Some examples of the carboxylation of aromatic compounds are shown in Table 10.

In the case of azulenes, one or two carboxyl groups can be introduced in yields of up to 96 %, depending on the reaction conditions and on the amount of *(135)* [256].

6. Reactions with Diazo Compounds

The reaction of α-halogeno ethers and sulfides with diazomethane, diazoacetic ester, or diazo ketones has so far proved unsatisfactory [257]. 1-Bromoisochroman *(139a)* reacts with diazomethane to give 1-bromomethylisochroman *(139b)* in 23 % yield [64].

(139a), X = Br
(139b), X = CH_2Br

On the other hand, vigorous reaction takes place when diazo compounds are mixed with α-halogeno amines. Dialkyl β-chloroethylamine *(140a)* and ethyl α-chloro-β-dialkylaminopropionate *(140b)* have been obtained by reaction of dialkylchloromethylamine with diazomethane and diazoacetic ester, respectively [237].

$$[R_2\overset{\oplus}{N}{=}CH\text{-}R^1]\,Cl^{\ominus} + N_2CH\text{-}R^2 \longrightarrow R_2N\text{-}\underset{\displaystyle CHCl\text{-}R^2}{\overset{\displaystyle R^1}{CH}}$$

(140a), R^1, R^2 = H
(140b), R^1 = H, R^2 = $CO_2C_2H_5$
(140c), R^1 = CO_2CH_3, R^2 = H

The α-halogeno amine *(35)*, Z = OCH_3, reacts with diazomethane to form *(140c)* [258]. *N*-Cylohexylindenepiperidinium chloride and diazomethane give (1-chloromethylcyclohexyl)piperidine [259].

B. α-Halogeno Ethers as Nucleophiles

1. Grignard Compounds from α-Halogeno Ethers

In the reactions described so far, the α-halogeno ethers have always acted as electrophiles. However, after conversion into Grignard compounds, they should also be able to react as nucleophiles. The preparation of Grignard compounds such as *(141)* was recently accomplished by the reaction of α-chloro ethers with magnesium in methylal, $CH_2(OCH_3)_2$, [260] or in tetrahydrofuran [261, 262].

These rather unstable[268] alkoxymethylmagnesium halides *(141)* have been used for the preparation of 1,2-glycol monoalkyl ethers *(142)*, glycerol 1,3-dialkyl ethers *(143)*, and alkoxyacetic acids[261–263] (see Table 11). Tris(ethoxymethyl)carbinol *(144)* was obtained by reaction with diethyl carbonate[261,267], 1-ethoxypentan-2-one *(145)* by reaction with *N,N*-diethylbutyramide, and α-ethoxyacetophenone *(146)* by reaction with benzonitrile[261].

Table 11. Glycol monoalkyl ethers *(142)* formed in accordance with equations (k) and (l).

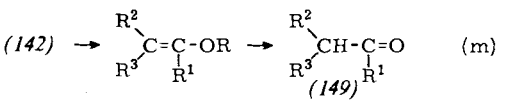
(141) + $C_3H_7-CO-N(C_2H_5)_2$ → $C_3H_7-CO-CH_2-OC_2H_5$ *(145)*

(141) + C_6H_5-CN → $C_6H_5-CO-CH_2-OC_2H_5$ *(146)*

Lithium may be used instead of magnesium as the "reducing agent" for the α-halogeno ether. Methoxymethyl-lithium, which is obtained from monochloromethyl ether and lithium[266], reacts in the same way as methoxymethylmagnesium chloride with carbonyl compounds and CO_2.

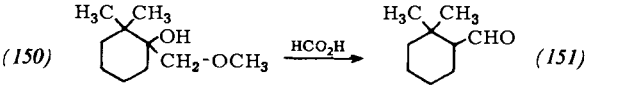
Chloromethyl benzyl sulfide gives the Grignard compound *(147)*, which reacts *e.g.* with acetone to give 1,1-dimethylthioglycol *S*-benzyl ether *(148)*[262].

2. Simultaneous Action of Magnesium and a Ketone on α-Halogeno Ethers



The unstable[268] Grignard compounds of α-halogeno ethers can be prepared only in methylal or tetrahydrofuran. However, α-chloroethers, magnesium, and carbonyl compounds will react directly in ether in a one-step reaction. This leads, in accordance with equation (l), to the same 1,2-glycol monoalkyl ethers *(142)* as are obtained from alkoxymethylmagnesium chloride and carbonyl compounds at low temperatures[264,269]. The glycol ethers *(142)* can be converted into the aldehydes *(149)*, R^1 = H, or ketones

$$R-O-CHR^1-Cl + Mg + R^2-CO-R^3 \xrightarrow{HgCl_2} (142) \qquad (l)$$



(149), R^1 = alkyl, having one C atom more than the original carbonyl compound, by dehydration and acid hydrolysis of the resulting vinyl ether[264] (see Table 12).

Table 12. Examples of the chain-lengthening of carbonyl compounds to *(149)* in accordance with equations (l) and (m) [264].

similar manner from fenchone [270]. Methyl chloromethoxyacetate *(16)* also undergoes this reaction, and with magnesium and a ketone it gives methyl esters of β-hydroxy-α-methoxycarboxylic acids, *e.g. (153)* [271]. Chloromethyl alkyl ethers also react directly with

(152) 

 *(153)*

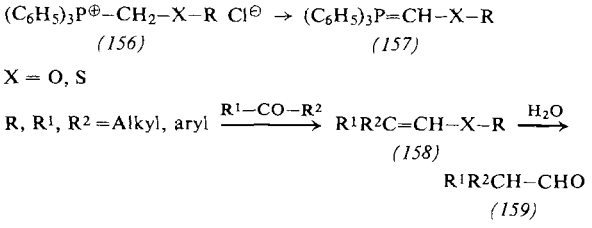
magnesium and esters in methylal or terahydrofuran to yield bis(alkoxymethyl)carbinols *(154)* [267].

 *(154)*

3. Wurtz Syntheses with α-Halogeno Ethers

The reaction of α-halogeno ethers with metals, which is formally analogous to the Wurtz synthesis, has been little investigated. Equimolar quantities of α-chloroether and sodium give glycol diethers *(155)*, R = CH_3 to C_5H_{11}; R^1 = H, in yields of up to 79 % [130, 272, 273], while with Cu and Fe, derivatives with R = CH_3 to

(155)



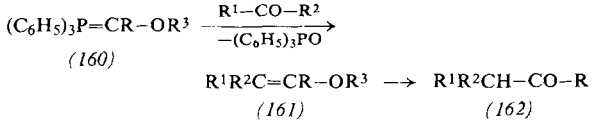
$C_{16}H_{32}$ and R^1 = H to C_3H_7 can be obtained [274]. Diethyl 2,3-diethoxysuccinate *(155)*, R = C_2H_5, R^1 = $CO_2C_2H_5$, has been obtained in the same way by reaction of ethyl ethoxychloroacetate with copper powder [275].

C. Reactions of the α-Halogeno Ethers, Sulfides and Amines Involving α-Elimination

1. Syntheses *via* Phosphorus Ylides

The versatile Wittig olefination process, when applied to compounds of the types *(1a)* or *(2b)*, permits the conversion of carbonyl compounds into vinyl ethers or aldehydes having one C atom more, and into the methyl ketone having two C atoms more than the original compound.

For this reaction, the phosphonium salt *(156)*, X = O, R = aryl (the aliphatic analogues give only low yields [278, 279]), obtained from triphenylphosphine and the α-halogeno ether, is converted into the ylide *(157)*, X = O, by treatment with phenyl-lithium or sodium alkoxide. These ylides react with carbonyl compounds,



(156) *(157)* *(158)* *(159)*

sometimes in very good yields, to give vinyl ethers or vinyl thioethers *(158)*, which have been hydrolysed in some cases to give aldehydes *(159)* [276–279]. Some of the vinyl compounds prepared are shown in Table 13.

Table 13. Vinyl ethers *(158)*, X = O and vinyl thioethers *(158)*, X = S, prepared.

Starting compound	X	R	Yield (%)	Ref.
Diethylketone	O	*p*-CH_3–C_6H_4	72	[278]

Triphenylphosphonium chlorides obtained from α-halogeno derivatives such as ethyl chloromethoxyacetate or α-chloroethyl methyl ether react with bases [$KOC(CH_3)_3$, $NaOC_2H_5$] to give phosphorus ylides *(160)*. With formaldehyde, *(160a)* gives the enol ether of ethyl pyruvate *(161a)* [280], while the reaction of the derivate *(160b)* with aldehydes and ketones has led to the development of a synthesis for vinyl ethers *(161b)* and methyl ketones *(162b)* [281].

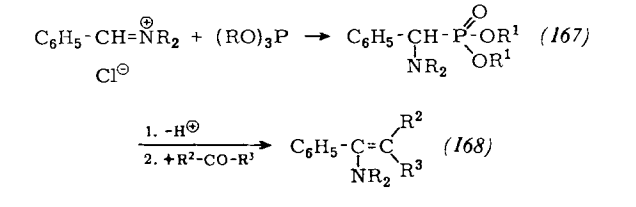
Acylation of ylides of the type *(157)*, X = O, with acyl chlorides or esters leads to acyl derivatives *(160c)*, which can be converted into acylated enol ethers *(161c)* by a Wittig reaction with carbonyl compounds. Hydrolysis *(161c)* gives the dicarbonyl compound *(162c)*. On acylation of *(157)* with formic acid, the same reaction sequence leads to α-keto esters *(162d)* *via* *(161d)* [282]. Finally, α-keto esters *(163)* can be obtained readily from compounds of the type *(160)* by oxidation with lead tetraacetate under mild conditions [283].

(160) $\xrightarrow[-(C_6H_5)_3PO]{Pb(OAc)_4}$ $R-CO-OCH_3$ *(163)*

$R = C_4H_9-CO$, $c\text{-}C_3H_5-CO$, $c\text{-}C_4H_7-CO$, $C_6H_5-CH=CH-CO$

The formation of allenes from α-halogeno amines and alkylidenephosphoranes also proceeds formally by α-elimination [284]. Thus ethylidenetriphenylphosphorane *(164)* and α-chlorobenzyldimethylamine react to form the phosphonium salt *(165)*, which, after loss of the α-proton (by transylidation with a second mole of ylide), undergoes β-elimination to give phenylallene *(166)* in 60 % yield.

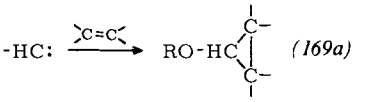


$(C_6H_5)_3P=CH-CH_3$ + $C_6H_5-CH(\oplus N(CH_3)_2)$ → $(C_6H_5)_3\overset{\oplus}{P}-CH(CH_3)-CH(N(CH_3)_2)-C_6H_5$

(164) $Cl^{\ominus}$ $^{\ominus}Cl$ *(165)*

→ $(C_6H_5)_3P=C(CH_3)-CH(N(CH_3)_2)-C_6H_5$ $\xrightarrow[-NH(CH_3)_2]{(C_6H_5)_3P}$ $CH_2=C=CH-C_6H_5$ *(166)*

Enamines can be obtained from α-halogeno amines by the PO-activated olefination discovered by *Horner* [285]. α-Halogenobenzylamines and trialkylphosphines give first the diester *(167)* of the α-(dialkylamino)benzylphosphonic acid, which forms an enamine *(168)* on deprotonation and reaction with carbonyl compounds [286].

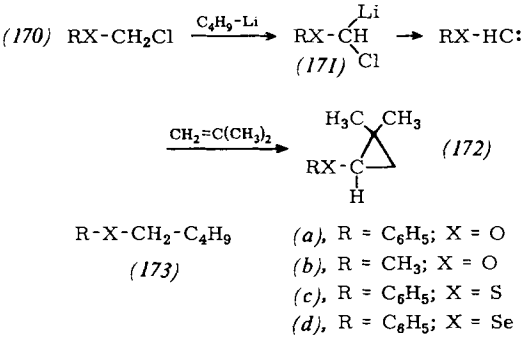


$C_6H_5-CH=\overset{\oplus}{N}R_2$ $Cl^{\ominus}$ + $(RO)_3P$ → $C_6H_5-CH(NR_2)-P(=O)(OR^1)-OR^1$ *(167)*

$\xrightarrow[2.\ +R^2-CO-R^3]{1.\ -H^{\oplus}}$ $C_6H_5-C(NR_2)=C(R^2)(R^3)$ *(168)*

2. Syntheses of Cyclopropane Derivatives [*]

α-Elimination of HCl from α-halogeno ethers in the presence of olefins yields alkoxycyclopropanes *(169a)*.



$RO-CH_2Cl$ $\xrightarrow{-HCl}$ $RO-HC:$ $\xrightarrow{>C=C<}$ $RO-HC(-C-)(-C-)$ *(169a)*

It is not yet certain whether this reaction, which was studied by *Schöllkopf* [287], proceeds *via* alkoxycarbenes or whether metalated intermediates react as "carbenoids" [288].

Alkoxycyclopropanes can be obtained in various ways from α-halogeno ethers. As was shown in Section A.3, α-halogeno ethers react with organometallic compounds by nucleophilic substitution. Under certain structural conditions, however, the H_α atom of the halogeno ether can be acidic, so that metalation can take place in the α-position. These two reactions can compete with each other.

For example, chloromethyl phenyl ether *(170)* can be metalated with butyl-lithium to give phenoxychloromethyl-lithium *(171a)*, which reacts further with isobutylene to form 2,2-dimethyl-1-phenoxycyclopropane *(172a)* [287]. The reaction with chloromethyl phenyl sulfide *(170c)* also proceeds *via* the lithium compound with formation of 2,2-dimethyl-1-phenylthiocyclopropane *(172c)* [289–291], while the reaction with chloromethyl methyl ether *(170b)* leads to 1-methoxy-2,2-dimethylcyclopropane *(172b)* [289, 292, 293]. Finally, the analogous phenylselenocyclopropane derivative *(172d)* can be prepared from chloromethyl phenyl selenoether *(170d)*, with potassium t-butoxide as the base in this case [294].

Since the acidity of the α-hydrogen atom increases in the order *(170b)* < *(170a)* < *(170c)*, α-chloromethyl aryl sulfides should be more easily metalated than α-chloromethyl methyl ether. In agreement with this, the yield of cyclopropane derivative is highest with *(170c)* (up to 90 % when potassium t-butoxide is

(170) $RX-CH_2Cl$ $\xrightarrow{C_4H_9-Li}$ $RX-CH(Li)(Cl)$ *(171)* → $RX-HC:$

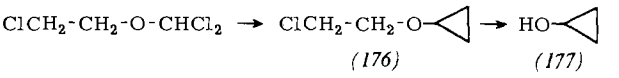
used)[290,292]. On the other hand, the nucleophilic substitution of the halogen atom is easiest in α-chloromethyl alkyl ethers. The side reaction, *i.e.* the nucleophilic substitution of the chlorine atom by the alkyl residue, is most prominent for these compounds. The reaction of *(170b)* with n-butyl-lithium proceeds almost exclusively by substitution with formation of *(173b)*, whereas with the bulky t-butyl-lithium, metalation occurs and *(172b)* is obtained in a yield of 32 %. Direct nucleophilic substitution with n-butyl-lithium has also been observed for *(170a)* [formation of *(173a)*]; however, this occurs only to a small extent, since the nucleophilic reaction is more difficult than for *(170b)* and the α-hydrogen atom is acidic[292,293]. The lower the electron density on the olefin, the more pronounced does the competitive nucleophilic reaction become[295].

As was found with *cis*- and *trans*-butene, the reaction proceeds stereospecifically as a *cis*-addition[295]. With cyclohexene, *(170a)* to *(170c)* give 7-substituted norcaranes *(174)*[292,295], the product always being a mixture of the *endo*- and *exo*-forms.

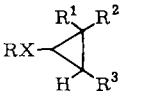


(174), R = Alkyl, Aryl
X = O,S

(175a), X = Cl
(175b), X = CH_3O

The *exo* form always predominates (*cis*:*trans* = 1.8:1 to 7:1) since the transition state leading to the *exo* compound is energetically more favorable. This is also shown by comparison of the isomer mixtures obtained in the reaction of chloromethyl methyl ether and chloromethyl isopropyl ether with cyclohexene. The *exo*:*endo* ratio was 7:1 for the bulky isopropyl derivative, and only 4.5:1 for the methyl derivative[292]. On the other hand, the phenoxycarbene is more reactive, and hence less selective, than the methoxycarbene, so that in this case an *exo*:*endo* ratio of only 1.8:1 is obtained[292,296]. 2,2-Diethoxy-1-phenylthiocyclopropanone can be obtained from *(170c)* with ketene acetal as the olefin[290].

A convenient route to alkoxycyclopropanes is the reaction of methyl-lithium with dichloromethyl alkyl ethers and olefins in the presence of lithium iodide. The reaction probably proceeds *via* chloroiodomethyl alkyl ethers, which react immediately with methyl-lithium to form the alkoxychloromethyl-lithium. The subsequent reaction then proceeds as a stereospecific *cis* addition[296,297]. When chloromethyl dichloromethyl ether is used, only the dichloromethyl group reacts; the reaction leads to chloromethyl cyclopropyl ether *(175a)*, which can be converted into the acetal *(175b)* by treatment with $NaOCH_3$[296].



Cyclopropanole *(177)* has been synthesized from β-chloroethyl dichloromethyl ether and ethylene. β-Chloroethoxycyclopropane *(176)* was first prepared,

(176) *(177)*

and this was then converted into *(177)* by elimination of HCl and hydrolysis of the resulting cyclopropyl vinyl ether, or by reaction with butyl-lithium to form cyclopropanol-lithium and subsequent hydrolysis[298]; the latter represents the superior method.

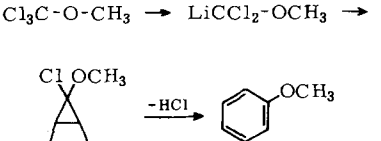


Table 14. Alkoxy-, alkylthio-, and alkylselenocyclopropanes synthesized.

R	X	R^1	R^2	R^3	Yield (%)	Ref.

[a] As a mixture of stereoisomers.

α-Elimination of two atoms of chlorine from trichloromethyl methyl ether with methyl-lithium in cyclopentadiene yields anisole (21 %). The reaction presumably involves initial formation, *via* methoxydichloromethyl-lithium, of 6-chloro-6-methoxybicyclo-[3.1.0]hex-2-ene *(178)*, which then loses HCl, with ring expansion to form anisole[296].

