_6$ or $(CH_3CN)_3Cr(CO)_3$. No tricarbonylchromium compound has so far been obtained from 1,4,4-trimethyl-1,4-dihydropyridine, the rearrangement of which to the 1,2-dihydropyridine is strongly hindered[1].

The reaction of 1,3,4-trimethyl-1,2-dihydropyridine with $(CH_3CN)_3Cr(CO)_3$ always yields 1,4,5-trimethyl-1,2-dihydropyridine-$Cr(CO)_3$ *(2)* as well as the complex *(1)* of the starting compound.



(1)



(2)

When heated to *ca.* 100 °C, *(1)* and *(2)* are reconverted to a mixture of isomers.

N-Methyldihydroquinoline and *N*-methyldihydroisoquinoline react with $(CH_3CN)_3Cr(CO)_3$ to form yellow *N*-methyldihydroquinoline-$Cr(CO)_3$ *(3)* and *N*-methyldihydroisoquinoline-$Cr(CO)_3$ *(4)*, respectively, the metal in these complexes being bonded to the benzenoid ring. Owing to the free enamine group, they are more reactive than the dihydropyridine complexes; in contrast to the latter, *e.g. (4)* reacts with trityl tetrafluoroborate with loss of hydride to form yellow [*N*-methylisoquinolinium-$Cr(CO)_3$]BF_4. NMR spectroscopy has proved very useful in the determination of the structure of these complexes.

(3)

(4)

Surprisingly, $Fe(CO)_5$ and $Ni(CO)_4$ are reduced directly to carbonylmetalates by dihydropyridine derivatives. Thus the reactions of *N*-methyl-1,2- and -1,4-dihydropyridines with $Fe(CO)_5$ and $Ni(CO)_4$ yield the *N*-methylpyridinium salts of $[Fe_4(CO)_{13}]^{2\ominus}$ and $[Ni_4(CO)_9]^{2\ominus}$.

Liquid Scintillation Counting of Benzene and Ethanol for ^{14}C Measurements in the Low-Level Range

By *R. L'Orange, K. Wagener*, and *K. E. Zimen*[*]

In the determination of ^{14}C, the test material is converted into pure benzene in the complete absence of air by three main steps: 1. Combustion to CO_2; 2. reduction to Li_2C_2 and preparation of acetylene; and 3. cyclization on a contact catalyst. The CO_2 is reduced with liquid Li in a vacuum-tight steel chamber. Continuous heating between 680 and 850 °C gives up to 98% of C_2H_2, the trimerization of which yields up to 95% of benzene, so that the total yield is over 90%. The trimerization is complete within an hour. During the reaction, the catalyst grains are spread out over a contact area of about 100 cm^2, which is cooled or heated as required.

The ^{14}C in the benzene is monitored at room temperature in a specially constructed apparatus with double coincidence and summation circuitry by means of a fully transistorized single-channel spectrometer. With a scintillator volume of 12 ml, a background of 6.5 counts per minute (above the tritium end point) is achieved by means of special shielding with boron/paraffin and low-radiation Pb and Hg. Range for dating with 10 ml of benzene: 48000 years. With 40 ml of benzene in a scintillator volume of 44 ml (measurement in quartz cells with windows plane-parallel to the photocathodes and a TiO_2 reflector), the background is 14 counts per minute and the maximum range of the age determination is 57000 years (2 sigma criterion, counting time 48 h, $T_{1/2} = 5570$ years).

The increase in ^{14}C from nuclear explosions, which began about 1954, can be used to date wines. A histogram of the ^{14}C content of German wines from 1952 to 1966 permits the determination of the age of the wine. The purified wine alcohol and toluene + scintillator (4:6 v/v) are counted directly in a volume of 44 ml. It is thus possible for the first time to make a simple check on the age of natural wines at present up to 12 years old.

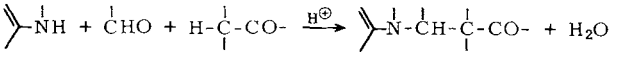
Molecular Structure and Magnetic Anisotropy of Amides

By *K. Todt* and *H. Paulsen*[*]

The action of the induced magnetic field of the amide group on adjacent protons has been studied in sterically fixed *N*-acylpiperidine derivatives. With a *cis* amide carbonyl group, the NMR signal of equatorial protons of the α-methylene group is shifted downfield (deshielding) and that of axial protons upfield (shielding). The magnetic field of the amide group therefore has different signs at the positions of these protons. The protons of freely-rotating *cis*-methyl groups of *N*-methylamides pass through alternating regions with deshielding and shielding magnetic fields; the observed shielding of these protons is an average value, which leads to further conclusions regarding the magnetic anisotropy of the amide group.



The knowledge gained concerning the magnetic action of the amide group in its environment can be utilized in two ways: If the position of a proton is known, its NMR signal, which is split when the rotation of the amide group is hindered, can be assigned to the rotational isomers on the basis of the chemical shift. Conversely, the position of a proton in relation to the amide group can be established by experimental determination (*e.g.* by the benzene dilution method) of whether it is in the deshielded or the shielded region, and can then be used to deduce the structure or the conformation of the amide. For example, the 2-methine proton of *N*-acetyl-2-methylpiperidine lies in the deshielded region; it follows that the compound has a chair conformation with an axial 2-methyl group. *N*-Acyl-2-methylpyrrolidine occurs in an envelope conformation in which the 2-methine proton is situated if the deshielded region. The isopropyl group in *N*-isopropyl-*N*-methylacetamide preferentially assumes a conformation in which the isopropyl methine proton is in the plane of the amide group.

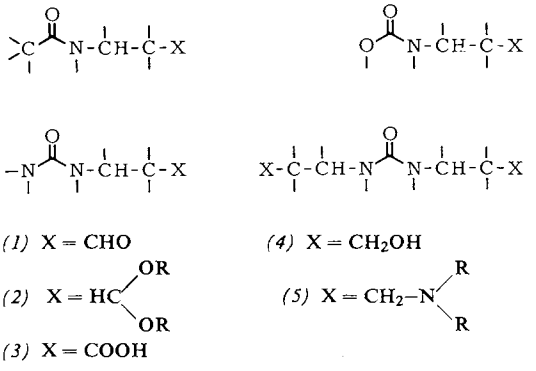
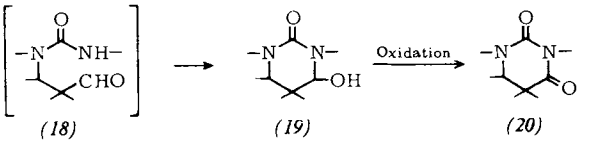
Synthesis and Reactions of Novel Carbonyl Compounds Containing Nitrogen



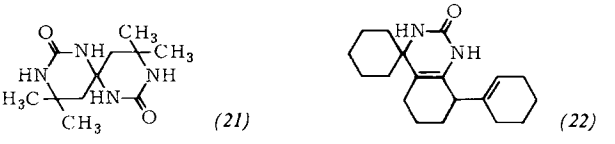
By *H. Petersen*[*]

Carbonyl compounds containing nitrogen are obtained by acidic condensation of an NH group of acyclic or cyclic ureas, amides, or carbamates with a carbonyl compound (particularly formaldehyde) and a CH-acidic aldehyde or ketone, in accordance with an α-ureidoalkylation principle[1,2].

This synthesis yields aldehydes *(1)* containing nitrogen, which can be converted *e.g.* into acetals *(2)* by reaction with monohydric or polyhydric saturated or unsaturated alcohols,

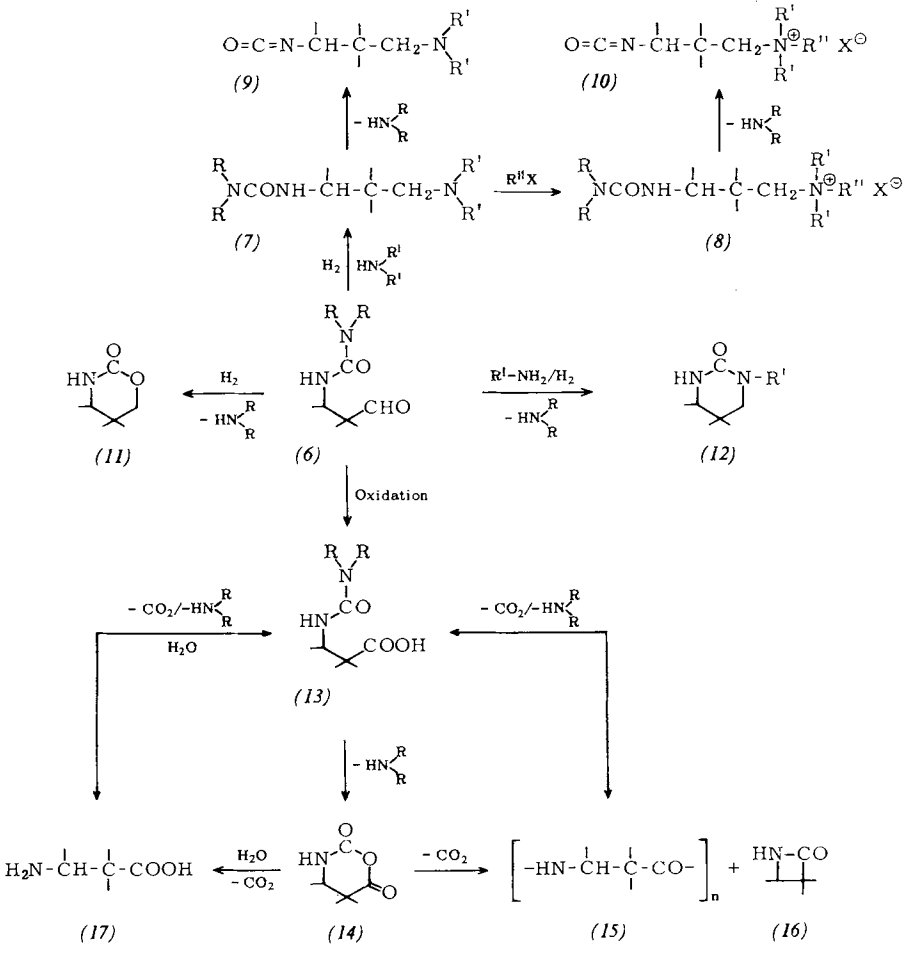


into monobasic or polybasic carboxylic acids *(3)* by oxidation, into monohydric or polyhydric alcohols *(4)* by hydrogenation, and into primary, secondary, or tertiary amines *(5)* of the ureas, amides, or carbamates by amination and hydrogenation. The compounds *(1)–(5)* are suitable for use *e.g.* in the synthesis of polycondensates and polymers, and can be converted into amino aldehydes, amino acids, amino alcohols, and polyfunctional amines by hydrolysis.

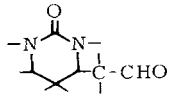


The amination and hydrogenation of the *N,N*-dialkylureido-*N'*-propionaldehydes *(6)* with secondary amines leads to 1-ureidopropylene-3-dialkylamines *(7)*, which can be quaternized at the basic nitrogen [*(8)*]. When heated, *(7)* give isocyanates [*(9)*], which react with H-acidic compounds to give a wide range of products.

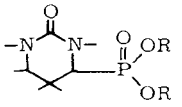
The heterocycles *(11)*, *(12)*, *(14)*, and *(16)* can also be prepared in this way. For example, *N,N*-dialkylureido-*N'*-propionaldehydes *(6)* can be converted by hydrogenation into tetrahydro-*2H*-1,3-oxazin-2-ones *(11)*, by amination and hydrogenation with NH_3 or primary amines into hexahydropyrimidinones *(12)*, and by oxidation *via N,N*-dialkylureidopropionic acids *(13)* into tetrahydro-*2H*-1,3-oxazine-2,6-diones *(14)*. When *(13)* and *(14)* are heated, they give polyamides *(15)* and 2-azetidinones *(16)*, or, in the presence of water, β-amino acids *(17)*.



The acidic condensation of urea or its mono- or disubstituted derivatives with two moles of an aldehyde, of which at least one mole must exhibit CH-acidic character, leads formally *via (18)* to heterocycles of the 4-hydroxyhexahydro-2-pyrimidinone type *(19)* [2,3]. These heterocycles can be oxidized to hexahydro-2,4-pyrimidinediones *(20)*, which react with water to form β-amino acids or decompose when heated to form polyamides and cyanuric acid.



Polycyclic ureas are obtained in an analogous manner from ureas and CH-acidic ketones in the presence of acids. Recent investigations [2,4] have shown that the 'triacetonediurea' obtained by *Weinschenk* [5] from acetone and urea is a 4,4'-



spirobi-(6,6-dimethylhexahydro-2-pyrimidinone) *(21)*. We obtained the polycyclic urea *(22)* from urea and cyclohexanone [4].

The heterocycles of the type *(19)* are cyclic α-alkylolureas, which condense with CH-acidic aldehydes to form 4-formyl-methylhexahydro-2-pyrimidinone *(23)* and with PH-acidic phosphorus compounds (*e.g.* dialkyl phosphites) to form dialkyl 2-oxohexahydropyrimidyl-4-phosphonates *(24)*.

(23)

(24)

The secondary reactions of *(19)* also include reactions with NH-acidic compounds, such as amines[2] and ureas[2,6,7], as well as with alcohols[2,8].

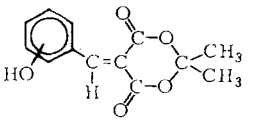
Reversibly Titratable Organic Lewis Acids

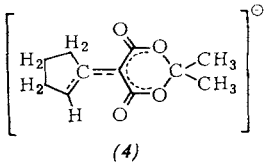
By *O. E. Polansky*[*]

Unsymmetrically substituted ethylenes *(1)*, in which X^1 and X^2 are strong electron-acceptor groups and R^1 and R^2 are weak acceptor or donor groups or H, have a relatively large partial positive charge on the C atom carrying R^1 and R^2. The Lewis-acid character of these compounds can be seen from the fact that bases are accepted reversibly at the position shown:



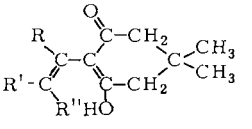
(1) *(2)*

The compounds *(1)* can accordingly be reversibly titrated in aqueous or aqueous-organic media, and have p*K* values of weak to medium-strong acids.



The UV spectra of the Lewis acid-base adducts *(2)* show superposition of the UV spectra of the chromophores R^1 and R^2, possibly of B, and of the anion $CHX^1X^{2\ominus}$, and thus prove structure *(2)*. Further evidence of the existence of *(2)* is provided by comparison of the NMR spectra of *(1)* and *(2)*, particularly when R^2 = H.

Corresponding to their Lewis-acid character, the olefins *(1)* very readily undergo nucleophilic attack at the C atom carrying R^1 and R^2, whereas the other C atom [even in *(2)*] is only slightly or not at all nucleophilic. The olefins *(1)* consequently do not enter appreciably into cycloadditions with diazoalkanes; instead, they react (probably in several steps) to form cyclopropanes, dihydrofurans, *etc.* The olefins *(1)*, as expected from their Lewis-acid character, catalyse the etherification of alcohols by diazoalkanes.



If the substituents R^1 and R^2 contain functional groups that can be acidified, the Brønsted-acid character becomes apparent, depending on the position of this group in relation to the double bond; *p*-hydroxybenzylidenemeldrum acid *(3a)* reacts as a Brønsted acid, while the *m*-hydroxy derivative *(3b)* reacts as a Lewis acid. The Lewis-acid character of the olefins *(1)* is occasionally suppressed by steric effects or by a tendency toward enolization. Thus the reaction of cyclopentylidenemeldrum acid with bases leads preferentially to the mesomeric anion *(4)*; the 2-alkylidenedimedones generally exist as the enol *(5)* if the alkylidene group contains β′-H atoms.

(3a): *p*-OH
(3b): *m*-OH

(4)

(5)

The p*K* values estimated by the HMO method exhibit a good agreement with the experimental values.

Use of Some Short-Lived Radionuclides for Activation Analysis by Irradiation with the Fast Neutrons of a Swimming-Pool Reactor

By *H.-J. Born* and *E. Pfeffermann*[*]

Swimming-pool reactors moderated with light water have a high proportion of fast fission neutrons, as well as thermal neutrons, close to the core. These fission neutrons, like the 14 MeV neutrons of an accelerator, are suitable for use in neutron activation analysis. The flux of fast neutrons from a reactor is mainly characterized by its high constancy and its high neutron intensity between 1 and 10 MeV. The threshold values of the desired nuclear reactions should lie below 10 MeV, since the flux of higher-energy neutrons is appreciably lower.

Of the (n,p), (n,α), (n,2n), and (n,n′) nuclear reactions that could be considered, some short-lived reaction products were studied in detail by means of their gamma spectra. The reactions studied were $^{16}O(n,p)^{16}N$, $^{89}Y(n,n')^{89m}Y$, $^{207}Pb(n,n')^{207m}Pb$, and $^{11}B(n,p)^{11}Be$. Owing to the short half-lives (1–16 sec), rapid transport from the irradiation position to the measurement position is necessary. A pneumatic tube with flight times of 1 sec is used in the research reactor at Munich. It is important to separate the sample container from the transport container (rabbit), so that only the sample falls directly into the measuring chamber. Because of this automatic ejection device, the rabbit can be fitted with a cadmium filter. This permits a marked reduction of parasitic activities induced by thermal neutrons. Measurement of the γ-activity of the samples is carried out with a 3″×3″ NaI(Tl) crystal.

The effective cross-sections for the flux spectrum at the irradiation position were first determined for the nuclear

reactions mentioned above. The reactions are suitable for the detection of oxygen, yttrium, and lead[1] by neutron activation analysis.

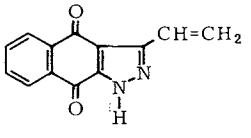
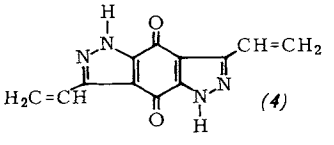
Institut für Radiochemie
der Technischen Hochschule München
8046 Garching bei München (Germany)

[1] For sample weights of 100–500 mg the detection limits are 250 μg for oxygen, 1–10 μg for yttrium, and 500 μg for lead.



Vinylpyrazoloquinones

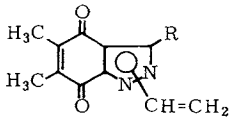
By *G. Manecke, G. Ramlow, W. Storck,* and *W. Hübner*[*]



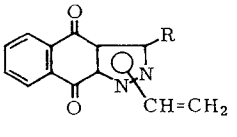
Whereas vinyl-substituted quinones have until now been obtainable only with difficulty, the vinylpyrazoloquinones *(1)* to *(4)* could be readily obtained by 1,3-dipolar addition of the diazoalkene vinyldiazomethane to quinones.

(1) R = CH_3
(2) R = Cl

(3)



(4)



Apart from the dichloro compound *(2)*, whose redox potential is so high that it inhibits self polymerization, all these compounds are polymerizable. If *(2)* is converted into the hydroquinone diacetate, polymerization again becomes possible.

Alkylations on the pyrazole ring yield mixtures of isomers, which can be separated by column chromatography. The main product is the N^1 isomer. If the pyrazoloquinone has H instead of a vinyl group in position 3, the N^2 isomer is formed in a higher yield. This effect is intensified with increasing size of the substituents in the order $CH_3 < CH = CH_2 < (CH_2)_nSO_3H$. In the sulfalkylation of 3-vinylpyrazoloquinones, the steric effects are so great that only the N^1 isomers are formed. The methyl isomers are obtained by methylation with dimethyl sulfate. *N*-Vinylpyrazoloquinones are formed in the mercury acetate-catalysed reaction with vinyl acetate, and sulfalkylated water-soluble pyrazoloquinones result from the reaction of the *N*-alkali metal salts with sultones.

The *N*-vinylpyrazoloquinones *(5)–(12)* were prepared with vinyl acetate.

(5) 1-vinyl, R = H
(6) 2-vinyl, R = H
(7) 1-vinyl, R = vinyl
(8) 2-vinyl, R = vinyl

(9) 1-vinyl, R = H
(10) 2-vinyl, R = H
(11) 1-vinyl, R = vinyl
(12) 2-vinyl, R = vinyl

Only the *N*-vinyl groups of the pyrazolonaphthoquinones *(9)–(12)* were polymerizable. The *N*-vinylpyrazoloquinones could not be polymerized, even as derivatives of the corresponding hydroquinones. On the other hand, the 5,6-epoxy derivatives of the compounds *(5)–(8)* could be very readily polymerized.

Since the polymeric epoxy compounds could also be converted back into the quinones with potassium iodide in acetic acid/water, redox polymers could be obtained in this way.

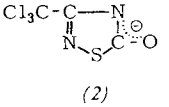
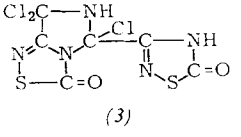
Contribution to the Chemistry of Substituted Δ^2-1,2,4-Thiadiazolin-5-ones

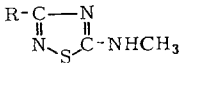


By *R. F. W. Rätz* and *H. D. Hoberecht*[*]

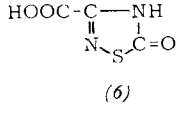
The Δ^2-1,2,4-thiadiazolin-5-ones are a class of reactive compounds, of which the few known members were previously regarded as 5-hydroxy-1,2,4-thiadiazoles. Chemical reactivity and spectroscopic data indicate that these compounds exist, both as the solid and in solution, in the lactam form *(1)*. Their acidity makes them capable of salt formation with inorganic and organic bases. These salts are so stable that they can be used as nucleophiles in a number of acylation reactions.



In aqueous solution, the anion *(2)* forms a dimer, which reacts with ammonia to form the previously unknown 5,7,7-trichloro-6,7-dihydro(5-oxo-Δ^2-1,2,4-thiadiazolin-3-yl)-3*H*,5*H*-imidazo[5,1-*c*][1,2,4]thiadiazol-3-one *(3)*. The compound was characterized by elemental analysis and by IR and mass spectroscopy.



(1)



(2)

(3)

(4), R = Cl_3C-
(5), R = CH_3NH-C(=O)-

(6)

Attempts to obtain an analogous *N*-methylated compound by treatment of the dimer with methylamine instead of with ammonia were unsuccessful. Solutions of the compound *(1)*, R = Cl_3C, have a ketonic character in aqueous methylamine; the compounds *(4)* and *(5)* are formed.

In the presence of an excess of sodium hydroxide, *(1)*, R = Cl_3C, is converted into the disodium salt of the acid *(6)*. The free acid melts at about 140 °C with decarboxylation to give the parent substance of this series.

Electrochemical Studies on the Electron and Ion Defect State in α-Silver Selenide

By *D. O'Briain* and *H. Rickert*[*]

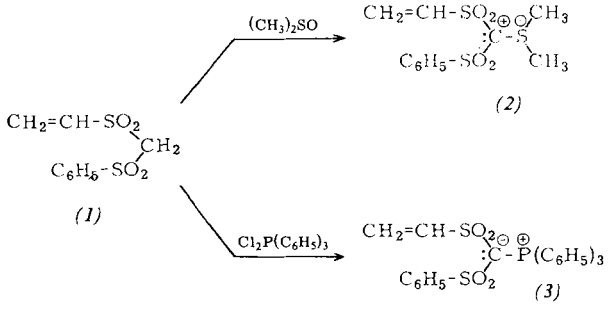
The relationship between the chemical potential of silver in α-silver selenide and the deviation from the ideal stoichiometric composition was determined by an electrochemical titration with the aid of the solid cell Ag/AgI/Ag_2Se at 200 °C. Owing to the highly imperfect arrangement of the silver ions in Ag_2Se, its chemical potential may be assumed to be constant. When the stoichiometric composition is

changed, the chemical potential of the silver depends only on the change in the concentration of the quasi-free ions and defect electrons. The thermodynamic behavior of the electrons in Ag_2Se can be quantitatively described by the application of Fermi-Dirac statistics, *i.e.* by taking into account the degeneracy of the electrons. The electrochemical thermodynamic method provides a means for the determination of the band gap in Ag_2Se. The partial conductivity of the silver ions was also studied as a function of the stoichiometric composition. In agreement with the lattice defect model, the partial conductivity σ is independent of the chemical potential of the silver, and can be expressed as a function of temperature by the following equation:

$$\sigma_{Ag^+} = 11.4 \exp(-1180\ \text{cal}/RT)\ \text{ohm}^{-1}\ \text{cm}^{-1}$$

The self-diffusion coefficient D of silver is also independent of the stoichiometric composition:

$$D_{Ag} = 7.95\times10^{-8}\ T \exp(-1370\ \text{cal}/RT)\ \text{cm}^2\ \text{sec}^{-1}$$



Comparison of the partial conductivity and the self-diffusion coefficient of silver ions gives a correlation factor of 0.36 at 300 °C for the self-diffusion. Conclusions regarding the diffusion mechanism can be drawn from this result.

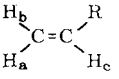
Investigation of *S*-Vinylsulfonylylides

By *H. Diefenbach*, *H. Ringsdorf*, and *R. Wilhelms* [*]



Dimethylsulfonium phenylsulfonylvinylsulfonylmethylide *(2)* and triphenylphosphonium phenylsulfonylvinylsulfonylmethylide *(3)* were prepared by condensation of phenylsulfonylvinylsulfonylmethane *(1)* with dimethyl sulfoxide and with triphenylphosphine dichloride respectively.

Elemental analyses and the fragments and maximum masses (*m/e* 306 and 506, respectively) in the mass spectrum confirm the compositions and molecular weights of *(2)* and *(3)*. The two unsaturated ylides can be recrystallized from water, and cannot be further acylated with benzoyl chloride.

The predominance of the indicated ylide structure over a possible ylene structure is confirmed by the UV spectrum of *(2)* (in 95% ethanol). In contrast to *(1)*, the spectrum of *(2)* no longer exhibits the fine structure due to an aromatic system. The spectrum, which contains a broad, intense band at $\lambda_{max} = 248$ nm ($\log \varepsilon_{max} = 3.93$) is similar to that of the bis-(phenylsulfonyl)methane anion ($C_6H_5-SO_2-\overset{\ominus}{C}H-SO_2C_6H_5$).

The ylide carbanion is stabilized by the adjacent SO_2 groups. The SO_2 stretching vibrations occur accordingly at lower wavelengths than in *(1)* (cf. displacement of the carbonyl frequency in acylylides). An increase in the electron densities on the phenyl and vinyl groups is also to be expected from the delocalization of the electron pair on the ylide carbanion. This is confirmed by the position of the signals due to the phenyl and vinyl protons in the NMR spectrum (measured in $(D_3C)_2SO$, TMS as internal standard).

	τ_a	τ_b	τ_c	τC_6H_5
(1)	3.64	3.68	2.91	2.1
(2)	4.23	4.03	3.07	2.3
(3)	4.37	4.73	2.94	2.4

Compounds *(2)* and *(3)* undergo free-radical polymerization to form macromolecular ylides. Copolymerization experiments with styrene show that the reactivity of the vinylsulfonylylides corresponds roughly to that of vinylphenylsulfone.

Stability and Properties of the Complexes of Hexavalent Actinides with Pyridine-2-carboxylic Acids and Quinaldic Acid

By *W. Robel* and *S. H. Eberle* [*]

Chelates of hexavalent uranium, neptunium, plutonium, and americium with pyridine-2-carboxylic acid (HAPA), 6-methylpyridine-2-carboxylic acid (HMAPA), and quinaldic acid are obtainable by precipitation from aqueous solution. Compounds of the types MO_2L_2, $MO_2L_2{\cdot}2H_2O$, and $MO_2L_2{\cdot}HL$ (solvated complexes) are formed. Depending on the precipitation conditions, it is possible to isolate *e.g.* $UO_2(APA)_2$ or $H[UO_2(APA)_3]$. The solvated complex has the properties of a difficulty soluble acid. Extraction of the hexavalent actinide from aqueous solution is possible *via* its chloroform-soluble tetraphenylarsonium salt.

Thermogravimetric studies show that the solvated compounds change into the normal compounds with loss of a ligand molecule by sublimation at *ca.* 200 °C.

Potentiometric, and in the case of Pu(VI) spectrophotometric, titrations indicate the stepwise formation of 1:1 and 1:2 complexes in aqueous solution. The stability constants can be calculated from the formation curves, *e.g.* Pu–HAPA $\log \beta_1 = 4.8$, Pu–HMAPA $\log \beta_1 = 2.5$.

Exchange Reactions and the Annealing of Nuclear Recoil Defects in Crystalline Co-, Rh-, and Ir-Amine Complexes

By *K. Rössler* and *W. Herr* [*]

The radionuclides formed in complexes of the types $[M(en)_2X_2]X$ and $[M(NH_3)_5X]X_2$ (M = Co, Rh, Ir; X = Cl, Br) by neutron capture can be separated on the basis of their modified chemical state. The specific activities that can be reached are limited by the degree of annealing by heat and γ-rays, by exchange reactions, and by the tendency of the compound to be decomposed by radiation. We found that transition reactions in particular have to be taken into ac-

count in these amine complexes even when there was no reactor radiation.

First-order exchange curves were obtained for the ^{36}Cl and ^{82}Br isotope exchange between ionically and covalently bonded halogen atoms in labeled crystalline *cis*- and *trans*-$[Co(en)_2X_2^*]X$ and *trans*-$[Rh(en)_2Cl_2^*]Cl$:

$k_1 = 10^{12} \exp(-32 \text{ kcal mole}^{-1}/RT)\ (\text{sec}^{-1})$ [Co complexes; for ^{36}Cl and ^{82}Br]

$k_1 = 10^{8} \exp(-30 \text{ kcal mole}^{-1}/RT)\ (\text{sec}^{-1})$ [Rh complex]

For example, ligand exchange in *trans*-$[Co(en)_2Cl_2^*]Cl$ is accelerated by a factor of 2 to 40 by previous irradiation with X-rays or with ^{60}Co-γ-rays (2×10^4 to 2×10^7 rad). The activation energy $E_A = 31$ kcal/mole is almost identical with that for samples that have not been irradiated. It is concluded that halogen exchange takes place *via* the defect sites (anion vacancies) already present in the lattice as well as those produced by radiation. This exchange is probably favored by an intermediate reduction of the central atom.

Conductivity measurements on *trans*-$[Co(en)_2Cl_2]Cl$ show a relationship with the exchange behavior.

In the Co-, Rh-, and Ir-pentammine complexes, the exchange leads to plateau values, the position of which depends on the temperature and on previous irradiation. Thus solid $[Co(NH_3)_5Cl]Cl_2^*$ exhibits a maximum of only 6% ^{36}Cl exchange at 150 °C, with a half-life of $t_{1/2} = 140$ min, whereas after X-ray irradiation (dose = 1.75×10^6 rad) it exhibits about 30% ^{36}Cl exchange and $t_{1/2} = 108$ min.

In crystalline *trans*-$[Co(en)_2Cl_2]Cl$, the exchange between the central atom and absorbed $^{60}Co^{2+}$ ions was also studied. This exchange obeys first-order kinetics and is appreciable even at 170 °C ($t_{1/2} = 100$ min).

We concluded from the results that, in the systems studied, the annealing can be largely understood on the basis of the high mobility of the ligand and central atoms, *i.e.* by simple exchange mechanisms.

Electrochemical Determination of the Specific Surface Area and the Activity of Porous Platinum

By *H. Binder, A. Köhling, K. Metzelthin, G. Sandstede,* and *M. L. Schrecker*[*]

The specific surface area of porous platinum that has been precipitated on an electrically conducting support can be determined by cathodic adsorption of hydrogen or by anodic desorption (oxidation) of adsorbed hydrogen atoms, with the aid of the potentiostatic triangular voltage sweep method. Owing to surface diffusion, the entire surface of the platinum is determined.

Electrochemical determination of the surface area has an advantage over the gas adsorption methods, not only because of its speed, but also because the platinum catalysts do not age as a result of elevated temperatures. The surface area depends on the nature of the platinum catalyst, *e.g.* whether platinum black or Raney platinum is used. In the case of Raney platinum, the specific surface area increases with increasing Al/Pt ratio in the aluminum alloy used, from about 7 m²/g (Al/Pt = 1) to about 37 m²/g (Al/Pt = 6). The specific surface area can decrease by up to 30% as a result of aging of the catalyst during the operation of the electrode. The ratio of the various crystal faces to one another also changes. The proportion of faces with higher indices is greater in fresh catalyst samples than in aged samples. This can be shown by the determination of the ratio of the BET surface area to the electrochemically determined surface area at various stages of aging.

The activity of the catalysts was determined from galvanostatic current-voltage curves, which were recorded during the anodic oxidation of methanol in dilute sulfuric acid. The activity of the platinum catalyst is not a simple function of the specific surface area. The activity depends in a characteristic manner *e.g.* on the Al/Pt ratio of the Raney alloy.

Chemistry of Perfluorinated Aromatic Mono- and Dicarboxylic Acids

By *P. Sartori*[*]

In the thermal decomposition of aliphatic perfluoroacyloxy compounds of Group IV elements (salts of aliphatic perfluorocarboxylic acids), two paths were found to exist for the decomposition of the molecule and the subsequent stabilization of the perfluoroalkyl residue: 1. Decarboxylation and removal of fluoride with formation of perfluoroolefins and 2. decarboxylation, decomposition of the perfluoroalkoxide into fluoride and the fluoride of a perfluorocarboxylic acid having one less C atom in the chain [1]. Neither reaction is possible with derivatives of pentafluorobenzoic acid. Various pyrolysis products are formed, depending on the central atom: octafluoroxanthone, decafluorobenzophenone, decafluorobiphenyl, pentafluorophenylmetal compounds, pentafluorobenzene, and pentafluorobenzoic anhydride[2].

Tetrafluorophthalic acid can be obtained from octachloronaphthalene by halogen exchange with KF in sulfolane and oxidation of the resulting octafluoronaphthalene with concentrated nitric acid. Reaction of its alkali metal or silver salts with alkylchlorosilanes yields perfluoroacyloxysilane derivatives. Unlike $TiCl_4$, $SiCl_4$ does not react completely with tetrafluorophthalic acid. The pyrolysis of Hg or Ag tetrafluorophthalate leads to *(1)* or octafluorobiphenylene and octafluorofluorenone.

Experiments on the Poisoning of Catalysts used in the Synthesis of Ammonia

By *R. Brill, H. Schaefer,* and *G. Zimmermann*[*]

The poisoning by H_2S, S_2N_2, and thiophene of non-promoted and Al_2O_3-promoted iron catalysts for the ammonia synthesis was investigated in order to obtain information about the adsorption of sulfur on iron surfaces, the role of the promoter Al_2O_3 in relation to the tolerance for poisons, the effect of the poison on the ammonia synthesis, and the energy state of the catalytically active surface.

The iron surface of these catalysts chemisorb a maximum of 0.5 mg of sulfur/m² (corresponding to a monolayer). This

monolayer is retained even when the catalyst is treated with H_2 at 620 °C, whereas FeS formed on poisoning with high concentrations of H_2S can be reduced by H_2 above 300 °C. However, 0.16–0.25 mg of sulfur/m² is sufficient for complete poisoning of an iron catalyst. These experiments would suggest that only one or a few crystallographic surfaces are catalytically active and react preferentially with sulfur. On the other hand, in view of the vigorous reaction of sulfur, it is not impossible that the sulfur reacts nonspecifically in poisoning both by H_2S and by thiophene. However, experiments conducted with the field electron microscope[1] show that the activation of nitrogen is determined by the 111 face, so that the poisoning of this face will be important.

The adsorbed sulfur accelerates the sintering of the iron catalysts at high temperatures. The promoter Al_2O_3 hardly adsorbs sulfur. It increases the tolerance of iron catalysts by inhibition of sintering even in the partly poisoned state.

Torsional Vibration Measurements on Copolymers of Methyl Methacrylate and (Tri-n-propyl)tin Methacrylate

By *E. E. Schäfer* and *G. Rehage*[*]

The storage modulus G' and the loss modulus G'' [**] of copolymers and mixtures of polymers of methyl methacrylate and (tri-n-propyl)tin methacrylate were determined with a very sensitive torsion pendulum at a frequency of about 1 Hz and between −190 and 150 °C. It was found that the product was a true copolymer, a mixture of homopolymers, or a mixture of homopolymer and copolymer, depending on the polymerization conditions. The polymers prepared purely thermally, without the addition of a catalyst, consisted of a mixture of pure poly(tri-n-propyl)tin methacrylate and a copolymer of the two components. Similar heterogeneous products were also obtained when the temperature of polymerization was varied. However, when the polymerization was carried out in the presence of a catalyst (about 0.02-% of benzoyl peroxide) we obtained a true copolymer. Unlike the mixture, this did not solidify at two temperatures, but at a single point situated between that of pure poly(tri-n-propyl)tin methacrylate (−18 °C) and that of pure polymethyl methacrylate (about 120 °C).

Owing to its bulky side group, the poly(tri-n-propyl)tin methacrylate had a relatively low glass transition temperature, and so acted as an internal plasticizer on copolymerization with methyl methacrylate. It is therefore possible to determine by torsional-vibration measurements whether a product is a copolymer, a homopolymer mixture, or a mixture of homopolymer and copolymer, as is also shown by measurements reported by *Herwig*[1], *Oberst*[2], and *Heinze*[3].

Synthesis and Thermal Ring Cleavage of Bicyclic Cyclobutane Derivatives

By *H.-D. Scharf, M. Gallus,* and *F. Korte*[*]

The bicyclo-[*n*.2.0]alkane derivatives *(2)* are prepared by photocycloaddition (followed by hydrolysis and esterification) of dichloromaleic anhydride to cyclic olefins *(1)*, n = 3, 4, 5, 10. The steric course of the benzophenone-sensitized reaction, is being studied for various values of n.

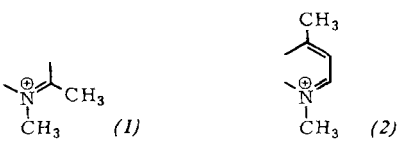
(1) *(2)* *(3)* *(4)* *(5)* *(6)*

In the bicyclic compounds *(2)* thus obtained, the chlorine atoms are vicinal and *cis* to each other. Zinc and nickel are used to eliminate the chlorine to form *(3)*. The electrocyclic ring cleavage of *(3)* on thermal excitation is also being studied and the stereochemistry of the cyclic dienes *(4)* is considered on the basis of the Woodward-Hoffman rules. Results:

a) *(3)*, n = 3, is cleaved at 360 °C with simultaneous hydrogen shift to give *(6)*.

b) *(3)*, n = 5, yields the *cis-cis*-cyclononadiene derivative *(4)*, n = 5, as sole product when heated to 300 °C.

c) *(3)*, n = 10, with the *trans*-fused bicyclo[10.2.0]tetradecene system undergoes a smooth reaction at 120 °C to give the *trans-trans*-cyclotetradecadiene derivative *(4)*, n = 10.



The thermal cleavage of the bicyclic compounds *(2)* leads to open-chain unsaturated dicarboxylic acids *(5)*. This reaction also proceeds stereoselectively.

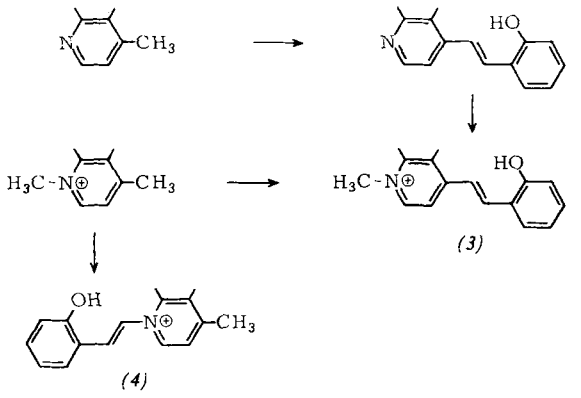
N- and *O*-Heterocyclic Spiro Compounds



By *C. Schiele*[*]

In an examination of literature data on the synthesis of *N*- and *O*-heterocyclic spiranes, it was found that our observations[1] did not always agree with the literature reports. We therefore tried first to clarify the course of the condensation of *N*-heterocyclic methyl-substituted compounds of the types *(1)* and *(2)* with salicylaldehyde and 2-hydroxy-1-naphthalenecarb-

(1) *(2)*

aldehyde. In the case of dinuclear heteroaromatics, we synthesized an *N*-alkylated (*o*-hydroxy)styryl compound *(3)* by the route methyl-substituted heteroaromatic compound → (*o*-hydroxy)styryl compound, whereas condensation according to *Wizinger*[2] gave the product *(4)*[3]. This observation is supported in particular by the IR spectra. It can be seen from the formulae that cyclization to form the spirane

(3)

(4)

can be expected only with condensation products of the type *(3)*; however, their formation has not been observed in such systems.

Calculation of Substituent Constants from Spectroscopic Data

By *G. P. Schiemenz* [*]

The σ constants of the Hammett relation are measures of the overall electronic effect of substituents X on the aromatic ring. They are obtained from the logarithms of the equilibrium constants (log *K*) or rate constants (log *k*) of reactions on a second substituent Y, *i.e.* from differences involving the properties of two species (educt and product or educt and transition state). The Hammett relation assumes that X has a similar influence on both species. It must then also be possible to obtain σ values for X from the properties of the groups Y in only one species. The position of an IR stretching band or of an NMR signal of Y has repeatedly been used for this purpose [1], a linear relationship being postulated between $\tilde{\nu}$ or δ and σ of X. However, the plots for *p*-X-substituted benzoic acids [2, 3], their esters [3] and nitriles [2–4], as well as benzaldehydes [3] and nitrobenzenes [3] do not give straight lines over the whole σ range.

The numerical values of σ are so chosen that the inductive and mesomeric effects, by definition, have equally strong influences on log *K*(*k*). This cannot be stipulated for other quantities. +M substituents have a different (stronger) influence on the bond order, and hence on the wave number $\tilde{\nu}$ of a stretching band of – M substituents than groups that have only an inductive effect, to which the –M substituents are adjacent. If one assumes that $\tilde{\nu}$ depends linearly, but to different degrees, on the partial terms σ_{+M}, σ_{-M}, and σ_I of the constant σ, then $\tilde{\nu}$ can be expressed by equation *(1)*, where $a > b \approx c$.

$$\tilde{\nu} = a\sigma_{+M} + b\sigma_{-M} + c\sigma_I + d \qquad (1)$$

For $\sigma < 0$ we have $\sigma_{-M} = 0$, and except for alkyl groups, $|\sigma_{+M}|$ is usually greater than $|\sigma_{-I}|$, *i.e.* $|a\sigma_{+M}| \gg |c\sigma_{-I}|$. σ_{-I} has a similar magnitude for common +M/–I groups, and can therefore be broken down into a constant component and a smaller, variable component ($\sigma_{-I} = \sigma_I^\circ + \Delta\sigma_I$); σ_I° is defined as the average of all σ_{-I} values, so that the sign of $\Delta\sigma_I$ changes. Eq. *(1)* then takes the form

$$\tilde{\nu} = a\sigma_{+M} + c\Delta\sigma_I + c\sigma_I^\circ + d$$

$c\sigma_I^\circ$ may be included in the constant *d*, and $c\Delta\sigma_I$ is negligible in relation to the much larger $a\sigma_{+M}$. Thus for $\sigma < 0$, a straight line of slope *a* is to be expected, except in the case of alkyl groups. The conditions for $\sigma > 0$ ($\sigma_{+M} = 0$, $b \approx c$, $\sigma_{-M} + \sigma_I = \sigma$) give, as an approximation, the equation $\tilde{\nu} = b\sigma + d$, *i.e.* a straight line having slope *b*. For the halogens, $\sigma_{+M} < \sigma_{-I}$, and consequently $a\sigma_{+M} \approx c\sigma_{-I}$, so that $\tilde{\nu}$ should be particularly low. The derivation therefore requires a steep straight line in the region $\sigma < 0$ and a shallower straight line for $\sigma > 0$, the two lines intersecting at about $\sigma = 0$; the points for the halogens lie appreciably below the lines, and those of alkyl groups slightly below. This picture is substantially in agreement with experimental findings (with individual values of *a* and *b* for each class of substances). The same is true of NMR signals.

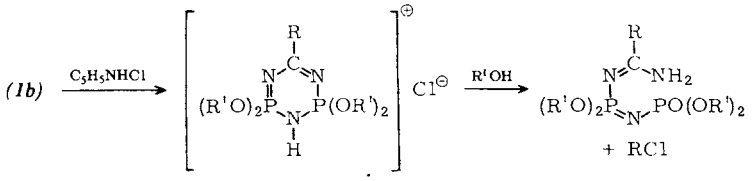
Substituted Diphospha-1,3,5-triazines

By *A. Schmidpeter, J. Ebeling,* and *N. Schindler* [*]

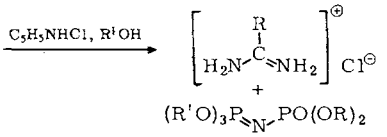
p-Alkyl- and aryl-substituted diphospha-1,3,5-triazines *(1)* are obtained by cyclocondensation of imidodiphosphinic trichlorides with amidinium chlorides [1] or by transamination of diphenylamidines with aminodiphosphazenes [2]; tetrachloro-substituted diphosphatriazines are best obtained by fusion or sintering of bis(trichlorophosphorus)nitride hexachlorantimonates *(2)* with an excess of amidinium chloride.

(1)

(a) X = X′ = Cl; R = alkyl, aryl
(b) X = X′ = OR′; R = alkyl, aryl
(c) X = R = C_6H_5; X′ = Cl



$$[N(PCl_3)_2]SbCl_6 + 2\ [RC(NH_2)_2]Cl \rightarrow 4\ HCl + [RC(NH_2)_2]SbCl_6 + \textit{(1a)}$$



(2)

The ring skeleton *(1)* is stable to nucleophilic attack; the chlorine atoms on the phosphorus can be replaced with amino, alkoxy, or aryloxy groups by treatment with amines or alkoxides. Alcoholysis of the ring may occur during substitution with alcohol/pyridine. The first step is a proton transfer from pyridinium chloride.

The various substituted derivatives of *(1)* all appear to be protonated in position 3; in any case, the ^1H- and ^{31}P–NMR spectra show that the diphospha-1,3,5-triazinium ions are symmetrical. The kinetically controlled methylation, on the other hand, regularly takes place in position 1.

(1c) is formed as a mixture of the *cis*- and *trans*-forms on cyclocondensation. On nucleophilic substitution, the isomer ratio generally remains the same, within the limits that can be recognized by NMR spectroscopy. The substitution therefore takes place by a uniform mechanism.

The shielding of the phosphorus, which decreases in the order $R = H > CH_3 > C_6H_5CH_2 > C_6H_5 > N(CH_3)_2 > NH_2$, evidently is determined mainly by an anisotropy term due to the ring system.

Adenosyl-B_{12}: Enzymatic Synthesis and Function

By *R. R. Schmidt*[*]

The results of recent investigations of the enzymatic synthesis of adenosyl-B_{12}[**] from vitamin B_{12} or hydroxocobalamin (B_{12a}) indicate the intermediate formation of the extremely nucleophilic hydridocobalamin (B_{12s}). This is then adenosylated by ATP in a second step to form adenosyl-B_{12}. Model investigations, which were closely based on the enzymatic findings, were carried out to study the mechanism of the enzymatic reduction of vitamin B_{12} or B_{12a} to B_{12s}. The main object of the investigations was to establish whether the reduction of B_{12a} (oxidation state of Co = +3) to B_{12s} (oxidation state of Co +1) proceeds as a one-step reaction with simultaneous transfer of two electrons by the reducing agent, or as a two step reaction in which only one electron is transferred in each step. In the latter case, reduced cobalamin (B_{12r}, oxidation state of Co = +2) would occur as an intermediate. The reduction was carried out *inter alia* with thiols, which act as reducing agents in enzymatic systems[1]. We found that the reduction proceeds as a one-step reaction. Thus the reduction of B_{12a} to B_{12s} with thioredoxin[2] and other biochemical reducing systems[3] does not occur in nature.

The function of adenosyl-B_{12} in enzymatic synthesis is still uncertain. Investigations on modified cobalamins should provide clues for the mechanistic interpretation of coenzyme B_{12}-catalysed reactions. Since the Co–C bond joining the adenosyl residue to the Co, and the 5′-hydrogen atoms of the adenosyl residue, play a central role in the mechanistic interpretation, 5′-modified adenosine derivatives were synthesized in order to convert them into suitably modified adenosyl-B_{12} and to examine their enzymatic behavior.

Ternary Alkali Metal and Alkaline Earth Fluorides of Neptunium, Plutonium, and Americium

By *H. Schmutz, M. Salzer,* and *C. Keller*[*]

Ternary fluorides of the trivalent and tetravalent actinides neptunium, plutonium, and americium having various compositions and structures were prepared by solid-phase reactions and precipitation reactions. The starting materials were the binary fluorides, carbonates, or oxides. The reactions were carried out at 350 to 1000 °C in a current of HF/N_2, to which H_2 or O_2 was added in some cases in order to obtain compounds of trivalent or tetravalent actinides, respectively.

As expected, the compounds such as $NaAmF_4$, $KAmF_4$, KAm_2F_7, and the corresponding plutonium compounds found in the systems $MF–MF_3$ (M^I = Na, K; M^{III} = Pu, Am) were found to be isostructural with the ternary fluorides of the lighter rare earth metals with the same formula. Attempts to prepare the analogous Np(III) compounds were unsuccessful, since oxidation of Np(III) to Np(IV) could not be prevented. The Np(IV) double fluorides $LiNpF_5$, Na_2NpF_6, $M_7Np_6F_{31}$, (M^I = Na, K, Rb) and the analogous Pu(IV) compounds were obtained in the pure state by direct synthesis. These compounds are isostructural with the similar ternary fluorides of thorium and uranium. The molar volume of the compounds prepared increases with increasing atomic number of the actinide.

The double fluorides of the type $M^{II}M^{IV}F_6$ (M^{II} = Ca, Sr, Ba, Pb and M^{IV} = Np; or M^{II} = Ca, Sr and M^{IV} = Pu) crystallize in the hexagonal LaF_3 lattice with random distribution of M^{II} and M^{IV}. Investigations on the systems $SrF_2–SrM^{IV}F_6$ (M^{IV} = Np, Pu) at 950 °C showed that 26 to 27 mole-% of SrF_2 dissolve in $SrM^{IV}F_6$, with formation of anion defects in the lattice. The solubility of SrF_2 in $SrM^{IV}F_6$ is practically independent of the M(IV) cation. Precipitations from aqueous solutions always yielded the stoichiometric compounds.

Carboranebis(sulfenyl chlorides) in Polymerization Reactions[**]

By *N. S. Semenuk, S. Papetti,* and *H. A. Schroeder*[*]

We attempted to use carboranes having a $B_{10}C_2$ skeleton (icosahedral) as structural units for thermally stable plastics. For example, polymers in which *m*-carborane units are linked by single carbon or phosphorus atoms were prepared.

Carborane polymers with sulfur bridges, which are derived from *m*-$B_{10}H_{10}C_2(SCl)_2$, have now been obtained for the first time. The bis(sulfenyl chloride) is readily obtainable by chlorination of *m*-$B_{10}H_{10}C_2(SH)_2$, and can be used for the preparation of several polymer systems, since the chlorine atoms can be readily replaced in nucleophilic reactions. It can be converted into polysulfides $(-CB_{10}H_{10}C–S–)_x$ *(1)* and polydisulfides $(-S–CB_{10}H_{10}C–S–)_x$ *e.g.* by reaction with the bifunctional *m*-$B_{10}H_{10}C_2Li_2$, or simply by heating in alcohol. Properties of the polysulfides: microcrystalline, $x \cong 30$, m.p. 219–222 °C. Properties of the polydisulfides: $x \cong 8$, m.p. 307–310 °C.

(1)

In addition to these polymers, the interesting bis(sulfonyl chloride) *m*-$B_{10}H_{10}C_2(SO_2Cl)_2$ was also prepared. Properties: colorless crystals, m.p. 62–63 °C.

The Reaction of Azides with Organometallic Compounds

By *H. Schumann* and *S. Ronecker*[*]

When refluxed in tetrahydrofuran, phenyl azide reacts with trimethylstannyllithium with liberation of nitrogen and formation of lithium *N*-phenyltrimethylstannylamide:

$$(CH_3)_3SnLi + C_6H_5N_3 \longrightarrow N_2 + (CH_3)_3Sn\text{-}N(C_6H_5)Li$$

Intermediate formation of a triazene can be ruled out on the basis of IR measurements.

In the reaction of phenyl azide with triphenylsilyl-, triphenylgermyl- triphenylstannyl-, and triphenylplumbyllithium, the reaction rate increases from the silicon to the lead derivative. The analogous reaction of trimethylstannane with phenyl azide leads to trimethylstannylphenylamine, which is stable at room temperature. Trimethylsilane and trimethylgermane react only at higher temperatures, and organometallically substituted amines containing NH functions cannot be isolated.

Hydrazoic acid and trimethylstannane react slowly at −78 °C to form trimethylstannylamine; however, owing to its extreme instability, this product can be detected only spectroscopically in solution, and attempts to isolate it yielded only tris(trimethylstannyl)amine.

Organometallic azides such as trimethylsilyl, trimethylgermyl, trimethylstannyl, or dibutylboron azide react only at high temperatures with organometallic lithium compounds or organometallic hydrides with replacement of the azide group. The lithium organometalamides isolated can be used as starting materials for the synthesis of organometalamides with mixed substituents.

The Search for New Neutron Emitters Among the Fission Products of Uranium-235

By *H.-D. Schüssler, W. Grimm,* and *G. Herrmann*[*]

The contributions of known and hitherto unknown neutron emitters to the groups exhibiting delayed neutron emission which are produced in the fission of uranium-235 by thermal neutrons were measured with the aid of a pneumatic tube conveyor installed in the Mainz reactor and automatically controlled separating apparatus. This permits transport times of 0.12 sec and separation times of 1 to 2 sec. The elements in question were isolated by ion or isotope exchange on preformed precipitates, *i.e.* iodine on silver iodide, iodine and bromine together on silver chloride, rubidium and cesium on ammonium molybdato- or thallium tungstatophosphate, and strontium and barium, accompanied by yttrium, zirconium, niobium, and the rare earths on barium sulfate, barium carbonate, and strontium carbonate; solvent extraction in bis-(2-ethylhexyl)orthophosphoric acid on polytrifluoromonochloroethylene powder was used for zirconium, niobium, and yttrium. Chemical yields and impurities were determined and corrected using long-lived radioisotopes. In this way nuclides having half-lives of less than a second, *e.g.* ^{140}I with $\tau_{1/2} = 0.8$ sec, can still be detected after pulsed irradiation.

Measurements for the fission of ^{235}U show contributions to the 22 sec group of 64.6 ± 2.2 % (± 2σ) for ^{137}I and 35.4 ± 2.3 % for ^{88}Br; the relative neutron intensities found are 1(^{137}I), 0.5(^{138}I), 0.8(^{139}I) and ≈ 0.5(^{140}I), and 0.4(^{87}Br), 1(^{88}Br), 1.7(^{89}Br) and 1.4(^{90}Br).

The components of the halogen nuclides are therefore: in the 6 sec group 33 % of ^{138}I and 67 % of ^{89}Br, in the 2 sec group 21 % of ^{139}I and 28 % of ^{90}Br, and in the 0.6 sec group ≈ 60 % of ^{140}I. Comparison of neutron-decay curves of the halogen fraction with analogous curves of unseparated samples shows that nonhalogens contribute < 5 % to the 22 sec group, 18 ± 5 % to the 6 sec group, and 50 ± 10 % to the 2 sec group. In the 6 sec group this contribution is due to ^{93}Rb, which is responsible for 22 ± 5 % of the neutron intensity of this group. The alkali metals (^{94}Rb, ^{142}Cs, ^{143}Cs) contribute 20 ± 6 % to the 2 sec group; there are also about 10 % each of the elements that are separated with alkaline earth precipitates and bis-(2-ethylhexyl)orthophosphoric acid, and (according to *del Marmol*[1]) of ^{85}As.

The percentages of the nuclides can be converted into absolute yields (neutrons per fission) with the aid of the known group yields. Comparison with estimated fission yields then gives the following neutron emission probabilities: 2.2 % (for ^{87}Br), 4.0 % (^{88}Br), 7.7 % (^{89}Br), 12 % (^{90}Br), 5.1 % (^{137}I), 2.8 % (^{138}I), 6.4 % (^{139}I), ~13 % (^{140}I), and 1.6 % (^{93}Rb).

Synthesis and Circular Dichroism of Optically Active Adamantane Derivatives

By *G. Snatzke, G. Eckhardt,* and *B. Ehrig*[*]

The dextrorotatory enantiomer of 4,8-dioxoadamantane-2-carboxylic acid was prepared with cinchonine, and the levorotatory enantiomer with cinchonidine. Partial reduction of one keto group with $NaBH_4$ followed by Clemmensen reduction and reoxidation leads to the 4-oxoadamantane-2-carboxylic acid *(1)* having an equatorial arrangement of the carboxyl group in relation to the ring containing the carbonyl group. Partial dithioketalization with ethanedithiol followed by Mozingo reduction yields the "axial" epimer of *(1)*. In all three acids, the carboxyl group could be replaced by Br or I in good yields by the Hunsdiecker method. Exchange of

(1)

bromine for chlorine took place with LiCl in DMF, for fluorine with AgF in chlorobenzene, and for azide with NaN_3 in DMF.

The carboxyl group of the "equatorial" keto acid was reduced to the primary alcohol after ketalization of the carbonyl group with glycol. The $-CH_2OH$ group could be converted, *via* the *p*-toluenesulfonate, into a methyl group by means of $LiAlH_4$.

The circular dichroism of "equatorial" β-methyladamantanone depends relatively strongly on the solvent, though the molecule is rigid. Thus the reduced rotatory strengths in cyclohexane, dioxane, and ethanol are 1.76, 2.23, and 2.52 biots, respectively; according to *Weigang*, this variation is due to the different refractive indices of the solvents. While the adamantanones with "equatorial" COOR or bromine follow the octant rule, the axial epimers exhibit "antioctant" behavior. This explains *e.g.* why 5,6β-dibromo-5α-cholestan-3-one gives a negative Cotton effect, contrary to the octant rule, a phenomenon that previously had to be attributed to a boat form of ring A.

The circular dichroism of the β-"equatorially" substituted halogenoadamantanones is unusually high, but this is because the dipole strength of the R band of these ketones is much greater than usual (*e.g.* $\varepsilon = 144$ for the bromine compound, $\varepsilon = 510$ for the iodine compound). The "axial" epimers, on the other hand, behave normally.

Photocatalysis by Semiconductors on Metal Supports. Photosensitized Oxidation of CO with Co_3O_4, NiO, and ZnO on Silver Supports [1]

By *F. Steinbach* [*]

In experiments carried out in the study of the mutual effects of metal and oxide in mixed catalysts, a photocatalytic reaction on a semiconducting layer in the immediate vicinity of a metal-semiconducting boundary layer is interpreted in terms of the internal photovoltaic effect.

An Ag layer (2000 Å) is vapor-deposited on quartz, and a semiconductor oxide suspended in acetone is painted on the silver (thinner than 1000 Å). The transparent double layer catalyst is irradiated from the Ag side with UV light; the reaction mixture has access to the oxide side. The kinetics and activation energy (kcal/mole) are determined. NiO: dark, $< 200\,^\circ C$ 40.0, $> 250\,^\circ C$ 21.0, light 10.0 NiO/Ag: dark, $< 280\,^\circ C$ 80.0, $> 300\,^\circ C$ 11.4, light 15.4. ZnO: dark, $> 400\,^\circ C$ 41.0, light 16.6. ZnO/Ag: dark, $> 370\,^\circ C$ 18.0, light 41.0. Co_3O_4: dark, $> 150\,^\circ C$ 18.8, light 8.8. Co_3O_4/Ag: dark, $> 150\,^\circ C$ 7.0, light 3.0. Ag: dark, $> 300\,^\circ C$ 14.6, light 6.25.

All the changes in activation energy due to the silver carrier and UV irradiation can be explained by changes in the distance between the Fermi level and the valence band ($E_V - E_F$) in the p-type semiconductor or the conduction band ($E_F - E_C$) in the n-type semiconductor. This distance is the principal parameter determining the activation energy. A common Fermi potential is assumed for the catalyst and the reaction mixture at thermal equilibrium. The catalysis consists in lowering of the energy threshold that has to be overcome in the electronic regrouping during the product formation. The conduction or valence band of the catalyst provides an energetically favorable transition level for the electrons of the substrate, the energy of which is characterized by the Fermi potential. Corresponding to the difference in the work function, electrons flow in the dark from the Ag into NiO and ZnO. The space charge layer in the oxide extends over the entire oxide layer, owing to its thinness. The activation energy on p-conducting NiO/Ag is increased, corresponding to an increase in ($E_V - E_F$), while that on n-conducting ZnO/Ag is decreased corresponding to a decrease in ($E_F - E_C$). Electron-hole pairs formed in light are separated by the electrostatic field at the Ag-oxide interface, leading to a flow of electrons back into the Ag. The bending of the bands becomes less, and the activation energy becomes smaller on the p-type oxide and greater on the n-type oxide. Co_3O_4 evidently has a smaller work function than Ag. Electrons flow into the Ag, even in the dark, with the result that the activation energy decreases. This tendency is intensified by the photoeffect.

The results for NiO with and without a support clearly show for the first time the proportionality between ($E_V - E_F$) and the activation energy. Dark reaction and conductivity measurement both give an Arrhenius diagram with four activation energies in four temperature ranges. In both cases the activation energies are in the ratio 4:2:0:1.

The catalytic photoeffects are reversible; light and dark measurements can be reproduced in any sequence. The advantage of this method of investigation is the possibility of a definite assignment of the observed catalytic action to the change in the electron distribution caused by photoexcitation.

Hydrogen Replacement by Recoil Tritium in Simple Aliphatic Compounds

By *G. Stöcklin* and *R. Cipollini* [*]

"Hot" tritium atoms were produced *in situ* by the $^3He(n,p)T$ or $^6Li(n,\alpha)T$ nuclear processes in simple aliphatic compounds of the type RX [R = CH_3, C_2H_5, C_3H_7; X = F, Cl, OH, NH_2, SH]. The reaction products were determined by radio-gas chromatography.

Comparative studies on binary CH_3X systems containing radical scavengers show a pronounced increase in the radiochemical yield of the H-substitution product CH_2TX with increasing C–X bond energy [C–SH < C–NH_2 < C–Cl < C–OH < C–F]. It is assumed that the primary substitution step by high-energy tritium atoms (eq. (1))

$$CH_3X + [T] \rightarrow [CH_2TX]^* + H \qquad (1)$$

is practically unaffected by chemical factors, but that the substitution product formed possesses a considerable excitation energy, and the resulting possibility of rupture of the weakest chemical bond (eq. (2b)) determines the yield.

$$[CH_2TX]^* \xrightarrow{a} \xrightarrow{+M} CH_2TX \qquad (2)$$
$$\xrightarrow{b} \cdot CH_2T + X\cdot$$

In the presence of iodine, the CH_2T radical can be scavenged as CH_2TI. The assumption of a highly excited primary substitution product, which either decomposes or is stabilized by collision, can be confirmed by pressure and phase effects; the yield of CH_2TX increases with increasing pressure and is greatest in the liquid phase.

As in the hydrocarbons, a distinct decrease in the H-substitution yield per C–H bond is observed in the series CH_3X, C_2H_5X, n-C_3H_7X. This can partly be explained by steric effects on the basis of 'the impact model' [1].

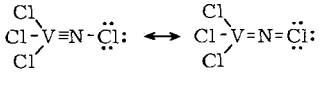
The Crystal Structure of Vanadium Chlorimide Trichloride Cl_3VNCl

By *J. Strähle* and *H. Bärnighausen*[*]



The triclinic unit cell of vanadium chlorimide trichloride[1] (a = 7.64, b = 7.14, c = 5.91 Å, α = 112.4°, β = 94.9°, γ = 107.8°) contains two molecules Cl_3VNCl in a centrosymmetric arrangement (space group $P\bar{1}$).

The structure was deduced from three-dimensional Patterson and Fourier syntheses and refined by the method of least squares. When the thermal anisotropy was taken into account, the reliability index R for the structure factors of the 1297 reflections evaluated was 6.5 %; when isotropic atomic vibrations were assumed (see table), R was 10.7 %.

Atomic coordinates and isotropic temperature parameters.

Atom	x	y	z	B(Å²)
V	0.1485	0.5020	0.2665	1.19
Cl(1)	0.4034	0.7585	0.5479	2.10
Cl(2)	0.0483	0.2917	0.4775	1.54
Cl(3)	0.1548	0.7204	0.0446	1.68
Cl(4)	0.3411	0.1970	−0.0947	2.80
N	0.2542	0.3515	0.0923	1.50

The Cl_3VNCl molecules have an approximately trigonal-pyramidal shape. A short distance (0.36 Å) above the base, which is formed by the atoms Cl(1), Cl(2), and Cl(3), is the V atom, followed by N and Cl(4). The VNCl grouping is almost linear (angle VNCl(4) = 175.2°), and is approximately perpendicular to the base. A careful analysis of the intramolecular atomic distances (V-Cl(1) = 2.204 ± 0.020, V-Cl(2) = 2.298 ± 0.008, V-Cl(3) = 2.383 ± 0.007, V-N = 1.642 ± 0.009, N-Cl(4) = 1.588 ± 0.009 Å) indicates that the bonding can be satisfactorily represented by the following resonance forms:

The distances V-Cl(2) and V-Cl(3) are greater than the distance V-Cl(1). This is connected with the fact that the atoms Cl(2) and Cl(3) act as "bridges" to vanadium atoms of adjacent molecules (intermolecular distances: Cl(2)....V′ = 2.600 ± 0.012, Cl(3)....V″ = 2.463 ± 0.020 Å). This gives a quasi-octahedral environment of Cl atoms for the V atoms. These "Cl octahedra" are joined by shared edges to form an infinite one-dimensional zigzag chain along [001].

Protactinium-238, a New Nuclide, and its Role in the Formation of Heavy Transuranium Elements by Multiple Neutron Capture in Uranium-238

By *N. Trautmann*, *R. Denig*, and *G. Herrmann*[*]

In nuclear explosions, transuranium nuclides with mass numbers of up to 257 are formed by multiple neutron capture in $^{238}_{92}U$. The quantities decrease roughly exponentially with increasing mass number; nuclides with even mass numbers are formed preferentially. However, the odd mass numbers predominate among the heaviest nuclides. According to *Bell*[1] this could be explained by the formation of $^{238}_{91}Pa$, from which the heaviest nuclides are built up; the reaction $^{238}U(n,p)^{238}Pa$ would in this case have to proceed with an effective cross section of about 10 mbarn at a neutron energy of 14 MeV[1].

^{238}Pa is prepared by bombardment of natural uranium with 14 MeV neutrons. It is separated from the strongly predominating fission products by removal of the halogens by exchange on AgCl, the protactinium then being extracted from 9N HCl/0.1M oxalic acid in 2,6-dimethyl-4-heptanol and re-extracted with 12N HCl/0.5N HF.

The β- and γ-decay curves give a half life of 2.3 ± 0.1 min. The element assignment is confirmed by the X-ray spectrum, which shows the uranium lines at 13.6 (L_α), 17.0 (L_β), and 20.2 keV (L_γ) in a xenon proportional counting tube. β transitions with energies of 2.9 (about 20 %), 2.1 (40 %), and 1.4 MeV (40 %) are found with a plastic scintillator. More than 30 γ peaks are observed with a Ge(Li) semiconductor detector, the strongest peaks being at 103 (relative intensity 15), 448 (70), 548 (45), 583 (39), 635 (100), 679 (80), 686 (42), 805 (67), 863 (69), 884 (51), 1013 (80), 1059 (31), and 1082 keV (49). It follows from these results and from the γ-γ sum spectrum that levels up to about 2.0 MeV are filled in ^{238}U; bands based on octupole vibrations predominate. The effective cross section of the reaction $^{238}U(n,p)^{238}Pa$ with 14.6 MeV neutrons is found to be 1.3 ± 0.2 mbarn.

In order to evaluate these measurements, a number of isotopes formed in side reactions are studied, these isotopes being produced by $^{235}U(n,p)^{235}Pa$ and $^{236}U(n,p)^{236}Pa$ with 14 MeV neutrons and by $^{238}U(\gamma,p)^{237}Pa$ with 20 to 100 MeV γ rays. The half-life of 24.4 ± 0.5 min and the β energy of 1.41 ± 0.05 MeV are confirmed for ^{235}Pa[2]; a γ radiation with energies of 165 and 320 keV and 3 % intensity is also observed. The half-life of 9.0 ± 0.3 min and the β energy of 2.1 MeV found for ^{236}Pa differ from the values reported so far[3]; in addition, ^{236}Pa is found to emit γ rays of 642 and (weaker) 310 keV energy. No 39 min ^{237}Pa[4] is observed, but a nuclide having a half-life of 9.1 ± 0.2 min[5] is found, with β transitions at 2.3, 1.4, and 1.1 MeV and with its strongest γ rays at 529 (49), 540 (24), 688 (15), 852 (100), and 864 keV (41).

Cycloadditions of Isocyanates

By *H. Ulrich*[*]

The base-catalysed dimerization and trimerization of isocyanates, which lead to carbodiimides and isocyanurates, proceeds *via* the linear allophanate ion. The course of the reaction can be controlled by the use of sterically hindered catalysts.

The linear 1:1 adducts *(1)* of the aryl isocyanates are intermediates in the formation of the asymmetric trimers *(2)*, which have not yet been described. (Examples of *(2)*: R = C_6H_5, m.p. 222–224 °C; R = 2-CH_3–C_6H_4, m.p. 287–288 °C; and R = 4-Cl–C_6H_4, m.p. 308 °C.)

Dipolar intermediates of the type *(1)* were detected by IR spectroscopy and intercepted as 2:1 adducts with 6-membered rings in the reaction of arylsulfonyl isocyanates and carbodiimides, which leads to the formation of cyclic 1:1 adducts.

(1) *(2)*

This proves conclusively that the cycloaddition of arylsulfonyl isocyanates and carbodiimides is a stepwise process, and not synchronous.

Investigations on the Mechanism of the Degradation of Polycaprolactam by Thermal Oxidation

By *G. Valk* and *H. Krüssmann*[*]

We were able to show in an earlier publication[1] that the primary attack in the degradation of polycaprolactam by thermal oxidation, as in photooxidation[2], takes place on the *N*-vicinal methylene group. After hydrolysis of the degraded material, adipic acid can be isolated as the principal product. Preferential reaction at this point can be readily explained by the greater stability of the intermediate radical as a result of participation in the amide resonance. At the same time, the chain conformation of the polymer leads to interaction of the protons of the *N*-vicinal methylene group with the π-electron system of the carbonamide group, with a resulting increase in the reactivity of these hydrogen atoms[3]. In addition to adipic acid, the lower dicarboxylic acids and the monocarboxylic acids up to n-valeric acid (which is the main component of this fraction) are also formed.

However, other reaction paths also appear to exist. The caprolactam group must be attacked from the acid side as well as from the amine side, since it would otherwise be impossible to explain the formation of the homologous ω-amino acids up to ε-aminocaproic acid, which were detected as their *N*-trifluoroacetyl methyl esters. In contrast to the mono- and dicarboxylic acids, all the amino acids are formed in almost equal quantities, since none of the methylene groups is attacked in preference to the others. This agrees with the results obtained by *Pritzkow*[4], who reported a statistical attack on the methylene groups in the degradation of methyl caproate by thermal oxidation. The alkylamines resulting from decarboxylation of the amino acids could be identified. Once again, there was no preferential formation of any of the homologous amines.

Other degradation products formed are carbonyl compounds, including acetaldehyde and traces of propionaldehyde and butyraldehyde, as well as cyclopentanone, which probably results from the cyclization of the principal degradation product, adipic acid. The carbonyl compounds were detected gas-chromatographically as the 2,4-dinitrophenylhydrazones.

To summarize, it can be said that the degradation of polycaprolactam by thermal oxidation is much more complicated than the photo-oxidative degradation studied by *Sharkey* and *Mochel*[2].

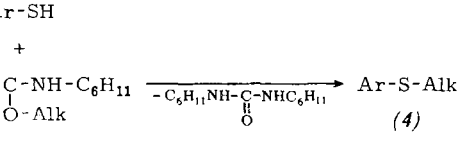
Alkylations with *O*-Alkyl-*N,N'*-dicyclohexylisoureas

By *E. Vowinkel* and *H. Kruse*[*]

β-Diketones react with *O*-alkyl-*N,N'*-dicyclohexylisoureas to form keto enol ethers *(1)*, 2-alkyl-1,3-diketones *(2)*, and/or 2,2-dialkyl-1,3-diketones *(3)*.



The ratio of *O*- to *C*-alkylation is determined, not only by the reactivity of the *O*-alkylisourea, but also by the acidity of the β-diketone used. *O*-Alkylation is favored by β-diketones having high acidities; the proportion of *C*-alkylation increases with decreasing acidity. Thus the reaction of dibenzoylmethane leads to the enol ether *(1)*, whereas acetylacetone gives both *O*- and *C*-alkylated products.

Since the acidity of the β-diketones is decreased by the introduction of an alkyl group on the central C atom, progressive alkylation favors *C*-alkylation with formation of *(3)*.

The *O*-alkyl products *(1)* do not rearrange into *C*-alkyl products *(2)* under the conditions of the reaction.

Thiophenols react with *O*-alkyl-*N,N'*-dicyclohexylisoureas to form aryl alkyl sulfides *(4)*.

Other functional groups do not affect the course of the reaction. Thus the formation of thioethers is not affected *e.g.* by unprotected amino groups, since it is faster than any transamidation of the isourea ether. There is no danger of competitive reactions even when free phenol and carboxyl groups are present; the alkylation of the thiol group predominates in every case because of its pronounced nucleophilicity. As is shown by the reaction with thiosalicylic acid, the thiol group is selectively alkylated when equimolar quantities of reactants are used.

The isourea ethers with primary and secondary alkyl groups all give very good yields with thiophenols. *O*-t-Butyl-*N,N'*-dicyclohexyl-isourea gives only a small quantity of thioether, together with appreciable quantities of isobutylene. In this case a t-butylcarbenium ion is first splitt off from the protonated isourea ether in an S_N1 reaction; this carbenium ion then either reacts with the thiophenolate anion to form the thioether or loses a proton to form isobutylene.

In some reactions, small quantities of diaryl disulfide and bis(arylthio)methane (which always occur together) are obtained as byproducts. These are formed in a combined oxidation-reduction reaction of the thiophenols with *S*-aryl-*N,N'*-dicyclohexylisothioureas, which are formed from the *O*-alkylisoureas by transetherification during the alkylation.

Kinetic Investigations of Substitution Reactions of Metal Carbonyl-Carbene Complexes

By *H. Werner*, *V. Kiener*, and *H. Rascher*[*]

Metal carbonyl-carbene complexes $M(CO)_5C(OCH_3)R$ (M = Cr, Mo, W; R = CH_3, C_6H_5) react with phosphines PR'_3 (R' = C_2H_5, n-C_4H_9, C_6H_{11}, *p*-$CH_3C_6H_4$) and phosphites

$P(OR'')_3$ ($R'' = C_2H_5$, C_6H_5) even under very mild conditions to form respectively the compounds $M(CO)_4(PR'_3)C(OCH_3)R$ and $M(CO)_4[P(OR'')_3]C(OCH_3)R$, which are very stable to oxidation and heat. Kinetic investigations based on IR spectroscopic and photometric measurements suggest that the rate-determining step in these substitutions is the initial elimination of a carbonyl group:

$$M(CO)_5C(OCH_3)R \rightarrow M(CO)_4C(OCH_3)R + CO$$

The activation energy is 28.2 ± 0.4 kcal/mole for M = Cr and R = CH_3, and 27.4 ± 0.6 kcal/mole for M = Cr and R = C_6H_5. These values are more than 10 kcal/mole lower than the activation energy for the elimination of a CO group from chromium hexacarbonyl.

The rate of formation of the compounds $Cr(CO)_4(PR'_3)C(OCH_3)CH_3$ ($R' = C_6H_{11}$, p-$CH_3C_6H_4$) does not vary considerably with the solvent. The first-order rate constants in di-n-butyl ether at 58.8 °C and in dioxane exceed those in saturated hydrocarbons (*e.g.* n-decane) only by about 15 and 30 %, respectively.

The reaction between the metal carbonyl-carbene complexes $M(CO)_5C(OCH_3)R$ and tertiary aliphatic phosphines PR'_3 is accompanied by the formation of the phosphine-metal carbonyls $PR'_3M(CO)_5$ [by the displacement of the carbene ligand from $M(CO)_5C(OCH_3)R$] and $(PR'_3)_2M(CO)_4$ [by the displacement of the carbene ligand from $M(CO)_4(PR'_3)C(OCH_3)R$] as by-products. These reactions most probably proceed *via* an S_N2 mechanism, with a direct attack by the phosphine on the formally divalent carbon atom of the carbene ligand. The fact that the $M-C(OCH_3)C_6H_5$ bond is cleaved much more easily than the $M-C(OCH_3)CH_3$ bond is in full agreement with concepts of the nature of this bond, developed by *E. O. Fischer et al.*[1].

Solvolysis Reactions of β-Tosyloxy Aldehydes

By *P. Weyerstahl*[*]

While the reaction between β-iodo- and β-trialkylammonium aldehydes and alkoxy ions $OR^{\ominus}$ leads to fragmentation, in the case of β-tosyloxy aldehydes *(1)* this reaction generally remains in the background (R = CH_3, C_2H_5, C_4H_9, R′ = CH_3, C_2H_5), for these compounds give instead cyclic acetals *(2)*, which may decompose into enol ethers and formaldehyde.

(1) *(2)*

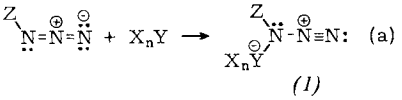
When R″ is a primary alcohol residue, compound *(2)* is relatively stable and, under suitable conditions, represents the only product. When R″ is a secondary or a tertiary alcohol residue, the stability of *(2)* rapidly decreases and enol ether is formed in increasing amounts. Enol ethers are also formed when the stable acetal having a four-membered ring is boiled with traces of acids, or else as a result of surface catalysts. Secondary β-tosyloxy aldehydes undergo fragmentation (R = R′ = CH_3).

2-Methyl-2-formylcyclohexyl tosylate was prepared in two isomeric forms *(3)* and *(4)* in order to study the effect of steric factors on the reactions.

These structures were assigned on the basis of comparing them with four isomeric 4-t-butyl-2-methyl-2-formylcyclo-

(3) *(4)*

hexyl tosylates whose configurations were known; (these compounds were so prepared that their configuration was assignable in an unambiguous manner).



The solvolysis of *(3)* and *(4)* gave no four-membered acetal ring. The tosylate *(4)* gave the fragmentation product 1-methylcyclohexene in an almost quantitative yield; the tosylate *(3)* gave 26 % of 1-methylcyclohexene, 35 % of 2-methylcyclohexane carboxylic acid, 17 % of 3-methyl-3-formylcyclohexene, and 7 % of 2-hydroxymethylcyclohexanecarbaldehyde dialkylacetal.

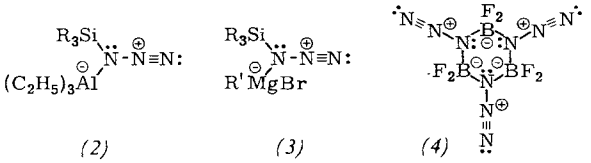
Structure and Reactivity of the *N*-Diazonium Group $\backslash\ddot{N}-N\equiv N:$

By *N. Wiberg*, *W.-Ch. Joo*, and *K. H. Schmid*[*]

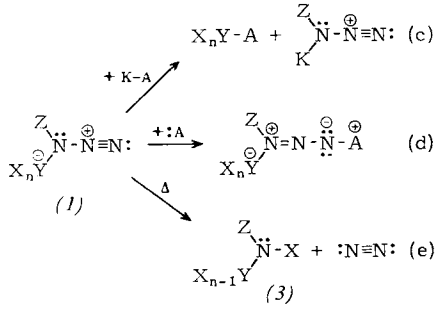


Compounds of the general formula *(1)*, containing an *N*-diazonium group are prepared by the addition of Lewis acids X_nY to azides ZN_3 (Reaction (a)):

(a)

(1)

For example, the Lewis acids $X_nY = (C_2H_5)_3Al$ and R′MgBr (R′, R = organic group) add to silyl azide $ZN_3 = R_3SiN_3$ [cf. *(2)*, *(3)*], and difluoroborazide, acting as a Lewis acid, can add to the azide group of a second molecule of difluoroborazide [$X_nY = F_2(N_3)B$, $ZN_3 = F_2BN_3$; cf. *(4)*].



(2) *(3)* *(4)*

The preparation of *(4)* and other inorganic halogeno-element azides or organo-element azides with *N*-diazonium groups (*e.g.* $[Cl_4SbN_3]_2$, $[Cl_2Sn(N_3)_2]_n$, $[(CH_3)_2AlN_3]_3$) is carried out in the simple manner shown in Scheme (b):

$$Z-Hal + R_3Si-N_3 \rightarrow Z-N_3 + R_3Si-Hal \quad (b)$$

The chemical behavior of the *N*-diazonium group is characterized by three types of reaction: 1) Compounds K–A with a highly polar bond between K and A (*e.g.* $Na^{\oplus}N_3^{\ominus}$,

(c)

(d)

(e)

(1) *(3)*

$(CH_3)_3Si-Cl$) or bases:A (*e.g.* tetrahydrofuran) can split the bridging bond Y—N in *(1)* [cf. (*c*); *e.g.* reaction of $Cl_2Sn(N_3)_2$ with $(CH_3)_3SiCl$[1]); 2) Bases:A (*e.g.* $(C_6H_5)_3P$:) can add on to the terminal nitrogen in *(1)* [cf. (*d*); *e.g.* reaction of $(Cl_4SbN_3)_2$ with $(C_6H_5)_3P$[2]); and 3) Heating leads to the elimination of N_2 from *(1)* [cf. (*e*)].

Kinetic studies show that the thermal stability of *(3)* increases with decreasing Lewis acidity of R'MgBr, decreasing tendency to migration of the ligands R', and with increasing bulk of the R_3Si group.

^{18}O-Isotope Exchange between TcO_4^- and ReO_4^- Ions and Water

By *A. Wiechen, W. Herr, B. Hess,* and *H. H. Pieper*[*]

The oxygen exchange

$$M^{18}O_4^- + H_2{}^{16}O \rightleftharpoons M^{16}O_4^- + H_2{}^{18}O$$

was investigated for the TcO_4^- and ReO_4^- ions as a function of the temperature, the H^+ activity, the concentration, and the added salt content. The effect of ionizing radiation on the exchange kinetics was of particular interest.

The oxo anions were labeled with $H_2{}^{18}O$ enriched by a factor of 8 to 10, and were precipitated at 0 °C as sparingly soluble $AgTcO_4$ and $AgReO_4$.

After the thermal decomposition of the silver salts at about 1000 °C, the O-isotope analysis was carried out mass spectrometrically by measuring the ratio $^{34}O_2/^{32}O_2$.

In the case of both oxo anions, the normal thermal oxygen exchange was found to be first order with repect to the MO_4^- concentration, and second order with respect to the H^+ activity. The reaction rate R in media with pH < 4 can be expressed as

$$R = k\,[H_2O]\,[MO_4^-]\,[H^+]^2$$

where $k = 1.2\times10^2$ l^3 mole^{-3} min^{-1} for $NaTcO_4$ and $k = 2.95\times10^3$ l^3 mole^{-3} min^{-1} for $NaReO_4$ (at 30 °C in both cases). The determination of the temperature-dependence of R in the range 10–75 °C gives activation energies of 8.4 and 8.20 kcal/mole for $NaTcO_4$ and $NaReO_4$, respectively.

The following reaction scheme may be assumed:

$$MO_4^- + 2\,H^+ \overset{\text{fast}}{\rightleftharpoons} H_2OMO_3^+$$

$$H_2OMO_3^+ + H_2O \overset{\text{slow}}{\rightleftharpoons} H_2OMO_3^+ + H_2O$$

The O-exchange of ReO_4^- ions induced by ^{60}Co-γ-radiation is accelerated by a factor of 10^2 to 10^3, according to the experimental conditions. The observation that electron-acceptors and hydrogen-radical acceptors (*e.g.* O_2 and acetone) act as inhibitors, while hydroxyl ion acceptors (*e.g.* H_2 and methanol) act as accelerators provides evidence concerning the mechanism of the radiation-induced exchange. The appearance of lower oxidation states indicates the participation of reducing species.

The radiation-induced exchange may consequently proceed according to the scheme:

$$Re^{VII}O_4^- + e_{aq} \rightarrow Re^{VI}O_4^{2-}$$
$$Re^{VI}O_4^{2-} + H_2O \rightarrow Re^{VI}O_3 + 2\,OH^-$$
$$\text{or } Re^{VII}O_4^- + H \rightarrow Re^{IV}O_3 + OH^-.$$

The OH radicals may partly re-oxidize lower oxidation states:

$$Re^{VI}O_3 + OH \rightarrow Re^{VII}O_4^- + H^+.$$

Apparatus for Measuring the Natural Optical Activity and the Faraday Effect in the UV and the Visible Regions

By *J. Winkler*[*]

The effects of magneto-optical activity have recently once more acquired interest, owing to the development of equipment that permits the measurement of the optical activity as a function of the wavelength. As in the case of natural optical activity, one must distinguish between magneto-optical rotation (MOR, Faraday effect) and magnetic circular dichroism (MCD, Cotton-Scherer effect). Both effects are proportional to the applied magnetic field intensity, the thickness of layer penetrated by the radiation, and – in the case of solutions – the concentration. The lines of force of the magnetic field must be parallel to the light beam, and therefore a hole must be drilled in a permanent magnet or an electromagnet with an iron core. The advantage of a solenoid is obvious and the development of superconducting magnets now places intense fields at our disposal.

The chief difficulty in MOR measurements is that the solution and the cell window have a considerably greater effect than the solute. A way of overcoming this difficulty lies in the use of two magnets with opposing lines of force and in the insertion of a cell with the solvent into one field and a second cell with the solution into the other field. The unwanted effects then cancel out, and the rotation of the solute can be directly recorded.

In the case of the Faraday effect, the measurement of circular dichroism is to be preferred to measuring the rotation even more than in the case of natural optical activity since the solvent and the cell window have no effect here.

The MOR is best measured with a spectropolarimeter whose cell volume is sufficiently large for housing a permanent double magnet or a suitable superconducting magnet. Adaption to fit a large electromagnet does not seem to be advantageous, because the accuracy and the sensitivity of the apparatus are generally greatly reduced on rearrangement of the setup. By contrast, the measurement of circular dichroism does not require high-precision mechanical construction, since, unlike in rotation, the measurement is carried out in an electro-optical manner. The sensitivity of an apparatus that we constructed from commercially available units was found to be 10^{-5} extinction units.

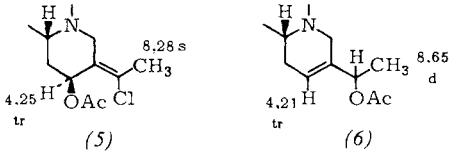
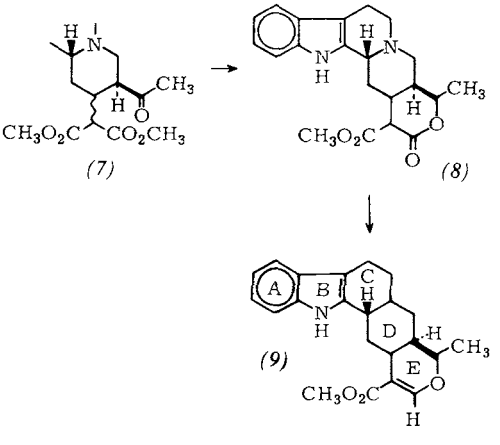
Investigations of Syntheses in the Indole Series



By *E. Winterfeldt* and *H. Radunz*[*]

The α,β-unsaturated ketone *(1)* seems to be a suitable starting material for the construction of ring E in heterocyclic indole alkaloids. After an improved method had been found



for the synthesis of the diketone *(2)*, it became possible to prepare *(1)* by selective reactions involving the β-dicarbonyl system of *(2)*.

Although the reactions of *(2)* with primary and secondary amines are selective, they lead exclusively to the enamine *(4)* which is of no use in this work. However, as the NMR data for enamines and their reduction products show, this selectivity may be utilized to prepare the chloride *(3)*. The structure of this compound is established by reduction and hydrolysis to the ketone *(1)*, as well as by reduction to alcohol, characterized as the acetate *(5)*. (The numbers in *(5)* and *(6)* refer to the NMR spectra).

The position of the functional groups in *(1)* has similarly been established by reduction and conversion into the acetate *(6)*. Furthermore, hydrogenation gives two epimeric saturated ketones. The Michael addition with malonic ester leads from *(1)* to the diester *(7)*, which can be converted into the lactone *(8)*.

Note added in proof: In the meantime, starting with stereochemically pure lactones, the borohydride reduction to the corresponding cyclosemiacetals and subsequent acid catalysed dehydration to yield structures of type *(9)* has been accomplished.

A Study of Primary Recoil Effects by Means of the Mössbauer Effect

By *J. Klöckner, P. Rother, F. Wagner,* and *Ursel Zahn*[*]

Products formed after nuclear transformations in a solid can be studied in favourable cases by Mössbauer effect measurements. The isomer shift and the quadrupole splitting of recoilless γ-lines yield information about the electron density and the electric field gradient at the nucleus. The emitted spectrum is therefore characteristic for the electron configuration of an atom after a nuclear transformation during the time of γ-emission. In contrast to radiochemical and mass spectrometric methods, Mössbauer spectroscopy allows an investigation of the electronic state of the atom 10^{-7} to 10^{-9} sec after the nuclear event without chemical analysis.

Using the method described we studied the formation of different valence states of iridium after the β^--decay of ^{193}Os in potassium hexachloroosmate(IV), K_2OsCl_6, at 4.2 °K. Well defined isomer shifts have been observed for the 73 keV transition in ^{193}Ir in Ir metal and various Ir(IV) and Ir(III) compounds. The shift of -2.4×10^{-7} eV of Ir^{3+} with respect to Ir^{4+} and the equally large shift between Ir^{4+} and Ir metal can be interpreted using a calibration scheme deduced from optical isotope shift data. The isomer shift between Ir^{3+} and Ir^{4+} with electron configurations $5d^6$ and $5d^5$ is attributed to the shielding effect of the sixth 5d electron. Isotope shift measurements on 5d elements show that the shielding effect of one 5d electron depends but little on the number of the other 5d electrons present. Using this calibration scheme one can predict the isomer shifts expected for valence states chemically less stable than Ir^{3+} and Ir^{4+}. The recoilless emission spectrum of a K_2OsCl_6 source yields a number of lines which can be attributed to different valence states of Ir atoms. Besides lines of Ir^{4+} and Ir^{3+} a strong line characteristic for Ir^{2+} was observed. Several weak lines may belong to higher valence states of Ir but cannot be assigned unequivocally. An attempt is made to interpret the high yield of Ir^{2+}, observed after the β^--decay during the lifetime of the Mössbauer level ($\tau = 5.8$ nsec) as a consequence of the secondary ionization processes following the change in nuclear charge.

K_2OsCl_6 sources synthesized from radioactive Os metal and sources prepared by direct neutron activation of K_2OsCl_6 yield similar Mössbauer spectra. Some additional weak lines in the emission spectrum of the directly neutron activated K_2OsCl_6 could be due to radiation damage.

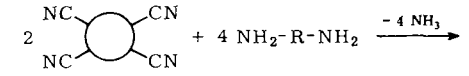
Semiconducting Properties of Some Nitriles and their Polymers with a Porphyrazine Structure

By *G. Manecke* and *D. Wöhrle*[*]

Disodium 1,2-dicyanoethylene-1,2-dithiolate *(1)* reacts with metal ions (K_1) such as Cu^{2+}, Ni^{2+}, Co^{2+}, Fe^{2+}, and Fe^{3+} to form bis-(1,2-dicyano-ethylene-1,2-dithiolo)metal chelates. These complexes contain a second, ionically bonded, cation (K_2). Compounds *(4)–(10)*, *(12)*, and *(15)* have now been prepared for the first time. Adducts formed with the solvent may arise during synthesis and purification.