(178)

Finally, substituted cyclopropanes of the type *(180)* can be obtained by metalation of oligochloromethyl phenyl sulfides[296,299]. Dichloromethyl phenyl sulfide

(179), M = K, Li

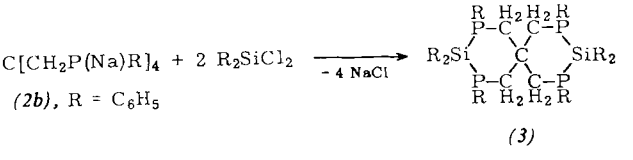
Tetrakis[(alkali-metalphenylphosphino)methyl]-methanes and their Conversion into Metal-Containing and Metal-Free Spiroheterocycles [1]

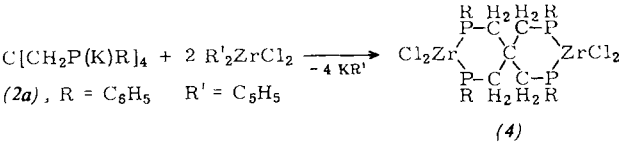
By *J. Ellermann* and *F. Poersch*

Since reaction of the potassium cyanometalates(0) $K_6[Cr(CN)_6]$ and $K_4[Ni(CN)_4]$ with tetrakis[(diphenylphosphino)methyl]methane *(1)* [2] does not, like that of the isoelectronic metal carbonyls $Cr(CO)_6$ and $Ni(CO)_4$, yield spiro-heterocyclic complex compounds [3,4], but instead leads to their conversion into tetrakis[(potassiumphenylphosphino)methyl]methane [5], the direct preparation of compound *(2a)* and the analogous sodium derivative *(2b)* appeared to be of interest.



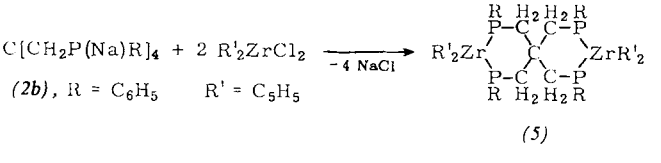
With this object we treated the phosphine *(1)* with potassium or sodium in liquid ammonia in the molar ratio 1:8 at −33 °C with vigorous stirring (reaction in dioxane [6] is extremely slow). A color change from blue through green accompanies formation of the orange-yellow compounds *(2a)* and *(2b)*, respectively. The C_6H_5M formed simultaneously undergoes ammonolysis in the liquid ammonia [7] to benzene and alkali-metal amide, the latter being subsequently

$$\underset{(1)}{C[CH_2P(C_6H_5)_2]_4} + 8\,M \xrightarrow[-33\,^\circ C]{NH_3} \underset{\substack{(2a),\ M=K\\(2b),\ M=Na}}{C[CH_2P(M)C_6H_5]_4} + 4\,C_6H_5M$$



decomposed to NH_3 and alkali-metal bromide by an equimolar amount of NH_4Br [2]. After evaporation of the ammonia and benzene at room temperature, compounds *(2a)* and *(2b)* are separated from MBr by extraction with tetrahydrofuran, precipitated by petroleum ether (after concentration of the extract), filtered off, washed with petroleum ether, and dried in a high vacuum.

Compounds *(2a)* and *(2b)* are extremely sensitive to air and moisture and must be kept under argon; they dissolve readily in THF and ethanol but only slightly in benzene and are insoluble in aliphatic hydrocarbons. Because of the very high solubility in THF the yields are only *ca.* 75 to 80 % although, as is shown by determination of the alkali-metal bromides the conversion was almost quantitative. Elemental analysis, osmometric determination of molecular weights in THF, and IR spectra, which show only vibrations of the neopentane skeleton and of the $>P-C_6H_5$ group [3] [ν(P–Na) ≈ 860 cm^{-1}; ν(P–K) ≈ 410 cm^{-1} (?)], prove the structure of solvent-free products *(2a)* and *(2b)*. If the compounds are allowed to stand for about one hour in THF, the measured molecular weights are high; this is ascribed to formation of adducts (1:1 to 1:4) with the solvent. These products are unambiguously non-electrolytes according to conductivity measurements in THF.



By virtue of their neopentane skeletons, compounds *(2a)* and *(2b)* behave preferentially as doubly bidentate reagents, so that treatment with 2 mols of an organo-non-metallic or organometallic dihalide leads to synthesis of covalent spiroheterocyclic products containing the non-metal or metal. In this way reaction of compound *(2b)* with dichloro(diphenyl)-silane [8] in THF at 60 °C in a sealed tube leads to a decrease in the intensity of color and formation, simultaneously, of a gelatinous NaCl precipitate and THF-soluble, pale pink 2,3,3,4,8,9,9,10-octaphenyl-2,4,8,10-tetraphospha-3,9-disilaspiro[5.5]undecane *(3)*, which can be filtered from NaCl and precipitated with petroleum ether. Its composition and structure are proved by elemental analysis, molecular-weight determination, and the IR spectrum. This product *(3)*, m.p. 126 °C, is readily soluble in THF, dioxane, or ethanol, but barely soluble in aromatic or aliphatic hydrocarbons.

(2b), R = C_6H_5 *(3)*

(2a), R = C_6H_5 R' = C_5H_5 *(4)*

(2b), R = C_6H_5 R' = C_5H_5 *(5)*

Reaction of dichlorodi-(π-cyclopentadienyl)zirconium [9] with compound *(2a)* leads to formation of cyclopentadienylpotassium (crystallizes out at *ca.* 20 °C) and pale brown 3,3,9,9-tetrachloro-2,4,8,10-tetraphenyl-2,4,8,10-tetraphospha-3,9-dizirconaspiro[5.5]undecane *(4)*, but that with *(2b)* leads to separation of NaCl and formation of yellowish-white 3,3,9,9-tetra-(π-cyclopentadienyl)-2,4,8,10-tetraphenyl-2,4,8,10-tetraphospha-3,9-dizirconaspiro[5.5]undecane *(5)*. The KC_5H_5 and NaCl, respectively, are formed quantitatively The product *(4)* can be isolated only in about 10 % yield on addition of petroleum ether, although *(5)* is obtained in almost quantitative yield.

Product *(4)*, which crystallizes with 1 mol of THF, was characterized by elemental analysis, product *(5)* [m.p. 270 °C (decomp.)] by elemental analysis, molecular-weight determination, and IR spectrum which shows the typical absorption of π-bonded C_5H_5 groups [10] as well as vibrations

of the neopentane skeleton and P–C_6H_5 groups[2,3]. Both compounds are readily soluble in THF or ethanol but insoluble in benzene or petroleum ether.

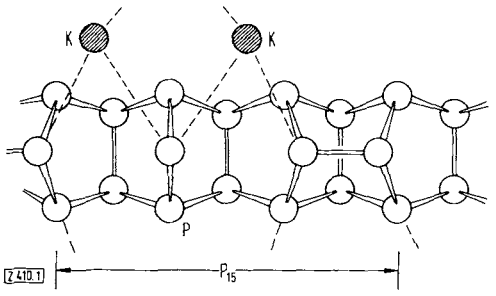
KP_{15}, a New Potassium Polyphosphide



By *H. G. von Schnering* and *H. Schmidt* [*]

After a detailed study of the reaction conditions in the system K/P, red needles of a compound could be prepared that had been observed previously[1–4] but had not been accurately characterized. Elemental analysis and determination of the structure showed that it was potassium polyphosphide KP_{15}.

Preparation and Properties: Potassium and red phosphorus are heated at 650 °C in a sealed quartz ampoule (length 20 cm; temperature gradient 650/200 °C); the yield depends on the K:P ratio, 5 to 20 atoms-% of K being favorable; traces of water favor the deposition appreciably (chemical transport by way of phosphines?). KP_{15} is deposited at 300–320 °C as transparent, ruby, flat needles; it is odorless and is stable indefinitely in air. It is not attacked by H_2O and only slowly by concentrated oxidizing acids. Samples are decomposed for analysis by bromine-nitric acid in a sealed tube at 120 °C.

Structure: KP_{15} crystallizes in the triclinic form [$a = 23.74$, $b = 9.69$, $c = 7.21$ Å, $\alpha = 116.7°$, $\beta = 97.5°$, $\gamma = 90.0°$; space group $P\bar{1}$; $Z = 4$] with marked twinning parallel to (100). Studies of single crystals show the structure contains phosphorus units in the form of infinite tubes, unidimensional along [010], of pentagonal cross-section, and divisible into P_{15} units (see Figure). Of the 15 P atoms only one is bound to two other P atoms ($>P^{\ominus}$), the others being bound to three other P atoms ($>P$). Each potassium atom unites four $(P_{15})_{\infty}$ units to each other, so that a two-dimensional framework parallel to (100) results. Each potassium atom has 6 near neighbors (2 P< at 3.48 Å; 4 P< at 3.24 or 3.37 Å). If these linkages are also taken into account, then the P_{15} unit contains P atoms linked in three different ways: (I) K–P<K, (II) K–P<, (III) :P<; (I) and (II) have a tetrahedral and (III) a pyramidal structure. The P–P distances are 2.18 to 2.30 Å; the bond angles at the phosphorus are between 93 and 112 °. If the peculiar relation of (I) to the K–P distances [d(K–P<) > d(K–P<)] is considered, the view that K^+ and P_{15}^- ions exist becomes tenable.

The structures of KP_{15} and of $HgPbP_{14}$[4] (here P< is replaced by Pb and one P–P bridge is missing) shows that P_5 units play a part in such polyphosphides (see Figure). Mention should also be made of the compounds KP_{10}[1] and TlP_5[5], whose structures are not yet known. *Thurn* and *Krebs*[6] have demonstrated recently that such tubular phosphorus units are in fact structural elements of violet phosphorus.

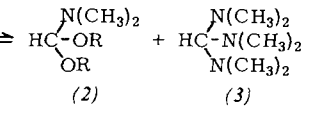
Stability of Aminal Esters and their Reactions with Aromatic Aldehydes

By *H. Bredereck, G. Simchen, H. Hoffmann, P. Horn*, and *R. Wahl* [*]

Since the synthesis of bis(dimethylamino)methoxymethane *(1a)*[1], we have prepared further aminal esters *(1)*[2–4] by treating *N,N,N',N'*-tetramethylformamidinium methyl sulfate[1] with sodium or potassium alkoxide (molar ratio 1:1) in ether or cyclohexane at room temperature. After filtration and distillation of the solvent under vacuum, the aminal esters *(1)* were obtained. Their purity was established by NMR spectrometry.

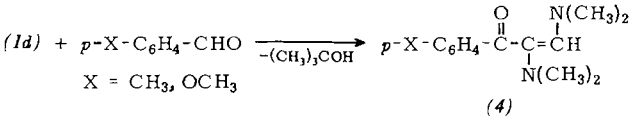


(1) M = Na, K

R	Yield (%)	Content of *(1)* in equil. mixture (%) [a]
(1a) CH_3	62 [1]	62–64
(1b) $C_2H_5C_3H_7$	60 [2]	62–66
(1c) iso-C_3H_7	45 [2]	54
(1d) t-C_4H_9	68 [3,4]	32–33

[a] After standing at room temperature; the content of *(1)* was determined by NMR spectrometry.

If the aminal esters are warmed to 100 °C or allowed to stand for about a week at room temperature, partial dismutation into *N,N*-dimethylformamide acetals *(2)* and tris(dimethylamino)methane *(3)* occurs [2].



When allowed to stand for several hours, equimolar mixtures of *(2)* and *(3)* undergo the reverse reaction to give the corresponding aminal esters *(1)* [2]. Pure aminal ester has not been isolated from such equilibrium mixtures.

(2) *(3)*

The reaction of bis(dimethylamino)-t-butoxymethane *(1d)* with aromatic aldehydes adopts a surprising course. If the reaction components (molar ratio 3:1) are warmed for 3–4 h at 110–140 °C, t-butyl alcohol distils off, the reaction being analogous to that of CH-acidic compounds [4,6].

In the case of reactions with *p*-tolualdehyde or *p*-anisaldehyde, contrary to expectation, 1,2-bis(dimethylamino)vinyl aryl ketone may be isolated in 30 % yield by fractional distillation of the reaction mixture.

(4)

The structure of the product *(4a)* [*(4)* with X = CH_3, m.p. 114 °C] was proved by independent synthesis from dimethylaminomethyl *p*-tolyl ketone and bis(dimethylamino)-t-butoxymethane *(1d)* [5]. The structure *(4b)* [*(4)* with X = OCH_3, m.p. 85–87 °C] follows from comparison of the NMR spectra with that of *(4a)*.

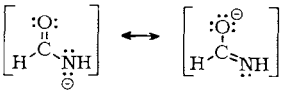
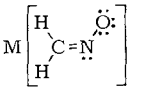
Carbonylation of Metal Amides to Metal Formamides

By *R. Nast* and *P. Dilly* [*]



Sodium and potassium formamide have hitherto been accessible only by treatment of formamide with the corresponding metal amide in liquid ammonia [1]. We have found that solutions or suspensions of alkali-metal amides in liquid ammonia react in general with gaseous CO at normal pressure and about −45 °C, giving the alkali-metal formamide in quantitative yield:



Pure gaseous CO is passed with a streaming velocity of at least 25 l/h, with rigid exclusion of moisture, through a solution of about 25 mmoles of MNH_2 (M = K, Rb, or Cs) in *ca.* 100 ml of liquid ammonia at about −45 °C for 2 h. The alkali-metal formamide is precipitated as a pure, colorless crystalline powder either at once or on concentration of the solution. Even $NaNH_2$, which is sparingly soluble in liquid ammonia, can be carbonylated quantitatively in this way since sodium formamide is more soluble than $NaNH_2$ in NH_3. The streaming velocity of CO should not be lower than the value given above, since prolonged action of an excess of $NH_2^{\ominus}$ dehydrogenates the alkali-metal formamide to the corresponding cyanate:

The alkali-metal formamides are very hygroscopic and are hydrolysed by water to formamide and by an excess of caustic alkali to formates. The ν_{CO} frequencies that appear in their IR spectra at 1580–1590 cm^{-1} ("amide-I bands") are substantially independent of the alkali-metal ion and are at about 100 cm^{-1} lower than for free formamide [2]. This indicates marked contribution of the polar carbonyl

structure to the bond structure of the formamide anion. The presence of the isomeric alkali formoximates can thus be excluded.

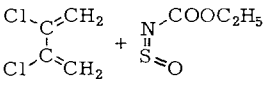
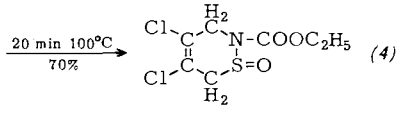
Synthesis of *N*-Sulfinylurethanes

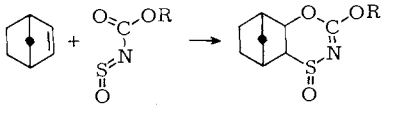


By *H.-H. Hörhold* [*]



We have found that *N*-sulfinylurethanes can be synthesized in *ca.* 50 % yield by treating *N*-chloroiminocarbonic esters *(1)* with thionyl chloride. The reaction begins below 0 °C with evolution of chlorine and continues with elimination of alkyl chloride when the temperature is raised. It is thus assumed that the thermally unstable (chlorosulfinylimino)-carbonic esters *(2)* occur as intermediates.

(3a), R = CH_3, b.p. 36 °C/12 mm
(3b), R = C_2H_5, b.p. 48 °C/12 mm



Compounds *(3a)* and *(3b)* are colorless liquids, and extremely sensitive to moisture. Their structures are proved by their compositions, their molecular weights (138 for *(3b)*, cryoscopically in benzene), hydrolysis to sulfur dioxide and the corresponding alkylurethanes, and their IR spectra, measured in the gas phase and showing the characteristic bands for the O=S=N group (1135 cm^{-1}, 1250 cm^{-1}, 1290 cm^{-1}, the last perhaps ν_{C-O}) and the C=O group (1790 cm^{-1}). In *N*-sulfinylurethanes, as in *N*-(benzenesulfonyl)sulfinylimines[1], the S=N double bond is activated for addition reactions. Reaction with 1,3-dienes readily gives 1:1 adducts, such as *(4)*, in which the alkoxycarbonyl group is retained.

(4): $\nu_{C=O}$ = 1735 cm^{-1}, m.p. 92–93 °C colorless crystals

A 1:1 adduct is formed surprisingly easily from *(3)*, R = C_2H_5, and norbornene; after heating equimolar quantities of these compounds in anhydrous ether for 1 h, the adduct crystallizes in *ca.* 80 % yield as colorless crystals of m.p. 79–81 °C. The IR spectrum (KBr) shows no absorption in the region of C=O bands but a strong band at 1600 cm^{-1} ($\nu_{C=N}$). Thus it follows that the carbonyl group has been involved in the addition reaction whose formulation as a 1,4-addition is probable:

Ethyl N-sulfinylurethane (3b):

70 g of diethyl *N*-chloroiminocarbonate is added, over a period of 1 h, to 160 ml of $SOCl_2$ with stirring and cooling (0 °C). The chlorine liberated is removed from the reaction mixture in a stream of dry argon. When evolution of chlorine ceases the mixture is stirred for a further 2 h at room temperature and the excess of $SOCl_2$ is distilled off in a vacuum at 30 °C (maximum bath temperature). The oily colorless residue is then further heated in a vacuum by placing the distillation flask in a preheated bath (120–130 °C). Ethyl *N*-sulfinyl urethane *(3b)* distils over and is collected in a cooled receiver. After repeated distillation at 12 mm the ethyl *N*-sulfinylurethane is obtained as a colorless liquid (yield 25–35 g). Compound *(3a)* is obtained analogously as a colorless liquid in 41 % yield.

2-Thioxo-1,3-thiazolidine-4,5-dione [1]

By *V. Hahnkamm* and *G. Gattow*[*]

Whereas the wine-red 2-thioxo-1,3-dithiolane-4,5-dione[2] is formed on treatment of trithiocarbonic acid $SC(SH)_2$ with oxalyl chloride, 2-thioxo-1,3-thiazolidine-4,5-dione *(1)* (which crystallizes in orange needles) was obtained for the first time by a similar reaction of dithiocarbamic acid[3].

A dilute solution of $(COCl)_2$ in $CHCl_3$ is added in excess, with exclusion of air and moisture, to a suspension of $SC(SH)(NH_2)$ or $NH_4[SC(S)(NH_2)]$ in $CHCl_3$; the reaction, which involves evolution of HCl or formation of NH_4Cl, respectively, is complete after the reactants have been stirred in a stream of N_2 for 5 h. The product *(1)* is obtained by distillation of $CHCl_3$ from the filtrate and is purified by recrystallization from petroleum ether (yield, about 60 %).

Compound *(1)* (m.p. 119 ± 1 °C, d_4^{25} = 1.795 ± 0.005 g/cm^3) is very soluble in water and alcohols, moderately soluble in $CHCl_3$, benzene, and ether, but only sparingly soluble in aliphatic hydrocarbons. Its mass spectrum shows, besides fragments, a strong peak at *m/e* = 147 [theoretical for the molecular weight of *(1)*, 147.18].

Compound *(1)* reacts acid in water and forms colored soluble complexes or precipitates with numerous heavy-metal ions, *e.g.*, with Fe^{3+} a pale red complex, with Ni^{2+} a deep red complex, with Cu^{2+} a red-brown precipitate, with Pb^{2+} an orange-yellow precipitate, and with Tl^{+} a pale brown precipitate.

IR spectrum of *(1)*: 3250 (m), 1742 (s), 1490 (w), 1426 (s), 1303 (m), 1220 (s), 1100 (w), 1075 (s), 974 (w), 948 (m), 748 (m), 637 (m), 552 (w), 530 (w), 485 (m) cm^{-1} [4].

X-Ray studies by use of rotating-crystal, equator Weissenberg, and equi-inclination Weissenberg photographs showed that *(1)* is monoclinic with *Z* = 4 formula units in the elementary cell; *a* = 9.30 ± 0.05, *b* = 5.08 ± 0.03, *c* = 11.35 ± 0.06 Å, β = 93.5 ± 0.5 °; X-ray density d_R = 1.82$_6$ g/cm^3. The space group C_{2h}^5–$P2_1/a$ (No. 14) follows from the extinctions [(*h*0*l*) only with *h* = 2*n*, and (0*k*0) only with *k* = 2*n*]; $C_{2h}^{1,2,4}$, $C_2^{1,2}$, and $C_s^{1,2}$ are also possible.

Six Oxidation States of the Iron-Phthalocyanine Complex

By *R. Taube* and *H. Drevs*[*]

The iron-phthalocyanine complex [FePc] is of particular interest because, *inter alia*, of the great similarity of the structure of this complex to that of the biochemically important heme. We have found that iron(II) phthalocyanine[1], and also other metal phthalocyanines, can be reduced in tetrahydrofuran (THF) in four stages:

$$[FePc] + n\,e^- \rightarrow [FePc]^{n-}.$$

Only the first two reduction states have hirtherto been isolated, and closely studied, as crystalline lithium salts containing tetrahydrofuran, Li[FePc]·4.5 THF *(1)* and Li_2[FePc]·5.5 THF *(2)* [2]. We have now obtained the third and the fourth reduction states in pure crystalline form.

In order to prepare the third reduction state, pure recrystallized *(2)* in boiling THF was treated with a solution of dilithiobenzophenone in THF in the molar ratio 1:3. The third reduction state precipitates immediately. The dry compound forms dark olive-green crystals of composition Li_3[FePc]·8THF *(3)*, which are very slightly soluble in THF but somewhat more soluble in dimethylformamide (DMF), to give intensely reddish-violet solutions.

The fourth reduction state was obtained in the same manner, by treatment of *(2)* with dilithiostilbene, as violet crystals of composition Li_4[FePc]·9 THF *(4)*.

The compound dissolves in THF to form an intensely bluish-green solution. It dissolves also in DMF but then rapidly decomposes with development of a violet color.

The salts *(3)* and *(4)* are oxidized in air, with loss of tetrahydrofuran, *(4)* occasionally becoming incandescent. On oxidation of *(3)* and *(4)* with iodine in THF in the absence of air, 2.95 and 3.91 atoms, respectively, of iodine are consumed and [FePc] is formed. The electrolytic character of compounds *(3)* and *(4)* could be proved by transfer experiments in DMF or THF. Magnetic measurements by Gouy's method at temperatures between 83 and 293 °K substantiated the applicability of the Curie-Weiss law, $\chi_M = C/T + \theta$.

Values found were[3]:

for *(3)*: $\theta = 35$ °K, $\chi_g(293\ °K) = 1.44\times10^{-6}$ cm³/g, $\mu'_{eff} = 2.60$ B.M. [4]

for *(4)*: $\theta = 12$ °K, $\chi_g(293\ °K) = 3.08\times10^{-6}$ cm³/g, $\mu'_{eff} = 3.43$ B.M. [4]

It follows that *(3)* and *(4)* are formed from *(2)* by stepwise addition of electrons to the iron-phthalocyanine complex. If we include FePcCl, which has been described by *Barrett et al.* [5], and whose structure as iron(III) phthalocyanine chloride we finally proved [6], we now know six iron-phthalocyanine complexes of differing total electron numbers.

Model calculations by the simplified LCAO–MO method [7] lead to the following electron configurations, which agree with the observed magnetic moments in respect of the number (*n*) of unpaired electrons:

Formula	Electron configuration	*n*	$\mu_{eff.}$ (293 °K) [8]
[FePc]Cl	$(b_{2g})^2(6e_g)^2(2a_{1g})^1$	3	4.35 B.M. [6]
[FePc]	$(b_{2g})^2(6e_g)^3(2a_{1g})^1$	2	3.90 B.M. [9]
Li[FePc]·4.5 THF	$(b_{2g})^2(6e_g)^4(2a_{1g})^1$	1	2.12 B.M. [2]
Li_2[FePc]·5.5 THF	$(b_{2g})^2(6e_g)^4(2a_{1g})^2$	0	0.31 B.M. [2]
Li_3[FePc]·8 THF	$(b_{2g})^2(6e_g)^4(2a_{1g})^2(7e_g)^1$	1	2.46 B.M.
Li_4[FePc]9 THF	$(b_{2g})^2(6e_g)^4(2a_{1g})^2(7e_g)^2$	2	3.36 B.M.

Greatly simplifying, one can regard the electrons in the molecular orbitals $2a_{1g}$, $6e_g$, and b_{2g} as d-electrons of the central atom and the electrons in the $7e_g$ orbitals as π-electrons of the phthalocyanine [7]. One can then describe the stepwise addition of electrons to the iron-phthalocyanine complex $[FePc]^+$ as a lowering of the oxidation state of the central atom from +3 to 0, which is followed by an increase in the negative charge on the phthalocyanine from −2 to −3 and −4 in the complexes *(3)* and *(4)*, respectively. The reducibility of the phthalocyanine, which theoretically corresponds to occupation of its lowest antibonding π-orbitals $6e_g$ [7], is proved by the existence of electron-rich lithium [10] and zinc phthalocyanines [11].

1-Hexadecene, an Intermediate in the Microbial Oxidation of n-Hexadecane *in vivo* and *in vitro* [1]

By *F. Wagner, W. Zahn*, and *U. Bühring* [*]

Primary alcohols, aldehydes, and carboxylic acids have been identified as intermediates in microbial oxidation of higher n-alkanes [2]; these intermediates contain the same number of carbon atoms as the original n-alkane. There is, however, little agreement about the first step in enzymic attack on an n-alkane; hydroxylation [3], hydroperoxidation, and dehydrogenation to the 1-alkene have been considered, but neither an alkyl hydroperoxide [2] nor an n-alkene [2,4] could be isolated and unambiguously characterized.

We have, for the first time, been able to isolate and identify 1-hexadecene as intermediate after cultivation of *Micrococcus cerificans, Mycobacterium phlei, Nocardia sp., Pseudomonas sp.*, or *Rhodotorula sp.* in an inorganic salt solution with alkene-free n-hexadecane [5] as sole source of carbon.

After aerobic cultivation of *Nocardia* sp. for 26 h in 6 liters of inorganic salt solution [5a] containing 100 g of purified n-hexadecane, we obtained 170 g of wet bacterial mass (*ca.* 60 % water content) after centrifugation and washing during the logarithmic growth phase. This material was extracted with acetone and then diethyl ether. The residue obtained on concentration of the united extracts was chromatographed on a silica gel column (diam. 4 cm, length 20 cm). Petroleum ether (b.p. 60–80 °C) eluted a mixture of n-hexadecane and 1-hexadecene, which was separated chromatographically by means of the mercury-hexadecene adduct; the adduct was cleaved by methanolic HCl [7]. After further chromatographic purification on silica gel thin-layer plates [6], 7 mg of pure 1-hexadecene was obtained. This was identified by IR-spectroscopic, gas-chromatographic, and thin-layer chromatographic comparison with an authentic specimen. The terminal double bond of the 1-hexadecene was also authenticated by oxidation with $KMnO_4$, in acetone containing acetic acid, to yield pentadecanoic acid which was identified by gas chromatography after esterification with diazomethane.

We also obtained 1-hexadecene (0.01 mg) when a crude enzyme extract [6a] from *Nocardia* sp. (1 g of protein in 75 ml of 0.1 M phosphate buffer of pH = 7.0) was stirred for 2 h at 30 ° with 1.5 g of *n*-hexadecane. It was isolated and chromatographically identified as above.

The role of 1-hexadecene as intermediate in the microbial oxidation of *n*-hexadecane is explained by the fact that it is easily oxidized further *in vivo* and *in vitro*.

A Novel Ring Fission of a 1,3-Dimethyl-1*H*-naphtho[1,8-*de*]-1,2,3-triazinium Salt

By *H. Beecken*[*]

If methylation of 1*H*-naphtho[1,8-*de*]-1,2,3-triazine *(1)* with dimethyl sulfate is carried out, not in alcoholic alkali[1], but in acetone containing potassium carbonate[2], then the two known methyl derivatives – the orange *(2)* and the blue 2-methyl isomer – are accompanied by larger amounts of 1,3-dimethyl-1*H*-naphtho[1,8-*de*]-1,2,3-triazinium methyl sulfate *(3)* and a pale yellow compound *(4)*, the relative yields depending on the excess of methylating agent and on the reaction time.

(1), R = H *(2)*, R = CH_3 *(3)*

(4)

On thin-layer chromatography on silica gel G (solvent: benzene/ethyl acetate 14:1 v/v) the products give R_F values: 0.01 *(3)*, 0.30 *(4)*, 0.45 *(2)*, and 0.56 (blue isomer).

The compound *(4)* is better obtained by starting from pure *(3)*, which is obtained in 96.5 % yield from *(2)* and dimethyl sulfate in boiling benzene [2].

(3): brown-violet crystals, m.p. 263–265 °C (from acetonitrile; decomp.), λ_{max} (in methanol) = 503, 332, 318, 306, 227 mμ with log ε = 3.13, 3.86, 3.85, 3.77, 4.89. The structure of *(3)* follows from the bathochromic shift of the longest wavelength band in comparison with *(2)* [in methanol, *(2)* has λ_{max} = 454, 337, 276, 230 mμ with log ε = 2.99, 4.07, 3.59, 4.63; in methanolic hydrochloric acid *(1)* absorbs at λ_{max} = 505, 332, 318, 305 (sh), 224 mμ with log ε = 2.99, 3.83, 3.79, –, 4.79], and also from the fact that, under the same conditions, the blue 2-methyl isomer gives no quaternary salt with dimethyl sulfate, and from studies[3] of quaternary salt formation in the naphtho[1,2-*d*]triazole system.

The hydrazone *(4)*, pale yellow prisms, m.p. 111 °C (from benzene/petroleum ether), is obtained together with *(2)* when *(3)* is boiled in acetone in the presence of anhydrous potassium carbonate. The product *(4)* is separated as a more slowly migrating zone from *(2)* by chromatography on aluminum oxide (activity II, neutral; eluent, petroleum ether/benzene 1:1.3 v/v). Its structure is proved by elemental analysis, the UV spectrum [λ_{max} (in methanol) = 343, 296, 253, 228, 208 mμ with log ε = 4.05, 4.28, 4.30, 4.33, 4.63], the IR spectrum [in KBr; ν_{N-H} = 3460 cm^{-1}, $\nu_{C=O}$ = 1678 cm^{-1}, $\nu_{C=N}$ = 1660 cm^{-1}], and the mass spectrum [*m/e* = 255 (calc. mol. wt. 255.3), 240 (weak), 212 (medium), 199/197 (medium), 185 (strongest peak; corresponds to cleavage of the N–N bond)]. The NMR spectrum confirms this structure.

The formation of *(4)* from *(3)* can be explained in either of two ways involving attack by a hydroxide ion: (i) attack on N atom 2 of the cation of *(3)*; the resulting *N*-hydroxy compound opens to a nitrosoamine that condenses with acetone to give the hydrazone *(4)*; or (ii) hydroxide ions produce acetone anions that are then bound to N atom 2; the intermediate is stabilized by ring opening with formation of a conjugated C=N double bond and proton shift.

ESR Spectrum of a Non-Degenerate State of the Benzene Radical Anion

By *W. Köhnlein, K. W. Böddeker*, and *U. Schindewolf*[*]

Benzene radical anions, $C_6H_6^-$, are obtained on reduction of benzene with alkali metals in solvent systems which dissolve the metals with formation of solvated electrons (*e.g.* tetrahydrofuran [THF], dimethoxyethane [DME]). The ESR spectrum of this anion[1] consists of a septet with binomial distribution of intensities and a hyperfine splitting of 3.75 gauss.

While investigating the temperature dependence of formation of the benzene radical anion in THF/DME with liquid K/Na alloy, we observed that the ESR septet found at low temperatures (below about −20 °C) (Fig. 1) gives way on warming to a new spectrum (Fig. 2) with 15 lines at the same *g*-value.

The new spectrum consists of a triplet, the lines of which are each split further into a quintet. The hyperfine splitting of the triplet (6.5 gauss) is about four times that of the quintets (1.7 gauss). Both triplet and quintet again show binomial distribution of intensities. Parallel to the change of the ESR

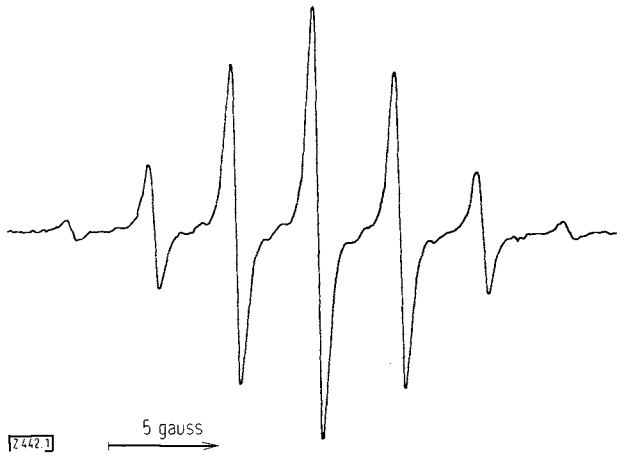

Fig. 1. ESR spectrum of the benzene radical anion in THF/DME at −30 °C in the presence of alkali metal.

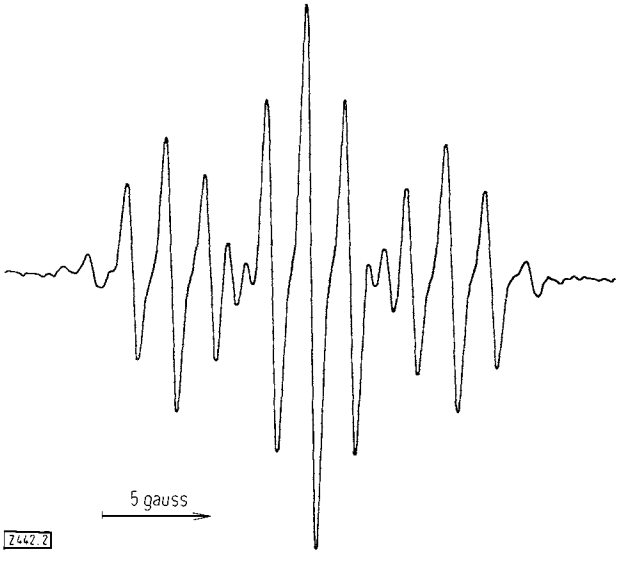

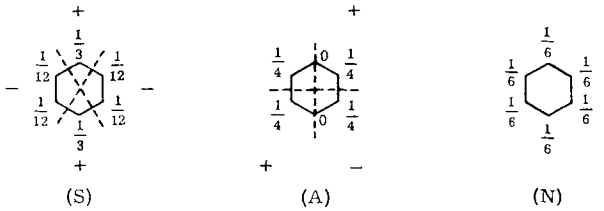

Fig. 2. ESR spectrum of the benzene radical anion in THF/DME at −30 °C after warming to 0 °C and recooling in the absence of alkali metal.

signal the color of the solution changes from deep green to brown-yellow. On cooling in the presence of alkali metal, the color of the solution changes to green again and the original 7-line spectrum is observed. In the absence of metal, however, the brown-yellow solution and its 15-line spectrum persist when the system is cooled.

According to the Hückel-MO theory, the ground state of the benzene radical anion consists of two degenerate states which differ in the distribution of spin density of the unpaired electron about the six C-atoms; the electronic wave functions of the two states are, respectively, symmetrical (S) and antisymmetrical (A) with respect to a plane of symmetry through opposite C-atoms perpendicular to the plane of the ring[2]. (The numbers on the formulae represent the spin densities at the C-atoms; + and − refer to the sign of the electronic wave functions.)

In the normal form of the undisturbed benzene radical anion, (N), resulting from mixing of the two degenerate states, the spin densities are evenly distributed and the ESR spectrum shows the well known septet.

Through perturbation of the symmetry the degeneracy can be removed. For example, in the radical anions of monodeutero benzene[3] and mono- and *p*-dialkylbenzene[4] state (A) is occupied preferentially; correspondingly, the ESR spectra of these anions basically consist of a quintet, with further hyperfine splitting depending on the system considered.

The 15-line spectrum reported here may be interpreted as resulting from the removal of degeneracy in favor of state (S) through interactions with alkali metal ions. Corresponding to the distribution of electron spin densities, the ESR spectrum of this state is expected to show a triplet with a further quintet splitting of the three lines; the triplet hyperfine splitting should be four times larger than the quintet splitting.

The spectra were recorded on an ESR spectrometer AEG 20–X. Samples were prepared by distilling the reagents (25 mg K plus 15 mg Na; 4 ml THF [Merck, for chromatography], 2 ml DME [Merck, for synthesis], and 0.5 ml benzene [Merck, for gas chromatography]; all reagents purified by distillation or drying over $LiAlH_4$) into the reaction vessel sealed to a vacuum line and furnished with a suitable side arm for recording the spectra.

A Simple Synthesis of 1,3,4-Thiadiazole

By *B. Föhlisch, R. Braun*, and *K. W. Schultze*[*]

1,3,4-Thiadiazole *(4)* was first synthesized by *Goerdeler, Ohm*, and *Tegtmeyer*[1], who used a four-stage process that started from thiosemicarbazide. *Jensen* and *Pedersen*[2] obtained the heterocycle from hydrazine and potassium dithioformate.

Our synthesis, by which quite large amounts of thiadiazole can be obtained, starts from *N,N*-dimethylformamide azine dihydrochloride *(2)*, which is obtained in 80–90 % yield

from dimethylformamidoyl chloride *(1)*[3] and *N,N'*-diformylhydrazine or hydrazine dihydrochloride. Sodium ethoxide converts compound *(2)* into the free dimethylformamide azine *(3)*; this reacts with H_2S at room temperature with loss of dimethylamine and formation of 1,3,4-thiadiazole *(4)* in 80 % yield. When treated with H_2S in methanol in the presence of 2 molar equivalents of sodium methoxide, the hydrochloride *(2)* gives *(4)* directly.