The d-c conductivities of the chelates (measured on tablets under 1500 kg/cm², between 20 and 120 °C) lie between



(1) *(2)–(15)*

	K_1	K_2		K_1	K_2
(2)	Cu^{2+}	$[N(CH_3)_4]_2^+$	*(9)*	Cu^{2+}	Co^{2+}
(3)	Cu^{2+}	$[N(CH_3)_4]_2^+$	*(10)*	Co^{2+}	Cu^{2+}
(4)	Cu^{2+}	H_2^+	*(11)*	Ni^{2+}	$[N(CH_3)_4]_2^+$
(5)	Cu^{2+}	Ag_2^+	*(12)*	Ni^{2+}	Cu^{2+}
(6)	Cu^{2+}	$Ag^+[N(CH_3)_4]^+$	*(13)*	Fe^{2+}	$[N(CH_3)_4]_2^+$

Comparative Determination of the Structure of Gaseous Molecules by Electron Diffraction and Microwave Spectroscopy

By *W. Zeil*[*]

Difficulties of a theoretical nature arise when we attempt to increase the accuracy of the determination of distances in gaseous free molecules by microwave spectroscopy and electron diffraction beyond 0.01 Å. These difficulties are due to the fact that the molecules are never rigid bodies. Even when the molecules are in the vibrational ground state, the calculated distances are unsharp because of zero-point vibration. Furthermore, the electron diffraction method averages over r the atomic coordinates which vary in time because of the vibrations, whereas the microwave spectroscopic method averages over $1/r^2$ both in the vibrational ground state and in the excited vibrational states.

These relationships are still manageable with diatomic and triatomic molecules, but virtually no comparative data obtained with these two methods have yet been published for larger molecules. – And it is precisely for these larger molecules that, in general, neither method alone can guarantee a complete determination of the structure.

The present aim was to combine the two methods for the determination of the structure of larger molecules, so as to obtain maximum information. Another aim was to establish the extent, in the combined method, of uncertainties pertaining to the structure and caused by the physical phenomena mentioned above. Investigations by this combined method on the molecules $(CH_3)_3CCl$, $(CH_3)_3SiCl$, $(CH_3)_3C-C\equiv C-Cl$, $(CH_3)_3Si-C\equiv C-Cl$, and COS have shown that the agreement between the two methods improves with the size and weight of the molecules.

Further Investigations on the Isotope Fractionation of Alkali Metal Ions by Filtration through Biological Membranes

By *K. Wagener* and *U. Zimmermann*[*]

Highly active ion pumps operate in most animal and plant membranes, and they can effect an intensive demixing of components. Such stationary demixing states may be connected with isotope fractionation whose extent is a function of the type of the ion pump. This fact may be utilized to elucidate the transport mechanism.

Having previously found no enrichment of potassium isotopes in measurements with an accuracy of 0.1 %, we have now attempted to intensify any isotope bias that may be present. This was best done with the isotopes of a physiologically suitable rare element.

In measurements involving potassium in the marine algae *Valonia macrophysa* and *Chaetomorpha linum*, these algae were allowed to grow in sea water in which all or part of the potassium had been replaced by rubidium. After a stationary rubidium distribution between the medium and the cell fluid had been reached, we extracted the cell fluid and used it to prepare a new culture medium for a second series. After a stationary rubidium distribution between the medium and the cell fluid had been reached, we again isolated the cell fluid to prepare a third culture medium, *etc.* If there is an isotope separation at all, such a treatment will intensify it several fold. If the enrichment factor between Rb in the cell fluid and Rb in the medium is $(1 + \varepsilon)$ for each step, the enrichment factor between the cell fluid of the n-th step and the medium of the first step is $(1 + \varepsilon)^n$.

A shortcoming of this technique is that the rubidium is progressively diluted in each successive preparation of the culture medium (this must be compensated by the addition of potassium). This effect is fast, and after 5–10 steps the concentration of rubidium is down to the detection limit. After the medium has been modified, the new stationary state is reached in about six days, but we invariably allowed eight or nine days to elapse before extracting the cell fluid. In the first fifteen days, rubidium caused no changes in the cells.

The isotope enrichment factor for rubidium in the cell fluid was determined mass spectrometrically, and the following

values were obtained (figures in brackets refer to the number of measurements):

Step 1	2.612 ± 0.005	(2)
Step 2	2.610 ± 0.006	(4)
Step 3	2.610 ± 0.005	(5)
Step 4	2.611 ± 0.006	(3)
Step 5	2.612 ± 0.004	(4)

The corresponding value for the first step in the culture medium was 2.613 ± 0.005 (4). This fivefold potentiation indicates that the isotope effect between the cell fluid and the medium must be smaller than 0.05 %. The transport models for single-file diffusion and kinetics of complexes on carriers are, in their present form, not compatible with this result[1].

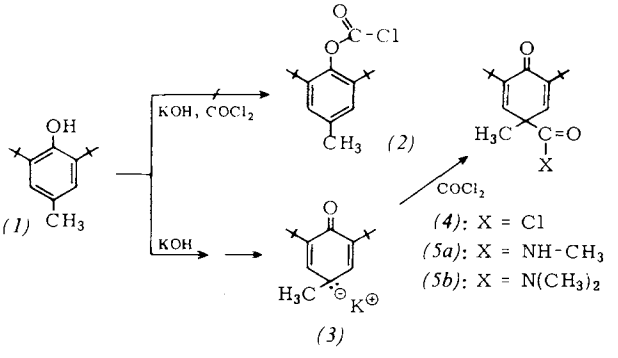
SELECTED ABSTRACTS



2,2,6,6-Tetramethylpiperidinothiyl *(1a)*, a new stable radical, has been synthesized by *J. E. Bennett*, *H. Sieper*, and *P. Tavs*. Reaction of the piperidines *(2a)* and *(2b)* with SCl_2 in DMF at −40 °C gave bis(2,2,6,6-tetramethylpiperidine) disulfide *(3a)* (66 %) or bis(2,2,6,6-tetramethyl-4-oxopiperidine) disulfide *(3b)* (81 %). When the disulfides were heated, alone or in solution, to 90–200 °C, an ESR spectrum with three lines was observed; this indicates homolysis of the S–S bond to give the 2,2,6,6-tetramethylpiperidinothiyl *(1a)* or 2,2,6,6-tetramethyl-4-oxopiperidinothiyl radicals *(1b)*.

A new dehydrogenation reaction with diethyl azodicarboxylate has been described by *F. Yoneda*, *K. Suzuki*, and *Y. Nitta*. The ester reacts selectively with primary or secondary alcohols to give aldehydes and ketones. The reaction is carried out in alcohol at room temperature in the dark over a period of 1 to 3 days. Alternatively, the starting materials may be refluxed in anhydrous benzene for 0.5 to 10 hours. The diethyl azodicarboxylate is hydrogenated to diethyl hydrazodicarboxylate. The yields are generally about 60–80 %. Thiols, *p*-anisidine, and hydrazobenzene are dehydrogenated to give disulfides, 4,4′-azodianisole, and azobenzene, respectively. The advantages of this dehydrogenation are the mild conditions used and the fact that after the dehydrogenation, there is no oxygen present to cause further oxidation. / J. org. Chemistry *32*, 727 (1967) / −WG. [Rd 712 IE]

The preparation of new oxocyclohexadienecarboxamides *(5)* is described by *H. A. Stansbury* and *R. F. Cantrell*. The reaction of 2,6-di-t-butyl-4-methylphenol *(1)* with KOH and phosgene leads, not to the chloroformate *(2)*, but by a novel reaction *via* the corresponding potassium phenoxide to a ketone *(3)*, which then reacts with phosgene to give 3,5-di-t-butyl-1-methyl-4-oxo-2,5-cyclohexadienecarbonyl chloride *(4)*.

(4) condenses with methylamine and with dimethylamine to give the crystalline amides *(5a)* (m.p. 98–99 °C) and *(5b)* (m.p. 84–86 °C) respectively, these amides being obtained in a very pure state. The yield of *(4)*, based on the quantity of phenol used, is 54 %. *(4)* can be quantitatively converted into *(5a)*. If *(4)* is not isolated, *(5b)* can be obtained in an overall yield of 84 %. / J. org. Chemistry *32*, 824 (1967) / −WG

[Rd 713 IE]

Alkali metal alkynides in dimethyl sulfoxide, can be obtained in almost quantitative yield from (methanesulfonyl)methyllithium or -sodium and the appropriate 1-alkynes, according to *J. Kříž*, *M. J. Beneš*, and *J. Peška*. Alkyl halides, dialkyl sulfates, aldehydes, ketones, and esters react directly with these solutions in accordance with equation (a) or (b) at 20 to 30 °C under argon (molar ratio ≈ 1.1 : 1; yield 70–90 %).

$$RC{\equiv}CM + R^1X \rightarrow RC{\equiv}CR^1 + MX \quad (a)$$

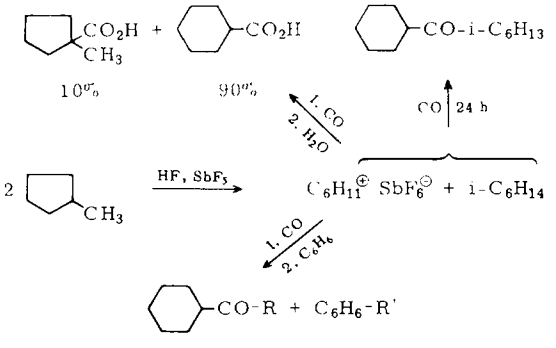
$$RC{\equiv}CM + R^2R^3CO \rightarrow RC{\equiv}C{-}CR^2R^3\,(OM) \quad (b)$$

M = Li, Na; R = H, CH_3, $CH_3(CH_2)_2$, C_6H_5
R^1X = $(CH_3)_2SO_4$, CH_3I, $CH_3(CH_2)_nBr$ (n = 2,3);
R^2R^3CO = CH_3CHO, CH_3COCH_3, $C_6H_5COCH_3$, cyclohexanone

The alkali metal alkynides generally react with 1-alkynes to give 1:1 adducts (also > 1:1 for R=H, CH_3), which are probably charge-transfer complexes of the alkynide anion and the 1-alkyne (λ_{max} = 480 to 350 nm). / Collect. czechoslov. chem. Commun. *32*, 398 (1967) / −Jg. [Rd 732 IE]

Cu^{II} exists in square-planar coordination in the well known Egyptian blue, $CaCuSi_4O_{10}$ (4 oxygen atoms arranged in a square around the Cu atom at a distance of 1.19 Å). *A. Ludi* and *R. Giovaloni* have studied the relationships between light absorption and coordination. In the ligand field of

symmetry D_{4h}, the ^2D term of the Cu^{II} splits into four terms, giving rise to three absorption bands. The broad band with $\lambda_{max} = 16000\ cm^{-1}$ can in fact be resolved into three bands: 12900 ($d_{xy} \rightarrow d_{x^2-y^2}$), 15900 ($d_{xz}$, $d_{yz} \rightarrow d_{x^2-y^2}$), and 18800 cm^{-1} ($d_{z^2} \rightarrow d_{x^2-y^2}$). Comparison with other complexes in which Cu^{II} is coordinated with oxygen shows:



tetragonally distorted octahedron → square planar

$Cu_{0.1}Mg_{0.9}O$	$Cu(OH)_2$	$CaCuSi_4O_{10}$
$\lambda_{max} = 12$	$\lambda_{max} = 14.3$	$\lambda_{max} = 16 \times 10^3\ cm^{-1}$

violet shift

Naturwissenschaften *54*, 88 (1967) / –Jg. [Rd 733 IE]

The carbonylation of aliphatic hydrocarbons in liquid hydrogen fluoride proceeds simply and in very good yields by a process described by *R. Paatz* and *G. Weisgerber*, in which SbF_5 is added to the solution. At 0 to 20 °C and at 1 atm of CO, the solution takes up a quantity of CO equivalent to the SbF_5 within a few minutes. Carbenium hexafluoroantimonate is probably formed first in every case, with disproportionation in the case of cycloalkanes (*e.g.* cyclopentane, cyclohexane, methylcyclopentane, and methylcyclohexane; open-chain saturated hydrocarbons being formed in a quantity equivalent to the quantity of SbF_5) and with evolution of H_2 in the case of alkanes (*e.g.* isopentane). The final products are carboxylic acids, esters, or simple or mixed ketones, depending on whether the primary product is solvolysed with H_2O or alcohol or allowed to react with a hydrocarbon for a long time, *e.g.*

R = C_6H_5, c-C_6H_{11}, C_6H_4-c-C_6H_{11}; R' = c-C_6H_{11}, C_6H_5

/ Chem. Ber. *100*, 984 (1967) / –Jg. [Rd 751 IE]

Uncharged fragments of aromatic molecules produced by electron impact were detected by *H. Genzel* and *O. Osberghaus*. The vapor of the substance under investigation (benzene, toluene, fluorobenzene, iodobenzene, azobenzene, anisole, biphenyl) is introduced into a vacuum chamber (10^{-4} to 10^{-6} mm Hg) as a molecular beam, and the molecules are fragmented by an electron beam (200 eV, approx. 10 mA) entering at right angles to the molecular beam. Some of the fragments pass into the ion source (where there is a second electron beam, 50 eV) of a mass spectrometer. Grids at a suitable potential prevent ions or electrons from passing from the electron-impact chamber into the ion source. The first electron beam is rectangularly modulated at 32 Hz. This enables the primarily formed neutral fragments to be distinguished from the particles formed in the ion source from the gas molecules. The ionization potentials of the neutral fragments C_6H_5, C_6H_4, and C_6H_2 were found to be 9.35 ± 0.15 eV, 9.50 ± 0.15 eV, and 9.85 ± 0.15 eV respectively. / Z. Naturforsch. *22a*, 331 (1967) / –Hz. [Rd 710 IE]

Pyruvate:ferredoxin oxidoreductase has been concentrated to a purity of about 90 % by *K. Uyeda* and *J. C. Rabinowitz* from *Clostridium acidi urici*. The enzyme catalyses the reaction

$$\text{pyruvate} + \text{CoA} + \text{X} \rightleftharpoons \text{acetyl-CoA} + CO_2 + XH_2.$$

X is ferredoxin, which may be replaced by rubredoxin, FAD, FMN, and artificial electron acceptors such as benzylviologen. The enzyme also catalyses the CoA-dependent $^{14}CO_2$-pyruvate exchange and the formation of acetoin from pyruvate (in the absence of electron acceptors); it is probably a TPP-enzyme. When substrate quantities of enzyme are used in the presence of CoA, the reduction of an enzyme chromophore at 410 nm is observed, with formation of acetyl-CoA. The reduced chromophore can be reoxidized by ferredoxin or FAD. The reactions are assumed to proceed as follows:

1. Pyruvate + TPP-enzyme$_{ox}$ ⇌ hydroxyethyl-TPP-enzyme$_{ox}$ + CO_2

2. Hydroxyethyl-TPP-enzyme$_{ox}$ + CoA ⇌ TPP-enzyme$_{red}$ + Acetyl-CoA

3. TPP-enzyme$_{red}$ + X ⇌ TPP-enzyme$_{ox}$ + XH_2

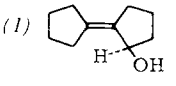
/ Federat. Proc. *26*, 561 (1967) / –Hö. [Rd 714 IE]

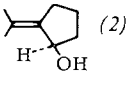
An enzyme-substrate intermediate of D-amino-acid oxidase was stabilized by *L. Hellerman* and *D. S. Coffey* by reduction with $NaBH_4$. The enzyme catalyses the oxidation of D-amino acids with oxygen to give α-keto acids and ammonia, the cofactor being FAD. On aerobic incubation of D-amino-acid oxidase, FAD, [^{14}C]-D-alanine, and $NaBH_4$, the enzyme becomes radioactive. After total hydrolysis of the protein, it was found that radioactive ε-*N*-(1-carboxyethyl)-L-lysine had been formed. When radioactive FAD and unlabeled D-alanine are used, no radioactivity is incorporated into the protein. The results are interpreted by assuming that a primary oxidation product of D-alanine containing an imino function (in the hydrophobic zone that almost certainly exists around the FAD) is aminolysed by the ε-amino group of a lysine residue bound to the enzyme. Subsequent hydrolysis releases ammonia, the amino group of the lysine, and the reaction product, *i.e.* pyruvate. When $NaBH_4$ is added, a hydrolysis-resistant secondary amine is formed. Radioactive pyruvate is not bound to the enzyme under any conditions. / J. biol. Chemistry *242*, 582 (1967) / –Hö. [Rd 715 IE]

The primary structure of yeast phenylalanine-tRNA has been established by *U. L. RajBhandary et al.* (*H. G. Khorana*'s research group). The tRNA contains 76 nucleosides including 1 thymidine, 2 pseudouridine, 2 dihydrouridine, 2 methylcytidine, 1 2′-*O*-methylcytidine, 1 methyladenosine, 1 2-methylguanosine, 1 dimethylguanosine, 1 2′-*O*-methylguanosine (2′OMeG) and 1 7-methylguanosine. The last two were isolated from a tRNA for the first time. An unidentified base was also found. The most likely anticodon is 2′-OMeG–A–A. The sequence contains no A–A–A-trinucleotide. In attempts to find a secondary structure by the principle of the maximum number of base pairs, the resulting structure largely corresponds to those of the tRNA's elucidated so far (for alanine, serine, and tyrosine, all from yeast). The assumed anticodon is present in the same place in all these hypothetical secondary structures. / Proc. nat. Acad. Sci. USA, *57*, 751 (1967) / –Hö. [Rd 716 IE]

In the reaction of liquid barium/sodium solutions with nitrogen, *C. C. Addison, B. M. Davies, R. M. Lintonbon,* and *R. J. Pulham* found rules that are valid for metal melts in general (*e.g.* for Li/Na + N_2, Li/Hg + N_2, Pb/Na + C_2H_5Cl). If the binary melt has discontinuities in its liquidus curve or in its electric conductivity at any composition, the composition of the reaction product changes at these points of discontinuity. Thus on reaction until all the barium has been consumed, a Ba/Na melt gives Ba_3N (melts with $>$ 8.5 atoms-% of Ba), Ba_2N (melts with $>$ 3.5 atoms-% of Ba), and Ba_3N_2 (melts with $<$ 3.5 atoms-% of Ba). The chemical reactivity depends less on the electropositivity (which is approximately the same for Na and Ba) than on the structure of the short-range order zones. / Chem. Commun. *1967*, 211 / –Jg. [Rd 737 IE]

Mercury derivatives of decaborane containing Hg—B σ bonds have been synthesized for the first time by *N. N. Greenwood* and *N. F. Travers*. Whereas $HgCl_2$ and $HgBr_2$ are reduced by decaborane $B_{10}H_{14}$ in tetrahydrofuran, $HgCl_2$ metalates decaborane in ether:





$$B_{10}H_{14} + n\,HgCl_2 \rightarrow B_{10}H_{14-n}(HgCl)_n + n\,HCl \quad (n = 7, 8)$$

CH_3HgX (X=Cl, Br, I) reacts with $B_{10}H_{13}Na$ in ether to give the mercury derivative $B_{10}H_{13}HgCH_3$ in yields of 50 to 80 %. The reaction of CH_3MgX with decaboranylmagnesium iodide (order of reaction rates: Cl > Br $\gg$ I) leads to the complexes $Mg[(B_{10}H_{12})_2Hg] \cdot 5\,MgX_2 \cdot n$ ether, *e. g.* $Mg[(B_{10}H_{12})_2Hg] \cdot 5\,MgCl_2 \cdot 11$ether, which dissolve in water without decomposing. The anion $[(B_{10}H_{12})_2Hg]^{2-}$ could be precipitated as the orange tetramethylammonium salt. The asymmetric M–B stretching vibrations due to the tetrahedral structures (MB_4) can be detected for the complexes $[(B_{10}H_{12})_2M]^{2-}$ in the long-wave IR region (Hg–B: 225; Cd–B: 235; Zn–B: 278 cm^{-1}). / Chem. Commun. *1967*, 216 / –Jg. [Rd 738 IE]

The stereoselective efficiency of hydrogenation catalysts has been studied by *T. J. Howard* and *B. Morley*. The hydrogenolysis of substituted benzyl alcohols on Raney nickel catalysts always leads to retention, and hydrogenolysis on Pd catalysts to inversion. This is explained by the difference in orientation of the OH groups, which are turned toward the surface of the catalyst in one case and away from the surface in the other. However, the hydrogenation (110 atm; 20 °C) of allyl alcohols such as *(1)* and *(2)* (see table) leads more or less

	Yield of *trans*-hydrogenation product (%) with:					
	Ni	Ni_2B	Ru/C	Pt	Rh/C	Pd/C
(1)	98	92	90	87	82	85
(2)	97	91	89	88	86	81

predominantly to *trans*-alcohols (identified as phenylurethanes). This suggests coordination of the OH group with the catalyst surface, *i.e.* interaction with the π-electrons of the double bond and the lone electrons the oxygen; partial inversion appears to occur only as a secondary process (the ability to isomerize generally increases in the order Ni<Ru<Pt<Rh<Pd).

BOOK REVIEWS

Natürliche Proteinasen-Inhibitoren. (Natural Proteinase Inhibitors). By *Rosemarie Vogel, I. Trautschold,* and *E. Werle*. From the series "Biochemie und Klinik". Edited by *G. Weitzel* and *N. Zöllner*. Georg Thieme Verlag, Stuttgart 1966. 1st Edit., xii, 108 pages, 4 figures, 20 tables, DM 29.70.

The present monograph presents the first German-language review of the now extensive field of natural proteinase inhibitors. The subject matter is divided according to the source of the proteinase inhibitors: plant (from Leguminosae, potatoes, grains, beets); microbial; animal and human proteinase inhibitors (from ascarides, egg-white, milk, blood serum, urine, organs, particularly endocrine glands such as the pancreas). Each chapter is subdivided into sections on isolation, properties, composition, and inhibition spectrum. The monograph is rounded off by an introductory chapter on determination methods and definitions, a concluding chapter on therapeutic possibilities, and an extensive bibliography.

The size of the bibliography is impressive and so far unequalled (more than 900 entries). The animal proteinase inhibitors, particularly those of the ox, and the serum proteinase inhibitors are discussed in great detail, considerable space being devoted to the work of the authors. The difficult characterization and differentiation of the proteinase inhibitors has been very successfully accomplished, though many simplifications in the case of the cattle proteinase inhibitors that have become widely used in therapy (*e.g.* the ox-organ inhibitor) make the dividing lines rather unclear. Research in this field is advancing so rapidly that the monograph can be recommended to all who are interested.

W. Appel [NB 618 IE]

Kunststoff-Handbuch. Band VI: Polyamide. Aufbau, Verarbeitung, Eigenschaften und Anwendung. (Handbook of Plastics, Volume VI: Polyamides. Constitution, processing, properties, and applications.) Edited by *R. Vieweg* and *A. Müller*. Carl Hanser-Verlag, Munich 1966. 1st Edit., xvi, 698 pp., 477 illustrations, 111 tables, DM 140.–; advance order DM 126.–; subscription price DM 112.–.

The present volume[*] about the polyamides demonstrates how necessary it is to present this class of compounds in a comprehensive handbook to all concerned with the subject. The field "polyamides" has assumed such proportions that it is difficult to be aware of all the relevant facts. For this reason, the present volume, with a good index and appendix tables, proves an excellent reference work and is also suited for the study of special points. The excellent subdivision of the material facilitates the search for answers to specific problems which are not listed as such in the index.

Following an introduction, which mentions such topics as history, nomenclature, and production, the book goes on to deal with the formation of polyamides by polymerization and polycondensation, their physical structure and melting behavior, as well as the synthesis of and production processes for polyamides in general. The next chapter describes the processing of polyamides, and includes an account of injection molding, screw extrusion molding, and casting. An account is also given of the processing of solutions and dispersions as well as forming, welding, adhesion, *etc.* The behavior of polyamides toward moisture and water, chemical reagents, and toward mechanical, thermal, and electrical influences is dealt with in a section which provides a transition to the

chapter headed "applications". A separate section is devoted to the identification and analysis of polyamides.

The volume presents information on the manufacture, properties, processing, and applications of polyamides to manufacturers, engineers, and constructors as well as to chemists, physicists, and students of these subjects. The reviewer feels that the application to textiles does not really belong in this volume but should be dealt with in a volume on textiles. To summarize, the volume is no less than excellent and can be whole-heartedly recommended. *O. Horn* [NB 621a IE]

[*] Cf. Angew. Chem. *78*, 832 (1966); Angew. Chem. internat. Edit. *5*, 855 (1966).

Kunststoff-Handbuch. Band VII: Polyurethane. Herstellung, Eigenschaften, Verarbeitung und Anwendung. (Handbook of plastics, Volume VII: Polyurethanes. Production, properties, processing, and applications.) Edited by *R. Vieweg* and *A. Hoechtlen*. Carl Hanser-Verlag, Munich 1966. 1st Edit., xix, 767 pp., 419 illustrations, 137 tables, DM 180.00: subscription price DM 144.00.

Polyurethanes are being used in ever increasing amounts, primarily as elastomers and as foams. The great difference between polyurethanes and other plastics, which are delivered as finished polymers and only have to be worked, lies in the fact that the former are actually produced on the premises of the user by polyaddition. Since it is up to the user to obtain a product of the desired properties by varying the types and amounts of the components, the publication of the present book is of great importance.

The work opens with an account of the chemistry and development of polyurethanes by their inventor *O. Bayer*. This is followed by a large chapter headed "starting materials" in which the components (polyesters, polyethers, as well as polyisocyanates) are dealt with, as are the auxiliary agents (accelerators, retarders, propellents, stabilizers, softeners, fillers, *etc.*). The next chapter is concerned with process plant, process technology, and methods of finishing; it contains much useful information for manufacturers.

The following chapters are devoted to the manufacture, technology, applications, and testing of elastomers and hard foams and soft foams; the text is well supported by illustrations. The volume closes with an account of the use of polyurethanes as adhesives, for injection molding, and for the finishing of textiles. A glossary of trade names facilitates use of the book.

The publication of each new volume underlines the value of this series, which contains such excellently presented information written by outstanding experts in the fields of construction, architecture, and engineering as well as chemistry. Following the appearance of this excellent volume, one can look forward with keen interest to the publication of further volumes of the series. The volume under review is an eminently successful work and can be warmly recommended to all who are interested in this field. *O. Horn* [NB 621b IE]

Lehrbuch der organischen Chemie (Textbook of Organic Chemistry). By *H. Beyer*. S. Hirzel Verlag, Leipzig 1966. 11th/12th Edit., xviii, 813 pages, 102 figures, 12 tables, DM 24.–.

In the reviewers opinion this textbook, which is now in its 11th/12th edition, owes its popularity among students to two factors: the first is its low price, and the second is the fact that in spite of its size and content, the book is laid out and written in a simple and readily understandable manner.

However, the frequent oversimplification can lead students to false conclusions. For example, the student must regard carbenes and nitrenes as isolable substances that exist as such, and not as reaction intermediates that cannot be isolated. In the formulation of onium (ammonium, oxonium) salts, the repeated insertion of a positive charge outside the (unnecessary) brackets as well as on the N or O atom, so that two positive charges are shown with only one negative charge, is misleading. Several other points that would not be difficult to improve could be mentioned. On the other hand, since new editions of the book are published in rapid succession, the author has been able to keep step with the results of research, as is particularly clear in the present edition. Many sections have been updated or rewritten to take into account developments in preparative and theoretical chemistry as well as in industrial chemistry, the chemistry of natural products, and biochemistry. The references to literature reviews and monographs may also prove very useful to the advanced reader. It is to be expected that the book will continue to enjoy a large readership.

F. Micheel [NB 610 IE]

Glycoproteins. Their Composition, Structure, and Function. Edited by *A. Gottschalk*. BBA Library, Vol. 5. Elsevier Publishing Company, Amsterdam 1966. 1st Edit., xvi, 628 pages, numerous figures and tables, Dfl. 100.–.

Our knowledge about the chemistry and biochemistry of the sugar-protein complexes, which, 10 years ago, was based on a few experimental observations, has grown enormously in the past decade. Findings concerning the chemical structure and biological function of glycoproteins have led to the appearance of several thousand publications. This first attempt to present a detailed survey of the present research position is therefore very welcome. The editor, *A. Gottschalk*, did not write the review himself, but divided the field into 12 sections, each of which was dealt with in a self-contained article by an appropriate specialist, though a few sections consist of subchapters.

Gottschalk himself contributes five sections, three in collabortation with other authors. Six contributions come from *A. Neuberger*'s research group. Authors of other chapters are: *R. W. Jeanloz, R. A. Gibbons, J. E. Eastoe, M. D. Melamed, P. Jollès, E. R. B. Graham, E. M. Press* and *R. R. Porter, A. G. Bearn* and *W. C. Parker, M. Maxfield, M. Watkins, M. T. McQuillan* and *V. M. Trikojus, H. Papkoff, E. Buddecke* and *L. Warren*. Thus the present work is not a detailed monograph, but is more of a handbook in which the specialist can find a wealth of methodic details. It is to the editor's credit that this did not become a pure collection of experimental procedures. Instead, authors of great experience in the field of glycoproteins discuss the scope and capabilities of selected methods, and the resulting book is of much more value to the reader. Most of the authors have also attempted to describe the chemical and biochemical reaction courses on which the methods are based in the light of the latest knowledge.

Special emphasis is placed on physicochemical methods, to which *R. A. Gibbons* devotes an entire chapter in connection with the determination of the purity, uniformity, and molecular size of glycoproteins. In addition to a general inventory interspersed with questions of nomenclature, the discussion includes the analysis of the various components of this class of compounds and of the functional groups, including amino-acid analysis and the bonding of the sugars to one another and to the peptide chain. Much space is also devoted to the amino acids and neuraminic acids, the glycoproteins, and the heterosaccharides that can be isolated from these. The last group of topics forms the subject of a very clearly written chapter by *L. Warren*. The reader who is particularly interested in the chemistry of the glycoproteins will find an article by *A. Neuberger, R. D. Marshall*, and *A. Gottschalk* on the conformation of the sugar components of this class of substances and the acid- and alkali-induced rearrangements of these carbohydrates; this is the only self-contained discussion of this subject that has been published so far.

Occasional overlapping is found in the treatment of similar topics, as *e.g.* in the case of the serum glycoproteins, which play an important part in the field of sugar-protein compounds; however this is practically unavoidable in a book written by several authors. The presentation is excellent, and the book offers the first self-contained survey of the field in question for the research worker who is interested in the biochemistry of the glycoproteins, a particularly valuable feature being the detailed critical appraisal and description of the methods used in this field.

H. Faillard [NB 602 IE]

Developments in Inorganic Nitrogen Chemistry. Edited by *Ch. B. Colburn*, Elsevier, Amsterdam-London-New York 1966. 583 pp., 180 s.

As a result of its many-sided nature the chemistry of nitrogen has always interested chemists in general. Developments in this branch of chemistry have by no means been neglected during the past decades, even if the results have not been and are not as spectacular as in other fields. Colburn suggested a discussion of the developments in the inorganic chemistry of nitrogen, and has now succeeded in persuading internationally famous authors to contribute to the individual fields.

In this first volume, *M. Green* discusses the results of MO and VB calculations for simple nitrogen-containing molecules in a section entitled "Bonding in nitrogen compounds" (71 pages). It becomes clear what difficulties must still be overcome before adequate agreement between calculated and experimental results is obtained. This exceptionally interesting and clear chapter is followed by a discussion of the chemistry of "Inorganic azides" (78 pages) by *A. D. Yoffe*, with emphasis on physical and physicochemical aspects.The chemical properties, particularly of the covalent azides, are dealt with too briefly, organometallic azides being almost entirely ignored. Nevertheless, *Yoffe*'s contribution contains perhaps unusual, but extremely useful, material for the chemist. *M. Becke-Goehring* and *E. Fluck* discuss in detail the chemistry of inorganic compounds with S–N bonds (92 pages). It is precisely in this field that substantial progress has been made and new knowledge gained during the past two decades. The contribution by *W. P. Griffith* (66 pages) on "Nitrogen ligands", *i.e.* transition metal complexes, in which the nitrogen atom behaves as a donor is necessarily restricted to a small range of selected examples As illustrations, the author has chosen NH_3, N_2H_4, NH_2OH, amide and imide, cyanate, fulminate, thiocyanate, selenocyanate, cyanide, alkylnitrile and alkyl cyanide complexes, with nitrido, azido, azo, nitrate, nitrite, NO, and NS complexes. Twenty pages are devoted to the chemistry of complexes with amines and heterocyclic bases.

A detailed though not very clearly arranged discussion of phosphorus-nitrogen compounds by *M. L. Nielsen* occupies 165 pages (without touching on the cyclic phosphorus nitrides). This work must be at present the most complete survey of compounds containing P–N bonds. The description by *J. K. Ruff* of the nitrogen compounds of boron, aluminum, gallium, indium, and thallium (51 pages) does less than full justice to boron-nitrogen chemistry (22 pages), but shows how quickly our knowledge of nitrogen compounds becomes scanty as soon as we pass on to the heavier elements of this group. In conclusion, *G. W.A.Fowles* gives a clear, very instructive summary on "Inorganic reactions in liquid ammonia" (54 pages). A very meager subject index is matched by the absence of an author index.

The book can serve as a very useful source of information for all those wishing to obtain a survey of the subject. Both the type of discussion and the level of the individual articles vary, and yet the book as a whole is surprisingly coherent. The price needs some consideration, especially in view of the fact that the literature considered does not as a rule extend beyond 1962.

H. Nöth [NB 642 IE]

Advances in Magnetic Resonance. Vol. 1. Edited by *J. S. Waugh*. Academic Press. New York-London 1966. 1st Edit., xi, 413 pages, numerous figures and tables, $ 15.00.

The first successful observations of magnetic resonance phenomena date back about twenty years. Developments in this field since then have been so extensive that it is practically impossible for the individual to obtain a full general picture. The appearance at this stage of progress reports on magnetic resonance methods is therefore very welcome. This thought has obviously been shared by others, since a similar work is to be published soon by Pergamon Press.However, it is clear from the list of forthcoming publications that there is little fear of excessive overlap in the near future.

The field covered by "Advances in Magnetic Resonance" is to be very wide, and in addition to nuclear spin resonance, electron spin resonance, and nuclear quadrupole resonance, it will also include related topics such as molecular beams, optical pumping, and microwave spectroscopy.

Each volume will contain five to ten review articles. Besides original theoretical articles, they will contain reports on speculative views or on individual phenomena, as well as accurate tables.

Volume 1 contains an article by *A. G. Redfield* on the "Theory of Relaxation Processes", which is essentially a revised and further annotated version of his paper in IBM J. Res. Develop. *1*, 19 (1957). In a chapter on "Chemical Rate Processes and Magnetic Resonance", *C. S. Johnson jr.* reports on the concepts and methods of this field, which is particularly important to nuclear magnetic resonance. A welcome article is the review by *D. R. Eaton* and *W. D. Phillips* on "Nuclear Magnetic Resonance of Paramagnetic Molecules", which shows what conclusions concerning the geometric and electronic structure of paramagnetic molecules and metal complexes can be drawn from the isotropic hyperfine contact and pseudocontact interaction between magnetic atomic nuclei and unpaired electrons.

The next two chapters form a well matched pair. In "Theory of Nuclear Spin-Spin Coupling", *M. Barfield* and *D. M. Grant* point out the difficulties and dangers of approximations (mainly VB and MO methods) for the calculation of nuclear spin coupling constants. This is followed by a valuable 120-page tabulation by *A. A. Bothner-By* of all that is known with certainty about "Geminal and Vicinal Proton-Proton Coupling Constants in Organic Compounds", with many structural formulae. Only 10% of the measurements that have been reported were accepted as sufficiently accurate. A short introduction gives rules for the estimation of the magnitude and sign of the coupling constants. The book closes with a useful tabulation by *K. W. Bowers* on "Electron Spin Resonance of Radical Ions", covering literature up to mid-1964. The table gives the empirical formula of the ion, name and structure of the neutral molecule, hyperfine splitting constants, solvent, and references.

The volume contains an author and subject index. It can be recommended in every respect.

R. F. Zürcher [NB 601 IE]

Bioorganic Mechanisms. By *T. C. Bruice* and *S. Benkovic*. From the series "Frontiers in Chemistry". W. A. Benjamin, Inc., New York-Amsterdam 1966. 1st Edit., Vol. 1, viii, 372 pp., numerous figures, bound $ 22.50. Vol. 2: viii, 419 pp., numerous figures, bound $ 25.00.

The reaction mechanisms of enzyme-chemical processes form an area between theoretical organic chemistry and biological chemistry, for which the new term "bioorganic mechanisms" has been coined. This new creation might lead one to think that it is associated with self-willed sensationalism. However, a perusal of the present two volumes shows that this is not so. This term describes exactly what is meant, *i.e.* the field in which enzyme reactions and enzyme mechanisms can be interpreted with the aid of more or less complete

models or in which the driving force of the transformations of biochemically important compounds and the function of the cofactors can be explained by theoretical considerations without the boundaries between enzymatically and chemically catalysed processes becoming blurred.

On closer examination, this work becomes even more deserving of the reader's admiration and gratitude. It is an excellent introduction for the advanced reader as well as a mine of information for the specialist, who will find the many references useful in dealing with his problems. The book is obviously based on a course of lectures, and anyone who is planning lectures on biochemical reaction mechanisms will find this carefully and intelligently written book full of extremely valuable information. Most biochemists lack the training required to tackle, without some help, the reaction-kinetic problems that arise. Two thoroughly experienced organic chemists, who are themselves working in this intermediate field, have now made an effort to help in this respect. The introductory chapter presents a perfectly clear and simple treatment of the basic views on acid-base catalysis. This chapter also includes a discussion of the concepts of neighborhood catalysis and of steric and polar effects on the hydrolysis of esters. This is the authors' own particular field, but this does not mean that they are any less careful or less critical in other sections. The excellent appraisal from the standpoint of the experienced theorist (they are by no means reticent with their judgement which is always fair) is particularly stimulating. Much of the work in this field the laws of which are only just starting to be recognized, is very deductive, and this is even openly stated Excessively speculative mechanisms are briefly dismiesed with a reference to the literature.

Further, in the first part, hydrolyses of esters and amides, the only biochemically important acyl cleavages, are discussed on the basis of the general point of view deduced previously. This is followed by an examination of the catalytic processes in various hydrolysis and transfer systems. These are the reactions of the thioesters and of the phosphate esters in the widest sense, and the mode of action of the cofactors thiamine, nicotinamide, folic acid, and biotin. Model reactions that take place under extreme conditions not found in biological systems are not considered. However, model reactions that have no precise physiological analogues, but that can contribute to an understanding of biochemical processes, are occasionally discussed. Though these two volumes already contain enough material with which the reader must become thoroughly acquainted, one still looks forward to the proposed third volume, which is to contain the mechanisms of the B_{12} coenzymes, the flavins, and the ribonucleases.

The thorough and critically compiled bibliography covers a wide field, ranging from a short historical introduction to completely new works. The presentation of the books is excellent and the printing of the text and of the formulae is outstanding and free from errors. The only unwelcome feature is the high price of the work, which can otherwise be recommended to anyone who is studying, or who wishes to study, enzyme mechanisms.

L. Jaenicke [NB 587 IE]

Adhesion and Adhesives. By *R. S. R. Parker* and *P. Taylor*. Pergamon Press, Oxford-London-Edinburgh-New York-Toronto-Paris-Frankfurt 1966. 1st Edit., vi, 142 pages, numerous figures, 25 s.

A great deal is still unknown about the process of adhesion, despite much fundamental research which has been conducted in an effort to answer the many open questions.

The authors begin with a historical survey ranging from the earliest adhesive processes of the distant past to the modern processes used, *e.g.*, in light-construction techniques, and including the technical principles underlying these processes. They then turn to the process of adhesion itself, which they describe as an exchange of secondary valences (van der Waals forces) and define accordingly. Other views such as the diffusion theory are discussed, but the magnitude of the adhesive force is mainly determined by wetting. Further chapters deal with the joint surface and its preparation as well as with the production and testing of adhesives and adhesive joints. The chemical and physical properties of polymers are then discussed, and the sources and applications of the principal adhesives are described in detail. Further sections deal with specific adhesives, such as the isocyanates and the cyanacrylates, and with their chemistry.

The book closes with a discussion of the cementing of reinforced plastics and of adhesive systems of various compositions. Adhesion to metals is mentioned only briefly.

Nonetheless, the book as a whole gives an impression of completeness, and provides an insight into a many-sided technology with a solid scientific foundation.

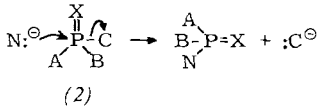
Nucleophilic Reactivity of the Thiophosphoryl Group

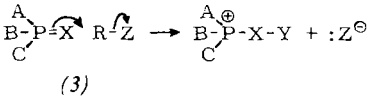
BY H. TEICHMANN AND G. HILGETAG [*]

The difference in the nucleophilic reactivities of the $\geq P{=}S$ and $\geq P{=}O$ groups can be satisfactorily explained on the basis of Pearson's acid-base concept [21]. The thiophosphoryl sulfur is a typical "soft base", and reacts preferentially with sub-group B metals, halogens, and sp^3 hybridized carbon, whereas it is largely inert to "hard acids" such as protons, carbonyl carbon, and tetrahedral phosphorus. Since a nucleophilic attack by the thiophosphoryl sulfur leads to a decrease in the charge density of the phosphorus atom, the latter (or the α-carbon atom in O-alkyl esters) becomes more open to nucleophilic attack. This reaction principle forms the basis of sulfur exchange, dealkylation, isomerization, and the Pistschimuka and Michalski reactions.



I. Introduction

Neutral phosphoryl and thiophosphoryl compounds *(1)* can react both as nucleophiles and as electrophiles. Apart from the reactivity of the substituents A, B, and



(1)

C (*e.g.* nucleophilic: PO-activated olefination [1]; electrophilic: dealkylation [2]), one can generally distinguish an electrophilic center at the phosphorus atom *(2)* and a nucleophilic center at the oxygen or sulfur atom *(3)*.

(2)

e.g. A,B = alkyl, alkoxy;
C = Cl; X = O,S; N = OH

(3)

e.g. A,B,C = alkyl; X = S;
RZ = CH_3I

Special attention has been paid in the past to the electrophilic center at the phosphorus atom, since this is the point of attack in such important reactions as hydrolysis [3] and phosphorylation [4]. The present article is confined to reactions in which the thiophosphoryl sulfur functions as a nucleophile. These are the reactions in which phosphoryl and thiophosphoryl compounds exhibit the greatest differences in behavior.

(1a) and *(1b)* differ:

1. in the electronegativities of oxygen (3.5) and of sulfur (2.5);

2. in the dissociation energy, which is 40–60 kcal/mole lower for the P=S bond (about 90 kcal/mole) than for the P=O bond (125–155 kcal/mole) [5];

3. in the extent of π bonding, which is lower for the P=S bond than for the P=O bond. This is shown by the force constants of the bonds [6], the difference in the shortening of the bond lengths [7], the difference between the dissociation

energies of the single and double PX bonds [8], the difference in electronegativity between P and X [9], and the ^{31}P-NMR signals, which always occur at lower fields for *(1b)* than for *(1a)* [10, 11].

The P=O bond may be regarded as a semipolar bond on which is superimposed a p_π–d_π bond due to back-donation of p electrons from the oxygen atom to empty d orbitals of the phosphorus atom. Since the overlap of the p and d orbitals is greatest near the oxygen atom, the p_π–d_π bond of the P=O group is much more strongly polar than the p_π–p_π bonds usually encountered in carbon chemistry [12]. The p_π–d_π interaction, and hence the P=O bond order, increases with increasing electronegativity of the substituents A, B, and C; this is clearly shown by the position of the PO frequency, which shows a linear relationship to the sum of the electronegativities of the substituents A, B, and C [13, 14]. Calculations of the P=O bond order yield different values according to the methods used, but the results always show the same trend.

Table 1. Bond order N of the P=O bond as found (A) from the force constants [6], (B) by an MO calculation [15]. Σx = sum of the electronegativities of the substituents.

	F_3PO	Cl_3PO	Br_3PO	$(CH_3)_3PO$
Σx	12	9	8.4	6.0
N (A)	2.34	2.09	2.02	1.7
N (B)	2.98	2.19	1.96	1.0

A similar situation is to be expected for the P=S bond, the π-bond component in this case being smaller. The bonding again depends on the electronegativity of the substituents [14, 16, 17], but this dependence is less pronounced in the P=S frequency, owing to the mechanical coupling between the P=S and P(A,B,C) stretching vibrations [14, 17, 18]. The similarity of the P=O and P=S bonds is also evidenced by the fact that the frequency shifts on complex formation with acceptor molecules (cf. Section II) take place in the same direction.

Differences between *(1a)* and *(1b)* are also found:

4. in the availability of empty 3d orbitals of the thiophosphoryl sulfur, which may explain the greater stability of some thiophosphoryl complexes [19, 20].

The experimental data on the nucleophilic reactivities of phosphoryl oxygen and of thiophosphoryl sulfur can be largely explained by *Pearson*'s concept [21], according to which oxygen is a "hard base" and so reacts preferentially with "hard acids" (protons, A metals, carbonyl carbon, phosphoryl phosphorus), whereas sulfur is a "soft base" and reacts mainly with "soft acids" (B metals, tetrahedral carbon, halogens). This is illustrated by the following examples.

1. Phosphine oxides form stable salts with inorganic and organic acids [22], and can be titrated acidimetrically [23]. The only known salt of a phosphine sulfide is evidently a hydrobromide (an oil) [24]; attempted resolutions of chiralic phosphine oxides [25], but not of phosphine sulfides [26], by salt formation with optically active acids have been successful.

Similarly, the hydrogen bonding ability is strong in phosphoryl compounds but much weaker in thiophosphoryl compounds [27]; the resulting lower solubility in water and greater resistance to hydrolysis were deciding factors in the development of the thiophosphate insecticides [28].

2. Phosphoryl compounds are extremely useful for the extraction of many metal salts from aqueous solution [29], whereas the corresponding thiophosphoryl compounds have much poorer extraction properties [30]. The only ions that are extracted particularly well by thiophosphoryl compounds [32] are those of the B metals (mainly group I, II, and VIII transition elements that are rich in d electrons and form readily polarizable cations [31]).

3. Trialkyl phosphates *(4)* react with diester chlorides of phosphoric and thiophosphoric acids *(5)* to form pyrophosphates or pyrothiophosphates *(6)*; trialkyl phosphorothionates give the same reaction only in so far as they are converted into thiol compounds [33]. The phosphoryl oxygen is thus able to carry out a nucleophilic attack on the chloro(thio)phosphate [34],

which is impossible in the case of the thiophosphoryl sulfur.

(4), X = O
(5), X = S

(6)

4. Whereas phosphine sulfides can be alkylated even with alkyl halides to form alkylthiophosphonium salts [35], the analogous reactions of phosphine oxides take place only with stronger alkylating agents [25, 36]. O→S transalkylation is a characteristic of many esters of phosphorothionic and phosphonothionic acids (cf. Section V 2b).

5. The "soft acids" ICl, IBr, and I_2 [21] form more stable adducts with thiophosphoryl compounds than with phosphoryl compounds [27, 37]. Even the less "soft" and more strongly oxidizing halogens Br_2 and Cl_2 give characteristic reactions with thiophosphoryl compounds (cf. Section III).

These examples already indicate a classification of the types of electrophiles to be discussed according to metal salts, halogenating agents, carbonyl and phosphoryl compounds, and alkylating agents.

II. Reactions with Metal Salts [*]

The many crystalline addition products of phosphine oxides and phosphinic, phosphonic, and phosphoric acid derivatives, as well as the solvates present in solution in extractions with phosphoryl compounds, result from a donor-acceptor interaction between phosphoryl oxygen and metal. Even in systems such as $OPCl_3/SbCl_5$, in which chloride ion transfer according to (a) (solvent system concept) was at first regarded as more likely than adduct formation at the oxygen atom (b) (coordination model), (b) has proved to be more significant [38–41].

$$OPCl_2^{\oplus}\,SbCl_6^{\ominus} \xleftarrow{(a)} OPCl_3 + SbCl_5 \xrightarrow{(b)} Cl_5Sb{\leftarrow}OPCl_3$$

Apart from X-ray structure analysis [41], P=O-metal coordination can be deduced in particular from IR measurements. The formation of a coordinate bond from the oxygen to the metal weakens the back-donation of electrons from the oxygen to the phosphorus, and so reduces the P=O bond order; this leads to a strong bathochromic shift of the P=O frequency [42,43]. If the simultaneous decrease in the electron density on the phosphorus cannot be compensated by other substituents, this also results in a downfield shift of the ^{31}P resonance line [44,45].

Until recently, the only thiophosphoryl addition compounds known were a few metal salt adducts. However, several research groups have now described new compounds that seem to call for a revision of the earlier view that the donor character of the thiophosphoryl sulfur is insignificant. Nevertheless, the adducts of the phosphoryl compounds are generally much more stable than those of the thiophosphoryl compounds except for a few adducts of phosphorothionates [46,47] and phosphine sulfides [20], mainly with Ag and Hg(II) salts. A plausible explanation of this is offered by *Ahrland*'s view [48] that the coordinate bond between a "soft base" and a typical B metal can be strengthened by back bonding by d electrons of the metal to the ligand.

It has recently been shown that the P=S frequency also undergoes an appreciable bathochromic shift as a result of metal-sulfur coordination [20,49–51].

1. Thiophosphoryl Halides

Whereas *e.g.* very many phosphorus oxychloride adducts are known [41], the only thiophosphoryl halide adducts obtained so far are evidently [53–55]

$SPCl_3 \cdot AlCl_3$ [52], $SPBr_3 \cdot AlBr_3$ [52a], $SPCl_3 \cdot SbCl_5$ [52–54], and $SPBr_3 \cdot SbCl_5$ [54]. $SPBr_3 \cdot SbCl_5$ decomposes at room temperature, and $SPCl_3 \cdot SbCl_5$ at temperatures above 140 °C [54]. The low stability and the results of calorimetric measurements [56] indicate a much weaker donor character for the sulfur in the thiophosphoryl halides than for the oxygen in $OPCl_3$.

According to ^{31}P–NMR and conductivity measurements, $SPCl_3 \cdot AlCl_3$ appears to exist in solution as the chloro complex $SPCl_2^{\oplus}$ $AlCl_2^{\ominus}$ [57]. However, X-ray structure investigations on comparable $OPCl_3$ adducts, which dissociate similarly in solution [40], have revealed unmistakable P–O-metal coordination [41]; no corresponding investigations on thiophosphoryl compounds have yet been reported.

2. Thiophosphoryl Amides

Adducts of thiophosphoryl tripiperidide and tripyrrolidide with $PdCl_2$, $CdBr_2$, and CdI_2 [49] and of thiophosphoryl trismethylamide, triscyclohexylamide, trimorpholide, and tripiperidide with $SnCl_4$ and $SnBr_4$ [58] have been obtained.

Metal-nitrogen coordination can be discounted for these compounds on the grounds of their IR spectra (the $CdHal_2$ adducts show bathochromic shifts of 20–40 cm^{-1} for the P=S frequency [49]; the P=S frequency of the triscyclohexylamide changes from 652 cm^{-1} to 610 cm^{-1} in the $SnCl_4$ adduct and to 607 cm^{-1} in the $SnBr_4$ adduct [58]).

3. Phosphine Sulfides and Diphosphine Disulfides

A compound of triethylphosphine sulfide with $PtCl_2$ was mentioned as early as 1857 [59]. With two exceptions, however, the phosphine sulfide adducts listed in Table 2 were obtained only in the last three years. Other attempted preparations have been unsuccessful [20,49,61,62].

The frequency shifts are of roughly the same order of magnitude as those for phosphine oxide adducts, confirming that the bonding is similar. However, no information about the stability of the complex can be deduced from the magnitude of $\Delta\nu_{P=S}$. Thus some of the adducts of the trialkylphosphine sulfides can be sublimed without decomposition [50], whereas those of triphenylphosphine sulfide generally decompose on heating [20]. The $SnHal_4$ adducts of the trialkylphosphine sulfides undergo complete ligand exchange with trialkyl phosphates or trialkyl phosphorothiolates:

$$[R'_3PS]_2SnHal_4 + 2\,(RO)_3PO \rightarrow 2\,R'_3PS + [(RO)_3PO]_2SnHal_4$$

Table 2. Addition compounds of tertiary phosphine sulfides. $\Delta\nu P{=}S$ = difference between the P=S frequencies in the free phosphine sulfide and in the adduct.

$(C_6H_5)_3PS \cdot AgNO_3$	82–83	−51	[67]

[*] This value is probably too high, since $\nu P{=}S$ in $(C_6H_5)_3PS$ was given incorrectly.

Unlike the very unstable $SnCl_4$ adduct of triphenylphosphine sulfide, they are not decomposed by trialkyl phosphorothionates or by diethyl ether. The relative donor strengths toward tin(IV) halides thus decrease in the order $(RO)_3PO, (RO)_2(RS)PO > R_3PS > (RO)_3PS$, $R_2O > Ar_3PS$ [68].

Phosphine sulfides reduce Cu(II) to Cu(I) [63], and, to some extent, Fe(III) to Fe(II) [20]; $Hg_2(ClO_4)_2$ disproportionates on reaction with triphenylphosphine sulfide [66]. The resulting ions are always "softer" acids than the starting materials, and are therefore better suited for complex formation with the phosphine sulfide.

The following compounds have been prepared from diphosphine disulphides: $2\,R_2P(S)P(S)R_2 \cdot CuClO_4$ ($R = CH_3, C_2H_5$); $R_2P(S)P(S)R_2 \cdot CuCl$ ($R = CH_3$) [51]; and $R_2P(S)P(S)R_2 \cdot SnHal_4$ ($R = CH_3, C_2H_5$, n-C_3H_7, n-C_4H_9; Hal = Cl, Br) [50,58]. The Cu(I) adducts are formed from diphosphine disulfides and Cu(II) salts in ethanol. A chelate structure *(7)* was deduced from

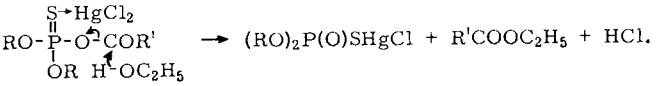
conductivity measurements[51]. The $SnHal_4$ compounds, some of which are extremely sparingly soluble, appear to have a different structure.

(7): X = ClO_4, $CuCl_2$

4. Phosphorothionates, Phosphonothionates, and Phosphinothionates

The reactions of these compounds clearly illustrate the difference in the behavior of "hard" and "soft" acids. While the metal-sulfur coordination is retained in the reaction products with soft acids, the A metals tend to loosen the metal-sulfur bond.

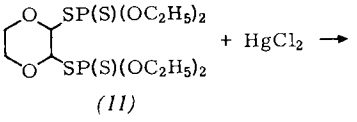


a) Reactions with "Soft" Acids

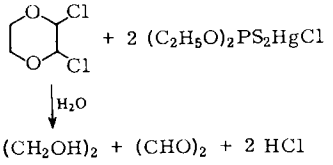
Solid adducts of triesters of phosphorothionic acid have been obtained with $HgCl_2$[47,69–71], $AuCl_3$, $PtCl_4$[69], $AgNO_3$[46,69], $AgNO_2$ and $AgBF_4$[46]. The formation of crystalline compounds of phosphorodithioates with Ag and Hg salts had been observed by *Carius*[72] as long ago as 1861. Phosphonothionates and phosphinothionates also give crystalline $AgNO_3$ adducts[73]. No corresponding compounds of esters of phosphoric acid are known; for example, triphenyl phosphate, unlike triphenyl phosphorothionate, does not react with $AgNO_3$[46].

The partial positive charge induced on the phosphorus atom by the sulfur-metal coordination makes either the phosphorus atom itself or (in alkyl esters) the α-carbon atom of an ester residue more open to nucleophilic attack. Consequently, the adducts of trialkyl phosphorothionates with B-metal salts are generally not very stable. Thus the $HgCl_2$ adducts *(8)* lose alkyl chloride, sometimes even during preparation, but in any case when heated[69,74]:

$$\underset{(8)}{(RO)_3PS\cdot 2\,HgCl_2} \rightarrow \underset{(9)}{(RO)_2P(O)SHgCl\cdot HgCl_2} + RCl$$



A series of dealkylation products *(9)* has been described[69]. Dialkyl phosphorochloridothioates and phosphorofluoridothioates react in the same way with mercury(II) chloride or acetate[75]. In dialkyl acyl phosphorothionates *(10)*, the acyl group is particularly readily removed, so that these compounds can

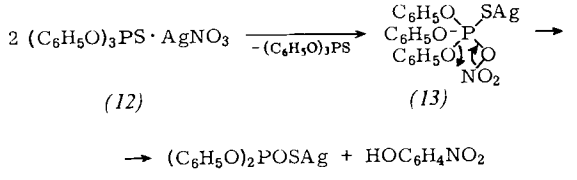


(10)

be determined alkalimetrically after addition of alcoholic $HgCl_2$ solution[76].

A similar reaction is used for the determination of the insecticide Delnav *(11)*[77].

(11)



However, this reaction is not characteristic of thiophosphates, but is observed with mercaptals in general[78].

The very large increase in electrophilic reactivity of the phosphorus atom as a result of sulfur coordination is particularly obvious in the transesterification reactions of trialkyl phosphorothionates in the presence of $HgCl_2$, which proceed even at room temperature[79]:

$$(C_2H_5O)_3PS \xrightarrow[HgCl_2]{CH_3OH} (CH_3O)_3PS\cdot 2\,HgCl_2$$

The Cu-ion catalysed hydrolysis of *p*-nitrophenyl phosphorothionates and phosphonothionates[80] and the Ag-ion catalysed formation of 4-t-butylmethylenecyclohexane from dimethyl 1-hydroxy-4-t-butylcyclohexylmethylphosphonothionate[81] probably take place for the same reason.

Another unusual reaction is the smooth cleavage of triaryl phosphorothionates by silver nitrate[46,82], which is best explained by an attack on the phosphorus atom by the nitrate ion.

(12) *(13)*

$$\rightarrow (C_6H_5O)_2POSAg + HOC_6H_4NO_2$$

On the other hand, the corresponding reactions of the trialkyl phosphorothionates, which also proceed *via* addition compounds *(14)*[46], are evidently true dealkylations.

$\rightarrow (C_2H_5O)_2POSAg + C_2H_5ONO_2.$

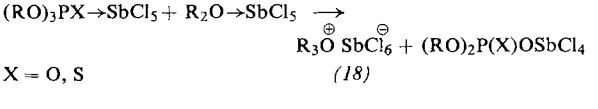
(14)

The reactions of methyl diphenyl and of phenyl dimethyl phosphorothionates with $AgNO_3$ should otherwise yield nitrophenol in addition to methyl nitrate, but they do not [83].

b) Reactions with "Hard Acids"

Triesters of phosphorothionic acid react with metal halides of the type used as Friedel-Crafts catalysts, such as $SbCl_5$ [84,85], $SnCl_4$, $SnBr_4$ [86], $TiCl_4$, $AlCl_3$, and $FeCl_3$ [47], the ease with which the reaction takes place increasing with the alkylating power of the ester. However, there is no sulfur-metal coordination in any of the crystalline products isolated. The partial positive charge induced on the phosphorus atom by adduct formation again facilitates the heterolysis of an *O*-alkyl bond, but this, together with the highly nucleophilic character of the sulfur toward tetrahedral carbon and the tendency of the A metals to coordinate with "harder" bases, leads to the formation of thiol compounds. For example, trimethyl phosphorothionate and $SbCl_5$ give a 1:1 adduct *(15)* at −80 °C, which changes quantitatively, even below room temperature, into a quasiphosphonium hexachloroantimonate *(16)* and an unstable dealkylation product *(17)* [84].

$2\ (CH_3O)_3PS{\rightarrow}SbCl_5 \rightarrow CH_3O\text{-}P^{\oplus}(OCH_3)\text{-}SCH_3\ SbCl_6^{\ominus}$



(15) (16)

+

$(CH_3O)_2P(S)OSbCl_4$

(17)

Trimethyl phosphate, on the other hand, gives a stable adduct $(CH_3O)_3PO{\rightarrow}SbCl_5$ [87]. The extremely powerful alkylating properties of this adduct, as well as those of *(15)*, can be used *e.g.* in a simple preparation of trialkyloxonium salts *(18)* [88].

$(RO)_3PX{\rightarrow}SbCl_5 + R_2O{\rightarrow}SbCl_5 \rightarrow R_3O^{\oplus}\ SbCl_6^{\ominus} + (RO)_2P(X)OSbCl_4$

X = O, S (18)

Since quasiphosphonium ions of the type *(16)* can be easily dealkylated, even by weak nucleophiles [89], to yield trialkyl phosphorothiolates, and since A metals generally favor coordination with oxygen rather than with chloride ions, reactions of phosphorothionates with most Lewis acids result in formation of phosphorothiolate adducts [47,85,86].

$[(RO)_3PS]_2SnCl_4 \rightarrow (RO)_3\overset{\oplus}{P}SR\ Cl_4Sn{\leftarrow}OP(OR)_2S^{\ominus} \rightarrow [(RO)_2(RS)PO]_2SnCl_4$

(For further details of this reaction, see Section V 2b.) A few phosphorothiolate adducts were prepared in this way some decades ago, but were wrongly regarded as phosphorothionate adducts [69] (starting from the isomeric thiolates identical adducts are obtained [47]).

The relationship between this type of isomerization and the alkylating power is clearly shown in the series

$$(CH_3O)_3PS > (CH_3O)_2CH_3PS > (CH_3O)(CH_3)_2PS.$$

Phosphonothionates are also isomerized (though much more slowly than phosphorothionate) into phosphonothiolate adducts by tin(IV) halides, but with phosphinothionates the reaction stops with the formation of the thiono ester adduct. This is the first case in which the thiono and thiolo esters give isomeric adducts instead of identical adducts [68]. In both isomeric series, strong bathochromic shifts of the P=O and P=S frequence indicate the bonding site [58] (cf. Table 3).

Table 3. Isomeric adducts of thiophosphinates.

Compound	M.p. (°C)	νP=O (cm^{-1})	νP=S (cm^{-1})
$(CH_3O)(CH_3)_2PS$	–	–	585
$[(CH_3O)(CH_3)_2PS]_2SnCl_4$	121–122	–	538

III. Reactions with Halogenating Agents

The most important electrophiles in this class are the elemental halogens and sulfuryl chloride. Two types of reactions can be distinguished here even more clearly than in the reactions with metal salts. Thus if the phosphorus atom carries alkoxy (or OH or SH) groups, the secondary attack by a nucleophile is directed toward the alkyl residue (or toward the proton); otherwise the nucleophile attacks the phosphorus atom, with replacement of sulfur by halogen (or, particularly with thionyl chloride, by oxygen).

Halogens oxidize thiophosphoryl compounds in the presence of water to form phosphoryl compounds and sulfate; the oxidizing agents in this reaction are hypohalite ions, which are characterized by their high nucleophilicity toward tetrahedral phosphorus. In spite of their preparative [90] and analytical importance [91], these and similar oxidations will not be discussed here.

1. Phosphine Sulfides and Diphosphine Disulfides

Triarylphosphine sulfides form crystalline adducts with ICl, IBr, and I_2 [19,37,92,93]. These adducts are more stable than those of the corresponding phosphine

oxides [19, 37]. IR spectra [19, 23] and X-ray structure investigations [19] indicate sulfur-halogen coordination and rule out the possibility of interaction between the halogen and the aromatic nuclei.

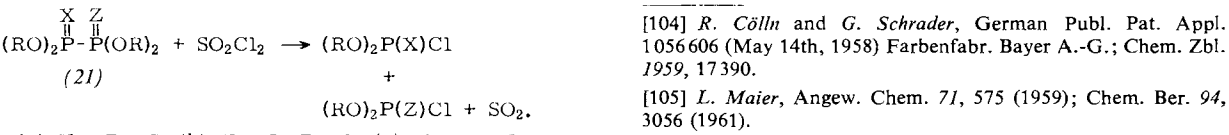
[*] This compound has the composition $2(C_6H_5)_3PS{\cdot}3\ I_2$.



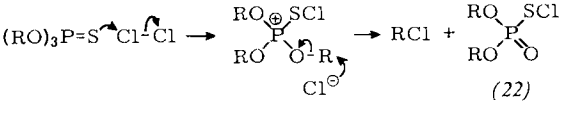
The reactions with Cl_2 and Br_2 do not stop with the formation of the adducts, but lead, by substitution at the phosphorus atom (which has acquired a partial positive charge), to halogenophosphoranes and sulfur halides. For example, diarylthiophosphinyl chlorides give diaryltrichlorophosphoranes [94]; the analogous chlorination of $SPCl_3$ to PCl_5 has been known for a long time [95].

The unusually easy cleavage of tetraalkyldiphosphine disulfides *(19)* by Cl_2 [96,97], Br_2 [96–98], or SO_2Cl_2 [97–99] to dialkylthiophosphinyl halides *(20)* can be explained in a similar manner [100]:

(19) *(20)*

In agreement with this view, dithio-*(21a)* [101] and monothiohypophosphates *(21b)* [102] are cleaved by SO_2Cl_2 in a strongly exothermic reaction even below 0 °C, whereas the sulfur-free compounds *(21c)* must be heated under reflux [103].

(a): X = Z = S; *(b)*: X = O, Z = S; *(c)*: X = Z = O



Since dialkylthiophosphinyl halides themselves react by the same principle with halogenating agents, the reaction of tetraalkyldiphosphine disulfides with an excess of Cl_2 or Br_2 yields dialkyltrihalogenophosphoranes [96], and the reaction with an excess of SO_2Cl_2 yields dialkylphosphinyl chlorides [98, 104]. When $SOCl_2$ is used instead of SO_2Cl_2, the intermediate thiophosphinyl chlorides, though detectable [105], can no longer be isolated [105–107].

Thiophosphonyl dihalides [107, 108] and phosphine sulfides [107–110] also form the corresponding phosphoryl compounds with $SOCl_2$. The determining factor in this reaction is the electron density, not at the phosphorus, but at the sulfur atom, as is shown by the marked decrease in reactivity in the order $(CH_3)_2P(S)Cl > (C_6H_5)CH_3P(S)Cl > C_6H_5P(S)Cl_2 > P(S)Cl_3$ [107]. A similar substituent effect is also observed in the reactions with SbF_3: phosphine sulfides and diphosphine disulfides give di- and trifluorophosphoranes respectively [111], trialkyl phosphorothionates do not react [111], and thiophosphonyl dichlorides [112] and thiophosphoramidic dichlorides [113] simply undergo halogen exchange.

2. Derivatives of Thiophosphoric, Thiophosphonic, and Thiophosphinic Acids

a) Esters, Ester Chlorides, and Ester Amides

Addition compounds of trialkyl phosphorothionates with I_2 have been detected in solution; they are more stable than the corresponding trialkyl phosphate adducts [27]. Trialkyl phosphorothionates react with Cl_2 and Br_2 even below 0 °C, with elimination of alkyl halide and formation of bis(alkoxy)phosphorylsulfenyl chlorides *(22)* (Michalski reaction) [114, 115].

Sulfuryl chloride is a better reagent than elemental halogen for the preparation of *(22)* [114–116]. Dialkyl ester amides, dialkyl aryl, and diaryl alkyl esters of thiophosphoric acid generally react in the same way [115]. However, conversion decreases rapidly in the order $(C_2H_5O)_3PS > (C_6H_5O)(C_2H_5O)_2PS > (4\text{-}O_2NC_6H_4O)(C_2H_5O)PS > (4\text{-}O_2NC_6H_4O)_2(C_2H_5O)PS$ (the ethyl bis-(4-nitrophenyl) ester does not react at all), again showing the effect of the substituents on the nucleophilic strength of the thiono sulfur [115]; the reverse order applies in the ease of dealkylation by nucleophilic attack at the α-carbon atom [2].

Since compounds *(22)*, like alkanesulfenyl chlorides, add to multiple bond systems [114–117], the Michalski reaction is of great preparative interest.

Dialkyl thiophosphoryl chlorides *(23)* also enter into this reaction [118].

$$(C_2H_5O)_2P(S)Cl + SO_2Cl_2 \rightarrow \underset{ClS\quad Cl}{\overset{C_2H_5O\quad O}{P}} + C_2H_5Cl + SO_2.$$

(23)

On the other hand, a different reaction course is reported [119] for esters of phosphonochloridothionic acids *(24)*, the nucleophilic attack in the second step taking place, not on the carbon, but on the phosphorus atom.

$$\underset{C_2H_5O\quad Cl}{\overset{C_2H_5\quad S}{P}} + SO_2Cl_2 \rightarrow \underset{C_2H_5O\quad O}{\overset{C_2H_5\quad SCl}{P}} + SOCl_2.$$

(24)

This type of reaction is necessarily also encountered with triphenyl phosphorothionate, which gives tris-(phenoxy)dichlorophosphorane (or ionic products having the same overall composition) with Cl_2 [115] or SO_2Cl_2 [115, 120].

The formation of methylphosphonochloridates from dialkyl phosphonothionates and thionyl chloride [121] may also proceed *via* a sulfenyl chloride, which splits off sulfur when heated.

The reaction of trialkyl phosphorothionates with alkanesulfenyl chlorides *(25)* [122] also follows the scheme of the Michalski reaction.

$$(CH_3O)_3PS + CH_3SCl \rightarrow (CH_3O)_3\overset{\oplus}{P}SSCH_3\ Cl^{\ominus} \rightarrow$$

(25)

$$\underset{CH_3O\quad SSCH_3}{\overset{CH_3O\quad O}{P}} + CH_3Cl$$

b) Thioacids and Thioacid Anhydrides

Dialkyl phosphorothioic acids and their salts, like the triesters, react with Cl_2 [123] or SO_2Cl_2 [123, 124] to form sulfenyl chlorides *(22)*. However, the overall

$$(RO)_2P(S)OH + Cl_2 \rightarrow (RO)_2P(O)SCl + HCl$$

(22)

equation conceals the fact that *(22)*, as an extremely strong electrophile, immediately reacts with the dialkyl phosphorothioate, which is present in excess, to form the disulfide *(26)*, which is then chlorinated with cleavage to form *(22)* [123].

$$(RO)_2P(S)OH + (22) \xrightarrow[-HCl]{} (RO)_2P(O)SSP(O)(OR)_2$$

(26) $\xrightarrow{+Cl_2}$ 2 *(22)*

The alkylalkoxyphosphorylsulfenyl chlorides *(27a)*, which can be prepared in a similar manner, decompose readily with deposition of sulfur [125, 126], while the dialkyl- [125] and diarylphosphorylsulfenyl chlorides [127] *(27b)* decompose during attempts to prepare them.

$$\underset{A\quad SCl}{\overset{R\quad O}{P}} \rightarrow \underset{A\quad Cl}{\overset{R\quad O}{P}} + S$$

(27) (a): A = RO; *(b)*: A = R

The chlorination of dialkyl phosphorodithioates *(28)*, which is used for the preparation of dialkyl phosphorochloridothioates *(29)*, also proceeds through the stages sulfenyl chloride, disulfide, and sulfenyl chloride [71, 128, 129]; the bis(alkoxy)thiophosphoryl-

$$(RO)_2PS_2H \xrightarrow[-HCl]{+Cl_2} \underset{RO\quad SCl}{\overset{RO\quad S}{P}} \rightarrow \underset{RO\quad Cl}{\overset{RO\quad S}{P}} + S$$

(28) *(29)*

sulfenyl chlorides *(28)* have themselves only recently become available by another method [129, 130].

The chlorination of diaryldithiophosphinic acids yields diaryltrichlorophosphoranes [94, 131], and that of aryldithiophosphonic anhydrides *(30)* leads *via* isolable thiophosphonyl dichlorides *(31)* to tetrachlorophosphoranes *(32)* [132].

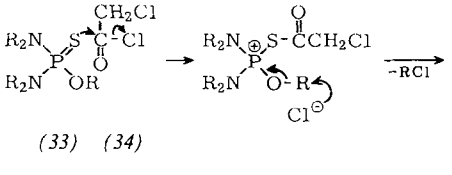
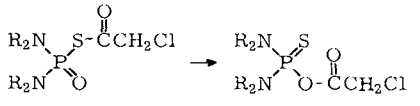
(30) (31) (32)



IV. Reactions with Carbonyl and Phosphoryl Compounds

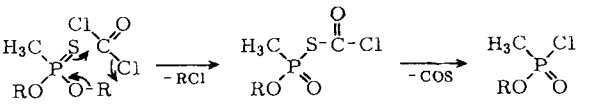
As has been mentioned, the thiophosphoryl sulfur should not be very reactive toward the "hard" carbonyl carbon and phosphoryl phosphorus. Accordingly, only a few reactions with particularly reactive carbonyl groups have been reported, and most of these are not very characteristic.



The replacement of carbonyl oxygen by sulfur[133], which has been used in preparative chemistry, and the more recently discovered, analogous replacement of phosphoryl oxygen by sulfur[134,135] with the aid of phosphorus(v) sulfide are of considerable importance. This reaction is only mentioned in passing, since it is not confined to thiophosphoryl sulfur, but even takes place with phosphorus sulfides, such as P_4S_3[136], which only contain P–S–P bonded sulfur.

1. Reactions with Carbonyl Compounds

The relatively smooth reaction of trialkyl phosphates with acyl chlorides to form dialkyl acyl phosphates[137] has evidently been achieved in the thiophosphate series only for a few diester monoamides and monoester diamides *(33)* with chloroacetyl chloride *(34)*[138].



(33) (34)

(35) (36)

S-Acyl thiophosphates *(35)* rearrange to the more stable *O*-acyl derivatives *(37)*[76].

Dialkyl methylphosphonothioates *(37)*, like their oxygen analogues, react with phosgene[139] or oxalyl chloride[121] to form esters of phosphonochloridic acids *(38)*.

(37) (38)

Contrary to earlier reports, triphenylphosphine sulfide and phenyl isocyanate do not form phenyl isothiocyanate[140] but diphenylcarbodiimide[110].

The phosphine sulfide, like esters of thiophosphonic acids[141], is effective even in catalytic quantities. Since neither carbon oxysulfide nor triphenylphosphine oxide could be detected in the reaction products[110] the reaction appears to proceed by a course different from that followed by the formation of carbodiimide in the presence of phosphine oxide[142].

Triphenylphosphine sulfide is desulfurized by diphenylketene to form the phosphine oxide[140], and trimethyl thionophosphate is desulfurized to trimethyl phosphate by chloral[143]. Both reactions are formally similar to the Wittig olefination.

$$(C_6H_5)_3PS + (C_6H_5)_2C{=}C{=}O \rightarrow (C_6H_5)_3PO + {}^1/_n[(C_6H_5)_2C{=}C{=}S]_n$$

$$(CH_3O)_3PS + Cl_3CCHO \rightarrow (CH_3O)_3PO + {}^1/_n[Cl_3CCHS]_n$$

2. Reactions with Phosphoryl Compounds

Thiophosphoryl compounds exchange their sulfur for phosphoryl oxygen at 150–200 °C, the exchange taking place more readily as the sum of the electronegativities of the substituents on the thiophosphoryl group increases and as that of the substituents on the phosphoryl group decreases. The reaction rate is directly proportional to this electronegativity difference[144], and so corresponds to the substituent effects in the formation of pyrophosphate from triesters and diester chlorides of phosphoric acid[33].

Thiophosphoryl chloride is therefore the most suitable reagent for the conversion of phosphonyl[135,144] and phosphinyl chlorides[144,145] into their thio analogues. Under similar conditions, phosphine oxides are converted into phosphine sulfides by salts or *O*-alkyl esters of dimethylthiophosphinic acid[146]. *O*-Methyl dimethylthiophosphinate reacts with its *S*-methyl isomer to give esters of the dithiophosphinic acid, among other products[146], and small quantities of *O,O*-diphenyl *S*-methyl dithiophosphate are formed during the thermal isomerization of methyl diphenyl thiophosphate[147].

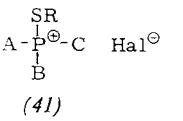
The observed substituent effects require a strong positive charge at the phosphorus atom of the thiophosphoryl compound and a high electron density at the phosphoryl oxygen of the phosphoryl compound. It may therefore be concluded that the exchange reaction is initiated by a nucleophilic attack on the phosphorus atom of the thiophosphoryl compound by the phosphoryl oxygen (similar to the pyrophosphate synthesis mentioned above). However, the sulfurization of phosphine oxides by the thiophosphinate ion can hardly be understood in this way. Similarly, the formation of diphenyldithiophosphinate *(40)* from diphenylphosphinothioic amide *(39)* and chloride [148] can be explained only by the nucleophilic reactivity of the sulfur.



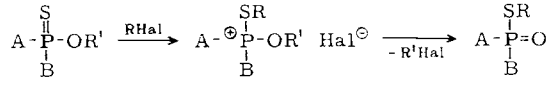
(39) *(40)*

V. Reactions with Alkylating Agents

The primary products of the action of alkylating agents on thiophosphoryl compounds are alkylthiophosphonium salts. However, these can be isolated unchanged only if they have no alkoxy groups attached to the phosphorus atom. Special conditions are required for the preparation of alkoxyalkylthiophosphonium salts [84,89]. Alkylations of compounds such as $(RO)_2P(S)OH$ [149], $(RO)_2P(S)NHSO_2Ar$ [150], or $(RO)_2P(S)NHCOAr$ [151], which undergo tautomeric changes, will not be dealt with here.

1. Thiophosphoric, Thiophosphonic, and Thiophosphinic Amides; Phosphine Sulfides

Triamides of thiophosphoric acid are alkylated to onium salts *(41a)* by alkyl halides, in some cases even at room temperature [152,153]; in contrast to *N*-alkylamides, *N*-arylamides do not react even under more rigorous conditions [152]. The compounds *(41b)–(41d)* are formed in a similar manner from thiophosphonic [153] and thiophosphinic amides [36,148] and from trialkylphosphine sulfides [35,154,155]. When the products are heated under vacuum, alkyl halides are sometimes split off again [153]. The salts *(41d)* obtained from aromatic phosphine sulfides are difficult to prepare with alkyl halides [26,156]; they are best isolated as the fluoroborates or the like [36].



(41)

(a): A, B, C = R^1R^2N
(b): A, B = R^1R^2N; C = R^3
(c): A = R^1R^2N; B, C = R^3
(d): A, B, C = R^1

2. *O*-Alkyl Thiophosphates, Thiophosphonates, and Thiophosphinates

a) Reactions with Alkyl Halides

Since alkoxyalkylthiophosphonium salts *(42)* are cleaved at the *O*-alkyl bond by nucleophiles, the action of alkyl halides on alkyl esters of the thionophosphoric, thionophosphonic, and thionophosphinic acid series leads to thiol esters *(43)* (Pistschimuka reaction).

(42) *(43)*

Suitable starting materials are trialkyl thionophosphates [69,153,157–159], dialkyl aryl thionophosphates [158], trialkyl dithiophosphates [69,153,157], trialkyl trithiophosphates [69], dialkyl thiophosphoric amides and alkyl thiophosphoric diamides [153,157], and esters of thiophosphonic [153,157,158,160] and thiophosphinic acids [158,161].

The Pistschimuka reaction is analogous to the Michalski reaction (Section III, 2), but requires much more rigorous conditions (heating for many hours at 100–150 °C); its preparative value is frequently limited by poor yields and by side reactions such as the formation of trialkylsulfonium salts. However, these disadvantages can be overcome to a large extent by the use of strongly polar solvents, which considerably increase the reaction rate [153,157]. The substituents A and B favor the reaction in the order Cl < RS < RO < R < R_2N [153] by increasing the nucleophilic strength of the sulfur atom.

b) Reactions without the Addition of Alkylating Agents

The role of the alkyl halide in the Pistschimuka reaction can be taken over by the thiophosphoryl com-

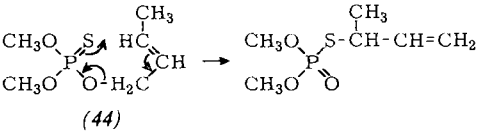
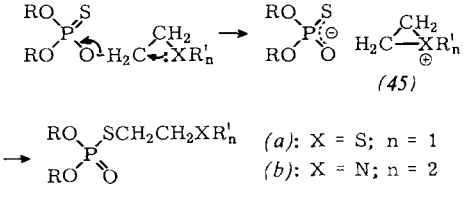
pound itself, since the esters mentioned all have alkylating properties. Trialkyl[70,153,162–164], dialkyl aryl[164,165–168], and alkyl diaryl thionophosphates[164,165,169,170], dialkyl thionophosphoryl halides[33,170], alkyl thionophosphoryl dihalides[170,171], *O,O,S*-trialkyl dithiophosphates[172], and alkyl esters of phosphonothionic[73] and phosphinothionic acids[173] can therefore be thermally isomerized into the thiol esters. However, the conditions are often even more severe than those of the Pistschimuka reaction, so that the formation of the thiol esters is frequently followed by secondary reactions (cf. the reviews[2,174]).



Solvents having a high dielectric constant again favor this reaction[153,163]. On the other hand, the substituent effect is opposite to that observed in the Pistschimuka reaction; the isomerization depends on the alkylating power of the ester, which is increased by electron-attracting substituents at the phosphorus atom[2,174]).

The thiophosphoryl sulfur is alkylated, not only by the thiono ester introduced, but also by the resulting thiol ester, provided that it still contains further P–O-alkyl groups; in this case the isomerization is autocatalytic[163]. Mixtures of thiono esters give mixed thiol esters[163].

$$(RO)_3PS + (R'O)_3PS \rightarrow (RO)_2P(O)(SR) + (R'O)_2P(O)(SR') + (RO)_2P(O)(SR') + (R'O)_2P(O)(SR).$$



In contrast to the thermal isomerization, the isomerization induced by Lewis acids (cf. Section II, 4b) often proceeds almost quantitatively at or below room temperature. Since the thiol ester adducts formed can be broken down into their components, thiono esters that are unsuitable for thermal isomerization because of the instability of the thiol isomers can be converted in high yields into the thiol esters with the aid of Lewis acids[47,58,86]. The substituent effects are of the same nature as in the thermal isomerization. The rate of isomerization also depends on the acceptor strength of the Lewis acid, and decreases rapidly *e.g.* in the order $SnCl_4 > SnBr_4 > SnI_4$[58,86].

The thermal isomerization takes place more readily in allyl esters *(44)* than in alkyl esters; the reaction undoubtedly proceeds by a different mechanism in this case, since the products obtained are those of a Claisen rearrangement[175].

(44)

Finally, a further considerable increase in the rate of isomerization is observed in phosphorothionates containing a β-alkylthio[176–178] or dialkylamino group[179–182] in an ester residue. The same is true of β-alkylthioalkyl phosphoramidothionates[183] and phosphonothionates[178,184]. In these cases the reaction is no longer induced by the nucleophilicity of the thiophosphoryl sulfur; instead, the neighboring group effect of the nucleophilic center in the β position leads to the ready release of a cyclic sulfonium *(45a)* or ammonium cation *(45b)*, which *S*-alkylates the remaining thiophosphate ion in the usual manner.

(45)

(a): X = S; n = 1
(b): X = N; n = 2

The intermediate formation of the thiiranium[177] and aziridinium ions[179–181] has been demonstrated in various ways.

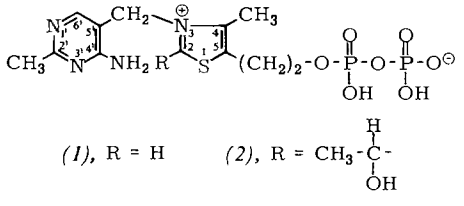
Structure and Mechanism of Action of the Active Center of Yeast Pyruvate Decarboxylase



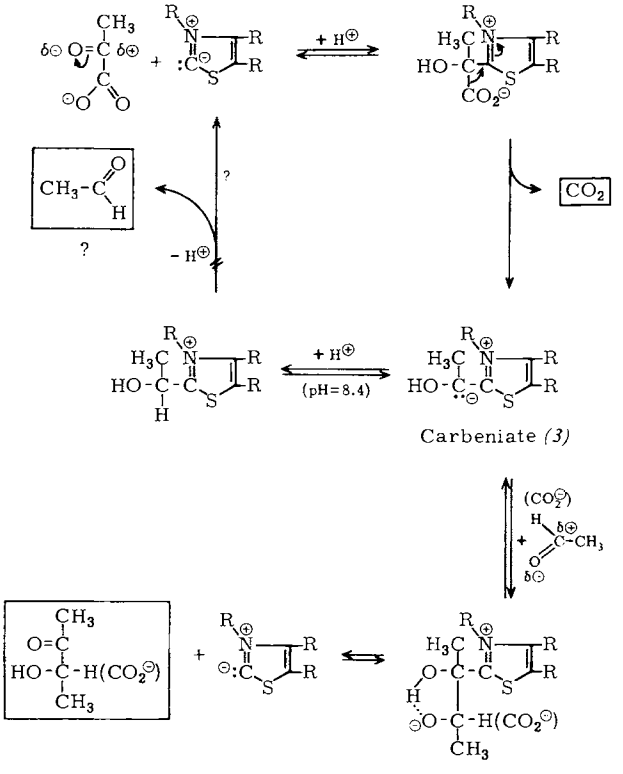
BY A. SCHELLENBERGER [*]

Dedicated to the memory of Prof. Dr. W. Langenbeck

Kinetic studies have shown that the two low molecular-weight components of yeast pyruvate decarboxylase (thiamine pyrophosphate and $Mg^{2\oplus}$ ions) first add rapidly and reversibly to the apoenzyme in binary equilibria. The resulting adduct then "cyclizes" in a rate-determining, practically irreversible reaction to form the thermodynamically stable holoenzyme. These results were supplemented and extended by the testing of numerous analogues of thiamine pyrophosphate in enzyme experiments and then used for the interpretation of the enzyme reaction.

Introduction

In 1961, *Holzer et al.* [1,2] showed that the enzymatic degradation of pyruvate by yeast pyruvate decarboxylase proceeds *via* a condensation product of thiamine pyrophosphate (TPP) *(1)*, which acts as the coenzyme, acetaldehyde. This relatively labile intermediate was called "active acetaldehyde" *(2)*.



(1), R = H *(2)*, R = $CH_3-\underset{\underset{OH}{|}}{\overset{\overset{H}{|}}{C}}-$

It therefore seemed reasonable to apply the essential features of the catalytic decarboxylation of α-keto acids (Scheme 1), which was studied by *Ugai* [3], *Mizuhara* [4], *Breslow* [5], and *Sykes* [6] with thiazolium models, to the enzyme mechanism.

Though this seemed to solve the fundamental problem of the action of pyruvate decarboxylase (PDC), a number of questions still remained unanswered:

1. Why is the rate of reaction of "active acetaldehyde" four orders of magnitude lower than that of pyruvate under the action of the enzyme [2]?

Scheme 1. Decarboxylation of α-keto acids for thiazolium models at pH = 8.4.

2. Why is no acetaldehyde formed by the model mechanism shown in Scheme 1 [4]?

3. Has the pyrimidine portion of the thiamine pyrophosphate molecule any function, and if so, what is it?

4. Since the decarboxylation of the α-keto acids is thermodynamically practically irreversible, what is the mechanism of the inhibition of PDC by the reaction product?

A careful study of these questions has become possible only by the use of new methods.

The first essential was to find mathematical statements concerning the bonding mechanism of the holoenzyme complex on the basis of the kinetic parameters of the recombination (*i.e.* the resynthesis of the holoenzyme

from its components, apo-PDC, metal ion, and thiamine pyrophosphate (TPP), in accordance with equation (1)).

$$\text{Apo-PDC} + \text{Mg}^{2\oplus} + \text{TPP} \underset{k_{back}}{\overset{k}{\rightleftharpoons}} \text{Holo-PDC} \qquad (1)$$

It was also desirable to study the function of the coenzyme with models whose structures substantially agreed with that of TPP. The experiments showed that the course of the enzyme reaction is much more complicated than was formerly thought.

I. Kinetics of the Recombination

In 1944, in a study of the cleavage and resynthesis of PDC, *Steyn-Parvé* and *Westenbrink* [7] pointed out a number of peculiarities, which we have been able to confirm and which are of general importance to the understanding of coenzyme-apoenzyme bonding.

Steyn-Parvé and *Westenbrink* demonstrated that resynthesized PDC is identical with the native enzyme, and found that the enzyme is cleaved into its components in accordance with equation (1) within a few minutes at pH = 8 without appreciable damage to the protein component. The resynthesis has a sharp optimum (stability optimum) at pH = 6.8, whereas the optimum of the pH-activity curve occurs at pH = 5.6.

An important observation in this work was the fact that when the quantity of TPP originally present in the yeast is brought together, under optimum conditions, with yeast that has been washed with alkali (*i.e.* freed from coenzyme), only a very small proportion recombines with the apoenzyme "... although carboxylase (PDC) is an undissociated enzyme...", and that the resynthesis does not proceed to completion even when a large excess of TPP is used. The authors concluded: "...so different end states are reached by dissociation and resynthesis..." (irreversible damage to the apoenzyme could be ruled out), and finally observed: "But why does potentially active apo-PDC not combine with sufficiently available TPP? This is the great riddle of the reconstitution that has not yet been solved".

This riddle, which we have called the "quasi-irreversibility" [8] of the bonding between the coenzyme and the apoenzyme, can be demonstrated very simply by the following experiment (cf. also [9]):

According to *Ullrich, Wittorf,* and *Gubler* [10], the molecular weight of highly purified PDC preparations is about 175000. Three to four TPP molecules and the same number of metal ions are incorporated into this protein molecule. A mixture of stoichiometric quantities of apo-PDC, TPP, and $Mg^{2\oplus}$ does not recombine within 3–4 hours even under optimum pH conditions. If, on the other hand, TPP and $Mg^{2\oplus}$ in considerable excess are allowed to act on purified apo-PDC, complete recombination takes place within 3–4 minutes, and, under favorable conditions, an enzyme having nearly the original activity can be obtained.

One should expect, therefore, that after separation of the excess of low molecular weight components (TPP and $Mg^{2\oplus}$), the holoenzyme would dissociate into its components again. The pure holoenzyme can be easily separated from the low molecular weight components (TPP and $Mg^{2\oplus}$) by filtration of the recombination reaction mixture through a molecular sieve (Sephadex G 25). It shows no decrease in activity due to dissociation [8] (Sephadex test).

1. Recombination and Stationary Phases

The quantity of holoenzyme formed by recombination of the components can be quickly and quantitatively determined from its catalytic activity by optical methods [11]. The acetaldehyde formed in the reaction is reduced to ethanol by reduced nicotinamide-adenine dinucleotide (DPNH) with alcohol dehydrogenase (ADH) as an auxiliary enzyme, and the consumption of DPNH is measured at 366 nm.

$$\text{Pyruvate} \xrightarrow{\text{PDC}} \text{Acetaldehyde} \underset{\text{DPNH}}{\overset{\text{ADH}}{\rightleftharpoons}} \text{Ethanol}$$

The use of a large excess of auxiliary enzyme and reducing agent (DPNH) shifts the rate-determining step into the PDC part of the enzyme chain and prevents feedback effects of the reaction product on the PDC.

The curves of extinction value against time (Fig. 1) show two characteristic phases [8]. In the first phase, the catalytic activity continuously increases (curved part of the graphs, recombination phase). In the second phase (linear part, recombination phase), the constant final rate has been reached and recombination to form the holoenzyme is practically ended.

The time occupied by the recombination phase depends on the nature of the metal ion built into the enzyme complex. The increase in the recombination rate in the order Mg < Co < Mn < Ca corresponds to the order of increasing complexing rates reported by *Eigen* and *Hammes* [12].

The stationary activity of the enzyme, on the other hand, is independent of the metal ion, as is shown by the fact that the linear parts of the curves $(dE/dt)_{max}$ are parallel. Thus the metal ion bound in the holoenzyme has no influence on the rate-determining step of the enzyme reaction.

The metal ion determines the stability of the holoenzyme complex. Though the Ca–PDC and Mg–PDC complexes have the same catalytic activity, the former dissociates completely into its components on filtration

through Sephadex G25 [8], whereas the magnesium complex remains intact (Table 1). The rate of formation and the stability of the holoenzyme are thus independent of each other. They obey the laws of coordination chemistry, but do not affect the catalytic activity of the PDC.

Table 1. Influence of the metal ion and of structural changes in the coenzyme on the stability of the PDC complex. The recombination mixtures were separated on a Sephadex G 25 column after an incubation time of 5 minutes (for experimental details see [13]).

2. Recombination Kinetics and the Rate-determining Step

We used $Mg^{2\oplus}$ ions in the following investigations, since these ions give an easily measurable recombination rate.

The amount of free apoenzyme (apo-PDC_f) at time t can be calculated from the slope of the extinction-time curve (Fig. 1). It can be seen in the case of the $Mg^{2\oplus}$ curve that for $dE/dt = 0$, the concentration of apo-PDC_f is equal to the initial concentration, whereas for $(dE/dt)_{max}$ (stationary rate) there is practically no free apoenzyme. The difference between the slope at time t and the maximum slope

$$(dE/dt)_{max} - (dE/dt)_t = C[\text{Apo-PDC}_f]_t$$

is proportional to the concentration of free apoenzyme at time t.

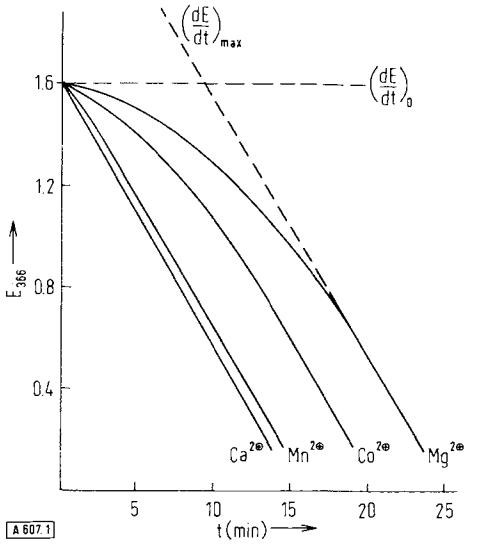

Fig. 1. Influence of metal ions on the recombination rate and the stationary rate for PDC at pH = 6.6 (for details see [8]).

When the concentrations of TPP, $Mg^{2\oplus}$, and pyruvate are constant, as is generally the case in view of the considerable excess of all three components over the apoenzyme, the recombination of the enzyme is a pseudo-first order reaction with respect to the apo-PDC_f [7, 16]. The rate equation for the recombination is then

$$v = -\frac{d[\text{Apo-PDC}_f]}{dt} = -\frac{d((dE/dt)_{max} - (dE/dt)_t)}{dt} = \bar{k}\,[\text{Apo-PDC}_f] \qquad (2)$$

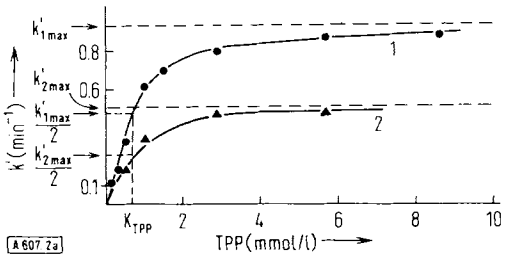
where $\bar{k}$ is a function of the TPP, $Mg^{2\oplus}$, and pyruvate concentrations at constant pH and constant temperature:

$$\bar{k} = f([\text{TPP}],\ [Mg^{2+}],\ [\text{pyruvate}])$$

If the TPP concentration is varied while the $Mg^{2\oplus}$ and pyruvate concentrations are kept constant, the corresponding $\log((dE/dt)_{max} - (dE/dt))$/time curves give $\bar{k}$ as a function (k') of the TPP concentration

$$\bar{k}_{[Mg^{2\oplus}],\ [\text{pyruvate}]} = f([\text{TPP}]) = k'$$

A plot of k' against the TPP concentration gives curves such as are shown in Fig. 2 for two $Mg^{2\oplus}$ concentrations.



The rate of recombination increases with increasing TPP concentration up to a value at which all the TPP-binding sites on the apoenzyme are saturated. Provided that the rate constant for the formation of the apo-PDC–TPP binary complex is much greater than k', the TPP concentration at which the rate reaches half its maximum value is, according to the Michaelis-Menten relationship, equal to K_{TPP}, *i.e.* the decomposition constant of the apo-PDC–TPP binary complex. This value of K_{TPP} (0.65×10^{-3}) is independent of $Mg^{2\oplus}$ concentration (Fig. 2a).

[16] *A. Schellenberger* and *G. Hübner*, Hoppe-Seylers Z. physiol. Chem. *348*, 491 (1967).

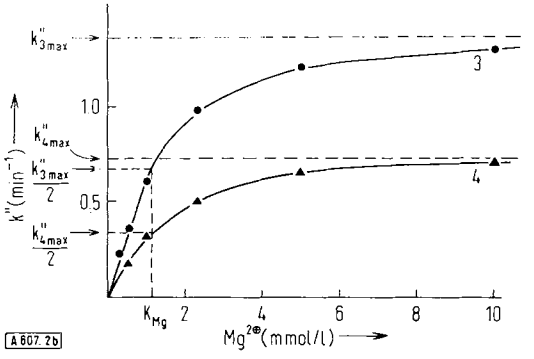

Fig. 2. Dependence of the recombination rate constant on the concentrations of TPP (k', Fig. 2a) and of Mg (k'', Fig. 2b) at pH 6.15. Concentrations: $Mg^{2\oplus}$ = 1 mM (curve 1), 0.5 mM (curve 2); TPP = 1 mM (curve 3); 0.5 mM (curve 4); pyruvate 34.3 mM.

In the same way, when the $Mg^{2\oplus}$ concentration is varied at constant TPP and pyruvate concentrations

$$\bar{k}_{[TPP],\ [pyruvate]} = f([Mg^{2\oplus}]) = k''$$

the dissocation constant of the apo-PDC–$Mg^{2\oplus}$ binary complex (K_{Mg} = 1.13×10^{-3}) is found as a quantity that is independent of the TPP concentration (Fig. 2b).

Thus the two primary steps in the recombination, *i.e.* the addition of TPP and $Mg^{2\oplus}$ to the active center of the apoenzyme, do not affect each other.

The dependence of the recombination rate constant $\bar{k}$ on the pyruvate concentration

$$\bar{k}_{[TPP],\ [Mg^{2\oplus}]} = f([pyruvate]) = k'''$$

is shown in Figure 3.

A recombination was started in the absence of substrate and the substrate was added after the times indicated in Fig. 3. From the parallel curves obtained after the introduction of pyruvate, extrapolation to the time at which the pyruvate

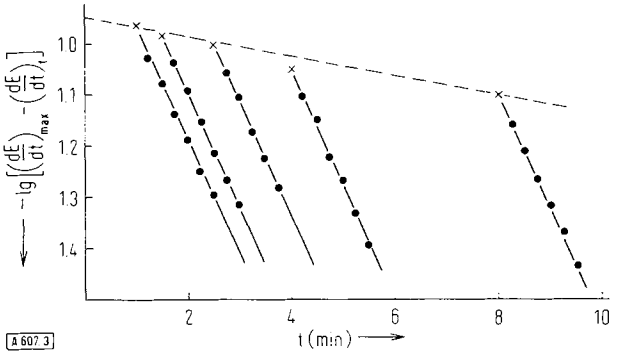

Fig. 3. $\mathrm{Log}((dE/dt)_{max}-(dE/dt)_t))$/time curves for the recombination of PDC after delayed addition of pyruvate. Temp. 25 °C, pH = 6.15 [16].

was added gave the values of $\log((dE/dt)_{max}-(dE/dt)_t)$ indicated by x. The resulting straight line corresponds to the rate of recombination of the enzyme in the absence of substrate. The recombination rate constant when pyruvate concentration is 0 can be calculated from the slope of this line, the value obtained being 4.36×10^{-2} min^{-1}.

The rate constant k''' = 5.25×10^{-1} min^{-1} obtained from the continuous lines (pyruvate concentration = 3.43×10^{-2} M) is one order of magnitude greater.

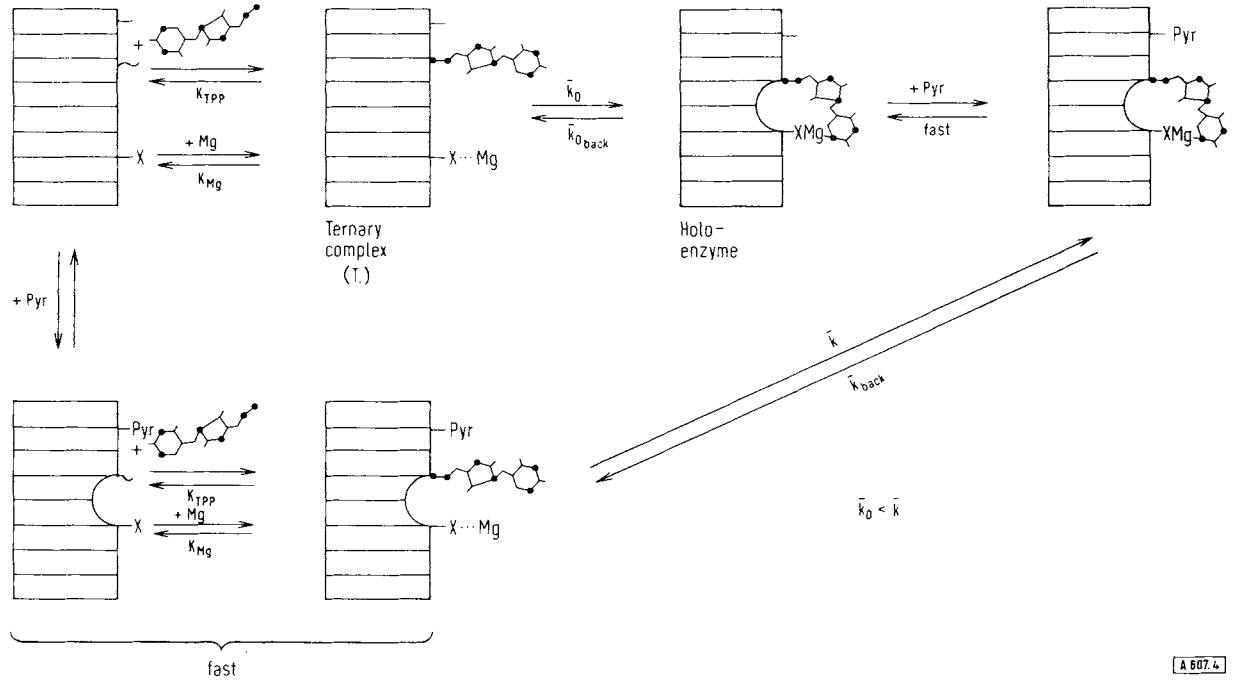

Fig. 4. Recombination scheme for PDC (active center) in the presence and absence of substrate. X: bonding site of the metal ion; ~: bonding center (basic) for the attachment of the pyrophosphate residue of TPP; —: position of substrate bonding (SH) $\bar{k}_0/\bar{k}_{0\ back}$: recombination in the absence of pyruvate (Pyr).

Variation of the pyruvate concentration at constant TPP and $Mg^{2\oplus}$ concentrations and comparison of the resulting curves with the pyruvate-dependence of the enzyme activity (stationary rate) showed the following[16]:

1. There is no preceding substrate-charging equilibrium controlling both the recombination and the stationary process.
2. The two primary equilibria between TPP and apo-PDC and between $Mg^{2\oplus}$ and apo-PDC are independent of the substrate concentration.

The mutually independent and relatively fast additions of TPP and of $Mg^{2\oplus}$ to the apoenzyme are followed by the formation of the thermodynamically stable ("quasi-irreversibility") holoenzyme complex, which is the rate-determining reaction ($\bar{k}$).

It could be shown by the Sephadex method described above, not only that $Mg^{2\oplus}$ ions are required for the stable bonding of apo-PDC to TPP (Table 1), but also that firm combination of $Mg^{2\oplus}$ ions with the apoenzyme takes place only in the presence of TPP[16]. Since no stable coordinate bonds could be detected between TPP and $Mg^{2\oplus}$, the thermodynamically stable holoenzyme complex[*] can only be formed by the simultaneous participation of all three components.

The "quasi-irreversibility" of the holoenzyme formation can thus be explained as a kinetically controlled equilibrium between the "cyclizable" ternary complex and the cyclized ("engaged") holoenzyme complex (Fig. 4). The concentration of the ternary complex is controlled *via* the two primary equilibria (K_{TPP} and K_{Mg}).

3. Formulae for the Recombination Kinetics[16]

The recombination rate, *i.e.* the rate of disappearance of apo-PDC$_f$ $\begin{pmatrix} A \\ \vdots \\ A' \end{pmatrix}$, is proportional to the concentration of "cyclizable" ternary product $\overset{A-TPP}{\underset{A'-Mg}{\vdots}}$ (T.):

$$v = -\frac{d\left[\begin{smallmatrix} A \\ \vdots \\ A' \end{smallmatrix}\right]}{dt} = \bar{k}\left[\begin{smallmatrix} A\text{-}TPP \\ \vdots \\ A'\text{-}Mg \end{smallmatrix}\right] \equiv \bar{k}\,[T.];\ \begin{smallmatrix} A \\ \vdots \\ A' \end{smallmatrix} \equiv \text{Apo-PDC}_f \quad (3)$$

The condition deduced from Fig. 2 that K_{Mg} and K_{TPP} do not affect each other can be introduced into the calculation *via* the following equilibria

$$\begin{smallmatrix} A \\ \vdots \\ A' \end{smallmatrix} + TPP \overset{K_{TPP}}{\rightleftharpoons} \begin{smallmatrix} A\text{-}TPP \\ \vdots \\ A' \end{smallmatrix}$$

$$\begin{smallmatrix} A \\ \vdots \\ A'\text{-}Mg \end{smallmatrix} + TPP \overset{K_{TPP}}{\rightleftharpoons} \begin{smallmatrix} A\text{-}TPP \\ \vdots \\ A'\text{-}Mg \end{smallmatrix}$$

$$\left(\begin{smallmatrix} A \\ \vdots \\ A' \end{smallmatrix} + \begin{smallmatrix} A \\ \vdots \\ A'\text{-}Mg \end{smallmatrix}\right) + TPP \overset{K_{TPP}}{\rightleftharpoons} \left(\begin{smallmatrix} A\text{-}TPP \\ \vdots \\ A' \end{smallmatrix} + \begin{smallmatrix} A\text{-}TPP \\ \vdots \\ A'\text{-}Mg \end{smallmatrix}\right)$$

Similar equilibria exist for K_{Mg}. Provided that [TPP] and [Mg] $\gg$ [apo-PDC$_f$], [T.] can be calculated from the resulting mass-action equations and correlated with the known quantity of apoenzyme used.

[*] We were able to confirm [16] the stability of the holoenzyme toward ethylenediaminetetracetic acid as described by *Juni* [9].

$$\left[\begin{smallmatrix} A \\ \vdots \\ A_0' \end{smallmatrix}\right] = \left[\begin{smallmatrix} A \\ \vdots \\ A' \end{smallmatrix}\right] + \left[\begin{smallmatrix} A\text{-}TPP \\ \vdots \\ A' \end{smallmatrix}\right] + \left[\begin{smallmatrix} A \\ \vdots \\ A'\text{-}Mg \end{smallmatrix}\right] + \left[\begin{smallmatrix} A\text{-}TPP \\ \vdots \\ A'\text{-}Mg \end{smallmatrix}\right]$$

One obtains

$$[T.] = \left[\begin{smallmatrix} A \\ \vdots \\ A_0 \end{smallmatrix}\right] \cdot \frac{[TPP]}{K_{TPP}+[TPP]} \cdot \frac{[Mg]}{K_{Mg}+[Mg]}$$

Insertion of [T.] in eq. 3 gives the desired rate equation for the recombination[*]

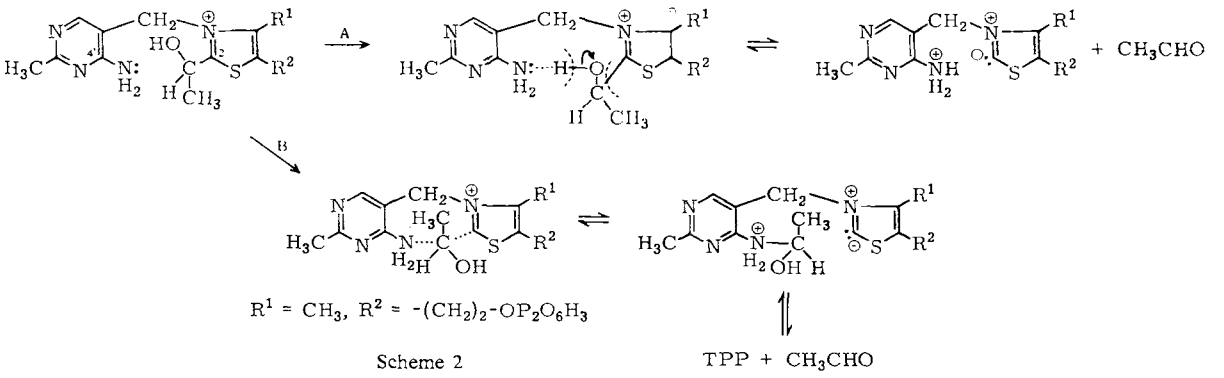
$$v = \bar{k}\left[\begin{smallmatrix} A \\ \vdots \\ A_0 \end{smallmatrix}\right] \frac{[TPP]}{K_{TPP}+[TPP]} \cdot \frac{[Mg]}{K_{Mg}+[Mg]} \quad (4)$$

Since the last two expressions in this equation must be $\leqslant 1$, the maximum recombination rate

$$v_{max} = \bar{k}\,[\text{Apo-PDC}_f] \cdot f;\ f = 1$$

is obtained when the TPP and $Mg^{2\oplus}$ concentrations are much greater than the order of magnitude of the two constants K_{TPP} and K_{Mg} ($\approx 10^{-3}$).

Though the $Mg^{2\oplus}$ concentration under physiological conditions is approximately of the same order of magnitude as K_{Mg}, the TPP concentration is much lower ($\approx 10^{-5}$ M), provided that there are no regions with greatly enriched TPP contents. Thus v_{max} decreases at least by a factor of $f \approx 10^{-3}$. It may therefore be assumed that TPP and $Mg^{2\oplus}$ are incorporated into the enzyme during the synthesis of the protein component on the ribosomes. Attempts to isolate the holoenzyme from the reaction mixture consisting of equivalent quantities of apo-PDC, metal ion, and TPP in accordance with eq. 1 must fail, despite the high thermodynamic stability of the holoenzyme, because of the order of magnitude of f ($\approx 10^{-8}$). Eq. 4 therefore provides the mathematical explanation of the "quasi-irreversibility riddle".



II. Mechanism of Action of the Enzyme

1. Model Experiments

In the investigation of enzyme mechanisms, model studies are still making important contributions to the determination of kinetic and thermodynamic parameters, owing to the fact that the nature of the protein component is unknown in most cases. In these studies it is possible to use very simple models, whose chemical characterization is easy, as was done by *Langenbeck* and his students. Models of this type led in 1933 to the fundamental discovery that the substrate and the catalyst can also react by way of covalent bonds[17].

[*] This equation is valid in principle for all reactions in which a macromolecule reacts with two different substrates at two positions that do not affect each other (inductively or sterically), the added residues then reacting with each other in the rate-determining reaction.

[17] *W. Langenbeck*, Ergebn. Enzymforsch. *2*, 314 (1933).

Scheme 2

Scheme 2. Extended model views of the decarboxylation of α-keto acids. Route A: general base catalysis, Route B: S_N2 reaction.

On the other hand, it is often difficult to decide whether observations made in model experiments are applicable to the enzyme process. For example, primary amines can bring about catalytic decarboxylation of α-keto acids, so that *Langenbeck* regarded these for a long time as decarboxylase models ("decarboxylators") [18]. However, it was finally found, partly by the work of *Langenbeck* and his students themselves, that neither the electronic situation of the amino group in thiamine [19] nor the chemical behavior of the α-imino acids detected as intermediates allowed any comparison to the enzyme process [20].

Ugai [3] recognized in 1951 that thiazolium salts can also decarboxylate α-keto acids. The mechanism proposed by *Breslow* [5] (Scheme 1) already contains essential elements of the enzyme process, but the results obtained in the model test and in the enzyme test differ, not only quantitatively, but also qualitatively (Table 2).

Table 2. Comparison of the catalytic activity of thiamine and thiamine analogues in the model test after *Mizuhara* (see Scheme 1) [4] with the coenzyme activity of the corresponding pyrophosphates [13,21].

Compound	Catalytic activity in model test. Acetoin formation in % from acetaldehyde	pyruvate	Coenzymatic activity of the pyrophosphate in %
Thiamine (T)	100	100	100
N-Methyl-T	165	96	0
N,*N*-Dimethyl-T	281	74	0
4′-Hydroxy-4′-deamino-T	65	15	0
6′-Methyl-T	–	18 [22]	0
2-Methyl-T	0	0	0

The only case in which the results are the same is that of 2-methylthiamine, which is blocked at the common reaction center.

A further approximation of the reactions of the model catalysts to the enzyme process was achieved by imitation of the pyrimidine part of the TPP molecule by the addition of organic bases such as alkoxide, imidazole, 2-aminopyridine, and 4-amino-2-methyl-5-hydroxymethylpyrimidine to the thiazolium catalysts [13]. These systems were the first enzyme models to produce acetaldehyde in detectable quantities. The experiments led us to assume that the elimination of aldehyde, which must be formulated for the model as a general base catalysis or as an S_N mechanism [13] (Scheme 2) takes place intramolecularly in the pyruvate decarboxylase under certain steric conditions, which will be discussed in Section II.4.

To support these views, the model catalysts had to be approximated still further to the TPP molecule. The compounds used differ from the natural prototype only in a few regions of the molecule. If the arrangement of the bonding groups of the analogue model corresponds to the specific situation in the apo-PDC component, the model can be tested enzymatically and under "physiological conditions" (pH, medium, concentration, temperature, *etc.*).

2. TPP Analogues as "Coenzyme Models"

The investigations on TPP analogues showed that some regions of the coenzyme can be changed without loss of the coenzyme activity, while other parts are highly constitution-specific. By systematic variation of the TPP molecule, it is possible in this way to study the bonding and function mechanism, provided that reliable and efficient methods are available for the characterization of the analogues.

Methods that have proved useful in the case of PDC are:

1. *The activity test*: The analogue is introduced during the recombination instead of TPP. If it is incorporated into the apoenzyme, one obtains information about the coenzyme activity of the analogue. Inactivity in this test can result from two causes: the analogue may not be functionally bound by the apoenzyme, or the course of the reaction on the analogue may be disturbed.

2. *The simultaneous test* [23]: An excess of TPP and analogue compete in a molar ratio of 1:1 for the bonding centers on the apoenzyme. Analogues that have no coenzyme activity, whose bonding to the apoenzyme in the presence of metal ions is irreversible and whose recombination proceeds as rapidly as the recombination with TPP, reduce the activity of the recombination mixture by half. If the analogue has no

"affinity" for the active center, the apoenzyme would be fully charged with TPP, and full enzyme activity would be achieved.

3. *The Sephadex sieve test* [13]: Like the simultaneous test, this method (Table 1) provides information about the stability of the bonds in the holoenzyme. In contrast to the simultaneous test, however, the dissociation of the thermodynamically more or less stable holoenzyme-analogue complex is recorded. The values obtained by this method are more definite (they belong in principle to only one equilibrium (k'/k'_{back} [*])) than those obtained in the simultaneous test by competition of several equilibria (K_{TPP}, $K_{TPP'}$, k/k_{back}, and k'/k'_{back}).

4. *Investigations with [1-^{14}C]- and [2-^{14}C]-labeled pyruvate* [14]: The ability of the analogue to decarboxylate and to eliminate aldehyde can be determined separately by comparative short-term experiments with differently labeled substrate, by a method based on that described by *Holzer* [1] (*e.g.* Fig. 5).

The results obtained in the activity test and in the simultaneous test on the TPP analogues are shown in Table 3.

Table 3. Coenzyme activity and inhibitor action (simultaneous test) on TPP analogues (for experimental details see [23]).

Coenzyme or analogue	Coenzyme activity (steady state value) (%)	Reduction of enzyme activity in simultaneous test (%)	Ref.
Thiamine	100	—	
4'-Hydroxy-4'-deamino-T [a]	0	52 ± 7	[13]

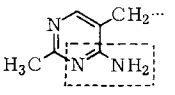
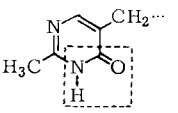
[a] T = thiamine.



[b] See footnote [c] under Table 1.

3. Blockage of the Active Centers



In the most favorable case, TPP analogues in which only the groups having catalytic function are blocked should still exhibit full binding capacity for apo-PDC. They should have no coenzyme activity, should give 50 % inhibition in the simultaneous test, and should not be separated from the holoenzyme complex on filtration through Sephadex molecular sieves. The only case in which this has been true so far is that of 4'-hydroxy-4'-deamino-TPP (hydroxy-TPP) *(4)* (cf. Tables 1 and 3).

[*] The primed constants belong to the coenzyme analogues.

[24] *A. Schellenberger, W. Rödel,* and *H. Rödel,* Hoppe-Seylers Z. physiol. Chem. *339*, 122 (1964).

TPP *(1)*

Hydroxy-TPP *(4)*

Since hydroxy-TPP, like TPP, forms stable bonds to apo-PDC only in the presence of metal ions (Table 1), the bonding between this analogue and apo-PDC may be assumed to be substantially the same as for the natural coenzyme. The amidine and amide regions surrounded by a dotted line are thus of no importance to the coenzyme-apoenzyme bonding.

According to the views outlined in Scheme 1, only C-2 of the thiazolium ring should be required for the decarboxylation of the substrate. However, the holoenzyme analogue prepared from hydroxy-TPP does not produce acetaldehyde (Table 3). This led to the assumption that the 4'-amino group is involved in the release of the aldehyde molecule (Scheme 2). Experiments with labeled pyruvate have confirmed the function of the 4'-amino group as a second reaction center (Fig. 5) [13]. After the addition to C-2, which can evidently take place without the operation of the apoenzyme (Fig. 5c), the pyruvate molecule is also decarboxylated by the hydroxy-TPP holoenzyme (Figs. 5b and 5d) (but as the optical test clearly shows, no acetaldehyde is eliminated).

In agreement with this result, no TPP analogue has so far been found in which the coenzyme activity is

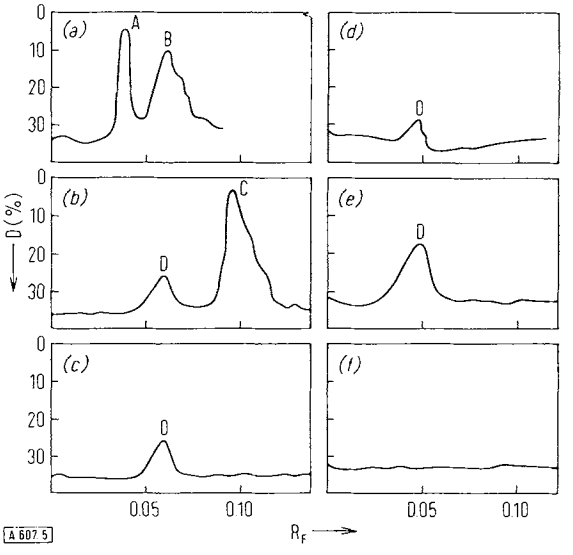


Fig. 5. Detection of the enzymatic formation of the "active acetaldehyde" analogues of hydroxy-TPP (autoradiogram of the reaction mixtures after separation by thin layer chromatography) [13].

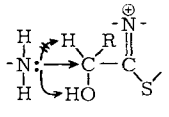
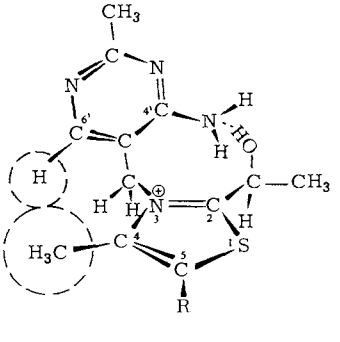
A = active acetaldehyde; B = active pyruvate (after *Holzer*); C = 4'-hydroxy-4'-deamino-2-(1-hydroxyethyl)thiamine pyrophosphate; D = non-enzymatically formed condensation product of pyruvate and the 2-carbeniate atom of TPP.



Mixture	Apoenzyme	Coenzyme	Pyruvate
(a)	+	TPP	[2-^{14}C]
(b)	+	Hydroxy-TPP	[2-^{14}C]
(c)	—	Hydroxy-TPP	[2-^{14}C]
(d)	+	Hydroxy-TPP	[1-^{14}C]
(e)	+	*N*-Methyl-TPP	[2-^{14}C]
(f)	+	2-Methyl-TPP	[2-^{14}C]

obtained when the amino group is modified [23]. However, of the compounds mentioned in Tables 1 and 3, only hydroxy-TPP has the full capacity for bonding to the apoenzyme. This is due to steric factors, which will be discussed in the following section.

As expected, the substitution of the decarboxylation center (2-methyl-TPP) also leads to an analogue having no coenzyme activity. However, the results of the simultaneous test and of the Sephadex test show that the 2-methyl group blocks the recombination process, so that in this case the activity test demonstrates not the disturbance of catalysis, but the hindrance of recombination [8]. The same is true of the intermediate product 2-hydroxyethyl-TPP [8]. When used instead of TPP, this acts as a TPP analogue for which recombination is hindered.



4. Stereochemistry of the Reaction Centers

The 4′-amino group can fulfil its catalytic function, *i.e.* the cleavage of the "active" aldehyde bond, only if it is in direct contact with the aldehyde portion to be released. Of the three possibilities shown in Scheme 3, the interaction of the free electron pair on the amino group with the very stable (almost no H–D exchange below pH = 8 [25]) α-C–H bond is unlikely so that only direct contact with the α-C atom (S_N mechanism), which carries a partial positive charge owing to the action of the hydroxyl group and the thiazolium ring, or with the hydroxyl proton (base catalysis) need be considered (Scheme 3).

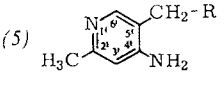
Scheme 3. Three possibilities for the cleavage of the "active" aldehyde.

In both cases, the Stuart model shows that the methyl group in position 4 is almost in contact with the 6′-H atom (Fig. 6). The introduction of a methyl group into position 6′ (6′-methyl-TPP) leads to twisting of the molecule about the CH_2 bridge, which results primarily in separation of the two reaction centers, but also in a shift of the bonding groupings of the coenzyme [8, 14].

R = $-(CH_2)_2-O-P_2O_6H_3$

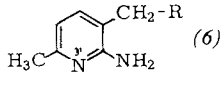
[A 607.6]

Fig. 6. Active acetaldehyde (redrawn Stuart model) in the position in which the two reaction centers are closest together (base catalysis mechanism A).



The intramolecular catalysis mechanism is accordingly much more sensitive to steric deformations than the bonding structure with the apoenzyme. The 6′-methylated TPP analogue has absolutely no enzyme activity, but still exhibits slight affinity for the apoenzyme (Table 3, simultaneous test). Hydroxy-TPP, on the other hand, completely loses its inhibiting action in the simultaneous test when methylated in position 6′. The twisting due to the 6′-methyl group is eliminated if the 4-methyl group is removed. 6′-Methyl-4′-nor-TPP exhibits coenzyme activity, and is not split off by Sephadex filtration [14]. 4-Demethyl-TPP (4-nor-TPP) is also active, but unlike the 4- and 6′-methyl analogues it is only loosely bound by the apoenzyme [14]. It follows that the methyl group in position 4 or 6′ takes part in the bonding between the coenzyme and the apoenzyme.

One might assume that, for steric reasons, the apoenzyme is capable of hydrophobic interaction with only one methyl group, whereas two methyl groups hinder each other in the bonding process. However, this is not so, since 4-ethyl-4-nor-TPP exhibits coenzyme activity, and is firmly bound by the apoenzyme (Tables 1 and 3 [8]). (A 4-ethyl group actually increases the affinity of 2-methyl-TPP (the recombination of which is hindered) for the apoenzyme to such an extent that it competes with TPP in the simultaneous test.)



The equivalence of positions 4 and 6′ is one of the most important pieces of evidence in favor of the two-center mechanism based on intramolecular interaction. The corresponding conformation of the TPP molecule bound in the active center of the PDC is not identical with the structure found by *Pletcher* and *Sax* [26] in X-ray studies on TPP crystals.

5. The Function of the Pyrimidine N Atoms and the S Atom

The high affinity of hydroxy-TPP (which exists in the lactam form) for the apoenzyme can be deduced from the fact that the part of the molecule around N-3 is not directly involved in the bonding. This was confirmed by investigation of the two pyridine analogues *(5)* (*N*-1-pyridine analogue) and *(6)* (*N*-3-pyridine analogue).

(5)

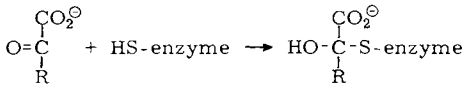
(6)

The *N*-1-pyridine analogue exhibits distinct coenzyme activity as the pyrophosphate [15], whereas the pyrophosphate of the *N*-3-pyridine analogue has no coenzyme activity and is not bound by the apoenzyme,

[25] *J. Ullrich* and *A. Mannschreck*, European J. Biochem. *1*, 110 (1967); *J. J. Mieyal, R. G. Votaw, L. O. Krampitz*, and *H. Z. Sable*, Biochim. biophysica Acta *141*, 205 (1967).

[26] *J. Pletcher* and *M. Sax*, Science (Washington) *154*, 1331 (1966).

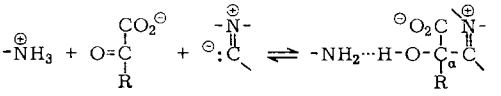
as is shown by the simultaneous test. It follows that the N-3 atom is neither catalytically active nor does it bind the apoenzyme. Mutual effects or tautomeric interaction between the 4′-amino group and the adjacent ring nitrogen atom are obviously also of no importance to the catalysis. However, the stability of the bonding between the coenzyme and the apoenzyme is reduced by the absence of the N-3 atom, as is particularly clear on filtration through Sephadex.



Since 4-aminopyrimidines are preferentially protonated in position 1 [27] it may be assumed that the bonding between N-1′ of the TPP molecule and the apoenzyme takes place through the intermediary of the metal ion, while the pyrophosphate residue, in agreement with the independence of K_{Mg} and K_{TPP}, is bound to the apoenzyme in the primary equilibrium without the assistance of the metal ion (acid-base interaction). This assumption is supported by the fact that unphosphorylated thiamine has no effect on the primary equilibrium TPP-apo-PDC and by the order of magnitude of K_{TPP} (the value 10^{-3} indicates salt-like bonding).

Replacement of the thiazole ring of thiamine by a pyridine ring gives pyrithiamine (2-methyl-1-(4-amino-2-methyl-5-pyrimidinylmethyl)-3-(2-hydroxyethyl)pyridinium halide [28]), whose pyrophosphate has no coenzyme activity and is not bound by the apoenzyme [8]. It thus behaves similarly to the *N*-3-pyridine analogue *(6)*. However, the conclusion that the sulfur also belongs to the binding group in the TPP molecule should be regarded with caution because of the large structural changes.

6. The Course of the Reaction



According to the experimental data available at present, the α-keto acids react on the enzyme in three stages: binding of the substrate, irreversible decarboxylation-, and cleavage of the active C–C bond.

Binding of the substrate: Experiments with Sephadex have shown that the pyruvate molecule is relatively strongly bound by the apoenzyme, even in the absence of metal ions. By inhibition experiments using SH reagents and by investigation of the n-π* transition of α-keto acids in the presence of cysteine we have recently been able to demonstrate [29] that this primary bonding of the substrate to the enzyme most probably proceeds *via* formation of a semimercaptal:

The following step is the attachment of the pyruvate molecule to C-2 of the thiazolium ring. According to NMR studies by *Ullrich* and *Mannschreck* [30] and MO calculations by *Pullman* [31], the TPP molecule very probably exists in the carbeniate form at the optimum pH value, a basic group of the active center or the carboxylate group of the substrate possibly favoring the cleavage of the (C-2)-H bond by accepting the proton. The results shown in Figure 5c suggest that the α-keto acid adds to the active form spontaneously, *i.e.* without the assistance of the apoenzyme.

Like the hydration of carbonyl compounds, the condensation is favored by protonation of the carbonyl oxygen. The adjacent 4′-NH_2 group in the protonated form may act as a donor. In this way, the hydrogen bonds required for the following steps would be formed during the binding process, and the new asymmetric α-C atom would be sterically oriented.

The substrate-specificity of yeast-PDC is not particularly pronounced. In addition to pyruvate, numerous β-monoalkylated and dialkylated α-keto acids (including cyclohexylglyoxylic acid) and phenylglyoxylic acid and their *m*- and *p*-substituted derivatives react [32]. According to the results obtained so far, the affinity and the rate of reaction are influenced in opposite directions by the inductive effect of the group in the β-position.

One of the few α-keto acids that are not made to react by the enzyme is glyoxylic acid. Recent investigations by *Hübner* with [^{14}C]-glyoxylic acid have shown that the acid is decarboxylated on the enzyme, but there is no cleavage of the "active" C–C bond, so that the coenzyme is blocked for the acceptance of further substrate molecules. The reason for the blockage of the elimination of aldehyde is described in connection with the models for the C–C cleavage.

Irreversible decarboxylation and stabilization of the α-carbanion (3): Since attempts to synthesize active pyruvate have so far been unsuccessful [33], it is not certain whether the apoenzyme participates in the decarboxylation by interaction with the thiazolium nitrogen or sulfur, or whether the active pyruvate is spontaneously decarboxylated to form active acetaldehyde.

The electron pair remaining after the elimination of CO_2 should (by analogy with the readily decarboxylated β-keto acids) lead to an increase in the bond order of the active bond, and so oppose the subsequent release of aldehyde.This resonance stabilization,which may be regarded as an important reason for the low aldehyde yields obtained with the thiazolium model catalysts, can occur only if the two residues (R,OH) remaining on the α-C atom lie in the same plane as the thiazolium ring.

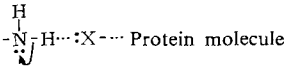
Examination of the Stuart model shows that owing to the formation of a hydrogen bond between the amino and hydroxyl groups, the two residues on the α-C atom are practically perpendicular to the plane of the thiazolium ring. This greatly limits the interaction of the free electron pair with the π electrons of the ring and hence also the increase in the bond order of the active bond. Moreover, the stereospecificity and the high basicity of the α-C atom are retained.

Scheme 4 shows the possibilities for the stabilization of the carbanion *(3)*.

Scheme 4

Scheme 4. Possibilities for the stabilization of the carbanion *(3)*.

According to investigations by *Ullrich* and *Mannschreck*, and *Mieyal*, *Votaw*, *Krampitz*, and *Sable*, the α-C–H bond of active acetaldehyde exhibits only a very small H–D exchange below pH = 8 [25]. This suggests a high basicity of the α-carbanion *(3)*, from which one would expect the principal reaction to be immediate protonation [*], with formation of 2-(1-hydroxyethyl)-TPP *(2)* (route I), while the condensation with carbonyl compounds (supplied from the medium) to give the active alkyloin derivatives (route 2) should be an insignificant side reaction. The isotope effect observed in the formation of acetoin in D_2O [34] would thus be explained by a change in the contributions of the two reactions.



Direct cleavage of the α-carbanion *(3)* with formation of TPP anion and aldehyde (route 3) would be conceivable only if the protonation reaction I were retarded by a proton-free zone in the active center (which, in view of the high basicity of *(3)*, would also exclude the proximity of NH, OH, and related bonds). Even if this were so, it would not appear easy to explain the aldehyde inhibition (which requires an equilibrium that can be influenced *after* the irreversible decarboxylation) and the blockage of the release of aldehyde when hydroxy-TPP is used as the coenzyme or when glyoxylic acid is used as a substrate by means of mechanism III.

Cleavage of the active bond: In an earlier report [13], we formulated the cleavage of the active aldehyde bond as an intramolecular nucleophilic substitution on the α-C atom (Scheme 2, route B) on the basis of model experiments. However, the Stuart model showed that a collinear arrangement of the free orbital of the amino group with the active bond, as required for S_N2-reactions, is not possible. The angle with respect to the axis of the active bond is about 80 °.

On the other hand, sterically favorable conditions would exist for an intramolecular base catalysis (Scheme 2, route A). If the 6′-H atom in the atomic model is brought into contact with the 4-methyl group (cf. Section II.4), the 4′-amino group and the α-hydroxy proton approach each other sufficiently closely for easy formation of a hydrogen bond.

There were two objections to the intramolecular base-catalysis mechanism. Firstly, the basicity of the 4′-amino group is greatly reduced by the pyrimidine ring. Secondly, unless steric factors play a decisive part, *N*-methyl-TPP should have at least the same action as TPP, but this is not the case (Table 3). However, it is found in the Sephadex test, that *N*-methyl-TPP is only weakly bound by the apoenzyme. We regard this as evidence of the close contact of the amino group with the apoenzyme surface, which is evidently essential for the fulfilment of the base-catalytic function.

This presents a new point of view. A sterically and chemically suitable region in the binding center of the apoenzyme forms a hydrogen bond with one of the relatively acidic hydrogen atoms of the amino group, so turning this group out of its original resonance position and making contact with the hydroxyl proton possible.

The basicity of the 4′-amino N atom, and hence its catalytic activity, are increased by the interaction with the apoenzyme. At the same time it becomes clear why the bifunctional N atom becomes inactive as a result of methylation.

When the system is saturated with substrate, the product inhibition of PDC, which according to *Juni* [36] is noncompetitive, becomes active even at very low aldehyde concentrations. It must therefore be assumed that the release of the aldehyde following the irreversible decarboxylation determines the catalytic activity of the enzyme in the stationary state. At very low substrate concentrations, on the other hand, the loading of the enzyme with substrate or the decarboxylation is rate-determining, since in this case the inhibiting action appears only at higher aldehyde concentrations.

[*] The rate of protonation of carbeniate ions can be estimated from the position of the equilibrium and the rate of isotope exchange. For example, in the case of diethyl malonate, for which the exchange is still measurable, the value is of the order of 10^8 mole l^{-1} min^{-1} [35].

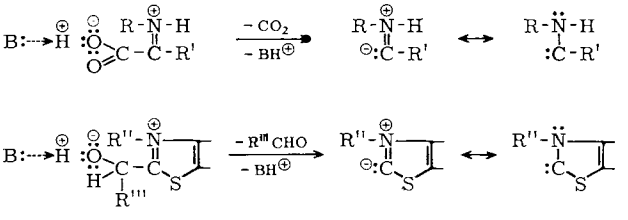
[36] *E. Juni*, J. biol. Chemistry *236*, 2302 (1961).

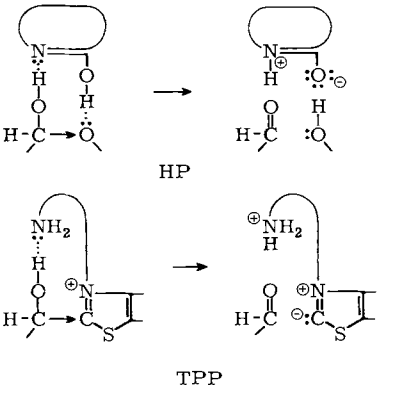
The problems connected with the cleavage of the active bond can be studied on two models, whose function mechanisms have been investigated in detail and exhibit far-reaching analogies with the enzyme mechanism.



In the first model, the cleavage of the active C–C bond is compared with the decarboxylation of α-imino acids (Scheme 5). It is known that these compounds (unlike the α-keto acids) are readily decarboxylated, the immonium carboxylate form being regarded as the reactive species [37].

Our own work on the behavior of *N*-substituted α-imino acids [38] has shown that the (C-1)–(C-2) cleavage associated with the decarboxylation is mainly favored by the following effects:

1. The residue (CO_2) to be removed is pre-stablized by elimination of the acid proton, so that the release of the pair of bonding electrons, which is accompanied by resonance stabilization of the CO_2 molecule, is favored.



2. The decarboxylating action of the α-immonium group is increased by electron-attracting substituents on the N atom. Thus under identical conditions, the decarboxylation of the *N*-benzylated imino acid is approximately twice as fast as that of the *N*-ethylated imino acid.

Similar conditions are found for the cleavage of the C–C bond in the active aldehyde. The aldehyde molecule to be removed is pre-stablized by proton abstraction, a process that will be described more fully in the discussion of the second model. Moreover, the rate of cleavage is considerably increased by the strongly electron-attracting 4-aminopyrimidine ring on the nitrogen.

Scheme 5. Analogies between the decarboxylation of α-amino acids and the cleavage of the active aldehyde.

The second model is based on the relatively high acidity of the 2-C–H bond in the thiazolium ring, which has repeatedly been confirmed both experimentally [30] and theoretically [31]. There are thus analogies between the mechanism of the intramolecular base catalysis and the base-catalysed dehydration of geminal diols [39] and the base-catalysed cleavage of hemiacetals. This last reaction, which has been extensively studied for the mutarotation of glucose [40] is both acid-catalysed and base-catalysed; 2-hydroxypyridine, in which the acidic and basic groups are fixed in a favorable position for the reaction, has proved to be a particularly effective bifunctional catalyst. The cleavage of the C–O bond is formulated as the rate-determining step (again in analogy to the TPP mechanism) (Scheme 6).

Scheme 6. Comparison of the catalysis of mutarotation by 2-hydroxypyridine (HP) according to *Swain* with the TPP catalysis of the cleavage of active aldehyde. Both reactions are rate-determining.

For a quantitative consideration of the analogies between TPP catalysis and hydration-dehydration equilibria, the equilibrium constants (K_d) collected by *Greenzaid et al.* [41] are shown in Table 4.

Table 4. Equilibrium constants for the dehydration of carbonyl compounds (for investigation methods and errors, see [41]).

Carbonyl compound	K_d
CH_2O	5.0×10^{-4}
CH_3CHO	0.7
CH_3CH_2CHO	1.4
CH_3COCO_2H	0.42
$CH_3COCO_2^{\ominus}$	18.5

If one assumes that the addition of the carbonyl compound to the acidic 2-C–H bond corresponds to hydration and the elimination to dehydration, the following information can be obtained from the K_d values:

1. The reactivity of the undissociated α-keto acid toward anionoid components is higher than that of the corresponding anion, emphasizing the acid catalysis [42] in the addition process (4′-$^{\oplus}NH_3$-catalysis in the substrate addition and aldehyde inhibition).

2. Comparison of the pyruvate ion, which is only weakly hydrated [43] with acetaldehyde, which exists in the hydrate form to the extent of more than 50 %, suggests that the bond to be cleaved in the active acetaldehyde is much more stable than the C–C bond in active pyruvate. Consequently, no reaction on the enzyme is observed without the base-catalytic ac-

[43] *M. Becker*, Ber. Bunsenges. physik. Chem. *68*, 669 (1964).

celeration of the release of the aldehyde (hydroxy-TPP).

This observation should be of general importance to catalysis processes involving covalently bonded intermediates. If the original substrate-catalyst bond is strengthened in the course of any reaction on the catalyst or enzyme, a co-catalyst that promotes the cleavage of the reaction product will strongly influence the stationary rate.

3. An extreme position among the aldehydes is occupied by the almost completely hydrated formaldehyde, whose K_d value is lower by about three powers of ten. On the basis of our analogy, therefore, the stability of the bonding of active formaldehyde in the enzyme should be about three powers of ten greater than in the case of active acetaldehyde. This is the reason for the failure of the release of aldehyde to take place when glyoxylic acid is used as the substrate.

Mitochondrial Oxidative Phosphorylation [**]

BY G. SCHATZ [*]

Mitochondria can form ATP from ADP and inorganic phosphate, the required energy being supplied by respiration. This coupled process, which in sufficiently aerated normal animal cells furnishes the bulk of the cellular ATP, is termed oxidative phosphorylation. The overall reaction is intimately associated with the mitochondrial inner membrane and proceeds via a primary high-energy intermediate. This intermediate, in a manner as yet unknown, energizes the anhydride formation between ADP and inorganic phosphate. The coupling between respiration and ATP synthesis is mediated by proteins of the mitochondrial inner membrane which are known as "coupling factors". The mechanism of oxidative phosphorylation is at present being discussed in terms of three hypotheses which are generally referred to as "chemical", "chemiosmotic", and "conformational" hypotheses. None of these hypotheses has as yet been experimentally verified.

Introduction

Respiring cells can couple the energy generated during substrate oxidation to the synthesis of ATP *via* oxidative phosphorylation (reaction (1)).

$$ADP + P_i \xrightarrow{\text{respiration}} ATP \qquad (1)$$

Coupling between respiration and ATP formation has been detected in many microorganisms and higher forms of life and is always associated with, and dependent on, a membrane structure. In respiring bacteria, the enzymes of the respiratory chain and of oxidative phosphorylation are bound to the cell membrane. In nearly all other types of cells they occur, together with the enzymes of the tricarboxylic acid cycle, in characteristically shaped cytoplasmic organelles known as mitochondria. The number of mitochondria per cell is subject to considerable phylogenic variation. One rat-liver cell, for example, contains several thousand mitochondria, whereas certain unicellular algae may have only a single mitochondrion.

The mechanism of oxidative phosphorylation remains unknown although, over the past three and a half decades, it has been investigated in many laboratories [1, 2]. One reason for the failure of these attempts may be that it has not yet been possible to observe the process in a soluble system in the absence of a membrane structure. It thus appears that oxidative phosphorylation is inherently dependent on a membrane, and differs in this respect from most of the biochemical pathways that have so far been elucidated. Another reason has been the incomplete knowledge about the

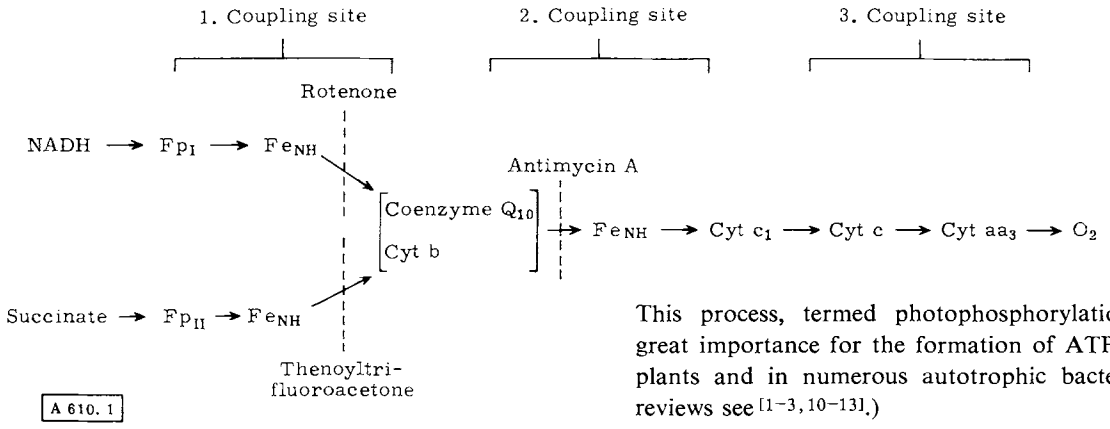

Fig. 1. The respiratory chain of mammalian mitochondria. Fp_I and Fp_{II}: flavoproteins of the NADH and succinate dehydrogenase, respectively; Fe_{NH}: nonheme iron; Cyt aa_3, b,c,c_1: cytochrome aa_3, b,c,c_1. The position of cytochrome b relative to coenzyme Q_{10} is not definitely known. It is also uncertain whether the components sensitive to rotenone [4], thenoyltrifluoroacetone [5], and antimycin A [6] are identical with known respiratory carriers or represent as yet unknown redox components. In mitochondria from *Saccharomyces cerevisiae*, the segment between NADH and cytochrome b appears to lack a coupling site [7, 8], a component sensitive to rotenone [7, 8], as well as nonheme iron involved in electron transport [9]. The broken lines symbolize an inhibition of electron transport.

mitochondrial respiratory chain. While the scheme given in Figure 1 is in agreement with most of the existing data, it has not been verified in all details and is probably incomplete [3].

It is generally assumed that in mammalian mitochondria the transport of one pair of electrons from NADH to oxygen generates a maximum of three molecules of ATP [1, 2]. However, the three "coupling sites" (cf. Fig. 1) cannot yet be assigned to definite redox reactions. This by itself makes it impossible to describe all steps of oxidative phosphorylation by chemical equations. Finally, progress has also been delayed by the fact that experiments dealing with oxidative phosphorylation often require elaborate preparative procedures or complex and costly equipment.

The present article is confined to a discussion of the results obtained with mitochondria. However, nearly all the main conclusions are also valid for bacteria, since in all the cases studied so far the coupling between respiration and the synthesis of ATP appears to obey a common principle. A similar principle probably also governs the light-coupled synthesis of ATP (reaction (1a)).

$$ADP + P_i \xrightarrow{\text{light}} ATP \qquad (1a)$$

This process, termed photophosphorylation, is of great importance for the formation of ATP in green plants and in numerous autotrophic bacteria. (For reviews see [1–3, 10–13].)

I. The Primary High-Energy Intermediate

Numerous observations suggest that the energy generated during respiration in the three segments of the electron-transport chain is not trapped directly as ATP, but first appears in a high-energy intermediate compound or in a high-energy "state" of the mitochondrial membrane. The energy of this still uncharacterized primary intermediate can be utilized either for anhydride formation between P_i and ADP *via* several unknown energy-transport reactions (Fig. 2, pathway 1), or for energizing directly (*i.e.* without passing through ATP) other endergonic reactions in mitochondria (Fig. 2, pathway 2).

Evidence that the actual synthesis of ATP is preceded by an intermediate of this type is provided *e.g.* by experiments with the antibiotic oligomycin, which blocks the synthesis of ATP in respiring mitochondria [6, 14] without affecting the active accumulation of inorganic cations [15–17] or the succinate-linked, energy-dependent reduction of acetylacetate [18] or α-ketoglutarate [19]. Still more conclusive evidence can be obtained with submitochondrial particles, which, in contrast to intact mitochondria, contain only extremely small amounts of endogenous adenine nucleotides and P_i. Even though these particles are thus unable to use the energy generated during res-

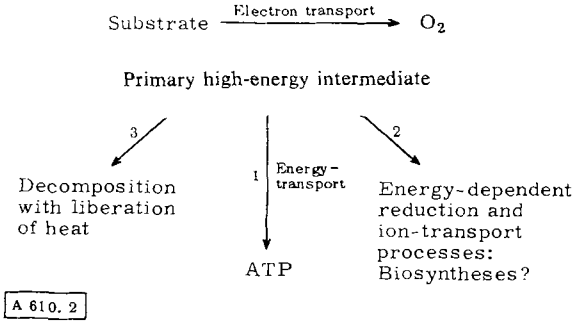

Fig. 2. Schematic diagram of possible reactions of the primary high-energy intermediate of oxidative phosphorylation.

piration for the synthesis of ATP unless both of these substances are added, they can still use this energy for endergonic reductions [20,21]. Thus P_i does not appear to be involved in the primary coupling reaction [20,21].

It might be argued that ATP synthesis and energy-dependent reduction and ion-transport processes could each proceed *via* a separate non-phosphorylated intermediate. Although this possibility cannot be entirely ruled out, it is unlikely since under suitable conditions energy-dependent mitochondrial reactions (*e.g.* the transport of ions [17,22,23], the rotenone-sensitive reduction of hexacyanoferrate(III) by succinate [24], and the transhydrogenase reaction [25]) can compete with ATP synthesis for the energy of respiration. This points to either a common intermediate or to different, but closely interacting intermediates.

Several authors have also discussed the participation of a non-phosphorylated intermediate of oxidative phosphorylation in mitochondrial protein synthesis [26,27] and in the activation of fatty acids [28,29,30]. However, the evidence that these processes are independent of ATP is not conclusive, since the rate of incorporation of amino acids by isolated mitochondria is at least four to five orders of magnitude lower, and the rate of fatty acid activation at least two orders of magnitude lower, than the maximum rate of oxidative phosphorylation [3,31,32].

Suppression of both ATP synthesis and reduction and ion-transport processes in intact respiring mitochondria causes an inhibition of substrate oxidation which is termed respiratory control [33]. While the exact mechanism of this inhibition has remained obscure, it is obviously the result of an accumulation of the primary high-energy intermediate of oxidative phosphorylation. This inhibition of electron transport represents a further possible reaction of the high-energy intermediate.

Finally, the intermediate may decompose spontaneously without providing useful chemical energy, the equivalent free energy probably being lost as heat (Fig. 2, pathway 3). In carefully isolated, intact mitochondria such a dissipative reaction is negligible. However, it can be greatly stimulated either by damage to the mitochondrial structure or by "uncouplers" such as 2,4-dinitrophenol [34], arsenate [35], or 2-(*m*-chlorophenyl)hydrazonomalonodinitrile [36]. ATP synthesis and other energy-coupled reactions are thereby inhibited and ultimately totally blocked while respiration remains unchanged or is even intensified.

It has been argued that ATP synthesis at each of the three coupling sites could involve several non-phosphorylated intermediates [11]. This view is not shared by the present author, since there appears to be no compelling reason for such a postulate.

While the existence of a primary high-energy intermediate of oxidative phosphorylation is virtually certain, its structure and reaction characteristics cannot yet be defined in chemical terms. Since the question as to the nature and mode of formation of the primary intermediate amounts to a question about the mechanism of oxidative phosphorylation, the definition of this intermediate constitutes the salient, and distinguishing, feature of each of the hypotheses discussed below.

II. Hypotheses on the Mechanism of the Reaction

The present discussion on the mechanism of oxidative phosphorylation centers around three hypotheses, *i.e.* the "chemical", the "chemiosmotic", and the "conformational" hypothesis. The following discussion considers how well each hypothesis satisfies the observed facts and whether it is amenable to experimental verification.

As mentioned earlier, the mechanism of oxidative phosphorylation resembles that of photophosphorylation which has also remained unknown [1,37,37a]. This similarity has proved important for testing the various hypotheses experimentally, since many experiments can be carried out more easily and more conclusively with isolated chloroplasts than with isolated mitochondria. In the present article, however, experiments with chloroplasts are mentioned only when they contribute to the discussion, as in the case of the "chemiosmotic" hypothesis.

1. The "Chemical" Hypothesis

According to the "chemical" hypothesis, which was first formulated by *Slater* [38], an exergonic redox reaction between two adjacent respiratory carriers AH_2 and B leads to a high-energy chemical bond (symbol ~) between A and a substance X (reaction (2)). The non-phosphorylated compound A~X, which is common to electron transport and ATP synthesis, reacts with P_i to form a phosphorylated intermediate X~P, whose phosphoryl residue is finally transferred to ADP (reactions (3) and (4)):

$$AH_2 + B + X \rightleftharpoons A\sim X + BH_2 \quad (2)$$

$$A\sim X + P_i \rightleftharpoons X\sim P + A \quad (3)$$

$$X\sim P + ADP \rightleftharpoons ATP + X \quad (4)$$

These reactions represent one of the simplest formulations of the "chemical" hypothesis. The direct participation of P_i in the redox reaction (reaction (2a)) appears to be ruled out by the above-mentioned ex-

$$AH_2 + B + P_i \rightleftharpoons A\sim P + BH_2 \quad (2a)$$

periments with submitochondrial particles [20,21]. According to the "chemical" hypothesis, the term "high-energy intermediate" in Figure 2 stands for a chemical substance having a high-energy chemical bond. It is not specified whether the respiratory carrier present in the intermediate is in the oxidized (corresponding to reaction (2)) or in the reduced form.

The "chemical" hypothesis thus postulates a close analogy between oxidative phosphorylation and the ATP-forming steps of the triose phosphate dehydrogenase reaction, which was elucidated some time ago [39–41]. This is one of the strongest arguments in favor of the "chemical" hypothesis.

Respiratory control is rationalized by the assumption that in intact mitochondria the high-energy bonds of A~X and X~P are relatively stable. Without the addition of P_i and ADP, A would thus quickly be trapped as A~X and become unavailable for electron transport. Uncouplers are thought to react with the intermediate A~X, thereby breaking its high-energy bond and regenerating A.

There are several possible starting points for subjecting the "chemical" hypothesis to experimental scrutiny. Certain conditions, *e.g.* the state of respiratory control, should allow the accumulation, and detection, of high-energy forms of individual respiratory carriers (corresponding to A~X). Moreover, the high-energy intermediates formed at the three coupling sites should differ, since in each case X is bound to a different component of the respiratory chain. Finally, the isolation of a phosphorylated intermediate different from ATP (corresponding to X~P in reaction (3)) would support, if not prove, the "chemical" hypothesis. However, none of these predictions has so far been verified.

Despite considerable effort it is not known whether respiratory carriers are directly involved in the formation of the primary high-energy intermediate. Although several authors have suggested the participation of quinone phosphates [42,43] or NADH~P [44] in oxidative phosphorylation, these possibilities have not been proven and, indeed, seem unlikely. The data available for cytochrome b_{555}, which is interpreted by *Chance et al.* as a high-energy form of cytochrome b [45–47], are not sufficient to identify this interesting pigment as a high-energy intermediate in the sense of the "chemical" hypothesis. The existence of site-specific high-energy intermediates has also not been established. On the contrary, experiments with submitochondrial particles indicated [48] that the three coupling sites responded similarly toward inhibitors and uncouplers of oxidative phosphorylation as well as toward "coupling factors" (see below).

Finally, all attempts to identify a phosphorylated intermediate of oxidative phosphorylation have failed. The protein-bound phosphohistidine [49] discovered in mitochondria by *Boyer* and co-workers is not involved in oxidative phosphorylation [50]. The functions of the mitochondrial phosphoprotein isolated by *Beyer* [51] and of the unidentified phosphate fraction described by *Norman et al.* [52] have not yet been established. It is also still under dispute [53,54,54a] whether phosphomonoiodohistidine [55], suggested by *Perlgut* and *Wainio* as an intermediate of the oxidative phosphorylation, actually occurs in mitochondria. Protein-bound serine phosphate [56,57] or lipid phosphate [52,58] can probably also be ruled out as intermediates.

In spite of considerable effort, the "chemical" hypothesis has therefore not yet been confirmed. Most important of all, it is unable to explain one of the most fundamental characteristics of oxidative phosphorylation, *i.e.* the intimate association with a membrane structure. On the other hand, it is more amenable to

experimental evaluation than the other hypotheses, and has therefore had a particularly stimulating effect on research.

2. The "Chemiosmotic" Hypothesis

According to the "chemiosmotic" hypothesis developed by *Mitchell*[37,59], respiration and ATP synthesis are coupled *via* a respiration-dependent proton transport through a "coupling membrane" rather than *via* formation of an energy-rich chemical compound. This proton transport is postulated to proceed synchronously with electron transfer from a reduced two-electron carrier AH_2 to an oxidized one-electron carrier B^{3+}, the active centers of which are arranged asymmetrically in the coupling membrane (cf. Fig. 3a and reaction (5)).

$$AH_2 + 2\,B^{3+} \rightarrow A + 2\,B^{2+} + 2\,H^+ \qquad (5)$$

The sum of one-electron and two-electron carriers participating in the transport of two protons is termed a "loop" (Fig. 3a); a "loop" formally corresponds to a coupling site of the "chemical" hypothesis.

The "chemiosmotic" hypothesis forbids passive diffusion of ions through the coupling membrane. The respiration-coupled proton pump thus generates not only a proton concentration gradient but also, by separating electric charges, an electric potential difference across the coupling membrane, *i.e.* a membrane potential. According to the "chemiosmotic" hypothesis, "primary high-energy intermediate" in Figure 2 stands for the free energy of an electrochemical potential.

Since there are obviously no membranes that are completely impermeable to ions, the relative contributions of the proton concentration gradient and of the membrane potential to the total energy of the electrochemical potential are difficult to predict. It is nevertheless clear that, contrary to the view of *Chance* and *Mela*[60], the "chemiosmotic" hypothesis does not necessarily invoke a considerable pH difference across the coupling membrane.

However, a coupling membrane impermeable to ions would also preclude the uptake of ionized substrates and cofactors into the interior of the mitochondria. The "chemiosmotic" hypothesis therefore assumes further that the coupling membrane contains ion-specific exchange-diffusion systems, which link the uptake of certain ions to the extrusion of similarly charged intramitochondrial ions.

The formation of ATP is explained in this hypothesis by the back-flow of protons through the coupling membrane, the free energy of the electrochemical potential driving the elimination of water between P_i and ADP *via* a membrane-bound vectorial ATPase system. The mechanism suggested for this ATP-forming step is not yet entirely satisfactory, and is one of the weakest points of the hypothesis.

Figure 3 schematically depicts the transport of two protons through the coupling membrane by a "loop" (and the simultaneous accumulation of OH^- on the other side) as well as the recombination of H^+ and OH^- by a vectorial ATPase system. The direction of the proton movements is not fixed by the "chemiosmotic" hypothesis; the direction shown in Figure 3 corresponds to empirical findings with isolated rat-liver mitochondria[61].

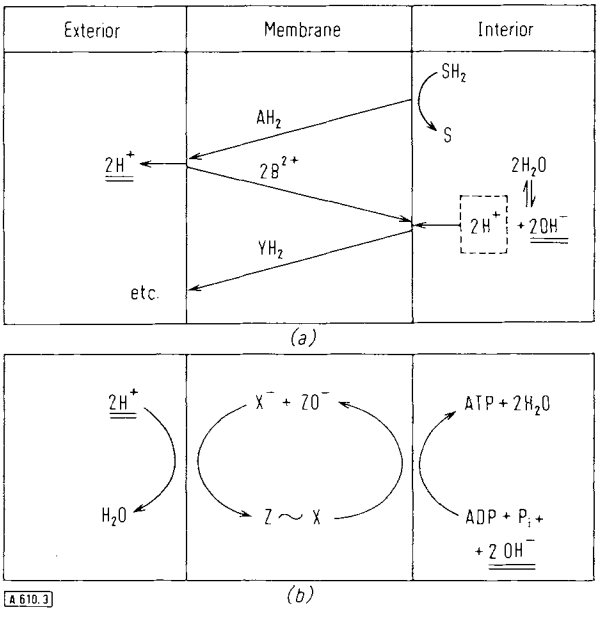

Fig. 3. Proton transport by a "loop" (a) and ATP synthesis (b) according to the "chemiosmotic" hypothesis. S and SH_2: oxidized and reduced substrate; AH_2 and YH_2: reduced two-electron (hydrogen) carriers; B^{2+}: reduced one-electron carrier; X^- and ZO^-: hypothetical functional groups involved in energy transport; Z~X: hypothetical high-energy intermediate involved in the energy transport, but not in electron transport.

Respiration in the absence of P_i and ADP would be expected to lead to an accumulation of H^+ and OH^- on opposite sides of the coupling membrane. This accumulation could inhibit electron transport by a back-reaction *via* the respiration-coupled "proton pump", thus inducing respiratory control.

According to the hypothesis, uncouplers increase the proton-permeability of the coupling membrane, and thereby collapse the electrochemical potential.

Mitchell[59] and *Mitchell* and *Moyle*[61,62] were able to show that, in agreement with the "chemiosmotic" hypothesis, both the oxidation of substrates and the hydrolysis of ATP led to proton movement in the same direction (*i.e.* an ejection of protons from the mitochondria). For each "loop" traversed by an electron pair and for each hydrolysed molecule of ATP, two protons were pumped from the mitochondria into the suspension medium. The required impermeability to ions of the mitochondrial inner membrane (as the actual "coupling membrane", see below) was also confirmed[37,63].

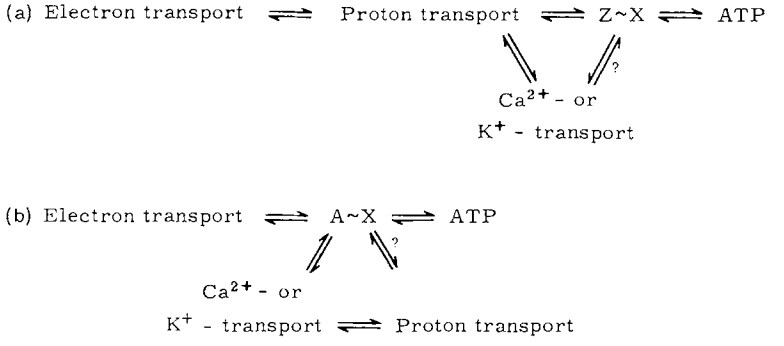
[63] *J. B. Chappell* and *K. Haarhoff* in: The Biochemistry of Mitochondria, Proc. Third Meeting Fed. European Biochem. Societies, Warsaw 1966, in press.



It should be emphasized that the term "impermeability to ions" simply implies a barrier to passive diffusion. Ions such as Ca^{2+}, P_i, or anions of certain dicarboxylic acids can in fact be taken up into the interior of the mitochondria; however, this uptake does not involve passive diffusion, but probably specific enzyme-controlled transport processes, which couple the uptake of cations or anions to the ejection of H^+ or OH^- [63]. Though little is known about these transport systems, they seem to correspond to the exchange-diffusion systems required by the "chemiosmotic" hypothesis.

This hypothesis received particularly strong support from investigations on the action of uncouplers, since such chemically unrelated uncouplers as 2,4-dinitrophenol, 2-(*m*-chlorophenyl)hydrazonomalonodinitrile, and dicoumarol all greatly increased the permeability of the mitochondrial membrane to protons [37,64,64a]. *Bielawski et al.* also showed that 2,4-dinitrophenol increases the electrical conductivity of synthetic lipid membranes by more than two orders of magnitude [65]. Both of these observations are difficult to explain in terms of the "chemical" or the "conformational" hypothesis (see below).

Assuming comparable reaction mechanisms, the experimental results obtained with chloroplasts may also be regarded as an argument for the "chemiosmotic" hypothesis. By suddenly raising the pH of the suspension medium, *Jagendorf et al.* [66,66a] were able to obtain ATP synthesis in non-illuminated chloroplasts that was blocked by uncouplers of photophosphorylation. Control experiments indicated that this ATP synthesis was due to the induction of an electrochemical potential across the grana membranes in the sense of the "chemiosmotic" hypothesis, and not to a pH-induced electron transport or unknown intermediates of photophosphorylation that were already preformed in the chloroplasts.

Attempts to detect an analagous pH-induced ATP synthesis in isolated mitochondria were at first unsuccessful [37,67,68]. *Reid et al.* [69] subsequently reported that rat-liver mitochondria incorporated $^{32}P_i$ into ATP if the pH of the suspension medium was suddenly lowered. However, the extent of this incorporation was too small to rule out formation of $AT^{32}P$ *via* any preformed intermediates of oxidative phosphorylation or *via* residual exchange and electron-transport reactions.

While these experimental data are no doubt impressive, they do not prove the "chemiosmotic" hypothesis. Indeed, according to more recent investigations, the proton movements observed in isolated mitochondria [61,62] appear to be secondary reactions of a respiration-coupled transport of Ca^{2+} or K^+ from the suspension medium into the mitochondria [63,70,71], and not reactions of "loops" and vectorial ATPase systems as envisioned by the "chemiosmotic" hypothesis (Fig. 4a).

A 610. 4

Fig. 4. Interrelationships between electron transport, ATP synthesis, and ion transport according to the "chemiosmotic" (a) and "chemical" (b) hypotheses.

As indicated in Figure 4b, the respiration- and ATP-coupled proton transport observed by *Mitchell* and *Moyle* can thus be relatively easily explained in terms of the "chemical" hypothesis.

According to Figure 4b, the "chemical" hypothesis could even account for the pH-induced ATP-synthesis in chloroplasts [66a], since a sudden change in the proton activity of the suspending medium could induce a back-reaction leading to the formation of A ~ X and, hence, of ATP. Moreover, the concept of the "loop" is difficult to reconcile with the structure of the respiratory chain, since the segment between cytochrome c and cytochrome aa_3 contains a coupling site, but no two-electron carriers. According to *Slater* [71a], the "chemiosmotic" hypothesis is also doubtful on thermodynamic grounds, since the free energy required for ATP synthesis appears to exceed the

energy content of the ion gradients proposed by *Mitchell*[37]. However, this objection is not necessarily valid, since the energy-requirement of ATP formation in mitochondrial membranes and the thermodynamic characteristics of extremely small volumes, such as those of submitochondrial particles, are still under dispute[71b–71e].

The experiments and arguments published thus far can neither prove nor refute the "chemiosmotic" hypothesis. It would be clearly disproved *e.g.* by the identification of an intermediate common to electron- and energy-transport or by the demonstration that oxidative phosphorylation can also take place in a soluble system. Nevertheless, the action of uncouplers, the tight linkage of oxidative phosphorylation to a membrane structure, and the pH-induced ATP synthesis can be more readily explained by the "chemiosmotic" than by either the "chemical" or "conformational" hypothesis.

3. The "Conformational" Hypothesis

The parallels between the ATPase reaction catalysed by mitochondria and by myosin led *Boyer* to assume that the energy liberated during the electron transport could be "captured" as a high-energy conformation of a protein and thus in principle be coupled to the ATP synthesis[13,72]. As a possible intermediate reaction *Boyer* discussed the formation of an intramolecular high-energy S~acyl bond (Fig. 5).

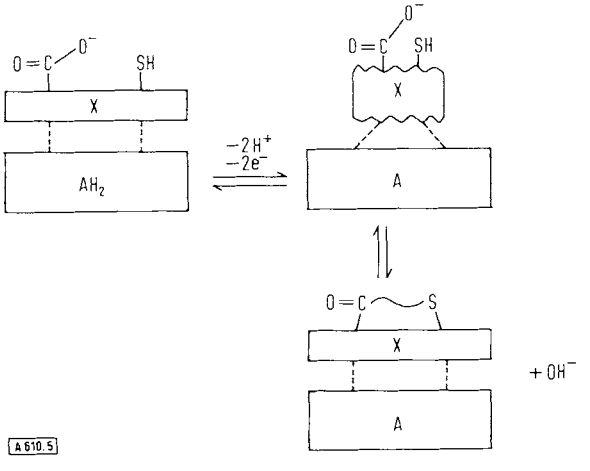

Fig. 5. The primary coupling reaction according to the "conformational" hypothesis. A and AH_2: oxidized and reduced respiratory carrier X: hypothetical coupling protein, which is either identical with or in close interaction with A.

This formulation resembles the "chemical" hypothesis in that it invokes an analogy with ATP synthesis catalysed by triose phosphate dehydrogenase, for which the intermediate formation of an S ~ acyl bond is well established[39–41]. The uncoupling action of 2,4 - dinitrophenol is interpreted as a cleavage of the S ~ acyl bond to form a grouping $2,4\text{-}(NO_2)_2\text{-}C_6H_3\text{-}O$ Acyl, which hydrolyses spontaneously.

It is left open whether the coupling process involves a conformational change of a respiratory carrier or of a protein not directly involved in electron transport. In the first case the "conformational" hypothesis would simply be a detailed variant of the "chemical" hypothesis. In the second case the "conformational" hypothesis would not call for an intermediate common to electron- and energy-transport, and would thus differ from the "chemical" hypothesis. According to this latter alternative it would even be conceivable that each respiratory chain contains only a single coupling site and that the energy generated in the three segments of the respiratory chain is always used for deforming the same protein (*e.g.* a "contractile protein" of the mitochondrial inner membrane). However, this presupposes interactions between the various membrane proteins that are still hypothetical[72].

The "conformational" hypothesis can plausibly account for the close linkage between oxidative phosphorylation and a membrane structure and is compatible with the great similarity of the three coupling sites as well as with the well-documented dependence of mitochondrial structure on the reactions of energy-coupling[2,73]. On the other hand, it shares with the "chemical" hypothesis the inability to explain the chemical diversity of uncoupler substances. At present this hypothesis offers few starting points for experimental investigations.

III. Coupling Factors

A coupling factor is a mitochondrial protein, which, when added to suitable mitochondrial particles, increases their ability to carry out oxidative phosphorylation. The most obvious interpretation of this stimulation is an acceleration of the energy-transport chain (Fig. 2, pathway 1), the coupling factor thus being regarded as an enzyme specifically involved in energy transport. While investigations on coupling factor 1 (F_1) do indeed suggest such a mode of action, there exists as yet no conclusive proof that this assumption is valid for any of the known coupling factors. In most cases it is merely possible to rule out, more or less, any trivial effect, such as binding of naturally occurring uncouplers[74].

Since the first coupling factors were isolated from beef heart mitochondria [75,76], numerous reports on the isolation and characterization of such factors have appeared which present a rather confusing pic-

ture[3,10,11]. The test particles and the purities of the coupling proteins differ so widely that the results obtained by different research groups can only occasionally be compared.

Investigations by *Racker* and co-workers have led to the identification and at least partial purification of three coupling factors which are designated as F_1, F_2, and F_3[77–80]. According to recent studies[80], the action of a fourth factor F_4[82], which is similar to the structural protein described by *Richardson et al.*[81] is at least partly due to F_2 and F_3 bound to structural protein. *Andreoli et al.*[83] and *Lam et al.*[84,84a] isolated two further coupling factors (FA and FB). Though these have not yet been carefully compared with F_1, F_2, or F_3, the published data suggest that at least part of the action of FA is due to F_1, which could be present in FA either as a modification product (see below) or complexed to the naturally occurring F_1 inhibitor[85]. On the other hand, the coupling factor described by *Beyer*[86] (termed ATP synthetase II) is not identical with F_1[87]; its relationship to the other coupling factors is still unclear.

All the coupling factors mentioned so far were isolated from bovine heart mitochondria. *Wadkins* and *Lehninger* described a coupling factor from rat-liver mitochondria, which differed from F_1 in that it catalysed an ADP–ATP exchange reaction[88]. However, *Groot* and *Van den Bergh*[88a] were unable to confirm the coupling factor activity of this protein. The coupling factors described by *Linnane*[76] and *Hommes*[89] have not yet been characterized in detail.

The existence of site-specific coupling factors, which was claimed only a few years ago[90–92], must now be seriously doubted. Reports of such factors were probably mainly due to inadequate methods for measuring the individual coupling sites. Until recently, only the third coupling site (cf. Fig. 1) could be assayed independently of the others[93]. However, a new method for the selective measurement of the first coupling site in submitochondrial particles[48] now permits the determination of the effect of each factor on two different coupling sites. It is now clear that F_1, F_2, and F_3 influence all three coupling sites[48,79,80]. Claims of a coupling factor specific for the first coupling site[91] could not be confirmed[95]. Moreover, reports on the existence of a specific factor for the third coupling site[90,92] have proved to be completely unfounded[94].

Most of the coupling factors isolated from mitochondria are quite inhomogeneous protein fractions whose mode of action is unknown. Detailed information only exists for coupling factor F_1, which will now be briefly discussed.

In 1958, *Pullman et al.*[75] solubilized F_1 from bovine heart mitochondria by shaking with glass beads, characterized it as mitochondrial ATPase[77], and purified it to homogeneity in the ultracentrifuge[77]. According to *Penefsky* and *Warner*[96], F_1 is a compact, symmetrical molecule of molecular weight 284000 which consists of about ten subunits each having a molecular weight of 26000. Recent studies indicate that the ATPase activity of isolated mitochondria is inactivated by irradiation with high-energy electrons; since an analysis according to the target theory gave a molecular weight of between 260000 and 290000, F_1 appears to exist in the mitochondrial membrane as the undissociated molecule[96a]. After negative staining with phosphotungstate, individual F_1 molecules appear in the electron microscope as approximately spherical structures having a diameter of 80 to 85 Å[97]. Addition of the purified protein to suitable submitochondrial particles of low phosphorylating capacity strongly stimulates ATP formation without significantly affecting the rate of respiration[78]. Solubilized F_1 catalyses an ATPase reaction that is not inhibited by oligomycin, and is rapidly denatured at 0 °C, but not at room temperature[77,96].

On the other hand, since the ATPase activity of membrane-bound F_1 is strongly inhibited by oligomycin[14,15] and is stable at low temperatures, the separation of the enzyme from mitochondrial membranes is accompanied by remarkable changes in its properties. This phenomenon, termed "allotopy"[97a], prompted *Racker* and associates to isolate a particulate

mitochondrial component (F_0) which could specifically bind soluble F_1 and thereby rendered it again cold-stable and sensitive to oligomycin [98,99]. F_0 was found to be a relatively crude membrane fraction devoid of F_1, but still containing phospholipids and the entire respiratory chain [98,99]. Further purification gave a product (CF_0) which contained only traces of cytochromes and phospholipid, yet had retained the characteristic ability of binding, and modifying, soluble F_1 [100].

The action of F_0 on soluble F_1 appears to be more than simple adsorption of F_1 on a structured matrix, since unpublished investigations [101] have shown that F_1 associated with mitochondria of the "petite" mutant of *Saccharomyces cerevisiae* is not inhibited by oligomycin and is rapidly inactivated in the cold. The F_1 bound to these respiration-deficient and largely non-functional mitochondria thus resembles in some respects the soluble enzyme, and differs from F_1 bound to the respiring mitochondria of the wild type [102]. Purified F_1 from the mutant has the same enzymic and immunological properties and the same molecular weight as purified wild-type F_1. Like the latter, it becomes cold-stable and sensitive to oligomycin on complex formation with beef heart F_0. This suggests that the "petite" mutation [103] in *S. cerevisiae* modifies an F_0-like mitochondrial component, rather than F_1 itself. The F_0-deficiency of the mutant mitochondria is evidently not a simple consequence of their respiratory deficiency; anaerobically grown wild-type yeast cells contain undifferentiated promitochondria which also lack a functional respiratory chain, yet contain membrane-bound F_1 that is cold-stable and inhibited by oligomycin [101, 103a].

Since F_1 catalyses an ATPase reaction [77] and forms complexes with ADP [104], it was assumed that F_1 in mitochondria catalyses the terminal, ATP-forming step of the energy-transport chain [1, 77]. However, *Lee* and *Ernster* reopened the question of the mode of action of F_1, and of coupling factors in general, with their observation that oxidative phosphorylation in submitochondrial particles of low phosphorylating capacity could be considerably increased by the addition of small quantities of oligomycin (< 0.4 µg per mg of mitochondrial protein). Larger amounts of oligomycin (> 0.4 µg per mg), on the other hand, inhibited oxidative phosphorylation. Since the stimulating action of oligomycin (which does not occur in mammals) evidently could not be explained by a direct participation in energy-transport, *Lee* and *Ernster* assumed that the stimulation of ATP synthesis by oligomycin was indirect, and resulted from inhibition of the "dissipative reaction" (Fig. 2, pathway 3), which in submitochondrial particles successfully competes with energy-transport for the primary high-energy intermediate. This interpretation of the stimulating effect of oligomycin was confirmed by *Fessenden* and *Racker* [79] and by *Lam et al.* [104a].

Lee and *Ernster* also tried to explain the stimulating action of the various coupling factors by an indirect effect of this type [105]. However, since they used submitochondrial particles that still contained considerable quantities of endogenous F_1 [79], their line of reasoning seemed doubtful, at least with regard to F_1. Indeed, their tacit assumption that oligomycin would stimulate oxidative phosphorylation even in particles completely devoid of F_1 was conclusively shown to be incorrect. *Racker* and *Horstmann* [106] obtained non-phosphorylating particles of extremely low F_1 content. While addition of F_1 and F_3 to these particles induced a significant respiration-coupled ATP synthesis, oligomycin alone was without effect. Stimulation by oligomycin was only observed in the presence of suboptimal amounts of F_1 (and an excess of F_3). Similar experiments by *Lam et al.* on FA-deficient beef heart particles indicated that the stimulation of oxidative phosphorylation by oligomycin also required FA [104a]. Furthermore, *Fessenden* and *Racker* [79] found that the effect of small quantities of oligomycin on beef-heart particles containing F_1 was completely blocked by a specific antiserum against beef-heart F_1. This clearly demonstrates that the stimulating effects of F_1 and of oligomycin are fundamentally different; it also suggests that the promotion of ATP synthesis by F_1 is at least partly due to an enzymic acceleration of a step in the energy-transport chain.

However, other experiments indicate that the action of F_1 as a coupling factor cannot be fully explained by an enzymic function [102]. F_1 isolated from normal yeast mitochondria stimulates oxidative phosphorylation in F_1-deficient bovine heart particles deficient in, but not completely devoid of F_1. This stimulation by the yeast enzyme requires the presence of enzymically active bovine heart F_1 in the test particles, but is not affected when the enzymic activity of the yeast enzyme bound to the bovine particles is almost completely inhibited by a specific antiserum. Thus yeast F_1 probably stimulates oxidative phosphorylation in bovine heart particles not by direct, *i.e.* enzymic, participation in the energy-transport chain, but (analogous to oligomycin) indirectly by inhibition of the competing dissipative reaction.

These experiments suggested, moreover, that a similar non-enzymic effect also contributes to the coupling action of bovine heart F_1, since the enzymic and physical properties of yeast F_1 and bovine F_1 are

virtually identical [102]. This non-enzymic effect of F_1 could be interpreted as a change in the structure of the mitochondrial membrane induced by F_1. F_1 would then act not as a catalyst, but as a membrane component, which in some unknown way prevents the spontaneous dissipation of the primary high-energy intermediate. However, while enzymic and "structural" effects are superimposed on each other in the binding of bovine heart F_1 to bovine heart particles, the interaction between yeast F_1 and bovine heart particles appears to involve only the "structural" effect.

A structural function of this nature could also explain why, according to ATPase measurements, F_1 accounts for at least 10 % of the protein of bovine heart particles [106]. It had previously been difficult to explain why a purely catalytic component of the energy-transport chain should be present in such large quantities.

A non-catalytic function is also indicated by the fact that F_1 stimulates the respiration-coupled, energy-dependent transhydrogenase reaction (Fig. 2, pathway 2). This effect of F_1, unlike its stimulating action on the respiration-coupled ATP synthesis, is not decreased by an antiserum against F_1 [107].

Treatment of bovine heart F_1 with dicyclohexylcarbodiimide represents an especially elegant means of differentiating the two F_1-effects. The chemically modified protein is enzymically inactive, yet as effective as a coupling factor as the enzyme from yeast [108].

While the existence of a "structural" effect of F_1 is thus very likely, it has not yet been directly documented experimentally. According to the "chemiosmotic" hypothesis, however, addition of F_1 to F_1-deficient beef heart particles should decrease their permeability to protons.

The foregoing sections show that a knowledge of the structure of the mitochondrial membrane is apparently essential to an understanding of oxidative phosphorylation. The last section of this survey is thus devoted to a brief discussion of some current questions relating to mitochondrial structure.

IV. The Structure of the Inner Mitochondrial Membrane

Mitochondria are composed of two membrane systems, an inner and an outer mitochondrial membrane. It is now firmly established that the two membranes differ in their ultrastructure [109–111], their chemical composition [112, 113], and their enzyme content [112–116].

The respiratory chain and oxidative phosphorylation are associated entirely with the inner mitochondrial membrane [112, 117].

Electron-microscopic studies on isolated, negatively stained mitochondria have shown that the inner mitochondrial membrane, unlike the outer one, is lined with densely and regularly spaced "knobs" about 80–90 Å in diameter, which are joined to the membrane continuum by cylindrical "stalks" [109–111, 118, 119]. Electron micrographs by *Smith* [118] and *Fernández-Morán et al.* [119] indicate, moreover, that this continuum itself consists of approximately globular "base pieces" about 90 Å in diameter (cf. Fig. 6).

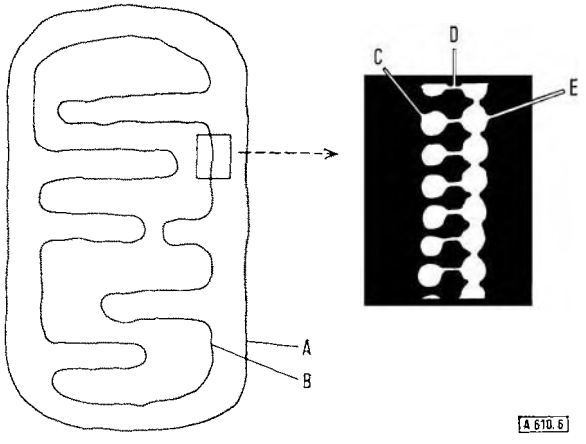

Fig. 6. Schematic representation of a positively stained miochondrion (left) and of the ultrastructure of the negatively stained inner mitochondrial membrane (right). A: outer membrane; B: inner membrane; C: "knob"; D: "stalk"; E: base piece.

The hypothesis that each "knob" represents a complete electron-transport chain [120, 121] proved to be untenable [2, 109, 118, 122]. The minimum molecular weight of an electron transport chain (1.2×10^6, cf. [123]) requires a sphere at least 170 Å in diameter, and is thus incompatible with the size of the membrane-bound "knobs". *Fernández-Morán et al.* [119] then suggested that each "knob" contains only a part of the respiratory chain, *i.e.* cytochrome oxidase. This possibility was also refuted, since treatment of mitochondrial particles with ultrasound [124, 125] or with trypsin and urea [117] led to

a loss of "knobs", without significant decrease in cytochrome content or electron-transport activity.

Racker et al. finally identified the "knobs" as the coupling factor F_1 (*i.e.* mitochondrial ATPase). Stepwise treatment of submitochondrial particles with trypsin and urea led to preferential degradation of the "knobs" and simultaneous loss of ATPase activity [97, 117]. Moreover, the individual molecules of highly purified, negatively stained F_1 preparations from bovine heart [97] and yeast [102] were indistinguishable from "knobs". Finally, it was possible to bind purified bovine heart F_1 to F_1-free mitochondrial membranes (F_0), thus restoring to the particles both ATPase activity and membrane-bound "knobs" [117, 97].

While a participation of the "knobs" in electron transport can now be definitely ruled out, the question of where and how the respiratory chain is anchored in the inner mitochondrial membrane cannot yet be answered. *Green* and *Tzagoloff* [126] speculate that each "base piece" represents one segment of the electron-transport chain, and that the electron transfer between the "base pieces" is effected by "mobile" redox components such as cytochrome c or coenzyme Q. This assumption is not supported by experimental observations of *Kagawa* and *Racker* [97], who obtained vesicle formation on addition of phospholipid to a complex of F_1 with CF_0 (see above). These vesicles were covered with numerous membrane-bound "knobs", and were morphologically indistinguishable from respiring submitochondrial bovine heart particles, although they were practically free from cytochromes and flavin.

The chemical and enzymic properties of the "stalk" are completely unknown. The localization and function of the "structural protein", first isolated by *Criddle et al.* [127] from bovine heart mitochondria, also remain to be established. This protein fraction, which is insoluble at pH values near 7, lacks prosthetic groups, but forms water-soluble complexes with myoglobin, cytochrome b, cytochrome aa_3, and phospholipids [127, 128, 81]. *Criddle et al.* [127] therefore assumed that the protein functions as the basic skeleton of the mitochondrial respiratory chain, ensuring the correct alignment of the individual carriers. Evidence from other laboratories suggested, moreover, that "structural protein" also functions in oxidative phosphorylation [99], the control of the tricarboxylic acid cycle [128a], and the extrachromosomal control of mitochondrial function [129].

Quantitative studies on complex formation with myoglobin and cytochrome c and end-group determinations suggest that "structural protein" is homogeneous [130–130b]. On the other hand, electrophoresis in acrylamide gels reveals numerous bands [131–133a]. The considerable discrepancies between the results of amino-acid analyses carried out on bovine heart "structural protein" in various laboratories [127, 129, 134] also argue against homogeneity. According to *Kopaczyk et al.* [135] the protein does not even seem to be the basic skeleton of the mitochondrial respiratory chain, as originally assumed; for example, it could be separated from individual segments ("complexes") of the respiratory chain (cf. [136]) without loss of electron-transport activity. However, these experiments are by no means conclusive, since it was not proved that "structural protein" had been completely removed. *Woodward* and *Munkres* [137], on the other hand, doubt the existence of a specific "structural protein" of the inner mitochondrial membrane, since they were able to isolate "structural protein", not only from mitochondria, but also from nuclei, from microsomes, and even from a high-speed supernatant. On the other hand, experiments with yeast cells showed that "structural protein" of mitochondria differs from that of other cell fractions in forming complexes with ATP, which are dissociated by the glycoside atractyloside [137a].