The ^1H–NMR spectrum of *(4)* in $DCCl_3$ shows a singlet at $\tau = 0.72$, $J_{^{13}C-H} = 213.5$ Hz.

Synthesis of (2):

Phosgene[5] (0.02 mole) is added dropwise to a solution of *N,N'*-diformylhydrazine[4] (8.8 g, 0.1 mole) in anhydrous dimethylformamide (100 ml) and methylene chloride (100 ml) at 0 °C (evolution of gas). The mixture is boiled for 20 h under reflux, and the precipitate is filtered off and purified by means of boiling chloroform. Yield, 18.6 g (86 %) of a colorless crystalline powder, m.p. 240–242 °C (decomp.).

Synthesis of (3):

An ice-cooled suspension of 10 g of *(2)* in ethanol (50 ml) is treated with 2 molar equiv. of sodium ethoxide solution. The sodium chloride is centrifuged off, the ethanol removed in a vacuum, and the residue crystallized from benzene, Yield, 6.3 g (95 %) of colorless plates, m.p. 75–76 °C. Dipicrate, yellow needles, m.p. 196–197 °C (from ethanol).

1,3,4-Thiazodiazole (4):

An ice-cooled solution of compound *(3)* (15 g) in methanol (75 ml) is saturated with H_2S. The reaction mixture is kept overnight at room temperature and the product *(4)* is subsequently isolated by vacuum-distillation. Yield, 7.3 g (80 %) of a colorless crystalline mass, b.p. 80 °C/11 mm, m.p. 42–43 °C (lit.[1], b.p. 82–83.5 °C/13 mm, m.p. 42–43 °C).

Synthesis of Nucleoside Diphosphates by means of Di-(2,2,2-trichloroethyl) Phosphorochloridate

By *F. Eckstein* and *K. H. Scheit*[*]

Phosphoric acid diester chlorides whose ester groups can be removed by Pd/H[1], alkali[2], or bromine[3] have been used for the preparation of nucleoside phosphates. We have found that the readily accessible[4] di-(2,2,2-trichloroethyl) phosphorochloridate (m.p. 37–42 °C) is excellently suited for phosphorylation of nucleosides because of the simple isolation of the nucleoside di-(2,2,2-trichloroethyl) phosphate and the mildness of the conditions needed for removal of the trichloroethyl groups.

We condensed some protected nucleosides with the diester chloride (1.2 equiv.) in pyridine (0 °C, 12 h). Evaporating the pyridine, taking up the residue in chloroform, and extracting the solution with aqueous $NaHCO_3$ gave the nucleoside di-(2,2,2-trichloroethyl) phosphate. On treatment with Zn/Cu in dimethylformamide (50 °C, 1 h)[5] or with Zn dust in 80 % acetic acid (room temp., 1 h) the triester was cleaved mainly to nucleoside phosphate with a small amount of nucleoside 2,2,2-trichloroethyl hydrogen phosphate (see Table). The nucleoside phosphates were isolated by chromatography an DAEA-cellulose. They did not contain inorganic phosphate as impurity.

The triesters are hydrolysed by concentrated ammonia solution (2 h) to nucleoside 2,2,2-trichloroethyl hydrogen phosphate (80 %) and nucleoside (20 %).

^{32}P-labeled nucleoside phosphates should also be readily preparable by this method.

Starting material	Yield (%) of triester	Reduction with Zn/Cu in DMF Yield [a] (%) of	
		nucleoside phosphate	nucleoside trichloroethyl phosphate

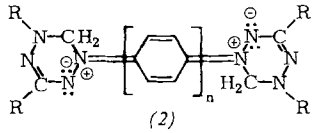
Bisverdazyls $N^1,N^{1'}$-Linked by Aromatic Systems[1]

By *F. A. Neugebauer, H. Trischmann*, and *M. Jenne*[*]

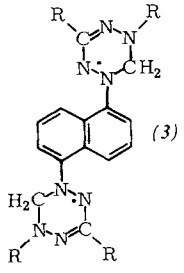
Whereas in solution and in the solid state the bisverdazyl *(1a)* exists in temperature-dependent equilibrium with the "electron-isomeric" diamagnetic form *(2a)*[2], the bisverdazyl *(1b)* occurs in the solid state up to 77 °K as a diradical ($\mu/\mu B = 2.43$). However, as shown by the absorption spectrum (298 °K; shoulder at 500 nm; 98 °K, maximum 500 nm), *(1b)* also exists in a temperature-dependent equilibrium with the double zwitterion *(2b)*. The diamagnetic form *(2c)* of the next homologue can be detected in solution only at low temperature (98 °K, shoulder at 790 nm).



(1)

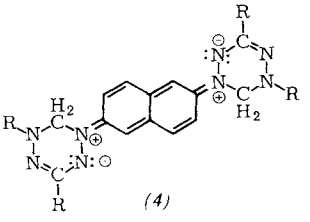
R = C_6H_5

(a), n = 2



(b), n = 3

(c), n = 4



(2)

The 1,5-bisverdazylnaphthalene *(3)* remains a diradical in the solid state and in solution up to 77 °K. It has a typical verdazyl absorption spectrum [maximum in dioxane: 713 nm (ε = 7700), 420 (14900), 270 (14900)].

(3)

(4)

However, 2,6-bisverdazylnaphthalene, like *(1a)*, is in temperature-dependent equilibrium with the quinonoid double zwitterion *(4)*, almost entirely in the diamagnetic form at low temperatures. The biradical concentration in the solid state is 36 % at 348 °K, 27 % at 298 °K, 11.5 % at 195 °K, and 6.1 % at 90 °K. The energy of conversion of the "electron-isomers" into each other between 348 and 298 °K is *ca.* 1.8 kcal/mole. The bisverdazyls *(1)* and *(4)* are examples (to be added to porphyrindine[3] and homologues of Chichibabin's hydrocarbon[4]) of compounds with an even total number of electrons that occur in diamagnetic and paramagnetic "electron-isomeric" forms[5].

Preparation of Tetrachlorodicyanophosphates and the Existence of Tetrachlorodifluorophosphates

By *H. W. Roesky*[*]

Although the hexachlorophosphate ion, $[PCl_6]^-$, and the hexafluorophosphate ion, $[PF_6]^-$, have long been known, it has hitherto proved impossible to prepare mixed hexahalogeno- or hexapseudohalogeno-phosphates.

For the synthesis of the tetrachlorodicyanophosphate ion, $[PCl_4(CN)_2]^-$, phosphorus pentachloride was treated with potassium cyanide (molar ratio 1:5) in anhydrous acetonitrile. Reaction occurred exothermally on vigorous stirring. The mixture was heated for 30 min at 40–50 °C and then filtered. An excess of a 1 % aqueous solution of tetrabutylammonium chloride solution was added to the filtrate and the resulting precipitate filtered off and reprecipitated from acetone/water. 2 g of PCl_5 gave 0.6 g of $(CH_3CH_2CH_2CH_2)_4N^+[PCl_4(CN)_2]^-$, m.p. 142 °C. Under the same conditions tetrapropylammonium chloride gave $(CH_3CH_2CH_2)_4N^+[PCl_4(CN)_2]^-$, m.p. 157 °C. These products are white solids that, when moist, slowly evolve HCN. The IR spectrum contains the bands between 700 and 420 cm^{-1} expected for $[PCl_4(CN)_2]^-$; these are the vibrations to be ascribed to ν(P–C), ν(P–Cl), and δ(PCN). Unambiguous assignment and determination of structure are possible only after measurements of the Raman spectrum. In the case of D_{4h} symmetry an alternative selection rule would apply. Provisional assignments are ν(PCN) 655(s), ν(PCl) 480(vs), δ(PCN) 435(vs) cm^{-1}. Assignment of ν(CN) to 2200(w) cm^{-1} is certain[1].

Phosphorus dichloride trifluoride, PCl_2F_3[2], reacts with CsF in dry acetonitrile at room temperature:

$$2\ PCl_2F_3 + 2\ CsF \rightarrow Cs^+[PF_6]^- + Cs^+[PCl_4F_2]^-$$

It was impossible to separate the cesium hexafluorophosphate completely from the cesium tetrachlorodifluorophosphate[3]. The tetrachlorodifluorophosphate is extraordinarily sensitive to moisture and decomposes the acetonitrile with development of a brown color. Provisional assignment of IR bands: ν(P–F) 760, ν(P–Cl) 455 cm^{-1}.

[3] The hexafluorophosphate, which is sparingly soluble in acetonitrile, is filtered off. The filtrate decomposes to a slight extent with formation of more hexafluorophosphate.

2,4-Dimethyl Carbonohydrazide

By *L. Raphaelian, H. Hooks,* and *G. Ottmann*[*]

Several methods have been described[1] for the preparation of 1,5-disubstituted carbonohydrazides but 2,4-dialkylcarbonohydrazides and 2,4-diarylcarbonohydrazides are apparently unknown. We have now prepared 2,4-dimethylcarbonohydrazide *(5)* from methylhydrazine and phosgene.

The primary amino group of methylhydrazine was blocked by conversion to the 1-benzylidene derivative *(1)*, which was then treated with phosgene. Depending on the conditions, this reaction afforded either 1,5-bis(benzylidene)-2,4-dimethylcarbonohydrazide *(2)* or 2'-benzylidene-1'-methylchloroformohydrazide *(3)*[2]. Compound *(2)* is obtained by slow addition of the stoichiometric amount of phosgene to a slurry of *(1)* or its hydrochloride in ether at 25–35 °C. *(3)* is formed exclusively (94 % yield) when a large excess of phosgene is added rapidly at 0–5 °C. Compound *(2)* is converted to *(5)* by transhydrazinolysis with 2,4-dinitrophenylhydrazine or by hydrolysis with 25 to 37 % hydrochloric acid. 20 % acid favors formation of 1-benzylidene-2,4-dimethylcarbonohydrazide *(4)* m.p. 139.5–140.5 °C, as well as *(5)*.

2'-Benzylidene-1'-methylchloroformohydrazine *(3)*, which can be recrystallized from ethanol, reacts readily with methyl hydrazine to form an oily mixture; hydrolysis of this product gave pure *(5)* in 23 % yield.

The reaction of methylhydrazine with phosgene in ether gave *(5)* in less than 2% yield. Attempts to synthesize *(5)* by the reaction of diethyl carbonate with methylhydrazine were unsuccessful and gave only ethyl 2-methylcarbazinate [3].

Procedure:

Phosgene (175 g) is passed into a stirred slurry of 473 g of benzaldehyde methylhydrazone in 6 liter of ether for 8 h at a temperature of 25–30 °C (external cooling). After standing at room temperature for 15 to 18 h, the precipitate is separated and washed with water to remove the hydrochloride of compound *(1)*. The water insoluble portion is dried and recrystallized from heptane to afford 465 g (89 % yield) of 1,5-bis(benzylidene)-2,4-dimethylcarbonohydrazide *(2)*, m.p. 159–160 °C.

A mixture of 226 g of *(2)*, 335 g of 2,4-dinitrophenylhydrazine, 5 liter of ethyl alcohol, and 165 ml of concentrated hydrochloric acid is refluxed for 48 to 72 h, and benzaldehyde dinitrophenylhydrazone is removed by filtration. The filtrate is evaporated to dryness *in vacuo* and extracted with water. The aqueous solution is neutralized, the water is evaporated, and the dry residue recrystallized from ether or acetonitrile to afford pure 2,4-dimethyl carbohydrazide, m.p. 65 °C.

1,2,5-Selenadiazole

By *L. M. Weinstock*, *P. Davis*, *D. M. Mulvey*, and *J. C. Schaeffer* [*]

3,4-Dicyanoselenadiazole [1] and 4-amino-1,2,5-selenadiazole-3-carboxylic acid [2] are known. We have now synthesized the previously unknown parent compound 1,2,5-selenadiazole *(1)*.

(1)

The synthesis of *(1)* is analogous to the recently reported one-step preparation of 1,2,5-thiadiazole [3]. Ethylenediamine dihydrochloride was allowed to react with selenium monochloride (molar ratio 1 : 8) in dimethylformamide, first for 1 h at −20 °C and then for 6 h at 0 °C. Subsequent steam distillation of the reaction mixture afforded 7 % of 1,2,5-selenadiazole.

IR-Spectrum (liquid film): 3030 (w), 1359 (s), 1230 (s), 1005 (m), 878 (s), 725 (s) cm^{-1} [4].

The 12 eV mass spectrum of 1,2,5-selenadiazole displays a signal at *m/e* 134 corresponding to $^{12}C_2H_2{}^{14}N_2{}^{80}Se$. Four satellite molecular peaks at *m/e* 136, 132, 131, and 130 appear in proportion to the relative isotopic abundances of Se^{82}, Se^{78}, Se^{77}, and Se^{76}. In the 70 eV mass spectrum, $HCNSe^+$, HCN^+, and Se^+ appear as the major fragmentation products, analogous to the fragmentation of 1,2,5-thiadiazole [5].

The properties of 1,2,5-selenadiazole are compared with those of 1,2,5-oxadiazole (furazan) [6] and 1,2,5-thiadiazole [3, 7]. The data indicate that 1,2,5-selenadiazole, like 1,2,5-thiadiazole and selenophene, is a thermally stable, aromatic ring system.

Bis-(1,5-cyclooctadiene)platinum(0)

By *J. Müller* and *P. Göser* [*]

If $CODPtCl_2$ [1] (COD = 1,5-cyclooctadiene) is treated with an excess of iso-C_3H_7MgBr in ethereal solution, under N_2 at −40 °C, and in the presence of COD, a dark yellow solution results when the mixture is stirred for 3 h. After methanolysis at −50 °C, removal of the solvent by distillation, and crys-

tallization of the residue from hexane at a low temperature, an almost colorless, well-crystallizing, light-sensitive compound CODPt(iso-C_3H_7)$_2$ *(1)* can be isolated in 40% yield (m.p. 54–56 °C).

If a solution of this product *(1)* in COD at 20 °C under N_2 is irradiated for 22 h with UV light (Hg high-pressure lamp Hanau Q 81), subsequent distillation of the COD in a high vacuum and chromatography of the residue on neutral Al_2O_3 ("Woelm", 7% H_2O) with n-hexane as eluent gives a colorless solution from which, on cooling to −78 °C, colorless diamagnetic $(COD)_2Pt(0)$ *(2)* [m.p. 110–111 °C (decomp.)] crystallizes in 22% yield.

Compound *(2)* is the first purely olefinic complex of zerovalent platinum. For comparison we prepared the known[2] yellow nickel complex $(COD)_2Ni$ *(3)* [m.p. 140–142° (decomp.)] in 13% yield by treating anhydrous $NiCl_2$ under N_2 with an excess of iso-C_3H_7MgBr and COD in ether and irradiating the resulting dark brown solution with UV light for 8 h. The compounds *(2)* and *(3)* have similar properties but *(2)* is more resistant to atmospheric oxidation.

In the ^1H–NMR spectrum of *(2)* in C_6H_6, two signals (intensity ratio, 1:2) appear at $\tau = 5.82$ (olefinic protons) and $\tau = 7.81$ (methylene protons).

The corresponding signals of *(3)* are at $\tau = 5.64$ and 7.84. The signal of *(2)* at $\tau = 5.82$ shows two satellites ($J = 55$ Hz) caused by ^1H-^{195}Pt coupling; the corresponding satellites of the methylene protons signal are poorly resolved.

The mass spectrum of *(3)* (Atlas mass spectrometer CH4, ion source TO4, 50 eV) shows mainly the ions $(COD)_2Ni^+$ (relative intensity $I_r = 27.9$), $CODNi^+$ ($I_r = 100.0$), $C_4H_6Ni^+$ ($I_r = 65.9$), and Ni^+ ($I_r = 8.2$). Under similar conditions the complex *(2)* gives an appreciably more complicated mass spectrum; the principal ions $(COD)_2Pt^+$ and $CODPt^+$ are accompanied by several groups of less intense peaks arising mainly by successive loss of C_2 and C_3 units from the molecular ion. The mass spectrum of the free ligand, which is liberated on thermal decomposition of the complex, is also detectable with both *(2)* and *(3)*.

The IR spectrum of *(2)*, which contains many lines, is characterized by the following bands (KBr): 2994, 2907, 2853, 2801, 1471, 1458, 1445, 1392, 1361, 1323, 1299, 1230, 1203, 1171, 1151, 1085, 1068, 1000, 990, 954, 879, 860, 845, 820, 813, 803, 779, 760, and 673 cm^{-1}.

Attempts to prepare di(norbornadiene)platinum(0) have so far failed. Treatment of nor-$C_7H_8PtCl_2$[3] with an excess of iso-C_3H_7MgBr in ether under N_2 at −40 °C gave almost an 80% yield of well-crystalline yellow nor-C_7H_8Pt(iso-C_3H_7)$_2$, but UV irradiation of this material in norbornadiene did not give the desired purely olefine complex.

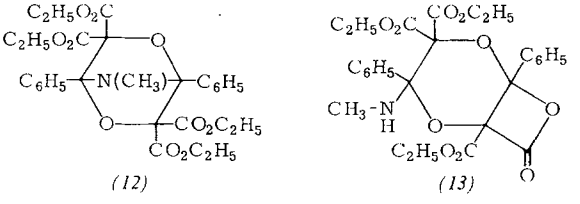
1,3-Cycloadditions of Mesoionic Oxazolones to Carbonyl Compounds

By *R. Huisgen* and *E. Funke*[*]

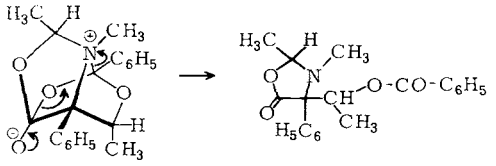
The mesoionic oxazolone *(1)* is a very active azomethine ylide; its 1,3-adducts with acetylene derivatives or with olefins are stabilized by loss of carbon dioxide, yielding pyrrole[1] or 2-pyrroline derivatives, respectively[2]. Aldehydes, α-diketones, and α-keto carboxylic esters can also induce elimination of carbon dioxide from *(1)*, such reactions yielding the *N*-benzoylalkenylamines *(4)* to *(11)*.



(1) *(2)* *(3)* *(4)–(11)*

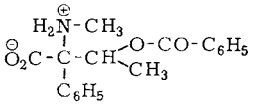
	R	R′	Reaction temp. (°C)	CO_2 (%) from (1)	Yield (%)	M.p. (°C)
(4)	H	H	80	48	45	93–94
(5)	CH_3	H	[a]		32	139
(6)	C_6H_5	H	33	49	46	110.5–111.5
(7)	(4)-ClC_6H_4	H	37	59	52	140–141
(8)	(4)-$CH_3OC_6H_4$	H	36	66	45	149–150
(9)	CO–C_6H_5	C_6H_5	100	73	60	191
(10)	CH_3	CO_2CH_3	20	49	51	103–103.5
(11)	$CO_2C_2H_5$	$CO_2C_2H_5$	20	66	57	103–104.5

[a] From *(15)* at 120 °C.