Existence, specificity, and function of a "structural protein" of the inner mitochondrial membrane thus remain an open question. Since electrophoretic investigations on "structural protein" fractions are subject to some uncertainty because of their low solubility and their tendency toward complex formation, the author feels that also the question of homogeneity is still unsettled.

Reports on the isolation of an actomyosin-like "contractile protein" from mitochondria [136, 138, 139], on the other hand, have definitely been shown to be incorrect. The published results could not be reproduced [140], and in one case appear to be explained by the isolation of an impurity in the mitochondrial fraction under

investigation[141]. However, the participation of an unknown "contractile protein" in energy-coupled mitochondrial volume-changes[73] or in oxidative phosphorylation (*e.g.* in the sense of the "conformational" hypothesis) is thereby by no means excluded.

Outlook

The problem of oxidative phosphorylation appears to be adequately defined from the phenomenologic point of view, *i.e.* most of the possible reactions of the primary highenergy intermediate are probably known or can be predicted.

Research on oxidative phosphorylation is being concentrated increasingly on structural aspects, a strong incentive being provided by the steady improvement of electron-optical methods and by the restatement of the "chemiosmotic" hypothesis. Promising developments can be expected from experiments with artificial lipid bilayers, whose properties strikingly resemble those of biological membranes. If individual purified coupling factors could be bound to such artificial membranes, it might be possible to study the influence of this binding on the catalytic properties of the proteins and on the electrical conductivity of the membrane or a membrane potential. This experimental system could also furnish direct proof for a "structural" function of coupling factors. The long-range objective of such experiments would be the reconstruction of the energy-transport chain and the mitochondrial inner membrane.

Many of the views expressed in this article are the outcome of extensive discussions with Dr. M. E. Pullman and Dr. P. C. Hinkle, whom I should like to thank at this point. I am grateful to Prof. H. Tuppy, Prof. E. Racker, and my colleagues at the Institut für Biochemie, Vienna, for critical examination of the manuscript. Much of the author's own work described here was made possible by a Fulbright Travel Grant.

Hexamethylphosphoramide

BY H. NORMANT[*]

Growing interest is being shown in the role of the solvent (particularly polar solvents) in chemical reactions[1–4]. The most remarkable polar aprotic solvent appears to us to be the hexamethylated triamide of orthophosphoric acid, $OP(N(CH_3)_2)_3$, which is known as hexamethylphosphoramide or tris(dimethylamino)phosphine oxide. Hexamethylphosphoramide[5–7] has recently been studied with respect to its solvent properties for gases[5], for many organic and inorganic salts[7], and for polymers[5], as well as its use as a polymerization co-catalyst. However, these aspects are not considered in the present paper, which deals with the physical and chemical properties of hexamethylphosphoramide, and in particular with its use as a reaction medium. Our own work on hexamethylphosphoramide began in 1961, and until then very little work had been done on this compound. Even in a paper published by Parker[1b] in 1965, very little reference is made to hexamethylphosphoramide.

I. Physical and Chemical Properties of Hexamethylphosphoramide (HMPT)

A. Preparation

Michaelis[8] prepared triamides of orthophosphoric acid by treatment of phosphorus oxide trichloride with an excess of secondary amine. The reaction with dimethylamine leads in accordance with eq. (a) to hexamethylphosphoramide (HMPT):

$$OPCl_3 + 6\ HN(CH_3)_2 \rightarrow OP(N(CH_3)_2)_3 + 3\ H_2N(CH_3)_2^{\oplus}Cl^{\ominus} \qquad (a)$$

The chlorine atoms can be replaced one at a time. The first replacement is strongly exothermic, whereas the other steps proceed less readily, and only on heating. The reaction is

generally carried out in an inert organic solvent[7]. The quantity of $HN(CH_3)_2$ required can be reduced by the addition of Na_2CO_3 or NH_3. After removal of the precipitated chlorides, the filtrate is rectified.

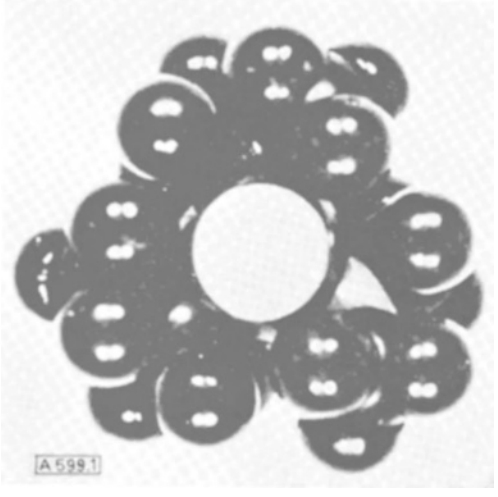
HMPT is a colorless mobile liquid, which is miscible with water in all proportions. It is also miscible with many polar and nonpolar organic solvents, but not with saturated hydrocarbons. It can be extracted from aqueous solution by chlorinated solvents, with which it forms complexes[9]. This property makes it superior to amides of carboxylic acids (cf. Table 1). The toxicity of HMPT is low: LD ≈ 6 g/kg[7] for oral administration to rats.

Table 1. Partition coefficients of a few acid amides between water and chlorinated hydrocarbons.

	Dimethyl-formamide	*N*-Methyl-acetamide	HMPT
$CHCl_3/H_2O$	0.77	0.099	5.53
CH_2Cl_2/H_2O	0.57	0.088	2.07
$ClCH_2-CH_2Cl/H_2O$	0.29	0.039	0.58

B. Structure

The HMPT molecule is pyramidal, as can be seen from the Stuart-Briegleb model (see Fig. 1). The polar or double-bond character of the P–O bond varies



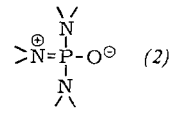


Fig. 1. Stuart model of $OP(N(CH_3)_2)_3$ (HMPT). The phosphorus atom is concealed by the oxygen atom.

according to the other substituents[10,11]; 50% ionic character must be assumed in HMPT (see formula *(1)*).

$$F_3P{=}O \quad ((CH_3)_2N)_3\overset{\delta\oplus}{P}{-}\overset{\delta\ominus}{O} \quad (CH_3)_3\overset{\oplus}{P}{-}\overset{\ominus}{O}$$

(1)

Formula *(2)* has also been proposed[12].

(2)

The symmetrical distribution of the positive charge over the  grouping and the high electron density on the oxygen give rise to a large dipole moment and an unusually high basicity.

C. Physical Constants

Table 2. Physical constants of HMPT.

Physical quantity	Numerical value
M.p. (°C)	7.20
Cryoscopic const.	6.93 ± 0.07 [13]

D. Basicity

A particularly suitable method for the determination of the ability of a solvent to contribute part of a pair of electrons to a compound AH (*e.g.* $CHCl_3$), *i.e.* the basicity of the solvent, is NMR spectroscopy [26]. For each solvent there is a value $\Delta\delta_\infty$ ($CHCl_3$) = $\delta_\infty - \delta$ (cf. Table 4) [3, 27, 28], where δ_∞ and δ respectively are the chemical shifts at infinite dilution of a solution of chloroform in the solvent in question and in an inert solvent such as cyclohexane.

Table 4. Comparison of the $\Delta\delta_\infty$ values [3, 27, 28] of various solvents.

Solvent	$\Delta\delta_\infty$	Solvent	$\Delta\delta_\infty$
Cyclohexane	0	Cyclohexanone	1.06
Dioxane	0.64	$OP(OC_4H_9)_3$	1.28
$P(N(CH_3)_2)_3$	0.68	DMF	1.30
Ether	0.70	DMSO	1.34
THF	0.80	Tetramethylurea	1.37
Acetone	0.94	HMPT	2.03

A similar basicity scale was obtained from the C–Br vibrations in the IR spectra of alkyl or vinyl bromides. These C–Br vibrations are strongly dependent on the basicity of the solvent. It could be shown [28, 29] that the solvent-bromide interaction varies in the same manner as the solvent-proton interaction.

Table 5 [4] shows a comparison of the polar aprotic solvents in current use. HMPT has the lowest dielectric constant and the highest basicity of all the solvents listed.

Table 5. Physical properties of solvents.

Solvent	DC	μ (Debye)	Δδ (ppm)
Dimethylformamide	36.7	3.90	0.78
Dimethylsulfoxide	49	4.03	1.05
Ethylene glycol carbonate	95	4.86	0.41
Tetramethylenesulfone	44	4.7	0.78
HMPT	30	4.3–5.3	1.89

E. Hexamethylphosphoramide as an Electron Donor in Complexes

1. Complexes with Organic Compounds

The donor properties of some OP compounds in relation to compounds containing active hydrogen vary in the following order [31]:

$$((CH_3)_2N)_3PO > (C_2H_5O)_3PO > (C_2H_5S)_3PO > (C_6H_5S)_3PO > ((C_2H_5)_2N)_3PO$$

(It is interesting to note that HMPT and its hexaethyl analogue are situated at opposite ends of this series.)

The acceptor properties of the chlorinated hydrocarbons studied [23, 30] vary in the order:

$$CHCl_3 > Cl_2CH-CCl_3 > Cl_2CH-CHCl_2 > CH_2Cl_2$$

Mono- and dicarboxylic acids (*e.g.* nicotinic and isonicotinic acids, *o*- and *m*-methylbenzoic acids), phenols and diphenols (α- and β-naphthols, chlorophenols [33]), alcohols and aromatic amines, glycols, *etc.* react with HMPT to form stable crystalline stoichiometric complexes [32] (cf. Table 6). An H donor can be liberated from its complex by a stronger H donor (*i.e.* in this case a weaker acid). Thus water or methanol displace carboxylic acids. Terephthalic and isophthalic acids could be separated by fractional crystallization of the complexes followed by liberation of the acids [32].

IR studies on the stability of hydrogen halide-ketone and hydrogen halide-acid hydrazide complexes [173] confirm the conclusion that the association constants decrease in the order HBr > HCl > HF, corresponding to the decrease in acidity from HBr to HF.

Table 6. HMPT Complex formation.

HMPT-Complex with:		M.p. (°C)
o,- *m*-, *p*-$(HO_2C)C_6H_4$	2:1	70/52/128
p-$(OH)_2C_6H_4$	2:1	152
$HOCH_2-C_6H_5$	1:1	10
$H_2N-C_6H_5$	1:1	<0
p-$H_2N-C_6H_4-C_6H_4-NH_2$(*p*)	2:1	132
$HOCH_2-CH_2OH$	2:1	−20

HMPT also forms complexes with unsaturated hydrocarbons [32] (*e.g.* $HC\equiv CH$, $CH\equiv C-CH=CH_2$, $CH\equiv C-C_6H_5$, $CH_2=CH-CH=CH_2$, $CH_2=CH-C_6H_5$); however, the structure of these complexes is not yet known.

2. Complexes with Lewis Acids

Basic solvents form complexes with Lewis acids, the stability of the complex increasing with increasing basicity of the solvent; *e.g.* $(C_2H_5)_2O\cdot BF_3 < THF\cdot BF_3 < OP(N(CH_3)_2)_3\cdot BF_3$.

A number of crystalline complexes of HMPT are known: $OP(N(CH_3)_2)_3\cdot BF_3$ (m.p. 175 °C) [34]; $OP(N(CH_3)_2)_3\cdot BCl(C_6H_5)_2$ (m.p. 159–160 °C) [35]; $OP(N(CH_3)_2)_3\cdot OPCl_3$ (m.p. 170–180 °C); $OP(N(CH_3)_2)_3\cdot OPBr_3$ (m.p. 165–180 °C).

It is known from IR data [12] and dipole moment measurements [36] that metal salts also form complexes with HMPT by solvation of the cation (*via* the oxygen of the OP group) (see Table 7). Neutral molecules $MX_2\cdot 2\ OP(N(CH_3)_2)_3$ and ions $[M\cdot 4\ OP(N(CH_3)_2)_3]^{2\oplus}$ have a tetrahedral structure [12, 36].

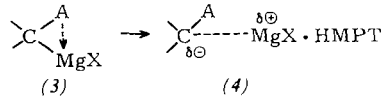
Table 7. Types of metal salt–HMPT Complexes.

M	Complex	Anion
Ag	$M(HMPT)X$	Halide
Co, Ni, Mn, Fe^{II}, Cu^{II}	$M(HMPT)_2X_2$	Halide
Pb^{II}	$M(HMPT)_3X_2$	Halide
Mg, Zn, Cd	$M(HMPT)_4X_2$	Halide
Co, Ni, Mn, Fe^{II}	$M(HMPT)_4X_2$	$ClO_4^{\ominus}$
Cr^{III}, Fe^{III}	$M(HMPT)_6X_3$	Halide
Ti, Sn	$M(HMPT)_2X_4$	Halide

HMPT-complexes of the tetrachlorides and tetrabromides of thorium and uranium have recently been detected, and their stabilities were compared with those of the corresponding dimethyl sulfoxide complexes [37].



The tendency of a polar solvent to form complexes with a Lewis acid generally increases with increasing basicity of the solvent, *i.e.* the tendency increases in the order DMSO < DMF < HMPT.

3. Complexes with Organometallic Compounds

The stability of solvated Grignard compounds increases with increasing stability of the solvent [34]: $2(C_2H_5)_2O{\cdot}RMgX < 2THF{\cdot}RMgX < 2OP(N(CH_3)_2)_3{\cdot}RMgX$.

Thus less basic solvents can be displaced from the complex by more basic solvents [37]. Magnesium compounds of the type MgR_2 dissolve in HMPT [38], while compounds of the type RMgBr precipitate out as $MgBr_2{\cdot}2\,OP(N(CH_3)_2)_3$; $MgBr_2$ forms the stable adduct $MgBr_2{\cdot}4\,OP(N(CH_3)_2)_3$ [39]. This generally strong solvation has the following consequences:

Organomagnesium compounds of the type *(3)* (A = OR [40], halogen [41]) exhibit autosolvation. Their stability and reactivity is increased by the addition of $OP(N(CH_3)_2)_3$, since this leads to disappearance of the "carbenoid" form *(3)* in favor of an ionic structure *(4)*.

(3) *(4)*

It has also been found that the rate of the exchange reaction

$$(CH_3{-}CH{=}CH{-}CH_2)_2Zn + CdCl_2 \rightleftarrows (CH_3{-}CH{=}CH{-}CH_2)_2Cd + ZnCl_2 \qquad (b)$$

decreases (THF > DMSO > HMPT) with increasing basicity of the solvent, *i.e.* with increasing solvation of the cadmium ion [42]. The solvation in HMPT even makes possible the direct synthesis of organometallic compounds from RX and magnesium or cadmium [43]. Unsaturated bromine compounds react at 0 °C; only the iodides react in the saturated series.

The isolable, acetone-soluble complex $CdBr_2{\cdot}4OP(N(CH_3)_2)_3$ (m.p. 112 °C [43]) is formed in this way, but can also be obtained directly from $CdBr_2$ and HMPT.

F. Hexamethylphosphoramide in Electrochemistry

Until recently very little use had been made of HMPT as a solvent for electrochemical processes. For example, no mention has been made of its use in polarography. A stable $Ag^{\oplus}/Ag$ reference electrode can be used for voltametry [44] in HMPT. Solutions of $NaClO_4$ and $LiClO_4$ and their mixtures have been specially studied in relation to their water content. The results indicate that the behavior of HMPT differs from that of other solvents [45].

HMPT can also be used as a solvent for electrolysis [46]. Metal salts dissolve to give ion pairs and in some cases even form free ions. Anions are practically unsolvated (steric hindrance around the $P^{\delta\oplus}$), whereas cations are strongly solvated (owing to the sterically easy accessibility of the $O^{\delta\ominus}$ atom). Thus $(C_6H_5)_3CM$, $(C_6H_5)_2CHM$, and $C_6H_5CH_2M$ (M = alkali metal or MgX) dissolve to give intensely red solutions (see Section IV). $C_6H_5CH_2MgCl$ prepared in ether solution is colorless; on addition of HMPT, however, the solutions assumes the characteristic red color of the benzyl anion [45a].

Though to our knowledge no organometallic compounds have so far been electrolysed in HMPT, metal salts such as $MgBr_2{\cdot}2(C_2H_5)_2O$ and CaI_2 have been electrolysed with the aid of a consumable Mg or Cd anode and a Pt cathode. In both cases 2,3,4,5-tetrahydrobenzophenone present in the solution could be reduced in a yield of more than 80% to 1,2,3,4,5,6-hexahydrobenzophenone.

G. Polarity of the Solvent

Polar solvents can give rise to various molecular interactions. These polarity effects are related to a first approximation to the dipole moments μ, the dielectric constants ε, and $\Delta\delta$ the chemical shift of the $CHCl_3$ proton in the ^1H-NMR spectrum. For example, a nucleophilic substitution in accordance with eq. (c) may be carried out and compared in various solvents. The rate constants k and activation energies $E^{\neq}$ obtained are shown in Table 8. The special position of

Table 8. Data for the reaction (c) in various solvents.

Solvent	$k_{25\,°C}$ ($l{\cdot}mole^{-1}\,sec^{-1}$)	$E^{\neq}$ ($kcal{\cdot}mole^{-1}$)

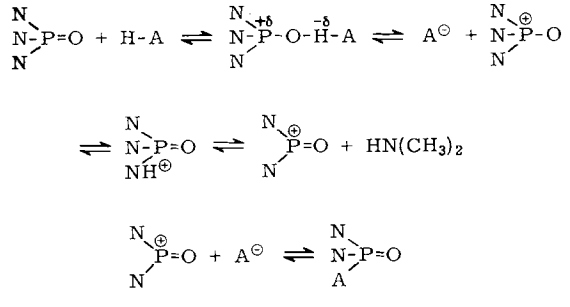
II. Chemical Reactions of Hexamethylphosphoramide



A. Reaction with Nucleophiles

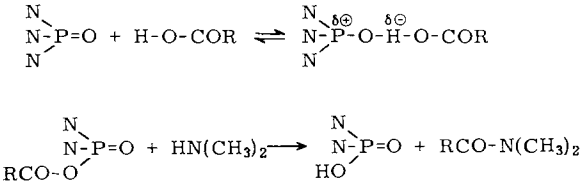
HMPT is remarkably stable to nucleophiles (evidently because of steric screening of the $P^{\delta\oplus}$), and unlike the amides of carboxylic acids it is not hydrolysed in alkaline media (alkali metal hydroxides do not attack below 80 °C [127–132]; however, HMPT appears to react at 110–120 °C [151]). Thus HMPT is an ideal solvent for reactions with nucleophilic or basic reactants (cf. also Sections IV and V) [49].

B. Reaction with Electrophiles

HMPT is attacked by both Brönsted and Lewis acids. A reagent $H^{\oplus}A^{\ominus}$ brings about the replacement of one or more $N(CH_3)_2$ groups by A.

It is likely that a 1:1 complex is first formed by binding of the acid HA (*e.g.* HCl) *via* the oxygen of the OP group. This more or less stable complex gives a corresponding substitution product when heated. The reaction may be assumed to proceed by the following mechanism:

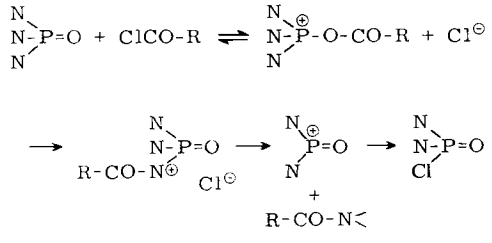
This reaction also takes place with the other $N(CH_3)_2$ groups though less readily. In aqueous acid solution the $N(CH_3)_2$ groups are replaced by OH (HA = H_2O).



The rate of hydrolysis is of the same order of magnitude as that of a $-CO-N(CH_3)_2$ group [15].

The complex HMPT·$CHCl_3$ is also decomposed by heat. $HO-P(N(CH_3)_2)_2$ has been detected among the reaction products by NMR spectroscopy [174]. The reaction is assumed to proceed by the above mechanism, *i.e. via* a pentacoordinated intermediate, which seems rather unlikely to us (NMR investigations are in progress).

Carboxylic acids often give very stable 1:1 complexes with HMPT. At 180–200 °C, transamidation takes place [50]:



$$OP(N(CH_3)_2)_3 + 3\ RCO_2H \rightleftharpoons OP(OH)_3 + 3\ RCO-N(CH_3)_2.$$

A mechanism similar to that described would involve the formation of a mixed anhydride of the phosphorodiamidic acid and the carboxylic acid. The reaction

could also be extended to aromatic, unsaturated, and heterocyclic carboxylic acids (*e.g.* acetic, valeric, lauric, monochloroacetic, trichloroacetic, succinic, adipic, phthalic, benzoic, *p*-nitrobenzoic, *m*-toluic, and isonicotinic acids) and to sulfonic acids (yields = 50 to 95%). When the HMPT and the acid are present in a molar ratio of 1:3, H_3PO_4 and the amide of the acid are formed [51].

This substitution reaction does not appear to have been applied to alcohols as yet. Phenols give relatively stable 1:1 complexes (cf. Section I. E. 1) of unknown structure with HMPT. Acyl chlorides undergo nucleophilic attack by HMPT even in the cold; when the complex is heated, $N(CH_3)_2$ is replaced by Cl.

HMPT also reacts with chlorides of mineral acids (*e.g.* $SOCl_2$ and $POCl_3$). The monochloro derivative *(5)* could in principle be formed by a reaction [52] in accordance with eq. (d) or by a reaction [53] in accordance with equation (e).

$$2\ OP(N(CH_3)_2)_3 + OPCl_3 \rightleftharpoons 3\ \underset{(5)}{OP(Cl)(N(CH_3)_2)_2} \qquad (d)$$

$$OP(N(CH_3)_2)_3 + OP(N(CH_3)_2)Cl_2 \rightleftarrows 2\ \underset{(5)}{OP(Cl)(N(CH_3)_2)_2} \qquad (e)$$

[47] *E. M. Kosower*, J. Amer. chem. Soc. *80*, 3253 (1958); J. chem. Physics *61*, 230 (1964).

[53] *M. Pianka* and *B. D. Owen*, J. appl. Chem. *5*, 525 (1955); Chem. Abstr. *50*, 10642d (1956).

The alkali metal derivatives $OP(N(CH_3)_2)_2M$ (M = Li, Na, K) can be obtained in excellent yield from *(5)* [54, 18]. These in turn react with electrophilic reagents such as CH_3Br, C_2H_5Br, $C_7H_{15}Br$, $C_6H_5CH_2Cl$, CH_3OCH_2Cl, $C_4H_9OCH_2Cl$, and $C_4H_9SCH_2Cl$ to form phosphonic diamides.

C. Reaction with Alkali Metals

The reaction of HMPT with alkali metals leads *via* a radical-anion (see Section V) to two anions, the dimethylamine anion *(6)* and the diamidophosphite anion *(7)*.

$$OP(N(CH_3)_2)_3 + 2\ M \longrightarrow \begin{cases} (CH_3)_2N^{\ominus}\ M^{\oplus} & (6) \\ OP(N(CH_3)_2)_2\ M^{\oplus} & (7) \end{cases}$$

These react with alkyl bromides to give tertiary amines and phosphonic diamides. The reaction with benzyl chloride, on the other hand, does not lead to the expected phosphonic diamide *(9)*; on the contrary, the diamide *(8)* is formed by reaction with two molecules

$$((CH_3)_2N)_2PO\text{-}CH_2\text{-}C_6H_5 \underset{\ominus N<}{\rightleftharpoons} ((CH_3)_2N)_2PO\text{-}\overset{\ominus}{C}H\text{-}C_6H_5$$
(9)

$$\longrightarrow ((CH_3)_2N)_2PO\text{-}CH(C_6H_5)\text{-}CH_2\text{-}C_6H_5$$
(8)

of benzyl chloride. However, compound *(9)* could be obtained from $OP(N(CH_3)_2)_2M$ and benzyl chloride in an ether/benzene mixture. $NaNH_2$ can actually replace a methylene H atom in *(9)* by Na in HMPT as solvent; the compound *(8)* is obtained in good yield by the addition of benzyl chloride. Thus in the mixture *(6)*/*(7)*, the strong base *(6)* converts the compound *(9)* into a carbanion as it is formed; the carbanion is immediately benzylated to form *(8)*.

The presence of the base *(6)* also explains why a mixture *(6)*/*(7)* can metallate a hydrocarbon so weakly acidic as triphenylmethane (a blood-red solution is formed). In benzene [55], the radical-ion is not stabilized, but decomposed. The weak base *(7)* cannot be the metallating agent, since $OP(N(CH_3)_2)_2M$ does not react with triphenylmethane even at high temperatures; on the contrary, $OP(H)(N(CH_3)_2)_2$ [56] liberates triphenylmethane from triphenylmethylsodium.

The compound *(7)* can add to unsaturated compounds. With azobenzene, hydrolysis yields the adduct *(10)* [57], while with phenylacetylene (or α-bromostyrene) the adduct *(11)* is formed [58]. It is interesting to note that compound *(7)* can bring about the reductive dimerization of non-enolizable ketones with formation of epoxides *(12)* [59]. This new epoxidation method has also been applied to aldehydes ArCHO.

$$\begin{matrix} C_6H_5\text{-}N\text{-}NH\text{-}C_6H_5 \\ | \\ OP(N(CH_3)_2)_2 \end{matrix} \quad (10)$$

$$\begin{matrix} C_6H_5\text{-}CH\text{-}CH_2\text{-}P(N(CH_3)_2)_2 \\ | \qquad\qquad\quad \| \\ (N(CH_3)_2)_2PO \qquad O \end{matrix} \quad (11)$$

$$2\ Ar_2CO + \overset{\ominus}{O}P(N(CH_3)_2)_2M^{\oplus} \longrightarrow$$

$$Ar_2C\text{-}CAr_2 + O{=}P\text{-}N(CH_3)_2$$
$$\quad\ \diagdown O \diagup \qquad\quad |$$
$$\qquad O \qquad\quad O^{\ominus}\ M^{\oplus}$$
(12)

The reaction is also possible with $OP(OC_2H_5)_2M$ in place of $OP(N(CH_3)_2)_2M$ (M is preferably Na) [60].

D. Catalytic Action of Hexamethylphosphoramide

The reactions discussed in this section proceed more readily in the presence of HMPT, though this compound is not consumed in the reactions.

The formation of carbodiimides from isocyanates is accelerated by the addition of a small quantity of a polar solvent [61]. HMPT is much more effective than DMSO, as is shown by the data in Table 9 for the synthesis of diphenylcarbodiimide.

Table 9. Catalysis of the diphenylcarbodiimide synthesis.

Catalyst	C_6H_5–N=C=O	Temp. (°C)	Time (h)	Yield (%)
DMSO 0.006 mole	0.45 mole	162–164	2.5	13
HMPT 0.008 mole	0.45 mole	113–135	1.6	27

It has been assumed [6] that a cyclic imide *(13)* is formed as an intermediate:

$$\begin{matrix} N \\ N\text{-}\overset{\oplus}{P}\text{-}\overset{\ominus}{O} \\ N \end{matrix} + R\text{-}N{=}CO \rightleftharpoons \begin{matrix} \gtrdot P\text{-}O \\ | \quad | \\ R\text{-}N\text{-}C{=}O \end{matrix} \rightleftharpoons CO_2 + \gtrdot P{=}N\text{-}R$$

$$\gtrdot P{=}N\text{-}R + R\text{-}N{=}C{=}O \longrightarrow \begin{matrix} \gtrdot P\text{-}N\text{-}R \\ | \quad | \\ O\text{-}C{=}N\text{-}R \end{matrix}$$
(13)

$$\longrightarrow \gtrdot P{=}O + R\text{-}N{=}C{=}N\text{-}R$$

HMPT increases the rate of substituent exchange between trialkylboranes and 1-alkenes [62], *e.g.*:

$$B(C_4H_9)_3 + CH_2{=}CH\text{–}(CH_2)_7\text{–}CH_3 \rightarrow$$
$$(C_4H_9)_2B\text{–}(CH_2)_9\text{–}CH_3 + CH_2{=}CH\text{–}CH_2\text{–}CH_3$$

In the presence of 0.5 to 15% of HMPT, dismutation of chlorosilanes takes place at fairly low temperatures[63], *e.g.* in accordance with eq. (f), probably in three steps: removal of a proton by the basic solvent, reduction by $H^{\ominus}$, and regeneration of the HMPT.

$$H_3C\text{-}SiCl_2H + H^{\ominus} \rightleftharpoons H_3C\text{-}SiClH_2 + Cl^{\ominus}$$

$$2\ H_3C\text{-}SiCl_2H \rightleftharpoons H_3C\text{-}SiCl_3 + H_3C\text{-}SiClH_2 \quad (f)$$

III. Hexamethylphosphoramide as a Reaction Medium with Electron Donor Properties

A. Anion Formation or Transmetallation

Hydrogen-metal exchange reactions lead to the formation of a salt or another organometallic compound:

$$AH + MR \rightleftharpoons RH + MA \text{ (or } M^{\oplus} + A^{\ominus})$$

The equilibrium lies to the right-hand side when AH is more strongly acidic than RH or when the base $R^{\ominus}$ is stronger than the base $A^{\ominus}$. (The acidities of various compounds AH are given in Table 10.)

Table 10. Acidity of various compounds.

AH	pK_a	AH	pK_a
CH_4	50	liq. NH_3	34
$C_6H_5CH(CH_3)_2$	37	$C_6H_5NH_2$	27
$(C_6H_5)_2C{=}CH{-}CH_3$	36	Acetone	19
$C_6H_5CH_3$	37	$(CH_3)_3COH$	19
$(C_6H_5)_2CH_2$	35	$CH_3{-}OH$	16
$(C_6H_5)_3CH$	33	H_2O	14
$HC{\equiv}CH$	26	$C_6H_5{-}OH$	9.9
Fluorene	25	Acetylacetone	9
Indene	21	C_6H_5SH	8
$C_6H_5C{\equiv}CH$	21	*p*-Nitrophenol	7.2
Cyclopentadiene	17	Pyrrole	5

The solvent plays an important part in exchange reactions of this type. Solvents possessing electron donor properties favor ionization, solvation (particularly of the cations $M^{\oplus}$), and dissociation of AH and MR. This is particularly true of HMPT, which is the best electron donor of all the common aprotic solvents, and also has excellent solvation properties. For example, it causes strong solvation of the alkali metal cations and formation of highly reactive free anions.

1. Alkoxide and Phenoxide Anions[64]

Alcohols and phenols, which are relatively strong acids, react readily with alkali metal hydrides and amides. The advantage of HMPT is that stoichiometric quantities of ROH or ArOH may be used, and since the $RO^{\ominus}$ and $ArO^{\ominus}$ anions are not solvated, the reactants are more reactive than in excess ROH or ArOH with autosolvated anions. It is even possible in HMPT to use such weakly acidic reactants as tert-butyl alcohol or allyl alcohol; diols give dianions under these conditions. Alkali metal carboxylates can be satisfactorily prepared in HMPT and converted into esters; this avoids the conventional preparation *via* silver carboxylates. Alkali metal salts have extremely high or even unlimited solubilities in HMPT[64].

2. Amide Anions[64]

Alkylamines are too weakly acidic to be converted into alkali metal amides by the action of alkali metal hydrides or amides (M = Na, K, Ca); the reaction takes place only with M = Li[65].

$$H_3C{-}NH_2 + MNH_2 \rightleftharpoons H_3C{-}NH{-}M + NH_3$$

In the case of higher alkylamines the more strongly basic organometallic compounds must be used.

On the other hand, arylamines ArNHR (R = H, alkyl, aryl), indole, carbazole, and phenothiazine react with NaH or $NaNH_2$ at room temperature in HMPT. The dianion $C_6H_5N^{2\ominus}$ can be formed from aniline. Amides of carboxylic acids and imides react readily even in the cold. The Na derivatives of indole, acetanilide, and phthalimide have unlimited solubility in HMPT.

3. Carbanions from Hydrocarbons

The rate of a hydrogen-metal exchange depends here on the acidity of the hydrocarbon and the basicity and polarity of the solvent.

a) Alkynes

Grignard compounds react in the cold with 1-alkynes in polar solvents as indicated in eq. (g)[66]; organozinc compounds react similarly in accordance with eq. (h)[67]. The accelerating effect of the solvent (HMPT is again the best) can be seen from Table 11[67].

$$R{-}C{\equiv}C{-}H + (CH_3)_2CH{-}MgCl \rightarrow R{-}C{\equiv}C{-}MgCl + C_3H_8 \quad (g)$$

$$2\ C_6H_5{-}C{\equiv}CH + Zn(C_2H_5)_2 \rightarrow (C_6H_5{-}C{\equiv}C)_2Zn + 2\ C_2H_6 \quad (h)$$

Table 11. Half-times of the reaction (h) at 50 °C in polar solvents [67].

THF	DMF	DMSO	HMPT
2.15 h	270 sec	200 sec	< 8 sec

[63] French Pat. 1444735 (March 19th, 1965), Rhône Poulenc.

[64] *H. Normant* and *T. Cuvigny*, Bull. Soc. chim. France *1965*, 1867.

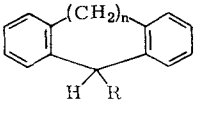
[65] *E. Rengade*, Ann. Chim. Physique *11* (8), 348 (1907).

[66] *H. Normant* and *T. Cuvigny*, Bull. Soc. chim. France *1964*, 2004.

[67] *O. Okhlobystin* and *L. Zakharkin*, Ž. org. Chim. *3*, 257 (1965).

The behavior of 1-alkynes in HMPT depends on the base present as the other reactant [68]. Thus NaH does not react either with phenylacetylene or with acetylene. Higher 1-alkynes such as 1-heptyne isomerize to give a mixture of heptynes, in which the principal component is the 2-alkyne. The more strongly basic alkali metal amides, *e.g.* $NaNH_2$, on the other hand, react at room temperature to form 1-alkynides such as $R-C\equiv C-Na$. However, phenylacetylene and acetylene are not converted into the sodium derivatives in pure HMPT, since they form complexes with HMPT.

b) Triphenylmethane



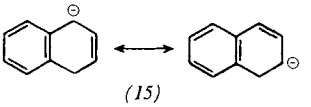
Triphenylmethylmagnesium halides cannot be prepared from triphenylmethane and Grignard compounds in weakly polar solvents such as ether or tetrahydrofuran; however, this reaction takes place with isopropylmagnesium chloride at 90 °C in HMPT [69], as is shown by the blood-red color of the solution.

Triphenylmethane cannot be metallated with alkali metal amides or hydrides (M = Li, Na, K) in tetrahydrofuran (stronger bases such as benzylsodium or allylsodium are required [70]), but is metallated even at room temperature in HMPT; the HMPT solutions are stable. Compounds $(C_6H_5)_3CM$ (M = Li, Na, K) have so far been prepared with alkali metal amides in liquid ammonia. Triphenylgermane can be metallated in a similar manner. Lithium aminoacetylides also react with triphenylmethane in HMPT as indicated in eq. (i) [71].

$$\text{N}-\text{C}\equiv\text{C}-\text{Li} + (C_6H_5)_3CH \rightarrow \text{N}-\text{C}\equiv\text{CH} + (C_6H_5)_3CLi \qquad \text{(i)}$$

c) Diphenylmethane

Diphenylmethane and the related hydrocarbons *(14a)* to *(14d)* can also be metallated in HMPT [72].



(14a), R = H, n = 0
(14b), R = C_2H_5, n = 0
(14c), R = H, n = 1
(14d), R = H, n = 2

Diphenylmethane is much less acidic than triphenylmethane, and reacts with isopropylmagnesium chloride only in HMPT and not below 100 °C (reaction recognized from the red color). However, it can be metallated with alkali metal amides and hydrides even at room temperature in HMPT. In less polar solvents, organosodium compounds must be used.

Fluorene *(14a)* can be converted into 9-fluorenylmagnesium chloride at 135–140 °C in xylene; this reaction proceeds at 40 °C in HMPT. Bis(9-fluorenyl)zinc can also be prepared in HMPT [67]. The acidic 9,10-dihydroanthracene *(14c)* can be metallated with isopropylmagnesium chloride or with sodium hydride even at room temperature. Dibenzocycloheptadiene *(14d)* reacts with $NaNH_2$ in HMPT, even in the cold, to give the deep orange 5-carbanion.

d) Hydrocarbons with Diene Structural Units [72]

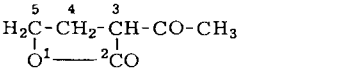
Indene reacts with ethylmagnesium bromide at 100 °C in weakly polar solvents to form the mesomeric indenylmagnesium bromide, while the analogous reaction with isopropylmagnesium chloride in HMPT takes place at 30 °C. The strongly exothermic metallation of indene with sodium hydride in HMPT is best carried out at 0 °C; an orange-red anion is formed. 1-Alkylated indenes behave similarly. An H ↔ MgX exchange is possible at 35 °C in HMPT; the mesomeric anion is intensely red. The anions of the metallation products of 1,4-cyclohexadiene and 1,4-dihydronaphthalene exhibit a remarkable tendency toward aromatization [72],

(15)

$H_5C_6-CH=CH-\overset{\ominus}{C}H-C_6H_5$ *(16)*

The red anion *(15)* is formed in HMPT with isopropylmagnesium chloride at 90–95 °C; $NaNH_2$ leads to considerable polymerization of 1,4-dihydronaphthalene even in the cold.

1,3-Diphenylpropene also gives a red anion *(16)* on reaction with isopropylmagnesium chloride in HMPT at room temperature, while alkali metal compounds again cause polymerization.



4. Carbanions from Heterosubstituted Hydrocarbons or from Hydrocarbons with Functional Groups [73]

a) Phenylacetic Acid and Malonic Acid Derivatives

The CH_2 protons of a benzyl residue are mobile if the benzyl residue is joined to an electron-attracting group. Thus phenylacetic acid reacts in the cold with isopropylmagnesium chloride or with sodamide in HMPT to form a dianion; the solubility of the disodium salt is infinite. Benzyl cyanide is metallated by NaH or $NaNH_2$ at 0 °C; the dianion is formed as well as the red-violet anion. The nitriles $C_6H_5-CHR-CN$ give the monoanion at 0 °C.

The following compounds can be monometallated with NaH or $NaNH_2$ in HMPT at 0 °C, the lactone in position 3:

$CH_2(CO_2C_2H_5)_2$, $CH_2(CN)CO_2C_2H_5$, $CH_2(CN)_2$,

$CH_2(CO_2CH_3)CO_2C_2H_5$, $CH_2(CO_2CH_3)_2$

[68] *T. Cuvigny* and *H. Normant*, Bull. Soc. chim. France *1965*, 1876.

[69] *T. Cuvigny* and *H. Normant*, Bull. Soc. chim. France *1964*, 2022.

[70] *T. Cuvigny* and *H. Normant*, Bull. Soc. chim. France *1965*, 1873.

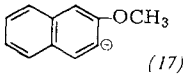
[71] *J. Ficini* and *G. Barbara*, Bull. Soc. chim. France *1965*, 2787.

[72] *T. Cuvigny* and *H. Normant*, Bull. Soc. chim. France *1965*, 1874.

[73] *H. Normant* and *T. Cuvigny*, Bull. Soc. chim. France *1965*, 1881.

b) Methylated Aromatic Compounds

Toluene and 2-methylfuran cannot be metallated, while 2-methylthiophene reacts only with difficulty. β-Picoline does not react with $NaNH_2$ in HMPT; in the α- and γ-isomers, in which the anion is resonance-stabilized, the CH_3 group is acidic. α-Picoline reacts with $(CH_3)_2CH-MgCl$ in HMPT to give a red anion. α-Picoline and γ-picoline are also metalled by $NaNH_2$ at 0 °C; the reactions do not proceed so readily with NaH. 2,3-Dimethylquinoxaline is more acidic than α-picoline, and both methyl groups react with NaH even at room temperature to give a green-violet dianion.



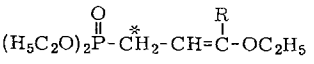
c) Other Compounds containing Replaceable Hydrogen

The haloforms react with the alkali metal compounds mentioned to give the anion $X_3C^{\ominus}$, which readily adds to the carbonyl group of a ketone in liquid ammonia [74]. This reaction does not proceed so smoothly in HMPT. On the other hand, the haloforms react readily with isopropylmagnesium chloride in HMPT. Trihalogenomethylmagnesium chlorides were obtained for the first time in a THF/hexamethylphosphoramide mixture (5:1 v/v) at −80 °C in accordance with eq. (k)[75]; the reaction does not take place with CF_3H.

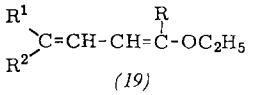
$$X_3CH + (CH_3)_2CH\text{-}MgCl \rightarrow C_3H_8 + X_3C\text{-}MgCl \qquad (k)$$

X = Cl, Br

The only methoxylated aromatic compound that has so far been made to react with $NaNH_2$ in HMPT is methyl β-naphthyl ether; the reaction presumably yields the red anion *(17)*.



(17)



In the case of anions that contain the stronger acceptor group SR instead of OR, resonance stabilization is expected in accordance with:

The compounds $HC(SC_2H_5)_3$, $H_2C(SC_2H_5)_2$, $C_6H_5CH(SC_2H_5)_2$, and $C_6H_5CH(SC_6H_5)_2$, which had previously been converted into their anions [76] with alkali metal amides in liquid ammonia, were treated with $NaNH_2$ in HMPT. In the first two compounds the C–S bonds were cleaved; $C_6H_5CH(SC_2H_5)_2$ gives a black-green anion at 0 °C; the more acidic $C_6H_5CH(SC_6H_5)_2$ is metallated by NaH even at 0 °C. Acetophenone and acetonitrile react with sodium hydride in HMPT at 0 °C, with loss of one or two protons. Phosphonates of the type *(18)* can be readily deprotonated in the indicated position by NaH in HMPT to give carbanions. These add on to carbonyl compounds to give ethoxydienes *(19)*, which are otherwise difficult to obtain [77].

(18)

(19)

It may be assumed from these examples that the strong bases (*e.g.* organolithium compounds in THF) used so far in many other reactions can also be replaced by weaker bases if the reactions are carried out in HMPT, even at low temperatures.

B. Isomerization and Polymerization

Many isomerizations take place in alkaline media; such isomerizations depend on mesomeric carbanions and the possibility of prototropy. The reactions are strongly accelerated by polar solvents. An example of such a reaction is the allyl rearrangement of 2-phenylbut-1-ene [78].

The isomerization of 3-phenylpropene can be brought about in HMPT with NaH, even in the cold, the yield being about 70% [72]:

$$C_6H_5\text{-}CH_2\text{-}CH{=}CH_2 \rightarrow C_6H_5\text{-}CH{=}CH\text{-}CH_3$$

No appreciable polymerization takes place under these conditions. Anionic polymerization becomes more important when a stronger base (*e.g.* $NaNH_2$) is used or when the 3-phenylpropene is heated in the presence of a weak base (*e.g.* $(CH_3)_2CH-MgCl$) [79] The hydrocarbons listed in Table 12 react readily with $(CH_3)_2CH-MgCl$ in HMPT.

Table 12. Formation of anions from hydrocarbons and $(CH_3)_2CH-MgCl$ in HMPT.

Hydrocarbon	Color
$H_5C_6-CH_2-CH=CH-CH_3$	red
$(H_5C_6)_2C=CH-CH_3$	red
$H_5C_6-CH=CH-CH_2-CH=CH-CH_3$	faint pink
$H_5C_6-CH=CH-CH_2-C\equiv C-C_5H_{11}$	Prussian blue
$H_5C_6-C\equiv C-CH_2-CH=CH_2$	red
$H_5C_6-CH_2-C\equiv C-C_5H_{11}$	red

In the reaction with NaH or $NaNH_2$, the rapid disappearance of the color shows that polymerization has taken place. Similar polymerizations of olefins have been achieved even with organomagnesium compounds, but only in less polar solvents and only in the presence of halides of group IV B, V B, or VI B elements at low pressures.

[74] *H. G. Viehe* and *P. Valange*, Chem. Ber. *96*, 420 (1963).

[76] *H. Normant* and *T. Cuvigny*, Bull. Soc. chim. France *1965*, 1883.

[77] *G. Sturtz* and *G. Lavielle*, C. R. hebd. Séances Acad. Sci. *261*, 2679 (1965).

[78] *D. J. Cram et al.*, J. Amer. chem. Soc. *84*, 4358 (1962).

[79] *T. Cuvigny* and *H. Normant*, Bull. Soc. chim. France *1964*, 2003.

The mesomerism of the red anion formed from the thioether *(20)* (with $NaNH_2$ at room temperature in HMPT) is shown by the fact that it reacts mainly as the structure *(21)* [80].

$$(H_3C)_2C{=}CH\text{-}S\text{-}C_4H_9 \longrightarrow$$

(20)

$$H_2\overset{\ominus}{C}\text{-}C(CH_3){=}CH\text{-}S\text{-}C_4H_9 \longleftrightarrow H_2C{=}C(CH_3)\text{-}\overset{\ominus}{C}H\text{-}S\text{-}C_4H_9$$

(21a) *(21b)*

Alkyl cinnamyl ethers *(22)* are very readily rearranged into alkyl 3-phenylpropenyl ethers *(23)* by bases in HMPT [162]. The pure ethers are obtained in THF from cinnamyl bromide

$$H_5C_6\text{-}CH{=}CH\text{-}CH_2OR \rightleftharpoons H_5C_6\text{-}CH_2\text{-}CH{=}CH\text{-}OR$$

(22) *(23)*

$R = C_2H_5, C_7H_{15}$

and the corresponding alkoxide. However, if the reaction is carried out in HMPT, or if sodium cinnamylate is allowed to react with an alkyl halide RX in hexamethylphosphoramide, the main product is the ether *(23)*. The isomerization *(22)* → *(23)* is evidently caused by alkoxide; it proceeds very rapidly in a HMPT/benzene mixture (1:9) in the presence of anhydrous $NaOC(CH_3)_3$. The mesomeric carbanion is obtained in HMPT with bases such as alcoholates.

$$H_5C_6\text{-}CH{=}CH\text{-}\overset{\ominus}{C}H\text{-}OR \leftrightarrow H_5C_6\text{-}\overset{\ominus}{C}H\text{-}CH{=}CH\text{-}OR$$

Experience so far has shown that DMSO is the most suitable solvent for the isomerization of olefins. The solvent series found for the rearrangement 1-butene → 2-butene with $KOC(CH_3)_3$ was DMSO ≫ HMPT > TMU [172].

C. Anions in Hexamethylphosphoramide

As was mentioned earlier, anion reactivity is increased in polar aprotic solvents. Reactions involving anions, such as bimolecular elimination and bimolecular nucleophilic substitution, should therefore be accelerated by such solvents. Thus it has been shown [81] that the rate of alkylation of sodiomalonic acid derivatives in benzene is considerably increased by the addition of 10 to 20% of a polar aprotic solvent. The reactions with C_2H_5Br and with C_4H_9Br are accelerated by factors of 21 and 54 respectively by HMPT, and by factors of 6.3 and 15 respectively by DMSO.

1. Substitution

a) Carbon-Halogen Bond

The result of nucleophilic substitution in accordance with eq. (l) depends on the solvent (protonic or aprotic) [2].

$$MX + RX' \rightleftharpoons RX + MX' \qquad (l)$$

Halide anions are specifically solvated by protonic solvents *via* hydrogen bonds, smaller anions being more strongly solvated than larger anions. The variation of nucleophilic strength ($I^\ominus > Br^\ominus > Cl^\ominus > F^\ominus$) runs contrary to this basicity series. In polar aprotic solvents, on the other hand, the nucleophilicity and the basicity of the anions change in the same direction, in accordance with the electronegativity of the halogen atoms.

Elimination very often competes with substitution in HMPT (and in HMPT/THF mixtures) [82]. (The percentage of elimination product for RX′ = n-$H_{15}C_7Br$ with MX = LiF, LiCl, NaF, NaCl, KI, and Cu_2Cl_2 is zero to 62%; the transformations RBr → RCl and RBr → RI are unusual.) The $F^\ominus$ and $Cl^\ominus$ anions act as strong bases in HMPT; they therefore cause almost complete elimination of HBr from secondary alkyl bromides [82] (79% of elimination product from cyclohexyl bromide with LiCl + Li_2CO_3), and so provide a good method for the synthesis of olefins. A t-alkyl *p*-toluenesulfonate *(24)* exhibits substitution even in the cold; no olefins are formed [82].

$$p\text{-}CH_3\text{-}C_6H_4\text{-}SO_2\ OC(CH_3)_3 \xrightarrow{LiCl}$$

(24)

$$p\text{-}C_6H_4\text{-}SO_2\text{-}OLi + (CH_3)_3CCl$$

The result of the reaction is also influenced by the temperature, substitution being favored at about 60 °C and elimination at about 100–110 °C.

b) Carbon-Oxygen Bond

Alcohols (*e.g.* C_4H_9OH, t-C_4H_9OH, $CH_2{=}CH\text{-}CH_2OH$, $H_5C_2O\text{-}CH_2\text{-}CH_2\text{-}OH$, C_6H_5OH, $HO\text{-}(CH_2)_3\text{-}OH$) and carboxylic acids (*e.g.* propionic and hexanoic acids) can be alkylated in 40 to 100% yield with benzyl chloride, ethyl iodide, ethyl bromide, butyl chloride, or 1,4-dibromobutane in the presence of NaH or $NaNH_2$ [64]. The basic properties of the alkoxide anions $RO^\ominus$ lead to eliminations with formation of epoxides (*e.g.* 2,2-dimethyloxirane from $(CH_3)_2C(OH)CH_2Br$) and olefins (*e.g.* 1-octene from $C_8H_{17}Br$; butadiene from $Br\text{-}(CH_2)_4\text{-}Br$ with C_2H_5ONa and C_4H_9ONa).

c) Carbon-Nitrogen Bond

NH functional groups (*e.g.* in aniline, *N*-methylaniline, indole, carbazole, phenothiazine, saccharin, acetamide, phthalimide) can be alkylated with alkyl halides and alkyl sulfates (*e.g.* ethyl bromide, ethyl iodide, phenyl bromide, benzyl chloride, diethyl sulfate) in HMPT in the presence of NaH, $NaNH_2$ or K_2CO_3; the yields are excellent, and often quantitative [64].

The formation of alkyl azides from primary alkyl bromides and inorganic azides is greatly accelerated in HMPT; reaction (m) is 72 times as fast as in DMF and 150 times as fast as in DMSO. The activation

[80] *H. Normant* and *T. Cuvigny*, Bull. Soc. chim. France *1965*, 1884.

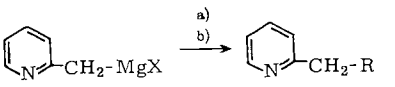
[81] *H. E. Zang et al.*, J. Amer. chem. Soc. *82*, 2895 (1960).

[82] *J. F. Normant* and *H. Deshayes*, Bull. Soc. chim. France *1967*, 2455.

energy, which is 15 to 17 kcal·mole^{-1} on average in polar aprotic solvents, is only 13.5 kcal·mole^{-1} in HMPT [3].

$$C_4H_9Br + N_3^{\ominus} \rightarrow C_4H_9{-}N_3 + Br^{\ominus} \qquad (m)$$

d) Carbon-Carbon Bond



Carbanions occur in very diverse reactions. The reactions that have been most thoroughly studied with HMPT as the solvent are alkylations, which generally proceed in excellent yields; moderate yields are obtained on acylation and carboxylation in HMPT. A nitrile group can be introduced in accordance with a reaction such as (n) [83]; higher nitriles can be synthesized by alkylations, starting *e.g.* with C_6H_5-CH_2-CN or CH_3-CN [84]:

$$H_5C_2O{-}OC{-}(CH_2)_5{-}Cl + NaCN \rightarrow H_5C_2O{-}OC{-}(CH_2)_5{-}CN \quad (90\%) \qquad (n)$$

α) *C–C Linkages by Organomagnesium Compounds*

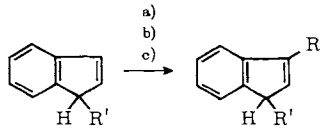
Hydrocarbon derivatives R'X' in which the halogen atom X' is very firmly bound cannot be induced to react with Grignard compounds RMgX in aliphatic ethers, even in THF. Such reactions take place only in HMPT [85] (cf. Table 13).

A selection of the derivatives that can be obtained *via* 1-indenyl-, 9-fluorenyl-, and α-pyridylmethyl organomagnesium compounds with alkyl halides, *p*-toluenesulfonates, and sulfates, as well as epoxides and CO_2 is shown in the following scheme [86].

a): + CH_2=CH-CH_2Br *(27a)*, R = CH_2-CH=CH_2

b): + H_5C_6-CHO *(27b)*, R = CHOH-C_6H_5

β) *C–C Linkages by Organometallic Compounds of the Alkali Metals*



Alkyl bromides do not react with monosodium acetylide in THF. Reaction takes place only in polar aprotic solvents such as dimethylformamide [87]; higher yields (60 to 70%) are obtained in HMPT [88]. The reactions also proceed in THF with added HMPT (about 10%), and the elimination of HBr is suppressed in this medium. The yields are particularly high with primary alkyl bromides, chlorides, and *p*-toluenesulfonates, and higher than in liquid ammonia, in which the reactants are less soluble. The acetylide ion $HC{\equiv}C^{\ominus}$ behaves as a strong base in HMPT, and leads to considerable elimination from secondary and tertiary alkyl halides and *p*-toluenesulfonates.

Alkoxylated 1-alkynes can be obtained by the reaction of suitably substituted halides with monosodium acetylide in HMPT [88] (cf. Table 14).

Table 13. Results for the reaction RMgX + R'X' [a] → R–R' + MgXX' in HMPT.

RMgX	R'X'	R–R'	Yield (%) in THF	Yield (%) in HMPT
n-C_4H_9–MgBr	*n*-C_7H_{15}–Br	*n*-$C_{11}H_{24}$	8	42
n-C_5H_{11}–MgBr	C_6H_5–CH=CH–Br	C_6H_5–CH=CH–C_5H_{11}	30	29
n-C_5H_{11}–MgBr	C_6H_5–C≡C–Br	C_6H_5–C≡C–C_5H_{11}	10	55
CH_3–CH=CH–MgBr	*n*-C_7H_{15}–Br	CH_3–CH=CH–C_7H_{15}	71	43
C_6H_5–MgBr	C_6H_5–CH=CH–Br	C_6H_5–CH=CH–C_6H_5	20	20
C_6H_5–C≡C–MgBr	*n*-C_5H_{11}–Br	C_6H_5–C≡C–C_5H_{11}	0	43

[a] Vinyl bromides split off HBR to a great extent under these conditions; only in the case of aromatic Grignard compounds can this be avoided.

$(C_2H_5O)_2CH(CH_2)_3Cl$	HMPT	20 → 40–50	1	$(C_2H_5O)_2CH(CH_2)_3C{\equiv}CH$	47

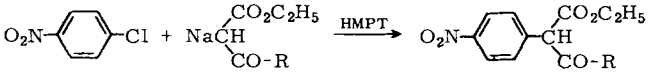
ω-Alkyn-1-yl-trialkylgermanes, *e.g. (28)*, could be obtained by the same method in 60% yield [89].

$$(C_2H_5)_3Ge(CH_2)_4Br + NaC{\equiv}CH \rightarrow (C_2H_5)_3Ge{-}(CH_2)_4{-}C{\equiv}CH \quad (28)$$

In a process similar to that described above, alkynes with non-terminal triple bonds are obtained in yields of 50 to 80% from alkali metal 1-alkynides and halogenated compounds [90]. Metallation with NaH in THF (method A) is recommended when an acyl or carboxy residue is to be introduced in the next stage. In another method B, the metallation is carried out with $NaNH_2$ in HMPT and the product is alkylated in the same medium. Finally, in method C, the following scheme is used without isolation of the intermediates:

$$CH{\equiv}CH \xrightarrow[THF]{Na} CH{\equiv}C{-}Na \xrightarrow[HMPT]{RX} R{-}C{\equiv}C{-}H$$

$$\xrightarrow[HMPT]{NaNH_2} R{-}C{\equiv}C{-}Na \xrightarrow{R'X} R{-}C{\equiv}C{-}R'$$



With the aid of these techniques it is possible to metallate dialkylethynylamines, *e.g.* to obtain the lithium derivative *(29)*, which can then be converted into ynamines having the general formula *(30)* by reaction with alkyl halides or *p*-toluenesulfonates [91].

$$RR'N{-}C{\equiv}C{-}Li \xrightarrow{RX} RR'N{-}C{\equiv}C{-}R$$
$$(29) \qquad (30)$$

Phenylacetic and malonic acid derivatives and 3-acetyl-2-oxotetrahydrofuran can be metallated with NaH or $NaNH_2$ and alkylated in good yields in HMPT or HMPT/THF [92].

γ) *Arylations*

Nucleophilic substitutions on aromatic compounds are always accelerated by polar aprotic solvents. It has so far been possible to use only the very reactive halogenobenzenes. Sodiomalonic acid and sodioacetoacetic ester can also be arylated in good yields with elimination of NaCl, by 2- or 4-nitrochlorobenzene (accelerating action of the solvents: HMPT > DMSO > DMF); while DMF gives partial $Cl \rightarrow N(CH_3)_2$ substitution in the aromatic compounds, HMPT is inert [93], *e.g.*:

$R = OC_2H_5, CH_3$

HMPT and copper salts have also been shown to accelerate reactions (o) and (p) [94–96].

$$p\text{-}O_2N{-}C_6H_4{-}Cl + HNAr \rightarrow p\text{-}O_2N{-}C_6H_4{-}NAr \quad (o)$$

$$p\text{-}Cl{-}C_6H_4{-}Cl + 2\ MS{-}C_6H_5 \rightarrow C_6H_5S{-}C_6H_4{-}SC_6H_5 \quad (p)$$

(M = K: 81% in *N*-methylbutyramide after 15 hours at 180 °C; M = Na: 26% in HMPT after 5 hours at 110 °C).

Substitutions of bromo-, chloro-, and fluorobenzenes with mercaptans, secondary amines, and phenylacetylenes in HMPT have been achieved in good yields (generally about 50 to 80%), and under mild conditions [64,97]. These reactions must involve an elimination-addition mechanism, though no intermediate dehydrobenzene derivative has ever been found.

e) Alkylation of Ambident Ions

The relative reactivities of the various nucleophilic centers of an ambident anion depend on numerous factors, *e.g.* in alkylations on the cation, the alkylating agent, and the solvent.

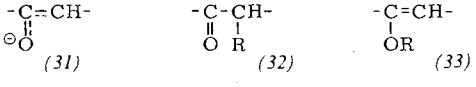

Table 15 illustrates the dependence of the course of the alkylation of sodium phenoxide and of sodium β-naphthoxide on the basicity of the solvent [98].

Table 15. Alkylation of sodium phenolate and β-naphtholate.

Solvent	Alkylation (%) at: C	O	Ref.
CH_3OH	35	65	[98]
CF_3-CH_2OH	93	7	[98]

In basic solvents, pyrroles are preferentially alkylated in the most strongly electronegative position *i.e.* on the nitrogen atom [99]. Thus the reaction of indolylsodium with benzyl chloride in HMPT leads to an 81% yield of *N*-benzylindole [64].

Enolates *(31)* in protonic solvents generally give *C*-alkylation to *(32)* [100]. In polar aprotic solvents, on the other hand, the principal reaction is found to be

(31) *(32)* *(33)*

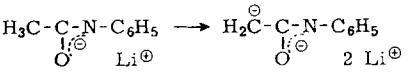
O-alkylation with formation of the enol ether *(33)* [101]. This solvent-dependence was studied in the alkylation of metallated derivatives of the ketones cyclohexanone, acetophenone, acetylacetone, ethyl acetoacetate (alkylating agent: alkyl sulfates, $(C_2H_5)_3OBF_4$) [101], α,α-diphenylacetone (with ethyl bromide) [102], and 9-benzoylfluorene (with isopropyl bromide) [103]. The results obtained with 9-benzoylfluorene are shown in Table 16.

Table 16. Alkylation of 9-benzoylfluorene with isopropyl bromide.

Solvent	DC	Alkylation (%) at: C	O
t-Butanol	10–11	96	4
Ethanol	24–25	83	17
Methanol	32–33	82	18
Diglyme	7–7.5	61	39
THF	7–7.5	90	10
HMPT	29–30	44	56
DMSO	45–49	72	28

The more weakly basic organomagnesium compounds can react with enolizable ketones in HMPT to give very good yields of the enolized form [104]. The results for diisopropyl ketone are given in Table 17.

Table 17. Reaction of diisopropyl ketone in HMPT with organomagnesium compounds.



Organomagnesium compound	Enolization (%)	Reduction (%)	Addition (%)
H_3CMgBr	33	0	66
H_5C_2MgBr	100	Trace	Trace
$(H_5C_2)_2Mg$	40	Trace	60
H_9C_4MgBr	100	0	Trace
$(H_9C_4)_2Mg$	60	Trace	40
$i\text{-}H_7C_3MgBr$	100	0	0
$(i\text{-}H_7C_3)_2Mg$	100	0	0

2-Butanone, 2,4-dimethylpentan-3-one, and cyclohexanone react with C_4H_9MgBr at 55 °C in HMPT to give 75, 95, and 90% respectively of the Mg enolates [104]. These Mg enolates could be alkylated with methyl iodide, methyl sulfate, and methyl *p*-toluenesulfonate in HMPT (this reaction does not take place in less polar solvents). As in the case of *N*-magnesium imino compounds [105], the reaction leads exclusively to *C*-alkylation:

$$XMg-O-C{=}CH \xrightarrow{RX} MgX_2 + O{=}C-CHR$$

If the cation of an imine can be strongly solvated as in its alkali metal derivative, alkylation can take place on the hetero atom. Thus sodium derivatives of enamines can be *N*-alkylated [106] (see Table 18).

The "ambident" anion can also give a dianion with strong bases. Thus acetanilide could be quantitatively *N*-alkylated by treatment with $NaNH_2$ in HMPT [64]. $NaNH_2$ in liquid ammonia gives only the same monoanion, whereas an excess of C_4H_9Li in ether or THF leads to a dianion *(34)*, which is then *C*-alkylated [107]. Methanesulfonamides behave in a similar manner [108].

f) Cyclopropane Derivatives and their Stereochemistry

Cyclopropane derivatives containing functional groups can be obtained by the reaction of compounds contain-

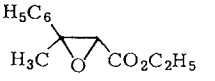
ing activated double bonds *e.g.* (esters, nitriles, ketones, *etc.*) with carbanions of α-halogenated compounds (esters, nitriles, ketones, *etc.*). The base NaH gives much higher yields in HMPT than in nonpolar solvents [109]. The solvent influences, not only the rate of reaction but also the stereochemistry [2]. Whereas the reaction in benzene leads mainly to the *cis* isomer *(35a)*, the principal product in HMPT is the *trans* isomer *(35b)*. Some results are shown in Table 19.

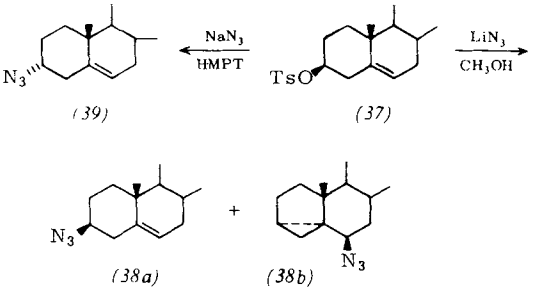


(35a) *(35b)*

Table 19. Yields and stereochemistry in the formation of the cyclopropane derivatives *(35a)* and *(35b)*.

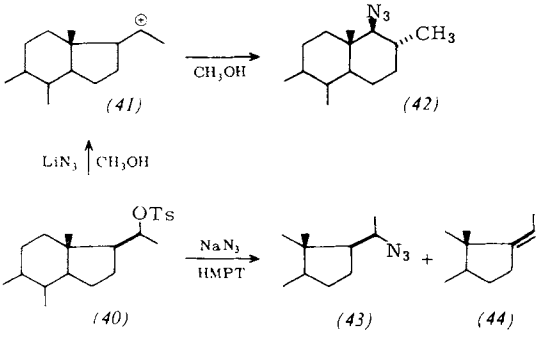
	In Benzene		In Benzene + HMPT (50:50 v/v)	
	Yield (%)	*trans* : *cis* *(35b)* : *(35a)*	Yield (%)	*trans* : *cis* *(35b)* : *(35a)*
$R=R'=CH_3$	71	7 : 93	60	64 : 26
$R=H$, $R'=CH_3$	70	17 : 83	70	90 : 10
$R=R'=C_2H_5$	55	0 : 100	67	75 : 25
$R=H$, $R'=C_6H_5$	43	0 : 100	65	56 : 21
$R=CH_3$, $R'=C_6H_5$	38	0 : 100	46	43 : 25

If the same method is applied to α-halogenated ketones, the high reactivity of the carbanion in hexamethylphosphorane permits a) the competitive Favorsky reaction in the case of ketones with mobile α'-hydrogen, and b) the use of methyl vinyl ketone [110], which polymerizes when used in previous methods. *cis*- (25%) and *trans*-1,2-Diacetyl-1-phenylcyclopropane (75%) are obtained in a total yield of 70% from methyl vinyl ketone and α-chloro-α-phenyl acetone.



This group of reactions includes the Darzens reaction *e.g.* between acetophenone and ethyl chloroacetate [111], the yield of which can be increased in HMPT to 70% (50% in hexane, 57% in benzene), with preferential formation of the isomer *(36)* (59:41). Two stereoisomers of 3-methyl-3-phenyl-2-oxiranecarbonitrile are obtained from acetophenone and chloroacetonitrile; total yield and proportions of isomers depend upon the base and solvent used.

(36)



Relationships between the solvent and stereochemistry are also known in steroid chemistry. Both the 3β-Δ⁵-*p*-toluenesulfonate *(37)* [181] and the 20β-*p*-toluenesulfonate *(40)* [182] give different substitution products with alkali metal azides, depending on whether a protonic or aprotic solvent is used.

Thus in methanol *(37)* gives an i-steroid derivative *(38b)* by an S_N1 reaction *via* a carbenium ion. In polar aprotic media, on the other hand, an S_N2 reaction with inversion leads mainly to the 3α-azide *(39)*, the yield of which increases with increasing basicity of the solvent (DMSO: 30%; *N*-methylpyrrolidone: 71%; HMPT: 93%).

(39) *(37)* *(38a)* *(38b)*

The reaction of *(40)* in methanol leads mainly to a derivative of the D-homo series *(42)* by rearrangement of the carbenium ion *(41)*. In polar aprotic solvents, however, an azide *(43)* having an inverted configuration on C-18 is formed by an S_N2 reaction; the yield again depends on the basicity of the solvent (DMSO: 46%; *N*-methylpyrrolidone: 53%; HMPT: 65%). The elimination product *(44)* is also formed.

(41) *(42)* *(40)* *(43)* *(44)*

[109] *L. L. McCoy*, J. Amer. chem. Soc. *82*, 6416 (1960); *84*, 2246 (1962); *L. L. McCoy* and *C. W. Nachtigall*, J. org. Chemistry *27*, 4312 (1962).

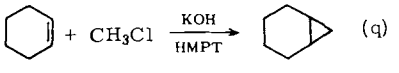
[111] *J. Seyden-Penne*, *Ch. Gibert*, and *B. Daurée*, C. R. hebd. Séances Acad. Sci., Sér. C *263*, 895 (1966).

Reduction of the azides with $LiAlH_4$ gives the corresponding amino steroids in very good yields.



2. Eliminations

Halogenated compounds, sulfonated compounds, other compounds containing sulfur, and azides can enter into elimination reactions with formation of olefins, carbenes, alkynes, or amines. In the basic HMPT, nucleophilic substitutions (S_N2) compete with these E2 reactions. Table 20 shows the results obtained on elimination of hydrogen halide from halogenated vinyl compounds in HMPT with the aid of organomagnesium compounds [112–114].

Table 20. HX-elimination with Grignard compounds in HMPT.

RMgX	Halogenovinyl compound	Product	Yield (%)	Ref.
n-C_4H_9MgBr	n-$C_5H_{11}CCl{=}CHCl$(*cis*)	$C_5H_{11}-C{\equiv}C-Cl$ + $C_5H_{11}-C{\equiv}C-C_4H_9$	14 10	[112]
n-$C_7H_{15}MgBr$	$CHCl{=}CCl_2$	$C_7H_{15}-C{\equiv}C-Cl$	48	[113]
n-$C_5H_{11}MgBr$	$H_5C_6-CH{=}CHBr$	$H_5C_6-C{\equiv}C-H$	27	[114]
H_5C_6MgBr	$H_5C_6-CH{=}CHBr$	$H_5C_6-C{\equiv}C-H$	20	[114]

Similar results were obtained with stronger bases ($H^{\ominus}$, $NH_2^{\ominus}$, $HC{\equiv}C^{\ominus}$) in HMPT [115–117]. The formation of norcaradiene in accordance with eq. (q) [118] may involve a carbene mechanism.

(q)

Arylsulfonates such as *(45)* decompose to form olefins when heated in polar aprotic solvents [119].

$$Ar{-}SO_2{-}O{-}\underset{|}{CH}{-}CH_2{-} \rightarrow {-}CH{=}CH{-} + ArSO_3H$$

(45)

Cyclohexyl benzenesulfonate gives a 58% yield of cyclohexene at 40 °C in HMPT in the presence of $NaNH_2$ [116]. Similarly, the $CH{\equiv}C^{\ominus}$ anion in HMPT causes decomposition of β-ethoxyethyl methanesulfonate into ethyl vinyl ether [117].

The basic oxidation of mercaptans, disulfides, and sulfoxides often results in β-elimination in accordance with equations (s) to (u) to form olefins [120–123]. Aliphatic sulfones normally enter into this reaction only with difficulty (in KOH solution above 200 °C), but react readily in HMPT at 80 °C [121].

$$R{-}\overset{\ominus}{C}H{-}CH_2{-}S^{\ominus} \longrightarrow R{-}CH{=}CH_2 + S^{2\ominus}$$

$$R{-}\overset{\ominus}{C}H{-}CH_2{-}S{-}SR \longrightarrow R{-}CH{=}CH_2 + RS{-}S^{\ominus}$$

$$\overset{\ominus}{C}H_2{-}CH(CH_3){-}SO{-}C_3H_7 \longrightarrow CH_3{-}CH{=}CH_2 + C_3H_7{-}SO^{\ominus}$$

3. Autoxidation of Carbanions

Many compounds that form anions are autoxidized in appreciable yields in DMF or DMSO, even at room temperature; potassium t-butoxide has been used as the base in this reaction [124]. The accepted mechanism [125] is illustrated below for toluene:

$$C_6H_5{-}CH_2{-}H + B^{\ominus} \rightarrow BH + C_6H_5{-}CH_2^{\ominus}$$
$$C_6H_5{-}CH_2^{\ominus} + O_2 \rightarrow C_6H_5{-}CH_2{\bullet} + O_2{\bullet}$$
$$C_6H_5{-}CH_2{\bullet} + O_2 \rightarrow C_6H_5{-}CH_2{-}O{-}O{\bullet}$$
$$\rightarrow \ldots\ldots$$

The autoxidation should be accelerated as the formation of the carbanion is facilitated. HMPT, which was apparently first used as an autoxidation medium by *Wallace* [120–122, 127–132], is superior to other polar aprotic solvents for two reasons:

1) HMPT itself does not form carbanions, and so cannot autoxidize. Table 21 gives the data for 10% tritium exchange between toluene labeled in the CH_3 group and polar solvents [126]. DMSO exhibits considerable autoxidation, as do diglyme and dioxane [127].

2) HMPT is stable to bases, even to KOH at 80 °C, and is therefore superior to amides and lactams.

Table 21. Tritium exchange between $H_2TC{-}C_6H_5$ and polar solvents; time required for 10% exchange [126].

Solvent	Time (min)
DMSO	6
Dimethylsulfone	12
N-Methyl-2-pyrrolidone	48
Tetramethylene sulfoxide	420
HMPT	14000

When no β-elimination takes place, mercaptans and disulfides autoxidize in alkaline media to give sulfonic acids, often in yields of more than 90% (see Table 21a) [128]. The autoxidation of thioethers in 2 M K-t-butylate/HMPT leads to a carboxylic acid/sulfonic acid mixture [129]. With thioethers of the benzyl sulfide type, yields of 30 to 70% are obtained after 1 to 3 days; other thioesters give lower yields. Sulfoxides autoxidize in HMPT/$(CH_3)_3COK$ or HMPT/KOH at 80 °C, again with formation of carboxylic acid/

sulfonic acid mixtures[130]. Worthy of mention is the autoxidation of dimethylsulfone under these conditions.

Ketones autoxidize to give carboxylic acids, and diketones to give dicarboxylic acids; the rate of autoxidation in both cases increases with increasing ease of formation of carbanions[131]. The rate is highest in HMPT (HMPT > $(CH_3)_3COH \gg H_2O$); the yield of autoxidation product varies with the base in the order KOH ≈ NaOH ≫ LiOH.

Aromatic hydrocarbons that can form carbanions autoxidize in the presence of strong bases such as $KOC(CH_3)_3$ or KOH in HMPT to give carboxylic acids[126]. A number of examples are shown in Table 22. The methylthiophenes[132] and particularly the α-isomer, which has a resonance-stabilized carbanion, react in the same way.

Table 22. Autoxidation of aromatic hydrocarbons in $KOC(CH_3)_3$/HMPT or KOH/HMPT.

ArH	Ar—COOH	Yield (%)
Toluene	H_5C_6—COOH	25—30
o-Xylene	Phthalic acid	35—40
m-Xylene	Isophthalic acid	50
p-Xylene	Terephthalic acid	15
Tetralin	Phthalic acid	46

D. Comparison of Polar Aprotic Solvents

The ability to accelerate S_N2 and E2 reactions changes in the same direction as the electron-donating power: DMF < DMSO < TMU < HMPT. Differences in stability and in influence on chemical reactions are evidently also partly due to differences in the distances between the polar groups and the groups carrying hydrogen.

1. Reactivity of the Polar Group

In the polar group the oxygen is negatively polarized and the C, S, or P atom attached to it is positively polarized. Consequently, nucleophiles $B^{\ominus}$ introduced or formed during the reaction attack the positive C, S, or P atom. This can lead to the removal of amide ions from dimethylformamide and from tetramethylurea, and these ions then compete with the nucleophile $B^{\ominus}$ in substitution, addition, and autoxidation reactions. A substitution of this type is unlikely in the case of HMPT, since phosphoramides are much more stable than amides of carboxylic acids.

The strongly basic organometallic compounds of alkali metals and KOH attack DMF, DMSO, and tetramethylurea very effectively, whereas HMPT is not affected under the usual reaction conditions (even by KOH at 80 °C). Organomagnesium compounds do not attack even tetramethylurea[133,134]. Metallations are best carried out with strongly basic organometallic compounds in a mixture of HMPT with a nonpolar solvent such as benzene or toluene. On the other hand, organometallic compounds of cadmium, zinc, and tin can be prepared directly from the metals and alkyl halides in HMPT.

When sodium hydride is used the reaction may be carried out in DMF; however, part of the NaH reacts with the solvent even at room temperature[135]. Since DMSO is an oxidizing agent, the use of NaH in this solvent leads to an explosion hazard, even at temperatures only slightly above room temperature[136]. TMU and HMPT are inert to alkali metal amides and hydrides.

2. Ease of Removal of Hydrogen

Hydrogen atoms α to the polar group, *e.g.* in dimethylacetamide and even more so in DMSO, can be readily split off by bases[137] with formation of the anions $(CH_3)_2N\text{—}CO\text{—}CH_2^{\ominus}$ and $CH_3\text{—}SO\text{—}CH_2^{\ominus}$ respectively. Consequently, DMSO is an ideal reactant[137] rather than an ideal solvent in carbanion chemistry. Tetramethylurea and HMPT lose the hydrogen β to the polar group only under extreme conditions, if at all.

From all points of view, HMPT is the best polar aprotic solvent, and has great advantages even over liquid ammonia, in which most of the reactions discus-

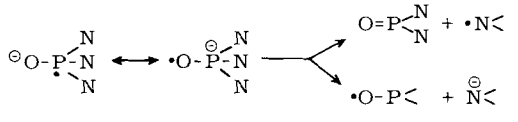
sed can be carried out. These advantages include ease of handling, absence of autoprotolysis (*e.g.* $(C_6H_5)_3CM$ can be synthesized), and greater solvent power for a large number of substances (*e.g.* for aliphatic bromine compounds).

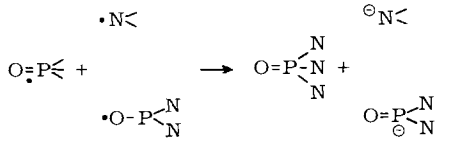
IV. Hexamethylphosphoramide as an Electron Acceptor

A. Formation of Radical-Anions



H. Normant et al. found that HMPT has the remarkable property of dissolving alkali metals (Li, Na, K) to form blue solutions (λ_{max} = 770 μ)[138]. It was shown[139–141] that these blue solutions contain radical-anions and are paramagnetic.

$$M + O{=}P(N(CH_3)_2)_3 \rightarrow [O^{\bullet}{-}P(N(CH_3)_2)_3]^{\ominus} + M^{\oplus}$$



The EPR spectra are concentration-dependent, suggesting differences in the degree of solvation of the electron, *i.e.* of the radical-anion. The stability of the radical-anion accordingly depends on the alkali metal concentration and on the nature of the cation. In 1 M solutions, the blue color disappears after 10 to 15 min in the case of potassium and after 6 hours in the case of sodium or lithium. Mg[143], Ca, Sr, and Ba[144] also dissolve in HMPT to give blue solutions.

Mg solutions are more stable than Na solutions at the same concentration; solutions of alkaline earth metals, particularly Ba, are unstable. Decomposition gives a yellow color (λ_{max} = 390 μ). Our first suggestion[145] was that a mechanism involving two anions might be involved. However, the following mechanism is more probable.

The mesomeric radical-anion forms an anion and a free radical:

and the new radical is converted into another anion:

so that the overall reaction is:

$$2\ O{=}P\lessdot \rightarrow O{=}P\lessdot + O{=}\underset{\oplus}{P}\lessdot + {}_{\cup}N\lessdot$$

When polycyclic aromatic hydrocarbons are added to a solution of a metal in HMPT, they act as electron acceptors. The formation of hydrocarbon radical-anions depends mainly on three factors[146]:

a) The electron affinity, which is lower for all hydrocarbons than for the non-enolizable ketones[147]:

benzene < phenanthrene < biphenyl < naphthalene < anthracene < *o*- and *p*-terphenyl < benzophenone < fluorenone.

b) The reducing power of the metal, which decreases from the alkali metals, *via* magnesium, to the alkaline earth metals.

c) The solvating properties of the solvent (HMPT is greatly superior to dimethoxyethane and to THF in this respect).

The formation of radical-anions from biphenyl and naphthalene in THF solution with Li or Na has been used in syntheses[148]. A stable solution of anthracene radical-anions can also be prepared with sodium in HMPT[149]. Neither biphenyl nor naphthalene gives a radical-anion with magnesium in THF. Naphthalene reacts with Mg only in liquid ammonia[150] or in HMPT to give the radical-anion (detected by EPR spectroscopy)[144]. The green residue Mg(naphthalene)$(NH_3)_x$ that is left when the solvent is distilled off decomposes in DMSO and is insoluble in THF; it dissolves in HMPT to give a stable green solution, which can be used in exchange reactions for the preparation of aromatic radical anions $ArH^{\ominus}$ of anthracene, pyrene, and 1,1-diphenylethylene[143,179]. Biphenyl radical anions are obtained from biphenyl and solutions of Ca (or Sr or Ba) in HMPT. Electron exchange takes place on addition of naphthalene, which is a stronger electron acceptor:

$$H_5C_6{-}C_6H_5^{\ominus}{\bullet} + C_{10}H_8 \rightarrow H_5C_6{-}C_6H_5 + C_{10}H_8^{\ominus}{\bullet}$$

The electronic spectra of these radical anions in HMPT are only slightly influenced by the cation (Na^+, Mg^{2+}); the wavelengths at which the maxima occur are about 20 μ higher than in the spectra recorded in THF. Hexamethylphosphoramide is an excellent medium for the synthesis of metal ketyls[151].

The required alkali metal solutions (ammonia, lower amines) can be obtained, not only by dissolution of the metals, but also by electrolysis of suitable metal salt solutions. This second method can also be used when the solvent is HMPT (electrolysis of $MgBr_2$, CaI_2, and LiCl)[46,180]. Hydrogen is not liberated even in a HMPT/alcohol mixture, and a slight blue color, which rapidly disappears, is observed at the cathode; this color must be due to the HMPT anion-radical.

B. Use of the Radical Anions in Syntheses

Solutions of alkali metals in HMPT can be used in the same way as solutions of alkali metals in liquid ammonia, *i.e.* for metallation, reduction, isomerization, polymerization, *etc.* [139].

1. Anion Formation and Metallation

Molecules ZH containing active hydrogen are metallated by solutions of alkali metals in HMPT, with formation of salt-like or covalent derivatives. However, no hydrogen is liberated, and a reaction in accordance with eq. (r) takes place instead. Solutions of K and of Li react more rapidly than Na solutions.

Table 23. Metallation in alkali metal-HMPT-solutions.

Compound metallated	Metal	Reaction partner	Product	Yield (%)
$n\text{-}C_4H_9OH$	Na	$Cl\text{-}CH_2\text{-}C_6H_5$	$C_4H_9\text{-}O\text{-}CH_2Ph$	77
$H_5C_6\text{-}NH\text{-}C_2H_5$	K	C_2H_5I	$Ph\text{-}N(C_2H_5)_2$	77
Phenthiazine	Na	CH_3I	*N*-Methylphenthiazine	85
CH_3CONH_2	K	$Cl\text{-}CH_2\text{-}C_6H_5$	$CH_3\text{-}CO\text{-}NH\text{-}CH_2\text{-}Ph$	[*]
$(C_6H_5)_3CH$	Na	CO_2	$(C_6H_5)_3C\text{-}CO_2H$	50
$(C_6H_5)_2CH_2$	K	$Br(CH_2)_4Br$	$[(C_6H_5)_2CH\text{-}(CH_2)_2\text{-}]_2$	87
Fluorene	Na	C_2H_5I	9-Ethylfluorene	73
$C_6H_5\text{-}CH_3$	Li	CO_2	$C_6H_5\text{-}CH_2\text{-}CO_2H$	little

[*] Low yields, also with $NaNH_2$.

$$2\ Z\text{-}H + 2\left[M^{\oplus}, O\overset{\ominus}{=}P\lesssim\right] \rightleftharpoons 2\ (Z^{\ominus}M^{\oplus}) + O{=}P\lesssim + \left[H_2, O{=}P\lesssim\right] \quad (r)$$

A mixture of HMPT and a nonpolar solvent such as ether, THF, or benzene may also be used. To avoid premature decomposition of the $HMPT^{\ominus}$ anion, the reactant ZH is added to the HMPT at the very beginning, and is added in the stoichiometric quantity.

All the reactions described in Section IV for alkali metal hydrides and amides can be carried out more economically with solutions of the alkali metal itself in HMPT. Table 23 shows the results of some reactions involving metallation on hetero atoms [152] or on "acidic carbon" [153].

Since HMPT is an aprotic solvent, it can be used for the metallation of acids as weak as toluene with alkali metal. With Li or K, the characteristic deep red solution of the benzyl anion is formed. Introduction of CO_2 into this solution gives phenylacetic acid (in small yields), together with $C_6H_5\text{-}(CH_2)_3\text{-}C_6H_5$, $C_6H_5\text{-}C_2H_5$, and other products.

It should also be possible to use this metallation method with high molecular weight compounds containing mobile hydrogen, *e.g.* with polyvinyldiphenylmethane, polyvinylfluorene, *etc.*

Alkali metals in pure HMPT surprisingly do not metallate the much more acidic 1-alkynes, even the relatively acidic phenylacetylene. In the case of phenylacetylene it was found that the diamidophosphite anion $OP(N(CH_3)_2)_2^{\ominus}$, which is formed by further reaction of the primary radical anion, adds to the triple bond. (Concerning complex formation and the entirely different behavior in liquid NH_3, see Section II.) 1-Alkynes must therefore be metallated in mixtures of HMPT with nonpolar solvents such as benzene or toluene (equilibrium between complexed and free 1-alkyne). The results are shown in Table 24 [154].

Table 24. Reactions of 1-alkynes in HMPT/benzene or HMPT/toluene mixtures [154].

Alkyne	M = Li	Product	Yield (%)
$(H_5C_2)_2N\text{-}CH_2\text{-}C{\equiv}CH$	$Br(CH_2)_4Br$	$[\text{-}(CH_2)_2\text{-}C{\equiv}C\text{-}CH_2\text{-}N(C_2H_5)_2]_2$	50
$H_5C_6\text{-}C{\equiv}CH$	CO_2	$H_5C_6\text{-}C{\equiv}C\text{-}CO_2H$	70
$HC{\equiv}CH$	$n\text{-}C_6H_{13}Br$	$CH_3(CH_2)_5\text{-}C{\equiv}CH$	14 [*]
$HC{\equiv}CH$	Cyclohexanone	1-Ethynylcyclohexanol	50
1,3-Dioxolan-2-yl-$(CH_2)_5\text{-}C{\equiv}CH$	$^{14}CH_3I$	$^{14}CH_3\text{-}(CH_2)_7\text{-}CHO$ [155]	80

[*] Low yields, since the strong base $HC{\equiv}C^{\ominus}$ causes cleavage of HBr from $C_6H_{13}Br$.

Compounds containing reactive hydrogen (carboxylic acids, esters, nitriles) as well as functional groups can be metallated and then allowed to react *e.g.* with halogen derivatives. In some cases (*e.g.* for $C_6H_5\text{-}CO\text{-}CH_3$, CH_3CN) the HMPT must be diluted with an inert solvent to avoid polymerization; this is always advisable for acylations and for the addition of CO_2.

2. Reduction of Unsaturated Compounds

A dianion of the monomer (see eq. (s)) or of the dimer (see eq. (t)) of an unsaturated compound can be formed by electron transfer from the $HMPT^{\ominus}$ anion. For example, the reduction of esters to vicinal diketones proceeds in accordance with eq. (t) [151]. We have paid special attention to reaction (s).

$$A{=}Z + 2\left[M^{\oplus}, O\overset{\ominus}{=}P\lesssim\right] \rightleftharpoons 2\ O{=}P\lesssim + M^{\oplus}\overset{\ominus}{A}\text{-}\overset{\ominus}{B}\ \overset{\oplus}{M} \quad (s)$$

$$2\ A{=}Z + 2\left[M^{\oplus}, O\overset{\ominus}{=}P\lesssim\right] \rightleftharpoons 2\ O{=}P\lesssim + 2\ \dot{A}\text{-}B^{\ominus}, 2\ M^{\oplus} \longrightarrow B^{\ominus}\text{-}A\text{-}A\text{-}B^{\ominus}, 2\ M^{\oplus} \quad (t)$$

In the aprotic HMPT, the reaction stops with the formation of the monomeric dianion $A^{\ominus}\text{-}B^{\ominus}$, whereas protonation takes place in primary amines or in liquid NH_3. However, the dianion can also be alkylated.

[155] *L. Pichat* and *J. P. Guermont,* personal communication.

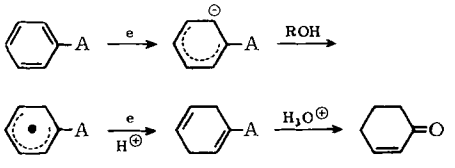
a) Reduction of N=N or C=N Bonds

Metallation of *e.g.* azobenzene in a solution of an alkali metal in HMPT yields the compound *(46)*, from which *(47a)* is obtained by hydrolysis and *N,N'*-dimethyl-*N,N'*-diphenylhydrazine *(47b)* by methylation with CH_3I [156]. The analogous reductions of imines,

oximes, and hydrazones [156] leads to 30 to 70% yields of secondary amines, together with imines in the reactions of oximes and hydrazones.

b) Reduction of Aromatic Compounds

The products obtained by metallation of phenol ethers and arylamines with alkali metals can undergo an elimination, or the aromatic nucleus may be reduced. The (Birch) reduction proceeds as follows:



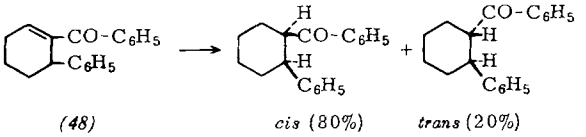


Table 25 shows the results obtained in a mixture of HMPT and $(CH_3)_3COH$ [156, 159].

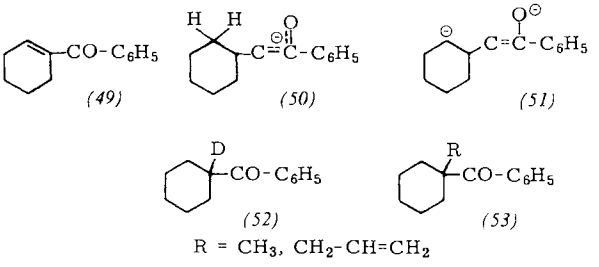
Table 25. Reduction in HMPT/$(CH_3)_3COH$ (according to *Birch*).

	Products	Yield (%)
Anisole	Cyclohex-2-enone	50
Phenetole	Cyclohex-2-enone	25
N,N-Dimethyl- or *N,N*-Diethylaniline	Cyclohex-2-enone	20
Ethyl β-naphthyl ether	Tetralone	60
Methyl 2-naphthyl ether	1-Methoxytetralin + 1,2-Dihydronaphthalin + 1,4-Dihydronaphthalin	15 + 15 + 30

c) Reduction of α-Unsaturated Ketones

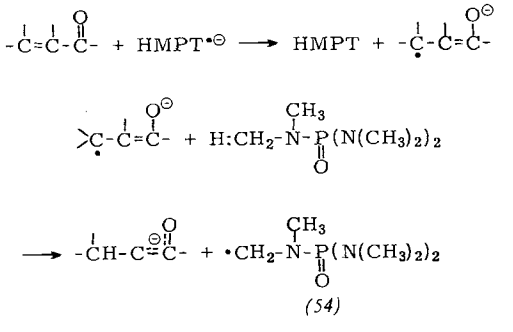
The reduction of α-unsaturated ketones with alkali metals in liquid ammonia or in lower amines leads to saturated ketones.



(48) *cis* (80%) *trans* (20%)

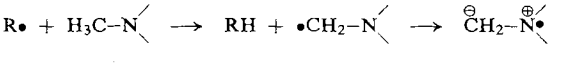
In the case of phenyl 6-phenylcyclohex-1-enyl ketone *(48)*, K or Li in liquid NH_3 or in HMPT gives the same overall yield (80%), and the isomer ratio of the reduced ketone is the same [46]. Isophorone, carvone, and pulegone, as well as ketones such as CH_3–CO–R (R = $CH{=}C(CH_3)_2$, $CH{=}CH{-}C_6H_5$, $CH{=}CH{-}C_2H_5$, $CH{=}CH{-}CH(CH_3)_2$, $CH{=}CH{-}C_5H_{11}$, $C(CH_3){=}CH{-}CH(CH_3)_2$) could be reduced to the saturated ketones in yields of 30 to 65% by this method [159].

In the electrochemical reduction of α-unsaturated ketones in HMPT, an electron is transferred from the $HMPT^{\ominus}$ radical-anion to the ketone molecule; the cathodic solution is colorless.



The ketone *(49)* can be reduced to the saturated ketone in a yield of more than 80%, irrespective of the electrolyte used (*e.g.* $MgBr_2$·Ether or CaI_2). A number of observations suggest that the reduction takes place *via* the enolate ion *(50)* rather than *via* the dianion *(51)*. Thus after storage of *(49)* in a solution of Li in HMPT, treatment with D_2O yields the deuterated ketone *(52)* [46]. The lithium derivative similarly gives α-alkylated ketones *(53)* [159]. It has been shown that

R = CH_3, CH_2–CH=CH_2



the reaction in liquid ammonia proceeds *via* the enolate ion *(50)* [157, 158].

The following mechanism is possible for the reduction of α-unsaturated ketones in HMPT:

(54)

It is in fact known that tertiary amines can act as H donors toward free radicals [142]:

The radical *(54)* may also be formed in solutions of alkali metals in HMPT in the presence of alkylated aromatic hydrocarbons, since CH_2 is inserted into the alkylated aromatic compound under these conditions. Thus toluene gives mainly ethylbenzene and 1,3-diphenylpropane, ethylbenzene gives cumene, and tetralin gives 1-methyl- and 1,4-dimethyltetralin and dimers [183]. Tetralin gives the same result on electrolytic reduction in HMPT (in the absence of protonic solvents) [180].