Proofs of structure: *(4)* was hydrogenated to a product identical with authentic *N*-methyl-*N*-(α-phenethyl)benzamide. *(5)* and an acid solution of 2,4-dinitrophenylhydrazine gave a 92% yield of the propiophenone derivative. Analogously *(6)* was converted into deoxybenzoin 2,4-dinitrophenylhydrazone in 81% yield. With 85% phosphoric acid the benzil adduct *(9)* afforded ω,ω′-dibenzoyltoluene in 65% yield; similar treatment of *(11)* yielded acetophenone, benzoic acid, methylamine, and CO_2. The amide I bands of *(4)* to *(11)* are at 1627–1655 cm^{-1}.

If the oxazolone *(1)* is stirred slowly into an ethereal solution of an excess of diethyl mesoxalate, addition of the dipolarophile to the intermediate *(3)*, which is a new cyclic azomethine ylide, competes with ring opening of this intermediate to give *(11)*. The product is the bicyclic diadduct *(12)* which on mild treatment with acid gives the β-lactone *(13)* (C=O at 1820, 1755, 1737 cm^{-1}) and on energetic hydrolysis in the presence of 2,4-dinitrophenylhydrazine gives phenylglyoxal osazone. *(12)* decomposes at 160 °C into mesoxalic ester and 80% of *(11)*.



(12) *(13)*

Treating the oxazolone *(1)* with acetaldehyde at 0 °C afforded 73% of a bisadduct *(15)*, without loss of carbon dioxide. Presumably here the intermediate *(2)* is trapped by addition of the second molecule of acetaldehyde, which yields *(14)*. Ring opening thereof then explains the formation of the oxazolidone derivative *(15)* [NMR (in $CDCl_3$), 2 CH–CH_3 3.89 (q) and 8.44 (d) τ, as well as 5.48 (q) and 8.83 (d) τ; IR (KBr), ring C=O 1788, ester C=O 1715 cm^{-1}].

(14) (15)

(16)

2,4-Dinitrophenylhydrazine in acid solution converts *(15)* into the acetaldehyde derivative (90 %) and into the threonine derivative *(16)* (88 %), the latter being cleaved by alkali to *N*-methylphenylglycine, acetaldehyde, and benzoic acid. At 120 °C *(15)* yields 32 %, and at 170 °C *(16)* yields 49 %, of the *N*-benzoylalkenylamine *(5)*.

The reaction path *(1)* → *(4)* to *(11)* is thus proved by trapping of the intermediates *(2)* and *(3)*.

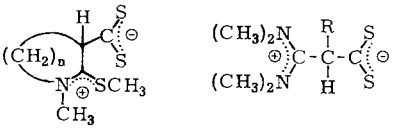
Stable 1,4-Dipoles from Ketene Acetals and Carbon Disulfide and their Use for Synthesis of Heterocycles

By *R. Gompper* and *W. Elser* [*]

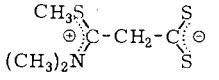
Reaction of simple ketene *S,N*-acetals *(1)* [1] with acylating agents *(2)* gives either acylated ketene *S,N*-acetals *(5)* or, by way of *(4)* and *(5)*, heterocycles such as pyrimidines [2].

(1) (2) (3)



(5) (4)

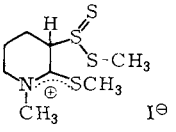
Products [2]



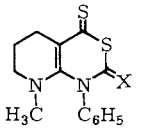
R = H, Alkyl, Aryl
X, Y = O, S, NR'', CR_2''

To test whether 1,4-dipoles *(4)* are intermediates and whether they arise directly from *(1)* and *(2)* or from the cycloaddition products *(3)*, we treated *(1)* and corresponding ketene aminals with carbon disulfide in acetonitrile at −40 °C. Orange to red crystalline compounds were obtained (in some cases isolated only on precipitation by ether), which are stable at −40 to −20 °C but decompose slowly at room temperature.

According to their elemental analyses they are 1:1 adducts. Their IR spectra (in Hostaflon oil) are characterized by intense bands at 1590–1620 cm^{-1}, such as are observed also in the spectra of quaternary salts of thioamides. We thus conclude that we are dealing with the 1,4-dipoles *(6)*, *(7)*, and *(8)*.

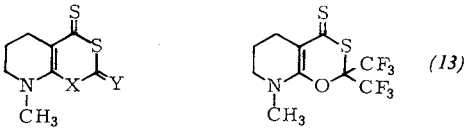


(6a), n = 2 *(7a)*, R = H
(6b), n = 3 *(7b)*, R = CH_3

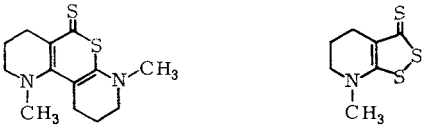


(8)

The NMR spectra (determined in liquid SO_2) are in agreement with this formulation. The temperature-dependence of the NMR spectrum of *(7)* is remarkable: at 0 to −10 °C the signal of the N–CH_3 protons appears as a singlett; however, at −50 °C a doublet (intensity ratio 1:1) appears in the spectrum of *(7a)*, and in that of *(7b)* there is also a doublet but with an intensity ratio of 3:1. The N–CH_3 signal in the spectrum of *(8)* is always a singlet. Compounds *(6)*, *(7)*, and *(8)* can be readily alkylated; for instance, the red compound *(6b)* reacts with methyl iodide to give the yellow salt *(9)*, m.p. 143–145 °C.

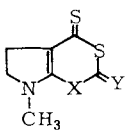


(9)

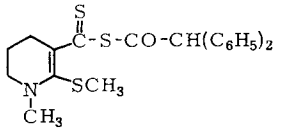


(10a), X = O
(10b), X = S
(10c), X = NC_6H_5

The 1,4-dipoles *(6)* undergo (4 + 2)-cycloadditions [when carried out at −20 to 0 °C in acetonitrile; only *(14)* was prepared at 40 °C]. Thus, with *(6b)*, phenyl isocyanate yields *(10a)*, m.p. 197–199 °C, phenyl isothiocyanate yields *(10b)*, m.p. 194 °C, diphenylcarbodiimide yields *(10c)*, m.p. 191–193 °C, diphenylketene yields *(11)*, m.p. 210 to 211 °C, cyanomethoxycarbonylthioketene [3] yields *(12)*, m.p. 223 °C, hexafluoroacetone yields *(13)*, m.p. 133 °C, 1,4,5,6-tetrahydro-1-methyl-2-methylthiopyridine [1] yields *(14)*, m.p. 182–183 °C, and sulfur yields *(15)*, m.p. 143–144 °C. Elemental analyses and IR and NMR spectra correspond to the structures indicated. On treatment of *(6a)* with diphenylketene the product *(16)*, m.p. 202–203 °C, is accompanied by the isomer *(17)*, m.p. 262–265 °C.



(13)



(11) X = O, Y = $C(C_6H_5)_2$
(12) X = S, Y = $C(CN)CO_2CH_3$

(14) *(15)*

(16), X = O, Y = $C(C_6H_5)_2$
(17), X = $C(C_6H_5)_2$, Y = O

(18)

When compound *(18)* (red needles, decomp. at 88 °C), obtained from *(6b)* and diphenylacetyl chloride, is kept in solution in acetonitrile, it affords compound *(11)*. It is thus shown that cycloadditions to *(6)*, *(7)*, and *(8)* can occur in two stages; nevertheless a synchronous process is not excluded.

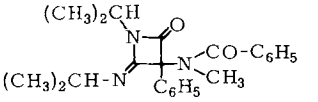
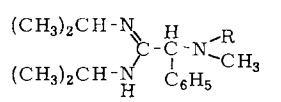
Possible Valence Tautomerism of a Mesoionic Oxazol-5-one with an Acylaminoketene

By *R. Huisgen*, *E. Funke*, *F. C. Schaefer*, and *R. Knorr* [*]

Anhydro-5-hydroxy-3-methyl-2,4-diphenyloxazolium hydroxide *(1)* reacts as a 1,3-dipole with olefins, acetylenes, nitriles, as well as with carbonyl and thiocarbonyl compounds [1] in accord with the cycloaddition scheme 3 + 2 → 5. In reaction with C=N double bonds a new mode of reaction appears, namely cycloaddition 2 + 2 → 4: on reaction of compound *(1)* with azomethines at 80 to 100 °C we obtained the α-acylamino-β-lactams *(3)* to *(7)* (the penicillins also belong to this class of compounds). The azetidinones *(3)* to *(7)* show the lactam carbonyl band at 1730 to 1755 cm^{-1} as well as the amide I band at 1630 to 1656 cm^{-1}.



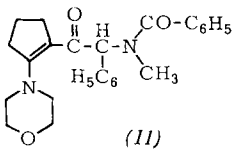
(1) *(2)*



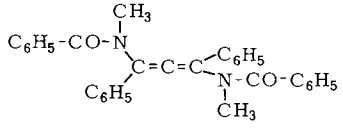
(3) - *(7)*

	R	R^1	R^2	Yield (%)	M.p. (°C)
(3)	H	C_6H_5	CH_3	62	158–159
(4)	H	C_6H_5	CH_2–C_6H_5	47	156–157
(5)	H	C_6H_5	C_6H_5	33	162.5–163
(6)	C_6H_5	C_6H_5	C_6H_5	25	170.5–171
(7)	Fluorenylidene		C_6H_5	56	208.5–209

Compound *(1)* reacts with diisopropylcarbodiimide at 137 °C to give the azetidinedione imine *(8)* (yield 63 %; m.p. 159–160 °C), whose IR spectrum (KBr) shows bands at 1808 (lactam C=O), 1687 (C=N), and 1637 cm^{-1} (amide I). Dilute hydrochloric acid converts this product into the *N,N'*-diisopropylamidine *(9)* of α-(*N*-benzoylmethylamino)phenylacetic acid, whereas concentrated hydrochloric acid yields *(10)* in 87 % yield.



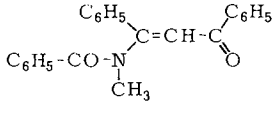
(8)



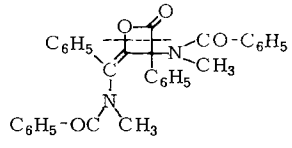
(9), R = CO-C_6H_5
(10), R = H

The simplest explanation of these reactions rests on valence tautomerism of the mesoion *(1)* with (*N*-benzoylmethylamino)phenylketene *(2)*. Formation of β-lactams from ketenes and azomethines has been known for 60 years [2], and cycloaddition to carbodiimides has also been described [3].

We have been able to confirm the hypothesis that enamines (the most active "ketenophiles" [4]) react with the ketene form *(2)*. We obtained compound *(11)* (yield 45 %) from *(1)* and 4-(1-cyclopentenyl)morpholine. Ring opening of the initially formed cyclobutanone derivative to yield the β-acylalkenylamine *(11)* follows a known pattern [5].



(11)



(12)

The presence of the ketene tautomer has not yet been demonstrated spectroscopically; the equilibrium concentration must be very small. Thermolysis of *(1)* in boiling xylene can be simply explained by way of *(2)*: loss of 1 mole of CO_2 from 2 moles of *(1)* yields the tetrasubstituted allene *(12)*, decomp. 186–187 °C (yield 86 %). The IR spectrum of *(12)* shows the typical allene band at 1920 cm^{-1}. The two N–CH_3 groups are equivalent (NMR in $CDCl_3$, s 6.98 τ). In the presence of HCl one equivalent of water in dioxane at room temperature causes partial hydrolysis to *(13)*, whereas on reaction with 3N HCl double enamine hydrolysis leads to dibenzoylmethane.

(13)

(14)

Dimerization of the ketene tautomer to the β-lactone could be the initial step, which is followed by loss of carbon dioxide with formation of *(12)*. Analogous formation of the allene from the β-lactone dimer of dimethylketene [6] or bis(trifluoromethyl)ketene [7] occurs only at 450 °C or 600 °C, respectively. Apparently the acylamino groups in *(14)* promote cleavage of the molecule.

Loss of CO_2 from a solution of *(1)* in benzonitrile at 115, 120, and 140 °C is a second-order reaction with $\Delta H^{\neq} = 19.1$ kcal/mole and $\Delta S^{\neq} = -17$ cal deg^{-1} $mole^{-1}$.

The evidence for the tautomerism *(1)* ⇌ *(2)* is thus only chemical at present; there is as yet no physical evidence to support this hypothesis.

Isomerism of *N'*,*N'*-Diethylthioformohydrazide with Its Betaine

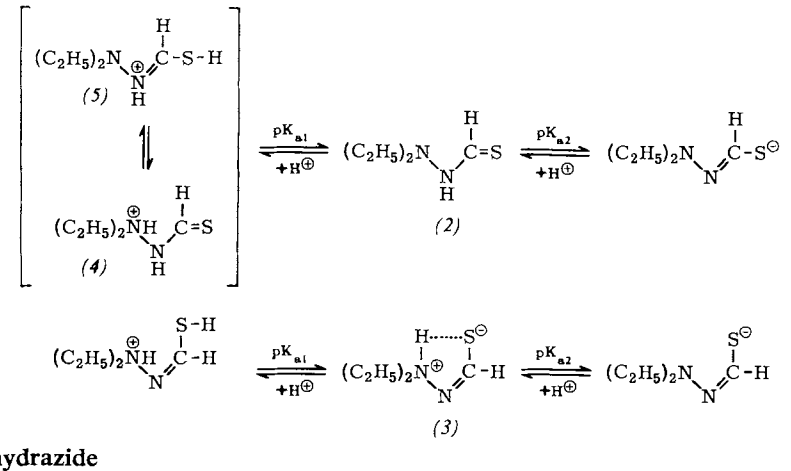
By *W. Walter* and *K.-J. Reubke* [*]

On the basis of spectroscopic results, structure *(1)* has been assigned to *N'*,*N'*-diethylthioformohydrazide, which was recently synthesized by *Bredereck et al.* [1].

(1)

On thioformylation of asymmetric diethylhydrazine with thioformic ester [2] we obtained a product *(2)* which differs in melting point (77–78 °C) and IR spectrum, as well as in behavior on thin-layer chromatography, from the compound prepared by *Bredereck*'s method (m.p. 102–104 °C; lit. [1] 101–105 °C), although in agreement with the latter in molecular weight and composition, We ascribe the thioformohydrazide structure to the isomer *(2)*, and a betaine structure *(3)* with mainly intramolecular hydrogen bridges to the isomer formulated as *(1)* by *Bredereck et al.*, Structures *(1)* and *(3)* are both in accord with the IR spectrum.

The two substances are interconvertible. When *(2)* is dissolved in boiling ethyl formate, *(3)* separates on cooling. If *(3)* is boiled in chloroform for 20 min and the solution is poured into an ice-cooled vessel, then *(2)* can be detected by thin-layer chromatography and by its IR spectrum in the equilibrium mixture that is precipitated.



The ^{1}H–NMR spectrum of *(3)* contains, not only the signals of the ethyl protons (triplet at τ = 8.72, quadruplet at 6.77) and a sharp signal at τ = 0.97 (thioformyl proton), but also a broad strong signal that we attribute to a hydrogen bridge between sulfur and nitrogen (a sharp signal would be expected for a S–H proton).

The ^{1}H–NMR spectrum of *(2)* contains the ethyl signals at higher field (triplet at τ = 8.97, quadruplet at τ = 7.23). At τ = 0.90 and 0.73 there are two sharp signals, and at τ = 1.30 and 1.13 two broad signals of unequal intensity; these four signals together correspond to two protons. The spectrum can be interpreted as that of the thioformohydrazide structure if hindered rotation around the C–N bond is assumed. The IR spectrum of *(2)* contains all the bands that are characteristic of thioacylhydrazines [3].

We ascribe the three bands between 2700 and 2780 cm^{-1} in the IR spectrum of *(3)* to a $^+$NHR$_2$ group; dimethylhydrazine hydrochloride also shows a split band in this region. We ascribe the strong band at 1460 cm^{-1} to a C–N double bond.

The betaine structure *(3)* is favored by the pK_a values that were determined photometrically for the two isomers: *(2)*, pK_{a1} = 2.8, pK_{a2} = 10.4; *(3)*, pK_{a1} = 3.4, pK_{a2} = 11.7. The value pK_{a2} = 10.4 for *(2)* was confirmed by potentiometric titration.

We interpret these findings by means of the following equilibria.

Comparison of the pK_a values for *(2)* with those of other thioacylhydrazines [4] shows agreement for pK_{a2} (9.2 to 11.1), but pK_{a1} for *(2)* is smaller than for other thioacylhydrazines (4.2 to 6.2). Since the pK_{a2} for *(3)* is greater than that for *(2)*, the former compound cannot be a thiol since then the pK_a would be smaller – or at least not higherthan that for compounds in which the form *(1)* can be considered toccur by inclusion of the N–N–C(=S) group in a ring that is capable of mesomerism. *Sandström* [5] recently found pK_a values between 5.01 and 8.19 for such compounds.

Isolation of Cyanocobalamine 5'-Phosphate [1]

By *P. Renz* [*]

When a crude extract of *Propionibacterium shermanii* is incubated with cobinamide and 5,6-dimethylbenzimidazole in the presence of tris/HCl buffer (pH = 7.5) for 10 h at 37 °C, subsequent product recovery in the presence of KCN gives cyanocobalamine 5'-phosphate *(2)* (*ca.* 15 %) along with cyanocobinamide (*ca.* 70 %) and cyanocobalamine (*ca.* 15 %) *(1)*.

The phosphate was identified as follows: On electrophoresis it moves rapidly to the anode in 0.5 N acetic acid. It contains two atoms of phosphorus per corrinoid molecule. Its UV spectrum is the same as that of vitamin B_{12} *(1)*. It behaves

like synthetic cyanocobalamine 5′-phosphate[3] on paper chromatography in four solvents[2] and on paper electrophoresis at pH 2.5, 7.5, or 11.0. Like the synthetic product, it is degraded to vitamin B_{12} *(1)* by acid phosphatase at pH = 4.8.

[Co] = Cobinamide residue
B = 5,6-Dimethylbenzimidazole
(1), X = H (Cyanocobalamine)
(2), X = PO_3H^- (Cyanocobalamine 5′-phosphate)

Evidence for location of the second phosphate group of *(2)* at the 5′-position of ribose is the color reaction with carbazole in sulfuric acid that is characteristic of ribose 5-phosphates[4]. The spectrum, which was recorded with the product of the carbazole reaction of *(2)* in the sample cell and the product from *(1)* in the comparison cell, shows an absorption maximum at 585 nm; the product of the carbazole reaction of adenosine 5′-phosphate also has a maximum at this position. Since incubating *(2)* with crude extracts of *P. shermanii* in the presence of 2-mercaptoethanol affords vitamin B_{12} *(1)*, it is possible that *(2)* is a biosynthetic precursor of *(1)*.