[159] *M. Larchevêque*, unpublished.

d) Reduction of α-Unsaturated Carboxylic Acids

α-Unsaturated carboxylic acids can be reduced to saturated carboxylic acids with lithium as described in the previous Section[159]. The yields obtained in the reduction of $C_6H_5-CH=CH-CO_2H$ and $(CH_3)_2CH-CH=CH-CO_2H$ are 60 and 65% respectively.

e) Reduction of Alkynes containing Non-terminal Triple Bonds

3-Octyne and 3-hexyne are not reduced by solutions of Li in HMPT/ether or in HMPT/THF, but isomerize to form 1-alkynes[159]. 2-Methylhex-4-yn-3-ol isomerizes in the same way to give 2-methylhex-5-yn-3-ol. On the other hand, the reaction of alkynes (*e.g.* 2-nonyne, hex-1-ynylcyclohexane) with a solution of Li in HMPT/benzene (1:5 v/v) leads, on addition of water, to the corresponding *trans*-alkenes (55–60%).

3. Reductive Elimination

Electron transfer from an $HMPT^{\ominus}$ anion to a molecule A–Z can have the following consequences:

a) A–Z forms an anion and a new radical, which readily dimerizes;

b) A–Z forms two anions (this happens very readily where resonance stabilization is possible).

Table 26[160] shows the final products that can be obtained on addition of another reactant.

The cleavage of Ge-Ge bonds by solutions of potassium in HMPT[160] has recently been studied in the hexalkyldigermanes[161]. The trialkylgermylpotassium, which is stable in HMPT, reacts readily with trialkylgermyl, -silyl, and -stannyl halides to give mixed hexaalkyl-digermanes, -silylgermanes, and -germylstannanes, $R_3Ge-MR'_3$ (M = Ge, Si, Sn).

The cleavage ethers, R–O–R, by solutions of alkali metals in HMPT has been particularly intensively studied[162].

Dialkyl ethers are not cleaved, while diaryl ethers give phenols. The products obtained on cleavage of some alkyl aryl ethers, alkyl benzyl ethers, and α-unsaturated ethers are shown in Table 27. The reductions do not always proceed in the same manner. Thus with dibenzyl ether in liquid ammonia, an elimination brought about by the carbanion yields 1,2-diphenylethane[163] (just as in HMPT):

$$H_5C_6-\overset{\ominus}{C}H_2 + H_5C_6-CH_2-O-CH_2-C_6H_5 \rightarrow H_5C_6-CH_2O^{\ominus} + H_5C_6-CH_2-CH_2-C_6H_5$$

Ethers of the type $Ar-O-CH\diagup\diagdown$ can undergo Wittig rearrangement[164] to form alcohols. The reduction of aryl *p*-toluenesulfonates with potassium in HMPT leads mainly to phenols, while aryl phosphates (as in liquid ammonia[165]) give hydrocarbons[162].

$$(H_5C_2O)_2P(O)OAr \xrightarrow[2)\ H_2O]{1)\ K,\ HMPT} ArH$$

Compounds of the type Ar–O–Z ($Z \approx B\diagup\diagdown$, $Si\diagup\diagdown$, $Ge\diagup\diagdown$, $Sn\diagup\diagdown$) are broken down into two anions $ArO^{\ominus}$ and $Z^{\ominus}$ by solutions of potassium in HMPT. Protonation and alkylation give ZH and ZR respectively[166].

4. Polymerizations

Though HMPT has been used as a Lewis base with many other polymerization catalysts (*e.g.* organomagnesium and organoaluminum compounds as adducts with halides of elements of the Group IV, V, and VI triads)[167], it does not appear to have been used much for anionic polymerizations. Anionic polymerizations of reactive vinyl compounds[146,147,168] have frequently been initiated by solutions of alkali metals, which contain radical anions. Solutions of ($M^{\oplus}$ + $HMPT^{\ominus\bullet}$) or ($M^{\oplus}$ + $ArH^{\ominus\bullet}$), which can be readily prepared in HMPT, may become important in this application.

Table 26. Reaction of A–Z with another reaction partner and alkali-metal in HMPT.

Starting material A–Z	Alkali metal	Reaction partner	Product	Yield (%)
$H_5C_6-CH_2-Cl$	K	H_2O	$H_5C_6-CH_2-CH_2-H_5C_6$	75
$H_5C_6-O-CH_3$	K	H_2O	H_5C_6-OH	80
$H_5C_6-O-CH(H_5C_6)_2$	K	H_2O	$H_5C_6-OH + (H_5C_6)_2CH_2 + (H_5C_6)_3C-OH$	47 + 52 + 46

Table 27. Cleavage of alkylaryl ethers in alkali metal/HMPT solutions.

Ether	Product	Yield (%)
$C_6H_5-O-CH_3$	C_6H_5OH	76–80
$C_6H_5-O-C_2H_5$	$C_6H_5OH + C_6H_5OH \cdot HMPT$	20 + 65
β-$C_{10}H_7-O-CH_3$	$C_{10}H_8$ + β-Naphthol·HMPT	43 + 38
β-$C_{10}H_7-O-C_2H_5$	β-Naphthol·HMPT	51

Thus the reaction of *trans*-stilbene with solutions of sodium in HMPT followed by hydrolysis yields the dimeric *meso*-1,2,3,4-tetraphenylbutane[138] *(55)*:

$$H_5C_6-CH=CH-C_6H_5$$
$$\rightarrow \; H_5C_6-\overset{\ominus}{C}H-CH(C_6H_5)-CH(C_6H_5)-\overset{\ominus}{C}H-C_6H_5,\ 2\ Na^{\oplus}$$
$$\xrightarrow{H_2O} [H_5C_6-CH_2-CH(C_6H_5)]_2$$
(55)

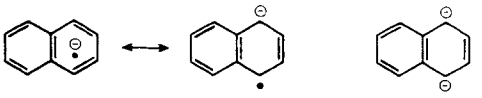
Styrene and α-methylstyrene have been dimerized in a suspension of sodium in THF in the presence of *o*-terphenyl as an electron transfer agent[169]:

$$H_5C_6-CR=CH_2 \xrightarrow{2\ Na} H_5C_6-\overset{\ominus}{C}H-CH_2-\overset{\ominus}{C}H-C_6H_5,\ 2\ Na^{\oplus}$$
$R = H,\ CH_3$

The reaction continues a little further with potassium at −30 or −40 °C and in the presence of a small quantity of HMPT to act as the electron transfer agent. Only a little dimer is found on hydrolysis, the main products being low polymers.

Solutions of biphenylmagnesium in HMPT have been used to initiate the quantitative anionic polymerization of styrene, of α-methylstyrene, and of 2-vinylpyridine[170]. Solutions of magnesium in HMPT containing naphthalene polymerize styrene in a similar manner[179].

The results obtained so far[171], some of which have not yet been published, lead to the following conclusions: Even small quantities of alkali metal/HMPT increase the polymerization rate and permit the use of lower reaction temperatures. Many difficult copolymerizations can be satisfactorily carried out only in this system. The conventional polymerization promoters are active in HMPT.



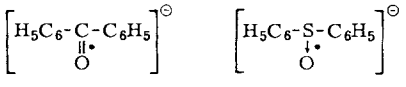
C. Comparison of Electron Acceptor Properties

An electron acceptor is taken here to be a system that is either completely regenerated (reducing action) or is reduced to the extent of 50% (anion-forming or metallation). These electron acceptors contain one or more double bonds; the most common are aryl ketones and polycyclic aromatic hydrocarbons.

Aryl ketones react with alkali metals to give metal ketyls; the radical-ions *(56)* are converted stepwise into alcohols *(57)* by protonation and reduction.

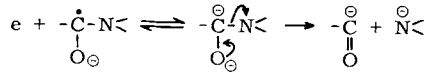
$$Ar_2C\overset{\ominus}{\cdot}O \longleftrightarrow Ar_2C\cdot-O^{\ominus} \qquad Ar_2CH-OH$$
(56) *(57)*

The polycyclic aromatic hydrocarbons form radical-ions and dianions under the action of reactive metals. Thus naphthalene forms the anion *(58)* and the dianion *(59)*. The dianion reacts with ZH to form dihydronaphthalene and the anion $Z^{\ominus}$ or the metallation product Z−M.



(58) *(59)*

These alkali metal/acceptor systems may be used for many metallation reactions in THF, *e.g.* when the metallation is followed by addition of CO_2 or when chemical separation of all the components of the solution is possible[148]. However, these cases are relatively rare. The difficulties are reduced if the reaction is carried out in alkali metal/HMPT, since the electron acceptor and its reduction product are soluble in water.



D. Comparison of Polar Aprotonic Solvents

The solvents DMF, TMU, and DMSO, whose electron donor character has already been discussed in Section IV, can also act as electron acceptors owing to their polar group, and can give generally unstable radical-anions.

(60) *(61)*

Aryl ketones form radical-ions such as *(60)*, which are stabilized by charge delocalization. The anions of the DMF and TMU molecules, which cannot be stabilized in this way, rapidly decompose into two ions[175,176].

Alkali metals actually give very unstable blue solutions in TMU; the color persists for only a few seconds at room temperature, and for a minute at −40 °C[175]. Triphenylmethane is the only substrate that can be metallated with an Na/K alloy in TMU. The decomposition follows the same course in HMPT, but the radical-anion is considerably more stable in this case (half-life of the blue color with potassium approx. 10–15 min, with Li and Na a few hours).

The aromatic sulfoxides should be similar to the diaryl ketones, since there is strong conjugation between the SO group and the aromatic nuclei; however, the radical-ion *(61)* is not very stable.

Diphenyl sulfone reacts with potassium in 1,2-dimethoxyethane to give blue solutions which are unstable even at −70 °C, but which give an EPR spectrum[177]. It may therefore be concluded that alkali metals react with DMSO to form the "dimsyl" anion *(62)*[178], and that the radical-ion *(63)* is extremely unstable.

[178] *A. Lewith* and *N. McFarlane*, Proc. chem. Soc. (London) *1964*, 108.

(63) (62)

Similarly, amides of carboxylic acids with hydrogen atoms in the α position (*e.g.* dimethylacetamide and *N*-methylpyrrolidone) and enolizable ketones should give enolate ions *(64)* with alkali metals.

(64)

The stability of the radical-ions decreases in the order $HMPT^{\ominus\bullet} > TMU^{\ominus\bullet} > DMSO^{\ominus\bullet}$; this explains why HMPT is the only known polar aprotonic solvent that can be used for syntheses involving dissolved reactive metals.

N-Persubstituted 3,5-Diaminophenols and 1,3,5-Benzenetriamines and their Protonation

By *F. Effenberger* and *R. Niess*[*]

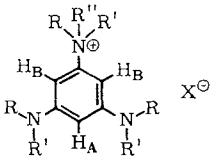
N-Persubstituted 3,5-diaminophenols *(2)* and 1,3,5-benzenetriamines *(3)* have not been described previously. We have prepared aminobenzenes *(2)* and *(3)* by heating phloroglucinol *(1)* with secondary amines in an autoclave[1].

(1) (2) (3)

The reactions are carried out with an excess of amine (phloroglucinol : amine = 1:4), the molar ratio *(2)*:*(3)* obtained depending solely on the reaction temperature. The products can be purified by fractional distillation or recrystallization.

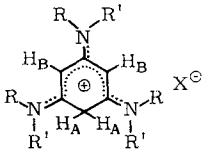
Amine used	Temp. (°C)	(2) Yield (%)	(2) M.p. (°C) (b.p., °C/mm)	(3) Yield (%)	(3) M.p. (°C) (b.p., °C/mm)
Pyrrolidine	20	100	174–185	–	
	180–200	–		95	179–181
Piperidine	180–200	98	154–156	–	
	280–300	–		40	184
Morpholine	180–200	91	185–187	–	
	280–300	–		37	308–312
Dimethylamine	130–150	68	(148/0.008)	22	
	220	14		69	(131/0.01)

With mineral acids the benzenetriamines *(3)* form definite salts containing 1, 2, or 3 moles of acid.



Depending on the substituents R and R′, stable *N*- or *C*-protonation products, *(4)* and *(5)* respectively, are formed on monoprotonation. *N*-protonation of tripiperidinobenzene [*(3)*, R and R′ = $(CH_2)_5$] for example leads to the formation of *(4)*, whilst with tripyrrolidinobenzene [*(3)*, R and R′ = $(CH_2)_4$] a crystalline compound of the type *(5)* is produced. (Physical properties: *e.g. (5)*, X = BF_4, yellow needles. m. p. 254–257 °C).

Assignment of structure was based on ^1H–NMR-spectroscopic data. The ^1H–NMR spectrum of tripyrrolidinobenzene hydroiodide [*(5)*, R and R′ = $(CH_2)_4$, X = I] in $CDCl_3$ showd H_B as a singlet at τ = 5.17 and H_A as a singlet at τ = 6.20 (relative intensities 1:1).



Particular structural characteristics can be gleaned from the ^1H–NMR spectra of tripiperidinobenzene monoperchlorate [*(4)*, R and R′ = $(CH_2)_5$, X = ClO_4]. In polar solvents (*e.g.* $(CD_3)_2CO$ or $(CD_3)_2SO$) the three nuclear protons appear as a singlet at τ = 3.6, whilst the proton attached to the nitrogen (whose presence can be seen only on integration) indicates rapid proton exchange among the amino groups. On the other hand, in $CDCl_3$ this proton is fixed on an amino function and the signals of the three nuclear protons are widely separated in the spectrum (1 H at τ = 2.10 [N–H], 2 H at τ = 3.38 and 1 H at τ = 4.63). A *meta* coupling of the ring protons H_A and H_B was not observed. The comparable *N*-methyl compound [*(6)*, R and R′ = $(CH_2)_5$, X = ClO_4], however, shows only a small amount of splitting of the nuclear protons (τ-values centered at 3.5) and a distinct *meta* coupling (J_{AB} = 2 Hz).

We conclude from the NMR spectra that there is a strong electronic disturbance of the aromatic π-electron system in tripiperidinobenzene monoperchlorate. An alternative to the benzenoid structure *(4)* is a valence isomer with a "Dewar structure"; although this would certainly agree with the NMR spectrum, we have no other evidence to support this structure.

Further investigations, in particular X-ray structural analysis of the tripiperidinobenzene monoperchlorate, are in progress.

A New Route to the Tetracyclo[3.2.0.0^{2,7}0^{4,6}]-heptan-3-one System [1]

By *H. Prinzbach* and *J. Rivier* [*]

Syntheses hitherto available [2] for the tetracyclo-[3.2.0.0^{2,7},0^{4,6}]heptan-3-one system ("quadricyclanone") have been very devious and unsatisfactory. In the reaction series *(1)* → *(2)* → *(3)* → *(4)* we have found a new route which, according to results to date, is very productive. Many variations are known for the step *(1)* → *(2)*; according to the nature of the substituent at position 8, the photochemical valence isomerization of the homotriene *(2)* to the methylenetetracyclene *(3)* can be effected in good to very good yield by direct or sensitized excitation [3]. The oxidation *(3)* → *(4)* also occurs almost quantitatively under controlled conditions.

(a), $R^1 = H$, $R^2 = R^3 = CH_3$
(b), $R^1 = H$, $R^2 = R^3 = C_6H_5$
(c), $R^1 = R^2 = H$, $R^3 = C_6H_5$
(d), $R^1 = CO_2CH_3$, $R^2 = R^3 = CH_3$

As first examples we have prepared the crystalline quadricyclanones *(4a)* and *(4d)* by degrading the methylenequadricyclane derivatives *(3a)* and *(3d)* by ozone. Spectroscopic data (see Table) show that the oxidation proceeds without skeletal rearrangement; the structures *(4a)* and *(4d)* are also proved by numerous reactions, cycloadditions [4] or condensations [*e.g.* with malonitrile to give *(5a)*]. In the pyrolysis (> 120 °C), the 3σ → 3π-process which predominates for 3-oxa- [1] and 3-aza-tetracyclene [5] plays no part, since the tropones *(6a)* and *(6d)* could not be detected by NMR spectroscopy. As with the analogously substituted 3-methylene compounds [3], and in at least formal agreement with the markedly different resonance stabilization of free radicals by *O*- and *N*-substituents or carbonyl groups [6], the bonds A are cleaved exclusively, with simultaneous or subsequent elimination of CO, to yield the aromatic compounds *(7a)* and *(7d)*. Mass spectra indicate that the radical cations produced at 70 eV from *(4a)* and *(4d)* decompose analogously. We are at present studying the stabilization of *(4a)* and *(4d)*, and of quadricyclanones containing additional substituents on the bridgeheads, after selective n→π*excitation.

Experimental

An O_2 stream containing 23 mg of O_3 per liter was passed slowly into a CH_2Cl_2 solution (−10 °C) of *(3a)*, *(3b)*, or *(3c)* (27 mmoles in 120 ml), until the KI indicator was distinctly colored. After removal of the excess of ozone in a stream of N_2 and addition of 180 ml of glacial acetic acid, a total of 5 g of zinc powder and 1.5 ml of water was added in portions. On extraction with ether, drying, and removal of the solvent by distillation there remained *(4a)* (yield, 90 to 100 %) as a slowly crystallizing oil. *(4d)* was obtained (yield, 90–100 %) similarly from *(3d)* [**].

Cycloadditions to Derivatives of Methylenequadricyclane and of Quadricyclanone (Bishomocyclobutadiene) [1]

By *H. Prinzbach* and *J. Rivier* [*]

3-Methylenetetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane derivatives *(2)*, substituted at position 8, are obtained by photoisomerization of compound *(1)* [2]. These compounds, and the tetracyclic ketones *(5)* [1] obtained from them, behave towards dienophiles formally as if they were bishomocyclobutadienes (C^1–C^2–C^7–C^6–C^4–C^5).

(a), R = C_6H_5, R^1 = CO_2CH_3
(b), R = C_6H_5, R^1 = H
(c), R = CH_3, R^1 = CO_2CH_3
(d), R = CH_3, R^1 = H

Heating *(2a)* with a five- to ten-fold excess of dimethyl acetylenedicarboxylate (DMA, 1 h, 130 °C) or methyl propiolate (MP, 6 h, 125 °C, bomb tube) affords the 1:1 adducts *(3a)* (*ca.* 90 %) and *(3b)* (*ca.* 60 %), respectively. The "forbidden" process *(2)* → *(3)* [3] is irrelevant under these conditions. The structure *(3)*, which was expected from earlier findings [4], is proved by the data collected in the table. Since these results prove the *exo*-arrangement of the four-membered ring ($J^{12} \leqslant 1.2$ Hz in *(3a)* and *(3b)*) stereospecific *exo*-attack [5] is established. That addition occurs at positions 6/7, to give *(3)*, and not at positions 2/4, to give *(4)*, is convincingly demonstrated by the fact that the olefinic

	M.p. (°C)	UV λ_{max} (nm)	UV ε	NMR (τ, TMS = 10)
(3a)	170–171	235 (s) 222 (s)	20800 [a] 24500	2.1–3.0 (10,M) [c] 5.83 (2,S) 6.61 (12,S) 6.98 (2,S)
(3b)	148	238 (s) 220 (s)	19000 [b] 23500	2.4–2.9 (10,M) [c] 3.00 (1,dD), J < 1.0 Hz 5.80 (1,T), J = 1.2 Hz 6.14 (1,T), J = 1.2 Hz 6.48 (3,S) 6.64 (6,S) 6.78 (1,dT), J = 4.0; 1.2 6.78(1,dT),J=4.0;1.2 Hz) 7.32(1,dT),J=4.0;1.2 Hz)

[a] In Isooctane. – [b] In Acetonitrile. – [c] In C_6D_6.

proton of the propiolic ester adduct (R^1) couples with the singly allylic proton H^2 *(3b)* and not with the doubly allylic proton H^1 *(4b)*.

The importance of the substituents at position 8 is illustrated by the fact that, for example, the dimethyl compound *(2c)*, even when in excess, always reacts with two equivalents of DMA or MP, giving 1:2 adducts. The structure of these products is not yet established unambiguously; it is possible that *(2c)* reacts primarily as a monohomodiene (C^1–C^7–C^2–C^3–C^8) [6].

Under the conditions of the addition *(2)* → *(3)*, the ketone *(5a)* affords the cycloctatetraene derivatives *(8, 9)*, which, according to the NMR spectra (see table), at 30 °C exist almost exclusively as the compound designated *(9)* [7]. It is reasonable to formulate the addition leading to *(9)* as analogous to that for *(3a)* and *(3b)*, *i.e.* as proceeding by way of *(6)* and *(7)* (it must be left an open question as to whether the individual steps are or are not synchronous). It would then be understandable why the ketone *(5c)*, which is substituted by acceptor groups at positions 6 and 7 and is sterically shielded, is resistant to DMA and MP under conditions that are sufficient for reaction of *(5a)* and *(5b)*.

(a), R = H, R^1 = CO_2CH_3
(b), R = H, R^1 = H
(c), R = CO_2CH_3, R^1 = CO_2CH_3
(d), R = CO_2CH_3, R^1 = H

	M.p. (°C)	UV λ_{max} (nm)	UV ε	NMR (τ, TMS = 10)
(9a)	187	232	24800 [a]	2.62 (4,S) [b] 6.24 (12,S)
(9b)	108	230	19100 [a]	2.66 (3,S) [b] 3.66 (2,S) 6.18 (3,S) 6.20 (3,S) 6.27 (3,S)

[a] In Methanol. – [b] In CCl_4.

It is doubtful whether the bishomocyclopentadienone system *(5)* has the same importance for the synthesis of derivatives of cyclooctatetraene as cyclopentadienones have for the preparation of substituted benzene derivatives[8]. Experiments with cycloctatetraene, methyl 1,2-dimethylcyclopropene-1-carboxylate, and dimethyl 1-cyclobutene-1,2-dicarboxylate as dienophilic reagents for *(5a)* did not give decisive results, even under drastic conditions.

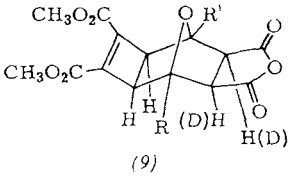
Cycloadditions to Derivatives of Oxaquadricyclanes (Bishomofuran) [1]

By *H. Prinzbach*, *M. Argüelles*, *P. Vogel*, and *W. Eberbach* [*]

The tetracyclic ethers *(2)* are readily accessible from oxanorbornadiene derivatives *(1)* by photochemical valence isomerization and can be pyrolysed to oxepins *(3)* under very mild conditions[2]. We have used the strain energy indicated by this pyrolysis of system *(2)* to advantage for a series of cycloadditions. In the temperature region where the change *(2)* → *(3)* plays only a subordinate role [small proportions of *(6)* can be separated by crystallization], the tetracycles *(2)* afford 1:1 adducts with reactive dienophiles.

(a), R = R^1 = H, R^2 = CO_2CH_3
(b), R = R^1 = H, R^2 = H
(c), R = R^1 = CH_3, R^2 = CO_2CH_3
(d), R = R^1 = CH_3, R^2 = H

For this purpose, the bishomodiene *(2)* is heated with a five- to ten-fold excess of dimethy lacetylenedicarboxylate (DMA), methyl propiolate (MP), or maleic anhydride (MA). Depending upon the substituents in *(2)* and the reactivity of the dienophile, temperatures between 80 and 110 °C and reaction times between 30 min and 9 h are necessary. The



adducts *(7)* and *(9)/(10)* are obtained in good to very good yield. The physical data relevant to proof of structure are given in the Table[3].

That addition to *(2)* occurs at positions 2/4 [giving *(7)* or *(9)/(10)*], and not, as with the isocyclic analogues[1] and their 3-methylene[1] and 3-oxo derivatives[1], at positions 6/7 [to give *(8)* or *(11)/(12)*], is shown, at least for *(7b)* and

	M.p. (°C)	UV λ_{max} (nm)	UV ε	Molecular ion at *m/e* [5]	NMR (τ, TMS = 10)

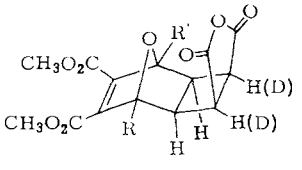
(7d)					2.93 (1,S) 6.12 (6,S) 6.19 (3,S) 7.12 (2,S) 8.36 (3,S) 8.47 (3,S)

[a] In CH_3OH. — [b] In isooctane. — [c] In $CDCl_3$. — [d] In CCl_4.



(10a), as follows: The alternative formula *(8b)* is excluded by the vicinal coupling, shown in the NMR spectrum of the MP adduct *(7b)*, between the olefinic proton (τ = 2.78) and the proton R in the α-position to the bridging oxygen atom (τ = 5.17). Similarly, formulae *(11)/(12)* are excluded by the coupling existing in the MA adduct *(10a)* between the protons introduced by MA (τ = 6.10) (assigned with the aid of $[D_2]$-MA) and the bridgehead protons R/R' (τ = 5.00). Evidence in favor of the structure *(9a)* (which then becomes probable for the second MA adduct) and against *(11a)/(12a)*[6] is provided by the singlet character of the signal of the MA protons (τ = 6.72), which also proves the *exo*-arrangement of the anhydride ring in *(9a)*. A second indication of the correctness of this assignment is the finding that the signals of the MA protons *cis* to the O atom in *(10a)* are shifted paramagnetically by 0.62 ppm in relation to those of *(9a)*[7].

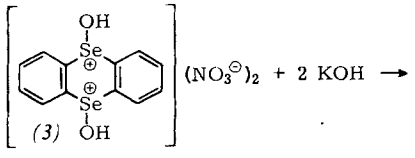
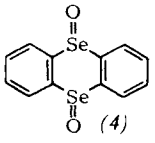
Formation of Selenanthrene from Diphenyl Selenide and of Dipotassium Triimidotellurite from Diphenyl Telluride



By *O. Schmitz-DuMont* and *B. Ross*[*]

Whereas diphenyl sulfide $S(C_6H_5)_2$ in liquid ammonia containing KNH_2 undergoes partial ammonolysis with formation of C_6H_5SK and aniline[1], reaction of diphenyl selenide $Se(C_6H_5)_2$ *(1)* under the same conditions leads to selenanthrene *(2)*, the yield thereof depending on the amount of KNH_2 present; byproducts are K_2Se_x ($x \geq 2$) and C_6H_5SeK.



(2)

Diphenyl selenide is treated with about one equivalent of KNH_2 in liquid ammonia at −70 °C in a pressure apparatus [2] On warming to 0 °C. all the diphenyl selenide dissolves. After a few hours, colorless needles separate from the yellow solution. These are filtered off and washed several times at 0 °C with liquid ammonia. The compound is then pure (m.p. 181–182 °C) and agrees in all its properties with the selenanthrene described previously [3]. The reaction with HNO_3, which is said [3] to lead to an addition compound $C_6H_4Se_2C_6H_4 \cdot 2HNO_3$, is particularly characteristic. We have found that this compound, when treated with aqueous potassium hydroxide, yields selenanthrene dioxide *(4)*, which regenerates selenanthrene with evolution of O_2 when heated above its melting point. To accord with this, the compound *(3)* and its reaction with KOH is to be formulated as:

(3) $(NO_3^{\ominus})_2$ + 2 KOH →

+ 2 KNO_3 + 2 H_2O

(4)

When two equivalents of KNH_2 are used the yield of selenanthrene decreases from 50 to 30 %; and there is no reaction in pure liquid ammonia at room temperature.

The reaction of diphenyl telluride $Te(C_6H_5)_2$ *(5)* with liquid ammonia in the presence of KNH_2 leads, however, by complete ammonolysis to formation of benzene and dipotassium triimidotellurite $K_2[Te(NH)_3]$ *(6)*. In this salt, Te has oxidation state +4 as a result of valency disproportionation of the Te^{2+} present in *(5)*:

$$7\ Te(C_6H_5)_2 + 10\ KNH_2 + 2\ NH_3 \rightarrow$$
$$4\ K_2[Te(NH)_3] + K_2Te_3 + 14\ C_6H_6$$

The red color of the mixture and the good solubility in liquid NH_3 (K_2Te is insoluble) suggest the formation of K_2Te_3.

Diphenyl telluride is treated at −70 °C with two equivalents of KNH_2 in liquid NH_3 and warmed to 20 °C, whereupon it dissolves with red coloration. The product *(6)* separates as colorless crystals within several hours, and is then filtered off, washed several times with liquid ammonia, and freed from adhering solvent by passing anhydrous N_2 over it. The substance, which is weighed for analysis with exclusion of air and moisture, must be wetted with benzene before it is hydrolysed since otherwise it explodes violently. Hydrolysis with exclusion of air and subsequent addition of acetic acid yields $TeO_2 \cdot H_2O$ as a gelatinous precipitate, which is converted into crystalline TeO_2 by warming.

On reaction of *(6)* with an excess of NH_4NO_3 in liquid NH_3 a highly explosive, yellow deposit is obtained. After being washed with liquid ammonia and freed from adhering NH_3 by passage of anhydrous N_2 at −70 °C, the product has the composition of pure tellurium(IV) nitride Te_3N_4. It could not be weighed out for analysis because of its tendency to explode. Instead, the whole material was hydrolysed in a stream of moist N_2 (absorption of the NH_3 evolved in 2 % boric acid solution, removal of the residual NH_3 by heating of the hydrolysis product with water to the boiling point, and titrimetric determination of the NH_3). The residue from the hydrolysis is TeO_2, which is weighed as elemental Te. Since the substance contains only Te and N (H can be excluded because of the exact ratio Te:N = 3:4 and the proved oxidation state +4 of the Te), the amounts of Te and N found indicate the composition Te_3N_4 unambiguously. Analysis, hydrolysis, and reaction with NH_4NO_3 accord with formulation of product *(6)* as potassium triimidotellurite. The product is formally derived from K_2TeO_3 by replacement of the O atoms by NH.

The electronegativity of the element bound to C is decisive for the course of hydrolysis of the diphenyl compounds of S, Se, and Te. If this is lower than that of the phenyl-C atom, then the ammonolysis occurs with formation of benzene and a N-compound of the element in question (cf. the ammonolysis of the phenyl compounds of phosphorus [4] and of arsenic, antimony, and bismuth [5]).

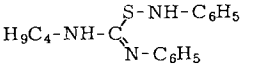
Preparation of *S*-Aminoisothioureas by Nucleophilic Substitution of *S*-Chloroisothiocarbamoyl Chlorides [1]

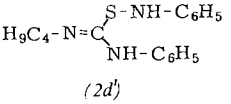
By *G. Ottmann* and *H. Hooks, jr.* [*]

N-Alkyl and *N*-aryl-*S*-chloroisothiocarbamoyl chlorides *(1)* are conveniently prepared by chlorination of isothiocyanates [2]. We have found that compounds *(1)* react very readily with primary and secondary, aliphatic and aromatic amines to form *S*-aminoisothioureas *(2)* [3] in high yields. These compounds are obtained in satisfactory purity if the reaction is performed below 0 °C and in absence of moisture.

(1)



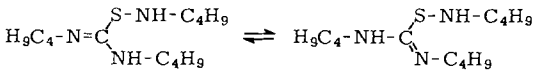
(2)



The stability of compounds *(2)* depends on the substituents: phenyl groups stabilize, whereas alkylamino groups weaken the structure. Thus, *(2a)* is stable above its melting point, while *(2b)* decomposes slowly to a tar at *ca.* 25 °C. On heating *(2c)*, 2-dibutylamino benzthiazole *(3)* was formed alongside other products by elimination of dibutylamine.

The structures of compounds *(2)* are confirmed by synthesis, elemental analysis, molecular-weight determination, and NMR spectroscopy. A migration of the C=N double bond anticipated for reactions of *(1)* with primary amines, was detected by NMR spectrometry in the case of the reaction of *(1d)*, R = C_4H_9, with aniline, which gave *(2d)* and not *(2d')*. In contrast, the original $C_6H_5N{=}C$ structure of *(1b)*, R = C_6H_5, was maintained in the reaction with butylamine.

The NMR spectrum of *N*,*N*^{1},*N*^{2}-tributyl-*S*-aminoisothiourea *(2e)* shows 2 triplets with an intensity ratio of 2:1, which



(2d)

(2d')

	R	R^1	R^2		Yield (%)	δ-^{1}H Relative intensity α-CH_2 in C_4H_9—N (ppm)			λmax (mμ)
						R^1	R^2	R	
(2a)	C_6H_5	C_6H_5NH	C_6H_5NH	m.p. 150—150.5 °C	71				257
(2b)	C_6H_5	C_4H_9NH	C_4H_9NH	oil, not distillable	83	2.70 (1)	3.35 (1)		249

(2f)	C_4H_9	$(C_4H_9)_2N$	$(C_4H_9)_2N$	b.p. 138—139 °C/0.14 mm	71	2.91 (2)	3.29 (2)	3.49 (1)	

represent two equivalent and one non-equivalent CH_2N_{butyl} group. The triplet of relative intensity 2 has a chemical shift between those of $-CH_2NH$ and $-CH_2N=$; this indicates a delocalization of the double bond of the butylimino group and the proton of the butylamino group in *(2e)*.

(2e)

Contrary to their reactions with amines, the reactions of *(1)* with sodium thiolates did not lead to stable products, but gave isothiocyanates and diaryl disulfides instead of the desired compounds *(4)*.

(4)

The reactions of *(1)* with sodium *O,O*-diethyl dithiophosphate also afforded isothiocyanates.

Syntheses:

(a) A solution of 42.0 g of *N*-phenyl-*S*-chloroisothiocarbamoyl chloride in 100 ml of ether was added dropwise at 0 °C to a stirred solution of 74.4 g of aniline in 300 ml of ether. The reaction mixture was stirred overnight at 25 °C and then filtered. The filter cake was extracted with cold water to dissolve aniline hydrochloride. The water insoluble portion was dried, and recrystallized from toluene and finally from alcohol to give 46 g of pure *S*-anilino-*N,N'*-diphenylisothiourea.

(b) The reaction mixture obtained from 37.2 g of *N*-butyl-*S*-chloroisothiocarbamoyl chloride and 113 g of dibutylamine was filtered and the solvent evaporated. The residue was extracted with 1200 ml of pentane. Distillation of the crude reaction product in 6 portions in a high vacuum yielded 52 g of pure *S*-dibutylamino-*N*-butyl-*N'*-dibutylisothiourea in the form of yellow oily liquid, and 10 g of a resinous distillation residue.

Preparation of 5-Alkyl-1,3-thiazolin-2-ones by Reaction of *S*-Chloroisothiocarbamoyl Chlorides with Aldehydes and Vinyl Ethers [1]

By *G. Ottmann*, *H. Hoberecht*, and *H. Hooks, jr.* [*]

The chlorination product of isothiocyanates, *S*-chloroisothiocarbamoyl chlorides *(1)*, react with aliphatic or cycloaliphatic ketones to form 2-imino-1,3-oxathioles or 4-alkyl- and 4,5-dialkyl-1,3-thiazolin-2-ones [2]. Thiazolin-2-ones *(2)*, mono-substituted at C-5 or unsubstituted at both C-4 and C-5, cannot be prepared by this reaction, nor have they been obtained by any other method.

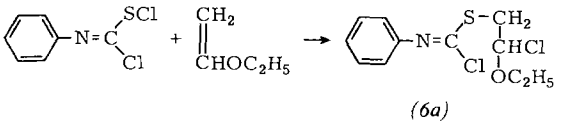
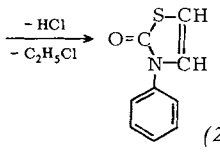
[a] From *(1)* and acetaldehyde.
[b] From *(1)* and vinyl ethyl ether.
[c] The 3-alkyl substituted derivatives of *(2)* were obtained in a pure state only by vapor phase chromatography (column: 30 % SE 30 on Chromosorb, W 60—80 mesh). Fractional distillation over a spinning band column gave products of only 80—85 % purity.

We have now synthesized compounds *(2)* by the reaction of *N*-alkyl- and *N*-aryl-*S*-chloroisothiocarbamoyl chlorides with primary aliphatic aldehydes as well as with vinyl alkyl ethers; the expected isomeric iminooxathioles *(3)* were not obtained.



Isothiocyanates, condensation products of the aldehydes, *e.g.* *(4)* from heptaldehyde, and adducts which, upon treatment with water, give 3-imino-1,2,3-dithiazolidin-5-ones *(5)*, are obtained as by-products [3].

Thiazolin-2-ones *(2)*, R^1 = H, carrying no substituents on C-4 and C-5 can be prepared readily and in high yields from *S*-chloroisothiocarbamoyl chlorides and vinyl ethyl ether [4]. This reaction is superior to that of *(1)* with acetaldehyde. For



(4) (5)

instance, compound *(1)* and vinyl ethyl ether give at, or below, 0 °C *S*-(2-chloro-2-ethoxyethyl)-*N*-phenylisothiocarbamoyl chloride *(6a)*, which is only stable in the cold or in solution. At room temperature *(6a)* undergoes an exothermic ring closure reaction with elimination of ethyl chloride and hydrogen chloride to form 3-phenyl-1,3-thiazolin-2-one *(2a)* in 81 % yield. The conversion of *(6)* to *(2)* is also effected by treatment with water[5].

(6a)

(2a)

The structure of compounds *(2)* is supported by elemental analysis, by NMR, IR, and (in some cases) mass spectroscopy The fragmentation patterns of *(2a)*, *(2b)*, and *(2c)* upon electron bombardment are very similar, with $(C_6H_5NCH)^+$ at *m/e* 104 being the common principal fragment. Other major fragments observed were $(C_6H_5NCHCHS)^+$ at *m/e* 149 in case of *(2a)*, and $(C_6H_5NCHC(CH_3)S)^+$ at *m/e* 163 for *(2b)*. The proton magnetic resonance spectra of *(2)* are in agreement with the chemical shifts established recently[2] for 4-alkyl- and 4.5-dialkyl-1,3-thiazolin-2-ones.

5-Pentyl-3-phenyl-1,3-thiazolin-2-one

103 g of *N*-phenyl-*S*-chloroisothiocarbamoyl chloride is added dropwise with stirring to 72 g of n-heptaldehyde in 250 ml of dry ether over a period of 2 h at 20–25 °C. When the reaction becomes exothermic, the addition is continued at 0–5 °C. After several hours at 10 °C, the reaction mixture is filtered and low boiling components distilled. The residue is dissolved in 150 ml of cold, dry n-pentane. After storage for several hours at −20 ° to −25 °C, 85 g (69 %) of 3-phenyl-5-pentyl-1,3-thiazolin-2-one was obtained in form of white needles m.p. 40–41 °C (from methanol).

3-Phenyl-1,3-thiazolin-2-one

206 g of *N*-phenyl-*S*-chloroisothiocarbamoyl chloride *(1)* is added slowly to 79 g of vinyl ethyl ether in 150 ml of carbontetrachloride at 0–5 °C. The clear solution is then concentrated *in vacuo*. Upon standing at room temperature, an exothermic evolution of C_2H_5Cl and HCl commences after a short time to yield a solid product which is freed from contaminating oil (porous plate) and recrystallized from heptane. Yield: 143 g of 3-phenyl-1,3-thiazolin-2-one. The latter product is also obtained by adding the original reaction mixture (CCl_4-solution) slowly to water. Vigorous agitation and efficient cooling is essential. Yield: 79 %.

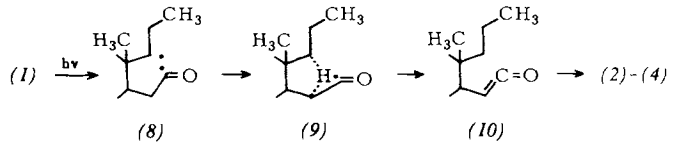
Photolysis of 3β-Hydroxy-5α-pregnan-16-one [1]

By *G. Adam* [*]

In order to clarify the photochemical behavior of 16-oxo steroids a 0.025 M solution of 3β-hydroxy-5α-pregnan-16-one *(1)* [2] in aqueous dioxane was irradiated externally, under argon, by means of a 500 W high-pressure mercury lamp (3 h, 25 °C, quartz apparatus, distance from the flask 6 cm). Separation and purification by way of the well crystalline piperidine salt (m.p. 118 °C) gave a 61 % yield of a steroidal carboxylic acid $C_{21}H_{36}O_3$ [m.p. 178–180 °C, $[\alpha]_D^{20}$ −15.7 ° ($CHCl_3$)], giving IR bands (Nujol) at 1683, 1718, 1743 (acid-carbonyl), and 3460 cm^{-1} (hydroxyl) and, in the electron-addition mass spectrum [3], principal fragments at *m/e* = 355 (M−1) and 317 (M−1−18, removal of water).

(1)



(2), R^1 = H, R^2 = OH
(3), R^1 = H, R^2 = OCH_3
(4), R^1 = H, R^2 = NH-$(CH_2)_3$-CH_3
(5), R^1 = Ac, R^2 = OH

(6), R = H
(7), R = Ac

The 3β-hydroxy-16,17-seco-5α-pregnan-16-oic acid structure *(2)* of the photoproduct was proved by synthesis from 3β-hydroxy-16,17-seco-5α-pregnan-16-al *(6)* [2]: acetylation of *(6)* with acetic anhydride/pyridine (15 h, 20 °C) gave almost quantitatively the amorphous *O*-acetyl derivative *(7)*, $[\alpha]_D^{20}$ = −14.9 °, with IR bands at 1245 and 1748 (*O*-acetyl) as well as 1732 and 2720 cm^{-1} (aldehyde), which was converted in 60 % yield by oxidation with chromic acid in acetone/dilute sulfuric acid to the seco acid *(5)*, m.p. 148–150 °C, $[\alpha]_D^{20}$ = −23.0 °, IR bands at 1245 (*O*-acetyl), 1697, 1718, 1745 (acid- and ester-carbonyl), and 3475 cm^{-1} (acid-OH). Hydrolysis by 2.5 % methanolic potassium hydroxide (1 h, 80 °C) affords the acid *(2)* in 81 % yield [4].

Corresponding carboxylic acid derivatives are formed on UV irradiation of the 16-ketone *(1)* in other protic solvents. For instance, photolysis in anhydrous methanol affords, after chromatography on Al_2O_3, a 52 % yield of the amorphous methyl 3β-hydroxy-16,17-seco-5α-pregnan-16-oate *(3)*, $[\alpha]_D^{18}$ =

$-28.3°$, IR bands (CCl_4) at 1155, 1748 (methyl ester), and 3629 cm^{-1} (hydroxyl), electron-addition mass spectrum m/e = 349 (M−1) and 331 (M−1−18). UV irradiation of *(1)* in n-butylamine gives analogously a 49 % yield of the amide *(4)*, m.p. 218–220 °C, $[\alpha]_D^{20} = -5.0°$, IR bands (Nujol) at 1555, 1660 (sec. amide), and 3315 cm^{-1} (hydroxyl), electron-addition mass spectrum m/e = 390 (M−1).

As proved for other cyclic ketones[5], a homolytic α-fission of the $n \rightarrow \pi^*$ excited 16-ketone to give the alkyl-acyl diradical *(8)* is to be assumed as responsible for the UV-induced formation of the 16,17-seco compounds *(2)–(4)*, the radical disproportionating by intramolecular migration of hydrogen to give *(10)* by way of *(9)*. Addition of nucleophilic solvent molecules affords *(2)–(4)*. Intermediate occurrence of the ketene *(10)* was confirmed by a characteristic IR band at 2108 cm^{-1} on UV irradiation of *(1)* in benzene.

Synthesis of a Morphinan Derivative by Oxidative Ring Closure [1]

By *B. Franck*, *G. Dunkelmann*, and *H. J. Lubs*[*]

Earlier attempts to obtain aporphine *(5)* and morphinan alkaloids *(8)* from laudanosoline by biogenetic-type condensation led to the formation of pyrrocoline *(4)*[2]. Later we showed that aporphines were also formed from laudanosoline, in good yield, if during the oxidation the nitrogen was quaternized[3] or the pyrocatechol groups were protected as complexes[4]. By using isotope dilution analysis *Barton et al.*[5] were able to prove that a morphinan derivative, salutaridine *(11)*, was formed in 0.024 % yield on oxidation of the dimethyllaudanosoline, reticuline *(3)*, by MnO_2.

We now report the preparative synthesis of the morphinan derivative *(9)* by oxidative condensation of reticuline *(3)*. Experience with oxidative condensations of other alkaloid precursors[3] indicates that in order to obtain higher yields it is necessary to prevent oxidative side reactions on the nitrogen, and intramolecular condensation and polymerization. Since oxidation on nitrogen can be prevented by acylation, *N*-mesylnorreticuline *(2)* (m.p. 205 °C) was first prepared and was oxidized with MnO_2 in $CHCl_3$. This led to the formation of crystalline *N*-mesylnorisoboldine *(6)*[6] (yield 40 %, m.p. 238 °C), whose mass spectrum at 70 eV showed fragments at m/e = 391 (M), 311 (M−CH_3SO_2H), and 283 (base peak, M−$CH_2{=}\overset{\oplus}{N}H{-}SO_2CH_3$), and whose UV spectrum in CH_3OH gave λ_{max} (log ε) = 220 (4.57), 282 (4.06), and 305 nm (4.16). Thus condensation of *N*-mesylnorreticuline *(2)* gives the aporphine preferentially. Morphinan derivatives could not be detected in the oxidation mixture by chromatographic investigation.

The tertiary reticuline *(3)* was then oxidized by MnO_2 in $CHCl_3$ using a heterogeneous variant of the Ziegler dilution principle. To keep the concentration of reticuline molecules on the surface of the oxidizing agent low and the distance between them large, an additional active adsorbing surface was provided by mixing the MnO_2 with three times its weight of silica gel (particle size < 0.08 mm, E. Merck). By chromatography of the reaction mixture on silica gel with benzene/methanol (5:1) as eluant a 4 % yield of the morphinan derivative, isosalutaridine *(9)*, was isolated as its crystalline acetate *(10)*: m.p. 203 °C; mass spectrum at 70 eV, m/e = 369 (M) (base peak), 341 (M−CO), 326 (M−$COCH_3$), 298 (326−CO), 284 (326−$CH_2{=}\overset{\oplus}{N}{=}CH_2$); UV spectrum in CH_3OH, λ_{max} (log ε) 204 (4.51), 232 (4.15), 283 nm (3.81); IR spectrum in KBr, 1760 (ester), 1666, 1641, 1620 cm^{-1} (dienone); NMR spectrum in $CDCl_3$, δ = 6.33 (H on C-8), 6.36 (H on C-1), 6.92 and 6.83 (H on C-5 and C-4), 2.30 ($COCH_3$), 2.47 (NCH_3), 3.81 (OCH_3). The structure of the isosalutaridine is derived unambiguosuly from these data, and it is confirmed by proton-catalysed rearrangement by acetic anhydride/conc. H_2SO_4, which, as with morphine, leads to a crystalline aposphine.

The oxidation utilizing the heterogeneous dilution principle, which led to the first isolation of a morphinan derivative after oxidation of the reticuline, probably comes particularly close to conditions in the cell. Crystalline isoboldine *(7)* (m.p. 124 °C)[7] (6 % yield) (but no salutaridine *(11)*) was isolated from the oxidation mixture alongside isosalutaridine *(9)*. Since isosalutaridine *(9)* differs only slightly from the two alkaloids, flavinine *(12)*[8] and amurine *(13)*[9], isolated from *Croton* and *Papaver* species, preparation of *(9)* can be regarded as the first, almost complete, total synthesis of these two new alkaloids *(12)* and *(13)*.

Effect of Pressure on the Equilibrium between Hydrogen and Solvated Electrons in Potassium Amide-Ammonia Solutions. The "Volume" of Solvated Electrons.

By *U. Schindewolf*, *R. Vogelsgesang*, and *K. W. Böddeker*[*]

Solvated electrons are formed by the reversible reaction of alkali amides with hydrogen in liquid ammonia[1]; they are detected by their strong absorption in the near infrared and by electron spin resonance (ESR).

$$^1/_2\,H_2 + KNH_2 \rightleftharpoons e^-_{sol} + NH_3 + K^+ \qquad (1)$$

The equilibrium constant $K = 2\times10^{-5}$ (25 °C) and the enthalpy $\Delta H = 16$ kcal/mole of the reaction, derived from the temperature dependence of K, agree reasonably well with the values calculated from thermodynamic data.

If the pressure dependence of the equilibrium constant is known, the change of volume, ΔV, associated with the reaction can be calculated according to

$$d \ln K/dp = -\Delta V/RT \qquad (2)$$

From this, in conjunction with the molar volumina of all other reacting species, the "volume" of the solvated electrons in ammonia can be estimated. This quantity is of significance to the theory of the solvated electron[2] and has not hitherto been determined experimentally. The published density measurements of alkali metal-ammonia solutions afford information only as to the volume of the spin-compensated electron pairs, e_2^-, predominating in solutions of medium concentration which still permit a meaningful evaluation of density measurements ($V_{e_2^-} = 65$ to 93 ml/mole at −33 °C[2,3]).

For the determination of the pressure dependence of the reaction, a 0.23 M solution of potassium amide in liquid ammonia was saturated, at room temperature, with hydrogen (100 atm) in an autoclave. The solution was transferred *via* a high pressure capillary into a high pressure optical cell fitted with sapphire windows (distance between windows 0.4 ± 0.01 cm), in which the pressure could be raised to 2000 atm and the temperature to 150 °C. The cell was located in the light path of a spectrophotometer with which the absorption spectrum of the solution in the pertinent interval of 1.0 to 2.3 μ was recorded. For comparison, the same solution after the hydrogen had been pumped off was measured under otherwise identical conditions. Concurrently, the spin concentration of the solutions was followed ESR-spectrometrically up to 500 atm and 50 °C. The solutions were contained in a heavy walled quartz capillary fitted into the resonator cavity of the spectrometer; connection to a pressure generator was made by means of the pressure coupling described by *Eucken* and *Suhrmann*[4].

The difference in optical density between the hydrogen-saturated and the hydrogen-free solutions yields the broad absorption spectrum of the solvated electrons[5], the intensity of which, as shown in Fig. 1, decreases with increasing pressure and increases with increasing temperature. The intensity of the ESR signal of the hydrogen-saturated solution shows the same pressure- and temperature dependence. No ESR signal is observed with the hydrogen-free solution.

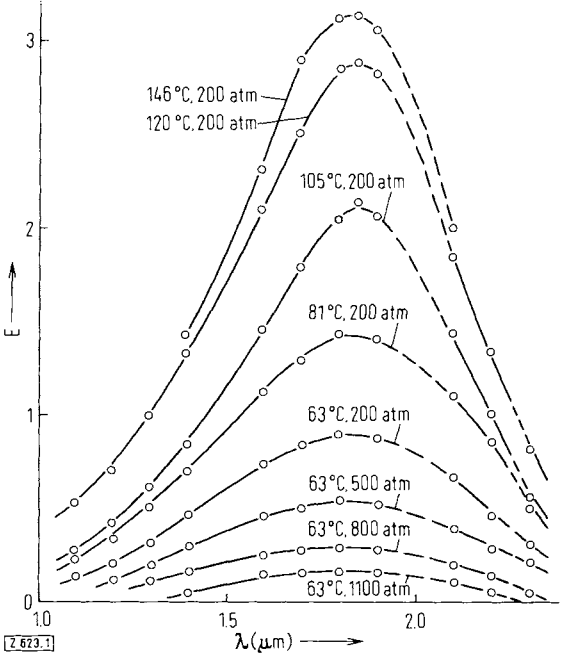

Fig. 1. Absorption spectrum of the solvated electrons as function of pressure at 63 °C and of temperature at 200 atm (0.23 M KNH_2–NH_3 solution saturated with 100 atm of H_2 at 23 °C).

The equilibrium concentration of solvated electrons of the hydrogen-saturated solution, calculated from the intensity of the absorption maximum (molar extinction coefficient 4.8×10^4 l mol^{-1} cm^{-1}[6]) between 200 and 1100 atm, and between 23 and 146 °C lies between 5×10^{-7} and 2×10^{-4} mole/l[7]; it is thus small enough to exclude the presence of spin-compensated electron pairs.

The temperature dependence of the electron concentration in the range of 23 to 63 °C at 200 atm results in an enthalpy,

ΔH, of 12 ± 1 kcal mole^{-1} for reaction (1); this value is somewhat smaller than that reported[1], without error limits, for 100 atm. From the pressure dependence at 23 °C, in conjunction with Eq. (2), a volume change, ΔV, associated with the reaction of 64 ± 3 ml/mole is obtained. Both ΔH and ΔV decrease with increasing temperature.

The apparent molar volume of KNH_2 and H_2 in ammonia are 10 ± 2 and 110 ± 20 ml/mole, respectively, as determined by density measurements at 23 °C and 100 atm. The molar volume of ammonia under these conditions is 27.8 ml. The apparent molar volume of the K^+ ions is reported as 3 ml/mole[3b]. With these values and

$$V_{e^-} = \Delta V - V_{NH_3} - V_{K^+} + V_{KNH_2} + {}^1/_2 V_{H_2} \qquad (3)$$

an apparent "volume" of the solvated electrons of 98 ± 15 ml/mole at 23 °C and 100 atm is obtained. By taking into consideration the temperature dependence of the volume of the solvated electrons, estimated from the variation of absorption frequency with temperature[8], a value of 84 ml/mole at −33 °C results; within the limits of error, this value is the same as that for the spin-compensated electron pairs.

Reaction of Perchloro-1,3,5-trisilacyclohexane with Methylmagnesium Chloride

By *G. Fritz* and *N. Szczepanski*[*]

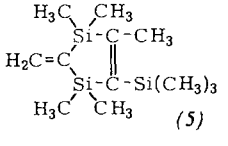
1,1,3,3,5,5-Hexachloro-1,3,5-trisilacyclohexane $(SiCl_2{-}CH_2)_3$ *(1)* reacts at the $SiCl_2$ group[1] without change in the ring skeleton. Reactions at the skeletal C atom require substitution at the CH_2 group, *e.g.* by photochlorination to give $(SiCl_2{-}CCl_2)_3$ *(2)*[2]. Chlorine on the bridging C atom of carbosilanes is extremely reactive, and this can be recognized also with $(SiH_2{-}CCl_2)_3$[3]. Reactions of $(Cl_3Si)_2CCl_2$ with CH_3MgCl lead to $[(CH_3)_3Si]_2C{=}CH_2$, $[(CH_3)_3Si]_2CH_2$, and $[(CH_3)_3Si]_2CH(CH_3)$[4].

With an excess of CH_3MgCl, perchloro-1,3,5-trisilacyclohexane *(2)* gives a mixture of several compounds[5], the three major components of which, having formulae $Si_3C_{11}H_{24}Cl_2$ *(3)*, $Si_3C_{12}H_{26}$ *(4)*, and $Si_3C_{12}H_{26}$ *(5)* (verified by mass spectrometry) were isolated by gas chromatography.

Compound *(3)* forms white crystals, m.p. 35 °C. The structure illustrated follows from the NMR spectrum and reactions with HI, $LiAlH_4$, and CH_3MgCl. The C≡C group was recognized by the Raman line at 2105 cm^{-1}[6], and excludes cyclic structural formulae.

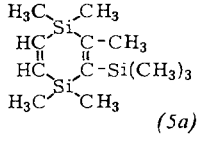
The structure illustrated for compound *(4)* follows from the fission reaction with HBr, as well as from the NMR and Raman spectra; and was confirmed by synthesis. The course of the fission of *(4)* by HBr depends on the reaction conditions: in CCl_4 the first product is

$$(CH_3)_3Si{-}CH(CH_2Br){-}Si(CH_3)_2{-}C{\equiv}C{-}Si(CH_3)_3;$$



on passage of HBr into the solvent-free substance one obtains

$$H_2C{=}CH{-}Si(CH_3)_2{-}C{\equiv}C{-}Si(CH_3)_3$$



and

$$BrH_2C{-}CH_2{-}Si(CH_3)_2{-}C{\equiv}C{-}Si(CH_3)_3.$$

According to its Raman spectrum, compound *(5)*, which is isomeric with *(4)*, does not contain an acetylene group. All our observations indicate a cyclic structure, for which all except *(5)* and *(5a)* can be excluded. Structure *(5)* is considered the more probable.

(5)

(5a)

All the other compounds obtained from *(2)* are linear and contain three Si atoms. In none of the products from *(2)* is the ring skeleton intact.

Reactions of Silylphosphines. — Formation of Lithium Tris(diethylphosphinyl)silicide

By *G. Fritz* and *G. Becker* [*]

Chlorosilanes such as $HSiCl_3$ which contain SiH groups react with $LiP(C_2H_5)_2$ to give large amounts of $(C_2H_5)_2PH$ together with silylphosphines. $(C_2H_5)_2P{-}P(C_2H_5)_2$ is formed from chlorosilanes such as $SiCl_4$ which do not contain SiH groups, provided that an excess of $LiP(C_2H_5)_2$ is present [1]. In addition, red polymers containing Si–Si groups are formed. These side reactions are almost completely suppressed if an excess of the chlorosilane is maintained during the whole reaction, as can be done by adding dropwise an ethereal solution of the phosphide to the chlorosilane [2]. Thence it can be assumed that a silylphosphine formed as intermediate is reactive towards the strongly nucleophilic phosphide. We have therefore prepared silyl- and methylsilyl-phosphine and have studied their behavior towards $LiP(C_2H_5)_2$ in diethyl ether. The course of the reaction was followed by measurement of the NMR spectrum.

We found that $(CH_3)_3Si{-}P(C_2H_5)_2$ and $LiP(C_2H_5)_2$ do not react with each other, even during a long period. However, SiH-containing silylphosphines do react, giving phosphorylated products:

$$H_3SiP(C_2H_5)_2 + LiP(C_2H_5)_2 \rightarrow H_2Si[P(C_2H_5)_2]_2 + LiH \quad (a)$$

$$H_3Si{-}P(C_2H_5)_2 + 2\,LiP(C_2H_5)_2 \rightarrow HSi[P(C_2H_5)_2]_3 + 2\,LiH \quad (b)$$

$$(CH_3)_2HSi{-}P(C_2H_5)_2 + Li(P(C_2H_5)_2 \rightarrow (CH_3)_2SiP[(C_2H_5)_2]_2 + LiH \quad (c)$$

$$(CH_3)HSi[P(C_2H_5)_2]_2 + LiP(C_2H_5)_2 \rightarrow CH_3Si[P(C_2H_5)_2]_3 + LiH \quad (d)$$

Since reaction (a) is the fastest, it is understandable why the compounds $H_2Si[P(C_2H_5)_2]_2$ and $HSi[P(C_2H_5)_2]_3$ always occur as by-products in the preparation of $H_3Si{-}P(C_2H_5)_2$ from H_3SiBr and $LiP(C_2H_5)_2$. Reaction of LiH with H_3SiBr gives SiH_4.

Reactions (c) and (d) are appreciably slower. Reaction (d), the slowest, requires several days for completion.

$HSi[P(C_2H_5)_2]_3$ and $LiP(C_2H_5)_2$ react quite differently. If the two compounds are mixed in ether in an NMR tube and the NMR spectrum is measured immediately, the following observations can be made: The quartet of the SiH resonance, which arises by spin-spin coupling with the three phosphorus atoms, has almost disappeared and simultaneously the multiplet of the phosphorus-hydrogen resonance of diethylphosphine appears. After about 2 hours the Si–H resonance can hardly be seen at all in the spectrum. The color of the ethereal solution has changed from pale yellow to bright red. The reaction occurs in accordance with

$$HSi[P(C_2H_5)_2]_3 + LiP(C_2H_5)_2 \rightarrow LiSi[P(C_2H_5)_2]_3 + HP(C_2H_5)_2 \quad (e)$$

The diethylphosphine formed can be distilled off with the solvent in a vacuum and oxidized by iodine solution to diethylphosphinous acid. This analysis shows 80% of the $HP(C_2H_5)_2$ expected for the complete reaction.

$$LiSi[P(C_2H_5)_2]_3 + CH_3Cl \rightarrow CH_3{-}Si[P(C_2H_5)_2]_3 + LiCl \quad (f)$$

$$LiSi[P(C_2H_5)_2]_3 + (CH_3)_3SiCl \rightarrow (CH_3)_3Si{-}Si[P(C_2H_5)_2]_3 + LiCl \quad (g)$$

$$LiSi[P(C_2H_5)_2]_3 + (CH_3)_2SiHCl \rightarrow (CH_3)_2HSi{-}Si[P(C_2H_5)_2]_3 + LiCl \quad (h)$$

$$LiSi[P(C_2H_5)_2]_3 + H_3SiBr \rightarrow H_3Si{-}Si[P(C_2H_5)_2]_3 + LiBr \quad (i)$$

Lithium tris(diethylphosphinyl)silicide, $LiSi[P(C_2H_5)_2]_3$, cannot be isolated in crystalline form. It is obtained as a red resinous substance which redissolves completely in ether. It reacts with CH_3Cl, $(CH_3)_3SiCl$, $(CH_3)_2SiHCl$, and H_3SiBr according to equations (f)–(i). In reaction (f) a Si–C bond is formed, but in (g)–(i) phosphinyl derivatives of disilane are obtained.

Experimental: $HSi[P(C_2H_5)_2]_3$ was mixed with the stoichiometric amount of $LiP(C_2H_5)_2$ in ether, then kept at 20 °C for about 5 h, after which the diethylphosphine was pumped off with the solvent. There remained the red resinous $LiSi[P(C_2H_5)_2]_3$, which dissolved without residue on renewed addition of ether. The halogen compound was condensed on to the frozen solution, in which it dissolved at about −90 °C. Reaction occurs only between −50 ° and −60 °C, the solution being decolorized and the appropriate amount of lithium halide precipitated. The products were isolated by distillation. Yields are 30–40%.

The products indicated in equations (f)–(i) are accompanied by less volatile products containing Si–Si bonds and by simple silylphosphines such as diethyl(trimethylsilyl)phosphine, which is formed by reaction of $LiSi[P(C_2H_5)_2]_3$ with $(CH_3)_3SiCl$. Thus substitution of the lithium [eq. (g)] is accompanied by fission of the Si–P bond by the halogen compound [eq. (k)].

$$[(C_2H_5)_2P]_3SiLi + ClSi(CH_3)_3 \rightarrow (C_2H_5)_2P{-}Si(CH_3)_3 + [(C_2H_5)_2P]_2ClSiLi \quad (k)$$

This product, which contains lithium and halogen on the same Si atom, gives substances of high molecular weight with loss of LiCl.

In contrast to reaction (e), $HSi[P(C_2H_5)_2]_3$ and butyllithium in pentane do not react with metalation of the Si atom:

$$HSi[P(C_2H_5)_2]_3 + 3\,LiC_4H_9 \rightarrow HSi(C_4H_9)_3 + 3\,LiP(C_2H_5)_2$$

Metalation in accord with equation (e) occurs only with $HSi[P(C_2H_5)_2]_3$. If either one or two $(C_2H_5)_2P$ groups are attached to the Si atom, then reaction occurs with formation of LiH [eq. (a)–(d)]. Apparently the Si–H hydrogen loses its hydride character as the number of $(C_2H_5)_2P$ on the Si atom increases, so that the exchange for lithium becomes understandable in the case of $HSi[(C_2H_5)_2]_3$. Similar conclusions can be drawn from the NMR spectra of the SiH-containing compounds of this series.

Resolution of Racemates of Asymmetric Phosphinylacetic Acids, Model Compounds for Reactions of Phosphinate Carbanions

By *J. Michalski* and *St. Musierowicz* [*]

Dedicated to Professor G. Wittig on his 70th Birthday

In connection with our work on the stereochemistry of reactions of the carbanions formed from phosphonates [1] and thiophosphonates [2], we have synthesized phosphinylacetic

acids $R(R_1O)P(O)CH_2COOH$ in which the phosphorus atom is an asymmetric center, and we have resolved them into optical antipodes.

Starting materials were t-butyl phosphinylacetates $R(R_1O)P(O)CH_2COOC_4H_9$-t, which we prepared by the Arbusov reaction from equimolar amounts of t-butyl chloroacetate and dialkyl phosphinites $RP(OR_1)_2$ at 140 °C and isolated by distillation.

R	R_1	B.p. (°C/mm)	n_D^{20}	Yield (%)
C_6H_5	C_2H_5	92/0.01	1.5008	70
C_6H_5	CH_3	108/0.1	1.5050	76
C_2H_5	C_2H_5	80/0.03	1.4430	66

Selective removal of the t-butyl group by 5% hydrochloric acid at 100 °C gives the free phosphinylacetic acids, which were obtained pure by extraction with benzene, evaporation of the solvent, and crystallization.

R	R_1	M.p. (°C)	Yield (%)	Solvent
C_6H_5	C_2H_5	88–91 [3]	80	Acetone
C_6H_5	CH_3	83–85 [3]	70	Acetone/ether
C_2H_5	C_2H_5	48–52	73.5	Ether

The racemic phosphinylacetic acids were separated into their antipodes by fractional crystallization of the quinine and cinchonidine salts from acetone or acetone/ether. The optically active acids, which were liberated from the alkaloid salts on an ion-exchange column (Amberlite IR 120), are yellow viscous oils. Their reaction with diazomethane led to the optically active methyl esters. Esters with rotations of $[\alpha]_{589}^{25} = -10.1°$ (acetone, $c = 5.064$), and $[\alpha]_{589}^{25} = +10.4°$ (acetone, $c = 5.537$) were obtained from the (−)- and (+)-acids with $R = C_6H_5$ and $R' = CH_3$ respectively.

(1)		Salt			Acid
		M.p. (°C)	Solvent	$[\alpha]_{589}^{25}$ (in ethanol); c	$[\alpha]_{589}^{25}$; c
$R = C_6H_5$	Cinchonidine	149–150	Acetone	− 81.5°; 3.777	− 8.8°; 5.42 (benzene)
$R_1 = C_2H_5$		154–155	Acetone	− 59.2; 2.5124	+ 9.1; 3.0 (benzene)
$R = C_6H_5$	Quinine	124–125	Acetone	−126.6; 4.578	−25.9°; 3.265 (water)
$R_1 = CH_3$		93–95	Acetone/ether	− 87.4°; 4.827	+26.6; 2.081 (water)
$R = C_2H_5$	Quinine	134–135	Acetone	−136.3°; 4.724	+24.1°; 5.142 (benzene)
$R_1 = C_2H_5$		86–88	Acetone/ether	−124.0°; 4.885	−24.5°; 6.088 (benzene)

All the products gave correct elemental analyses.

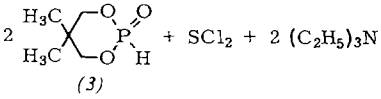
Synthesis of Bis(5,5-dimethyl-2-oxo-1,3,2-P^V-dioxaphosphorinanyl) Sulfide

By *J. Michalski, M. Mikołajczyk, B. Młotkowska*, and *A. Zwierzak* [*]

In 1963, *Edmundson* [1] reported the synthesis of the isomeric thiopyrophosphates *(1)* and *(2)* containing cyclic groups which stabilized the rather unstable thiol form *(1)*.



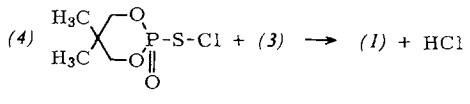
(1)

(2)

Our attempts to synthesize the isomer *(1)* in the pure state by *Edmundson*'s method always led to a difficulty separable mixture of comparable amounts of *(1)* and *(2)* [**].

In the treatment of 5,5-dimethyl-2-oxo-1,3,2-P^V-dioxaphosphorinane *(3)* with sulfur dichloride in the presence of triethylamine we have found a new procedure for the synthesis of *(1)*.

(3)



Treating *(3)* with piperidinesulphenyl chloride also leads to *(1)*.

In both cases the desired thiopyrophosphate *(1)* is obtained chemically pure in good yield. The purity of *(1)* was determined chromatographically [silica gel G (E. Merck); benzene/acetone/chloroform (3:2:1); R_F values, 0.64 for *(1)* and 0.88 for *(2)*].

Compound *(1)* is completely stable at room temperature and is unchanged in boiling benzene; however, it rearranges to *(2)* when boiled for *ca.* 10 hours in xylene.

It is remarkable that *(1)* is also formed by the action of *(3)* on 2-(chlorothio)-5,5-dimethyl-2-oxo-1,3,2-P^V-dioxaphosphorinane *(4)*, which is assumed to be an intermediate in the above-mentioned reactions [2].

It is thus proved that oxophosphoranesulfenyl chlorides >P(O)SCl and esters of tervalent phosphorus acids <P–O–R(H) give first the thiol form *(3)* of the monothiopyrophosphate system [3].

Synthesis of bis(5,5-dimethyl-2-oxo-1,3,2-P^V-dioxaphosphorinanyl)sulfide (1):

A solution of sulfur dichloride (2.06 g, 0.02 mole) in benzene (20 ml) was added dropwise to a solution of 5,5-dimethyl-2-oxo-1,3,2-dioxaphosphorinane *(3)* (6.0 g, 0.04 mole) and triethylamine (4.04 g, 0.04 mole) in benzene (50 ml) at 20 to 30 °C (ice cooling). The whole was stirred at room temperature for 1 h and the crystal mass was filtered off with suction, washed with benzene (2 × 50 ml) and water (2 × 50 ml), and dried. Yield, 4,0 g; m.p. 162–167 °C; m.p. 185–188 °C after recrystallization from benzene/chloroform.

Detection of Aryl(vinyl)nitroxides by ESR Spectroscopy

By *H. G. Aurich* and *F. Baer* [*]

If 2,3-diphenylpropionitrile *(1)*, R = H, is treated with an aromatic nitroso compound *(2)* in methanol containing sodium methoxide, the expected nitrone *(3)*, R = H, is not obtained because it reacts at once with further nitroso compound, giving the α,α',*N*,*N*'-tetraphenyldinitrone [benzoin bis(phenylimide *N*-oxide)] *(4)* by dehydrogenation [1].

The second step in the reaction is blocked if the starting material is a nitrile with a secondary β-carbon atom, as *(1)*, R = C_6H_5 or CH_3; but even then the reaction proceeds beyond the nitrone stage *(3)*, giving the aryl(vinyl)nitroxides *(5)*, which can be detected by their ESR spectra.

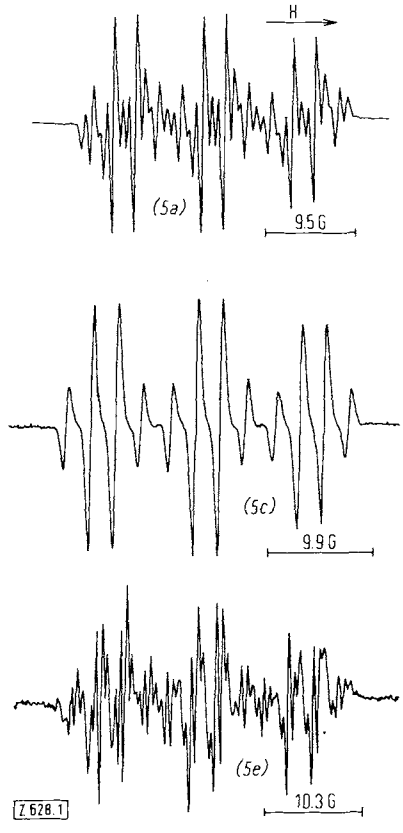

Fig. 1. ESR spectra of the aryl(vinyl)nitroxides *(5a)*, *(5c)*, and *(5e)*.

A solution of a nitrile *(1)* (1 mmole) and a nitroso compound *(2)* (1 to 2 mmoles) in t-butyl alcohol (20 ml) is added to a solution of potassium t-butoxide (5 mmoles) in t-butyl alcohol (20 ml) under nitrogen. The dark red mixture is stirred for 45 min at room temperature. Glacial acetic acid is added to give a weakly acid reaction, the solvent is distilled off in a rotary evaporator, and the solid residue is taken up in benzene (50 ml) and water (50 ml). The benzene phase is separated, washed several times with water, and dried. For determination of the ESR spectra samples of the benzene solutions were further diluted.

In accord with the coupling of the unpaired electron with the nitrogen atom, the ESR spectra of these nitroxides consist of three line groups of about the same intensity [2]. Quadruplet splitting of the individual line groups (approximate intensity ratio 1:3:3:1) in the spectrum of *(5c)* is caused by the three equivalent *o*- and *p*-protons of the phenyl nucleus on the nitroxide group. In the spectrum of *(5a)* each of these lines is additionally split three-fold by the *m*-protons of this phenyl nucleus.

The density of the unpaired electron in the vinyl group and the three neighboring phenyl nuclei is apparently too small for visible splitting by these phenyl protons to arise. On the

	R	Ar	Coupling constants (gauss)			
			a_N	a_H (*o*,*p*-Ar)	a_H (*m*-Ar)	a_H (CH_3)
(5a)	C_6H_5	C_6H_5	9.5	2.37	0.82	–
(5b)	C_6H_5	4-$(CH_3)_3C$–C_6H_4	9.8	2.37	0.82	–
(5c)	C_6H_5	3,5-[$(CH_3)_3C$]$_2$–C_6H_3	9.9	2.33	–	–
(5d)	CH_3	C_6H_5	10.0	2.62	0.95	0.6
(5e)	CH_3	3,5-[$(CH_3)_3C$]$_2$–C_6H_3	10.3	2.64	–	0.62

other hand, coupling with the protons of the methyl group in *(5d)* and *(5e)* increases the number of lines. Although the spectrum of *(5d)* is thus rendered very complex, the quadruplet splitting by the methyl protons can be readily recognized on comparison of the spectra of *(5e)* and *(5c)*.

[2] For the nitroxides studied here, the intensity of the outside group of lines at the high field side is somewhat decreased. This phenomenon has often been observed in the ESR spectra of nitroxides: *K. Umemoto, Y. Deguchi*, and *H. Takaki*, Bull. chem. Soc. Japan *36*, 560 (1963).

μ-Cyanogenbis(pentacarbonylmetal) Complexes

By *J. F. Guttenberger* [*]

Cyanogen reacts photochemically with hexacarbonylmetals with formation of intensely colored compounds of composition $[(OC)_5MNC]$ *(1)*, that are not attacked by oxygen.

Determination of the molecular weights of these products gives values that correspond to twice the molecular weights of *(1)*. It is therefore assumed that the C–C bond in $(CN)_2$ remains intact and that this substance links two pentacarbonylmetal fragments as a bifunctional donor, so that μ-cyanogenbis(pentacarbonylmetal) complexes

$$(OC)_5MNC{-}CNM(CO)_5 \qquad (2)$$

are formed. This behavior is in agreement with the high dissociation energy (145 kcal/mole[1]) of the C–C bond in cyanogen and is supported by calculations of electron density distribution[2] according to which the external bonds in $(CN)_2$ are barely changed by conjugation. Further, the spectroscopic data given in the Table accord with structure *(2)*.

Preparation of the Complexes:

An apparatus described by *Strohmeier*[3] was used for irradiation of the substances. Cyanogen was prepared and purified as described in[4]. It was carried into the irradiation cuvette in a slow N_2 stream that passed through the $(CN)_2$ production apparatus and the cuvette during the irradiation.

1. μ-Cyanogenbis(pentacarbonylchromium): 2 mmoles (440 mg) of $Cr(CO)_6$ in 25 ml of tetrahydrofuran was irradiated for 2 h under a stream of N_2 and $(CN)_2$. Then the solvent was removed in a rotary evaporator at 40 °C/40 mm, and the residue was dried in a vacuum at 40 °C/10^{-2} mm. The compound was freed from decomposition products by dissolution in benzene, filtration, and removal of the solvent. After renewed drying in a vacuum 139 mg [32% calc. on $Cr(CO)_6$] of the reddish-violet complex was isolated.

2. μ-Cyanogenbis(pentacarbonylmolybdenum): Preparation as for 1, but benzene was used as solvent for the irradiation. Yield: 115 mg (22%).

3. μ-Cyanogenbis(pentacarbonyltungsten): Preparation as for 1. Yield: 252 mg (36%).

Preparation and Properties of Diammonium Dioxodiselenomolybdate(VI)

By *A. Müller, B. Krebs*, and *E. Diemann* [*]

If hydrogen selenide is led into a saturated solution of molybdenum trioxide in 25% aqueous ammonia until a deep red color appears, and the solution is then saturated with oxygen-free carbon dioxide with strong cooling (ice-salt mixture), olive-green crystals of the compound $(NH_4)_2MoO_2Se_2$ *(1)* separate after a short time. The $MoO_2Se_2^{2-}$ ion has not been previously observed either in solution or in the crystalline state. Substance *(1)* was identified by elemental analysis and by its IR and UV spectra.

Compound *(1)* dissolves in water with an intense orange-red color and is almost insoluble in ether or alcohol. Like the corresponding tetraseleno salt it is extraordinarily sensitive to oxygen, and all operations with it must therefore be carried out in a closed system with an atmosphere of a protecting gas.

The IR spectrum of the solid between 4000 and 250 cm^{-1} shows the internal vibrations of the NH_4^+ ion at *ca.* 3200 cm^{-1} [$\nu_3(F_2)$] and 1395 cm^{-1} [$\nu_4(F_2)$]. The absorption frequencies of the dioxodiselenomolybdate(VI) ion can be assigned approximately on the basis of point group C_{2v}: 830 cm^{-1}: $\nu_s(MoO) \wedge \nu_1(A_1)$; 790 cm^{-1}: $\nu_{as}(MoO) \triangleq \nu_6(B_1)$; also 362, 344, and 285 cm^{-1}: $\nu_s(MoSe) \wedge \nu_2(A_1)$, $\nu_{as}(MoSe) \wedge \nu_8(B_2)$, and $\delta(MoO_2)\ \nu_3(A_1)$. $\wedge$ The assignment $\nu_s(MoO) > \nu_{as}(MoO)$ can be regarded as certain since the bands of higher vibration in the IR spectrum occur with lower intensity and since only this assignment leads to a reasonable value for the length-length interaction force constant. Not much can be said about the series $\nu_2(A_1)$, $\nu_3(A_1)$, and $\nu_8(B_2)$; exact assignment is not possible without a knowledge of the Raman spectrum.

$(OC)_5MNC{-}CNM(CO)_5$

	M = Cr	M = Mo	M = W
IR [a] ν_{CN}(cm^{-1})	2263 vw, 2118 vw	2267 vw	2267 vw, 2107 vw
ν_{CO}(cm^{-1})	2067 w, 2038 m, 1980 s, 1959 m	2075 w, 2043 m, 1985 s, 1960 m	2069 w, 2027 m, 1975 s, 1955 m
Mol. wt. [b]	425 (436)	*ca.* 600 (524)	*ca.* 900 (700)
Color	Reddish-violet	Dark brown	Violet
Stability	The benzene solutions are stable in air for a few hours, the solid substance for several days.		
Solubility	The compounds are insoluble in water, difficulty soluble in CH_3OH, slightly soluble in aliphatic hydrocarbons, and moderately soluble in benzene and acetone.		
M.p.	The complex compounds do not melt.		

[a] In CCl_4; accuracy ±3 cm^{-1}; vw = very weak; w = weak; m = medium; s = strong.

[b] Osmometric in benzene. The low solubility of the molybdenum and tungsten compounds prevented accurate measurement. The theoretical values are given in parantheses.

On the basis of our previous studies [1], bands at *ca.* 300 cm^{-1} are characteristic of transition metal-selenium bonds with π-bond contributions.

The Table lists the absorption maxima in the UV spectrum of an aqueous solution of the $MoO_2Se_2^{2-}$ ion. As expected, the maxima are shifted to longer wavelengths in comparison with those of $MoO_2S_2^{2-}$ and $WO_2Se_2^{2-}$. It seems remarkable that $MoO_2Se_2^{2-}$ has the same color as MoS_4^{2-}, and correspondingly that $WO_2Se_2^{2-}$ has the same color as WS_4^{2-} (cf. the longest-wavelength bands). It is difficult to assign all the bands found for $MoO_2Se_2^{2-}$. Probably, however, the band at 455 nm corresponds to a transition $3b_2 \rightarrow 5a_1$, *i.e.* to an electron transition that represents a charge transfer Se→Mo (cf. [2]).

	Band 1 nm	Band 2 nm	Band 3 nm	Band 4 nm	Ref.
$MoO_2Se_2^{2-}$	455	352	313	245	
$MoO_2S_2^{2-}$	394	319	288	219	[2]
$WO_2Se_2^{2-}$	370	293	264		[3]
$WO_2S_2^{2-}$	327	273	244		[2]
MoS_4^{2-}	463	316	241		[4]
WS_4^{2-}	391	276	222		[4]

The MoO stretching force constant can be estimated from equations given by us [5]:

$f_{MoO} = 5.3$ mdyn/Å ($f_{MoO/MoO} = 0.5$).

As expected, it is somewhat smaller than the values for MoO_4^{2-} [5] and $MoO_2S_2^{2-}$ [5].

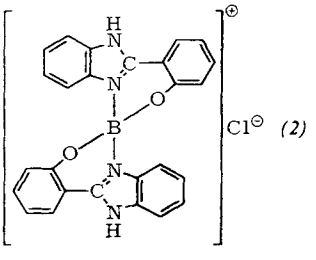
Boron Chelate Compounds in the 2-(*o*-Hydroxyphenyl)benzazole Series

By *F. Umland* and *E. Hohaus* [*]

We have synthesized fused six-membered heterocycles of type *(1)* containing O–B–N groups where Y = S, O, NH, or CH_2 and Z = C_6H_5, F, or Cl.

(1)

The compounds behave as metal chelates where the BZ_2^+ group takes the place of a coordinatively bidentate metal cation.



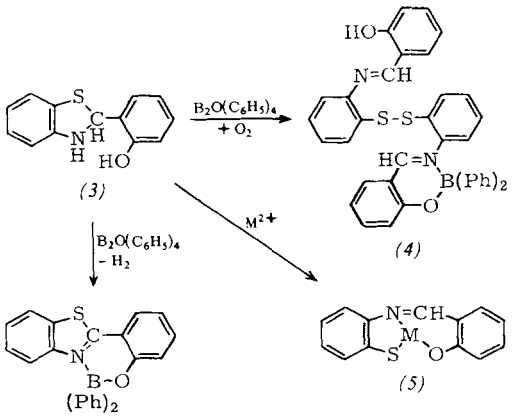
The chelating agents used were the 2-(*o*-hydroxyphenyl) derivatives of benzothiazole, benzoxazole, benzimidazole, and indole. In the last case the indole-indolenine tautomeric equilibrium was shifted to the indolenine side by the chelate formation: the C=N stretching vibration at *ca.* 1610 cm^{-1} occurs only weakly in free indole, but in the indolenine-BZ_2 chelates it is in the same strength as for the other chelates.

Experimental: The chelating agent was dissolved in benzene, dioxane, or ether and mixed with a slight excess of a solution of the boron compound (tetraphenyldiboron oxide, BF_3, or BCl_3), and the whole was heated under reflux for 1–2 hours. The boron chelates crystallize after evaporation of the solvent and cooling. They were recrystallized or (for Y = NH) were reprecipitated by addition of toluene and evaporation. Compounds with Z = Cl can be purified only by washing with ether or dioxane. The compound with Y = CH_2 and Z = Cl has been prepared at −40 °C.

Y	Z	M.p. (°C)	Color	Fluorescence [a]
S	C_6H_5 [1]	220	Intense yellow	Strong yellowish-green
	F	280	Pale yellow	Weak pale blue
	Cl [b]	330–340 (decomp.)	Yellow	Weak blue
O	C_6H_5	195	Colorless to pale greenish	Blue to pale blue
	F	218–219	Colorless	Bluish-violet
NH	C_6H_5	400–440 (decomp.)	Colorless	Dark blue
	F	356–357	Colorless	Blue
	Cl	240–245 (decomp.)	Colorless to pale violet	Pale blue
CH_2	C_6H_5	227–229	Strong yellowish-green	Strong yellowish-green
	F	280 (decomp.)	Yellowish	Pale blue
	Cl [b]	200–205 (decomp.)	Yellow	Pale yellow

[a] In the solid state. [b] Sensitive to hydrolysis.

It was not possible to isolate a compound of type *(1)* after treatment of 2-(*o*-hydroxyphenyl)benzimidazole with BCl_3 in dioxane; the salt-like compound *(2)* was formed at once. This colorless substance neither melts nor decomposes below



(2)

370 °C, and is difficultly soluble in the usual organic solvents and in water, but it is slowly hydrolysed when kept in water, as shown by the increase in conductivity.

Diphenylboron and difluoroboron chelates of 2-(*o*-hydroxyphenyl)benzothiazole are formed, with evolution of hydrogen, also from 2-(*o*-hydroxyphenyl)benzothiazoline *(3)* and tetraphenyldiboron oxide or BF_3. In the presence of oxygen the reaction involves also formation of *ca.* 25% of a disulfide, in which with tetraphenyldiboron oxide only one [cf. *(4)*] (m.p. 130–135 °C, yellow) but with BF_3 both chelating groups react (m.p. 276–277 °C, yellow, fluorescence blue green).

The reaction of the thiazoline *(3)* with boron compounds contrasts with its reaction with metal cations (Cu, Zn, Cd); in the latter case the thiazoline reacts as a tridentate chelating agent with fission of the C–S bond and formation of an azomethine chelate *(5)* [2]. It is known [3] that, in the reaction of boron compounds with tridentate chelating agents that contain only O and N as ligating groups, a reaction analogous to that with metal chelates and involving loss of a second Z group is possible; therefore, the cause of the differing behavior of the thiazoline may lie in the lower stability of the B–S bond. This view is supported by the fact that it is also impos-

sible to obtain aphenyl boron-azomethine chelate $[B(C_6H_5)^{2+}]$ in which with tetraphenyldiboron oxide only one [cf. *(4)*] (m.p. 130–135 °C, yellow) but with BF_3 both chelating groups react (m.p. 276–277 °C, yellow, fluorescene blue green).

Biosynthesis of 5,6-Dimethylbenzimidazole [1]

By *P. Renz* and *K. Reinhold*[*]

Anaerobically, in the presence of cobalt, *Propionibacterium shermanii* forms cobinamide. Aerobically, on addition of lactic acid, mainly cobalamine [α-(5,6-dimethylbenzimidazolyl)cobamide] is formed. Since lactic acid is converted by propionic acid bacteria into acetyl-coenzyme A[2], it was possible, by using sodium [2-^{14}C]-D,L-lactate and [2,3-$^{14}C_2$]-D,L-lactate, to determine whether the 5,6-dimethylbenzimidazole *(1)* contained in cobalamine is formed from acetate units as are numerous other aromatic compounds.

(1)

For this purpose, the moist bacterial mass from *P. shermanii* was harvested by centrifugation after two days' anaerobic growth. Ten 25 g batches of this material (cobinamide content 1–2 mg/25 g) were slurried in 400 ml of sterile 1/15 M phosphate buffer (pH 7.0) and treated with 8 ml of a 50% sodium lactate solution that contained 10 μCi of radioactive lactate. The batches were shaken for 50 h at 30 °C. After isolation, the vitamin B_{12} formed was degraded to *(1)* by HCl[3]. For determination of the radioactivity of the two methyl groups and of C-5 and C-6, the compound *(1)* was degraded by the *Kuhn-Roth* method[4], yielding 2 molecules of acetic acid per 1 molecule of *(1)*. The acetic acid was further degraded to methylamine and CO_2[5]. Since the remaining C atoms are oxidized to CO_2 in the *Kuhn-Roth* degradation, the radioactivity at C-4, C-7, C-8, and C-9 was determined by degradation of *(1)* to 4,5-imidazoledicarboxylic acid (as in the method due to *Efros et al.*[6]) and this acid was decarboxylated to imidazole[7]. The radioactivity at C-2 was not determined separately.

Distribution of radioactivity in labeled 5,6-dimethylbenzimidazole (counts min^{-1} $mmole^{-1}$)

	[2-^{14}C]Lactate	[2,3-$^{14}C_2$]Lactate
(1)	4230	12000
CH_3	146	1170
C-5 + C-6	730	1170
C-4 + C-7	0	2090
C-2 + C-8 + C-9	1022	730
Total	1898	5160
% of original radioactivity	45 [a]	43 [a]

[a] That only 45 or 43% of the original radioactivity was found in the fragments is due to the fact that *(1)* was measured in ethanol/dioxane/toluene, and the fragments in hyamine/toluene.

The Table shows that mainly C-2, C-5, C-6, C-8, and C-9 are labeled on introduction of [2-^{14}C]lactate, but that all the fragments are labeled when [2,3-$^{14}C_2$]lactate is used. This distribution is the same as *Plaut*[8] found for the dimethylbenzene ring of riboflavin. Formation of this ring thus occurs by the same route in cobalamine as in riboflavin.

Reductive Dehalogenation of Organic Compounds by Sodium Telluride

By *W. Mack*[*]

As a rule it is not easy to substitute hydrogen for halogen in aromatic compounds[1]. In Na_2Te a reducing agent has been found that makes this exchange possible. In particular perhalogeno aromatic compounds, which are often easy to prepare, can be converted by this reagent, smoothly and in good yield, into partially halogenated compounds which are not easy to obtain by other methods.

(a), R = Cl, 91%
(b), R = H, 96%
(c), R = OC_6H_5, 91% [2]
(d), R = Piperidino, 82% [3]

The organic compound is heated with a stoichiometric amount of Na_2Te[4] in aqueous-methanolic solution until separation of Te is complete, and the mixture is worked up after filtration from the Te/NaCl precipitate. Hexachlorobenzene is thus converted into 1,2,4,5-tetrachlorobenzene, and octachloronaphthalene into heptachloronaphthalene.

Perhalogenated olefins also undergo this reaction. Tetrachloroethylene affords 51% of trichloroethylene, which in turn can be reduced to *cis*-1,2-dichloroethylene in 12% yield. A variant of the reaction consists of using, in place of Na_2Te, elemental Te with a reducing agent, *e.g.* Rongalite[5], which converts Te into telluride.

Experimental:

Tetrachlorothiophene (333 g) is heated under reflux with Rongalite (485 g), Te (192 g), and NaOH (330 g) in 50% aqueous methanol (4.2 l) under N_2 for 33 h. This affords *(2a)* (208 g, 74%) as well as *(2b)* (5.4 g) and unused *(1a)* (30 g). The products are separated by distillation. The tellurium used is recovered quantitatively.

Na_2Te (1980 g, 11.4 moles) in methanol (10 l) and then water (3 l) are added to a solution of compound *(1a)* (1280 g), 5.77 moles) in boiling methanol (2 l), and the whole is boiled for 42 h. Then O_2 is passed in for a short time, the mixture is neutralized with gaseous HCl, and Te and NaCl are filtered off. Pouring the filtrate in water (20 l) and distillation affords *(2b)* (907 g, 84%) together with *(2a)* (162 g, 13%). 99% (1434 g) of the Te is recovered.

Synthesis of 1,2,4-Thiadiazoles from Nitriles and Sulfur

By *W. Mack*[*]

1,2,4-Thiadiazoles *(1)* are formed by reaction of aromatic nitriles with sulfur in the presence of basic catalysts. Alkylamines are particularly suitable for this purpose, their catalytic activity increasing with increasing chain length. For

(1a), R = Phenyl
(1b), R = ß-Naphthyl
(1c), R = *p*-Tolyl

instance, tri-n-octylamine is five times as active as the same molar proportion of triethylamine.

Synthesis of (1a)

0.6 mole of benzonitrile is heated with 0.2 mole of sulfur and 1.8 mmole of tri-n-octylamine in a bomb tube for 42 h at 250 °C. Subsequent distillation affords 35.7 g (75%) of *(1a)*, b.p. 156–160 °C/0.2 mm, m.p. 90 °C (from ethanol).

Synthesis of (1b)

60 mmoles of 2-naphthonitrile, 30 mmoles of sulfur, and 0.3 mmole of tri-n-octylamine are heated in a bomb tube for 158 h at 250 °C. All the volatile materials are then sublimed off in a high vacuum and the alcohol-insoluble portion of the sublimate is recrystallized from benzene. Yield 3.2 g (28%) of *(1b)*, m.p. 180 °C.

Synthesis of (1c)

200 mmoles of *p*-tolunitrile, 100 mmoles of sulfur, and 0.1 mmole of tri-n-octylamine are heated in a bomb tube for 21 h at 250 °C. Then all the material that volatilizes from the reaction mixture at about 200 °C/10^{-3} mm is recrystallized from ethanol. Yield: 3.2 g (12%) of *(1c)*, m.p. 128 °C.