Formation of *(2)* can be explained as follows: *P. shermanii* extracts give α-ribazole 5′-phosphate from 5,6-dimethylbenzimidazole[5]. On the other hand, under mildly aerobic conditions *in vivo*[6], *P. shermanii* yields much *P*(1)-cobinamide *P*(2)-guanosine 5′-pyrophosphate *(3)*, along with *(1)*, from cobinamide[7]. It is thus possible that *(2)* arises directly by transfer of the cobinamide phosphate part of *(3)* to the 3′-position of α-ribazole 5′-phosphate.

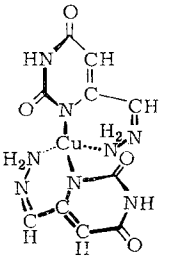
4-Uracilcarbaldehyde Hydrazone[1]

By *R. Brossmer* and *D. Ziegler*[*]

Whereas 5-uracilcarbaldehyde and hydrazine give only a stable azine, the isomeric 4-carbaldehyde gives also a hydrazone *(1)* [yield 82% (without product recovery from the mother liquor); m.p. 260 °C (decomp.)], that is difficultly soluble in water and has λ_{max} = 311 nm ($\varepsilon = 15.8\times10^3$) 1 and λ_{min} = 250 nm($\varepsilon = 3.4\times10^3$).



(1)

The hydrazone *(1)* reacts with aliphatic, aromatic, and heterocyclic aldehydes in hot aqueous or aqueous-alcoholic solution, giving mixed azines. The pale yellow to orange-yellow products usually crystallize out directly and are pure

Mixed azine of *(1)* with	Yield [2] (%)	M.p. (°C)
Crotonaldehyde	75	212–213
Salicylaldehyde	83 [3]	> 300
Terephthaldehyde[4]	82	> 300
1-Naphthaldehyde	64	274 (decomp.)
3-Pyridinecarbaldehyde	96	278–280 (decomp.)
5-Uracilcarbaldehyde	90	> 300

without recrystallization. Dialdehydes, *e.g.* terephthalaldehyde, react with *(1)* in the molar ratio 1:2, yielding bisazines. An aqueous solution of *(1)* with Cu(II) salts gives quantitatively the well crystalline, olive-green, and very insoluble paramagnetic complex *(2)*.

(2)

As a molecular model shows, this complex must be tetrahedral. It is the first inner orbital complex, of this kind, of copper with a pyrimidine derivative. It is decomposed by mineral acids to Cu(II) salt and yellow crystals which, according to the composition and the IR spectrum, are 4-uracilcarbaldehyde azine.

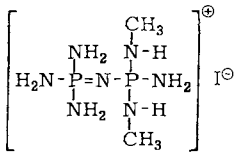
The Structure of $[P_2N_7H_{10}(CH_3)_2]I$



By *M. Ziegler*[*]

Gutmann et al.[1] obtained the compound $P_2N_7C_2H_{16}Cl$ by the ammonolysis of $(Cl_3PNCH_3)_2$; they suggested the symmetrical structure *(1)*.

(1)

On the other hand, X-ray structure analysis of the iodide[2] showed that both the N–CH_3 groups are bound to the same phosphorus atom *(2)*.

(2)

The iodide crystallizes as monoclinic crystals with C_{2h}^5-$P2_1/n$ space grouping. The lattice constants are a = 6.03 Å, b = 23.87 Å, c = 8.27 Å, β = 97°46′. There are four structural units in the unit cell. The structure is established by three-dimensional Patterson- and Fourier-syntheses.

Provisional parameters are:

	x	y	z		x	y	z
I	0.9892	0.1271	0.0824	N_4	0.6198	0.9939	0.7557
P_1	0.4136	0.0379	0.7332	N_5	0.8107	0.1010	0.5105
P_2	0.5744	0.1259	0.5528	N_6	0.4424	0.1620	0.4066
N_1	0.4283	0.0756	0.5781	N_7	0.6633	0.1694	0.6976
N_2	0.4571	0.0665	0.9102	C_1	0.5400	0.2085	0.3330
N_3	0.1706	0.0087	0.7094	C_2	0.4696	0.2032	0.7495

The iodine is ionically bound and the angle at the nitrogen bridge atom is approximately 130°. The distance of the two phosphorus atoms from this nitrogen bridge are different and less than the other P–N distances; the latter are similar and average 1.61 Å. The provisional residual value amounts to 0.13.

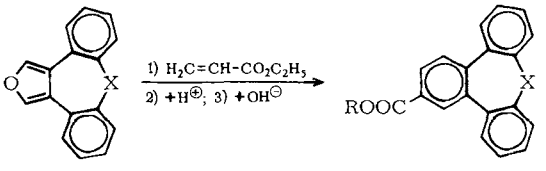
Synthesis of an Optically Active Tribenzothiepin *S,S*-Dioxide[1]

By *W. Tochtermann* and *C. Franke*[*]



Tribenzocyclohepten-9-ylideneacetic acid[1a] and methylenedibenzocycloheptenes[2] can be resolved into optical antipodes. In order to determine whether optical antipodes can also be obtained when the seven-membered ring contains a heteroatom we synthesized tribenzothiepin-2-carboxylic acid *S,S*-dioxide *(5b)*. As the formulae show, the same process can be used for synthesis of 9-oxotribenzocycloheptene-2-carboxylic acid *(5a)*, and we have thus a generally available route to chiral benzologous seven-membered ring systems.

The Diels-Alder adducts *(2)* from the epoxides *(1)*[3] and tetraphenylcyclopentadienone decompose in boiling xylene, yielding carbon monoxide, 1,2,3,4-tetraphenylbenzene, and the furan derivatives *(3)*; the last products undergo a further Diels-Alder addition with ethyl acrylate[4]. The epoxide *(1)* and tetraphenylcyclopentadienone (molar ratio 1.1:1) are heated in boiling xylene under nitrogen until the characteristic color of the ketone has disappeared, then an excess of ethyl acrylate is added and the whole is boiled for a further 16 h. The 1,2,3,4-tetraphenylbenzene is then separated (yield 80 to 90%) from the acrylic ester adduct [yield 50% from *(1a)*, 25% from *(1b)*] by chromatography on Al_2O_3 (eluent CCl_4 and $CHCl_3$). In each case, this procedure yields two stereoisomeric adducts [(from *(1a)*, m.p. 173–175 °C and m.p. 153–154 °C)], which can be dehydrated by acetic anhydride (10 min at 140 °C; a little concentrated H_2SO_4 is added) to *(4)* [*(4a)*, m.p. 132–133 °C, yield 75 %; *(4b)*, m.p. 197–199 °C, yield 50 %)]. Hydrolysis of *(4)* yields the carboxylic acids *(5a)*, m.p. 280–281 °C, and *(5b)*, m.p. 335–337 °C, the structure of which was confirmed by elemental analysis and IR and UV spectra.

(1)(a), X = CO
(b), X = SO_2

(2)

(3)

(4), R = C_2H_5
(5), R = H

Tribenzothiepin-2-carboxylic acid *S,S*-dioxide *(5b)* can be resolved by brucine into the enantiomers, since the brucine salt of the levorotatory acid crystallizes preferentially from acetone/ethanol (1:1, v/v). The specific rotations for *(5b)* are $[\alpha]_{436}^{24} = -250°$ and $[\alpha]_{436}^{24} = +200°$ (c = 0.01 g/ml in diglyme). Racemization occurs when the solutions are heated. At 92 °C $t_{1/2}$ is *ca.* 5 h, whence it follows that for *(5b)* ring inversion of the boat-form of the seven-membered ring requires an energy of about 29 kcal/mole.

Difluoro(trifluoromethylsulfenylimino)sulfur $CF_3SN{=}SF_2$ and Bis(trifluoromethylsulfenylimino)sulfur $CF_3SN{=}S{=}NSCF_3$

By *A. Haas* and *P. Schott*[*]

When a mixture of trifluoromethylsulfenylamine $CF_3S{-}NH_2$ and SF_4 (molar ratio 1:1.3) is heated in the presence of CsF (as HF-absorber) in an autoclave at 20–60° (2–5 atm), a mixture of $CF_3SN{=}SF_2$ *(1)* and $CF_3SN{=}S{=}NSCF_3$ *(2)* is formed. Compund *(1)* distils at −20 °C/0.1 mm into a cold trap cooled in liquid air. Repeated fractional condensation in a Stock vacuum apparatus yields pure *(1)* as a pale yellow liquid that decomposes in glass at 20 °C (yield 30 %). The residue is purified by distillation at reduced pressure, compound *(2)* distilling over as a pale red liquid, whose dilute solution in benzene is yellow (yield 40 %). Both substances were characterized by elemental analysis, determination of molecular weight, and IR, ^{19}F-NMR, and mass spectra.

The IR spectrum of *(1)*, measured in the NaCl and KBr regions, shows strong bands at 1287 (νS=N), 1189 (ν_{as}C–F), 1135 (ν_sC–F) 736 (ν_{as}S–F), and 665 cm^{-1} (ν_sS–F). The ^{19}F–NMR spectrum contains two signals, at −59.8 ppm (SF_2) and 51.9 ppm (CF_3S), referred to CCl_3F as external standard. The mass spectrum shows, besides the molecule ion at *m/e* = 185, typical fragments $CF_3SN{=}SF$ (*m/e* 166), CF_3SN (115), SNS (78), and SN (46) as well as other peaks.

Product *(1)* is also formed, along with other products, on reaction of CF_3SNCO with SF_4 in a 300 ml steel autoclave at 100 °C and 15 atm.

Compound *(2)* boils at 77 °C/80 mm and melts at −58 °C. Its IR spectrum contains two very intense bands at 1171 and 1105 cm^{-1}. Absorptions of medium intensity occur at 940, 753, 650, 503, and 464 cm^{-1}. The chemical shift of the ^{19}F signal is at 52.39 ppm (Cl_3CF as external standard). Typical fragments CF_3SNSNS (*m/e* 193), CF_3SNS (147), SNS (78), CF_3 (69), SN (46), and S (32) appear in the mass spectrum along with the molecular ion at *m/e* = 262.

Synthesis of 1-Deuterioalkyl Halides from Cyclic *S*-Alkylsulfonium Salts and Heavy Water

By *H. Dorn* [*]

Dedicated to Professor A. Rieche on his 65th birthday

Alkyl halides deuterated on the 1-carbon atom were previously accessible only from 1-deuterated alcohols, which are obtained from carbonyl compounds by means of $LiAlD_4$ [1]. We have now found a simple synthesis of 1-deuterioalkyl halides, *i.e.* deuteration of cyclic *S*-alkylsulfonium salts *(1)* and subsequent thermal fission of the deuterated products to sulfides and alkyl halides.

(1) *(2)* *(3)* *(4)*

	X	R	R¹		R²	R³	R⁴
(a)	Cl	CH_3	H	D_2O	CD_3	H	H
(b)	Cl	CH_3	OH	⟶	CD_3	OD	H
(c)	Br	C_2H_5	OH		CD_2CH_3	OD	D

In D_2O containing 0.04 mole of NaOD per mole of sulfonium salt, the salts *(1a)* and *(1b)* exchange all three protons of the CH_3 in 56 h at 35 °C and 120 h at 36 °C, respectively. If there is a longer alkyl chain on the sulfur atom more energetic conditions must be used, with the result that not only the protons of the 1-methylene group of the alkyl chain but also the protons at positions 2 and 6 of the ring are exchanged for deuterium. Thus, when the salt *(1c)* is heated (150 min at 100 °C) with D_2O containing 5 mole-% of NaOD, the compound *(2c)* is obtained.

The sulfonium salts *(2)* are isolated in crystalline form with yields of over 90 % and give the 1-deuterated alkyl halides *(4)* on dry heating at 160–170 °C *(2a)*, 170 °C *((2b)*, or 125–150 °C *(2c)*. Yields of deuterated alkyl halide amount to 100 %.

The sulfides *(3)* can be alkylated again in yields of 90–98 %. The sulfonium bromides can be prepared directly from the sulfide and alkyl bromide; the sulfonium chlorides, quantitatively, from ethereal HCl and an acetone solution of the picrates which are quantitatively precipitated from solutions of, *e.g.*, the iodides or bromides by 25 % lithium picrate solution. 4-Phenylthiacyclohexane *(3a)*, m.p. 55 °C, is formed on catalytic hydrogenation of 4-phenylthiacyclohex-3-ene [2] in ethanol in the presence of Adams catalyst at 45 °C and 6 atm. Sulfides with R^1 = OH are less suitable for preparative purposes since traces of acid or overheating cause partial loss of HDO which interferes with re-use of the sulfides. It is unnecessary to separate the diastereoisomers of *(1)* for the synthesis described above.

Preparation of 2-Alkyl-1,3-cycloalkanediones by Cyclization of γ- and δ-Keto Carboxylic Acids

By *H. Schick, G. Lehmann*, and *G. Hilgetag* [*]

Dedicated to Professor A. Rieche on his 65th birthday

2-Alkyl-1,3-cyclopentanediones hold a key position in the total synthesis of steroids. We have found that γ-keto carboxylic acids *(1)*, $n = 1$ [1], can be cyclized to 2-alkyl-1,3-cyclopentanediones *(2)*, $n = 1$, under the conditions of the Friedel-Crafts reaction in the presence of an acylating agent such as propionyl chloride, acetyl chloride, or acetic anhydride. δ-Keto carboxylic acids *(1)*, $n = 2$ [2], give 2-alkyl-1,3-cyclohexanediones *(2)*, $n = 2$, analogously.

(1) *(2)*

Yields are higher than from any other known process [3], particularly for the higher alkyl derivatives.

R	*n*	Acylating agent (mole)		$AlCl_3$ (mole)	Solvent	Yield (%) [a]	M.p. (°C)
CH_3	2	Propionyl chloride	0.1	0.12	Nitromethane	35	204–206
CH_3	1	Propionyl chloride	0.1	0.24	Nitrobenzene	70	214–216
	1	Acetyl chloride	0.1	0.12	Nitromethane	45	
C_2H_5	1	Acetic anhydride	0.1	0.24	Nitromethane	50	175–177
n-C_3H_7	1	Propionyl chloride	0.1	0.24	Nitromethane	50	180–182
n-C_5H_{11}	1	Propionyl chloride	0.1	0.12	Nitrobenzene	65	149–151

[a] In each case from 0.05 mole of keto acid.

2-Methyl-1,3-cyclopentanedione

4-Oxohexanoic acid (6.5 g, 0.05 mole), sublimed aluminum chloride (32 g, 0.24 mole), and propionyl chloride (9.3 g, 0.1 mole) are heated in nitrobenzene (30 ml) for 3 h at 80 °C with exclusion of moisture. The mixture is cooled to 10 °C, then poured onto ice (50 g), the whole is cooled to 0 °C, and the crude 2-methyl-1,3-cyclopentanedione that separates is filtered off, washed with cold water, and recrystallized from water with addition of active charcoal. A further fraction can be obtained by boiling the aqueous phase of the filtrate with active charcoal, filtering, and continuously extracting the filtrate with ether. Total yield, 3.9 g (70 %).

Preparation of Alkoxyphosphonium Salts by Alkylation of Phosphoryl Compounds

By *H. Teichmann, M. Jatkowski,* and *G. Hilgetag* [*]

Dedicated to Professor A. Rieche on his 65th Birthday

Phosphinic [1], phosphonic [2], and phosphoric esters [2,3] undergo exchange reactions with alkyl halides. The first step is clearly nucleophilic substitution by the phosphoryl oxygen:

R^2 and R^3 = alkyl or alkoxyl

Whereas the intermediate corresponding to *(1)* in the alkylation of thiophosphoric esters can be isolated [4], isolation of the alkoxyphosphonium salts *(1)* has hitherto not been accomplished. The only reports published recently concern the alkylation of triphenylphosphine oxide to stable alkoxytriphenylphosphonium salts [5] and the preparation of tetramethoxyphosphonium hexachloroantimonate *(1g)* from trimethyl phosphite, methyl hypochlorite, and antimony(v) chloride [6].

On alkylation of phosphinic, phosphonic, and phosphoric esters by trialkyloxonium salts in methylene chloride we obtained high yields of the alkoxyphosphonium hexachloroantimonates as unexpectedly stable, well crystalline substances. Analytical values and IR and ^{1}H–NMR spectra agree with the structure assumed.

	R	R^1	R^2	R^3	M.p. (°C)
(1a)	C_2H_5	CH_3	CH_3	CH_3	182
(1b)	C_2H_5	C_2H_5	CH_3	CH_3	179
(1c)	C_2H_5	CH_3	C_2H_5	C_2H_5	178
(1d)	C_2H_5	C_2H_5	C_2H_5	C_2H_5	174
(1e)	C_2H_5	i-C_4H_9	C_2H_5	C_2H_5	48
(1f)	C_2H_5	C_2H_5	C_2H_5	OC_2H_5	144–145
(1g)	CH_3	CH_3	OCH_3	OCH_3	135
(1h)	C_2H_5	C_2H_5	OC_2H_5	OC_2H_5	125

The ^{31}P resonance lines of the dialkylphosphinic esters are shifted by *ca.* 40 ppm to lower field on alkylation to *(1a)* to *(1e)*. However, the ^{31}P values for the tetraalkoxyphosphonium salts [–5 and –3 (±3) ppm for *(1g)* and *(1h)*, respectively] are very close to those for the trialkyl phosphates; the recorded value [6] for the tetramethoxy compound *(1g)* could not be reproduced. IR and ^{1}H–NMR spectra of *(1g)* agree well with published data [6].

Alkoxyphosphonium salts are strong alkylating agents. The alkylating power of the tetraalkoxy compounds *(1g)* and *(1h)* is particularly marked and they react analogously to trialkyloxonium salts, *e.g.* with phosphinic esters:

$$(CH_3)_2P(O)OCH_3 + (1h) \rightarrow (1a) + (C_2H_5O)_3PO$$

Tetraethoxyphosphonium Hexachloroantimonate (1h):

A solution of triethyl phosphate (4.5 g, 24.7 mmoles) in methylene chloride (10 ml) is added dropwise to a solution of triethyloxonium hexachloroantimonate (7.5 g, 17.2 mmoles) in methylene chloride (saturated at room temperature) at –78 °C, with stirring and exclusion of moisture. Warming to room temperature then gives a clear solution which is treated an hour later with anhydrous ether to incipient turbidity and cooled in a CO_2/acetone bath. Filtration of the precipitate gives 7.2 g (77.5 %) of the product *(1h)* as fine leaflets, m.p. 118–120 °C (125 °C after one recrystallization from n-butyl chloride).

In the preparation of *(1a)–(1f)* the ester need not be used in excess; the product can be recovered immediately after warming to room temperature; yields [except for *(1e)* which is precipitated as an oil and is difficult to crystallize] amount to 80–90 %.