Photochemical Synthesis of Alkyl- and Aryl-cyclopropenes [1]

By *H. Dürr*[*]

Dedicated to Professor B. Eistert on his 65th Birthday

Bamford and *Stevens*' reaction[2] can be used to prepare alkylcyclopropenes by thermal decomposition of the sodium salts of tosylhydrazones of α,β-unsaturated carbonyl compounds[3,4], but the method fails with the tosylhydrazones of aryl-substituted ketones.

However, photolysis of the alkali salts of the tosylhydrazones *(1)* affords both alkyl- and aryl-cyclopropenes *(2)*.

(1) *(2)*

	R¹	R²	R³	R⁴	Solvent	Photolysis conditions [a]	Yield (%) Photochem.	Thermal
(2a)	CH_3	CH_3	H	CH_3	Diglyme	I	42 [b]	39 [3]
(2b)	CH_3	CH_3	CH_3	CH_3	Diglyme	II	28 [b]	22 [4]
(2c)	C_6H_5	H	H	C_6H_5	Dioxane	I	19	0
(2d)	C_6H_5	H	C_6H_5	C_6H_5	Dioxane	II	21	–

[a] Photolysis conditions: I. One Philips HPK 125W lamp and one Hanau-Q-81 lamp. – II. Two Philips HPK 125W lamps. [b] Determined by gas chromatography.

Experimental: 3,4-Dimethyl-3-penten-2-one tosylhydrazone *(1b)* 16.50 g) and sodium methoxide (3.63 g) (molar ratio 1:1) are stirred in anhydrous diglyme[5] with exclusion of moisture for 18 h at atmospheric pressure, then for $^1/_2$ h at water-pump vacuum, and finally for $^1/_2$ h at oil-pump vacuum (all at room temperature) and are thus dried. The solution is irradiated for 6 h at 14–16 °C in a Duranglas 50 apparatus by means of two high-pressure Hg lamps[6], whereupon 91% of the theoretical amount of N_2 is evolved. The mixture is treated with 50 ml of ethanol and then distilled. The distillate is shaken with H_2O and toluene, the tetramethylcyclopropene passing into the toluene phase.

The structures of *(2a)*, *(2b)*, and *(2d)* were proved by mixed melting points or mixed chromatograms with authentic samples and by comparison of the IR spectra [3, 7].

Alkyl- and aryl-cyclopropenes are stable under the above conditions, but on longer irradiation, particularly in the presence of sensitizers, are converted into tricyclohexanes [4, 8].

Organic Compounds in Fossil Plants (Equisetum; Horsetails) [1]

By *H. Knoche* and *G. Ourisson* [*]

Chemotaxonomic classification of fossil plants would be particularly interesting since it could be carried out on mutilated and incomplete specimens, and because conclusions could be drawn about the history of the fossils from comparison of the constituents of fossil and fresh plants.

We have begun experiments designed to isolate organic compounds, in particular hydrocarbons, from fossil plants from the bunter sandstone of the Northern Vosges (Trias, 2×10^8 years old) and to compare them with the compounds in present-day plants. Of the fossils available to us a horsetail *Equisetum brongniarti* [2] was especially interesting because numerous *Equisetum* species still grow today. The stems of the plants were approximately 30 mm in diameter. In addition, horsetails have few parasites [3], which diminishes the danger of the compounds found originating from foreign organisms. Great attention was paid to purity during the collection, and contamination during working up was excluded by control experiments. The *Equisetum* described here came from a clay inclusion in the bunter sandstone of the Northern Vosges (Hangvillier, Moselle).

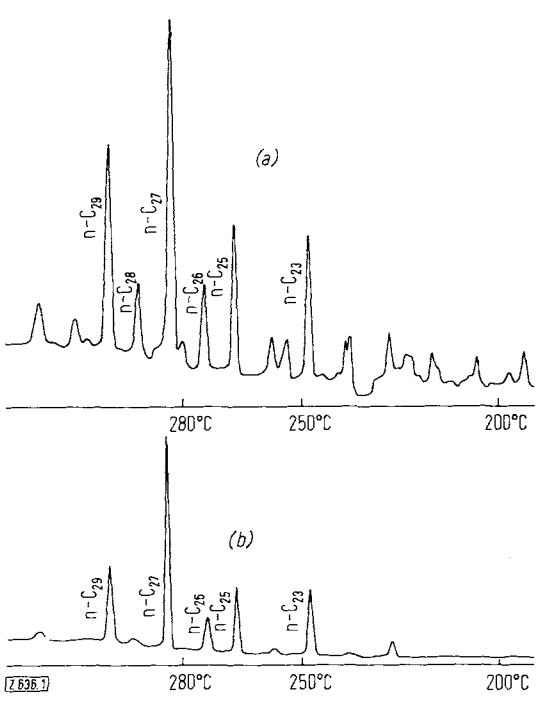

Fig. 1. Gas chromatograms [5] of the hydrocarbon fractions from (a) fossil and (b) fresh *Equisetum*.

400 g of dried rock containing *ca.* 20% of fossil plants (further separation from the rock is rather difficult and unnecessary since the surrounding material contains very little organic material [4]) were ground and extracted with 400 ml of a benzene/methanol mixture (3:1 v/v) using an ultrasonic technique (25 kHz). Centrifugation, decantation, and removal of the solvent by distillation gave 3 mg of residue, which was desulfurized in a small column by 100 mg of active copper and then separated on 2 g of silica gel (Merck, 0.05–0.2 mm). Elution with 50 ml of petroleum ether gave the hydrocarbon fraction (*ca.* 0.5 mg). The gas chromatogram (Fig. 1a) showed four main components in the ratio 1:1:2.4:2 [5].

50 g of fresh, dried *Equisetum sylvaticum* (wood horsetail) was extracted with 500 ml of benzene (ultrasonically). The hydrocarbon fraction (18 mg) was isolated from the extract by column chromatography. The gas chromatogram of this fraction (Fig. 1b) showed the same four main components in almost the same proportions, namely, 1:1:2.4:1.3 [**].

The products were identified as the normal hydrocarbons n-$C_{23}H_{48}$, n-$C_{25}H_{52}$, n-$C_{27}H_{56}$, and n-$C_{29}H_{60}$ by their gas-chromatographic retention times [6], mass spectra, and inclusion in Linde molecular sieves (5 Å, 6 h in boiling isooctane). The extract of the fresh plant does not contain the numerous minor components of the fossil plant.

In this work the same compounds have been isolated for the first time from a living and a fossil plant and it has been proved that hydrocarbons can remain unchanged in a fossil for 200 million years.

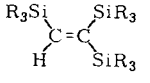
Ionization Energies of Silyl- and Alkyl-ethylenes [**]

By *H. Bock* and *H. Seidl* [*]



The differing properties of simple π-electron systems containing R_3Si- and R_3C-substituents can be considered as being due to the different inductive polarization ($+I_{SiR_3} >$

$+I_{CR_3}$) and additional conjugative back-donation of electrons $Si_d \leftarrow C_\pi$. The relative energy changes of the highest occupied and lowest unoccupied molecular orbitals caused by interaction with the substituents can be measured individually be means of *e.g.* half-wave potentials[1], electron spin densities[2], or charge-transfer band maxima[3], while the resulting total energy differences can be determined from the corresponding transitions in the electronic spectra[2,3]. Of the cross-conjugated[1], cyclic[2,3], and linear π-electron systems containing R_3Si-groups, ethylene derivatives were the first for which we were able to determine ionization energies by mass spectroscopy[4] and thence to obtain, by means of the *Koopman* theorem[5], direct information about the highest occupied (π)-levels[6].

The hitherto unknown[7] tris(trimethylsilyl)ethylene *(2)* can be prepared as shown:

R = CH_3 *(1)*

(2)

60 mmoles of dichloro(methyl)silane is added dropwise and slowly to an equimolar amount of bis(trimethylsilyl)acetylene to which has been added 0.3 ml of a 0.1 N solution of H_2PtCl_6 in 2-propanol. After 20 hours' boiling under reflux, distillation affords 13% of *(1)*, b.p. 57–60 °C/0.5 mm, which affords 47% of *(2)*, b.p. 43–45 °C/0.5 mm, by a Grignard reaction. The product is purified by gas chromatography (SE-30 column). The ^1H–NMR-spectrum contains three singlets in the ratio 1:18:9 at τ = 2.67, 9.86, and 9.91; the C=C stretching frequency appears at 1499 cm^{-1}. Comparison with the corresponding data for trimethyl ethylene[8] (^1H–NMR signal of the ethylene proton: 4.83 τ; C=C stretching frequency 1667 cm^{-1}) illustrates to what extent characteristic properties of the ground state of simple R_3Si- and R_3C-substituted π-electron systems may differ.

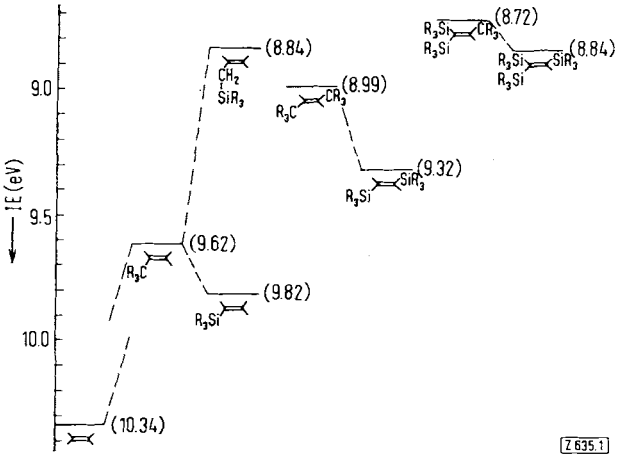


Fig. 1. Ionization energies (IE) of silyl- and alkyl-ethylenes.

The diagram (Fig. 1) for the highest occupied (π)-molecular orbitas[6] of silyl- and alkyl-ethylenes permits the following conclusions: (+I)-Substituents such as R_3Si- and R_3C-groups lower the ionization energy of the ethylene π-electron system, corresponding to a rise of the π-level, which for the silyl derivatives $C_nH_{4-n}(SiR_3)_n$ is linearly proportional, within a good approximation, to the number of substituents. The effect of the R_3Si-groups is, however, in all cases less than required for inductive polarization ($I_{SiR_3} > +I_{CR_3}$), and applying the usual model of the $Si–C_{sp^2}$ bond this provides further evidence[1–3] in favor of a conjugative $Si_d \rightarrow C_\pi$ electron back-donation. A minimum value for the $+I_{SiR_3}$ effect follows from the ionization energy of t-butylethylene which is 0.8 eV higher than that of 1-trimethylsilyl-2-propene where the β-situated R_3Si group is separated from the π-electron system by a tetrahedral C atom.

The d-orbital interactions demonstrated by the ionization energies for the ground state of silylethylenes were used previously to explain why the NMR signals of the ethylene protons are shifted to lower field in comparison with the alkyl derivatives[9] and why the C=C stretching frequencies are lowered[10]. In this connection, extreme differences are shown by the values for tris(trimethylsilyl)- and trimethylethylenes, where a difference of 5000 cm^{-1} ≙ 14 kcal/mole in the $\pi \rightarrow \pi^*$ excitation energies also indicates considerable π^*/d splitting[11]. Smaller, but similar, differences between the properties of silyl- and alkyl-polyenes and -polyynes[11] confirm the d-orbital effects for silyl substituted linear π-electron systems.

Cyclization of Acid Chlorides by Polyphosphoric Acid

By *A. Bhati* and *N. Kale*[*]

We have cyclized arylalkanecarbonyl chlorides *(1)*, namely, 4-phenylbutyryl, 5-phenylvaleryl, 4-(2-chloro-5-methoxyphenyl)butyryl, and 4-(5-chloro-2-methoxyphenyl)butyryl chloride, with polyphosphoric acid and thus obtained the cyclic ketones *(2)* in excellent yield.

(1) *(2)*

Synthesis of 1-tetralone (2):

The acid chloride obtained from 1.65 g of 4-phenylbutyric acid and thionyl chloride was treated with 23 g of freshly prepared[1] polyphosphoric acid with exclusion of moisture, and the whole was stirred at 70 °C for 15 min. HCl was evolved. The mixture was poured into water and extracted with ether. After washing with 10 % sodium hydroxide solution and drying, the ether was removed, leaving 1.38 g (94.6 %) of 1-tetralone.

Under the same conditions 1-indanone is formed from 3-phenylpropionyl chloride, but with only 57.3 % yield.

Irregularities in the Partial Molar Enthalpies of Mixing of Water and Water-Alcohol Mixtures at Constant Temperature

By *G. Kortüm* and *K. A. Steiner*[*]

In the neighborhood of specific temperatures, irregularities (called "kinks" in the Anglo-Saxon literature) occur in the temperature-dependance of numerous properties of water and aqueous solutions[1]. They are interpreted as indicating that such systems contain various mixed phases that are arranged in the manner of clathrates and are transformed into one another at specific temperatures. The best known example of such a liquid structure if the "water hydrate" $(H_2O)_{21}$ proposed by *Pauling*, in which one molecule is surrounded by 20 other molecules, after the manner of a clathrate; as in gas hydrates, these 20 molecules form the corners of a dodecahedron. The transition temperatures are considered to depend on the nature and concentration of the material dissolved in the water, whence it is concluded that the anomalies denote sudden changes in the structure of the water and have nothing to do with interactions between water and the solutes.

Using a very sensitive differential calorimeter[2] we have measured the intermediate enthalpy of mixing of water with water-alcohol mixtures at 30 °C, and from the results have determined the partial molar enthalpies of mixing as a function of the molar fraction of the components. In contrast to the measurements by other authors the molar fraction was varied by very small amounts. Surprisingly, we observed numerous irregularities which exceeded the experimental error in the measurements by an order of magnitude. Figure 1 shows some of our results. From them there is no doubt that structured mixed phases occur also in ethanol-water mixtures, a fact that may be important for the still little understood structure of liquids.

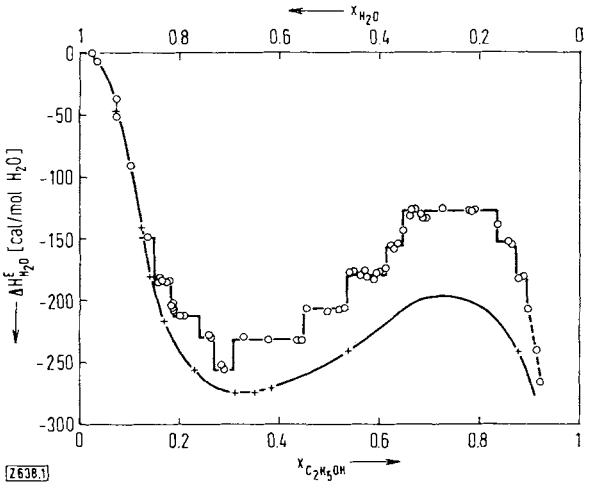

Fig. 1. Partial molar enthalpy of mixing $\Delta H^E_{H_2O}$ of water with water-ethanol mixtures. o = our measurements at 30 °C; + = calculated from measurements by *Bose* [4] at 21 °C. Analogous irregularities were observed at 20 and 40 °C.

It is true that participation of dissolved gases (O_2, N_2) in these structures[3] cannot be excluded with certainty, but such participation is very unlikely at the temperatures selected for our work. Our measurements further show that the iregularities in the properties of aqueous solutions are not determined solely by the structure of the water and its temperature-dependance, since they are observed at almost constant temperatures (temperature variations on mixing amounted to about 0.01 °C).

CONFERENCE REPORTS

Preparation and Properties of Inorganic Halogenoamines

By *J. Jander*[*]

Inorganic halogenoamines have recently been obtained by disproportionation of halogens with ammonia at about −75 °C. That the reddish-brown $NI_3 \cdot NH_3$ isolated, *inter alia*, actually has the structure corresponding to this formula and is not, *e.g.*, a 1:1 adduct of NHI_2 and NH_2I follows from the reaction (studied analytically and by IR spectroscopy) with pyridine or quinoline, in which the ammonia is replaced by the nitrogenous bases without destruction of the NI_3 component[1]. The structure, which was clarified by *Bärnighausen* and *Hartl*[2] by X-ray analysis shows NI_4 tetrahedra which are joined together into chains by common iodine atoms. One iodine atom of each NI_4 tetrahedron is additionally attached to one ammonia molecule by a charge-transfer bond.

In order to explain the decomposition of monochloramine NH_2Cl by way of the unstable imene or nitrene NH, monochloramine was treated with phenyl-lithium in dimethyl-2-butene at −75 °C. The expected α-elimination took place in good yield, as shown by the benzene formed, but only 3 % of 2,2,3,3-tetramethylaziridine was obtained. During the reaction a white precipitate was formed, which evolved N_2 and NH_3 when warmed. The precipitate is moderately soluble in ether at −75 °C; LiCl separates from the clear

solutions on warming. Further study is needed to show whether the precipitate consists of LiNHCl or another compound resulting therefrom[3].

Kinetic Studies of the Cyclotrimerization of Butadiene by Ziegler Catalysts

By *W. Ring* [*]

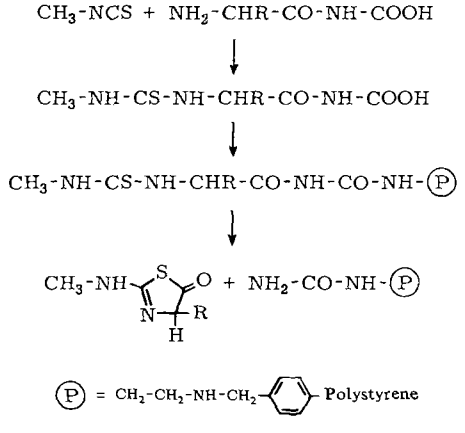
In the presence of a suitable catalyst, the cyclizing trimerization of 1,3-butadiene to 1,5,9-cyclododecatriene, first described by *G. Wilke* [1], occurs with high yield and steric selectivity. Titanium-containing catalyst systems, for example, lead to formation of *cis,trans,trans*-cyclododecatriene in more than 90 % yield with almost complete conversion of the butadiene.

The mechanism of the cyclotrimerization of butadiene on titanium has not hitherto been so thoroughly clarified as has that on the nickel catalyst (*Wilke et al.*). However, it can be regarded as certain that synthesis of the 12-membered ring in presence of titanium also occurs by way of π-complexes of the butadiene or one of its products with the heavy-metal atom. Up to 85 % conversion the reaction displays first-order kinetics with respect to butadiene, but it then becomes slower. When the cyclododecatriene concentration is increased the reaction rate decreases, and at the same time divergences from first-order reaction rate are observed.

Kinetic analysis of the cyclotrimerization of butadiene was supplemented by measurement of the spectral changes in the reacting solutions between 480 and 380 nm as a function of time and of the conversion. The kinetic and spectroscopic results led to the conclusion that the trimerization involves a closed series of partial reactions including a replacement equilibrium (1):

$$\text{K·(Cyclododecatriene)} + \text{Butadiene} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{K·(Butadiene)} + \text{Cyclododecatriene} \quad (1)$$

The expressions K·(cyclododecatriene) and K·(Butadiene) denote π-complexes of the olefins with the heavy-metal atom. The changes of concentration and absorption with time permit the equilibrium constant $K' \equiv k_1/k_{-1}$ to be estimated as about $3 < K' < 10$. The slower reaction with higher concentrations of cyclododecatriene in solution can be quantitatively explained by the effect of the equilibrium on the overall reaction.



Lecture at Stuttgart on November 2nd, 1967 [VB 96 IE]

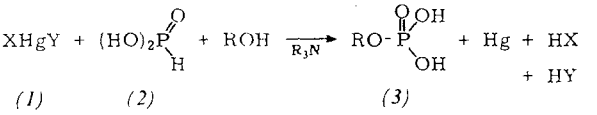
SELECTED ABSTRACTS



α-Dehydrobiotin *(1)*, which was hitherto unknown, has been isolated by *L. J. Hanka, M. E. Bergy*, and *R. B. Kelly* from the culture filter of *Streptomyces lydicus* and identified by IR and NMR spectrometry; m.p. 238–240 °C, $[\alpha]_D^{25} = 92°$ (0.1 N NaOH). *(1)* is active *in vitro* against a number of gram-positive and -negative bacteria and fungi. The antimicrobial activity is counteracted by biotin. *(1)* is a biotin

antimetabolite. On catalytic hydrogenation with Pd/C, compound *(1)* is converted into (+)-biotin. / Science (Washington) *154*, 1667 (1967) / –Ma. [Rd 644 IE]

Dinonylnaphthalenesulfonic acid has been used as a liquid ion exchanger by *J. Prášilova* and *Z. Satorie*. The reagent is best prepared by alkylation of naphthalene at 164–170 °C with the $BF_3 \cdot 2ROH$ complex of anhydrous nonyl alcohol; the dinonylnaphthalene fraction distilling at 150 to 165 °C is then sulfonated at about 100 °C with 90 % H_2SO_4. The strongly acidic cation exchanger is an approximately 10^{-3} M solution of dinonylnaphthalenesulfonic acid in heptane (readily soluble in nonpolar solvents, practically insoluble in H_2O), which is shaken with an aqueous solution for about 2 hours; the ionic strengths and pH values must be kept constant by the addition of salts and acids. The authors have used this method *e.g.* to determine the stability constant of the thiocyanatoindium species $[In(SCN)]^{2+}$, $[In(SCN)_2]^+$, and $In(SCN)_3$. / Collect. czechoslov. chem. Commun. *32*, 322 (1967) / –Jg. [Rd 735 IE]

A new synthesis of monoalkyl phosphates is reported by *T. Obata* and *T. Mukaiyama*. Monoalkyl dihydrogen phosphates *(3)* are obtained in good yields from alcohols, phosphonic acid *(2)*, and inorganic mercury compounds *(1)* in the presence of tertiary amines.

(1) *(2)* *(3)*

In the absence of amine, mercury(II) acetate and dry phosphoric acid in boiling ethanol give impure monoethyl phosphate *(3a)*, R = C_2H_5. If four molar equivalents of triethylamine are added to the mixture, chromatographically pure *(3a)* can be isolated *e.g.* as the monoanilinium salt (m.p. 164–166 °C, yield 69–92 %) after a few minutes.

The reaction is thought to proceed *via* the deprotonated phosphite ion $PO_3^{3\ominus}$, which is readily oxidized by Hg(II) salts into the metaphosphate anion $PO_3^{\ominus}$. The alcohol adds to this ion. Even solid alcohols such as benzyl alcohol and borneol can be converted, in yields of 80 % and 48 % respectively, into the anilinium salts of the monoalkylphosphates (m.p. 150–152 and 194–196 °C, respectively) in acetonitrile. / J. org. Chemistry *32*, 1063 (1967) / –WG. [Rd 711 IE]

A covalent bond between Pt or Au and Si, Sn, or Pb exists in a number of complexes prepared by *M. C. Baird* in accordance with reactions (a) to (d). Analogous C and Ge compounds are well known. The structures were determined by comprehensive IR measurements. $(P(C_2H_5)_3)_2Pt(H)SiPh_3$

$$(R_3P)_nMCl_x + Ph_3M'Li \rightarrow (R_3P)_nM(Cl_{x-1})\text{-}M'Ph_3 \quad (a)$$
R = Ph, C_2H_5; M = Pt, Au; M' = Si, Sn, Pb

$$(PPh_3)_2PtHCl + Ph_3M'NO_3 \rightarrow (PPh_3)_2Pt(Cl)\text{–}M'Ph_3 \quad (b)$$
M' = Sn, Pb

$$trans\text{-}(PPh_3)_2PtHCl + 2\ SnCl_4 \rightarrow (PPh_3)_2Pt(Cl_2)\ (SnCl_3)_2 \quad (c)$$
(1)

$$trans\text{-}(PPh_3)_2PtHCl + SnCl_2 \rightarrow (PPh_3)_2Pt(H)\text{–}SnCl_3 \quad (d)$$
(2)

(pale yellow; unstable to heat and in $CHCl_3$); $Ph_3PAuSiPh$ (light yellow - brown; ν_{Au-Si} (?) = 305 cm^{-1}); $(PPh_3)_2Pt(Cl)SnPh_3$ (*trans*-isomer: white, stable to light and to air; thermal decomp. > 278 °C; Pt–Sn bond cleaved by anhydrous HCl. *cis*-Isomer: orange); $(PPh_3)_2Pt(Cl)PbPh_3$ (white; easy intramolecular disproportionation by Ph migration; *(1)*, complicated IR spectrum between 350 and 250 cm^{-1}; decomposes on recrystallization into $(PPh_3)_2Pt(Cl)SnPh_3$; 6 Cl very loosely bound toward $AgNO_3$); *(2)*, orange-yellow, *trans*-isomer, m.p. 130–135 °C; *cis* form already known. / J. inorg. nuclear Chem. *29*, 367 (1967) / –Jg. [Rd 752 IE]

The synthesis of acetate from carbon dioxide and Co-methylcobalamin in *Clostridium thermoaceticum*, according to *J. M. Poston* and *E. R. Stadtman*, is ferredoxin-dependent. The strictly anaerobic organism can synthesize acetate from CO_2. An intermediate in this synthesis is Co-methylcobalamin. The incorporation of [^{14}C]-methyl from Co-[^{14}C]-methylcobalamin into acetate is catalysed by two enzyme fractions, which were purified and separated by chromatography on DEAE-cellulose. The reaction also requires the presence of ferredoxin, which was first obtained from *Clostridium pasteurianum*. A corresponding ferredoxin has been concentrated from *C. thermoaceticum*. This ferredoxin catalyses the acetate synthesis in question, and is active in the hydrogenase system from *C. pasteurianum*. The two ferredoxins behave similarly on disk electrophoresis, and have very similar spectra. / Biochem. biophysic. Res. Commun. *26*, 550 (1967) / –Hö. [Rd 717 IE]

The collinearity of the amino-acid sequence and the gene map of the structural gene has been demonstrated by *C. Yanofsky et al.* for the α-subunit of tryptophan synthetase from *E. coli*. The amino-acid sequence of this protein was elucidated (267 amino acids). In eleven tryptophan-deficient mutants with point mutations in the α-subunit of the tryptophan synthetase, it was possible to locate the positions of the point mutations within the amino-acid sequence. The relative distances between the codons for the exchanged amino acids could be determined by recombination analysis. Comparison of the relative distances with the lengths of the peptide chains between the mutated amino acids shows an exact agreement between the gene map and the amino-acid sequence. / Proc. nat. Acad. Sci. USA *57*, 296 (1967) / –Hö. [Rd 718 IE]

The torsional vibrations of the chlorinated ethanes have been assigned in the IR and Raman spectra by *G. Allen*, *P. N. Brier*, and *G. Lane*. For molecules having a symmetrical rotor (CH_3–, CCl_3–) the height of the energy barrier to internal rotation was calculated from the torsional frequencies (80 to 250 cm^{-1}); the result varies from 3.3 (1,1-dichloroethane) to 14.2 (pentachloroethane) kcal/mole. The energy barriers calculated from the torsional frequencies of molecules with asymmetric rotors do not appear to be so reliable, but their sequence is reasonable. The energy barrier is greatest when a Cl atom on C-1 is situated between two Cl atoms on C-2. In the molecules $CH_3CH_xCl_{3-x}$, the steric hindrance is evidently more than compensated for by the opposite polarities of the two halves of the molecule: the (thermodynamically calculated) height of the energy barrier in 1,1,1-trichloroethane is smaller (2.8 kcal/mole) than in ethylene itself. / Trans. Faraday Soc. *63*, 824 (1967) / –Hz. [Rd 719 IE]

Solutions of potassium amide in liquid ammonia show an absorption band at about 335 nm, which *R. E. Cuthrell* and *J. J. Lagowski* assign to the amide ion or to ion associations that contain the amide ion. The position and extinction coefficient of this band vary relatively strongly with temperature, as can be seen from the table (last column: extinction coefficient corrected for the density change). On the other hand, Beer's law is valid over a wide range of concentrations (from about 0.4 to 2.5 × 10^{-4} mole/l). These observations were interpreted with the aid of a model, according to which the absorption corresponds to the transfer of an electron from the amide ion to the solvent cage. / J. physic. BOOK REVIEWS

Quantenchemie für Chemiker. Elementare Einführung in die mathematischen und wellenmechanischen Grundlagen. (Quantum chemistry for chemists. Elementary introduction to mathematical and wave-mechanical fundamentals.) By *H. Preuß*. Verlag Chemie GmbH., Weinheim/Bergstr. 1966. 1st Edit., xii, 159 pp., 50 figures, 3 tables, paperback DM 24.–.

The subtitle of the book – elementary introduction to mathematical and wave-mechanical fundamentals – characterizes the content of the book better than its main title. 94 of the 148 pages of text are devoted to a discussion of fundamental mathematical concepts. Justification for this step is to be found in the many gaps generally left in the mathematical training of chemists.

The book begins with admirable thoroughness by discussing number sequences and follows with an explanation of the concept of a function by means of elementary examples. Matrices, determinants, vector analysis, and coordinate

systems are dealt with in the next two chapters. The treatment of these concepts, which are generally skimped in mathematics lectures for chemists, is of particular value to the prospective quantum chemist. The introduction to mathematical fundamentals concludes with a discussion of differential and integral calculus.

The second part of the book deals with the fundamentals of wave mechanics and quantum-mechanical approximation procedures. A consideration of the wave function, electron spin, and the Pauli exclusion principle leads to a treatment of the time-dependent and time-independent Schrödinger equations. Some information about operator equations is given in the following chapter. The Schrödinger equation, the angular momentum, and the electron spin are formulated with the aid of operators. Subsequently the Born-Oppenheimer approximation, energy hypersurfaces, and nucleus motion are discussed. The chapter dealing with approximation procedures is devoted to a treatment of the variation principle and of the calculus of perturbation theory.

Certain special procedures for solving electron problems are described in the third part of the book. The various quantum-mechanical methods are distinguished on the basis of the differences between the Hamiltonian operators used. In logical manner, the procedures for solving the Schrödinger equation with the use of exact Hamiltonians (H atom, CI, SCF, LCAO methods) are contrasted with the procedures that use a modified Hamiltonian (Hückel's procedure, free-electron model). It is unfortunate that this chapter, which contains the methods for the treatment of molecular problems that are so important to the chemist, is very short. While three pages are devoted to the treatment of number sequences, the Hückel procedure, for example, is dealt with in a few lines. Because of this brevity of treatment the reader is merely able to appreciate certain fundamental aspects underlying the various approximation procedures. Suitable references are given to more extensive treatments or for the application of the various methods to chemical problems. The book can thus serve as a useful introduction.

The reader can test his progress by means of practice exercises. A few misprints, for example those that have crept into the superscripts of eq. (70) on p. 111, should be amended in the next edition. As an elementary introduction, the book is intended mainly for undergraduates. Considering this it is regrettable that the price is relatively high.

H. Zimmermann [NB 629 IE]

Physical Organic Chemistry. By *O. H. Wheeler*. Principles of Modern Chemistry, Monograph 2. Elsevier Publishing Company, Amsterdam-London-New York 1966. 1st Edit., ix, 172 pages, 42 tables, Dfl. 27.50; paperback Dfl. 15.00.

The present introduction to physical organic chemistry is claimed to be the first so far that "achieves a balanced treatment of the two principal aspects – the empirical study of mechanisms and the fundamental theoretical background". This claim is not entirely justified. The author has failed to stress important principles and to confine himself to important points. The attempt to cover the entire field in 160 pages was bound to lead to a superficial treatment. Some examples are:

Even fundamental concepts such as "transition state" and "intermediate" are not clearly defined (no mention is made of the reaction coordinates), and are frequently confused (pages 59, 72, 106, 133); the difference between bond energy and dissociation energy is not explained (page 19).

The fundamentals of spectroscopy are not discussed, though spectra are occasionally used in the discussion of mechanisms. The classification of reaction mechanisms does not include multi-center reactions. Diels-Alder syntheses and the Claisen rearrangement are formulated as involving "cyclic intermediates", and pyrolytic *syn* eliminations as proceeding *via* "free radicals or ion pairs". Both $C_6H_5COO\cdot$ and $C_6H_5CO\cdot$ are described as benzoyl radicals (pages 141 and 145).

The formulae are generally clear. The two-page index is too short and 36 references are inadequate. Many recent results have not been referred to. The last chapter, which is entitled "New Frontiers", seems completely out of place. The book cannot be recommended. *C. Rüchardt* [NB 615 IE]

Glas im Laboratorium. Eine Einführung für den Laborpraktiker. (Glass in the Laboratory. An Introduction for the Laboratory Worker). By *E. Deeg* and *H. Richter*. Volume 6 of the series "Der pharmazeutische Betrieb" (Pharmaceutical Practice). Edition Cantor KG., Aulendorf i.Württ. 1965. 1st Edit., 160 pp., 74 illustrations, DM 36.–.

This 160-page book could easily carry a more ambitious title, perhaps "All about Glass Laboratory Apparatus". There is hardly a question connected with the use, care, and manufacture of glass apparatus that it does not deal with. The authors have compiled much useful information which would otherwise require a laborious search.

After a chapter on glass as a material, glass apparatus and glassware are described in detail. Many illustrations of apparatus are included, and their properties are described in numerous tables. Special emphasis is laid on the details given in the DIN standards. The types of bottles for stocking varions substances, how to free stuck ground-glass joints and glass taps, precautions to be taken during glass cutting and glass blowing – all are described in an easily understandable form. The volume concludes with a section on glass-to-metal joints, hints on laboratory practice, and a subject index. *H. Grünewald* [NB 644 IE]

The Chemistry of Selenium, Tellurium and Polonium. By *K. W. Bagnall*. No. 7 of the Series of Monographs 'Topics in Inorganic and General Chemistry', edited by P. L. Robinson. Elsevier Publishing Company, Amsterdam-London-New York 1965. 1st Edit., viii, 190 pp., 11 diagrams, 25 tables, Dfl. 35.00.

The author, who, by virtue of his own investigations, is an expert on the chemistry of the extremely rare element polonium, has attempted to present the chemical properties of this element briefly and comprehensively in close comparison with those of the two lighter elements of the same group, tellurium and selenium. In view of the hitherto unsatisfactory treatment of the chemistry of these main-group elements, this attempt has met with great success in a small, well presented, and comprehensible volume. The modern literature is almost completely covered. The book provides a useful review for those concerned with the chemistry of the heavy elements of group VI b (a quarter of the book is devoted to the organic derivatives of Se, Te, and Po) and it may also be recommended generally as a source of stimulating information. Quite justifiably, most chemists will regard the book as too specialized since it considers the three elements alone and not in conjunction with the characteristic Group VI element sulfur. As a result of the high price, the book will probably only be found in libraries, where, however, it should on no account be absent. *Max Schmidt* [NB 627 IE]

Modern Approach to Inorganic Chemistry. By *C. F. Bell* and *K. A. K. Lott*, Butterworth and Co. Ltd., London 1966. 2nd Edit., xiii, 331 pp., numerous figures and tables, 45 s.

The book covers the "Higher National Certificate" syllabus and is intended for "General Degree" students. Its plan departs markedly from that of conventional German textbooks, in that the principles fundamental to inorganic chemistry are emphasized. This is clear also from the chapter headings: (1) Atomic structure I, (2) Atomic structure II, (3) Valency, (4) The structure of the elements and their compounds, (5) Reactions in water and in non-aqueous solvents, (6) Coordination chemistry, (7) Distribution and

extraction of the elements, (8) Extraction with solvents and ion exchange, (9) Comparative chemistry of representative elements, (10) Comparative chemistry of the transition elements. Each chapter has an appended list of references for further study.

Generally speaking, there is a need for a short and modern introduction to inorganic chemistry in the German language, and a German translation of *Bell* and *Lott's* book could fill this gap were it not for the assumption of too much prior knowledge. For example, the use of radioisotopes in elucidating the course of chemical reactions is discussed on p. 21, without previously introducing the reader to the chemical symbolism or to the formulation of reaction equations. Surprising use is made of Bohr's model of the atom, while subsequent discussion suggests that the exclusive use of the wave-mechanical model is considered suitable. The general principles are clearly brought out and the discussion is on a relatively high level. Ionic and covalent bonds are treated in detail and with clarity. The relationships involved in metal bonding are discussed separately, and, together with van der Waals forces, are postponed until Chapter 4.

The structural chemistry of solids is discussed on classic examples, but many classes of compounds, *e.g.* the silicates, are dealt with too summarily. Some recent developments have been ignored. For example, the acid-base theories contain no reference to the Schwarzenbach-Pearson definitions. In the same way, the $Na-NH_3$ system has not been treated according to the most recent results..

Only about a third of the book is devoted to "descriptive chemistry". Thus, for example, ammonia synthesis is dealt with in four lines. Nonetheless, these sections similarly contain many interesting cross-references.

The book cannot be recommended unreservedly as an "introduction" to inorganic chemistry, but certainly as a supplement to standard textbooks. In this respect the study of "Bell-Lott" is likely to be of considerable value to students of chemistry and especially to aspiring chemistry teachers.

H. Nöth [NB 641 IE]

The Chemistry of Organic Sulphur Compounds, Vol. 2. By *N. Kharasch* and *C. Y. Meyers*. Pergamon Press, Symposium Publications Division, Oxford 1966. 1st Edit., vii, 465 pp., numerous figures and tables, bound £7.

Volume 2 of this series of monographs on organosulfur chemistry deals predominantly with rather specialized subjects in its 15 chapters. The following are discussed, in the order given: Electron relationships and bond properties of selected sulfur compounds (*H. A. Bent*), mechanisms of desulfurization by Raney nickel (*W. A. Bonner* and *R. A. Grimm*), isomerization of organic thiocyanates (*A. Fava*), newer aspects of the chemistry of olefinic sulfides (*L. Goodman* and *E. J. Reist*), desulfonylation (*J. L. Kice*), polyfluoroalkyl derivatives of sulfur (*R. E. Banks* and *R. N. Haszeldine*), properties of 1-alkynylthioethers (*W. Drenth*), anionic oxidation of thiols and cooxidation of thiols with olefins (*A. A. Oswald* and *T. J. Wallace*), radical addition of thiols to olefins and acetylenes (*A. A. Oswald* and *K. Griesbaum*), the chemistry of the 1,2-dithiol ring (*N. Lozac'h* and *J. Vialle*), thiohydantoins (*J. T. Edward*), thiophosgenes (*H. Tilles*), alkaline decomposition of aliphatic disulfides (*J. P. Danehy*), reactions of cyanides with cystines and cystine peptides (*O. Gawron*), and finally oxidation of disulfides with special reference to cystine (*W. E. Savige* and *J. A. Maclaren*).

This survey demonstrates that the authors were not restricted in the choice of their subject matter the consequently somewhat fragmentary character of the work was deliberately allowed for, because the issue of further volumes (volume 3 is already in the press) is intended to fill in some of the gaps. The very welcome list of literature references in the appendix deals with important work of the past few years. Anyone interested in these special fields will undoubtedly benefit by reading the book.

J. Gosselck [NB 630 IE]

Elementary Practical Organic Chemistry. Part 1: Small Scale Preparations. By *A. I. Vogel*. Longmans, London 1966. 2nd Edit., xx, 435 pp., numerous figures, bound 35s.

No change has been made in the basic conception of the book for the second edition. The first chapter deals with the theoretical principles of procedures such as distillation, crystallization, and sublimation, as well as the mode of action of drying agents.

This is followed by a detailed description of experimental techniques (about 125 pages). Numerous instruments are illustrated and their use is described, and even the bending of glass tubes and the use of air driers are not forgotten. The various types of stirrers are described, as well as methods for the determination of melting points.

The preparations are divided in the usual manner into aliphatic (Chapter 3) and aromatic compounds (Chapter 4). As a result of this arrangement, the aliphatic and aromatic carbonyl compounds are discussed separately, and too little space is devoted to the effects of substituents on the reactivity of the CO group. Reactions and compounds that do not fit into the above scheme are described in Chapter 5, which ends with some very good experiments on chromatographic methods and electrophoresis. Most of the preparations are preceded by a short description of the relevant reaction mechanisms. The selection of the preparations and reactions could have been rather more up-to-date.

The present book is what students call a cookery book in the best sense of the word. The procedures given are well proven, and can be carried out even by beginners. A number of preparations from Vogel should be carried out by every student, as is already usual in many places. However, it can be recommended as a practical handbook only if used in conjunction with a second book that includes spectroscopic methods for structural elucidation and for the characterization of substances used and prepared, as well as more modern preparative methods.

H. J. Bestmann [NB 592 IE]

Elementary Practical Organic Chemistry. Part 2. Qualitative Organic Analysis. By *A. I. Vogel*. Longmans, London 1966. 2nd Edit., xv, 431 pp. numerous figures and tables, 35s.

The book opens with a short introduction on the qualitative analysis of organic compounds and the determination of physical constants.

The text begins with the determination of melting point in all its aspects with *Vogel's* well known thoroughness, including illustrations and a discussion of the most common apparatus. Whether it is necessary to describe the drawing out of a melting-point tube at epic length is debatable. The determination of boiling point follows. Here the mention of the Siwoloboff method for small amounts of liquid is welcome, because it is no longer generally known to the probationer. Measurement of density and refractive index is then discussed. The chapter concludes with the determination of optical rotation followed by an unfortunately rather short section on rotatory dispersion.

Chapter 2 is devoted to the qualitative analysis of the elements, but only C, H, N, S, and the halogens are described. A useful chapter on the solubility of different classes of substances in diverse solvents follows. 120 pages are then devoted to the reactions and characteration of various organic compounds. The characterization of a substance by the preparation of a derivative has unfortunately come into some disrepute today. This chapter is warmly recommended for constant use to all demonstrators. The preparation of crystalline derivatives of olefins by reaction with 2,4-dinitrophenylsulfenyl chloride is likewise described, as is the often very useful cleavage reaction of ethers with 3,5-dinitrobenzyl chloride in the presence of zinc chloride. In many cases a procedure is given for preparing the reagents. These 120 pages are a rich source for every chemist who does not wish to rely solely on spectral results.

Whether the following Chapter 5, in which classification reactions, *i.e.* reactions for identifying certain functional groups, are discussed, is necessary at all needs careful consideration. Extensive overlapping and repetition of Chapter 4 are the rule. For instance, the preparation of a 2,4-dinitrophenylhydrazine solution is described both on p. 118 and on p. 189. A combination of the table on pp. 215 and 216, listing the principal identification reactions, with Chapter 6, which once more lists the principal derivatives, would be adequate.

Following an introduction to the qualitative analysis of mixtures of substances, Chapter 8 discusses spectroscopic methods (UV, IR, NMR, and mass spectrometry). In every case a short theoretical introduction is given, the relevant apparatus is sketched in ready-for-use arrangement, and the possible applications of the spectra are discussed with examples. This chapter, which is introduced for the first time in this edition, is a very valuable contribution to the book, which concludes with a number of tables containing the physical characteristics for a large number of compounds. Chromatographic methods are not discussed here but are described in Volume 1; however, pages 237 and 238 contain a bibliography of the various chromatographic methods. The volume represents a successful compilation of chemical and physical methods of analysis. It can be recommended without reservation, even if one would like to see a condensation of certain sections and an extension of the spectroscopic methods. No organic chemical laboratory should be without it.

H. J. Bestmann [NB 636 IE]

Technique of Inorganic Chemistry. Vol. IV. Edited by *H. B. Jonassen* and *A. Weissberger*. Interscience Publishers, a Division of John Wiley and Sons, New York-London-Sydney 1965. 1st Edit., 400 pp., 98 illustrations, 115s.

Five contributions of varying scope, weight, and level go to make up the fourth volume of the series which was started in 1963, and the unfortunate title of which gave rise to serious doubts when the first volume was reviewed [*].

In view of the scope and quality of discussions of the theory and practise of ion exchange which have already been published, the first article headed "Ion Exchange Techniques" (30 pp., with only 16 references, six of which refer to books and reviews) would appear rather superfluous. In contrast, the second contribution "The growth of oxide single crystals from the fluxed melt" (33 pp., 67 references) is a successful comprehensive presentation of the development of a relatively new experimental technique which has proved extraordinarily useful in special cases. The third article "High-temperature Techniques" (70 pp., 316 references) deserves particular attention as a very welcome review of the newest methods of investigating chemical reactions at high temperatures – a field of study which will certainly assume ever increasing interest in the future. The fourth article "Magnetochemistry" (105 pp., 142 references gives a good idea of the eminent importance of magnetic measuremonts in gaining information about the nature of the bonding in a given substance, with particular reference to the recent rapid developments in the complex chemistry of transition metals. Only 33 pages are devoted to the "technique" as such, whereas 66 pages deal with theory and a further six pages are taken up by results of experiments conducted on the lanthanides and actinides. Who would consider looking for these 72 pages under the heading given?

The same applies to the last article "Techniques of optical rotatory dispersion and circular dichroism" (108 pp., 448 references) in which only 18 pages are devoted to the methods of measurement, the rest being reserved for general theory, procedures for preparing optically active substances, and results of measurements. The general impression given by this contribution is no less than "very good". However, for this reason it is to be regretted all the more that such papers are undeservedly camouflaged by the unsuitable title of the series. A comforting thought is, however, that the excellently presented volume will certainly take its place in all libraries and for this reason its full value will be exploited, even if only indirectly. The reviewer would hesitate to recommend the purchase of such a heterogeneous collection of articles to the individual chemist.

Max Schmidt [NB 626 IE]

Chemistry and Physics of Carbon, Vol. 1 and 2. Edited by *P. L. Walker jr.* Marcel Dekker, Inc., New York 1966. Vol. 1, xv, 382 pp., numerous figures and tables, $ 13.75. Vol. 2, xiv, 384 pp.

Carbon is often described as one of the most long-established, and yet newest materials to be used in technology. This observation is made in the light of, firstly, the classical use of diamond, activated charcoal and carbon blacks, artificial carbon as refractory material, and artificial graphite as electrode material; secondly, its novel use in nuclear technology and as a rocket material; finally, its use as a reinforcing agent in future composite materials, with a potential scope that must at present remain a matter for conjecture. As a result of its industrial importance, carbon has during the past 20 years again assumed a key position in the chemistry and physics of solids. The number of books written on the subject has not kept pace with this development. Apart from a monograph about reactor graphite and a French collective work on carbon, no modern monographs exist. A book on the physics and chemistry of carbon, therefore, meets an urgent need.

The present two initial volumes of a four-volume series are each divided into six chapters written by authors of international standing. Volume 1 contains a chapter by *S. Amelinckx* on "Dislocations and stacking faults in graphite", which, by means of excellent electron micrographs of natural graphite introduces the reader to the results of this technique. In Chapter 2, *G. F. Hewitt* discusses the "Gaseous mass transport within graphite". This section, containing extensive literature references and a discussion of technical problems, is of technological significance. *J. M. Thomas*, in Chapter 3, describes the results, mainly his own, of "Microscopic studies of graphite oxidation'. Chapter 4, by *S. Ergun* and *M. Mentser*, gives an exhaustive ssuvey of the "Reactions of carbon with carbon dioxide and steam". "The formation of carbon from gases" is discussed, fundamentally rather than exhaustively, by *H. B Palmer* and *C. F. Cullis* in Chapter 5. This section contains a good review of the literature. Chapter 6 consists of a rather specialized treatise on "Oxygen chemisorption effects on graphite thermoelectric power" by the editor, P *L. Walker*, and his coworkers.

The second volume continues the series of individual chapters. Chapter 1, by the late *G R. Henning*, gives an excellent account of "Electron mictoscopy of reactivity changes near lattice defects in graphite". The subject matter in the chapter is related to that dealt with in Chapters 1 and 3 of Volume 1 In Chapter 2, *M. M. Dubinin* discusses the problems invelved in the "Pore structure and adsorption properties of active carbons". Particular reference is made to the author's own work, and to Soviet literature in general. *W. N. Reynolds*' chapter on "Radiation damage in graphite" largely follows the recently published monograph by *Simmons*. This section deals predominantly with the problems of Radiation damage in graphite at medium temperatures (a point of interest to British reactor development), and to a lesser extent with irradiation at high temperatures. A comprehensive bibliography is appended. Chapter 4 by *A. C. Zettlemoyer* and *K. S. Narayan* deals with the "Absorption from solution by graphite surfaces", a narrow, specialized field. Chapter 5 by *C. R. Klein* likewise has a specialized character. The author deals with the "Electronic transport in pyrolytic graphite and boron alloys of pyrolytic graphite", mainly on the basis of his own investigations. Finally, Chapter 6 of Volume 2 contains a description of

the "Activated diffusion of gases in molecular sieve materials" by the editor and his co-workers. This chapter covers a very wide scope.

In attempting to formulate an overall opinion on the two published volumes one is immediately struck by the topical choice of subject of most chapters, and by the international eminence of the contributors. The modern and in parts particularly lucid presentation of the most recent research results as well as some excellent illustrations also deserve mention. This new series differs in the above respects from the collective work of French scientists on carbon that appeared two years ago.

The depth of treatment varies between the individual chapters. It ranges from a comprehensive survey and critical comparison of all available data, *e.g.* Chapters 2 and 4 in Volume 1, to excessively concise treatment of important subjects, *e.g.* Chapter 5 in Volume 1; elsewhere incomplete treatments under too general a title are given alongside excellent detailed descriptions of specialized subjects (*e.g.* Vol. 1, Chapter 3). Literature reference are also abstracted with varying thoroughness. Some chapters provide a valuable scientific basis for the study of complex technological problems, others are restricted to simplified models which, nevertheless, provide a stimulant for further research.

Subsequent Volumes of this series will show whether the editor of this work succeeded in presenting a self-contained monograph on current knowledge of the physics and chemistry of carbon by a skilful choice of the individual subjects. Even now the present two volumes may be regarded as important chronicles of progress in the field of carbon. They are very warmly recommended to every scientist and technologist with an interest in this subject. *E. Fitzer* [NB 652 IE]

SUBJECT INDEX

FP = Full paper (review article) CR = Conference report
SC = Short communication LA = Literature abstract
G.E. = Reference to the German Edition of Angewandte Chemie. References are given for Review Articles, Short Communications, and Conference Reports only.

ABC of chemistry, ABC der Chemie (Book Review) 276

Absolute configuration, of the enantiomeric 4-methylcyclohexylideneacetic acids (LA) 188

Acetals, Light-induced addition of cyclic ~ to terminal olefins (LA) 576

Acetamido groups, Concerted elimination of ~ and a nitro group (LA) 98 [G.E. *79*, 66 (1967)]

4-Acetamido-3-nitroanisole, Concerted elimination of an acetamido and a nitro group (LA) 98 [G.E. *79*, 66 (1967)]

Acetate, The synthesis of ~ from carbon dioxide and Co-methylcobalamin (LA) 1089

Acetone, Chemistry of ~ (CR) 375 [G.E. *79*, 384 (1967)]

Photodimerization of uracil sensitized by ~ (SC) 956 [G.E. *79*, 944 (1967)]

3-Acetonylglutaric acid, Dehydration of ~ (SC) 172 [G.E. *79*, 148 (1967)]

Acetylacetone, Schiff bases of ~ form chelates with Ir(I) and Rh(I) (LA) 814

Acetylacetonates, Simple methods of preparing ~ (SC) 569 [G.E. *79*, 530 (1967)]

Acetylcholinesterase (FP) 615 [G.E. *79*, 604 (1967)]

Acetyl-CoA, Nucleophilic enzymatic reactions of ~ (CR) 377 [G.E. *79*, 383 (1967)]

Acetylenes, Additions to the activated CC-triple bond (FP) 423 [G.E. *79*, 389 (1967)]

Double 1,3-dipolar addition to a triple bond to give the bicyclo[1.1.0]butane system (SC) 79 [G.E. *79*, 98 (1967)]
Oleic acid as precursor of naturally occurring ~ (LA) 890

Acetylenedicarboximide, Evidence for the intermediate occurrence of ~ (SC) 75 [G.E. *79*, 51 (1967)]

Acids, The concept of hard and soft ~ and bases as applied to multi-center chemical reactions (FP) 928 [G.E. *79*, 966 (1967)]

Reversibly titratable organic Lewis ~ (CR) 991 [G.E. *79*, 1011 (1967)]

Acid chlorides, Cyclization of ~ by polyphosphoric acid (SC) 1086 [G.E. *79*, 1100 (1967)]

Acidic hydrocarbon, Tris-(7*H*-dibenzo-[*c*,*g*]fluorenylidenemethyl)methane a new highly ~ (SC) 635 [G.E. *79*, 648 (1967)]

Acridines (Book Review) 894

Actinamine, Simple synthesis of streptamine and ~ (SC) 254 [G.E. *79*, 239 (1967)]

Actinides, Stability and properties of the complexes of hexavalent ~ with pyridine-2-carboxylic acids and quinaldic acid (CR) 993 [G.E. *79*, 1013 (1967)]

Actinide dioxide, Quasibinary phase diagrams of the systems rare earth metal (Ho, Tm, Lu) oxide/~ (Th, U, Np, Pu) (CR) 982 [G.E. *79*, 1002 (1967)]

Actinide nitrates, Liquid-liquid extraction of tetravalent and hexavalent ~ by a long-chain trialkylmethylammonium nitrate (CR) 979 [G.E. *79*, 999 (1967)]

Activated esters, 1,3-Disubstituted 5-acyloxyimino-4-alkyliminouracils as new ~ (SC) 258 [G.E. *79*, 234 (1967)]

Active center, Structure and mechanism of action of the ~ of yeast pyruvate decarboxylase (FP) 1024 [G.E. *79*, 1050 (1967)]

Active site, Method for the study of the polarity of the microenvironment of the ~ in chymotrypsin (LA) 187

Active transport, of ions through biogenic membranes (CR) 640 [G.E. *79*, 624 (1967)]

Acraldehyde imine, and 2-methylacraldehyde imine (SC) 803 [G.E. *79*, 818 (1967)]

Acrylonitrile, Cross-linked polymers from α,α'-*p*-phenylenediacrylonitrile (CR) 639 [G.E. *79*, 624 (1967)]

Acylaminoketene, Possible valence tautomerism of a mesoionic oxazol-5-one with an ~ (SC) 367 [G.E. *79* 321 (1967)]

Acyl peroxides, Induced decomposition of unsymmetrical ~ (CR) 986 [G.E. *79*, 1006 (1967)]

Adamantane, New synthesis of the ~ ring system (SC) 554 [G.E. *79*, 529 (1967)]
New fragmentation in the ~ series (SC) 864 [G.E. *79*, 860 (1967)]

1-Adamantaneacetic acids, Synthesis of α-chloro-~ and α-chloro-2-norbornaneacetic acid by means of trichloroethylene (SC) 946 [G.E. *79*, 943 (1967)]

Adamantane derivatives, Synthesis and circular dichroism of optically active ~ (CR) 998 [G.E. *79*, 1018 (1967)]

Addition reactions, to the activated CC-triple bond (FP) 423 [G.E. *79*, 389 (1967)]

Adenosyl-B_{12}, Enzymatic synthesis and function of ~ (CR) 997 [G.E. *79*, 1017 (1967)]

Adhesion, and Adhesives (Book Review) 1011

Adsorbed molecules, Surface diffusion and relaxation times of ~ (CR) 886 [G.E. *79*, 908 (1967)]

Adsorption, Measurement of heats of ~ on the surfaces of single crystals with the field electron microscope (CR) 966 [G.E. *79*, 987 (1967)]

~ of nitrogen on iron (SC) 882 [G.E. *79*, 905 (1967)]

~ on, and desorption from, pigments (CR) 181 [G.E. *79*, 192 (1967)]

~ and partition (CR) 373 [G.E. *79*, 323 (1967)]

Adsorption layers, Polymerization reactions on ~ of solids (CR) 988 [G.E. *79*, 1008 (1967)]

Advances in, heterocyclic chemistry (Book Review) 191

~ organic chemistry (Book Review) 191

Aging, Physical causes of ~ in plastics (FP) 844 [G.E. *79*, 877 (1967)]

Alanine, General method for the preparation of β-perfluoroalkyl-~-s (SC) 807 [G.E. *79*, 822 (1967)]

Simple synthesis of 3,3,3-trifluoro-~ (SC) 808 [G.E. *79*, 822 (1967)]

Alcohol dehydrogenase, Quaternary structure and activity of enzymes (~, glutamic dehydrogenase, catalase) (CR) 460 [G.E. *79*, 423 (1967)]

Alcohols, Reactions of trichlorogermane with ketones and ~ (SC) 628 [G.E. *79*, 617 (1967)]

The reaction of alkylgallium halides with lower aliphatic ~ (CR) 986 [G.E. *79*, 1005 (1967)]

Rodd's chemistry of carbon compounds (Book Review) 894

Aldehydes, Stability of aminal esters and their reactions with aromatic ~ (SC) 356 [G.E. *79*, 311 (1967)]

Synthesis of cyclic 1,2,3-triamines by the reaction of dialdehydes with nitromethane and benzylamine (SC) 568 [G.E. *79*, 530 (1967)]

Preparation of 5-alkyl-1,3-thiazolin-2-ones by reaction of *S*-chloroisothiocarbamoyl chlorides with ~ and vinyl ethers (SC) 1073 [G.E. *79*, 1063 (1967)]

Solvolysis reaction of β-tosyloxy ~ (CR) 1002 [G.E. *79*, 1022 (1967)]

Aldehyde syntheses, Gattermann ~ with *s*-triazine in place of hydrogen cyanide (SC) 940 [G.E. *79*, 978 (1967)]

Aldimines, Acraldehyde imine and 2-methylacraldehyde imine (SC) 803 [G.E. *79*, 818 (1967)]

Aldolases, Structure and mode of action of ~ (CR) 962 [G.E. *79*, 948 (1967)]

Alkali metal, Mass-spectrometric detection of extremely small quantities of ~ (LA) 718

Alkali metal ions, Further investigations on the isotope fractionation of ~ by filtration through biological membranes (CR) 1005 [G.E. *79*, 1025 (1967)]

Alkali metal t-butoxides, Structure of ~ (SC) 801 [G.E. *79*, 816 (1967)]

Alkaloid, Synthesis of ~ skeletons by biogenetic-type ring closure (CR) 969 [G.E. *79*, 989 (1967)]

Alkaloids, Mass-spectrometric determination of the structure of peptide ~ from Rhamnaceae (CR) 968 [G.E. *79*, 988 (1967)]

~, chemistry and physiology (Book Review) 192

Alkenylamines, Action of carbon disulfide and sulfur on enamines, ketimines, and CH acids (FP) 294 [G.E. *79*, 298 (1967)]

Synthesis of enamines from allenes (LA) 98

Versatile new enamine synthesis (LA) 814

N-Alkenylcarboxamides, Preparation and reactions of enamides (CR) 377 [G.E. *79*, 385 (1967)]

Alkoxydiazenium salts, Synthesis of carbonylazo compounds by the reaction of ~ salts with carboxylates (SC) 699 [G.E. *79*, 681 (1967)]

Synthesis of s-triazolium cations by reaction of ~ with nitrogen heterocycles (SC) 699 [G.E. *79*, 682 (1967)]

Alkoxyphosphonium salts, Preparation of ~ by alkylation of phosphoryl compounds (SC) 372 [G.E. *79*, 379 (1967)]

Alkylations, with *O*-alkyl-*N*,*N*'-dicyclohexylisoureas (CR) 1001 [G.E. *79*, 1021 (1967)]

2-Alkyl-1,3-cycloalkanediones, Synthesis of ~ by Friedel-Crafts acylation (SC) 80 [G.E. *79*, 97 (1967)]

Preparation of ~ by cyclization of γ- and δ-keto carboxylic acids (SC) 371 [G.E. *79*, 378 [1967]

O-Alkyl-*N*,*N*'-dicyclohexylisoureas, Alkylations with ~ (CR) 1001 [G.E. *79*, 1021 (1967)]

Alkylgallium halides, The reaction of ~ with lower aliphatic alcohols (CR) 986 [G.E. *79*, 1005 (1967)]

S-Alkylthiosulfates, Chemistry of Bunte salts (FP) 544 [G.E. *79*, 520 (1967)]

Alkynides, Alkali metal ~ in dimethyl sulfoxide (LA) 1006

Alkynylamines, Synthesis and reactions of ~ (FP) 767 [G.E. *79*, 744 (1967)] Acylation, alkylation, and protonation of ~ (SC) 77 [G.E. *79*, 53 (1967)]

1-Alkynyltrialkylborates, Preparation of substituted oxaboroles from sodium ~ and acyl chlorides (SC) 84 [G.E. *79*, 57 (1967)]

Allene, Tetramethoxy-~, the diacetal of carbon suboxide (SC) 808 [G.E. *79*, 823 (1967)]

Synthesis of enamines from ~-s (LA) 98

Photoaddition of carbonyl compounds to ~-s (LA) 576

Allylamines, Reaction of ~ with dichlorocarbene (LA) 644

Allyl halides, Nickel-catalysed reactions of ~ and related compounds (FP) 124 [G.E. *79*, 177 (1967)]

(π-Allyl)nickel systems, *cis*- and *trans*-bis-~ (SC) 804 [G.E. *79*, 817 (1967)]

Aluminate, Trisodium hexahydrido-~ (LA) 577

Aluminum compounds, 2,3-Diazabuta-1,3-diene-1,4-diamines (1,4-disubstituted) and *N*-acylamidrazones from nitriles and bis(diethylalumino)-substituted amidrazones and acid hydrazides (SC) 256 [G.E. *79*, 243 (1967)]

Diethylmetal thiocyanates of aluminum, gallium, and indium (SC) 947 [G.E. *79*, 942 (1967)]

Diethyl-(5-hexenyl)aluminum-ether (SC) 872 [G.E. *79*, 862 (1967)]

Aluminum halides, Viscosity of liquid ~ (CR) 713 [G.E. *79*, 727 (1967)]

Americium, Ternary alkali metal and alkaline earth fluorides of ~ (CR) 997 [G.E. *79*, 1017 (1967)]

Amide Acetals, Reaction of bicyclic ~ with carboxylic acids and their anhydrides (SC) 178 [G.E. *79*, 189 (1967)]

Amides, Carbonylation of metal ~ to metal formamides (SC) 357 [G.E. *79*, 312 (1967)]

Molecular structure and magnetic anisotropy of ~ (CR) 989 [G.E. *79*, 1009 (1967)]

Amidines, "Dimerization" of organic nitrogen compounds via copper-containing intermediates (SC) 633 [G.E. *79*, 620 (1967)]

Amidothiophosphate, NH···S Hydrogen bonds and the structure of the anions in ammonium di-~ and in diammonium ~ (SC) 960 [G.E. *79*, 981 (1967)]

Amidrazones, 2,3-Diazabuta-1,3-diene-1,4-diamines (1,4-disubstituted) and *N*1-acyl-~ from nitriles and bis(diethylalumino)-substituted amidrazones and acid hydrazides (SC) 256 [G.E. *79*, 243 (1967)]

Aminal esters, Stability of ~ and their reactions with aromatic aldehydes (SC) 356 [G.E. *79*, 311 (1967)]

Amination, Acid-catalysed ~ of aromatic compounds (LA) 100

Amines, Formation of C-C-bonds with the aid of α-halogeno ethers, sulfides, and ~ (FP) 335 [G.E. *79*, 358 (1967)]

Synthesis and reactions of the alkynyl-~ (FP) 767 [G.E. *79*, 744 (1967)]

Syntheses with ketones, sulfur, and ammonia or ~ at room temperature (FP) 907 [G.E. *79*, 953 (1967)]

Acylation, alkylation, and protonation of alkynyl-~ (SC) 77 [G.E. *79*, 53 (1967)]

Synthesis of germylsilylstannyl-~ (SC) 446 [G.E. *79*, 410 (1967)]

Wittig rearrangement of tertiary ~ (SC) 557 [G.E. *79*, 574 (1967)]

Synthesis of cyclic 1,2,3-tri-~ by reaction of dialdehydes with nitromethane and benzylamine (SC) 568 [G.E. *79*, 530 (1967)]

"Dimerization" of organic nitrogen compounds via copper-containing intermediates (SC) 633 [G.E. *79*, 620 (1967)]

Quadrant rule for the n→π* Cotton effect of dithiourethanes from optically active ~ (SC) 704 [G.E. *79*, 721 (1967)]

Reactions of heterocyclic ~ with formaldehyde (CR) 967 [G.E. *79*, 987 (1967)]

Synthesis of enamines from allenes (LA) 98

Trimethylsilyl group as protective group for aromatic ~ in organometallic syntheses (LA) 273

Reaction of some silyl-~ with CO_2, COS, and CS_2 (LA) 642

Reaction of allyl-~ with dichlorocarbene (LA) 644

Versatile new enamine synthesis (LA) 814

Trichlorovinyl-~ (LA) 890

Amine complexes, Exchange reactions and the annealing of nuclear recoil defects in crystalline Co-, Rh-, and Ir-~ (CR) 993 [G.E. *79*, 1013 (1967)]

Amine oxides, Syntheses and reactions of cyclic ~ with activated methylene groups (CR) 980 [G.E. *79*, 1000 (1967)]

Amino acids, Formation of ~ and their precursors from primitive compounds by high-temperature synthesis (SC) 247 [G.E. *79*, 239 (1967)]

N-[(Methylthio)-*N*-tosylformimidoyl]-~ (SC) 862 [G.E. *79*, 858 (1967)]

Preparation of heterocyclic compounds by treatment of ~ with trifluoroacetic anhydride (CR) 184 [G.E. *79*, 155 (1967)]

Biosynthesis of aromatic ~ and its control (CR) 811 [G.E. *79*, 825 (1967)] Two new ~ (LA) 643

Methods for the automatic determination of ~ sequences (LA) 888

Amino acid anhydrides, Synthesis of *N*-carboxy-α-~ (SC) 248 [G.E. *79*, 237 (1967)]

D-Amino-acid oxidase, An enzyme-substrate intermediate of ~ (LA) 1007

Amino-acid sequence, The collinearity of the ~ and the gene map of the structural gene (LA) 1089

Aminoacyltransferase, Evidence of the Interaction between Aminoacyl-tRNA and ~ I (LA) 100

Ribosomes and ~ II (LA) 274

α-Aminoalkylation, of white phosphorus (CR) 984 [G.E. *79*, 1004 (1967)]

2-Aminoethylation, of indole and of 2-methylindole (SC) 178 [G.E. *79*, 188 (1967)]

S-Aminoisothioureas, Preparation of ~ by nucleophilic substitution of *S*-chloroisothiocarbamoyl chlorides (SC) 1072 [G.E. *79*, 1062 (1967)]

5-Aminolevulic acid, Preparation of porphobilinogen from ~ by means of *Propionibacterium shermanii* (SC) 883 [G.E. *79*, 905 (1967)]

7-Amino-6-methoxy-5,8-quinolinedione, Synthesis of ~ (SC) 82 [G.E. *79*, 100 (1967)]

Aminopeptidase, Thermophilic and mesophilic ~-s from *Bacillus stearothermophilus* (SC) 880 [G.E. *79*, 906 (1967)] ~ B (LA) 186

Aminophosphazenes, Synthesis of phospha- and diphospha-1,3,5-triazines by cyclizing transamination with ~ (SC) 565 [G.E. *79*, 534 (1967)]

4-Amino-1-phthalazinones, Synthesis of ~ (SC) 173 [G.E. *79*, 173 (1967)]

Aminopropionic acid, Properties and application of an amphoteric ion-exchange resin based on ~ (CR 374 [G.E. *79*, 324 (1967)]

2-Aminopyridine, Reversible hydrolytic ring opening of ~ (LA) 98 [G.E. *79*, 104 (1967)]

Amino sugars (Book Review) 474

Ammonia, Syntheses with ketones, sulfur, and ~ or amines at room temperature (FP) 907 [G.E. *79*, 953 (1967)]

Experiments on the poisoning of catalysts used in the synthesis of ~ (CR) 994 [G.E. *79*, 1014 (1967)]

Solutions of potassium amide in liquid ~ (LA) 1089

~, Anorganische und allgemeine Chemie in flüssigem Ammoniak (Inorganic and general chemistry in liquid ammonia) (Book Review) 719

Ammonium diamidothiophosphate, NH···S Hydrogen bonds and the structure of the anions in ~ and in diammonium amidothiophosphate (SC) 960 [G.E. *79*, 981 (1967)]

Ammonium thiocyanate, New condensation reaction of α,β-unsaturated cyclic ketones with ~ (LA) 891

Analgetics, Chemistry and Pharmacology (Book Review) 103

Anion radicals, from 1-nitroolefins (SC) 251 [G.E. *79*, 240 (1967)]

ESR spectrum of a non-degenerate state of the benzene ~ (SC) 360 [G.E. *79*, 318 (1967)]

Stable ~ from 2,4,6-triphenylphosphorine (SC) 445 [G.E. *79*, 410 (1967)]

Anisotropic effects, in heterocyclic nitrosamines (SC) 75 [G.E. *79*, 51 (1967)]

Annulenes, Thermal and photochemical behavior of [16]-~ (SC) 870 [G.E. *79*, 861 (1967)]

Electron spin resonance studies of bridged ~ (CR) 715 [G.E. *79*, 693 (1967)]

amphi-Anthraquinone, Derivatives of ~ a new quinone system (LA) 889

Anthraquinones, Model reactions for biological ring opening of ~ (SC) 952 [G.E. *79*, 935 (1967)]

Antibiotics, Commercial processes for ~ fermentation (CR) 470 [G.E. *79*, 478 (1967)]

Antimonate(III), Bis(triphenylphosphine)-triazenium tetrachloro-~ (SC) 953 [G.E. *79*, 938 (1967)]

Antimony compounds, Influence of the solvent on coordination-chemical reactions (CR) 271 [G.E. *79*, 279 (1967)]

Apatite, New compounds with ~ or garnet structure (CR) 573 [G.E. *79*, 584 (1967)]

D-Apiose, Investigations on the biosynthesis of ~ (CR) 971 [G.E. *79*, 991 (1967)]

Apoferredoxin, has been reactivated (LA) 274

Aporphines, from laudanosoline and norlaudanosoline (SC) 799 [G.E. *79*, 815 (1967)]

Arabinonucleotides, Synthesis of poly-~ with esters of polyphosphoric acid (CR) 460 [G.E. *79*, 422 (1967)]

Arenesulfonylazides, Acid-catalysed amination of aromatic compounds with ~ (LA) 100

Argentodiazoacetate, Diazocarboxylic esters from ethyl ~ and alkyl halides (SC) 261 [G.E. *79*, 238 (1967)]

Aroma component, 4-Hydroxy-2,3-dimethyl-2,3-dihydro-3-furanone (LA) 187

Aromatic amino acids, Biosynthesis of ~ and its control (CR) 811 [G.E. *79*, 825 (1967)]

Aromatic character, of six-membered chelates (CR) 182 [G.E. *79*, 153 (1967)]

Aromatic substitutions, Isomer distribution in electrophilic ~ on neopentylbenzene (LA) 379

Aromatic systems, Biosynthesis of ~ (CR) 575 [G.E. *79*, 586 (1967)]

Aromatization, of cyclohexanecarboxylic acid to benzoic acid (LA) 472

Arsene ylide (LA) 889

Arsenide, Epitaxy of gallium ~ with gallium ~ from organogallium compounds (CR) 987 [G.E. *79*, 1007 (1967)]

Arylation, of aromatic and heterocyclic compounds by nitro compounds at high temperatures (LA) 892

Arylhydrazines, Two new syntheses of (SC) 84 [G.E. *79*, 57 (1967)]

Association, of macromolecules (CR) 465 [G.E. *79*, 417 (1967)]

Asymmetric synthesis, Spatial arrangement and preparative organic synthesis (FP) 778 [G.E. *79*, 774 (1967)]

Atomic absorption spectroscopy (Book Review) 721

Atropisomeric hydrocarbon, Optically active 2,2'-dimethylbiphenyl, the simplest ~ (SC) 251 [G.E. *79*, 232 (1967)]

Autoxidation, of polyepoxides (CR) 182 [G.E. *79*, 192 (1967)]

1,2-Azaboretidine (LA) 272

Azepine, X-ray structure analysis of a dimer of 1-methyl-~ (SC) 805 [G.E. *79*, 820 (1967)]

Azides, Reactions of halogen ~ (FP) 240 [G.E. *79*, 253 (1967)]

Nitrenes and the decomposition of carbonyl-~ (FP) 897 [G.E. *79*, 922 (1967)]

The reaction of ~ with organometallic compounds (CR) 998 [G.E. *79*, 1018 (1967)]

Cyclic N_3 species having D_{3h} symmetry (LA) 379

Syntheses and rearrangements of hydrazonic acid ~ (LA) 890

4-Azido-1-butyne, Polymerization of ~ (LA) 892

2-Azidoethylene-1,1-dicarbonitriles, Degradation of ~ (SC) 959 [G.E. *79*, 980 (1967)]

Azido-metal complexes, Ligand addition and redox reactions of ~ (SC) 196 [G.E. *79*, 146 (1967)]

Azidophosphates, Preparation of hexa-~ (SC) 637 [G.E. *79*, 651 (1967)]

Aziridinium tetrafluoroborates, Synthesis of oxalactams (2-morpholinones) from ~ and hydroxyesters (SC) 178 [G.E. *79*, 188 (1967)]

Aziridinylsulfanes, Preparation of di-imidazolylsulfanes and di-~ (SC) 703 [G.E. *79*, 690 (1967)]

Azo compounds, Free-radical decomposition of ~ induced by organotin hydrides (SC) 76 [G.E. *79*, 52 (1967)]

Azo coupling, to Schiff bases. A new synthesis of naphthimidazole derivatives (SC) 250 [G.E. *79*, 237 (1967)]

Azo group, 1,2-Cycloaddition of an ~ to an olefin (LA) 577

Azulenediiron pentacarbonyl, Crystal and molecular structures of ~ (LA) 813

BACILLUS stearothermophilus, Thermophilic and mesophilic aminopeptidases from ~ (SC) 880 [G.E. *79*, 906 (1967)]

Bacteria, Chloramphenicol as the only source of carbon and nitrogen (LA) 717

Barium, Reaction of liquid ~ /sodium solutions with nitrogen (LA) 1008

Bases, The concept of hard and soft acids and ~ as applied to multi-center chemical reactions (FP) 928 [G.E. *79*, 966 (1967)]

Benz[*a*]anthraquinone, Tetrangomycin and tetrangulol, the first ~ derivatives obtained from natural sources (LA) 272

7-Benz[*de*]anthrones, Synthesis of 7,9-dioxo- and 7-alkylidene-9-keto derivatives of cyclopenta[*a*]phenalene and their conversion into substituted ~ (SC) 172 [G.E. *79*, 187 (1967)]

Benzene, 1,4-Photoaddition of pyrrole to ~ (LA) 888

Benzene oxide, ~-oxepin valence tautomerism (FP) 385 [G.E. *79*, 429 (1967)]

Benzenepolycarboxylic acids, Low-pressure hydrogenation of ~ (LA) 379

Benzene radical anion, ESR spectrum of a non-degenerate state of the ~ (SC) 360 [G.E. *79*, 318 (1967)]

1,3,5-Benzenetriamines, *N*-Persubstituted 3,5-diaminophenols and ~ and their protonation (SC) 1067 [G.E. *79*, 1100 (1967)]

Benzimidazole, Biosynthesis of 5,6-dimethyl-~ (SC) 1083 [G.E. *79*, 1073 (1967)]

1,6-Benzodioxocin, Synthesis and properties (SC) 697 [G.E. *79*, 684 (1967)]

Benzofurans, Use of Fischer's indole synthesis for the preparation of ~ (LA) 378

Benzoic acid, Determination of ~ and phthalic acid in terephthalic acid by partition chromatography (CR) 373 [G.E. *79*, 323 (1967)]

Aromatization of cyclohexanecarboxylic acid to ~ (LA) 472

Benzo[b]thiepin, Rearrangements of derivatives of ~ and ~ 1,1-dioxide (SC) 255 [G.E. *79*, 238 (1967)]

Benzoquinone, Half-wave reduction potentials of 2,5-bis(trimethylsilyl)- and 2,5-di-t-butyl-1,4-~ (SC) 941 [G.E. *79*, 932 (1967)]

Benzoylcyclobutenes, Reactions of ~ (CR) 984 [G.E. *79*, 1004 (1967)]

Benzyne, Reaction of ~ with α-methylstyrene (SC) 555 [G.E. *79*, 575 (1967)]

Berkelium, New ~ isotope $^{251}_{97}Bk$ (LA) 815

Beryllium complexes, Monomeric diphenyl-~ (LA) 814

Bicyclo[1.1.0]butane, Double 1,3-dipolar addition to a triple bond to give the ~ system (SC) 79 [G.E. *79*, 98 (1967)]

Synthesis of 1,3-dimethyl-~ (SC) 444 [G.E. *79*, 467 (1967)]

Bicyclo[4.2.2]deca-2,4,7,9-tetraene, Preparation of derivatives of ~ from tricarbonylcyclooctatetraeneiron (SC) 79 [G.E. *79*, 55 (1967)]

Bicyclo[6.2.0]deca-2,4,6,9-tetraene, 10-Chloro-9-fluoro-~ and 3-chloro-2-fluorobicyclo[2.2.0]hexa-2,5-diene (SC) 806 [G.E. *79*, 820 (1967)]

Bicyclo[2.2.0]hexa-2,5-diene, Hexamethyl(Dewar benzene) (Hexamethyl-~) (FP) 518 [G.E. *79*, 566 (1967)]

Tetracarbonyl(hexamethylbicyclo-[2.2.0]hexadiene)-chromium(0) (SC) 634 [G.E. *79*, 623 (1967)]

10-Chloro-9-fluorobicyclo[6.2.0]-deca-2,4,6,9-tetraene and 3-chloro-2-fluoro-~ (SC) 806 [G.E. *79*, 820 (1967)]

Bicyclooctane, Fragmentation of bicyclic keto-*p*-toluenesulfonates (CR) 980 [G.E. *79*, 1000 (1967)]

Bile salt, Myxinol disulfate, the principal ~ of the hagfish (LA) 187

2,2-Bi-(1,4-naphthoquinone), Oxidation and elimination reactions of the diazomethane-~ adduct (CR) 470 [G.E. *79*, 477 (1967)]

Biological oxidations, Comprehensive biochemistry (Book Review) 646

Bioorganic mechanisms (Book Review) 1010

Biosynthesis, of aromatic systems (CR) 575 [G.E. *79*, 586 (1967)]

~ of aromatic amino acids and its control (CR) 811 [G.E. *79*, 825 (1967)]

Biotin, Comprehensive biochemistry (Book Review) 191

Electron diffraction, Comparative determination of the structure of gaseous molecules by ~ (CR) 1005 [G. E. 79, 1025 (1967)]

Electron-pair repulsions, and molecular shape (FP) 819 [G.E. 79, 885 (1967)]

Electron paramagnetic resonance, Introduction to ~ (Book Review) 579

Electrophilic substitution, of heteroaromatic compounds with six-membered rings (FP) 608 [G.E. 79, 629 (1967)]

Electrophoretic painting, on the rotating disk electrode (CR) 964 [G. E. 79, 984 (1967)]

Elementary analysis, Zahlentafeln zur Elementaranalyse (Tables for ~) (Book Review) 275

Elimination, in cyclic *cis-trans*-isomers (FP) 534 [G.E. 79, 555 (1967)]

Elimination catalyst, Stereoselective synthesis of 1-butene with lithium sulfate as ~ (SC) 170 [G.E. 79, 187 (1967)]

Enamides, Preparation and reactions of ~ (CR) 377 [G.E. 79, 385 (1967)]

Enamines, see Alkenylamines

Encyclopedia, Ullmanns Encyklopädie der technischen Chemie (Ullmann's ~ of industrial chemistry) (Book Review) 719

~ of chemical technology (Book Review) 720

Chemie-Lexikon (~ of chemistry) (Book Review) 893

Endrin, Metabolic fate of ~ (CR) 977 [G. E. 79, 997 (1967)]

Enol ethers, Stereochemistry of the cycloaddition of sulfonyl isocyanates and *N*-sulfinylsulfonamides to ~ (SC) 951 [G.E. 79, 936 (1967)]

Enthalpy, and entropy changes on formation of complexes (CR) 265 [G.E. 79, 276 (1967)]

Entropy, Enthalpy and ~ changes on formation of complexes (CR) 265 [G.E. 79, 276 (1967)]

Enzymatic reactions, Nucleophilic ~ of acetyl-CoA (CR) 377 [G.E. 79, 383 (1967)]

Enzymes, Structure and mechanism of action of the active center of yeast pyruvate decarboxylase (FP) 1024 [G. E. 79, 1050 (1967)]

Quaternary structure and activity of ~ (alcohol dehydrogenase, glut amic dehydrogenase, catalase) (CR)460 [G.E. 79, 423 (1967)]

Regulation of the specificity of ~ (LA) 274

Enzyme-bound coenzyme A (LA) 643

Epoxides, Ring expansion in 1-(isopropenyl)-cycloalkanol ~ (LA) 889

ESR spectroscopy, Spin density distribution in 2,4,6-triphenylphenoxyl (FP) 34 [G.E. 79, 69 (1967)]

ESR spectrum of a non-degenerate state of the benzene radical anion (SC) 360 [G.E. 79, 318 (1967)]

Determination, by ~ of the constitution of the phosphorus radicals formed on oxidation of phosphorins (SC) 711 [G.E. 79, 725 (1967)]

UV and ~ of *p*-bis(trimethylsilyl)- and *p*-dialkylbenzenes (SC) 941 [G. E. 79, 933 (1967)]

~ of *N*-oxides of imidazolyls (SC) 947 [G. E. 79, 941 (1967)]

Detection of aryl(vinyl)nitroxides by ~ (SC) 1080 [G. E. 79, 1070 (1967)]

Detection of mesomeric limiting structures by ~ (CR) 639 [G.E. 79, 625 (1967)]

~ studies of bridged annulenes (CR) 715 [G.E. 79, 693 (1967)]

~ studies of nitroxide radicals that are capable of mesomerism (CR) 810 [G.E. 79, 825 (1967)]

Essences, The gas-chromatographic and spectrophotometric investigation of ~ (CR) 968 [G. E. 79, 988 (1967)]

Ethanes, The torsional vibrations of the chlorinated ~ (LA) 1089

Ethers, Formation of C–C-bonds with the aid of α-halogeno ~, sulfides, and amines (FP) 335 [G.E. 79, 358 (1967)]

Ethoxycarbonyliodocarbene, Ethyl diazoiodoacetate and its decomposition to ~ (SC) 74 [G.E. 79, 50 (1967)]

Ethylene, Active species in homogeneous Ziegler-Natta catalysts for the polymerization of ~ (FP) 790 [G.E. 79, 764 (1967)]

Excitation functions, Determination of some ~ for deuteron reactions with ^{141}Pr (CR) 981 [G. E. 79, 1001 (1967)]

Exopeptidase, Aminopeptidase B (LA) 186

Experimental organic chemistry, Organisch-chemische Experimentierkunst (~) (Book Review) 380

~ (Book Review) 721

Extraction, Liquid-liquid ~ of tetravalent and hexavalent actinide nitrates by a long-chain trialkylmethylammonium nitrate (CR) 979 [G. E. 79, 999 (1967)]

Extraction chromatography, Separation of fission products by ~ (CR) 269 [G.E. 79, 247 (1967)]

FARADAY effect, Apparatus for measuring the ~ in the UV and the visible regions (CR) 1003 [G. E. 79, 1023 (1967)]

Fatty acids, Decontamination of radioactive waste water by salts of ~ (CR) 269 [G.E. 79, 247 (1967)]

Ferredoxin, Apo-~ has been reactivated (LA) 274

Field electron microscope, Measurement of heats of adsorption on the surfaces of single crystals with the ~ (CR) 966 [G. E. 79, 987 (1967)]

Fission products, Separation of ~ by extraction chromatography (CR) 269 [G.E. 79, 247 (1967)]

Radiochemical determination of the activities of ~ in irradiated fuel elements (CR) 270 [G.E. 79, 248 (1967)]

Flames, Lean $H_2/N_2/O_2$ ~ containing alkali metal (LA) 100

Flotation, Ion ~ as a separation process in toxicology (CR) 373 [G.E. 79, 324 (1967)]

Flow behavior, Investigations on the ~ of polymers in relation to their molecular structure (CR) 466 [G.E. 79, 420 (1967)]

Flow birefringence, Examples of the ~ of viscoelastic systems (CR) 466 [G.E. 79, 419 (1967)]

Fluorimetry, Fluorimetrie (~) (Book Review) 892

Fluorination, Preparation of dichlorohexafluoropropane by ~ of 1,2-dichloropropane (SC) 627 [G.E. 79, 622 (1967)]

Fluorine, Aromatic ~ as a chemical label for detecting reaction mechanism (FP) 596 [G.E. 79, 636 (1967)]

Fluoroalkylalanines, General method for the preparation of β-per-~ (SC) 807 [G.E. 79, 822 (1967)]

Fluorocarbonyl pseudohalides, Preparation of carbonyl and ~ in molten salts (SC) 871 [G.E. 79, 860 (1967)]

Fluoro-coenzyme Q_1, (Fluoroubiquinone-5) (SC) 957 [G. E. 79, 979 (1967)]

Fluoro compounds, Chemistry of perfluorinated aromatic mono- and dicarboxylic acids (CR) 994 [G. E. 79, 1014 (1967)]

Fluorocyclohexenes, Poly-~ (LA) 379

Fluorocyclopropanes, Preparation of ~ by reductive dechlorination of chloro-~ (SC) 629 [G.E. 79, 617 (1967)]

Fluorophosphine, Dimethyl-~ (SC) 708 [G.E. 79, 686 (1967)]

Fluorothiocarbonyl isothiocyanate (SC) 940 [G. E. 79, 987 (1967)]

Fluoroubiquinone-5, Fluoro-coenzyme Q_1 (~) (SC) 957 [G. E. 79, 979 (1967)]

Food chemistry, Handbuch der Lebensmittelchemie (Manual of ~) (Book Review) 189

Foodstuffs, Use of viridic acid as coloring matter for ~ (CR) 885 [G.E. 79, 872 (1967)]

Formaldehyde, Isolation and characterization of cyclic oligomers of ~ (CR) 464 [G.E. 79, 416 (1967)]

Reactions of heterocyclic amines with ~ (CR) 967 [G. E. 79, 987 (1967)]

States responsible for the photochemical decomposition of ~ (LA) 274

Formamide, Carbonylation of metal amides to metal ~s (SC) 357 [G.E. 79, 312 (1967)]

H/D Exchange in *N,N*-dimethyl-~ acetals and orthoformic esters (SC) 875 [G.E. 79, 869 (1967)]

~s Separation and equilibration of conformeric ~ (CR) 984 [G.E. 79, 1004 (1967)]

Formates, Reaction of isocyanato- and isothiocyanato-~ with activated phenols (SC) 455 [G.E. 79, 474 (1967)]

Formic acid, Electrochemical oxidation of ~ and carbon monoxide on platinum catalysts in acid electrolytes (CR) 471 [G.E. 79, 477 (1967)]

Formimidates, Simple synthesis of alkyl ~ (SC) 566 [G.E. 79, 531 (1967)]

Formylalkyl group, Simple method for introduction of a ~ into quinones (SC) 174 [G.E. 79, 150 (1967)]

Fossil plants, Organic compounds in ~ (Equisetum; horsetails) (SC) 1085 [G. E. 79, 1107 (1967)]

Fragmentation, Heterolytic ~. A class of organic reactions (FP) 1 [G.E. 79, 1 (1967)]

New ~ reaction of 20-chloro-16β-hydroxy steroids (SC) 631 [G.E. 79, 619 (1967)]

Photo-~ of oxaziranes (SC) 634 [G.E. 79, 648 (1967)]

New ~ in the adamantane series (SC) 864 [G.E. 79, 860 (1967)]

~ of bicyclic keto-*p*-toluenesulfonates (CR) 980 [G. E. 79, 1000 (1967)]

Novel ~ of cyclic α,β-unsaturated carbonyl systems (LA) 890

Carbonyl compounds, 1,3-Cycloadditions of mesoionic oxazolones to ~ (SC) 365 [G.E. 79, 320 (1967)]

Synthesis and reactions of novel ~ containing nitrogen (CR) 989 [G.E. 79, 1009 (1967)]

Photoaddition of ~ to allenes (LA) 576

Carbonylmetal complexes, First ~ of hydrogen isocyanide (LA) 716

Carbonylmetal-π-complexes, of dihydropyridine derivatives (CR) 988 [G.E. 79, 1008 (1967)]

Carbonyl pseudohalides, Preparation of ~ and fluorocarbonyl pseudohalides in molten salts (SC) 871 [G.E. 79, 860 (1967)]

Carboranebis(sulfenyl chlorides), in polymerization reactions (CR) 997 [G.E. 79, 1017 (1967)]

Carboranes, Structures and syntheses of ~ (FP) 218 [G.E. 79, 197 (1967)]

Carbosilanes, Formation and properties of ~ (FP) 677 [G.E. 79, 657 (1967)]

Carboxamides, Preparation and reactions of enamides (CR) 377 [G.E. 79, 385 (1967)]

N-Carboxy-α-amino acid anhydrides, Synthesis of ~ (SC) 248 [G.E. 79, 237 (1967)]

Carboxylase, Ribulose diphosphate ~ from spinach leaves (LA) 186

Carboxylic acids, Reaction of bicyclic amide acetals with ~ and their anhydrides (SC) 178 [G.E. 79, 189 (1967)]

Synthesis of di-~ by the Willgerodt-Kindler reactions (SC) 944 [G.E. 79, 943 (1967)]

Catalase, Quaternary structure and activity of enzymes (alcohol dehydrogenase, glutonic dehydrogenase ~) (CR) 460 [G.E. 79, 423 (1967)]

Catalysis, Nickel-catalysed reactions of allyl halides and related compounds (FP) 124 [G.E. 79, 177 (1967)]

Boundary-layer ~ (CR) 375 [G.E. 79, 325 (1967)]

Catalysts, Active species in homogeneous Ziegler-Natta ~ for the polymerization of ethylene (FP) 790 [G.E. 79, 764 (1967)]

Attempts to characterize the catalytically active center in homogeneous Ziegler-Natta polymerization (CR) 464 [G.E. 79, 418 (1967)]

Experiments on the poisoning of ~ used in the synthesis of ammonia (CR) 994 [G.E. 79, 1014 (1967)]

Effective hydrogenation ~ obtained by reduction of Pt(IV) (LA) 643

The stereoselective efficiency of hydrogenation ~ (LA) 1008

Catalytic hydrogenation, techniques and applications in organic synthesis (Book Review) 192

Catena compounds, Synthesis of ~ by the semistatistical principle (SC) 956 [G.E. 79, 945 (1967)]

C–C Bonds, Formation of ~ with the aid of α-halogeno ethers, sulfides, and amines (FP) 335 [G.E. 79, 358 (1967)]

C–C Condensations, with the uracilylmethyl cation (SC) 702 [G.E. 79, 691 (1967)]

Cesium pentafluoroethoxide, and rubidium pentafluoroethoxide (SC) 256 [G.E. 79, 246 (1967)]

Chain-length effects, Some ~ of paraffins (CR) 979 [G.E. 79, 999 (1967)]

Chain rigidity, Influence of ~ on the crystallization process in macromolecules (CR) 465 [G.E. 79, 416 (1967)]

Charge distribution, Potential and ~ at semiconductor-electrolyte interfaces (FP) 851 [G.E. 79, 833 (1967)]

Chelate, Boron ~ compounds in the 2-(*o*-hydroxyphenyl)benzazole series (SC) 1082 [G.E. 79, 1072 (1967)]

Chelates, Aromatic character of six-membered ~ (CR) 182 [G.E. 79, 153 (1967)]

Reactions of boron compounds with metal ~ and chelating agents (CR) 574 [G.E. 79, 583 (1967)]

Schiff bases of acetylacetone form ~ with Ir(I) and Rh(I) (LA) 814

Chloramphenicol, as the only source of carbon and nitrogen (LA) 717

α-Chloro-1-adamantaneacetic acids, Synthesis of ~ and α-chloro-2-norbornaneacetic acid by means of trichloroethylene (SC) 946 [G.E. 79, 943 (1967)]

4-Chloro-1α,2α:6β,7β-bismethylenesteroids (SC) 799 [G.E. 79, 815 (1967)]

Chloroethane, The torsional vibrations of the chlorinated ethanes (LA) 1089

10-Chloro-9-fluorobicyclo[6.2.0]deca-2,4,6,9-tetraene, and 3-chloro-2-fluorobicyclo[2.2.0]hexa-2,5-diene (SC) 806 [G.E. 79, 820 (1967)]

3-Chloro-2-fluorobicyclo[2.2.0]hexa-2,5-diene, 10-Chloro-9-fluorobicyclo[6.2.0]-deca-2,4,6,9-tetraene and ~ (SC) 806 [G.E. 79, 820 (1967)]

O-Chloroformylhydroxylamine, *N,N*-disubstituted derivatives of ~ as reagents for peptide synthesis (SC) 570 [G.E. 79, 532 (1967)]

m-Chloro-*N*^{1}-indanylideneaniline, Synthesis and reactions of ~ (SC) 248 [G.E. 79, 236 (1967)]

S-Chloroisothiocarbamoyl chlorides, Preparation of 5-alkyl-1,3-thiazolin-2-ones by reaction of ~ with aldehydes and vinyl ethers (SC) [G.E. 79, 1063 (1967)]

α-Chloro-2-norbornaneacetic acid, Synthesis of α-chloro-1-adamantaneacetic acids and ~ by means of trichloroethylene (SC) 946 [G.E. 79, 943 (1967)]

Chloroperoxidase (LA) 186

Chorophosphonium salts, Tetra-~ and chloro(phenyl)-phosphonium perchlorates and hexachloroantimonates (SC) 564 [G.E. 79, 535 (1967)]

2-Chlorovinyl ketones, Reaction of phosphorylides with ~ (SC) 877 [G.E. 79, 899 (1967)]

cis-~ (LA) 891

Chroman, Biogenetically important component of teak wood is 2,2-dimethylbenzo[*h*]-~ (LA) 577

Chromatography, Determination of benzoic and phthalic acids in terephthalic acid by partition ~ (CR) 373 [G.E. 79, 323 (1967)]

Chromatographic separation of metal ions with anomalous exchange properties on chelating ion-exchange resins (CR) 373 [G.E. 79, 324 (1967)]

Distribution ~ for the analysis of terephthalic acid (CR) 374 [G.E. 79, 325 (1967)]

Multilayer ~ in difficult separations (CR) 374 [G.E. 79, 325 (1967)]

Efficiency of gel permeation ~ (CR) 464 [G.E. 79, 420 (1967)]

Einführung in die Chromatographie (Introduction to ~) (Book Review) 277

Advances in ~ (Book Review) 279

Dynamics of ~ (Book Review) 279

Chromium, New results in the chemistry of ~ (CR) 574 [G.E. 79, 538 (1967)]

Chromium complexes, Addition of isocyanides to transition metal carbene complexes (SC) 879 [G.E. 79, 900 (1967)]

Chromium compounds, Sigma-bonded organo-~ – Hydrogen transfer reactions (FP) 435 [G.E. 79, 401 (1967)]

Tricarbonylhexamethylborazolechromium (SC) 91 [G.E. 79, 63 (1967)]

Tetracarbonyl(hexamethylbicyclo-[2.2.0]hexadiene)-chromium(0) (SC) 634 [G.E. 79, 623 (1967)]

Chromium peroxides, New results in the chemistry of chromium (CR) 574 [G.E. 79, 538 (1967)]

Chromophore, Cyclobutenediylium cation, a novel chromophore from squaric acid (SC) 553 [G.E. 79, 581 (1967)]

Chymotrypsin, Change in the specificity of ~ (LA) 186

Method for the study of the polarity of the microenvironment of the active site in ~ (LA) 187

Circular dichroism, in phorbol derivatives (CR) 974 [G.E. 79, 994 (1967)]

Synthesis and ~ of optically active adamantane derivatives (CR) 998 [G.E. 79, 1018 (1967)]

cis-trans-Isomers, Elimination in cyclic ~ (FP) 534 [G.E. 79, 555 (1967)]

Cobalamin, The synthesis of acetate from carbon dioxide and Co-methyl-~ (LA) 1089

Cobalt, Gmelins Handbuch der anorganischen Chemie (Gmelin's handbook of inorganic chemistry) (Book Review) 100

Cobalt amine complexes, Exchange reactions and the annealing of nuclear recoil defects in crystalline ~ (CR) 993 [G.E. 79, 1013 (1967)]

Cobalt(III) complexes, rac.-Dicyano-(1,2,2,7,7,12,12-heptamethylcorrin)-cobalt(III) (SC) 864 [G.E. 79, 863 (1967)]

Reactivity of ligands in synthetic cobalt(III)- and nickel(II)-corrin complexes (SC) 868 [G.E. 79, 867 (1967)]

Cobalt oxide, Photocatalysis by semiconductors on metal supports. Photosensitized oxidation of CO with ~ on silver supports (CR) 999 [G.E. 79, 1019 (1967)]

Cobalt thiolates, Thiolates of cobalt, nickel, copper, and zinc (LA) 716

Cobamide, Comprehensive biochemistry (Book Review) 191

Coenzyme A, Enzyme-bound ~ (LA) 643

Colorimetry, Handbuch der Kolorimetrie (Manual of ~) (Book Review) 380

Complexes, Trifluorophosphine ~ of transition metals (FP) 53 [G.E. 79, 27 (1967)]

Borate ~ derived from lithium carbenoids – mechanism of the "inverse Stevens rearrangement" (SC) 74 [G.E. 79, 50 (1967)]

Ligand addition and redox reactions of azido-metal ~ (SC) 169 [G.E. 79, 146 (1967)]

Metal ~ of diethylthiophosphinic acid (SC) 175 [G.E. 79, 148 (1967)]

Novel rearrangement processes of transition metal carbene ~ (SC) 181 [G.E. 79, 191 (1967)]

Coordination compounds with stationary and oscillating acceptors (SC) 448 [G.E. 79, 411 (1967)]

PF_2 bridges in metal ~ (SC) 454 [G.E. 79, 474 (1967)]

~ of alkoxy(dialkylamino)carbenes and Hg^{2+} obtained from dicarbamoylmercury compounds (SC) 560 [G.E. 79, 578 (1967)]

Reaction of halogeno(phosphine)-nickel ~ with nitric oxide (SC) 566 [G.E. 79, 536 (1967)]

Synthesis of metal-boron coordination compounds by oxidative addition (SC) 696 [G.E. 79, 683 (1967)]

Synthesis of tetramethylcyclobutadienenickel(II) bromide with new nickel(0) ~ (SC) 873 [G.E. 79, 897 (1967)]

Nitrogen fixation on new transition metal ~ (SC) 873 [G.E. 79, 898 (1967)]

Formation of fluoroorganocarbonylmanganese and -rhenium ~ from hexafluoro-1,3-butadiene and pentacarbonylmanganese and -rhenium hydrides (SC) 878 [G.E. 79, 900 (1967)]

Addition of isocyanides to transition metal carbene ~ (SC) 879 [G.E. 79, 900 (1967)]

Synthesis of hydridopentacyanoiridate ~ (SC) 881 [G.E. 79, 902 (1967)]

Addition-rearrangement reactions of transition metal-carbene ~ with selenophenol (SC) 961 [G.E. 79, 982 (1967)]

μ-Cyanogenbis(pentacarbonylmetal)-~ (SC) 1081 [G.E. 79, 1071 (1967)]

Metal ~ of oxotripyrrene-α-carboxylic acid (CR) 184 [G.E. 79, 155 (1967)]

Enthalpy and entropy changes on formation of ~ (CR) 265 [G.E. 79, 276 (1967)]

Spectroscopic and electrical properties of polymeric donor-acceptor ~ (CR) 268 [G.E. 79, 278 (1967)]

Influence of the solvent on coordination-chemical reactions (CR) 271 [G.E. 79, 279 (1967)]

Side-chain interactions in polypeptides. Experiments with donor-acceptor ~ (CR) 469 [G.E. 79, 425 (1967)]

Some aromatic ~ of the transuranium elements (CR) 964 [G.E. 79, 984 (1967)]

Spectrophotometric studies on the hydrolysis and complex formation of the plutonyl and neptunyl ions (CR) 967 [G.E. 79, 987 (1967)]

Synthesis and reactions of stable mercury-carbene ~ (CR) 970 [G.E. 79, 990 (1967)]

Carbonylmetal π-~ of dihydropyridine derivatives (CR) 988 [G.E. 79, 1008 (1967)]

Stability and properties of the ~ of hexavalent actinides with pyridine-2-carboxylic acids and quinaldic acid (CR) 993 [G.E. 79, 1013 (1967)]

Exchange reactions and the annealing of nuclear recoil defects in crystalline Co-, Rh-, and Ir-amine ~ (CR) 993 [G.E. 79, 1013 (1967)]

Kinetic investigations of substitution reactions of metal carbonylcarbene ~ (CR) 1001 [G.E. 79, 1021 (1967)]

Isomerism in metal ~ (LA) 642

First carbonylmetal ~ of hydrogen isocyanide (LA) 716

Monomeric diphenylberyllium ~ (LA) 814

Meisenheimer ~ containing only one nitro group (LA) 888

Condensed milk, Tin content of ~ (CR) 885 [G.E. 79, 872 (1967)]

Conductivity, Metallic ~ in supercritical mercury (LA) 379

Configuration, Absolute ~ of the enantiomeric 4-methylcyclohexylideneacetic acids (LA) 188

Conformational analysis (Book Review) 382

Conformational isomerism, Intramolecular ~ of the cyclohexane rings in crystalline 2,3-bis-(*cis*-4-chloro-1-methylcyclohexyl)-*trans*-2-butene (SC) 445 [G.E. 79, 408 (1967)]

Coordination compounds, with stationary and oscillating acceptors (SC) 448 [G.E. 79, 411 (1967)]

Coordination numbers, Higher ~ of the typical elements (FP) 749 [G.E. 79, 756 (1967)]

Cope rearrangement, Catalysed ~ of *cis*-1,2-divinylcyclobutane (SC) 800 [G.E. 79, 814 (1967)]

Copolymerization, Novel method of determining reactivity ratios in ~ (CR) 463 [G.E. 79, 419 (1967)]

Influence of the anomalous chain-growth reaction on the ~ kinetics (CR) 464 [G.E. 79, 417 (1967)]

Copolymers, Frequency distribution of the chemical composition in binary ~ (CR) 464 [G.E. 79, 420 (1967)]

Copper compounds, Synthesis of dienes from vinyl halides via organocopper compounds (SC) 85 [G.E. 79, 101 (1967)]

"Dimerization" of organic nitrogen compounds via copper-containing intermediates (SC) 633 [G.E. 79, 620 (1967)]

Cu(II) exists in square-plan arcoordination (LA) 1006

Copper thiolates, Thiolates of cobalt, nickel, copper, and zinc (LA) 716

Corrins, Synthetic route to metal-free ~ (SC) 866 [G.E. 79, 865 (1967)]

Reactivity of ligands in synthetic cobalt(III)- and nickel(II)-~ complexes (SC) 868 [G.E. 79, 867 (1967)]

Corrosion, of zirconium and zirconium alloys (CR) 269 [G.E. 79, 247 (1967)]

Cotton effect, Quadrant rule for the $n\rightarrow\pi^*$ ~ of dithiourethanes from optically active amines (SC) 704 [G.E. 79, 721 (1967)]

Countercurrent electrolysis, Isotope concentration by ~ at high electrolyte concentrations with the aid of separating columns having capillary properties (CR) 965 [G.E. 79, 985 (1967)]

Cross-linked polymers, from α,α'-*p*-phenylenediacrylonitrile (CR) 639 [G.E. 79, 624 (1967)]

Crystals, Measurement of heats of adsorption on the surfaces of single ~ with the field electron microscope (CR) 966 [G.E. 79, 987 (1967)]

Crystal structure, of dimethyltin difluoride (LA) 188

~ of gold trifluoride (LA) 813

Crystallization, Influence of chain rigidity on the ~ process in macromolecules (CR) 465 [G.E. 79, 416 (1967)]

Cumulenes, UV-Absorption of α,α,ω,ω-tetraphenyl-~ with coplanar benzene rings (SC) 954 [G.E. 79, 931 (1967)]

Curium, Preparative isolation of ^{242}Cm in the 100 Ci range (CR) 976 [G.E. 79, 996 (1967)]

Curium oxides (CR) 973 [G.E. 79, 993 (1967)]

Cyanamide, Thionyl-~ (SC) 701 [G.E. 79, 691 (1967)]

Cyanic esters, Synthesis and reactions of ~ (FP) 206 [G.E. 79, 219 (1967)]

N-Cyaniminosulfur difluoride (SC) 90 [G.E. 79, 98 (1967)]

Cyanobenzenes, Halogenated 1,3-di-~ and 1,3,5-tricyanobenzenes (LA) 643

Cyanocobalamine 5'-phosphate, Isolation of ~ (SC) 368 [G.E. 79, 311 (1967)]

N-(Cyano)diphenylphosphonimidic fluoride, *N*-(Cyano)phenylphosphonimidic difluoride and ~ (SC) 709 [G.E. 79, 723 (1967)]

μ-Cyanogenbis(pentacarbonylmetal) complexes (SC) 1081 [G.E. 79, 1071 (1967)]

Cyanogen *N*-oxide, Formation of ~ (LA) 472

N-(Cyano)phenylphosphinimidic difluoride, and *N*-(cyano)diphenylphosphinimidic fluoride (SC) 709 [G.E. 79, 723 (1967)]

Cycli-alkylation, with 1,4-dihalo compounds as a convenient way of preparing polycyclic hydroaromatic compounds (CR) 973 [G.E. 79, 993 (1967)]

Cyclization, of acid chlorides by polyphosphoric acid (SC) 1086 [G.E. 79, 1100 (1967)]

Cycloadditions, 1,3-~ of mesoionic oxazolones to carbonyl compounds (SC) 365 [G.E. 79, 320 (1967)]

1,3-Dipolar ~ of fulminic acid (SC) 456 [G.E. 79, 471 (1967)]

1,3-~ of nitrones to methylenephosphoranes (SC) 457 [G.E. 79, 457 (1967)]

~ of ketoximes (SC) 709 [G.E. 79, 722 (1967)]

Stereochemistry of the ~ of sulfonyl isocyanates and *N*-sulfinylsulfonamides to enol ethers (SC) 951 [G.E. 79, 936 (1967)]

~ to derivatives of methylenequadricyclane and of quadricyclanone (bishomocyclobutadiene) (SC) 1069 [G.E. 79, 1102 (1967)]

~to derivatives of oxaquadricyclanes (bishomofuran) (SC) 1070 [G.E. 79, 1103 (1967)]

Diels-Alder-type ~ with indoles (CR) 964 [G.E. 79, 984 (1967)]

~ of isocyanates (CR) 1000 [G.E. 79, 1020 (1967)]

1,2-~ of an azo group to an olefin (LA) 577

1,3-Cycloalkanediones, Synthesis of 2-Alkyl-~ by Friedel-Crafts acylation (SC) 80 [G.E. 79, 97 (1967)]

Preparation of 2-alkyl-~ by cyclization of γ- and δ-keto carboxylic acids (SC) 371 [G.E. 79, 378 (1967)]

Cyclobutadienenickel(II) bromide, Synthesis of tetramethyl-~ with a new nickel (0) complex (SC) 873 [G.E. 79, 897 (1967)]

Cyclobutane, Neighboring-group effects and rearrangements in reactions of cyclopropylmethyl, cyclobutyl, and homoallyl systems (FP) 666 [G.E. 79, 709 (1967)]

Catalysed synthesis of *cis*-1,2-divinyl-~ (SC) 800 [G.E. 79, 813 (1967)]

Catalysed Cope rearrangement of *cis*-1,2-divinyl-~ (SC) 800 [G.E. 79, 814 (1967)]

Synthesis and thermal ring cleavage of bicyclic ~ derivatives (CR) 995 [G.E. 79, 1015 (1967)]

Cyclobutenes, Reactions of benzoyl-~ (CR) 984 [G.E. 79, 1004 (1967)]

Cyclobutenediylium cation, a novel chromophore from squaric acid (SC) 553 [G.E. 79, 581 (1967)]

Cyclododecasulfur, Occurrence of ~ in sulfur melts (SC) 955 [G.E. 79, 944 (1967)]

Cycloheptane, Ring inversion in ~ and in cycloheptene derivatives (SC) 556 [G.E. 79, 577 (1967)]

Cycloheptene. Ring inversion in ~ and in cycloheptane derivatives (SC) 556 [G.E. 79, 577 (1967)]

Cyclohexane, Intramolecular conformational isomerism of the ~ rings in crystalline 2,3-bis-(*cis*-4-chloro-1-methylcyclohexyl)-*trans*-2-butene (SC) 445 [G.E. 79, 408 (1967)]

Cyclohexanecarboxylic acid, Aromatization of ~ to benzoic acid (LA) 472

Cyclooctadiene, Bis-(1,5-~)platinum(0) (SC) 364 [G.E. 79, 380 (1967)]

1,5-Cyclooctadienenickel, bromide and iodide (SC) 452 [G.E. 79, 414 (1967)]

Cyclooctatetraeneiron, Preparation of bicyclo[4.2.2]deca-2,4,7,9-tetraene from tricarbonyl-~ (SC) 79 [G.E. 79, 55 [G.E. 79, 55 (1967)]

Cyclopentadienylgold(I), and cyclopentadienyl-(triphenylphosphine)gold(I) (SC) 862 [G.E. 79, 859 (1967)]

Cyclopentadienylidenepyrans, Synthesis of substituted ~ and tetramethyl 7,8,9,10-sesquifulvalenetetracarboxylate (SC) 82 [G.E. 79, 96 (1967)]

Cyclopentadienylvanadium, Synthesis of pentacarbonyldicyclopentadienyldivanadium and new carbonylphosphine-~ compounds (SC) 569 [G.E. 79, 537 (1967)]

Cyclopenta[*a*]phenalene, Synthesis of 7,9-dioxo- and 7-alkylidene-9-keto derivatives of ~ and their conversion into substituted 7-benz[*de*]anthrones (SC) 172 [G.E. 79, 187 (1967)]

Cyclophosphazatrienes, Thermal decomposition of some diphenylphosphinothioic amides. New rout eto aryl-~ (SC) 556 [G.E. 79, 575 (1967)]

Cyclopolyphosphines, Structure, preparation, and properties of ~ (CR) 887 [G.E. 79, 908 (1967)]

Cyclopropane, Neighboring-group effects and rearrangements in reactions of cyclopropylmethyl, cyclobutyl, and homoallyl systems (FP) 666 [G.E. 79, 709 (1967)]

Preparation of fluoro-~ by reductive dechlorination of chlorofluoro-~ (SC) 629 [G.E. 79, 617 (1967)]

Synthesis of a triquino-~, a diquino-~ and a diquinoethylene (LA) 814

Cyclopropenes, Photochemical synthesis of alkyl- and aryl-~ (SC) 1084 [G.E. 79, 1104 (1967)]

Cyclopropyldiazomethane, Di-~ (SC) 702 [G.E. 79, 687 (1967)]

(Cyclopropylmethylene)triphenylphosphorane (SC) 557 [G.E. 79, 576 (1967)]

Cyclotrimerization, Kinetic studies of the ~ of butadiene by Ziegler catalysts (CR) 1088 [G.E. 79, 1074 (1967)]

Cysteine, Enzymatic transfer of sulfur from ~ to tRNA (LA) 186

Cytochrome C peroxidase (LA) 99

DECABORANE, Mercury derivatives of ~ (LA) 1008

Decarboxylation, Oxidative ~ of glycine (LA) 274

Decontamination, of radioactive waste water by salts of fatty acids (CR) 269 [G.E. 79, 247 (1967)]

Dehalogenation, Reductive ~ of organic compounds by sodium telluride (SC) 1083 [G.E. 79, 1105 (1967)]

Dehydration, of 3-acetonylglutaric acid (SC) 172 [G.E. 79, 148 (1967)]

Dehydrobenzene, Reaction of benzyne with α-methylstyrene (SC) 555 [G.E. 79, 575 (1967)]

α-Dehydrobiotin (LA) 1088

Dehydrogenation, A new ~ reaction with diethyl azodicarboxylate (LA) 1006

Demixing phenomena, in high polymers and their technical importance (CR) 962 [G.E. 79, 949 (1967)]

Desorption, Adsorption on, and ~ from, pigments (CR) 181 [G.E. 79, 192 (1967)]

1-Deuterioalkyl halides, Synthesis of ~ from cyclic *S*-alkylsulfonium salts and heavy water (SC) 371 [G.E. 79, 378 (1967)]

Deuterium, H/D Exchange in *N,N*-dimethylformamide acetals and orthoformic esters (SC) 875 [G.E. 79, 869 (1967)]

Deuteron reactions, Determination of some excitation functions for ~ with ^{141}Pr (CR) 981 [G.E. 79, 1001 (1967)]

Dewar benzene, see Bicyclo[2.2.0]hexa-2,5-diene

8,9-Diacetylsesquifulvalene (SC) 627 [G.E. 79, 616 (1967)]

p-Dialkylbenzenes, UV and ESR studies of *p*-bis(trimethylsilyl)- and ~ (SC) 941 [G.E. 79, 933 (1967)]

Dialkylgallium fluorides, Synthesis and structure of ~ (SC) 806 [G.E. 79, 821 (1967)]

3,5-Diaminophenols, *N*-Persubstituted ~ and 1,3,5-benzenetriamines and their protonation (SC) 1067 [G.E. 79, 1100 (1967)]

Diammonium amidothiophosphate, NH···S Hydrogen bonds and the structure of the anions in ammonium diamidothiophosphate and in ~ (SC) 960 [G.E. 79, 981 (1967)]

1,5-Diazabicyclo[5.4.0]undec-5-ene, a new hydrogen halide acceptor (SC) 76 [G.E. 79, 53 (1967)]

2,3-Diazabuta-1,3-diene-1,4-diamines, (1,4-disubstituted) and N^1-acylamidrazones from nitriles and bis(diethylalumino)-substituted amidrazones and acid hydrazides (SC) 256 [G.E. 79, 243 (1967)]

1,3,2,4-Diazadiboretidine, Crystal and molecular structures of hexakis-(trimethylsilyl)-2,4-diamino-~ (CR) 975 [G.E. 79, 995 (1967)]

Diazenium salts, Synthesis of carbonylazo compounds by the reaction of alkoxy-~ with carboxylates (SC) 699 [G.E. 79, 681 (1967)]

Synthesis of s-triazolium cations by reaction of alkoxy-~ with nitrogen heterocycles (SC) 699 [G.E. 79, 682 (1967)]

Diazetidine, Preparation and reactions of ~ derivatives (CR) 183 [G.E. 79, 154 (1967)]

1,2-Diazetidinones, Ortho-semidine rearrangement of 1,2-diphenyl-~ (SC) 630 [G.E. 79, 619 (1967)]

~ (LA) 472

Di(aziridinyl)sulfanes, Preparation of diimidazolylsulfanes and ~ (SC) 703 [G.E. 79, 690 (1967)]

Diazoacetaldehyde (LA) 888

Diazoalkanes, Polymers and copolymers of ~ (CR) 462 [G.E. 79, 423 (1967)]

Diazocarboxylic esters, from ethyl argentodiazoacetate and alkyl halides (SC) 261 [G.E. 79, 238 (1967)]

Diazo groups, Transfer of ~ (FP) 733 [G.E. 79, 786 (1967)]

Diazoiodoacetate, Ethyl ~ and its decomposition to ethoxycarbonyliodocarbene (SC) 74 [G.E. 79, 50 (1967)]

Diazomethane, Dicyclopropyl-~ (SC) 702 [G.E. 79, 687 (1967)]

Oxidation and elimination reactions of the ~-2,2-bi-(1,4-naphthoquinone) adduct (CR) 470 [G.E. 79, 477 (1967)]

N-Diazonium group, Structure and reactivity of the ~ (CR) 1002 [G.E. 79, 1022 (1967)]

Dibenzofulvalene, Symmetrical ~ (LA) 99 [G.E. 79, 103 (1967)]

Dibenzonorcaradiene, New route to ~ derivatives (SC) 561 [G.E. 79, 578 (1967)]

Dibenzo[*b,e*]phosphorine (SC) 567 [G.E. 79, 533 (1967)]

Dicarboxylic acids, Synthesis of ~ by the Willgerodt-Kindler reactions (SC) 944 [G.E. 79, 943 (1967)]

Dicarbenium ions, of the biphenyl series (LA) 891

Dichlorocarbene, Reaction of allylamines with ~ (LA) 644

Dichlorohexafluoropropane, Preparation of ~ by fluorination of 1,2-dichloropropane (SC) 627 [G.E. 79, 622 (1967)]

N-(Dichloromethylene)chlorosulfonamide, Preparation of ~ and -fluorosulfonamide (SC) 882 [G.E. 79, 904 (1967)]

N-(Dichloromethylene)fluorosulfonamide, Preparation of *N*-(dichloromethylene)-chlorosulfonamide and ~ (SC) 882 [G.E. 79, 904 (1967)]

Dictionary, of organic compounds (Book Review) 722

Technisches Taschenwörterbuch (Pocket technical ~), English-German, German-English (Book Review) 894

Dicyanocarbene, Reaction of ~ (LA) 98

rac.-Dicyano-(1,2,2,7,7,12,12-heptamethylcorrin)cobalt(III) (SC) 864 [G.E. 79, 863 (1967)]

Dicyclohexylisoureas, Alkylations with *O*-alkyl-*N,N'*-~ (CR) 1001 [G.E. 79, 1021 (1967)]

Dicyclopentadiene, *endo*-~ undergoes intermolecular rearrangement to form *exo*-~ (LA) 185

Dicyclopentadienyliridium, Monomeric and dimeric dicyclopentadienylrhodium and ~ (LA) 188

Dicyclopentadienylrhodium, Monomeric and dimeric ~ and -iridium (LA) 188

Dicyclopentadienyltechnetium hydride (SC) 93 [G.E. 79, 99 (1967)]

Dicyclopropyldiazomethane (SC) 702 [G.E. 79, 687 (1967)]

Diels-Alder reactions, Reaction Mechanism (FP) 16 [G.E. 79, 76 (1967)]

Diels-Alder-type cycloadditions with indoles (CR) 964 [G.E. 79, 984 (1967)]

Dienes, Synthesis of ~ from vinyl halides via organocopper compounds (SC) 85 [G.E. 79, 101 (1967)]

Diethyl azidocarboxylate, A new dehydrogenation reaction with ~ (LA) 1006

Diethylcarbamoyllithium, Preparation of ~ (diethylamino)lithiooxycarbene from bis(diethylcarbamoyl)mercury (SC) 805 [G.E. 79, 819 (1967)]

Diethylgallium azide (LA) 718

Diethyl-(5-hexenyl)aluminum-ether (SC) 872 [G.E. 79, 862 (1967)]

N',N'-Diethylthioformohydrazide, Isomerism of ~ with its betaine (SC) 368 [G.E. 79, 381 (1967)]

Diethylthiophosphinic acid, Melta complexes of ~ (SC) 175 [G.E. 79, 148 (1967)]

Diffraction methods, Advances in structure research by ~ (Book Review) 474

Diffusion, Surface ~ and relaxation times of adsorbed molecules (CR) 886 [G.E. 79, 908 (1967)]

Measurement of self-~ coefficients of Na by heterogeneous solid/melt and solid/solid isotope exchange on sodalite, obsidian, and NaCl (CR) 983 [G.E. 79, 1003 (1967)]

Difluorothiophosphoryl fluorosulfate (SC) 959 [G.E. 79, 980 (1967)]

N,N'-Dihalogeno-*S,S*-dimethylsulfur diimide (SC) 91 [G.E. 79, 96 (1967)]

2,3-Dihydro-3-furanone, 4-Hydroxy-2,3-dimethyl-~ (LA) 187

Dihydroheptachlor, Metabolic fate of ~ (CR) 977 [G.E. 79, 997 (1967)]

Dihydroisoquinolines, Rearrangement of ~ (CR) 183 [G.E. 79, 154 (1967)]

Dihydropyridine, Carbonylmetal π-complexes of ~ derivatives (CR) 988 [G.E. 79, 1008 (1967)]

Diimidazolylsulfanes, Preparation of ~ and di(aziridinyl)sulfanes (SC) 703 [G.E. 79, 690 (1967)]

Dimerization, of organic nitrogen compounds via copper-containing intermediates (SC) 633 [G.E. 79, 620 (1967)]

5,6-Dimethylbenzimidazole, Biosynthesis of ~ (SC) 1083 [G.E. 79, 1073 (1967)]

Dimethylbenzo[*h*]chroman, Biogenetically important component of teak wood (LA) 577

1,3-Dimethylbicyclo[1.1.0]butane, Synthesis of ~ (SC) 444 [G.E. 79, 467 (1967)]

2,2'-Dimethylbiphenyl, Optically active ~, the simplest atropisomeric hydrocarbon (SC) 251 [G.E. 79, 232 (1967)]

2,4-Dimethylcarbonohydrazide (SC) 363 [G.E. 79, 315 (1967)]

Dimethylfluorophosphine (SC) 708 [G.E. 79, 686 (1967)]

N,N-Dimethylformamide acetals, H/D exchange in ~ and orthoformic esters (SC) 875 [G.E. 79, 869 (1967)]

Dimethyl sulfoxide, as solvent (FP) 318 [G.E. 79, 340 (1967)]

Acid-catalysed oxidation of isocyanides with ~ (SC) 168 [G.E. 79, 145 (1967)]

Alkali metal alkynides in ~ (LA) 1006

Dimethyltin difluoride, Crystal structure of ~ (LA) 188

Dinonylnaphthalenesulfonic acid, has been used as a liquid ion exchanger (LA) 1088

Dioxaphosphorinanyl sulfide, Synthesis of bis(5,5-dimethyl-2-oxo-1,3,2-Pv-dioxaphosphorinanyl) sulfide (SC) 1079 [G.E. 79, 1069 (1967)]

1,3,5-Dioxazines, Trifluoromethylated and chlorodifluoromethylated 1,3,5-oxadiazines and ~ (LA) 99

Dioxodiselenomolybdate, Preparation and properties of diammonium ~ (SC) 1081 [G.E. 79, 1065 (1967)]

Diphenylberyllium complexes Monomeric ~ (LA) 814

1,2-Diphenyl-1,2-diazetidinone, Orthosemidine rearrangement of ~ (SC) 630 [G.E. 79, 619 (1967)]

Diphenylketene, Continuous process for the preparation of ~ (SC) 631 [G.E. 79, 622 (1967)]

Diphenylphosphinothioic amides, Thermal decomposition of some ~. New route to arylcyclophosphazatrienes (SC) 556 [G.E. 79, 575 (1967)]

Diphenylphosphinous amide, Synthesis and properties of ~ (SC) 875 [G.E. 79, 869 (1967)]

Diphospha^{v}-1,3,5-triazines, Tetraphenyl-~ and their salts (SC) 87 [G.E. 79, 100 (1967)]

Synthesis of phospha- and ~ by cyclizing transamination with aminophosphazenes (SC) 565 [G.E. 79, 534 (1967)]

Substituted ~ (CR) 996 [G.E. 79, 1016 (1967)]

1,3-Dipolar cycloaddition, Double ~ to a triple bond to give the bicyclo[1.1.0]-butane system (SC) 79 [G.E. 79, 98 (1967)]

~-s of fulminic acid (SC) 456 [G.E. 79, 471 (1967)]

1,4-Dipoles, Stable ~ from ketene acetals and carbon disulfide and their use for synthesis of heterocycles (SC) 366 [G.E. 79, 382 (1967)]

Stable ~ from ketene acetals and methylenemalononitriles (SC) 453 [G.E. 79, 473 (1967)]

Dipotassium diphenylphosphonate, and diphenyltetrathiohypophosphonate (SC) 883 [G.E. 79, 903 (1967)]

Dipotassium diphenyltetrathiohypophosphonate, Dipotassium diphenylhypophosphonate and ~ (SC) 883 [G.E. 79, 903 (1967)]

Dipotassium nitrosobissulfate, Specific oxidation of phenols by ~ (CR) 471 [G.E. 79, 426 (1967)]

Dipotassium triimidotellurite, Formation of selenanthrene from diphenyl selenide and of ~ from diphenyl telluride (SC) 1071 [G.E. 79, 1061 (1967)]

Diquinocyclopropanone, Synthesis of a triquinocyclopropane, a ~ and a diquinoethylene (LA) 814

Diquinoethylene, Synthesis of a triquinocyclopropane, a diquinocyclopropane, and a ~ (LA) 814

Diselenomolybdate, Preparation and properties of diammonium dioxo-~ (SC) 1081 [G.E. 79, 1065 (1967)]

Dissociation, Effect of solvent structure on ~ (CR) 266 [G.E. 79, 276 (1967)]

Disulfones, New method for the preparation of ~ (LA) 379

8*H*-1,3,5,6-Dithiadiazocin-2-one, 7-Methyl-4-phenyl-~, an eight membered heterocycle with chiral conformation (SC) 629 [G.E. 79, 618 (1967)]

1,2-Dithiin, a new type of heterocycle (SC) 698 [G.E. 79, 685 (1967)]

Dithioacetylacetonatoiron complexes (SC) 262 [G.E. 79, 273 (1967)]

Dithiophosphonic ester halides, Simple preparation of ~ and of the novel 1-thia-3-aza-2,4-diphospha^{v}cyclobutane *P,P*-disulfide system (SC) 260 [G.E. 79, 243 (1967)]

Dithiopyrophosphates, Synthesis of asymmetric *O,O,O,O*-tetraalkyl ~ (SC) 863 [G.E. 79, 859 (1967)]

Dithiourethanes, Quadrant rule for the n→π* Cotton effect of ~ from optically active amines (SC) 704 [G.E. 79, 721 (1967)]

Di-(2,2,2-trichlorethyl)phosphorochloridate, Synthesis of nucleoside diphosphates by means of ~ (SC) 362 [G.E. 79, 317 (1967)]

cis-1,2-Divinylcyclobutane, Catalysed synthesis of ~ (SC) 800 [G.E. 79, 813 (1967)]

Catalysed Cope rearrangement of ~ (SC) 800 [G.E. 79, 814 (1967)]

Documentation, Topological approach to the problem of ring structures (FP) 723 [G.E. 79, 802 (1967)]

Donor-acceptor complexes, Spectroscopic and electrical properties of polymeric ~ (CR) 268 [G.E. 79, 278 (1967)]

Side-chain interactions in polypeptides. Experiments with ~ (CR) 469 [G.E. 79, 425 (1967)]

Drug research, Fortschritte der Arzneimittelforschung (Progress in ~) (Book Review) 381

Dytiscus marginalis, Identification of the subsidiary steroids from the prothoracic protective gland system of ~ (SC) 881 [G.E. 79, 902 (1967)]

EDMAN degradation, of peptides (LA) 577

Electrochemical enrichment, of isotopes (FP) 757 [G.E. 79, 734 (1967)]

Electrochemical oxidation, of formic acid and carbon monoxide on platinum catalysts in acid electrolytes (CR) 471 [G.E. 79, 477 (1967)]

Electrochemistry, Electrochemical reactions at electrodes of solid hydrocarbons (CR) 984 [G. E. 79, 1005 (1967)]

Electrocyclic reactions, Theory of ring-opening reactions (CR) 813 [G.E. 79, 826 (1967)]

Electrolytes, Sulfur and selenium adsorbate on platinum electrodes in acid and alkaline ~ (SC) 884 [G.E. 79, 903 (1967)]

Electrolysis, Isotope concentration by countercurrent ~ at high electrolyte concentrations with the aid of separating columns having capillary properties (CR) 965 [G. E. 79, 985 (1967)]

Electron diffraction, Comparative determination of the structure of gaseous molecules by ~ (CR) 1005 [G. E. 79, 1025 (1967)]

Electron-pair repulsions, and molecular shape (FP) 819 [G.E. 79, 885 (1967)]

Electron paramagnetic resonance, Introduction to ~ (Book Review) 579

Electrophilic substitution, of heteroaromatic compounds with six-membered rings (FP) 608 [G.E. 79, 629 (1967)]

Electrophoretic painting, on the rotating disk electrode (CR) 964 [G. E. 79, 984 (1967)]

Elementary analysis, Zahlentafeln zur Elementaranalyse (Tables for ~) (Book Review) 275

Elimination, in cyclic *cis-trans*-isomers (FP) 534 [G.E. 79, 555 (1967)]

Elimination catalyst, Stereoselective synthesis of 1-butene with lithium sulfate as ~ (SC) 170 [G.E. 79, 187 (1967)]

Enamides, Preparation and reactions of ~ (CR) 377 [G.E. 79, 385 (1967)]

Enamines, see Alkenylamines

Encyclopedia, Ullmanns Encyklopädie der technischen Chemie (Ullmann's ~ of industrial chemistry) (Book Review) 719

~ of chemical technology (Book Review) 720

Chemie-Lexikon (~ of chemistry) (Book Review) 893

Endrin, Metabolic fate of ~ (CR) 977 [G. E. 79, 997 (1967)]

Enol ethers, Stereochemistry of the cycloaddition of sulfonyl isocyanates and *N*-sulfinylsulfonamides to ~ (SC) 951 [G.E. 79, 936 (1967)]

Enthalpy, and entropy changes on formation of complexes (CR) 265 [G.E. 79, 276 (1967)]

Entropy, Enthalpy and ~ changes on formation of complexes (CR) 265 [G.E. 79, 276 (1967)]

Enzymatic reactions, Nucleophilic ~ of acetyl-CoA (CR) 377 [G.E. 79, 383 (1967)]

Enzymes, Structure and mechanism of action of the active center of yeast pyruvate decarboxylase (FP) 1024 [G. E. 79, 1050 (1967)]

Quaternary structure and activity of ~ (alcohol dehydrogenase, glut amic dehydrogenase, catalase) (CR)460 [G.E. 79, 423 (1967)]

Regulation of the specificity of ~ (LA) 274

Enzyme-bound coenzyme A (LA) 643

Epoxides, Ring expansion in 1-(isopropenyl)-cycloalkanol ~ (LA) 889

ESR spectroscopy, Spin density distribution in 2,4,6-triphenylphenoxyl (FP) 34 [G.E. 79, 69 (1967)]

ESR spectrum of a non-degenerate state of the benzene radical anion (SC) 360 [G.E. 79, 318 (1967)]

Determination, by ~ of the constitution of the phosphorus radicals formed on oxidation of phosphorins (SC) 711 [G.E. 79, 725 (1967)]

UV and ~ of *p*-bis(trimethylsilyl)- and *p*-dialkylbenzenes (SC) 941 [G. E. 79, 933 (1967)]

~ of *N*-oxides of imidazolyls (SC) 947 [G. E. 79, 941 (1967)]

Detection of aryl(vinyl)nitroxides by ~ (SC) 1080 [G. E. 79, 1070 (1967)]

Detection of mesomeric limiting structures by ~ (CR) 639 [G.E. 79, 625 (1967)]

~ studies of bridged annulenes (CR) 715 [G.E. 79, 693 (1967)]

~ studies of nitroxide radicals that are capable of mesomerism (CR) 810 [G.E. 79, 825 (1967)]

Essences, The gas-chromatographic and spectrophotometric investigation of ~ (CR) 968 [G. E. 79, 988 (1967)]

Ethanes, The torsional vibrations of the chlorinated ~ (LA) 1089

Ethers, Formation of C–C-bonds with the aid of α-halogeno ~, sulfides, and amines (FP) 335 [G.E. 79, 358 (1967)]

Ethoxycarbonyliodocarbene, Ethyl diazoiodoacetate and its decomposition to ~ (SC) 74 [G.E. 79, 50 (1967)]

Ethylene, Active species in homogeneous Ziegler-Natta catalysts for the polymerization of ~ (FP) 790 [G.E. 79, 764 (1967)]

Excitation functions, Determination of some ~ for deuteron reactions with ^{141}Pr (CR) 981 [G. E. 79, 1001 (1967)]

Exopeptidase, Aminopeptidase B (LA) 186

Experimental organic chemistry, Organisch-chemische Experimentierkunst (~) (Book Review) 380

~ (Book Review) 721

Extraction, Liquid-liquid ~ of tetravalent and hexavalent actinide nitrates by a long-chain trialkylmethylammonium nitrate (CR) 979 [G. E. 79, 999 (1967)]

Extraction chromatography, Separation of fission products by ~ (CR) 269 [G.E. 79, 247 (1967)]

FARADAY effect, Apparatus for measuring the ~ in the UV and the visible regions (CR) 1003 [G. E. 79, 1023 (1967)]

Fatty acids, Decontamination of radioactive waste water by salts of ~ (CR) 269 [G.E. 79, 247 (1967)]

Ferredoxin, Apo-~ has been reactivated (LA) 274

Field electron microscope, Measurement of heats of adsorption on the surfaces of single crystals with the ~ (CR) 966 [G. E. 79, 987 (1967)]

Fission products, Separation of ~ by extraction chromatography (CR) 269 [G.E. 79, 247 (1967)]

Radiochemical determination of the activities of ~ in irradiated fuel elements (CR) 270 [G.E. 79, 248 (1967)]

Flames, Lean $H_2/N_2/O_2$ ~ containing alkali metal (LA) 100

Flotation, Ion ~ as a separation process in toxicology (CR) 373 [G.E. 79, 324 (1967)]

Flow behavior, Investigations on the ~ of polymers in relation to their molecular structure (CR) 466 [G.E. 79, 420 (1967)]

Flow birefringence, Examples of the ~ of viscoelastic systems (CR) 466 [G.E. 79, 419 (1967)]

Fluorimetry, Fluorimetrie (~) (Book Review) 892

Fluorination, Preparation of dichlorohexafluoropropane by ~ of 1,2-dichloropropane (SC) 627 [G.E. 79, 622 (1967)]

Fluorine, Aromatic ~ as a chemical label for detecting reaction mechanism (FP) 596 [G.E. 79, 636 (1967)]

Fluoroalkylalanines, General method for the preparation of β-per-~ (SC) 807 [G.E. 79, 822 (1967)]

Fluorocarbonyl pseudohalides, Preparation of carbonyl and ~ in molten salts (SC) 871 [G.E. 79, 860 (1967)]

Fluoro-coenzyme Q_1, (Fluoroubiquinone-5) (SC) 957 [G. E. 79, 979 (1967)]

Fluoro compounds, Chemistry of perfluorinated aromatic mono- and dicarboxylic acids (CR) 994 [G. E. 79, 1014 (1967)]

Fluorocyclohexenes, Poly-~ (LA) 379

Fluorocyclopropanes, Preparation of ~ by reductive dechlorination of chloro-~ (SC) 629 [G.E. 79, 617 (1967)]

Fluorophosphine, Dimethyl-~ (SC) 708 [G.E. 79, 686 (1967)]

Fluorothiocarbonyl isothiocyanate (SC) 940 [G. E. 79, 987 (1967)]

Fluoroubiquinone-5, Fluoro-coenzyme Q_1 (~) (SC) 957 [G. E. 79, 979 (1967)]

Food chemistry, Handbuch der Lebensmittelchemie (Manual of ~) (Book Review) 189

Foodstuffs, Use of viridic acid as coloring matter for ~ (CR) 885 [G.E. 79, 872 (1967)]

Formaldehyde, Isolation and characterization of cyclic oligomers of ~ (CR) 464 [G.E. 79, 416 (1967)]

Reactions of heterocyclic amines with ~ (CR) 967 [G. E. 79, 987 (1967)]

States responsible for the photochemical decomposition of ~ (LA) 274

Formamide, Carbonylation of metal amides to metal ~s (SC) 357 [G.E. 79, 312 (1967)]

H/D Exchange in *N,N*-dimethyl-~ acetals and orthoformic esters (SC) 875 [G.E. 79, 869 (1967)]

~s Separation and equilibration of conformeric ~ (CR) 984 [G.E. 79, 1004 (1967)]

Formates, Reaction of isocyanato- and isothiocyanato-~ with activated phenols (SC) 455 [G.E. 79, 474 (1967)]

Formic acid, Electrochemical oxidation of ~ and carbon monoxide on platinum catalysts in acid electrolytes (CR) 471 [G.E. 79, 477 (1967)]

Formimidates, Simple synthesis of alkyl ~ (SC) 566 [G.E. 79, 531 (1967)]

Formylalkyl group, Simple method for introduction of a ~ into quinones (SC) 174 [G.E. 79, 150 (1967)]

Fossil plants, Organic compounds in ~ (Equisetum; horsetails) (SC) 1085 [G. E. 79, 1107 (1967)]

Fragmentation, Heterolytic ~. A class of organic reactions (FP) 1 [G.E. 79, 1 (1967)]

New ~ reaction of 20-chloro-16β-hydroxy steroids (SC) 631 [G.E. 79, 619 (1967)]

Photo-~ of oxaziranes (SC) 634 [G.E. 79, 648 (1967)]

New ~ in the adamantane series (SC) 864 [G.E. 79, 860 (1967)]

~ of bicyclic keto-*p*-toluenesulfonates (CR) 980 [G. E. 79, 1000 (1967)]

Novel ~ of cyclic α,β-unsaturated carbonyl systems (LA) 890

Friedel-Crafts acylation, Synthesis of 2-alkyl-1,3-cycloalkanediones by ~ (SC) 80 [G.E. 79, 97 (1967)]

Fructose, Thermodynamic data on the "mutarotation" of ~ (LA) 889

Fructose-1,6-diphosphatase, Desensitization of ~ (LA) 99

Fuel cells, Developments of ~ (CR) 714 [G.E. 79, 726 (1967)]

Fulminic acid, 1,3-Dipolar cycloadditions of ~ (SC) 456 [G.E. 79, 471 (1967)]

Functional groups, Quantitative Bestimmung organischer funktioneller Gruppen (Quantitative determination of organic ~) (Book Review) 892

3-Furanone, 4-Hydroxy-2,3-dimethyl-2,3-dihydro-~ (LA) 187

Furylbenzoquinones, and thienylbenzoquinones (LA) 378

β-GALACTOSIDASE repressor (LA) 717

Gallium arsenide, Epitaxy of ~ with ~ from organogallium compounds (CR) 987 [G. E. 79, 1007 (1967)]

Gallium compounds, Synthesis and structure of dialkylgallium fluorides (SC) 806 [G.E. 79, 821 (1967)]

Diethylmetal thiocyanates of aluminum, gallium, and indium (SC) 947 [G. E. 79, 942 (1967)]

Diethylgallium azide (LA) 718

Gallium halides, The reaction of alkyl- ~ with lower aliphatic alcohols (CR) 986 [G. E. 79, 1005 (1967)]

Gamma-resonance spectroscopy, Chemical ~ (FP) 830 [G.E. 79, 844 (1967)]

Garnet, New compounds with apatite or ~ structure (CR) 573 [G.E. 79, 584 (1967)]

Gas chromatography, Separation of metal chlorides by ~ (CR) 376 [G.E. 79, 385 (1967)]

Capillary columns of high resolution in direct combination with a mass spectrometer (LA) 473

Gas reaction rates, Theory of elementary ~ (Book Review) 646

Gattermann aldehyde syntheses, with *s*-triazine in place of hydrogen cyanide (SC) 940 [G. E. 79, 978 (1967)]

Gel permeation chromatography, Efficiency of ~ (CR) 464 [G.E. 79, 420 (1967)]

The separation efficiency in ~ (CR) 973 [G. E. 79, 995 (1967)]

Gene map, The collinearity of the amino-acid sequence and the ~ of the structural gene (LA) 1089

Germacranolides, Sesquiterpenoids with ten-membered rings (CR) 94 [G.E. 79, 64 (1967)]

Germane, Reactions of trichloro-~ with ketones and alcohols (SC) 628 [G.E. 79, 617 (1967)]

Germanium compounds, Tetrasilacyclopentanes containing an additional hetero atom in the ring (LA) 473

Germanium radicals, Addition of R_3Ge and R_3Si radicals to multiple bonds (SC) 876 [G.E. 79, 870 (1967)]

Germylsilylstannylamine, Synthesis of ~ (SC) 446 [G.E. 79, 410 (1967)]

Gesellschaft Deutscher Chemiker, General meeting of the ~ 1967 (CR) 963 [G. E. 79, 983 (1967)]

Glass, Glas im Laboratorium (~ in the laboratory) (Book Review) 1090

Glauconite, Mössbauer spectrum of the iron in ~ (SC) 561 [G.E. 79, 581 (1967)]

β-Glucosidase, Isolation and properties of a crystalline ~ from *Aspergillus wentii* (CR) 981 [G. E. 79, 1001 (1967)]

D-Glucose, Synthesis of D-gulose from ~ (SC) 177 [G.E. 79, 151 (1967)]

~ und verwandte Verbindungen in Medizin und Biologie (D-Glucose and related compounds in medicine and biology) (Book Review) 816

Glutamic dehydrogenase, Quaternary structure and activity of enzymes (alcohol dehydrogenase, ~, catalase) (CR) 460 [G.E. 79, 423 (1967)]

Glycine, Oxidative decarboxylation of ~ (LA) 274

Glycoproteins, Their composition, structure, and function (Book Review) 1009

Gold complexes, Cyclopentadienylgold(I) and cyclopentadienyl(triphenylphosphine)gold(I) (SC) 862 [G.E. 79, 859 (1967)]

A covalent bond between Pt or Au and Si, Sn, or Pb (LA) 1089

Gold trifluoride, Crystal structure of ~ (LA) 813

Gomberg reaction, Mechanism of the ~ and of phenylation by *N*-nitrosoacetanilide (CR) 713 [G.E. 79, 693 (1967)]

Guanidines, Rearrangement of electronegatively substituted ~ to semicarbazones (SC) 704 [G.E. 79, 688 (1967)]

Guanosine triphosphate, Stoichiometry of ~ cleavage during protein biosynthesis (LA) 576

Guerbet reaction, Mechanism of the ~ (LA) 716

D-Gulose, Synthesis of ~ from D-glucose (SC) 177 [G.E. 79, 151 (1967)]

HAFNIUM, Separation of zirconium and ~ (LA) 272

Halides, Relations between structure and thermodynamic and chemical properties of molten ~ (CR) 641 [G.E. 79, 653 (1967)]

Halogen azides, Reactions of ~ (FP) 240 [G.E. 79, 253 (1967)]

Halogen compounds, Reactions of positive organic ~ with phosphorus(III) derivatives (CR) 265 [G.E. 79, 276 (1967)]

Halogen lamps, Chemistry of the incandescent lamp (FP) 68 [G.E. 79, 43 (1967)]

Halogenoamines, Preparation and properties of inorganic ~ (CR) 1087 [G. E. 79, 1073 (1967)]

Halogenoacids, New synthesis of esters of ~ (LA) 642

α-Halogeno amines, Formation of C–C-bonds with the aid of α-halogeno ethers, sulfides, and ~ (FP) 335 [G.E. 79, 358 (1967)]

(Halogenocarbonyl)sulfur pseudohalides (SC) 705 [G.E. 79, 687 (1967)]

α-Halogeno ethers, Formation of C–C-bonds with the aid of ~, α-halogeno sulfides, and amines (FP) 335 [G.E. 79, 358 (1967)]

α-Halogenoorganolithium compounds, Chemistry of stable ~ and the mechanism of carbenoid reactions (FP) 41 [G.E. 79, 15 (1967)]

β-Halogeno-α-phenylalkanes, Cleavage of ~ by sodium hydrazide (SC) 170 [G.E. 79, 147 (1967)]

α-Halogeno sulfides, Formation of C–C-bonds with the aid of α-halogeno ethers, ~, and amines (FP) 335 [G.E. 79, 358 (1967)]

Hammett constants, Linear relation between chemical shifts of the ^{31}P resonance and ~ (SC) 945 [G. E. 79, 946 (1967)]

Handbook, Handbuch der physiologisch- und pathologisch-chemischen Analyse, für Ärzte, Biologen und Chemiker (~ of physiological and pathological chemical analysis for physicians, biologists, and chemists) (Book Review) 893

Heats of adsorption, Measurement of ~ on the surfaces of single crystals with the field electron microscope (CR) 966 [G. E. 79, 987 (1967)]

Hedvall effect, Kinetics of the oxidation of a silver-cadmium alloy containing 51 atom-% of Cd. A contribution to the ~ (CR) 972 [G. E. 79, 992 (1967)]

Heptachlor, Metabolic fate of ~ (CR) 977 [G. E. 79, 997 (1967)]

Heteroaromatic compounds, Electrophilic substitution of ~ with six-membered rings (FP) 608 [G.E. 79, 629 (1967)]

Heteroaromatic substances, Hydration of C=N bonds in ~ (FP) 919 [G. E. 79, 913 (1967)]

Heterocycles, Syntheses with ketones, sulfur, and ammonia or amines at room temperature (FP) 907 [G. E. 79, 953 (1967)]

Hydration of C=N bonds in aromatic ~ (FP) 919 [G. E. 79, 913 (1967)]

Stable 1,4-dipoles from ketene acetals and carbon disulfide and their use for synthesis of ~ (SC) 366 [G.E. 79, 382 (1967)]

Synthesis of s-triazolium cations by reaction of alkoxydiazenium salts with nitrogen ~ (SC) 699 [G.E. 79, 682 (1967)]

Preparation of ~ by treatment of amino acid with trifluoroacetic anhydride (CR) 184 [G.E. 79, 155 (1967)]

Valence tautomerism in ~ (CR) 812 [G.E. 79, 827 (1967)]

Reactions of heterocyclic amines with formaldehyde (CR) 967 [G. E. 79, 987 (1967)]

N- and O-heterocyclic spiro compounds (CR) 995 [G. E. 79, 1015 (1967)]

Novel phosphonitrile ~ (LA) 188

Heterocyclic chemistry, Symposium on ~ (CR) 182 [G.E. 79, 153 (1967]

Advances in ~ (Book Review) 191

Heterolytic fragmentation, a class of organic reactions (FP) 1 [G.E. 79, 1 (1967)]

Hexaazidophosphates, Preparation of ~ (SC) 637 [G.E. 79, 651 (1967)]

Hexachlorodisilazane, Reactions of ~ (SC) 447 [G.E. 79, 409 (1967)]

Hexacyanobenzene, Semiconductor properties of ~ (CR) 267 [G.E. 79, 278 (1967)]

The structure of ~ (CR) 982 [G.E. 79, 1002 (1967)]

n-Hexadecane, 1-Hexadecene, an intermediate in the microbial oxidation of ~ in vivo and in vitro (SC) 359 [G.E. 79, 314 (1967)]

1-Hexadecene, an intermediate in the microbial oxidation of n-hexadecane *in vivo* and *in vitro* (SC) 359 [G.E. 79, 314 (1967)]

Hexafluoropropane, Preparation of dichloro ~ by fluorination of 1,2-dichloropropane (SC) 627 [G.E. 79, 622 (1967)]

Hexakis(trimethylsilyl)-2,4-diamino-1,3,2,4-diazadiboretidine, Crystal and molecular structure of ~ (CR) 975 [G. E. 79, 995 (1967)]

Hexamethyl(Dewar benzene), (Hexamethylbicyclo[2.2.0]hexa-2,5-diene) (FP) 518 [G.E. 79, 566 (1967)]

Tetracarbonyl(hexamethylbicyclo-[2.2.0]hexadiene)-chromium(0) (SC) 634 [G.E. 79, 623 (1967)]

Hexamethyphosphoramide (FP) 1046 [G. E. 79, 1029 (1967)]

Hexamethylprismane, Synthesis of ~ (SC) 78 [G.E. 79, 54 (1967)]

1,2,3,6,7,8-Hexathiecin, New sulfur-containing cyclic compounds (SC) 703 [G.E. 79, 690 (1967)]

High pressure research. Advances in ~ (Book Review) 645

High-temperature initiators, New ~ (SC) 949 [G. E. 79, 939 (1967)]

Histochemistry, Histochemical detection of thiol groups (LA) 187

History of chemistry, Geschichte der Chemie (~) (Book Review) 578

Geschichte der Chemie seit dem Wiederaufleben der Wissenschaften bis an das Ende des 18. Jahrhunderts (~ from the scientific renaissance to the end of the 18th century) (Book Review) 578

Homoallyl compounds, Rearrangements of cyclic ~ (CR) 972 [G. E. 79, 992 (1967)]

Homoallyl systems, Neighboring-group effects and rearrangements in reactions of cyclopropylmethyl, cyclobutyl, and ~ (FP) 666 [G.E. 79, 709 (1967)]

Hormones, Structure of the juvenile ~ (SC) 179 [G.E. 79, 190 (1967)]

Hückel molecular orbitals (Book Review) 189

Hydration, of C=N bonds in heteroaromatic substances (FP) 919 [G. E. 79, 913 (1967)]

Hydrazide, Cleavage of β-halogeno-α-phenylalkanes by sodium ~ (SC) 170 [G.E. 79, 147 (1967)]

Hydrazines, Two new syntheses of aryl-~ (SC) 84 [G.E. 79, 57 (1967)]

Hydrazone, Formation and degradation of 1-phenylazo 1-hydroperoxides derived from carbohydrates (SC) 168 [G.E. 79, 145 (1967)]

Hydrazonic acid azides, Syntheses and rearrangements of ~ (LA) 890

Hydrazyls, Stable triaryl-~ containing no nitro groups (CR) 965 [G. E. 79, 985 (1967)]

Hydrides, Organometallic and hydrogen compounds of some transition metals (CR) 571 [G.E. 79, 537 (1967)]

Hydridopentacyanoiridate complexes, Synthesis of ~ (SC) 881 [G.E. 79, 902 (1967)]

Hydroaromatic compounds, Cycli-alkylation with 1,4-dihalo compounds as a convenient way of preparing polycyclic ~ (CR) 973 [G. E. 79, 993 (1967)]

Hydrocarbons, Valence isomerizations of ~ containing three-membered rings (SC) 694 [G.E. 79, 680 (1967)]

Electrochemical reactions at electrodes of solid ~ (CR) 984 [G. E. 79, 1005 (1967)]

The carbonylation of aliphatic ~ in liquid hydrogen fluoride (LA) 1007

Hydrogen, Effect of pressure on the equilibrium between ~ and solvated electrons in potassium amide-ammonia solutions (SC) 1076 [G. E. 79, 1064 (1967)]

Hydrogen bonds, Detection of ~ between inosine and other nucleosides by NMR spectroscopy (SC) 180 [G.E. 79, 190 (1967)]

Transannular 1,4-~ in thiepanols (SC) 872 [G.E. 79, 863 (1967)]

NH···S ~ and the structure of the anions in ammonium diamidothiophosphate and in diammonium amidothiophosphate (SC) 960 [G. E. 79, 981 (1967)]

Intramolecular ~ in nitrosophenols (CR) 714 [G.E. 79, 692 (1967)]

Hydrogen bromide, Experiments on the scattering of molecular beams for the study of reactions of potassium with methyl iodide, ~, and bromine (CR) 887 [G.E. 79, 907 (1967)]

Hydrogenation, Katalytische Hydrierungen im Organisch-Chemischen Laboratorium (Catalytic hydrogenation in the organic chemistry laboratory) (Book Review) 103

Catalytic ~ (Techniques and applications in organic synthesis) (Book Review) 192

Hydrogenation catalysts, Effective ~ obtained by reduction of Pt(IV) (LA) 643

The stereoselective efficiency of ~ (LA) 1008

Hydrogen fluoride, The carbonylation of aliphatic hydrocarbons in liquid ~ (LA) 1007

Hydrogen halide acceptor, 1,5-Diazabicyclo[5.4.0]undec-5-ene, a new ~ (SC) 76 [G.E. 79, 53 (1967)]

Hydrogen isocyanide, First carbonylmetal complexes of ~ (LA) 716

Hydrogen transfer reactions, Sigma-bonded organochromium compounds, ~ (FP) 435 [G.E. 79, 401 (1967)]

Hydroperoxides, Formation and degradation of 1-phenylaza ~ derived from carbohydrates (SC) 168 [G.E. 79, 145 (1967)]

Hydrophobic interactions (FP) 195 [G.E. 79, 260 (1967)]

3-Hydroxyisoxazoles, Formation of 2-oxazolones by photorearrangement of ~ (LA) 888

Hydroxylamines, *N,N*-Disubstituted derivatives of *O*-chloroformyl-~ as reagents for peptide synthesis (SC) 570 [G.E. 79, 532 (1967)]

2-(*o*-Hydroxyphenyl)benzazole, Boron chelate compounds in the ~ series (SC) 1082 [G. E. 79, 1072 (1967)]

5'-Hydroxypolynucleotide kinase (LA) 99 [G.E. 79, 66 (1967)]

20α-Hydroxy-4,6-pregnadien-3-one, Identification of the subsidiary steroids from the prothoracic protective gland system of *Dytiscus marginalis* (SC) 881 [G.E. 79, 902 (1967)]

3β-Hydroxy-5α-pregnan-16-one, Photolysis of ~ (SC) 1074 [G. E. 79, 1066 (1967)]

20α-Hydroxy-4-pregnen-3-one, Identification of the subsidiary steroids from the prothoracic protective gland system of *Dytiscus marginalis* (SC) 881 [G.E. 79, 902 (1967)]

Hypophosphonic acid, Dipotassium diphenylhypophosphonate and diphenyltetrathiohypophosphonate (SC) 883 [G.E. 79, 903 (1967)]

ILYBIUS, Testosterone as protective agent of the water beetle ~ (SC) 558 [G.E. 79, 579 (1967)]

Imidazoles, Condensed ~ from *o*-diamines and isatoic anhydrides (SC) 878 [G.E. 79, 901 (1967)]

Imidazolyls, *N*-Oxides of ~ (SC) 947 [G. E. 79, 941 (1967)]

Imidazolylsulfanes, Preparation of di-~ and di(aziridinyl)sulfanes (SC) 703 [G.E. 79, 690 (1967)]

Imides, Organic syntheses with ~ of sulfur dioxide (FP) 149 [G.E. 79, 109 (1967)]

Imidobissulfamide, Derivatives of ~, (SC) 952 [G. E. 79, 937 (1967)]

Imidophosphinatotin halides (SC) 252 [G.E. 79, 242 (1967)]

Imines, "Dimerization" of organic nitrogen compounds via copper-containing intermediates (SC) 633 [G.E. 79, 620 (1967)]

α-Iminoalkyl isocyanates (SC) 864 [G.E. 79, 897 (1967)]

2-Imino-1,3-oxathioles (SC) 455 [G.E. 79, 470 (1967)]

Iminopyrimidines, Syntheses and reactions of 4-acylimino-5-acyloxy-~ (SC) 259 [G.E. 79, 234 (1967)]

Iminouracils, 1,3-Disubstituted 5-acyloxyimino-4-alkyl-~ as new "activated esters" (SC) 258 [G.E. 79, 234 (1967)]

Immunopathology (Book Review) 474

Inactivation repression (LA) 716

Incandescent lamp, Chemistry of the ~ (FP) 68 [G.E. 79, 43 (1967)]

N-1-Indanylideneaniline, Synthesis and reactions of *m*-chloro-~ (SC) 248 [G.E. 79, 236 (1967)]

Indium compounds, Diethylmetal thiocyanates of aluminum, gallium, and indium (SC) 947 [G.E. 79, 942 (1967)]

Indium phosphide, Synthesis of ~ from indium and phosphorus pentoxide (SC) 177 [G.E. 79, 189 (1967)]

Indole, 2-Aminoethylation of ~ and of 2-methylindole (SC) 178 [G.E. 79, 188 (1967)]

Diels-Alder-type cycloadditions with ~s (CR) 964 [G. E. 79, 984 (1967)]

Investigations of syntheses in the ~ series (CR) 1003 [G. E. 79, 1023 (1967)]

Indolenine, New ~ synthesis (SC) 453 [G.E. 79, 415 (1967)]

Industrial chemicals (Book Review) 192

Initiators, New high-temperature ~ (SC) 949 [G. E. 79, 939 (1967)]

Inorganic chemistry, Physikalische Anorganische Chemie (Physical ~) (Book Review) 276

Technique of ~ (Book Review) 1092

Modern Approach to ~ (Book Review) 1090

Inosine, Detection of hydrogen bridges between ~ and other nucleosides by NMR spectroscopy (SC) 180 [G.E. 79, 190 (1967)]

Insulin, Synthesis of ~ by the Merrifield method (CR) 460 [G.E. 79, 424 (1967)]

Iodine lamp, Chemistry of the Incandescent Lamp (FP) 68 [G.E. 79, 43 (1967)]

Iodine-tellurium, Halogen-deficient phase in the system ~ (SC) 706 [G.E. 79, 688 (1967)]

Ion exchanger, Dinonylnaphthalenesulfonic acid has been used as a liquid ~ (LA) 1088

Ion-exchange resins, Chromatographic separation of metal ions with anomalous exchange properties on chelating ~ (CR) 373 [G.E. 79, 324 (1967)]

Properties and application of amphoteric ~ based on aminopropionic acid (CR) 374 [G.E. 79, 324 (1967)]

Ion flotation, as a separation process in toxicology (CR) 373 [G.E. 79, 324 (1967)]

Ionization energies, of silyl- and alkylethylenes (SC) 1085 [G. E. 79, 1106 (1967)]

Ions, Nonclassical ~ (Book Review) 895

Iridate, Synthesis of hydridopentacyano-~ complexes (SC) 881 [G.E. 79, 902 (1967)]

Iridium amine complexes, Exchange reactions and the annealing of nuclear recoil defects in crystalline ~ (CR) 993 [G. E. 79, 1013 (1967)]

Iridium compounds, Monomeric and dimeric dicyclopentadienylthorium and -iridium (LA) 188

Schiff bases of acetylacetone form chelates with Ir(I) and Rh(I) (LA) 814

Iron, Adsorption of nitrogen on ~ (SC) 882 [G.E. 79, 905 (1967)]

Gmelins Handbuch der anorganischen Chemie (Gmelin's handbook of inorganic chemistry) (Book Review) 100

Iron complexes, Preparation of derivatives of bicyclo[4.2.2]deca-2,4,7,9-tetraene from tricarbonylcyclooctatetraeneiron (SC) 79 [G.E. 79, 55 (1967)]

Dithioacetylacetonato-~ (SC) 262 [G.E. 79, 273 (1967)]

ESR studies of model complexes for non-heme iron proteins (SC) 263 [G.E. 79, 274 (1967)]

Iron compounds, Mössbauer spectrum of the iron in glauconite (SC) 561 [G.E. 79, 581 (1967)]

Crystal and molecular structures of azulenediiron pentacarbonyl (LA) 813

Iron foundry, Handbuch für das Eisenhüttenlaboratorium (Handbook for the ~ laboratory) (Book Review) 473

Iron-phthalocyanine, Six oxidation states of the ~ complex (SC) 358 [G.E. 79, 313 (1967)]

Isatoic anhydrides, Condensed imidazoles from *o*-diamines and ~ (SC) 878 [G.E. 79, 901 (1967)]

Isocyanates, Preparation of ~ from carbamates by reaction with phosgene (SC) 636 [G.E. 79, 651 (1967)]

α-Iminoalkyl ~ (SC) 864 [G.E. 79, 897 (1967)]

Cycloadditions of ~ (CR) 1000 [G.E. 79, 1020 (1967)]

Isocyanato-formates, Reaction of ~ and isothiocyanato-formates with activated phenols (SC) 455 [G.E. 79, 474 (1967)]

Isocyanides, Syntheses of ~ dihalides (FP) 649 [G.E. 79, 663 (1967)]

Acid-catalysed oxidation of ~ with dimethyl sulfoxide (SC) 168 [G.E. 79, 145 (1967)]

Addition of ~ to transition metal carbene complexes (SC) 879 [G.E. 79, 900 (1967)]

First carbonylmetal complexes of hydrogen ~ (LA) 716

Isoindolinium iodide, Mechanism of the Wittig rearrangement of *N*-methyl-*N*-phenyl-~ (SC) 559 [G.E. 79, 574 (1967)]

Isomer distribution, in electrophilic aromatic substitutions on neopentylbenzene (LA) 379

Isomerism, of spirans (CR) 184 [G.E. 79, 155 (1967)]

~ in metal complexes (LA) 642

Isoprene, and organolithium compounds in hydrocarbons and ethers (CR) 463 [G.E. 79, 422 (1967)]

Isothiazoles, New synthesis of ~ (SC) 83 [G.E. 79, 56 (1967)]

Isothiocyanate, Preparation of phosphoryl difluoride ~ and phosphoryl fluoride di-~ (SC) 90 [G.E. 79, 61 (1967)]

Synthesis of thiophosphoryl difluoride ~ and thiophosphoryl fluoride di-~ (SC) 90 [G.E. 79, 61 (1967)]

New synthesis of aliphatic ~s (SC)174 [G.E. 79, 151 (1967)]

Carbamoyl ~ (SC) 262 [G.E. 79, 272 (1967)]

Fluorothiocarbonyl ~ (SC) 940 [G. E. 79, 978 (1967)]

p-Isothiocyanatobenzenesulfonyl isocyanate, a bifunctional compound with selective reactivity (SC) 708 [G.E. 79, 726 (1967)]

Isothiocyanatoformates, Reaction of isocyanato- and ~ with activated phenols (SC) 455 [G.E. 79, 474 (1967)]

Isotopes, Half-lives of the ^{129}Sn nuclear isomers (LA) 187

Isotopic composition of lead in archaeological objects and lead ores (LA) 379

Radioaktive Isotope in der organischen Chemie und Biochemie (Radioactive ~ in organic chemistry and biochemistry) (Book Review) 892

Isotope concentration, by countercurrent electrolysis at high electrolyte concentrations with the aid of separating columns having capillary properties (CR) 965 [G. E. 79, 985 (1967)]

Isotope exchange, ^{18}O-~ between TcO_4^- and ReO_4^- ions and water (CR) 1003 [G. E. 79, 1023 (1967)]

Isotope fractionation, Further investigations on the ~ of alkali metal ions by filtration through biological membranes (CR) 1005 [G. E. 79, 1025 (1967)]

Isotope frequency, Radiometric ~ analysis of ^{233}U/^{235}U mixtures (CR) 270 [G.E. 79, 248 (1967)]

Isotope separation, Separation of the isotopes of uranium by the separation nozzle process (FP) 507 [German version: Chemie-Ing.-Techn. 39, 80 (1967)]

Electrochemical processes for the enrichment of isotopes (FP) 757 [G.E. 79, 734 (1967)]

Isotopic compounds, Measurement of vapor-pressure differences for ~ (CR) 713 [G.E. 79, 728 (1967)]

Isoureas, Alkylations with *O*-alkyl-*N*,*N*'-dicyclohexyl-~ (CR) 1001 [G. E. 79, 1021 (1967)]

JUVENILE hormone, Structure of ~ (SC) 179 [G.E. 79, 190 (1967)]

KETENE, Continuous process for the preparation of diphenyl-~ (SC) 631 [G.E. 79, 622 (1967)]

Ketene acetals, Stable 1,4-dipoles from ~ and carbon disulfide and their use for synthesis of heterocycles (SC) 366 [G.E. 79, 382 (1967)]

Stable 1,4-dipolar compounds from ~ and methylenemalononitriles (SC) 453 [G.E. 79, 473 (1967)]

Ketimines, Action of carbon disulfide and sulfur on enamines, ~, and CH acids (FP) 294 [G.E. 79, 298 (1967)]

Photoreduction of ketones and ~ (CR) 468 [G.E. 79, 425 (1967)]

Keto carboxylic acids, Preparation of 2-alkyl-1,3-cycloalkanediones by cyclization of γ- and δ-~ (SC) 371 [G.E. 79, 378 (1967)]

Ketones, Syntheses with ~, sulfur, and ammonia or amines at room temperature (FP) 907 [G. E. 79, 953 (1967)]

Reactions of trichlorogermane with ~ and alcohols (SC) 628 [G.E. 79, 617 (1967)]

Reaction of phosphorylides with 2-chlorovinyl ~ (SC) 877 [G.E. 79, 899 (1967)]

Separation of selenium with the aid of saturated aliphatic and aromatic mono-~ (CR) 374 [G.E. 79, 325 (1967)]

Photoreduction of ~ and ketimines (CR) 468 [G.E. 79, 425 (1967)]

Reactions of aryl trifluoromethyl ~ with trialkylphosphines (LA) 576

"Birdcage ~" (LA) 890

Novel fragmentation of cyclic α,β-unsaturated carbonyl systems (LA) 890

New condensation reaction of α,β-unsaturated cyclic ~ with ammonium thiocyanate (LA) 891

New photochemical rearrangement (LA) 891

cis-(2-Chlorovinyl) ~ (LA) 891

Ketoximes, Cycloaddition of ~ (SC) 709 [G.E. 79, 722 (1967)]

Kinetics, Chemical ~ in homogeneous systems (Book Review) 278

LACTONES, Behavior of ~ under pressures of 20–24 kbar: A model reaction for the formation of petroleum (CR) 970 [G. E. 79, 990 (1967)]

Lamp, Chemistry of the incandescent ~ (FP) 68 [G.E. 79, 43 (1967)]

Laudanosoline, Aporphines from ~ and norlaudanosoline (SC) 799 [G.E. 79, 815 (1967)]

Lead, Isotopic composition of ~ in archaeological objects and ~ ores (LA) 379

Lead complexes, A covalent bond between Pt or Au and Pb (LA) 1089

Lead compounds, Chemistry and stability of lead(IV) compounds (CR) 572 [G.E. 79, 585 (1967)]

Acidolysis of organo-~ (CR) 976 [G. E. 79, 996 (1967)]

Lead-oxygen bond, Additions to the ~ (LA) 188

Lemon oils, Gas-chromatographic investigation of ~ (CR) 972 [G. E. 79, 002 (1967)]

Lewis acids, New class of ~ (CR) 640 [G.E. 79, 652 (1967)]

Reversibly titratable organic ~ (CR) 991 [G. E. 79, 1011 (1967)]

Ligand addition, and redox reactions of azido-metal complexes (SC) 169 [G.E. 79, 146 (1967)]

Ligand substitution processes (Book Review) 382

Light, Physical and biological action (Book Review) 381

Light scattering, Influence of the order in polymer solutions on ~ (CR) 465 [G.E. 79, 416 (1967)]

Lithium compounds, Chemistry of stable α-halogenoorgano-~ and the mechanism of carbenoid reactions (FP) 41 [G.E. 79, 15 (1967)]

Borate complexes derived from lithium carbenoids – mechanism of the "inverse Stevens rearrangement" (SC) 74 [G.E. 79, 50 (1967)]

Preparation of diethylcarbamoyllithium (diethylamino)lithiooxycarbene from bis(diethylcarbamoyl)mercury (SC) 805 [G.E. 79, 819 (1967)]

Isoprene and organo-~ in hydrocarbons and ethers (CR) 463 [G.E. 79, 422 (1967)]

Stable nitroaryl-~ (CR) 966 [G. E. 79, 986 (1967)]

Lithium sulfate, Stereoselective synthesis of 1-butene with ~ as elimination catalyst (SC) 170 [G.E. 79, 187 (1967)]

N-Lost phosphoramidate, The change in the properties of cyclic ~ on substitution on the ring nitrogen (CR) 963 [G. E. 79, 983 (1967)]

L-Lysine oxygenase (LA) 99

MACROMOLECULAR chemistry, Praktikum der makromolekularen organischen Chemie (Laboratory manual of organic ~) (Book Review) 276

Macromolecular colloquium (CR) 459 [G.E. 79, 416 (1967)]

Macromolecules, Influence of chain rigidity on the crystallization process in ~ (CR) 465 [G.E. 79, 416 (1967)]

Association of ~ (CR) 465 [G.E. 79, 417 (1967)]

Magnetic anisotropy, Molecular structure and ~ of amides (CR) 989 [G. E. 79, 1009 (1967)]

Magnetic resonance, Advances in ~ (Book Review) 1010

Maleic thioanhydride, Preparation of ~ (SC) 874 [G.E. 79, 870 (1967)]

Manganese complexes, Formation of fluoroorganocarbonyl-~ and -rhenium complexes from hexafluoro-1,3-butadiene and pentacarbonylmanganese and -rhenium hydrides (SC) 878 [G.E. 79, 900 (1967)]

Manometric methods, Manometrische Methoden und ihre Anwendung in der Biologie und Biochemie (~ and their use in biology and biochemistry) (Book Review) 190

Matrix spectroscopy (CR) 266 [G.E. 79, 277 (1967)]

Mass spectrometry, Electron-impact induced rearrangement reactions of organic molecules (FP) 477 [G.E. 79, 481 (1967)]

Investigation of inorganic systems at high temperature by ~ (FP) 581 [G.E. 79, 589 (1967)]

Mass-spectrometric determination of the structure of peptide alkaloids from Rhamnaceae (CR) 968 [G. E. 79, 988 [1967)]

Gas chromatographic capillary columns of high resolution in direct combination with a mass spectrometer (LA) 473

Detection of extremely small quantities of alkali metal by ~ (LA) 718

Compilation of mass spectral data (Book Review) 381

Mathematics, for quantum chemistry (Book Review) 278

Maya blue (LA) 642

Meisenheimer complex, containing only one nitro group (LA) 888

Melting behavior, Investigation of the ~ of crystalline polyethylene produced by degradation with HNO_3 (CR) 467 [G.E. 79, 418 (1967)]

Melting points, Thermodynamic (maximum) ~ of oligomeric and polymeric single-component and multi-component systems (CR) 467 [G.E. 79, 420 (1967)]

Melting temperature, Variation of ~ with pressure (LA) 577

Membranes, Active transport of ions through biogenic ~ (CR) 640 [G.E. 79, 624 (1967)]

Mercury, Metallic conductivity in supercritical ~ (LA) 379

~ derivatives of decaborane (LA) 1008

Mercury-carbene complexes, Synthesis and reactions of stable ~ (CR) 970 [G. E. 79, 990 (1967)]

Mercury compounds, Complexes of alkoxy(dialkylamino)carbenes and Hg^{2+} obtained from dicarbamoyl-~ (SC) 560 [G.E. 79, 578 (1967)]

Preparation of diethylcarbamoyllithium (diethylamino)lithiooxycarbene from bis(diethylcarbamoyl)mercury (SC) 805 [G.E. 79, 819 (1967)]

Hg(II)-catalysed vinyl exchange (LA) 187

Mesomeric limiting structures, Detection of ~ by electron spin resonance (CR) 639 [G.E. 79, 625 (1967)]

Metal-boron coordination compounds, Synthesis of ~ by oxidative addition (SC) 696 [G.E. 79, 683 (1967)]

Metal carbene complexes, Novel rearrangement processes of transition ~ (SC) 181 [G.E. 79, 191 (1967)]

Metal carbonyl-carbene complexes, Kinetic investigations of substitution reactions of ~ (CR) 1001 [G. E. 79, 1021 (1967)]

Metal carbonyls (LA) 889

Metal chlorides, Gas-chromatographic separation of ~ (CR) 376 [G.E. 79, 385 (1967)]

Metal complexes, Ligand addition and redox reactions of azido-~ (SC) 169 [G.E. 79, 146 (1967)]

~ of diethylthiophosphinic acid (SC) 175 [G.E. 79, 148 (1967)]

~ of oxotripyrrene-α-carboxylic acid (CR) 184 [G.E. 79, 155 (1967)]

Isomerism in ~ (LA) 642

Metal ions, Chromatographic separation of ~ with anomalous exchange properties on chelating ion-exchange resins (CR) 373 [G.E. 79, 324 (1967)]

Metallic conductivity, in supercritical mercury (LA) 379

Methacrylate, Torsional vibration measurements on copolymers of methyl ~ and (tri-n-propyl)tin ~ (CR) 995 [G. E. 79, 1015 (1967)]

2-Methylacraldehyde imine, Acraldehyde imine and ~ (SC) 803 [G.E. 79, 818 (1967)]

1-Methylazepine, X-ray structure analysis of a dimer of ~ (SC) 805 [G.E. 79, 820 (1967)]

4-Methylcyclohexylidene acetic acids, Absolute configuration of the enantiomeric ~ (LA) 188

Methylenephosphoranes, 1,3-Cycloadditions of nitrones to ~ (SC) 457 [G.E. 79, 457 (1967)]

Methylenequadricyclane, Cycloadditions to derivatives of ~ and of quadricyclanone (bishomocyclobutadiene) (SC) 1069 [G. E. 79, 1102 (1967)]

Methyl iodide, Experiments on the scattering of molecular beams for the study of reactions of potassium with ~, hydrogen bromide, and bromine (CR) 887 [G.E. 79, 907 (1967)]

7-Methyl-4-phenyl-8*H*-1,3,5,6-dithiadiazocin-2-one, an eight-membered heterocycle with chiral conformation (SC) 629 [G.E. 79, 618 (1967)]

N-Methyl-*N*-phenylisoindolinium iodide Mechanism of the Wittig rearrangement of ~ (SC) 559 [G.E. 79, 574 (1967)]

3-Methylpurine (LA) 100

α-Methylstyrene, Reaction of benzyne with ~ (SC) 555 [G.E. 79, 575 (1967)]

1-Methyl-3,3,5,5-tetraphenyl-1-thia-3,5-diphospha^{v}-2,6-diazine(SC) 560 [G.E. 79, 577 (1967)]

N-[(Methylthio)-*N*-tosylformimidoyl]-amino acids (SC) 862 [G.E. 79, 858 (1967)]

Microbial oxidation, 1-Hexadecene, an intermediate in the ~ of *n*-hexadecane in vivo and in vitro (SC) 359 [G.E. 79, 314 (1967)]

Microwave spectroscopy, Comparative determination of the structure of gaseous molecules by ~ (CR) 1005 [G. E. 79, 1025 (1967)]

Mineralization, Chemical affinity and structural relationships between protein and inorganic components in biogenous ~ (CR) 986 [G. E. 79, 1006 (1967)]

Mitochondrial oxidative phosphorylation (FP) 1035 [G. E. 79, 1088 (1967)]

Molar enthalpies, Irregularities in the partial ~ of mixing of water and water-alcohol mixtures at constant temperature (SC) 1087 [G. E. 79, 1105 (1967)]

Molecular beams, Experiments on the scattering of ~ for the study of reactions of potassium with methyl iodide, hydrogen bromide, and bromine (CR) 887 [G.E. 79, 907 (1967)]

Molecular orbital theory, of conjugated systems (Book Review) 475

Molecular shape, Electron-pair repulsions and ~ (FP) 819 [G.E. 79, 885 (1967)]

Molten halides, Relations between structure and thermodynamic and chemical properties of ~ (CR) 641 [G.E. 79, 653 (1967)]

Molybdate, Preparation of diammonium tetraseleno-~ (SC) 257 [G.E. 79, 245 (1967)]

Preparation and properties of diammonium dioxodiseleno-~ (SC) 1081 [G. E. 79, 1065 (1967)]

Monoalkyl phosphates, A new synthesis of ~ (LA) 1088

Monosaccharides, Reaction of ~ with thiocyanic acid (LA) 889

Morphinan, Synthesis of a ~ derivative by oxidative ring closure (SC) 1075 [G. E. 79, 1066 (1967)]

2-Morpholinones, Synthesis of oxalactams (~) from aziridinium tetrafluoroborates and hydroxy (SC) 178 [G.E. 79, 188 (1967)]

Mössbauer effect, Chemical gamma-resonance spectroscopy (FP) 830 [G.E. 79, 844 (1967)]

A study of primary recoil effects by means of the ~ (CR) 1004 [G. E. 79, 1024 (1967)]

Mössbauer spectrum, of the iron in glauconite (SC) 561 [G.E. 79, 581 (1967)]

Multi-Center reactions, The concept of hard and soft acids and bases as applied to ~ (FP) 928 [G. E. 79, 966 (1967)]

Multilayer chromatography, in difficult separations (CR) 374 [G.E. 79, 325 (1967)]

Mutarotation, Thermodynamic data on the "~" of fructose (LA) 889

Myxinol disulfate, the pricipal bile salt of the hagfish (LA) 187

NAPHTHIMIDAZOLE, Azo coupling to Schiff bases. A new synthesis of ~ derivatives (SC) 250 [G.E. 79, 237 (1967)]

1*H*-Naphtho[1,8-*de*]-1,2,3-triazinium salt, Novel ring fission of a ~ (SC) 360 [G.E. 79, 316 (1967)]

Natural products, Fortschritte der Chemie anorganischer Naturstoffe (Progress in the chemistry of organic ~) Book Review) 275

Neighboring-group effects, and rearrangements in reactions of cyclopropylmethyl, cyclobutyl, and homoallyl systems (FP) 666 [G.E. 79, 709 (1967)]

Nematic phases, Low-melting ~ for determination of NMR spectra of orientated molecules (SC) 450 [G.E. 79, 475 (1967)]

Neopentylbenzene, Isomer distribution in electrophilic aromatic substitutions on ~ (LA) 379

Neophorbol, X-ray structure analysis of ~ (SC) 809 [G.E. 79, 824 (1967)]

Neptunium, Ternary alkali metal and alkaline earth fluorides of ~ (CR) 997 [G. E. 79, 1017 (1967)]

Neptunium oxide, The solid-state chemistry of ~ (CR) 977 [G. E. 79, 997 (1967)]

Neptunyl ion, Spectrophotometric studies on the hydrolysis and complex formation of the plutonyl and neptunyl ions (CR) 967 [G. E. 79, 987 (1967)]

Neutralization, Anomalous course of the ~ of periodic acid by sodium hydroxide (SC) 707 [G.E. 79, 690 (1967)]

Neutron activation analysis, Investigations on the age and place of origin of paintings by ~ (CR) 983 [G. E. 79, 1003 (1967)]

Use of some short-lived radionuclides for ~ by irradiation with the fast neutrons of a swimming-pool reactor (CR) 991 [G. E. 79, 1011 (1967)]

Neutron capture, Protactinium-238, a new nuclide, and its role in the formation of heavy transuranium elements by multiple ~ in uranium-238 (CR) 1000 [G. E. 79, 1020 (1967)]

Neutron emitters, The search for new ~ among the fission products of uranium-235 (CR) 998 [G. E. 79, 1018 (1967)]

Nickel, Anodic behavior of ~ in aqueous solution (CR) 969 [G. E. 79, 989 (1967)]

Nickel complexes, Nickel-catalysed reactions of allyl halides and related compounds (FP) 124 [G.E. 79, 177 (1967)]

Oxygen complexes of zerovalent nickel, palladium, and platinum (SC) 92 [G.E. 79, 62 (1967)]

1,5-Cyclooctadienenickel bromide and iodide (SC) 452 [G.E. 79, 414 (1967)]

Synthesis of tetrakis(trimethoxyphosphine)nickel(0) (SC) 563 [G.E. 79, 582 (1967)]

Reaction of halogeno(phosphine)-~ with nitric oxide (SC) 566 [G.E. 79, 536 (1967)]

Tricarbonyl(organometalophosphine)-nickel(0) (SC) 701 [G.E. 79, 692 (1967)]

cis- and *trans*-Bis(π-allyl)nickel systems (SC) 804 [G.E. 79, 817 (1967)]

Reactivity of ligands in synthetic cobalt(III)- and nickel(II)-corrin complexes (SC) 868 [G.E. 79, 867 (1967)]

Synthesis of tetramethylcyclobutadienenickel(II) bromide with a new nickel(0) complex (SC) 873 [G.E. 79, 897 (1967)]

Nickel oxide, Photocatalysis by semiconductors on metal supports, photosensitized oxidation of CO with ~ on silver supports (CR) 999 [G. E. 79, 1019 (1967)]

Nickel thiolates, Thiolates of cobalt, nickel, copper, and zinc (LA) 716

Nicotinamide *N*-oxide, biological oxidant (CR) 468 [G.E. 79, 476 (1967)]

Nitrenes, and the decomposition of carbonylazides (FP) 897 [G. E. 79, 922 (1967)]

Nitriles, Synthesis of 1,2,4-thiadiazoles from ~ and sulfur (SC) 1084 [G. E. 79, 1106 (1967)]

Coupled addition to the carbon-carbon double bond (CR) 94 [G.E. 79, 63 (1967)]

Syntheses of triazines, pyrimidines, and pyridines from ~ (CR) 183 [G.E. 79, 154 (1967)]

Semiconducting properties of some ~ and their polymers with a porphyrazine structure (CR) 1004 [G. E. 79, 1024 (1967)]

Nitroarylithium compounds, Stable ~ (CR) 966 [G. E. 79, 986 (1967)]

Nitrosobissulfate, Specific oxidation of phenols by dipotassium ~ (CR) 471 [G.E. 79, 426 (1967)]

Nitrogen, Adsorption of ~ on iron (SC 882 [G.E. 79, 905 (1967)]

Fixation of molecular ~ (LA) 716

Reaction of liquid barium/sodium solutions with ~ (LA) 1008

Developments in inorganic ~ chemistry (Book Review) 1010

Nitrogen compounds, "Dimerization" of organic ~ via copper-containing intermediates (SC) 633 [G.E. 79, 620 (1967)]

Synthesis and reactions of novel carbonyl compounds containing nitrogen(CR) 989 [G. E. 79, 1009 (1967)]

Chemistry of open-chain organic ~ (Book Review) 278

Nitrogen fixation, on new transition metal complexes (SC) 873 [G.E. 79, 898 (1967)]

Nitrogen-silicon rings, New five- and six-membered ~ (LA) 472

Nitro group, Concerted elimination of an acetamido and a ~ (LA) 98 [G.E. 79, 66 (1967)]

Nitromethane, Synthesis of cyclic 1,2,3-triamines by the reaction of dialdehydes with ~ and benzylamine (SC) 568 [G.E. 79, 530 (1967)]

Nitrones, 1,3-Cycloadditions of ~ to methylenephosphoranes (SC) 457 [G.E. 79, 457 (1967)]

1-Nitroolefins, Anion radicals from ~ (SC) 251 [G.E. 79, 240 (1967)]

Nitrosamines, Anisotropic effects in heterocyclic ~ (SC) 75 [G.E. 79, 51 (1967)]

Separation and equilibration of conformeric ~ (CR) 984 [G. E. 79, 1004 (1967)]

N-Nitrosoacetanilide, Mechanism of the Gomberg reaction and of phenylation by ~ (CR) 713 [G.E. 79, 693 (1967)]

Nitrosobenzene, Inverse addition of phenyl-lithium to ~ (LA) 815

Nitroso compounds, Acid-catalysed reactions of aliphatic ~ (CR) 95 [G.E. 79, 65 (1967)]

Nitrosophenols, Intramolecular hydrogen bridges in ~ (CR) 714 [G.E. 79, 692 (1967)]

Nitroxides, Detection of aryl(vinyl)-~ by ESR spectroscopy (SC) 1080 [G. E. 79, 1070 (1967)]

Nitroxide radicals, ESR Spectroscopic studies of ~ (CR) 810 [G.E. 79, 825 (1967)]

Very stable ~ (LA) 472

NMR Spectroscopy, Detection of hydrogen bridges between inosine and other nucleosides by ~ (SC) 180 [G.E. 79, 190 (1967)]

Low-melting nematic phases for determination of NMR spectra of orientated molecules (SC) 450 [G.E. 79, 475 (1967)]

Linear relation between chemical shifts of the ^{31}P resonance and Hammett constants (SC) 945 [G. E. 79, 946 (1967)]

Chemical shifts of NMR signals of the acetyl protons of β-penta-*O*-acetylglucose (SC) 955 [G. E. 79, 937(1967)]

Detection of intramolecular mobility in quinoid systems by ~ (CR) 977 [G.E. 79, 997 (1967)]

Anwendungen der kernmagnetischen Resonanz in der Organischen Chemie (Applications of ~ in organic chemistry) (Book Review) 275

Théories moléculaires de la Résonance Magnétique Nucléaire (Molecular theories of ~) (Book Review) 277

Nonclassical ions (Book Review) 895

2-Norbornaneacetic acid, Synthesis of α-chloro-1-adamantaneacetic acids and α-chloro-~by means of trichloroethylene (SC) 946 [G. E. *79*, 943 (1967)]

Norcaradiene, The ~ problem (FP) 402 [G.E. *79*, 446 (1967)]

New route to dibenzo-~ derivatives (SC) 561 [G.E. *79*, 578 (1967)]

Norlaudanosoline, Aporphines from laudanosoline and ~ (SC) 799 [G.E. *79*, 815 (1967)]

Nuclear fuel, Recovery, in aqueous solution, of ~ of high plutonium content (CR) 886 [G.E. *79*, 872 (1967)]

Determination of ^{238}Pu in unirradiated-~ samples by γ-spectroscopy (CR) 982 [G. E. *79*, 1002 (1967)]