Adsorption and Partition

The Analytical Chemistry Group of the *Chemische Gesellschaft in der DDR* held a lecture meeting on "Adsorption and Partition" at Leipzig on October 31st and November 1st, 1966.

From the lectures:

Partition of Triphenyl-lead Derivatives between Aqueous and Organic Phases

By *R. Bock* and *H. Deister*[*]

On treatment of chloroform solutions of triphenyl-lead chloride or bromide with aqueous alkali, triphenyl-lead hydroxide is formed. It remains in the organic phase with extensive condensation to hexaphenyldilead oxide. With this reagent, many organic and inorganic anions can be extracted from aqueous solutions (*e.g.* $Cl^{\ominus}$, $Br^{\ominus}$, $I^{\ominus}$, $CO_3^{2\ominus}$, $AsO_4^{3\ominus}$).

The anions can be re-extracted from the organic phase with aqueous alkali, with regeneration of the reagent. In this way anion separations are possible, *e.g.* selenite-tellurite, chloride-sulfate, organic hydroxy acids – amino acids.

Determination of Benzoic and Phthalic Acids in Terephthalic Acid by Partition Chromatography

By *W. Czerwiński* and *J. Guberska*[**]

Differences in the adsorption of benzoic and phthalic acids on strongly acidic cation exchangers in the hydrogen form were used for the chromatographic separation and determination of small quantities of these acids in terephthalic acid. It is possible to determine from 0.05 to 2 % of benzoic acid and 0.1 to 2 % of phthalic acid.

The sample (about 0.4 g) is dissolved in pyridine, and most of the terephthalic acid is precipitated as the pyridinium salt with benzene. To determine the phthalic acid in the filtrate, this is evaporated to dryness under reduced pressure, and the residue is dissolved in a little pyridine and introduced into the cation-exchange column.

Since the chromatographic band of benzoic acid can be partly masked by the terephthalic acid still present, further terephthalic acid must be extracted from the benzene solution with dilute sulfuric acid before the benzoic acid can be determined. The solution is made alkaline with aqueous sodium hydroxide before the benzene is evaporated.

The separation is carried out in a column (inside diameter 0.4 cm, length 80 cm) containing Dowex 50 W-X4 cation exchanger (200–400 mesh). The separated acids are eluted with water/ethanol, the ethanol concentration being continuously increased (gradient elution). The eluate is automatically titrated to constant pH with sodium hydroxide solution.

Chromatographic Separation of Metal Ions with Anomalous Exchange Properties on Chelating Ion-Exchange Resins

By *R. Hering* and *D. Haupt*[*]

Ion-exchange resins with chelating groups such as those of sarcosine, iminodiacetic acid, or β-carboxymethylamino-propionic acid ("chelon resins") react with metal ions in the same way as the corresponding monomers to form complexes of different stability. The exchange behavior is influenced by the shift of redox potential associated with complex formation.

Metal ions with normal exchange properties are quantitatively complexed, transcomplexed, or decomplexed even at room temperature without kinetic inhibition. This group includes most bivalent metal ions (arranged in order of decreasing complex stability): Cu^{2+}, (UO_2^{2+}), Pb^{2+}, Ni^{2+}, Cd^{2+}, Zn^{2+}, Co^{2+}, Be^{2+}, Mn^{2+}, Ca^{2+}, Mg^{2+}, Sr^{2+}, Ba^{2+}. However, there are also a number of metal ions having anomalous exchange properties. The anomalies are due to kinetically inhibited complexing and transcomplexing reactions (inert complexes, *e.g.* with Pd^{2+}, Hg^{2+}, Fe^{3+}, Cr^{3+}, or VO^{2+}), displacement of the redox potentials (*e.g.* with Au^{3+}, Hg_2^{2+}, Co^{3+}, V^{2+}, VO_4^{3-}, Fe^{2+}), or the deposition of hydrated oxides in the pores of the resin (*e.g.* with Sn^{2+}, ZrO^{2+}, Th^{4+}, MoO_4^{2-}, WO_4^{2-}). The anomalous exchange properties revert to normal behavior so that the metal ions in question can then be dealt with by metal-specific filtration on chelon resins by:

1. Raising temperature to 90 °C,
2. Increasing concentration of elution acid to 5 N.

The anomalies can be utilized for special separations, *e.g.* Au^{3+}/Cu^{2+}, Mg^{2+}, Ca^{2+}; $Au^{3+}/Pd^{2+}/Pt^{4+}$; Cr^{3+}/Al^{3+} and others.

Ion Flotation as a Separation Process in Toxicology

By *M. Hofman*[**]

The idea of concentration by foaming, *i.e.* using the gas/liquid phase boundary, is not new. Apart from the purely phenomenological observations by *Wo. Ostwald* in 1928, there are a whole series of methods for the solution of this problem. For example, *F. Schütz* observed in 1946 that surface-active substances can be successively separated by foaming in order of decreasing surface activity; the deciding influence is the substance-specific lowering of the surface tension.

However, this is not the case in *Sebba*'s ion flotation process [1]. In contrast to "classical" flotation, the principal role in this new technique is played by the attractive forces between the ions in the solution and those of the detergent. Surface-active ions of opposite charge are added to the aqueous solution of the ion to be concentrated, and fine gas bubbles are produced

[*] Dieter Haupt
Pädagogisches Institut

Praha 6 (ČSSR)
Dejvice, Tylišovská 7

[1] *F. Sebba*: Ion Flotation. Elsevier Monograph, Engng. Sect., Amsterdam 1962.

near the surface of the liquid. After a certain time, the resulting dynamic foam containing the complex of the ion sought with the detergent is broken down, and the liquid is analysed. The substances that are most important in toxicology, such as barbiturates, analgesics, alkaloids, and basic drugs, can be concentrated from the biological material and determined *e.g.* by means of the relatively simple apparatus described by *Karger* and *Rogers* (1961)[2].

The separation involves the following steps: 1. preparation of the sample, with deproteination of the blood or of the organ homogenate, 2. production of the liquified foam, 3. treatment of the latter, including elimination of the detergent, and 4. paper-chromatographic analysis.

Properties and Application of an Amphoteric Ion-Exchange Resin Based on Aminopropionic Acid

By *E. Hoyer* and *G. Kühn*[*]

A uniform, chemically stable ion-exchange resin is obtained by the reaction of cross-linked polychloromethylstyrene with ethyl *N*-methyl-β-aminopropionate followed by hydrolysis. Owing to the low stability of the aliphatic six-membered chelate ring and the inductive effect of the methyl group, the ampholytic action predominates and the complex formation is very weak. Of the metal ions studied, Cu^{2+}, UO_2^{2+}, Cr^{3+}, Bi^{3+}, Fe^{3+}, $[PtCl_6]^{2-}$, $[PdCl_4]^{2-}$, $[AuCl_4]^-$, and VO_3^- are bound, but not Ni^{2+}, Co^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Mn^{2+}, NH_4^+, Tl^+, alkaline earth metal, alkali metal, or rare earth ions. This offers the following analytical possibilities: Copper(II) ions can be separated quantitatively from the ions of the second group above by simple filtration. UO_2^{2+}, and at about 85 °C Cr^{3+}, can be quantitatively separated from weakly acidic aqueous solutions. The resin is selective for bismuth at pH = 1 – 2. Fe^{3+} ions are quantitatively adsorbed in the presence of sodium sulfate. By use of the amphoteric properties it is possible to resolve a $Cu^{2+}/Mn^{2+}/VO_3^-$ mixture from weakly acidic to neutral solution, the vanadate being bound as the anion.

The resin has a high affinity for noble-metal ions, and can be used to concentrate such ions from extremely dilute solutions. The resin behaves towards acids as a medium-strong basic anion exchanger. It is suitable for the separation of glutamic acid/aspartic acid with 1 % acetic acid as the eluent.

Separation of Selenium with the Aid of Saturated Aliphatic and Aromatic Monoketones

N. Jordanov and *L. Futekov*[**]

In strong hydrochloric acid solution (> 4 N HCl), Se(IV) exists as a chloride complex, which reacts at room temperature with many saturated aliphatic (acetone, methyl ethyl ketone, diethyl ketone, *etc.*) and some aromatic ketones (*e.g.* acetophenone) to form organic selenium compounds. These are either white crystalline substances or yellow oils; they are soluble in chloroform. The solutions remain practically unchanged over long periods (about 7 days at about 25 °C). The ratio of selenium to ketone is 1:1 for the aliphatic ketones and 1:2 for acetophenone. The IR stretching vibrations show that the selenium is not bound *via* the carbonyl group, but *via* the methyl or methylene group of the ketone. The compounds decompose when heated with nitric acid.

This specific method was used for the separation of selenium from other elements such as: Te, Au, Fe, Cu.

Small quantities (0.05 to 0.2 ml) of ketone were added to a strong hydrochloric acid solution. The solution was allowed to stand for 20–30 min, and the organic selenium compound was then extracted with chloroform. After addition of water, the chloroform was evaporated on a water-bath, and the selenium compound remaining in the residue was decomposed with nitric acid. The selenium in the resulting solution can be determined by the tin chloride method in the presence of bismuth nitrate or with 3,3′-diaminobenzidine.

Multilayer Chromatography in Difficult Separations

R. Liebmann[*]

The adsorbents used in thin-layer chromatography are generally single substances. Thus variations in the experimental parameters are restricted to the eluent, the thickness of the layer, the development method, *etc.*

Attempts have been made to find a method permitting the utilization of the properties of different materials on a single plate for the resolution of mixtures, by direct and continuous transition between various adsorption layers. This "multilayer" was prepared with a modified version of *Stahl*'s coating apparatus. If strips (of variable number and thickness) of different materials, which are uniform in the flow direction, are arranged side by side (lane process), it is possible to test these materials simultaneously and under identical conditions for a given separation. However, if the adsorbents are arranged in succession across the flow direction (multilayer process), and if *e.g.* the activities of the adsorbents decrease in the flow direction, sample components that differ only slightly in their adsorption behavior are more effectively separated. On the other hand, if the activity increases in the flow direction, the distance between the spots of substances that differ greatly in their adsorption behavior will be reduced. The layers can also be arranged in any desired manner in order to match the adsorbent to the problem.

The possibilities are further widened by the use of multilayer chromatography in conjunction with the two-dimensional technique. In this way two basic operations (depending on whether the initial flow direction is along or across the layers) offer great versatility. The methods have been tested on combination pesticides and on mixtures of dyes.

Distribution Chromatography for the Analysis of Terephthalic Acid

By *J. Młodecka* and *B. Sekowska*[**]

The analysis of impurities (benzoic, isophthalic, and phthalic acids) in terephthalic acid prepared by disproportionation of potassium benzoate is carried out by multistage paper chromatography and by column chromatography.

In the first stage (flow distance: 1/3 of the length of the paper), a mixture of s-butyl alcohol, formic acid, and water (8:1:1) is used, and in the second stage (to the end of the paper) a mixture of chloroform, methyl alcohol, formic acid, and water (250:25:1:24); the detection limit is 0.3 %.

Two methods are available for the quantitative determination of benzoic acid. The first is based on the removal of dicarboxylic acids on a silica-gel column. For benzoic acid contents lower than 2 %, sublimation at 250 °C must first be carried out. A solution of the crude product in pyridine or of the sublimate in chloroform is introduced into the column. The benzoic acid in the eluate is determined volumetrically (0.02 N alcoholic potassium hydroxide solution, thymol blue) for contents greater than 0.2 %, and spectrophotometrically for contents between 0.02 and 0.2 %.

The second method is based on the separation of benzoic acid with benzene as the eluent on Whatman paper purified with acetic acid, followed by spectrophotometric determination. Phthalic acid is best determined fluorimetrically without chromatographic separation. The small quantity of isophthalic acid in the end product does not interfere. [VB 36 IE]

Boundary-Layer Catalysis [1]

By *G.-M. Schwab* [*]

Most of the mixed catalysts of interest in industry are systems of at least two phases on which the reaction concerned has a lower activation energy than on a single component.

In "normal" mixed catalysts the carrier is a semiconductor and the catalyst is a metal. For typical examples – nickel as catalyst and aluminum oxide or zinc oxide as carrier – it can be shown that the activation energy of a reaction taking place on the catalyst can be changed by doping of the semiconducting carrier (with *e.g.* Li_2O, BeO, Ga_2O_3, or TiO_2). Thus dehydrogenations and hydrogenations are better catalysed by nickel the less n-conducting or the more p-conducting is the carrier. The band model explains this behavior qualitatively, since the Fermi level of the metal is necessarily displaced by a shift of that of the carrier, and thus entry or exit of electrons at the metal/gas boundary is facilitated or inhibited ("chemical rectifier").

Because of the high electron density of the metal it is to be expected that doping of "inverse" mixed catalysts (metal as carrier, oxide as the active component) will have a greater effect. It should be possible to influence strongly the activation energies of reactions on a semiconducting catalyst if the metallic carrier is doped to achieve a lower or higher Fermi energy. Moreover, a change in the thickness of the layer of semiconducting carrier (from *ca.* 50 Å to *ca.* 1000 Å) should affect the catalytic properties. Both expectations have been confirmed. The rate of combustion of carbon monoxide on nickel oxide deposited on silver has a maximum with layer thicknesses of the order of one boundary layer [1], and the activation energy and thus the rate of reaction in the synthesis of SO_3 on ferric oxide is lowered or raised by doping a silver carrier with mercury or palladium, respectively. The theoretical explanation is as follows: After doping, silver emits more or fewer electrons into the semiconductor; thus, in the boundary layer – and only there – the bands are curved downwards and the Fermi boundary shifts into the neighborhood of the conduction band; this has the same effect as n-doping of the semiconductor. [VB 39 IE]

Lecture at Zürich, December 14th, 1966, and at Basel, December 15th, 1966

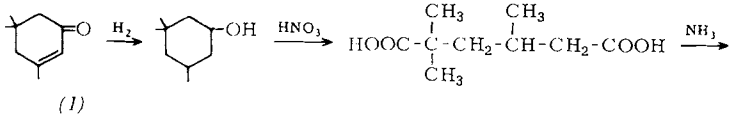
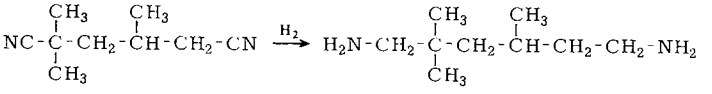
[1] The boundary layer is the surface layer of a semiconductor to the maximum depth (*ca.* 10^{-4} cm) at which the energy of the valence and conduction electrons is still dependent on their position (band curvature).



Chemistry of Acetone

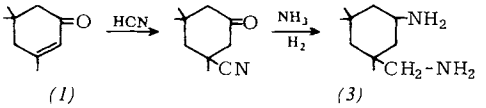
By *K. Schmitt* [*]



Besides the linear condensation of acetone, which leads in its first stage to diacetone alcohol and thence to important solvents such as mesityl oxide, isobutyl methyl ketone, 4-methyl-2-pentanol, hexylene glycol, and 2-methoxy-2-methyl-4-pentanone, the alkaline condensation of acetone to isophorone *(1)* is of special interest. Conditions for this reaction are: 200 °C; 30 atm gauge pressure; 0.03 % NaOH.

Owing to its energetically favored structure isophorone can be obtained in *ca.* 90 % yield; a particularly economical commercial process is that developed by Scholven-Chemie AG., in which the key step is a pressure-distillation reactor permitting successive condensation, fractionation, and hydrolysis; yields and quality are considerably improved in comparison with customary procedures. Whereas, up till recently, isophorone was used only as solvent, it has now achieved importance as raw material for chemical syntheses: Selective hydrogenation of the olefinic double bond leads to 3,3,5-trimethylcyclohexanone. This compound can be prepared by an elegant process of distillative hydrogenation in which reaction and distillation take place in one unit. (Conditions: 1 atm; 160 °C; palladium).

Under more specific conditions (100 atm of H_2, 200 °C, nickel catalyst) 3,3,5-trimethylcyclohexanol is obtained almost quantitatively. Hydrogenation in the presence of ammonia gives 3,3,5-trimethylcyclohexylamine, which is used as an anticorrosion agent and as an antiicer.



(1)

(2)

2,2,4-(2,4,4)-Trimethylhexamethylenediamine *(2)* is obtained from isophorone *(1)* by the following steps: (1) hydrogenation of isophorone to trimethylcyclohexanol; (2) oxidation to trimethyladipic acid; (3) conversion into the dinitrile; and (4) hydrogenation to trimethylhexamethylenediamine.

(1) *(3)*

A different diamine, 3-aminomethyl-3,5,5-trimethylcyclohexylamine *(3)*, is obtained as a mixture of two stereoisomers by addition of hydrogen cyanide to the carbon-carbon

double bond of isophorone (1 atm; 0.1 % alkali; 150 °C) and subsequent aminating hydrogenation of the ketonitrile.

The diamines *(2)* and *(3)* are used as, for example, hardeners for epoxy resins and as starting materials for the synthesis of diisocyanates. In spite of their structural differences, *(2)* and *(3)* behave similarly as amine components of polyamides, but they differ from hexamethylenediamine in respect of the crystalline form of the products. Owing to the unsymmetrical nature of the molecules, their reactions with dicarboxylic acids such as adipic acid and terephthalic acid yield completely transparent, amorphous polycondensates, even in admixture with conventional components.

Inorganic Components of the Hard Tissues of Bones and Teeth

By *H. Newesely* [*]

The homogeneity range of hydroxyapatite $Ca_5(PO_4)_3OH$ (as end product of continued hydrolysis of calcium phosphate in aqueous solution) and of tetracalcium hydrogen trisphosphate ("octocalcium phosphate") $Ca_4H(PO_4)_3 \cdot 2\,H_2O$ (prepared by controlled partial hydrolysis) has been determined for variations of the parameters temperature, pH, and concentration [1,2]. The apatitic structure has also been confirmed for the inorganic components of the hard tissue of teeth by X-ray and electron diffraction, as well as by electron microscopy [3]. However, it must be noted that the presence of other ions accelerates, or is indispensable for the formation of the apatite-like crystals by a reaction mechanism outlined below. Under physiological conditions, equilibrium is not attained in the dissolution and crystallization of hydroxyapatite and less crystalline precipitates are formed in weakly alkaline solution, particularly in the presence of pyrophosphate or carbonate [4].

Tetracalcium hydrogen trisphosphate would be stable in purely aqueous systems in neutral or weakly acidic conditions at temperatures up to 40 °C. The real structure of "octocalcium phosphate" crystals is of interest for characterization of biological mineralizations that lead to apatite: there is more or less complete conversion of pre-formed apatite-like lattice regions in the {100} direction of octocalcium phosphate by hydrolysis [2,4]. The composition of these phases varies within the limits Ca:P = 1.33 ("octocalcium phosphate") and 1.67 (hydroxyapatite).