Nuclear transformations, Chemical effects of ~ in solids (FP) 133 [G.E. *79*, 128 (1967)]

Nuclear quadrupole interaction, and molecular structure (CR) 981 [G. E. *79*, 1001 (1967)]

Nucleic acids, Determination of the secondary and tertiary structure of ~ by chemical methods (CR) 642 [G.E. *79*, 624 (1967)]

Chemistry and cytochemistry of ~ and nuclear proteins (Book Review) 380

Nucleophilic reactivity, of the thiophosphoryl group (FP) 1013 [G. E. *79*, 1077 (1967)]

Nucleosides, Detection of hydrogen bridges between inosine and other ~ by NMR spectroscopy (SC) 180 [G.E. *79*, 190 (1967)]

Nucleoside diphosphates, Synthesis of ~ by means of di-(2,2,2-trichloroethyl)-phosphorochloridate (SC) 362 [G.E. *79*, 317 (1967)]

Nucleotides, Synthesis and template properties of oligodeoxy-~ with repeating triplet sequences (SC) 562 [G.E. *79*, 580 (1967)]

Synthesis of oligo-~ by use of phosphoric triesters (SC) 695 [G.E. *79*, 684 (1967)]

Oligonucleotide syntheses by means of 2,2,2-trichloroethyl phosphorodichloridate (SC) 949 [G. E. *79*, 939 (1967)]

Dynamic investigations on oligo- and poly-~ (CR) 459 [G.E. *79*, 417 (1967)]

Synthesis of polyarabino-~ with esters of polyphosphoric acid (CR) 460 [G.E. *79*, 422 (1967)]

Bonding of ^{32}P-labeled tri-~ to t-RNA (LA) 643

OBSIDIAN, Measurement of self-diffusion coefficients of Na by heterogeneous solid/melt and solid/solid isotope exchange on ~ (CR) 983 [G. E. *79*, 1003 (1967)]

Olefins, Synthesis of dienes from vinyl halides via organocopper compounds (SC) 85 [G.E. *79*, 101 (1967)]

Coupled addition to the carbon-carbon double bond (CR) 94 [G.E. *79*, 63 (1967)]

Structural investigations on poly-~ by means of pyrolysis and gas chromatography (CR) 985 [C. E. *79*, 1005 (1967)]

Light-induced addition of cyclic acetals to terminal ~ (LA) 576

1,2-Cycloaddition of an azo group to ~ (LA) 577

Oleic acid, precursor of naturally occurring acetylenes (LA) 890

Oligodeoxynucleotides, Synthesis and template properties of ~ with repeating triplet sequences (SC) 562 [G.E. *79*, 580 (1967)]

Oligonucleotide, Synthesis of ~s by use of phosphoric triesters (SC) 695 [G.E. *79*, 684 (1967)]

~ syntheses by means of 2,2,2-trichloroethyl phosphorodichloridate (SC) 949 [G. E. *79*, 939 (1967)]

Optical activity, Apparatus for measuring the natural ~ in the UV and the visible regions (CR) 1003 [G. E. *79*, 1023 (1967)]

Optical behavior, of solutions of sodium in ammonia at high pressure (CR) 575 [G.E. *79*, 585 (1967)]

Optically active polymers, Recent studies of ~ (CR) 271 [G.E. *79*, 280 (1967)]

Organic chemistry, Modern textbook of ~ (Book Review) 104

Elementary Practical ~ Part 1. (Book Review) 1091

Elementary Practical ~ Part 2. (Book Review) 1091

Organoboron halides, Preparation of ~ from halogenoalkenes and organoboron hydrides (SC) 802 [G.E. *79*, 816 (1967)]

Organochromium compounds, Sigma-bonded ~ . – Hydrogen transfer reactions (FP) 435 [G.E. *79*, 401 (1967)]

Organocopper compounds, Synthesis of dienes from vinyl halides via ~ (SC) 85 [G.E. *79*, 101 (1967)]

Organolead compounds, Acidolysis of ~ (CR) 976 [G. E. *79*, 996 (1967)]

Organolithium compounds, Isoprene and ~ in hydrocarbons and ethers (CR) 463 [G.E. *79*, 422 (1967)]

Organometallic compounds, and hydrogen compounds of some transition metals (CR) 571 [G.E. *79*, 537 (1967)]

Organotin hydrides, Free-radical decomposition of azo compounds induced by ~ (SC) 76 [G.E. *79*, 52 (1967)]

Orthoformic esters, H/D Exchange in *N,N*-dimethylformamide acetals and ~ (SC) 875 [G.E. *79*, 869 (1967)]

Ortho-semidine rearrangement, of 1,2-diphenyl-1,2-diazetidinone (SC) 630 [G.E. *79*, 619 (1967)]

Orthothioformates, Metalated ~ (SC) 442 [G.E. *79*, 468 (1967)]

Oxaboroles, Preparation of substituted ~ from sodium 1-alkynyltrialkylborates and acyl chlorides (SC) 84 [G.E. *79*, 57 (1967)]

1,3,5-Oxadiazines, Trifluoromethylated and chlorodifluoromethylated ~ and 1,3,5-dioxazines (LA) 99 [G.E. *79*, 104 (1967)]

Oxalactams, Synthesis of ~ (2-morpholinones) from aziridinium tetrafluoroborates and hydroxy (SC) 178 [G.E. *79*, 188 (1967)]

1,3-Oxathioles, 2-Imino-~ (SC) 455 [G.E. *79*, 470 (1967)]

Oxaquadricyclanes, Cycloadditions to derivatives of ~ (bishomofuran) (SC) 1070 [G. E. *79*, 1103 (1967)]

Oxaziranes, Photofragmentation of ~ (SC) 634 [G.E. *79*, 648 (1967)]

Oxazolidinones, Preparation of heterocyclic compounds by treatment of amino acids with trifluoroacetic anhydride (CR) 184 [G.E. *79*, 155 (1967)]

Oxazolone, 1,3-Cycloadditions of mesoionic ~-s to carbonyl compounds (SC) 365 [G.E. *79*, 320 (1967)]

Possible valence tautomerism of a mesoionic 5-~ with an acylaminoketene (SC) 367 [G.E. *79*, 321 (1967)]

Formation of 2-~-s by photoarrangement of 3-hydroxyisoxazoles (LA) 888

Oxepin, Benzene oxide-~ valence tautomerism (FP) 385 [G.E. *79*, 429 (1967)]

Oxidases, Fluorimetric determination of ~ (LA) 814

Oxidation, Reactions with molecular oxygen (FP) 496 [G.E. *79*, 500 (1967)]

Acid-catalysed ~ of isocyanides with dimethyl sulfoxide (SC) 168 [G.E. *79*, 145 (1967)]

~ reactions of the thioamide group (CR) 468 [G.E. *79*, 426 (1967)]

Comprehensive biochemistry (Book Review) 646

Oxidative addition, Synthesis of metal-boron coordination compounds by ~ (SC) 696 [G.E. *79*, 683 (1967)]

Oxidative decarboxylation, of glycine (LA) 274

Oxidative phosphorylation, Mitochondrial ~ (FP) 1035 [G. E. *79*, 1088 (1967)]

Model experiments on ~ (CR) 811 [G.E. *79*, 826 (1967)]

Oxides, Compound formation in ternary metal(II) oxide, phosphorus(V) oxide, and boron(III) oxide systems (CR) 964 [G. E. *79*, 984 (1967)]

Oxocyclohexadienecarboxamides, The preparation of new ~ (LA) 1006

Oxotripyrrene-α-carboxylic acid, Metal complexes of ~ (CR) 184 [G.E. *79*, 155 (1967)]

Oxygen, Reactions with molecular ~ (FP) 496 [G.E. *79*, 500 (1967)]

^{18}O-isotope exchange between TcO_4^- and ReO_4^- ions and water (CR) 1003 [G. E. *79*, 1023 (1967)]

Gmelins Handbuch der anorganischen Chemie (Gmelin's handbook of inorganic chemistry) (Book Review) 100

Oxygen complexes, of zerovalent nickel, palladium, and platinum (SC) 92 [G.E. *79*, 62 (1967)]

PAHUTOXIN, the poison of the blue boxfish (LA) 716

Paint films, Drying of ~ in steam (CR) 181 [G.E. *79*, 192 (1967)]

Painting, Electrophoretic painting on the rotating disk electrode (CR) 964 [G. E. *79*, 984 (1967)]

Investigations on the age and place of origin of ~s by neutron activation analysis (CR) 983 [G. E. *79*, 1003 (1967)]

Palladium(II) chloride, Pd_6Cl_{12} and Pt_6Cl_{12} in the gaseous state (SC) 253 [G.E. *79*, 244 (1967)]

Palladium complexes, Oxygen complexes of zerovalent nickel, palladium, and platinum (SC) 92 [G.E. *79*, 62 (1967)]

Paraffins, Some chain-length effects of ~ (CR) 979 [G. E. *79*, 999 (1967)]

Partial molar enthalpies, Irregularities in the ~ of mixing of water and water-alcohol mixtures at constant temperature (SC) 1087 [G. E. 79, 1105 (1967)]

Partition, of triphenyl-lead derivatives between aqueous and organic phases (CR) 373 [G.E. 79, 323 (1967)]

Adsorption and ~ (CR) 373 [G.E. 79, 323 (1967)]

Partition chromatography, Determination of benzoic and phthalic acids in terephthalic acid by ~ (CR) 373 [G.E. 79, 323 (1967)]

Peas, Enzyme-catalysed changes in the volatile components of ~ (CR) 971 [G. E. 79, 991 (1967)]

Penicillin, group of drugs (Book Review) 277

β-Penta-*O*-acetylglucose, Chemical shifts of NMR signals of the acetyl protons of ~ (SC) 955 [G. E. 79, 937 (1967)]

Pentacyclo[4.3.0.0^{2,4}.0^{8,3}.0^{5,7}]nonane (SC) 247 [G.E. 79, 232 (1967)]

Pentahendecafulvalene (SC) 632 [G.E. 79, 620 (1967)]

Pentalene, 1,3-Bis(dimethylamino)-~ (SC) 451 [G.E. 79, 414 (1967)]

Peptidase, Amino-~ B (LA) 186

Peptides, Methods for the automatic determination of amino acid sequences (LA) 274

Edman degradation of ~ (LA) 577

The ~ (Book Review) 645, 646

Peptide alkaloids, Mass-spectrometric determination of the structure of ~ from Rhamnaceae (CR) 968 [G. E. 79, 988 (1967)]

Peptide synthesis, *N,N*-Disubstituted derivatives of *O*-chloroformylhydroxylamines as reagents for ~ (SC) 570 [G.E. 79, 532 (1967)]

Perfluorinated aromatic acids, Chemistry of ~ (CR) 994 [G. E. 79, 1014 (1967)]

β-Perfluoroalkylalanines, General method for the preparation of ~ (SC) 807 [G.E. 79, 822 (1967)]

Perhydrodibenzo-1,2,3,6,7,8-hexathiecin, New sulfur-containing cyclic compounds (SC) 703 [G.E. 79, 690 (1967)]

Perhydrodibenzo-1,2,5,6-tetrathiocin, New sulfur-containing cyclic compounds (SC) 703 [G.E. 79, 690 (1967)]

Periodates (CR) 812 [G.E. 79, 827 (1967)]

Periodic acid, Anomalous course of the neutralization of ~ by sodium hydroxide (SC) 707 [G.E. 79, 690 (1967)]

Peroxidase, Chloro-~ (LA) 186

Peroxides, New high-temperature initiators (SC) 949 [G. E. 79, 939 (1967)]

Induced decomposition of unsymmetrical acyl ~ (CR) 986 [G. E. 79, 1006 (1967)]

Peroxotungstates, New ~ (CR) 969 [G.E. 79, 990 (1967)]

Peroxy esters, Isomeric ~ of sugar carboxylic acids (SC) 950 [G.E. 79, 940 (1967)]

Petroleum, Behavior of lactones under pressures of 20–24 kbar: A model reaction for the formation of ~ (CR) 970 [G.E. 79, 990 (1967)]

Petroporphyrins, from bituminous shales (CR) 975 [G.E. 79, 995 (1967)]

Pharmaceutical exhibition, Therapy congress and ~ (CR) 96 [G.E. 79, 102 (1967)]

Pharmacology, Einfuhrung in die Allgemeine Pharmakologie (Introduction to general ~) (Book Review) 190

Phase diagrams, Quasibinary ~ of the systems rare earth metal (Ho, Tm, Lu) oxide/actinide (Th, U, Np, Pu) dioxide (CR) 982 [G.E. 79, 1002 (1967)]

Phenols, Reaction of isocyanato- and isothiocyanato-formates with activated ~ (SC) 455 [G.E. 79, 474 (1967)]

N-Persubstituted 3,5-diamino-~ and 1,3,5-benzenetriamines and their protonation (SC) 1067 [G.E. 79, 1100 (1967)]

Synthesis and reactions of siloxane-substituted ~ (CR) 462 [G.E. 79, 418 (1967)]

Specific oxidation of ~ by dipotassium *nitrosobissulfenate* (CR) 471 [G.E. 79, 426 (1967)]

Conversion of ~ into thiophenols (LA) 472

Phenoxyl, Spin density distribution in 2,4,6-triphenyl-~ (FP) 34 [G.E. 79, 69 (1967)]

Phenylalanine-tRNA, The primary structure of yeast ~ (LA) 1007

Phenylation, Mechanism of the Gomberg reaction and of ~ by *N*-nitrosoacetanilide (CR) 713 [G.E. 79, 693 (1967)]

α,α′-*p*-Phenylenediacrylonitrile, Cross-linked polymers from ~ (CR) 639 [G.E. 79, 624 (1967)]

Phenyl-lithium, Inverse addition of ~ to nitrosobenzene (LA) 815

Phenylthio groups, Selective cleavage of substituted ~ (phenylsulfenyl) protective groups in peptide syntheses (LA) 188

Phorbol, X-ray structure analysis of *neo*-~ (SC) 809 [G.E. 79, 824 (1967)]

Etherification of ~ (CR) 973 [G.E. 79, 993 (1967)]

Circular dichroism in ~ derivatives (CR) 974 [G.E. 79, 994 (1967)]

Determination of partial structures of ~ by cleavage with periodate and with lead tetraacetate (CR) 974 [G.E. 79, 994 (1967)]

Phosgene, Preparation of isocyanates from carbamates by reaction with ~ (SC) 636 [G.E. 79, 651 (1967)]

Phosphates, Preparation of tetrachlorodicyano-~ and the existence of tetrachlorodifluoro-~ (SC) 363 [G.E. 79, 316 (1967)]

A new synthesis of monoalkyl ~ (LA) 1088

Phospha-1,3,5-triazines, Synthesis of ~ and diphospha-1,3,5-triazines by cyclizing transamination with aminophosphazenes (SC) 565 [G.E. 79, 534 (1967)]

Phosphazenes, Structure of $[P_2N_7H_{10}(CH_3)_2]I$ (SC) 369 [G.E. 79, 322 (1967)]

Synthesis of phospha- and diphospha-1,3,5-triazines by cyclizing transamination with amino-~ (SC) 565 [G.E. 79, 534 (1967)]

Phosphide, KP_{15}, a new potassium poly-~ (SC) 356 [G.E. 79, 323 (1967)]

Phosphinato complexes, Imidophosphinatotin halides (SC) 252 [G.E. 79, 242 (1967)]

Phosphine, Trifluoro-~ complexes of transition metals (FP) 53 [G.E. 79, 27 (1967)]

Tetrakis[(alkali-metalphenylphosphino)methyl]-methanes and their conversion into metal-containing and metal-free spiroheterocycles (SC) 355 [G.E. 79, 380 (1967)]

PF_2-bridges in metal complexes (SC) 454 [G.E. 79, 474 (1967)]

Synthesis of tetrakis(trimethoxy-~)-nickel(0) (SC) 563 [G.E. 79, 582 (1967)]

Reaction of halogeno(~)nickel complexes with *nitric oxide* (SC) 566 [G.E. 79, 536 (1967)]

Synthesis of pentacarbonyldicyclopentadienyldivanadium and new carbonyl-~-cyclopentadienylvanadium compounds (SC) 569 [G.E. 79, 537 (1967)]

Resolution of chiralic triaryl-~-s (SC) 700 [G.E. 79, 721 (1967)]

Tricarbonyl(organometalo-~)nickel(0) (SC) 701 [G.E. 79, 692 (1967)]

Dimethylfluoro-~ (SC) 708 [G.E. 79, 686 (1967)]

Cyclopentadienylgold(I) and cyclopentadienyl-(triphenyl-~)gold(I) (SC) 862 [G.E. 79, 859 (1967)]

Structure, *preparation*, and properties of cyclopoly-~ (CR) 887 [G.E. 79, 908 (1967)]

Preparation and structure of open-chain and cyclic poly-~-s (LA) 187

Reactions of aryl trifluoromethyl ketones with trialkyl-~-s (LA) 576

Phosphine imide, Trimethyl-~: Synthesis and reactions with organometallic compounds (SC) 449 [G.E. 79, 413 (1967)]

Phosphine sulfides, Two new syntheses of secondary ~ (LA) 187

Phosphinic acid, Metal complexes of diethylthio-~ (SC) 175 [G.E. 79, 148 (1967)]

Phosphinimidic fluoride, *N*-(Cyano)phenylphosphinimidic difluoride and *N*-(cyano)diphenyl-~ (SC) 709 [G.E. 79, 723 (1967)]

Phosphinites, Synthesis of silyl ~ (SC) 88 [G.E. 79, 59 (1967)]

O-Phosphinohydroxylamine, Arbusov-type rearrangement of a >P–O–N grouping (LA) 272

Phosphinothioic amides, The thermal decomposition of some diphenyl-~. New route to arylcyclophosphazatrienes (SC) 556 [G.E. 79, 575 (1967)]

Phosphinous amide, Synthesis and properties of diphenyl-~ (SC) 875 [G.E. 79, 869 (1967)]

Phosphinylacetic acids, Resolution of racemates of asymmetric ~. Model compounds for reactions of phosphinate carbanions (SC) 1078 [G.E. 79, 1070 (1967)]

Phosphinylsilicide, Reactions of silylphosphines. – Formation of lithium tris(diethylphosphinyl)silicide (SC) 1078 [G.E. 79, 1068 (1967)]

Phospholes, Simple synthesis of ~ (SC) 86 [G.E. 79, 58 (1967)]

Phosphonimidic difluoride, *N*-(Cyano)-phenyl-~ and *N*-(cyano)diphenylphosphinimidic fluoride (SC) 709 [G.E. 79, 723 (1967)]

Phosphonitrile heterocycles, Novel ~ (LA) 188

Phosphonium salts, New ring-closure reaction (SC) 81 [G.E. 79, 95 (1967)]

Dialkyl(triphenylphosphoniomethyl)-sulfonium bis-salts and their conversion into stable ylide salts (SC) 249 [G.E. 79, 242 (1967)]

Preparation of alkoxy-~ by alkylation of phosphoryl compounds (SC) 372 [G.E. 79, 379 (1967)]

Tetrachlorophosphonium and chloro-(phenyl)-phosphonium perchlorates and hexachloroantimonates (SC) 564 [G.E. 79, 535 (1967)]

Phosphoramidate, The change in the properties of cyclic *N*-lost ~ on substitution on the ring nitrogen (CR) 963 [G.E. 79, 983 (1967)]

Phosphoramide, Hexamethyl-~ (FP) 1046 [G.E. 79, 1029 (1967)]

Phosphorane, New ring-closure reaction (SC) 81 [G.E. 79, 95 (1967)]

Trimethyl(methylene)-~ (SC) 448 [G.E. 79, 412 (1967)]

1,3-Cycloadditions of nitrones to methylene-~-s (SC) 457 [G.E. 79, 472 (1967)]

(Cyclopropylmethylene)triphenyl-~ (SC) 557 [G.E. 79, 576 (1967)]

Phosphoric triesters, Synthesis of oligonucleotides by use of ~ (SC) 695 [G.E. 79, 684 (1967)]

Phosphorin derivatives, Preparation of ~ from pyrylium salts and phosphine (SC) 944 [G.E. 79, 947 (1967)]

Phosphorine, Electrophilic reactions of 2,4,6-triphenylphosphabenzene (SC) 87 [G.E. 79, 59 (1967)]

Stable anion radicals from 2,4,6-triphenyl-~ (SC) 445 [G.E. 79, 410 (1967)]

New synthesis of ~ derivatives (SC) 458 [G.E. 79, 475 (1967)]

Dibenzo[*b,e*]-~ (SC) 567 [G.E. 79, 533 (1967)]

Determination, by ESR spectroscopy, of the constitution of the phosphorus radicals formed on oxidation of ~ (SC) 711 [G.E. 79, 725 (1967)]

Phosphorus, α-Aminoalkylation of white ~ (CR) 984 [G.E. 79, 1004 (1967)]

Gmelins Handbuch der anorganischen Chemie (Gmelin's handbook of inorganic chemistry) (Book Review) 100

Phosphorus compounds, Linear relation between chemical shifts of the ^{31}P resonance and Hammett constants (SC) 945 [G.E. 79, 946 (1967)]

Reactions of positive halogen organic compounds with phosphorus(III) derivatives (CR) 265 [G.E. 79, 276 (1967)

Spectroscopic substituent constants of phosphorus-containing groups (SC) 564 [G.E. 79, 533 (1967)]

Phosphorus nitride chloride, Substitution in trimeric ~: The formation of a spirane compound (CR) 982 [G.E. 79, 1002 (1967)]

Phosphorus(V) oxide, Compound formation in ternary metal(II) oxide, ~, and boron(III) oxide systems (CR) 964 [G.E. 79, 984 (1967)]

Phosphorus radicals, New, stable ~ (SC) 85 [G.E. 79, 85 (1967)]

Determination, by ESR spectroscopy of the constitution of the ~ formed on oxidation of phosphorins (SC) 711 [G.E. 79, 725 (1967)]

Phosphorylase, Apo-~ b from rabbit muscle (LA) 187

Phosphorylation, Mitochondrial oxidative ~ (FP) 1035 [G.E. 79, 1088 (1967)]

Phosphorylation, Model experiments on oxidative ~ (CR) 811 [G.E. 79, 826 (1967)]

Phosphoryl difluoride isothiocyanate, Preparation of ~ and phosphoryl fluoride diisothiocyanate (SC) 90 [G.E. 79, 61 (1967)]

Phosphoryl fluoride diisothiocyanate, Preparation of phosphoryl difluoride isothiocyanate and ~ (SC) 90 [G.E. 79, 61 (1967)]

Phosphoryl fluorosulfate, Difluorothio-~ (SC) 959 [G.E. 79, 980 (1967)]

Phosphorylides, Reaction of ~ with 2-chlorovinyl ketones (SC) 877 [G.E. 79, 899 (1967)]

Photoaddition, of carbonyl compounds to allenes (LA) 576

1,4-~ of pyrrole to benzene (LA) 888

Photocatalysis, by semiconductors on metal supports. Photosensitized oxidation of CO with Co_3O_4, NiO, and ZnO on silver supports (CR) 999 [G.E. 79, 1019 (1967)]

Photochemical rearrangement, New ~ (LA) 891

Photochemistry, Thermal and photochemical behavior of a [16]annulene (SC) 870 [G.E. 79, 861 (1967)]

Photochemical synthesis of alkyl- and aryl-cyclopropenes (SC) 1084 [G.E. 79, 1104 (1967)]

Photochemical studies of quinizarin (CR) 812 [G.E. 79, 826 (1967)]

Photochemical formation of titanium peroxide (CR) 978 [G.E. 79, 998 (1967)]

States responsible for the photochemical decomposition of formaldehyde (LA) 274

~ (Book Review) 720

Molecular ~ (Book Review) 720

Photodimerization, of uracil sensitized by acetone (SC) 956 [G.E. 79, 944 (1967)]

Photofragmentation, of oxaziranes (SC) 634 [G.E. 79, 648 (1967)]

Photographic process, Fundamental ~ in silver halide crystals (CR) 886 [G.E. 79, 871 (1967)]

Chemie photographischer Prozesse (Chemistry of ~es) (Book Review) 719

Photolysis, of 3β-hydroxy-5α-pregnan-16-one (SC) 1074 [G.E. 79, 1066 (1967)]

Photorearrangement, Formation of 2-oxazolones by ~ of 3-hydroxyisoxazoles (LA) 888

Photoreduction, of ketones and ketimines (CR) 468 [G.E. 79, 425 (1967)]

Photosensitized processes, Investigation of the preparative uses, kinetics, and energetics of ~ at low temperatures (CR) 978 [G.E. 79, 998 (1967)]

1-Phthalazinones, Synthesis of 4-amino-~ (SC) 173 [G.E. 79, 173 (1967)]

Phthalic acid, Determination of benzoic acid and ~ in terephthalic acid by partition chromatography (CR) 373 [G.E. 79, 323 (1967)]

Phthalocyanine, Six oxidation states of the iron-~ complex (SC) 358 [G.E. 79, 313 (1967)]

Macromolecular organic semiconductors with ~ structures (CR) 268 [G.E. 79, 279 (1967)]

Physical chemistry, Advanced ~ (Book Review) 382

Physical organic chemistry (Book Review) 1090

Pigments, Adsorption on, and desorption from ~ (CR) 181 [G.E. 79, 192 (1967)]

Maya blue (LA) 642

Piperidinothiyl, 2,2,6,6-Tetramethyl-~ (LA) 1006

Plastics, Physical causes of aging in ~ (FP) 844 [G.E. 79, 877 (1967)]

Platinum, Electrochemical determination of the specific surface area and the activity of porous ~ (CR) 994 [G.E. 79, 1014 (1967)]

Platinum(II) chloride, Pd_6Cl_{12} and Pt_6Cl_{12} in the gaseous state (SC) 253 [G.E. 79, 244 (1967)]

Platinum complexes, Oxygen complexes of zerovalent nickel, palladium, and platinum (SC) 92 [G.E. 79, 62 (1967)]

Bis-(1,5-cyclooctadiene)platinum(0) (SC) 364 [G.E. 79, 380 (1967)]

A covalent bond between Pt or Au and Si, Sn, or Pb (LA) 1089

Platinum compounds, Pt^{3+} compounds (CR) 980 [G.E. 79, 1000 (1967)]

Platinum electrodes, Sulfur and selenium adsorbate on ~ in acid and alkaline electrolytes (SC) 884 [G.E. 79, 903 (1967)]

Platinum salts, Effective hydrogenation catalysts obtained by reduction of Pt(IV) (LA) 643

Plutonium, Analytical studies on fuels containing ~ (CR) 268 [G.E. 79, 246 (1967)]

Recovery, in aqueous solution, of nuclear fuels of high ~ content (CR) 886 [G.E. 79, 872 (1967)]

Kinetics of the extraction of ~(IV) and of uranium(VI) in the purex process (CR) 969 [G.E. 79, 989 (1967)]

Separation of uranium and ~ by the fractional sublimation of the chlorides (CR) 976 [G.E. 79, 996 (1967)]

Determination of ^{239}Pu in unirradiated nuclear fuel samples by γ-spectroscopy (CR) 982 [G.E. 79, 1002 (1967)]

Dependence of the kinetic energy of some ^{239}Pu fission fragments on the excitation energy of the fissioning nucleus (CR) 986 [G.E. 79, 1006 (1967)]

Extraction of macro-quantities of ~ with tributyl phosphate in the presence of uranium (CR) 988 [G.E. 79, 1008 (1967)]

Ternary alkali metal and alkaline earth fluorides of ~ (CR) 997 [G.E. 79, 1017 (1967)]

Plutonyl ion, Spectrophotometric studies on the hydrolysis and complex formation of the plutonyl and neptunyl ions (CR) 967 [G.E. 79, 987 (1967)]

Poisoning, Klinik und Therapie der Vergiftungen (Clinical treatment and therapy of ~) (Book Review) 644

Polarity, Method for the study of the ~ of the microenvironment of the active site in chymotrypsin (LA) 187

Polarography, Grundlagen der Polarographie (Principles of ~) (Book Review) 579

Polonium, The Chemistry of Selenium, Tellurium and ~ (Book Review) 1090

Polyamides, Synthesis of ~ in the fine-grain form from diphenyl esters and diamines (CR) 461 [G.E. 79, 424 (1967)]

Kunststoff-Handbuch. Band VI: Polyamide. Aufbau, Verarbeitung, Eigenschaften und Anwendung (Handbook of plastics, Volume VI: ~. Constitution, processing, properties, and applications) (Book Review) 1008

Polyarabinonucleotides. Synthesis of ~ with esters of polyphosphoric acid (CR) 460 [G.E. 79, 422 (1967)]

Polycaprolactam, Investigations on the mechanism of the degradation of ~ by thermal oxidation (CR) 1001 [G.E. 79, 1021 (1967)]

Polycyano radicals (LA) 472

Polyepoxides, Autoxidation of ~ (CR) 182 [G.E. 79, 192 (1967)]

Polyesters, Mechanism of formation of ~ from cyclic anhydrides and cyclic ethers with cationic initiators (CR) 462 [G.E. 79, 421 (1967)]

Polyethylene, Investigation of the melting behavior of crystalline ~ produced by degradation with HNO_3 (CR) 467 [G.E. 79, 418 (1967)]

Polyfluorocyclohexenes (LA) 379

Polymerization, of trioxane (FP) 526 [G.E. 79, 512 (1967)]

Active species in homogeneous Ziegler-Natta catalysts for the ~ of ethylene (FP) 790 [G.E. 79, 764 (1967)]

~ reactions on adsorption layers of solids (CR) 988 [G.E. 79, 1008 (1967)]

Carboranebis(sulfenyl chlorides) in ~ reactions (CR) 997 [G.E. 79, 1017 (1967)]

~ of 4-azido-1-butyne (LA) 892

Polymers, Physical causes of aging in plastics (FP) 844 [G.E. 79, 877 (1967)]

Recent studies of optically active ~ (CR) 271 [G.E. 79, 280 (1967)]

~ with atropisomeric biphenyl structural units (CR) 461 [G.E. 79, 422 (1967)]

~ and co-~ of diazoalkanes (CR) 462 [G.E. 79, 423 (1967)]

Electron-microscope and X-ray investigations on the structure of drawn high ~ (CR) 465 [G.E. 79, 417 (1967)]

Investigations on the flow behavior of ~ in relation to their molecular structure (CR) 466 [G.E. 79, 420 (1967)]

Torsional vibration measurements on high ~ in the rubber-elastic range (CR) 466 [G.E. 79, 421 (1967)]

Thermodynamic (maximum) melting points of oligomeric and polymeric single-component and multi-component system (CR) 467 [G.E. 79, 420 (1967)]

Cross-linked ~ from α,α'-*p*-phenylenediacrylonitrile (CR) 639 [G.E. 79, 624 (1967)]

Demixing phenomena in high ~ and their technical importance (CR) 962 [G.E. 79, 949 (1967)]

Structural analysis of ~ in solution (CR) 966 [G.E. 79, 986 (1967)]

Investigation of high ~ by pyrolysis (CR) 987 [G.E. 79, 1007 (1967)]

Torsional vibration measurements on co-~ of methyl methacrylate and (tri-n-propyl)tin methacrylate (CR) 995 [G.E. 79, 1015 (1967)]

Semiconducting properties of some nitriles and their ~ with a porphyrazine structure (CR) 1004 [G.E. 79, 1024 (1967)]

Yellow to red co-~ (LA) 378

Polymer solutions, Influence of the order in ~ on light scattering (CR) 465 [G.E. 79, 416 (1967)]

Polynucleotides, Dynamic investigations on oligo- and ~ (CR) 459 [G.E. 79, 417 (1967)]

Polyolefins, Structural investigations on ~ by means of pyrolysis and gas chromatography (CR) 985 [G.E. 79, 1005 (1967)]

Polyoxymethylene, Polymerization of trioxane (FP) 526 [G.E. 79, 512 (1967)]

Polypeptides, Side-chain interactions in ~ Experiments with donor-acceptor complexes (CR) 469 [G.E. 79, 425 (1967)]

Polyphosphines, Structure, preparation, and properties of cyclo-~ (CR) 887 [G.E. 79, 908 (1967)]

Preparation and structure of open-chain and cyclic ~ (LA) 187

Polyphosphoric acid, Cyclization of acid chlorides by ~ (SC) 1086 [G.E. 79, 1100 (1967)]

Synthesis of polyarabinonucleotides with esters of ~ (CR) 460 [G.E. 79, 422 (1967)]

Polyurethanes, Kunststoff-Handbuch. Band VII: Polyurethane. Herstellung, Eigenschaften, Verarbeitung u. Anwendung (Handbook of plastics. Volume VII: ~. Production, properties, processing, and applications) (Book Review) 1009

Porphobilinogen, Preparation of ~ from 5-aminolevulic acid by means of *Propionibacterium shermanii* (SC) 883 [G.E. 79, 905 (1967)]

Porphyrazine, Semiconducting properties of some nitriles and their polymers with a ~ structure (CR) 1004 [G.E. 79, 1024 (1967)]

Porphyrins, Petro-~ from bituminous shales (CR) 975 [G.E. 79, 995 (1967)]

Potassium, Experiments on the scattering of molecular beams, for the study of reactions of ~ with methyl iodide, hydrogen bromide, and bromine (CR) 887 [G.E. 79, 907 (1967)]

Potassium amide, Solutions of ~ in liquid ammonia (LA) 1089

Potassium polyphosphide, KP_{15}, a new ~ (SC) 356 [G.E. 79, 323 (1967)]

Potential distribution, and charge distribution at semiconductor-electrolyte interfaces (FP) 851 [G.E. 79, 833 (1967)]

Praseodymium, Determination of some excitation functions for deuteron reactions with ^{141}Pr (CR) 981 [G.E. 79, 1001 (1967)]

5α-Pregnan-16-one, Photolysis of 3β-hydroxy-~ (SC) 1074 [G.E. 79, 1066 (1967)]

Preparative organic chemistry, New methods of ~: Organic syntheses with imides of sulfur dioxide (FP) 149 [G.E. 79, 109 (1967)]

New methods of ~: Synthesis and reactions of cyanic esters (FP) 206 [G.E. 79, 219 (1967)]

New methods of ~: Syntheses of thiocarbamates (FP) 281 [G.E. 79, 285 (1967)]

New methods of ~: Formation of C—C-bonds with the aid of α-halogeno ethers, sulfides, and amines (FP) 335 [G.E. 79, 358 (1967)]

New methods of ~: Syntheses of isocyanide dihalides (FP) 649 [G.E. 79, 663 (1967)]

New methods of ~: Transfer of diazo groups (FP) 733 [G.E. 79, 786 (1967)]

New methods of ~: Syntheses with ketones, sulfur, and ammonia or amines at room temperature (FP) 907 [G.E. 79, 953 (1967)]

Preparative organic synthesis, Spatial arrangement and ~ (FP) 778 [G.E. 79, 774 (1967)]

Pressure, Effect of ~ on the equilibrium between hydrogen and solvated electrons in potassium amide-ammonia solutions (SC) 1076 [G.E. 79, 1046 (1967)]

Variation of melting temperature with ~ (LA) 577

Propionibacterium shermanii, Preparation of porphobilogen from 5-aminolevulic acid by means of ~ (SC) 883 [G.E. 79, 905 (1967)]

Protease, Extraintestinal ~ of bluebottles (LA) 186

Protactinium-238, a new nuclide, and its role in the formation of heavy transuranium elements by multiple neutron capture in uranium-238 (CR) 1000 [G.E. 79, 1020 (1967)]

Protective groups, Selective cleavage of substituted phenylthio (phenylsulfenyl) ~ in peptide syntheses (LA) 188

Trimethylsilyl group as ~ for aromatic amines in organometallic syntheses (LA) 273

Proteins, Hydrophobic interactions (FP) 195 [G.E. 79, 260 (1967)]

Chemical affinity and structural relationships between ~ and inorganic components in biogenous mineralization (CR) 986 [G.E. 79, 1006 (1967)]

~: Composition, structure, and function (Book Review) 646

Protein biosynthesis, Stoichiometry of GTP-cleavage during ~ (LA) 576

Protein sequenator (LA) 888

Proteinase inhibitors, Natürliche Proteinasen-Inhibitoren (Natural ~) (Book Review) 1008

Pseudohalides, Preparation of carbonyl and fluorocarbonyl ~ in molten salts (SC) 871 [G.E. 79, 860 (1967)]

Purex process, Kinetics of the extraction of plutonium(IV) and of uranium(VI) in the ~ (CR) 969 [GIE. 79, 989 (1967)]

Purine, New, mild ~ ring closure (SC) 258 [G.E. 79, 233 (1967)]

3-Methyl-~ (LA) 100

Pyrazolones, Transformation of basically substituted ~ (CR) 266 [G.E. 79, 277 (1967)]

Pyrazolo[3,4-*b*]pyridines (SC) 958 [G.E. 79, 981 (1967)]

Pyrazoloquinones, Vinyl-~ (CR) 992 [G.E. 79, 1012 (1967)]

Pyridines, as stabilisers of free boron radicals (SC) 255 [G.E. 79, 241 (1967)]

Syntheses of triazines, pyrimidines, and ~ from nitriles (CR) 183 [G.E. 79, 154 (1967)]

2-Pyridinecarbaldehyde oximes (LA) 99 [G.E. 79, 67 (1967)]

Pyridine-2-carboxylic acids, Stability and properties of the complexes of hexavalent actinides with ~ (CR) 993 [G.E. 79, 1013 (1967)]

Pyrimidines, Syntheses and reactions of 4-acylimino-5-acyloxyimino-~ (SC) 259 [G.E. 79, 234 (1967)]

Syntheses of triazines, ~, and pyridines from nitriles (CR) 183 [G.E. 79, 154 (1967)]

Pyrimidinedithiones, One-step syntheses of pyrimidinethiones and ~ (LA) 815

Pyrimidinethiones, One-step syntheses of ~ and pyrimidinedithiones (LA) 815

Pyrophosphates, Synthesis of asymmetric *O,O,O,O*-tetraalkyl dithio-~ (SC) 863 [G.E. 79, 859 (1967)]

Pyrrole, 1,4-Photoaddition of ~ to benzene (LA) 888

Pyrolysis, Investigation of high polymers by ~ (CR) 987 [G.E. 79, 1007 (1967)]

Pyruvate decarboxylase, Structure and mechanism of action of the active center of yeast ~ (FP) 1024 [G.E. 79, 1050 (1967)]

Pyruvate:ferredoxin oxidoreductase (LA) 1007

QUADRANT rule, for the $n\rightarrow\pi^*$ Cotton effect of dithiourethanes from optically active amines (SC) 704 [G.E. 79, 721 (1967)]

Quadricyclanes, Cycloadditions to derivatives of ~ (bishomofuran) (SC) 1070 [G.E. 79, 1103 (1967)]

Quadricyclanone, Cycloadditions to derivatives of methylenequadricyclane and of ~ (bishomocyclobutadiene) (SC) 1069 [G.E. 79, 1102 (1967)]

Quadrupole interaction, Nuclear ~ and molecular structure (CR) 981 [G.E. 79, 1001 (1967)]

Quantum chemistry, Advances in ~ (Book Review) 278

Mathematics for ~ (Book Review) 278

Quantenchemie für Chemiker (~ for chemists) (Book Review) 1089

Quantum mechanics, Kleine Quantenmechanik (~ in brief) (Book Review) 276

Quinaldic acid, Stability and properties of the complexes of hexavalent actinides with ~ (CR) 993 [G.E. 79, 1013 (1967)]

Quinizarin, Photochemical studies of ~ (CR) 812 [G.E. 79, 826 (1967)]

Quinodimethanes, Stable *o*-~ (SC) 171 [G.E. 79, 147 (1967)]

Chemistry of quinonemethides and ~ (CR) [G.E. 79, 279 (1967)]

5,8-Quinolinedione, Synthesis of 7-amino-6-methoxy-~ (SC) 82 [G.E. 79, 100 (1967)]

Quinones, Simple method for introduction of a formylalkyl group into ~ (SC) 174 [G.E. 79, 150 (1967)]

Detection of intramolecular mobility in quinoid systems by NMR spectroscopy (CR) 977 [G.E. 79, 997 (1967)]

Vinylpyrazolo-~ (CR) 992 [G.E. 79, 1012 (1967)]

Derivatives of amphi-anthraquinone, a new ~ system (LA) 889

Quinonemethides, Chemistry of ~ and quinodimethanes (CR) [G.E. 79, 279 (1967)]

RACEMATES, Resolution of ~ of asymmetric phosphinylacetic acids. Model compounds for reactions of phosphinate carbanions (SC) 1078 [G.E. 79, 1070 (1967)]

Radicals, Spin density distribution in 2,4,6-triphenylphenoxyl (FP) 34 [G.E. 79, 69 (1967)]

Free-~ decomposition of azo compounds induced by organotin hydrides (SC) 76 [G.E. 79, 52 (1967)]

New, stable phosphorus ~ (SC) 85 [G.E. 79, 85 (1967)]

Anion ~ from 1-nitroolefins (SC) 251 [G.E. 79, 240 (1967)]

Pyridines as stabilisers of free boron ~ (SC) 255 [G.E. 79, 241 (1967)]

ESR spectrum of a non-degenerate state of the benzene ~ anion (SC) 360 [G.E. 79, 318 (1967)]

Bisverdazyls $N^1,N^{1'}$-linked by aromatic systems (SC) 362 [G.E. 79, 317 (1967)]

Stable anion ~ from 2,4,6-triphenylphosphorine (SC) 445 [G.E. 79, 410 (1967)]

~, formation on heating of trityl-aluminum or -boron compounds (SC) 452 [G.E. 79, 411 (1967)]

Determination, by ESR spectrocopy of the constitution of the phosphorus ~ formed on oxidation of phosphorins (SC) 711 [G.E. 79, 725 (1967)]

Addition of R_3Ge and R_3Si ~ to multiple bonds (SC) 876 [G.E. 79, 870 (1967)]

Investigation of unstable molecules and free ~ by rotational spectroscopy (CR) 714 [G.E. 79, 727 (1967)]

ESR Spectroscopic studies of nitroxide ~ that are capable of mesomerism (CR) 810 [G.E. 79, 825 (1967)]

Spin density distribution in stable triarylhydrazyls containing no nitro groups (CR) 965 [G.E. 79, 985 (1967)]

Formation and interception of 2,2,2-triphenylethyl-~ (LA) 378

Polycyano ~ (LA) 472

Very stable nitroxide ~ from nitroso-aromatic-olefin adducts (LA) 472

New stable sulfur ~ (LA) 716

2,2,6,6-Tetramethylpiperidinothiyl ~ (LA) 1006

Uncharged fragments of aromatic molecules produced by electron impact (LA) 1007

Advances in free ~ chemistry (Book Review) 475

Radioactive waste water, Decontamination of ~ by salts of fatty acids (CR) 269 [G.E. 79, 247 (1967)]

Radiocarbon, Liquid scintillation counting of benzene and ethanol for ^{14}C measurements in the low-level range (CR) 989 [G.E. 79, 1009 (1967)]

Radiometric analysis, Radiometric isotope-frequency analysis of $^{233}U/^{235}U$ mixtures (CR) 270 [G.E. 79, 248 (1967)]

Rare earth metal oxide, Quasibinary phase diagrams of the systems ~ (Ho, Tm, Lu)/actinide (Th, U, Np, Pu) dioxide (CR) 982 [G.E. 79, 1002 (1967)]

Reactiones organicae, Organische Reaktionen und Methoden (Organic reactions and methods) (Book Review) 816

Reaction mechanism, Aromatic fluorine as a chemical label for detecting ~ (FP) 596 [G.E. 79, 636 (1967)]

Reactivity ratios, Novel method of determining ~ ratios in copolymerization (CR) 463 [G.E. 79, 419 (1967)]

Reactor chemistry (CR) 268 [G.E. 79, 246 (1967)]

Reactors, Use of boron compounds in gas-cooled high-temperature reactors (CR) 270 [G.E. 79, 248 (1967)]

Reactor fuels, Analytical studies on fuels containing plutonium (CR) 268 [G.E. 79, 246 (1967)]

Radiochemical determination of the activities of fission products in irradiated fuel elements (CR) 270 [G.E. 79, 248 (1967)]

Rearrangement, Electron-impact induced ~ reactions of organic molecules (FP) 477 [G.E. 79, 481 (1967)]

Neighboring-group effects and ~ in reactions of cyclopropylmethyl, cyclobutyl, and homoallyl systems (FP) 666 [G.E. 79, 709 (1967)]

~ of the triasterane system (SC) 176 [G.E. 79, 152 (1967)]

Novel ~ processes of transition metal carbene complexes (SC) 181 [G.E. 79, 191 (1967)]

~ of derivatives of benzo[*b*]thiepin and benzo[*b*]thiepin 1,1-dioxide (SC) 255 [G.E. 79, 238 (1967)]

Wittig ~ of a tertiary amine (SC) 557 [G.E. 79, 574 (1967)]

Mechanism of the Wittig ~ of *N*-methyl-*N*-phenylisoindolinium iodide (SC) 559 [G.E. 79, 574 (1967)]

Ortho-semidine ~ of 1,2-diphenyl-1,2-diazetidinone (SC) 630 [G.E. 79, 619 (1967)]

~ of electronegatively substituted guanidines to semicarbazones (SC) 704 [G.E. 79, 688 (1967)]

Addition-~ reactions of transition metal-carbene complexes with selenophenol (SC) 961 [G.E. 79, 982 (1967)]

~ of dihydroisoquinolines (CR) 183 [G.E. 79, 154 (1967)]

~ of cyclic homoallyl compounds (CR) 972 [G.E. 79, 992 (1967)]

endo-Dicyclopentadiene undergoes intermolecular ~ to form *exo*-dicyclopentadiene (LA) 185

Arbusov-type ~ of a >P–O–N grouping (LA) 272

New photochemical ~ (LA) 891

Recoil effects, A study of primary ~ by means of the Mössbauer effect (CR) 1004 [G.E. 79, 1024 (1967)]

Recoil nuclei, Chemical effects of nuclear transformations in solids (FP) 133 [G.E. 79, 128 (1967)]

Recoil tritium, Hydrogen replacement by ~ in simple aliphatic compounds (CR) 999 [G.E. 79, 1019 (1967)]

Redox reactions, Ligand addition and ~ of azido-metal complexes (SC) 169 [G.E. 79, 146 (1967)]

Reduction potentials, Half-wave ~ of 2,5-bis(trimethylsilyl)- and 2,5-di-t-butyl-1,4-benzoquinone (SC) 941 [G.E. 79, 932 (1967)]

Reductive dechlorination, Preparation of fluorocyclopropanes by ~ of chlorofluorocyclopropanes (SC) 629 [G.E. 79, 617 (1967)]

Relaxation times, Surface diffusion and ~ of adsorbed molecules (CR) 886 [G.E. 79, 908 (1967)]

Repression, Inactivation ~ (LA) 716

Repressor, β-Galactosidase ~ (LA) 717

Resorcinols, Ring contraction on oxidation of phenyl-substituted ~ (SC) 948 [G.E. 79, 941 (1967)]

Rhenate, ^{18}O-isotope exchange between ~ ions and water (CR) 1003 [G.E. 79, 1023 (1967)]

Rhenium complexes, Formation of fluoro-organocarbonylmanganese and ~ from hexafluoro-1,3-butadiene and pentacarbonylmanganese and -rhenium hydrides (SC) 878 [G.E. 79, 900 (1967)]

Rhodium amine complexes, Exchange reactions and the annealing of nuclear recoil defects in crystalline ~ (CR) 993 [G.E. 79, 1013 (1967)]

Rhodium compounds, Monomeric and dimeric dicyclopentadienylrhodium and -iridium (LA) 188

Schiff bases of acetylacetone form chelates with Ir(I) and Rh(I) (LA) 814

Ribonucleic acid, Secondary and tertiary structure of transfer ~ (CR) 459 [G.E. 79, 416 (1967)]

Conditions for the binding of mRNA on ribosomes (LA) 99

Evidence of the interaction between aminoacyl-tRNA and transferase I (LA) 100

Conditions for the binding of tRNA on ribosomes (LA) 186

Enzymatic transfer of sulfur from cysteine to tRNA (LA) 186

The primary structure of yeast phenylalanine-tRNA (LA) 1007

Ribonucleotide reductase, Regulation of the specificity of an enzyme (LA) 274

Ribosomes, Conditions for the binding of tRNA on ~ (LA) 186

~ and aminoacyltransferase II (LA) 274

Ribulose diphosphate carboxylase, from spinach leaves (LA) 186

Ring cleavage, Synthesis and thermal ~ of bicyclic cyclobutane derivatives (CR) 995 [G.E. 79, 1015 (1967)]

Ring closure, New ~ Reaction (SC) 81 [G.E. 79, 95 (1967)]

Ring contraction, on oxidation of phenyl-substituted resorcinols (SC) 948 [G.E. 79, 941 (1967)]

Ring expansion, in 1-(isopropenyl)cycloalkanol epoxides (LA) 889

Ring fission, Novel ~ of a 1,3-dimethyl-1*H*-naphtho[1,8-*de*]-1,2,3-triazinium salt (SC) 360 [G.E. 79, 316 (1967)]

Ring inversion, in cycloheptane and in cycloheptene derivatives (SC) 556 [G.E. 79, 577 (1967)]

Ring opening, Model reactions for biological ~ of anthraquinones (SC) 952 [G.E. 79, 935 (1967)]

Theory of ~ reactions (CR) 813 [G.E. 79, 826 (1967)]

Reversible hydrolytic ~ of 2-aminopyridine (LA) 98

Ring structures, Topological approach to the problem of ~ (FP) 723 [G.E. 79, 802 (1967)]

Rodd's chemistry of carbon compounds (Book Review) 894

Rotating disk electrode, Electrophoretic painting on the ~ (CR) 964 [G.E. 79, 984 (1967)]

Rotational spectroscopy, Investigation of unstable molecules and free radicals by ~ (CR) 714 [G.E. 79, 727 (1967)]

Rubidium pentafluoroethoxide, Cesium and ~ (SC) 256 [G.E. 79, 246 (1967)]

Ruthenium complexes, Ruthenium(II, III) dimeric complexes (SC) 264 [G.E. 79, 273 (1967)]

SANDMEYER synthesis, Alternative to the ~ of aromatic bromo compounds (LA) 98 [G.E. 79, 66 (1967)]

Schiff bases, Azo coupling to ~. A new synthesis of naphthimidazole derivatives (SC) 250 [G.E. 79, 237 (1967)]

~ of acetylacetone form chelates with Ir(I) and Rh(I) (LA) 814

1,2,5-Selenadiazole (SC) 364 [G.E. 79, 315 (1967)]

Synthesis of ~ and some of its derivatives (SC) 563 [G.E. 79, 530 (1967)]

Scintillation counting, Liquid ~ of benzene and ethanol for ^{14}C measurements in the low-level range (CR) 989 [G.E. 79, 1009 (1967)]

Selenanthrene, Formation of ~ from diphenyl selenide and of dipotassium triimidotellurite from diphenyl telluride (SC) 1071 [G.E. 79, 1061 (1967)]

Selenide, Electrochemical studies on the electron and ion defect state in α-silver ~ (CR) 992 [G.E. 79, 1012 (1967)]

Selenium, Separation of ~ with the aid of saturated aliphatic and aromatic monoketones (CR) 374 [G.E. 79, 325 (1967)]

The Chemistry of ~, Tellurium and Polonium (Book Review)

Selenium adsorbate, Sulfur and ~ on platinum electrodes in acid and alkaline electrolytes (SC) 884 [G.E. 79, 903 (1967)]

Selenomolybdate, Preparation of diammonium tetra-~ (SC) 257 [G.E. 79, 245 (1967)]

Selenophenol, Addition-rearrangement reactions of transition metal-carbene complexes with ~ (SC) 961 [G.E. 79, 982 (1967)]

Self-diffusion coefficients, Measurement of ~ of Na by heterogeneous solid/melt and solid/solid isotope exchange on sodalite, obsidian, and NaCl (CR) 983 [G.E. 79, 1003 (1967)]

Semicarbazones, Rearrangement of electronegatively substituted guanidines to ~ (SC) 704 [G.E. 79, 688 (1967)]

Semiconducting properties, of some nitriles and their polymers with a porphyrazine structure (CR) 1004 [G.E. 79, 1024 (1967)]

Semiconductor, properties of hexacyanobenzene (CR) 267 [G.E. 79, 278 (1967)]

Macromolecular organic ~-s with phthalocyanine structures (CR) 268 [G.E. 79, 279 (1967)]

Photocatalysis by ~-s on metal supports. Photosensitized oxidation of CO with CO_3O_4, NiO, and ZnO on silver supports (CR) 999 [G.E. 79, 1019 (1967)]

Semiconductor-electrolyte interfaces, Potential and charge distribution at ~ (FP) 851 [G.E. 79, 833 (1967)]

Separation nozzle, Separation of the isotopes of uranium by the ~ process (FP) 507 [German version: Chemie-Ing.-Techn. 39, 1, 80 (1967)]

Sesquifulvalene, 8,9-Diacetyl-~ (SC) 627 [G.E. 79, 616 (1967)]

Sesquifulvalene-7,8,9,10-tetracarboxylate, Synthesis of substituted cyclopentadienylidenepyrans and tetramethyl ~ (SC) 82 [G.E. 79, 96 (1967)]

Sesquiterpenoids, with ten-membered rings (CR) 94 [G.E. 79, 64 (1967)]

Siderochromes, iron-containing substances from microorganisms (CR) 469 [G.E. 79, 424 (1967)]

Silacyclohexane, Reaction of perchloro-1,3,5-tri-~ with methylmagnesium chloride (SC) 1077 [G.E. 79, 1067 (1967)]

Silanes, Formation and properties of carbo-~ (FP) 677 [G.E. 79, 657 (1967)]

Silazanes, Synthesis of new ~ by reaction of silicon tetrachloride with ammonia (SC) 446 [G.E. 79, 409 (1967)]

Reactions of hexachlorodi-~ (SC) 447 [G.E. 79, 409 (1967)]

Silicides, Preparation and properties of titanium ~ (CR) 987 [G.E. 79, 1007 (1967)]

Silicon borides, Pyrolytic preparation of ~ (CR) 267 [G.E. 79, 278 (1967)]

Silicon complexes, A covalent bond between Pt or Au and Si, Sn, or Pb (LA) 1089

Silicon compounds, Substitution effects in organo-~ (CR) 96 [G.E. 79, 102 (1967)]

Silicon-nitrogen heterocycles, containing C=N double bonds (SC) 89 [G.E. 79, 60 (1967)]

New five- and six-membered ~ (LA) 472

Silicon radicals, Addition of R_3Ge and R_3Si radicals to multiple bonds (SC) 876 [G.E. 79, 870 (1967)]

Siloxane, compounds of the transition metals (FP) 683 [G.E. 79, 697 (1967)]

Synthesis and reactions of ~-substituted phenols (CR) 462 [G.E. 79, 418 (1967)]

Silver-cadmium alloy, Kinetics of the oxidation of a ~ containing 51 atom-% of Cd. A contribution to the Hedvall effect (CR) 972 [G.E. 79, 992 (1967)]

Silver compounds, Ag_2^+ ions from silver atoms and silver(I) (LA) 274

Silver halide crystals, Fundamental photographic process in ~ (CR) 886 [G.E. 79, 871 (1967)]

α-Silver selenide, Electrochemical studies on the electron and ion defect state in ~ (CR) 992 [G.E. 79, 1012 (1967)]

Silylamines, Reaction of some ~ with CO_2, COS, and CS_2 (LA) 642

Silylbenzenes, UV and ESR studies of *p*-bis(trimethylsilyl)- and *p*-dialkylbenzenes (SC) 941 [G.E. 79, 933 (1967)]

Silyl-1,4-benzoquinone, Half-wave reduction potentials of 2,5-bis(trimethylsilyl)- and 2,5-di-t-butyl-1,4-benzoquinone (SC) 941 [G.E. 79, 932 (1967)]

Silylethylenes, Ionization energies of silyl and alkyl-ethylenes (SC) 1085 [G.E. 79, 1106 (1967)]

Silyl groups, Substituent effects of β-trimethyl-~ in bis-, tetrakis-, and hexakis-(trimethylsilyl)-*p*-xylenes (SC) 942 [G.E. 79, 934 (1967)]

Silylphosphines, Reactions of ~. – Formation of lithium tris(diethylphosphinyl)silicide (SC) 1078 [G.E. 79, 1068 (1967)]

Silyl phosphinites, Synthesis of ~ (SC) 88 [G.E. 79, 59 (1967)]

Silylxylenes, Substituent effects of β-trimethylsilyl groups in bis-, tetrakis-, and hexakis(trimethylsilyl)-*p*-xylenes (SC) 942 [G.E. 79, 934 (1967)]

Silylstannylamine, Synthesis of a germyl-~ (SC) 446 [G.E. 79, 410 (1967)]

Small molecules, Structure of ~ (Book Review) 105

Sodalite, Measurement of self-diffusion coefficients of Na by heterogeneous solid/melt and solid/solid isotope exchange on ~ (CR) 983 [G.E. 79, 1003 (1967)]

Sodium, Optical behavior of solutions of ~ in ammonia at high pressure (CR) 575 [G.E. 79, 585 (1967)]

Measurement of self-diffusion coefficients of ~ by heterogeneous solid/melt and solid/solid isotope exchange on sodalite, obsidian, and NaCl (CR) 983 [G.E. 79, 1003 (1967)]

Gmelins Handbuch der anorganischen Chemie (Gmelin's handbook of inorganic chemistry) (Book Review) 100

Reaction of liquid barium/~ solutions with nitrogen (LA) 1008

Sodium hydrazide, Cleavage of β-halogeno-α-phenylalkanes by ~ (SC) 170 [G.E. 79, 147 (1967)]

Solids, Chemical effects of nuclear transformations in ~ (FP) 133 [G.E. 79, 128 (1967)]

Solvated electrons, Effect of pressure on the equilibrium between hydrogen and ~ in potassium amide-ammonia solutions (SC) 1076 [G.E. 79, 1064 (1967)]

Solvent, Dimethyl sulfoxide as ~ (FP) 318 [G.E. 79, 340 (1967)]

Hexamethylphosphoramide as ~ (FP) 1046 [G.E. 79, 1029 (1967)]

Influence of the ~ on coordination-chemical reactions (CR) 271 [G.E. 79, 279 (1967)]

Solvent structure, Effect of ~ on dissociation (CR) 266 [G.E. 79, 276 (1967)]

Spatial arrangement, and preparative organic synthesis (FP) 778 [G.E. 79, 774 (1967)]

Specificity, Change in the ~ of chymotrypsin (LA) 186

Spectroscopy, Chemical gamma-resonance ~ (FP) 830 [G.E. 79, 844 (1967)]

Matrix ~ (CR) 266 [G.E. 79, 277 (1967)]

Investigation of unstable molecules and free radicals by rotational ~ (CR) 714 [G.E. 79, 727 (1967)]

Determination of ^{239}Pu in unirradiated nuclear fuel samples by γ-~ (CR) 982 [G.E. 79, 1002 (1967)]

Anwendungen der Schwingungsspektroskopie in der Anorganischen Chemie (Applications of vibrational ~ in inorganic chemistry) (Book Review) 379

Atomic absorption ~ (Book Review) 721

UV-Atlas organischer Verbindungen (UV-atlas of organic compounds) (Book Review) 815

Spin density distribution, in 2,4,6-triphenylphenoxyl (FP) 34 [G.E. 79, 69 (1967)]

Spirans, Isomerism of ~ (CR) 184 [G.E. 79, 155 (1967)]

Spiro compounds, *N*- and *O*-heterocyclic ~ (CR) 995 [G.E. 79, 1015 (1967)]

Spiroheterocycles, Tetrakis[(alkali-metalphenylphosphino)methyl] - methanes and their conversion into metal-containing and metal-free ~ (SC) 355 [G.E. 79, 380 (1967)]

Sporidesmin C, Unusual eight-membered ring with 3 adjacent sulfur atoms (LA) 185

Squaric acid, Cyclobutenediylium cation, a novel chromophore from ~ (SC) 553 [G.E. 79, 581 (1967)]

Stannylamine, Synthesis of a germylsilyl-~ (SC) 446 [G.E. 79, 410 (1967)]

Statistical mechanics, Applications of ~ (Book Review) 722

Stereochemistry, Spatial arrangement and preparative organic synthesis (FP) 778 [G.E. 79, 774 (1967)]

Electron-pair repulsions and molecular shape (FP) 819 [G.E. 79, 885 (1967)]

Organic ~ (Book Review) 895

Stereoselective syntheses, Spatial arrangement and preparative organic synthesis (FP) 778 [G.E. 79, 774 (1967)]

Stereoselectivity, of the addition of olefins to phenylhalocarbenoids (LA) 273

The stereoselective efficiency of hydrogenation catalysts (LA) 1008

Steroids, New fragmentation reaction of 20-chloro-16β-hydroxy ~ (SC) 631 [G.E. 79, 619 (1967)]

4-Chloro-1α,2α:6β,7β-bismethylene-~ (SC) 799 [G.E. 79, 815 (1967)]

Identification of the subsidiary ~ from the prothoracic protective gland system of *Dytiscus marginalis* (SC) 881 [G.E. 79, 902 (1967)]

Stevens rearrangement, Borate complexes derived from lithium carbenoids – mechanism of the "inverse ~" (SC) 74 [G.E. 79, 50 (1967)]

Streptamine, Simple synthesis of ~ and actinamine (SC) 254 [G.E. 79, 239 (1967)]

Structural analysis, of polymers in solution (CR) 966 [G.E. 79, 986 (1967)]

Structure research, Advances in ~ by diffraction methods (Book Review) 474

Substituent constants, Spectroscopic ~ of phosphorus-containing groups (SC) 564 [G.E. 79, 533 (1967)]

Calcutation of ~ from spectroscopic data (CR) 996 [G.E. 79, 1016 (1967)]

Substitution effects, in organosilicon compounds (CR) 96 [G.E. 79, 102 (1967)]

Sugar carboxylic acids, Isomeric peroxy esters of ~ (SC) 950 [G.E. 79, 940 (1967)]

Sulfanes, Preparation of diimidazolyl-~ and di(aziridinyl)sulfanes (SC) 703 [G.E. 79, 690 (1967)]

Sulfenes, Sulfines and ~ – the *S*-oxides and *S,S*-dioxides of thioaldehydes and thioketones (FP) 107 [G.E. 79, 161 (1967)]

Sulfenic acids, Isomeric chlorides and fluorides of ~ (SC) 706 [G.E. 79, 686 (1967)]

Existence of t-butyl-~ (LA) 891

Sulfides, Formation of C–C-bonds with the aid of α-halogeno ethers, ~, and amines (FP) 335 [G.E. 79, 358 (1967)]

New syntheses of secondary phosphine ~ (LA) 187

New route to symmetrical tri-~ (LA) 889

Sulfines, and sulfenes – the *S*-oxides and *S,S*-dioxides of thioaldehydes and thioketones (FP) 107 [G.E. 79, 161 (1967)]

N-Sulfinylsulfonamides, Stereochemistry of the cycloadditions of sulfonyl isocyanates and ~ to enol ethers (SC) 951 [G.E. 79, 936 (1967)]

N-Sulfinylurethanes, Synthesis of ~ (SC) 357 [G.E. 79, 312 (1967)]

Sulfonamide, Preparation of *N*-(dichloromethylene)-chloro-~ and -fluoro-~ (SC) 882 [G.E. 79, 904 (1967)]

Sulfonation, and related reactions (Book Review) 104

Sulfonium salts, Dialkyl(triphenylphosphoniomethyl)sulfonium bis-salts and their conversion into stable ylide salts (SC) 249 [G.E. 79, 242 (1967)]

Synthesis of 1-deuterioalkyl halides from cyclic *S*-alkyl-~ and heavy water (SC) 371 [G.E. 79, 378 (1967)]

Sulfonylazide, Acid-catalysed amination of aromatic compounds with arene-~ (LA) 100 [G.E. 79, 67 (1967)]

Sulfonyl isocyanates, Stereochemistry of the cycloadditions of ~ and *N*-sulfinylsulfonamides to enol ethers (SC) 951 [G.E. 79, 936 (1967)]

Sulfonylylides, Investigation of *S*-vinyl-~ (CR) 993 [G.E. 79, 1013 (1967)]

Sulfur, Action of carbon disulfide and ~ on enamines, ketimines, and CH acids (FP) 294 [G.E. 79, 298 (1967)]

Syntheses with ketones, ~, and ammonia or amines at room temperature (FP) 907 [G.E. 79, 953 (1967)]

Occurrence of cyclododeca-~ in ~ melts (SC) 955 [G.E. 79, 944 (1967)]

Synthesis of 1,2,4-thiadiazoles from nitriles and ~ (SC) 1084 [G.E. 79, 1106 (1967)]

Enzymatic transfer of ~ from cysteine to tRNA (LA) 186

Sulfur adsorbate, and selenium adsorbate on platinum electrodes in acid and alkaline electrolytes (SC) 884 [G.E. 79, 903 (1967)]

Sulfur compounds, Difluoro(trifluoromethylsulfenylimino)sulfur $CF_3SN{=}SF_2$ and bis(trifluoromethylsulfenylimino)-sulfur $CF_3SN{=}S{=}NSCF_3$ (SC) 370 [G.E. 79, 322 (1967)]

New sulfur-containing cyclic compounds (SC) 703 [G.E. 79, 690 (1967)

Sulfur dichloride (fluorosulfonyl)imide, Preparation of sulfur oxide (fluorosulfonyl)imide and ~ (SC) 711 [G.E. 79, 724 (1967)]

Sulfur difluoride, *N*-Cyanimino-~ (SC) 90 [G.E. 79, 98 (1967)]

Sulfur difluoride (difluorophosphinyl)-imide, Synthesis of ~ and sulfur oxide difluoride (fluorosulfonyl)imide (SC) 710 [G.E. 79, 723 (1967)]

Sulfur difluoride (fluorosulfonyl)imide, Synthesis of ~ (SC) 179 [G.E. 79, 153 (1967)]

Sulfur diimide, *N,N'*-Dihalogeno-*S,S*-dimethyl-~ (SC) 91 [G.E. 79, 96 (1967)]

Sulfur dioxide, Organic syntheses with imides of ~ (FP) 149 [G.E. 79, 109 (1967)]

Sulfur oxide difluoride, Synthesis of sulfur difluoride (difluorophosphinyl)imide and ~ (fluorosulfonyl)imide (SC) 710 [G.E. 79, 723 (1967)]

Sulfur oxide difluoride (fluorosulfonyl)-imide, Synthesis of sulfur difluoride (difluorophosphinyl)imide and ~ (SC) 710 [G.E. 79, 723 (1967)]

Sulfur oxide (fluorosulfonyl)imide, Preparation of ~ and sulfur dichloride (fluorosulfonyl)imide (SC) 711 [G.E. 79, 724 (1967)]

Sulfur pseudohalides, (Halogenocarbonyl)-~ (SC) 705 [G.E. 79, 687 (1967)]

Sulfur radicals, New stable ~ (LA) 716

Sulfur ylides, Chemistry of ~ (CR) 575 [G.E. 79, 538 (1967)]

Chemistry of ~ (CR) 962 [G.E. 79, 948 (1967)]

Sulphur compounds, The Chemistry of Organic ~ (Book Review) 1091

Supercritical mercury, Metallic conductivity in ~ (LA) 379

Surface area, Electrochemical determination of the specific ~ and the activity of porous platinum (CR) 994 [G.E. 79, 1014 (1967)]

Surface chemistry, New results in the chemistry of chromium (CR) 574 [G.E. 79, 538 (1967)]

Surface diffusion, and relaxation times of adsorbed molecules (CR) 886 [G.E. 79, 908 (1967)]

Swimming-pool reactor, Use of some short-lived radionuclides for activation analysis by irradiation with the fast neutrons of a ~ (CR) 991 [G.E. 79, 1011 (1967)]

Swiss Chemical Society (CR) 265 [G.E. 79, 276 (1967)]

Synthetic methods, of organic chemistry (Book Review) 277

TEAK wood, Biogenetically important component of ~ (LA) 577

Technetate, ^{18}O-isotope exchange between ~ ions and water (CR) 1003 [G.E. 79, 1023 (1967)]

Technetium hydride, Dicyclopentadienyl-~ (SC) 93 [G.E. 79, 99 (1967)]

Teeth, Inorganic components of the hard tissues of bones and ~ (CR) 376 [G.E. 79, 384 (1967)]

Telluride, Reductive dehalogenation of organic compounds by sodium ~ (SC) 1083 [G. E. 79, 1105 (1967)]

Tellurium, The Chemistry of Selenium, ~ and Polonium (Book Review) 1090

Tellurium-iodine, Halogen-deficient phase in the system ~ (SC) 706 [G.E. 79, 688 (1967)]

Terephthalic acid, Determination of benzoic and phthalic acids in ~ by partition chromatography (CR) 373 [G.E. 79, 323 (1967)]

Distribution chromatography for the analysis of ~ (CR) 374 [G.E. 79, 325 (1967)]

Testosterone, as protective agent of the water beetle *Ilybius* (SC) 558 [G.E. 79, 579 (1967)]

O,O,O,O-Tetraalkyl dithiopyrophosphates, Synthesis of asymmetric ~ (SC) 863 [G.E. 79, 859 (1967)]

1,3,5,7-Tetraaza-2,6-disila-3,7-cyclooctadiene, Silicon-nitrogen heterocycles containing C=N double bonds (SC) 89 [G.E. 79, 60 (1967)]

1,4,7,9b-Tetraazaphenalene, Dodecahydro-~ (LA) 273

2,3,4,7-Tetrabenzo-1,4-thiazepin-3-one, Simple synthesis of ~ (CR) 185 [G.E. 79, 156 (1967)]

Tetracarbonyl(hexamethylbicyclo[2.2.0]-hexadiene)chromium(0) (SC) 634 [G.E. 79, 623 (1967)]

Tetrachlorodicyanophosphates, Preparation of ~ and the existence of tetrachlorodifluorophosphates (SC) 363 [G.E. 79, 316 (1967)]

Tetrachlorodifluorophosphates, Preparation of tetrachlorodicyanophosphates and the existence of ~ (SC) 363 [G.E. 79, 316 (1967)]

Tetracyclo[3.2.0.0^{2,7}0^{4,6}]heptan-3-one, A new route to the ~ system (SC) 1068 [G. E. 79, 1101 (1967)]

Tetrahydropterin, Phenyl-hydroxylation with ~ as activator. – Model for the enzymic synthesis of tyrosine (CR) 185 [G.E. 79, 156 (1967)]

Tetrakis(trimethoxyphosphine)nickel(0), Synthesis of ~ (SC) 563 [G.E. 79, 582 (1967)]

Tetramethoxyallene, the diacetal of carbon suboxide (SC) 808 [G.E. 79, 823 (1967)]

Tetramethylcyclobutadienenickel(II) bromide, Synthesis of ~ with a new nickel(0) complex (SC) 873 [G.E. 79, 897 (1967)]

2,2,6,6-Tetramethylpiperidinothiyl (LA) 1006

Tetrangomycin, and tetrangulol, the first benz[*a*]anthraquinone derivatives from natural sources (LA) 272

Tetrangulol, Tetrangomycin and ~, the first benz[*a*]anthraquinone derivatives from natural sources (LA) 272

Tetraphenylcumulenes, UV-Absorption of α,α,ω,ω-~ with coplanar benzene rings (SC) 954 [G. E. 79, 931 (1967)]

Tetraphenyldiphospha^{v}-1,3,5-triazines, and their salts (SC) 87 [G.E. 79, 100 (1967)]

Tetraselenomolybdate, Preparation of diammonium ~ (SC) 257 [G.E. 79, 245 (1967)]

Tetrasilacyclopentanes, containing an additional hetero atom in the ring (LA) 473

1,2,5,6-Tetrathiocin, New sulfur-containing cyclic compounds (SC) 703 [G.E. 79, 690 (1967)]

Tetrathiohypophosphonic acid, Dipotassium diphenylhypophosphonate and diphenyl-~ (SC) 883 [G.E. 79, 903 (1967)]

Textbook, Lehrbuch der organischen Chemie (~ of organic chemistry) (Book Review) 1009

Therapy congress, and pharmaceutical exhibition (CR) 96 [G.E. 79, 102 (1967)]

1-Thia-3-aza-2,4-diphospha-cyclobutane, Simple preparation of dithiophosphonic ester halides and of the novel ~ *P,P*-disulfide system (SC) 260 [G.E. 79, 243 (1967)]

1,2,4-Thiadiazoles, Synthesis of ~ from nitriles and sulfur (SC) 1084 [G. E. 79, 1106 (1967)]

1,3,4-Thiadiazole, Simple synthesis of ~ (SC) 361 [G.E. 79, 318 (1967)]

1-Thia-3,5-diphospha^{v}-2,6-diazine, 1-Methyl-3,3,5,5-tetraphenyl-~ (SC) 560 [G.E. 79, 577 (1967)]

Δ^{2}-1,2,4-Thiadiazolin-5-ones, Contribution to the chemistry of substituted ~ (CR) 992 [G. E. 79, 1012 (1967)]

1,3-Thiazolidine-4,5-dione, 2-Thioxo-~ (SC) 358 [G.E. 79, 313 (1967)]

1,3-Thiazolin-2-ones, Preparation of 5-alkyl-~ by reaction of *S*-chloroisothiocarbamoyl chlorides with aldehydes and vinyl ethers (SC) 1073 [G. E. 79, 1063 (1967)]

Thienylbenzoquinones, Furyl- and ~ (LA) 378

Thiepanols, Transannular 1,4-hydrogen bridges in ~ (SC) 872 [G.E. 79, 863 (1967)]

Thiepin 1,1-dioxide, Synthesis of ~ (LA) 717

Thin-layer chromatography, Dünnschichtchromatographie in der Aminosäure- und Peptidchemie (~ in amino acid and peptide chemistry) (Book Review) 473

Thioamide group, Oxidation reactions of the ~ (CR) 468 [G.E. 79, 426 (1967)]

Thiocarbamates, Syntheses of ~ (FP) 281 [G.E. 79, 285 (1967)]

Thiocarbonyl isothiocyanate, Fluoro-~ (SC) 940 [G. E. 79, 978 (1967)]

Thiocyanic acid, Reaction of monosaccharides with ~ (LA) 889

Thioformates, Metalated ortho-~ (SC) 442 [G.E. 79, 468 (1967)]

Thiol groups, Histochemical detection of ~ (LA) 187

Thionylcyanamide (SC) 701 [G.E. 79, 691 (1967)]

Thiophenols, Conversion of phenols into ~ (LA) 472

Thiophosphinic acid, Metal complexes of diethyl-~ (SC) 175 [G.E. 79, 148 (1967)]

Thiophosphoryl difluoride isothiocyanate Synthesis of ~ and thiophosphoryl fluoride diisothiocyanate (SC) 90 [G.E. 79, 61 (1967)]

Thiophosphoryl fluoride diisothiocyanate, Synthesis of thiophosphoryl difluoride isothiocyanate and ~ (SC) 90 [G.E. 79, 61 (1967)]

Thiophosphoryl fluorosulfate, Difluoro-~ (SC) 959 [G. E. 79, 980 (1967)]

Thiophosphoryl group, Nucleophilic reactivity of the ~ (FP) 1013 [G. E. 79, 1077 (1967)]

Thiosulfates, Chemistry of Bunte salts (FP) 544 [G.E. 79, 520 (1967)]

Thioureas, Preparation of *S*-aminoiso-~ by nucleophilic substitution of *S*-chloro-isothiocarbamoyl chlorides (SC) 1072 [G. E. 79, 1062 (1967)]

2-Thioxo-1,3-thiazolidine-4,5-dione (SC) 358 [G.E. 79, 313 (1967)]

Three-membered rings, Valence isomerizations of hydrocarbons containing ~ (SC) 694 [G.E. 79, 680 (1967)]

Tin, content of incondensed milk (CR) 885 [G.E. 79, 872 (1967)]

Half-lives of the ^{129}Sn nuclear isomers (LA) 187

Tin complexes, A covalent bond between Pt or Au and Sn (LA) 1089

Tin compounds, Free-radical decomposition of azo compounds induced by organotin hydrides (SC) 76 [G.E. 79, 52 (1967)]

Imidophosphinatotin halides (SC) 252 [G.E. 79, 242 (1967)]

Torsional vibration measurements on copolymers of methyl methacrylate and (tri-n-propyl)tin methacrylate (CR) 995 [G. E. 79, 1015 (1967)]

Crystal structure of dimethyltin difluoride (LA) 188

Dialkyltin dithiolates from dialkyltin dialkoxides and oxides (LA) 643

Titanium peroxide, Photochemical formation of ~ (CR) 978 [G. E. 79, 998 (1967)]

Titanium silicides, Preparation and properties of ~ (CR) 987 [G. E. 79, 1007 (1967)]

Topology, Topological approach to the problem of ring structures (FP) 723 [G.E. 79, 802 (1967)]

Torsional vibration, measurements on high polymers in the rubber-elastic range (CR) 466 [G.E. 79, 421 (1967)]

~ measurements on copolymers of methyl methacrylate and (tri-n-propyl)-tin methacrylate (CR) 995 [G. E. 79, 1015 (1967)]

The ~s of the chlorinated ethanes (LA) 1089

β-Tosyloxy aldehydes, Solvolysis reaction of ~ (CR) 1002 [G. E. 79, 1022(1967)]

Transamination, Synthesis of phospha- and diphospha-1,3,5-triazines by cyclizing ~ with aminophosphazenes (SC) 565 [G.E. 79, 534 (1967)]

Transfer ribonucleic acid, Secondary and tertiary structure of ~ (CR) 459 [G.E. 79, 416 (1967)]

Determination of the secondary and tertiary structure of nucleic acids by chemical methods (CR) 642 [G.E. 79, 624 (1967)]

Bonding of ^{32}P-labeled trinucleotides to ~ (LA) 643

Transglycosidation, Recent studies of mechanism in the carbohydrate field (CR) 95 [G.E. 79, 65 (1967)]

Transition metals, Trifluorophosphine complexes of ~ (FP) 53 [G.E. 79, 27 (1967)]

Siloxane compounds of the ~ (FP) 683 [G.E. 79, 697 (1967)]

Nitrogen fixation on new ~ complexes (SC) 873 [G.E. 79, 898 (1967)]

Organometallic and hydrogen compounds of some ~ (CR) 571 [G.E. 79, 537 (1967)]

~ chemistry (Book Review) 279

Transport, Active ~ of ions through biogenic membranes (CR) 640 [G.E. 79, 624 (1967)]

Transuranium elements, Some aromatic complexes of the ~ (CR) 964 [G. E. 79, 984 (1967)]

The true nature of the ~ reported by O. Hahn, L. Meitner, and F. Strassmann (CR) 985 [G. E. 79, 1005(1967)]

Protactinium-238, a new nuclide, and its role in the formation of heavy ~ by multiple neutron capture in uranium-238 (CR) 1000 [G. E. 79, 1020 (1967)]

Triarylhydrazyls, Stable ~ containing no nitro groups (CR) 965 [G. E. 79, 985 (1967)]

Triarylphosphines, Resolution of chiralic ~ (SC) 700 [G.E. 79, 721 (1967)]

Triasterane, Rearrangements of the ~ system (SC) 176 [G.E. 79, 152 (1967)]

1,3,5-Triaza-2,4-disila-5-cyclohexene, Silicon-nitrogen heterocycles containing C=N double bonds (SC) 89 [G.E. 79, 60 (1967)]

Triazenium tetrachloroantimonate(III), Bis(triphenylphosphine)- ~ (SC) 953 [G. E. 79, 938 (1967)]

s-Triazine, Gattermann aldehyde syntheses with ~ in place of hydrogen cyanide (SC) 940 [G. E. 79, 978 (1967)]

Triazines, Syntheses of ~, pyrimidines, and pyridines from nitriles (CR) 183 [G.E. 79, 154 (1967)]

Substituted diphospha-1,3,5-~ (CR) 996 [G. E. 79, 1016 (1967)]

s-Triazolium cations, Synthesis of ~ by reaction of alkoxydiazenium salts with nitrogen heterocycles (SC) 699 [G.E. 79, 682 (1967)]

[1,2,3]Triazolo[1,5-*a*]benzimidazole, Synthesis of 1,3-triaryl[1,2,3]triazolo[5,1-*b*]-benzothiazolium and -benzimidazolium salts and of 1,3-diphenyl-~ (SC) 261 [G.E. 79, 272 (1967)]

[1,2,3]Triazolo[5,1-*b*]benzothiazolium salts, Synthesis of 1,3-triaryl-~ and -benzimidazolium salts and of 1,3-diphenyl[1,2,3]triazolo[1,5-*a*]benzimidazole (SC) 261 [G.E. 79, 272 (1967)]

Tribenzothiepin *S,S*-dioxide, Synthesis of an optically active ~ (SC) 370 [G.E. 79, 319 (1967)]

Tributyl phosphate, Extraction of macroquantities of plutonium with ~ in the presence of uranium (CR) 988 [G. E. 79, 1008 (1967)]

Tricarbonylcyclooctatetraeneiron, Preparation of derivatives of bicyclo[4.2.2]-deca-2,4,7,9-tetraene from ~ (SC) 79 [G.E. 79, 55 (1967)]

Tricarbonylhexamethylborazolechromium (SC) 91 [G.E. 79, 63 (1967)]

Tricarbonyl(organometalophosphine)-nickel(0) (SC) 701 [G.E. 79, 692 (1967)]

Trichlorogermane, Reactions of ~ with ketones and alcohols (SC) 628 [G.E. 79, 617 (1967)]

Trichlorovinylamines (LA) 890

Tricyclo[4.1.0.0^{4,6}]heptane, and tricyclo-[5.1.0.0^{5,7}]octane (LA) 273

Tricyclo[5.1.0.0.^{5,7}]octane, Tricyclo-[4.1.0.0^{4,6}]heptane and ~ (LA) 273

Trifluoroacetic anhydride, Preparation of heterolytic compounds by treatment of amino acid with ~ (CR) 184 [G.E. 79, 155 (1967)]

3,3,3-Trifluoroalanine, Simple synthesis of ~ (SC) 808 [G.E. 79, 822 (1967)]

Trifluorophosphine complexes, of transition metals (FP) 53 [G.E. 79, 27 (1967)]

Trimethyl(methylene)phosphorane (SC) 448 [G.E. 79, 412 (1967)]

Trimethylphosphine imide, Synthesis and reactions with organometallic compounds (SC) 449 [G.E. 79, 413 (1967)]

Trimethylsilylethoxycarbonylcarbene, Triphenylstannyl- and ~ from ethyl diazo-(triphenylstannyl)- and -(trimethylsilyl)-acetate (SC) 884 [G.E. 79, 906 (1967)]

Trimethylsilyl group, Substituent effects of β-~s in bis-, tetrakis-, and hexakis-(trimethylsilyl)-*p*-xylenes (SC) 942 [G. E. 79, 934 (1967)]

~, as protective group for aromatic amines in organometallic syntheses (LA) 273

Trioxane, Polymerization of ~ (FP) 526 [G.E. 79, 512 (1967)]

2,2,2-Triphenylethyl radical, Formation and interception of the ~ (LA) 378

Triphenyl-lead, Partition of ~ derivatives between aqueous and organic phases (CR) 373 [G.E. 79, 323 (1967)]

2,4,6-Triphenylphenoxyl, Spin density distribution in ~ (FP) 34 [G.E. 79, 69 (1967)]

2,4,6-Triphenylphosphabenzene, Electrophilic reactions of ~ (SC) 87 [G.E. 79, 59 (1967)]

2,4,6-Triphenylphosphorine, Stable anion radicals from ~ (SC) 445 [G.E. 79, 410 (1967)]

Triphenylstannylethoxycarbonylcarbene, and trimethylsilylethoxycarbonylcarbene from ethyl diazo-(triphenylstannyl)- and -(trimethylsilyl)-acetate (SC) 884 [G.E. 79, 906 (1967)]

Triple bond, Additions to the activated CC-~ (FP) 423 [G.E. 79, 389 (1967)]

Double 1,3-dipolar addition to a ~, to give the bicyclo[1.1.0]butane system (SC) 79 [G.E. 79, 98 (1967)]

Triquinocyclopropane, Synthesis of a ~ a diquinocyclopropane and a diquinoethylene (LA) 814

Tris-(7*H*-dibenzo[*c,g*]fluorenylideneme-thyl)methane, a new highly acidic hydrocarbon (SC) 635 [G.E. 79, 648 (1967)]

1,3,5-Trisilacyclohexane, Reaction of perchloro-~ with methylmagnesium chloride (SC) 1077 [G. E. 79, 1067 (1967)]

Trisodium hexahydridoaluminate (LA) 577

Trisulfides, New route to symmetrical ~ (LA) 889

Tritium, Hydrogen replacement by recoil ~ in simple aliphatic compounds (CR) 999 [G. E. 79, 1019 (1967)]

Tritylaluminum, Radical formation on heating of ~ or -boron compounds (SC) 452 [G.E. 79, 411 (1967)]

Tritylboron, Radical formation on heating of tritylaluminum or ~ compounds (SC) 452 [G.E. 79, 411 (1967)]

Trivial names, Trivialnamenkartei (Card index of ~) (Book Review) 816

Tungstates, New peroxo-~ (CR) 969 [G. E. 79, 990 (1967)]

Tungsten chlorides, Detection of the molecules W_2Cl_6 and W_3Cl_9 in the gaseous state (SC) 637 [G.E. 79, 650 (1967)]

Tungsten trichloride $[W_6Cl_{12}]Cl_6$ (SC) 637 [G.E. 79, 650 (1967)]

Tyrosine, Phenyl-hydroxylation with tetrahydropterin as activator. – Model for the enzymic synthesis of ~ (CR) 185 [G.E. 79, 156 (1967)]

UBIQUINONE-5, Fluoro-coenzyme Q_1 (Fluoro-~)(SC) 957 [G. E. 79, 979 (1967)]

Ullmanns Encyklopädie der technischen Chemie (Ullmann's encyclopedia of industrial chemistry) (Book Review) 719

Uracil, 1,3-Disubstituted 5-acyloxyimino-4-alkylimino-~s as new "activated esters" (SC) 258 [G.E. 79, 234 (1967)]

Photodimerization of ~ sensitized by acetone (SC) 956 [G. E. 79, 944 (1967)]

4-Uracilcarbaldehyde hydrazone (SC) 369 [G.E. 79, 322 (1967)]

Uracilylmethyl cation, C–C-Condensations with the ~ (SC) 702 [G.E. 79, 691 (1967)]

Uranium, Radiometric isotope-frequency analysis of $^{233}U/^{235}U$ mixtures (CR) 270 [G.E. 79, 248 (1967)]

Kinetics of the extraction of plutonium-(IV) and of ~ (VI) in the purex process (CR) 969 [G. E. 79, 989 (1967)]

Separation of ~ and plutonium by the fractional sublimation of the chlorides (CR) 976 [G. E. 79, 996 (1967)]

Extraction of macro-quantities of plutonium with tributyl phosphate in the presence of ~ (CR) 988 [G. E. 79, 1008 (1967)]

The search for new neutron emitters among the fission products of ~ -235 (CR) 998 [G. E. 79, 1018 (1967)]

Uranium isotopes, Separation of ~ by the separation nozzle process (FP) 507 [German version: Chemie-Ing.-Techn. 39, 1, 80 (1967)]

Urethanes, Synthesis of *N*-sulfinyl-~ (SC) 357 [G.E. 79, 312 (1967)]

Uridine, Structure of the ~ dimer produced by UV irradiation of ~ (SC) 250 [G.E. 79, 235 (1967)]

VALENCE isomerizations, of hydrocarbons containing three-membered rings (SC) 694 [G.E. 79, 680 (1967)]

Valence tautomerism, Benzene oxide-oxepin ~ (FP) 385 [G.E. 79, 429 (1967)]

Possible ~ of a mesoionic oxazol-5-one with an acylaminoketene (SC) 367 [G.E. 79, 321 (1967)]

~ in heterocyclic systems (CR) 812 [G.E. 79, 827 (1967)]

Vanadium chlorimide trichloride, The crystal structure of ~ Cl_3VNCl (CR) 1000 [G. E. 79, 1020 (1967)]

Vanadium compounds, Synthesis of pentacarbonyldicyclopentadienyldivanadium and new carbonylphosphine-cyclopentadienylvanadium compounds (SC) 569 [G.E. 79, 569 (1967)]

Vapor pressure, Measurement of ~ differences for isotopic compounds (CR) 713 [G.E. 79, 728 (1967)]

Verdazyls, Bis-~ $N^1,N^{1'}$-linked by aromatic systems (SC) 362 [G.E. 79, 317 (1967)]

Vinyl ethers, Preparation of 5-alkyl-1,3-thiazolin-2-ones by reaction of *S*-chloroisothiocarbamoyl chlorides with aldehydes and ~ (SC) 1073 ([G. E. 79, 1063 (1967)]

Vinyl exchange, Hg(II)-catalysed ~ (LA) 187

Vinyl halides, Synthesis of dienes from ~ via organocopper compounds (SC) 85 [G.E. 79, 101 (1967)]

Vinylpyrazoloquinones, (CR) 992 [G.E. 79, 1012 (1967)]

S-Vinylsulfonylylides, Investigation of ~ (CR) 993 [G. E. 79, 1013 (1967)]

Viridic acid, Use of ~ as coloring matter for foodstuffs (CR) 885 [G.E. 79, 872 (1967)]

Viscosity, of liquid aluminum halides (CR) 713 [G.E. 79, 727 (1967)]

Vitamins, Chemisch-physikalische Vitamin-Bestimmungsmethoden (Physiochemical methods for the determination of ~) (Book Review) 893

WATER, Irregularities in the partial molar enthalpies of mixing of ~ and ~-alcohol mixtures at constant temperature (SC) 1087 [G. E. 79, 1105 (1967)]

The binding of ~ in crystalline zeolites (CR) 967 [G. E. 79, 987 (1967)]

Water beetle, Testosterone as protective agent of the ~ *Ilybius* (SC) 558 [G.E. 79, 579 (1967)]

Water structure, Hydrophobic interactions (FP) 195 [G.E. 79, 260 (1967)]

Willgerodt-Kindler reaction, Synthesis of dicarboxylic acids by the ~ (SC) 944 [G. E. 79, 943 (1967)]

Wittig rearrangement, of a tertiary amine (SC) 557 [G.E. 79, 574 (1967)]

Mechanism of the ~ of *N*-methyl-*N*-phenylisoindolinium iodide (SC) 559 [G.E. 79, 574 (1967)]

X-RAY structure analysis, of a dimer of 1-methylazepine (SC) 805 [G.E. 79, 820 (1967)]

~ of neophorbol (SC) 809 [G.E. 79, 824 (1967)]

YEAST pyruvate decarboxylase, Structure and mechanism of action of the active center of ~ (FP) 1024 [G. E. 79, 1050 (1967)]

Ylides, Reaction of phosphor-~ with 2-chorovinyl ketones (SC) 877 [G.E. 79, 899 (1967)]

Investigation of *S*-vinylsulfonyl-~ (CR) 993 [G. E. 79, 1013 (1967)]

Arsene ~ (LA) 889

Ylide chemistry (Book Review) 817

Ylide salts, Dialkyl(triphenylphosphoniomethyl)sulfonium bis-salts and their conversion into stable ~ (SC) 249 [G.E. 79, 242 (1967)]

Ynamines, see Alkynylamines

ZEOLITES, The binding of water in crystalline ~ (CR) 967 [G. E. 79, 987 (1967)]

Ziegler-Natta catalysts, Active species in homogeneous ~ for the polymerization of ethylene (FP) 790 [G.E. 79, 764 (1967)]

Kinetic studies of the cyclotrimerization of butadiene by ~ (CR) 1088 [G. E. 79, 1074 (1967)]

Ziegler-Natta polymerization, Attempts to characterize the catalytically active center in homogeneous ~ (CR) 464 [G.E. 79, 418 (1967)]

Zinc oxide, Photocatalysis by semiconductors on metal supports, Photosensitized oxidation of CO with ~ on silver supports (CR) 999 [G. E. 79, 1019 (1967)]

Zinc thiolates, Thiolates of cobalt, nickel, copper, and zinc (LA) 716

Zirconium, Corrosion of ~ and ~ alloys (CR) 269 [G.E. 79, 247 (1967)]

Separation of ~ and hafnium (LA) 272