This change is greatly favored by traces of fluoride, as well as by alkali:

$$Ca_4H(PO_4)_3 \cdot 2\,H_2O \xrightarrow{H_2O,\,(F^-)} Ca_5[(OH, F)(PO_4)_3]$$

Formation of the apatitic structure in this way is a more efficient effect in the fluoridization of teeth than are, say, the solubility differences between hydroxyapatite and fluoridated hydroxyapatite [5].

Further, for the paracrystalline "octocalcium phosphate"/hydroxyapatite system, the carbonate content of tooth and bone substance can be clearly explained: partial replacement of the HPO_4 group of "octocalcium phosphate" gives a product that approaches the apatite type in basicity, namely, $Ca_4(PO_4)_2(HPO_4)_{0.4}(CO_3)_{0.6}$. The morphological properties of this compound correspond to those of the inorganic crystalline components of bones and dentine [6]. Magnesium, as secondary constituent, is able to stabilize a tricalcium phosphate structure (as whitlockite) [7].

Gas-Chromatographic Separation of Metal Chlorides

By *E. Stumpp* [*]

Gas chromatography has hitherto been little used for separation of inorganic substances. We have studied the possibility of its application to the separation of elements that are chemically very similar, such as zirconium and hafnium, or niobium and tantalum, by means of their volatile derivatives.

Many metal chlorides can be volatilized unchanged and, further, are easy to prepare, so that they seem particularly suitable for gas-chromatographic separations. However, some metal chlorides have rather high boiling points, or are chlorinating agents, and, since they are strong Lewis acids, prevent the use, in general, of liquid phases of gas-liquid chromatography. In connection with investigations on metal chloride-graphite compounds, we have now found that graphite is a suitable stationary phase for separating metal chlorides: metal chlorides are strongly adsorbed on graphite, reversibly and differentially, and they can be separated by the technique of solid-gas chromatography.

For the experimental separations an all-Pyrex construction was used to avoid attack on the apparatus by the chlorides. Initially the detector was of the heat-conductivity type with platinum heating wires, but later was of the gas-density type. A novel construction permitted injection of the solid metal chlorides. Helium, or, with the gas-density detector, argon, was used as carrier gas.

The following mixtures, *inter alia*, were separated on a 2.5 m column filled with synthetic, highly purified graphite (grain size 0.5–0.6 mm): $AlCl_3/GaCl_3$ at 210 °C; $AlCl_3/ZrCl_4$ at 300 °C; $TaCl_5/NbCl_5$ at 270 °C; $NbCl_5/NbOCl_3$ at 450 °C; $HfCl_4/ZrCl_4$ at 295 °C; $AlCl_3/HfCl_4/ZrCl_4$ at 290 °C. Small amounts of zirconium-free hafnium chloride could be thus obtained preparatively.

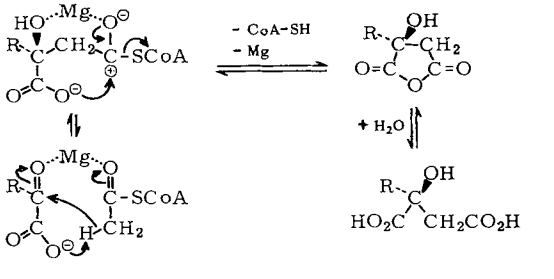
Nucleophilic Enzymatic Reactions of Acetyl-CoA

By *H. Eggerer* [*]

Since acetyl-CoA does not form a carbanion [**][1,2] it was difficult to determine the mechanism of enzymatic carboxymethylations of oxo acids by acetyl-CoA. An aldol-like mechanism has now been demonstrated for two enzymes. Three formal steps are necessary :



1) enolization of the acetyl-CoA, 2) addition of the enol to the carbonyl group, giving the 2-hydroxyacyl-CoA, and 3) hydrolysis of this intermediate.

Citrate synthase catalyses the synthesis of citrate from acetyl-CoA and oxaloacetate. Steps 2) and 3) could be demonstrated by simultaneous aldol fission and hydrolysis by citryl-CoA, and the isolated step 3) by (*S*)-malyl-CoA. Step 1) provides the key to understanding of the enzymatic catalysis: step 1) requires the carboxylate anion of the reactant oxaloacetate as basic co-factor [2]. Its proof was obtained with (*S*)-malate, which is bound by the enzyme in place of oxaloacetate but cannot add to the enol. (*S*)-Malate thus induces enol formation and leads to isotopic exchange between the methyl hydrogen atom of the acetyl group and tritiated water [3]. Citrate that is synthesized in tritiated water in the absence of (*S*)-malate is free from tritium; acetyl-CoA is unlabeled after partial reaction with oxaloacetate, *i. e.* enolic acetyl-CoA obtained in the slowest step of the synthesis reacts at once with the keto group, yielding (*S*)-citryl-CoA. Since its "chemical hydrolysis" in neutral aqueous solution occurs by way of 2-(carboxymethyl)-2-hydroxysuccinic anhydride [4,5], its enzymatic hydrolysis presumably begins with the same step.

Malate synthase catalyses the synthesis of malate from acetyl-CoA and glyoxylate and is dependent on Mg^{2+} ions as co-factors for this reaction [6]. The enzyme enolises acetyl-CoA (step 1); for this step it is dependent on the Mg^{2+} ions [7], whose action is considered as acid-catalysis. The thioester carbonyl group is polarized by linkage to the Lewis acid, the methyl hydrogen atom becoming acidic.

Since the enolization is slow it seemed probable that for each enzyme there are base- and acid-catalysis mechanisms that act cooperatively with both enzyme systems. A chemical model is *Swain* and *Brown*'s bifunctional catalyst [8]. Accordingly α-oxo acids induce enolization of acetyl-CoA by malate-synthase; the efficiency of this induction increases with decrease of their chain lenght *i.e.* with increasing similarity to glyoxylic acid. Pyruvate inhibits the synthesis of malate competitively ($K_i = 10^{-3}$ M) and has measurable affinity for the enzyme ($K_M = 10^{-3}$ M). The rate of enolization in the "bifunctional enzyme system" and the rate of synthesis of malate are almost identical. Carboxylate anions and Lewis acids act cooperatively: the enzymatic enolization ceases if Mg^{2+} ions or pyruvate are removed. Since enolic acetyl-CoA is formed in the slowest step of the synthesis (proof as for citrate-synthase), it reacts at once with the carbonyl group of the glyoxylate, giving (*S*)-malyl-CoA. If used as a substrate, (*S*)-malyl-CoA is hydrolysed by malate synthase (step 3).

The following reaction scheme is in accord with the experimental observations:

Citrate synthase: R = CH_2CO_2H Malate synthase: R = H

The reactants are bound to the enzyme in such a way that their intramolecular conversion into the products follows naturally. In the related enzyme catalyses and with citrate synthase Mg^{2+} ions can be replaced by Lewis acids that form part of the protein structure and can be arranged in steric opposition to the group R of the α-oxo acid. Preparation and Reactions of Enamides

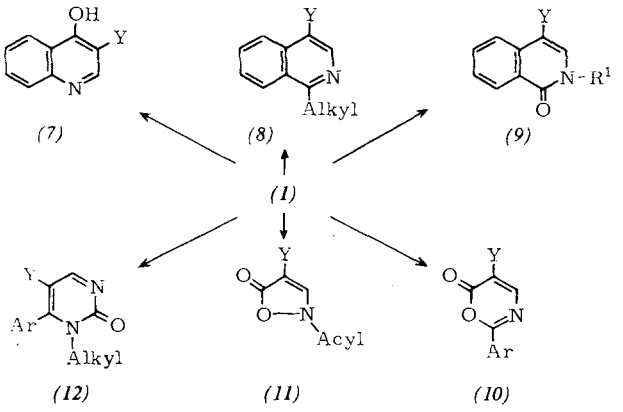
By *F. Eiden* [*]



According to the conditions, reaction of substituted acetaldehydes with carboxamides, sulfonamides, or phosphoramides in the presence of acid catalysts yields enamides *(1)*, enamines *(2)*, divinylamines *(3)*, or diacylaminals *(4)*. If hydroxamic acids are used in place of acid amides, then, *inter alia*, *N*-hydroxyenamides [*(1)*, R^1 = OH], *N*-hydroxydivinylamines [*(3)*, R^1 = OH], or, again, enamides are obtained; and use of hydrazides gives, *inter alia*, enehydrazides [*(1)*, R^1 = NHR].

N-Hydroxyaminoalcohols, which can be formulated as intermediates in the reactions of hydroxamic acids, can be trapped in some cases as dihydro-1,4,2-dioxazoles *(5)* or tetrahydro-1,4,2,5-dioxadiazines *(6)*.

The enamides *(1)* are often obtainable in good yield and are useful for synthesis of heterocyclic compounds. For instance; 4-hydroxyquinolines *(7)* result if in *(2)* X = CO–OAlkyl, R^1 = H, and R^2 = Aryl; isoquinolines *(8)* if X = Aryl, R^1 =

H, and R^2 = CO–R; isocarbostyrils *(9)* if X = Aryl, R^1 = H, and R^2 = CO–OAlkyl; oxazin-(6*H*)-6-ones *(10)* if X = CO–OAlkyl, R^1 = H, and R^2 = Acyl, isoxazolones *(11)* if X = CO–OAlkyl, R^1 = OH, and R^2 = Acyl, and 2-pyrimidinones *(12)* if X = benzoyl, R^1 = CO–NH-Alkyl, and R^2 = H.

The structures put forward have been proved by chemical methods as well as by means of UV, IR, and NMR spectra.

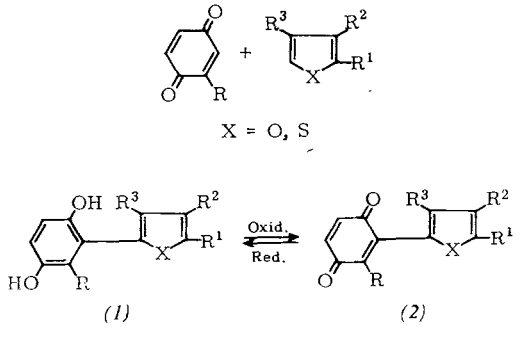
SELECTED ABSTRACTS

The formation and interception of the 2,2,2-triphenylethyl radical *(1)* has been reported by *L. Kaplan*. Reduction of 1-chloro-2,2,2-triphenylethane with triphenyltin hydrazide yields 1,1,1-triphenylethane *(2)*, the reaction being assumed to proceed as follows:

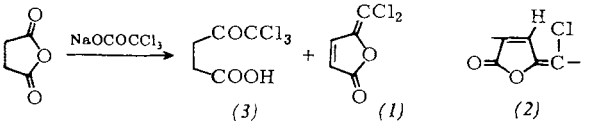


$$(C_6H_5)_3\cdot + (C_6H_5)_3C{-}CH_2Cl \longrightarrow (C_6H_5)_3SnCl + (C_6H_5)_3C{-}CH_2\cdot \quad (1)$$

$$(C_6H_5)_3C{-}CH_2\cdot + (C_6H_5)_3SnH \longrightarrow (C_6H_5)_3C{-}CH_3 + (C_6H_5)_3Sn\cdot, \text{ etc.} \quad (1) \quad (2)$$

The reaction is carried out in benzene at about 70–130 °C, and *(2)* is formed in yields of 27– > 90%. The free radical *(1)* has a strong tendency to rearrange, so that all previous attempts to isolate it have led to derivatives of the 1,1,2-triphenylethyl radical. 1,1,2-Triphenylethane is isolated as a by-product. / J. Amer. chem. Soc. *88*, 4531 (1966) / –Ma.

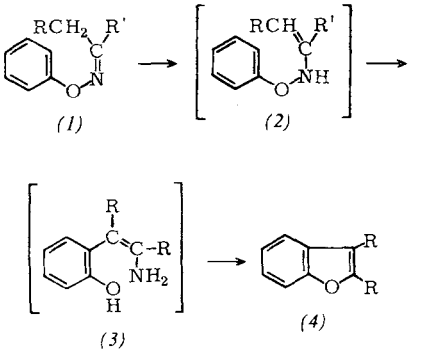
[Rd 609 IE]



Furyl- and thienylbenzoquinones *(1)*, a group of new dyes, were obtained by *N. Baumann, S. Fumagalli, G. Weisgerber*, and *C. H. Eugster* by the acid-catalysed addition of furan,

thiophene, and their alkyl homologues to negatively substituted quinones (*e.g.* acetyl-*p*-benzoquinone, methoxycarbonyl-*p*-benzoquinone, cyano-*p*-benzoquinone), alkylbenzoquinones, and benzoquinone. The initially formed hydroquinone derivatives *(2)* are readily oxidized to *(1)*. The new compounds have intense long-wave absorption bands in the visible region. / Helv. chim. Acta *49*, 1794 (1966) / –Ma.

[Rd 610 IE]



Yellow to red copolymers have been obtained by *A. Winston* and *G. T. C. Li* by polymerization of the now readily obtainable dichloroprotoanemonin (5,5-dichloro-4-hydroxy-2,4-pentadienolactone) *(1)* with methyl acrylate, methyl methacrylate, vinyl acetate, and vinylidene chloride. The polymerization proceeds as a 1,4-addition with subsequent elimination of HCl to form the highly conjugated structural

unit *(2)*. *(1)* is obtained together with 5,5,5-trichlorolevulinic acid *(3)* by reaction of sodium trichloroacetate with succinic anhydride; *(3)* also gives *(1)* on treatment with concentrated H_2SO_4. / 152nd Meeting Amer. chem. Soc. *1966*, W 30, p. 160 / –Ma.

[Rd 615 IE]

The use of Fischer's indole synthesis for the preparation of benzofurans has been described by *T. Sheradsky*. *O*-phenyloximes *(1)*, which can be obtained from carbonyl compounds and *O*-phenylhydroxylamine in boiling ethanol with a trace of HCl, are converted into benzofurans *(4)* at 100 °C with

boron trifluoride ether adduct as the catalyst. The reaction probably proceeds analogously to the indole synthesis, *via* *(2)* and *(3)*. Examples: 2-methylbenzofuran, yield 71% (based on the starting ketone); 2-phenylbenzofuran, 92%; 1,2,3,4-tetrahydro-9-oxafluorene, 74%. / Tetrahedron Letters *1966*, 5225 / –Ma.

[Rd 616 IE]

Polyfluorocyclohexenes can be prepared in good yields by fluorination of perfluorinated or partly fluorinated aromatic hydrocarbons with CoF_3 in the gas phase. Under these conditions, unfluorinated aromatic compounds give mainly saturated polyfluorohydrocarbons. For example, at 80 °C, perfluorotoluene gave 82% of perfluoro(1-methylcyclohexene), 15% of perfluoro(1-methyl-1,4-cyclohexadiene) (λ_{max} = 210 mμ; ε = 288), and 2% of perfluoro(1- or 2-methyl-1,3-cyclohexadiene) (λ_{max} = 255 mμ; ε = 4280) (gas-chromatographic product analysis). / *J. Riera* and *R. Stephens*, Tetrahedron *22*, 2555 (1966) / –Bu. [Rd 621 IE]

The isomer distribution in electrophilic aromatic substitutions on neopentylbenzene has been studied by *D. F. Gurka* and *W. M. Schubert*. The *o/p* ratios obtained were considerably higher than in the case of t-butylbenzene, as is shown by a comparison with values given by *H. C. Brown*:

Reaction	Toluene	t-Butyl-benzene	Neopentyl-benzene
Nitration in H_2SO_4, 25 °C	*o* 58.5	15.8	44.9
	m 4.4	11.5	3.2
	p 37.2	72.7	51.8
Chlorination in glacial acetic acid, 25 °C	*o* 59.8	21.5	25.5
	m 0.5	2.3	0
	p 39.7	76.2	74.5
Bromination in 85 % acetic acid, 25 °C	*o* 32.9	1.2	8.5
	m 0.3	1.5	0
	p 67.1	97.3	91.5

The product ratio was determined by gas chromatography. The substitution site of the various isomers separated by preparative gas chromatography was determined by comparison of the NMR, IR, and UV spectra. / J. org. Chemistry *31*, 3418 (1966) / –Bu. [Rd 623 IE]

A new method for the preparation of disulfones has been developed by *G. C. Denzer, P. Allen, P. Conway*, and *J. M. van der Veen*. These authors obtained relatively good yields in the oxidation of sulfinic acids in 10 N H_2SO_4 at about 5 °C with cobalt(III) sulfate. Known methods give disulfones in maximum yields of 16%, and it is difficult to separate the disulfones from other reaction products. Examples: n-$C_8H_{17}SO_2H$ gave 43% of $C_8H_{17}-SO_2-SO_2-C_8H_{17}$, *m*- or *p*-HOOC–$C_6H_4SO_2H$ gave 65% of (*m*-or *p*-HOOC–$C_6H_4-SO_2)_2$ (m.p. 190 and 265 °C respectively). / J. org. Chemistry *31*, 3418 (1966) / –Bu. [Rd 625 IE]

The low-pressure hydrogenation of benzenepolycarboxylic acids to cyclohexanecarboxylic acids, according to *M. Freifelder, D. A. Dunnigan* and *E. J. Baker*, can be carried out with rhodium catalysts in aqueous media at 60–70 °C and 2.7 atm. Hydrogenation is complete after about 90 min. Examples: phthalic acid gave 91% of cyclohexane-1,2-dicarboxylic acid (*cis*:*trans* = 86:13); isophthalic acid gave 96% of cyclohexane-1,3-dicarboxylic acid (*cis*:*trans* = 60:40); terephthalic acid gave 90% of cyclohexane-1,4-dicarboxylic acid (*cis*:*trans* = 80:20). / J. org. Chemistry *31*, 3438 (1966) / –Bu. [Rd 626 IE]

A cyclic N_3 species having D_{3h} symmetry has been detected by *J. I. Bryant* during the UV photolysis of alkali metal azides at 77 °K. In the infrared spectrum of the irradiated azides (single crystals and KBr disks), which were also used with isotopic labeling ($K^{14}N_3$, $K^{14}N^{15}N^{14}N$, $K^{14}N^{14}N^{15}N$, $K^{15}N_3$), one new band appears in the case of the salts that contained only one isotope of nitrogen; the azides containing two different isotopes give the spectrum of the unlabeled compound with the addition of three new bands, as is to be expected for C_{2v} symmetry (isosceles triangle). The frequency shifts between the bands of the azides containing different isotopes also correspond to the values calculated for the triangular structure. At higher temperatures the IR spectrum becomes more complex, and has not yet been fully interpreted. / Spectrochim. Acta *22*, 1475 (1966) / –Hz. [Rd 628 IE]

The isotopic composition of lead in archaeological objects and lead ores was studied by *N. Grögler, J. Geiss, M. Grünenfelder*, and *F. G. Houtermans*. These authors compared the mass ratios $^{207}Pb/^{206}Pb$ and $^{208}Pb/^{206}Pb$ in ten Roman lead pipes and lead ingots found on the European mainland (Portugal, Italy, Switzerland, Carinthia) with the isotope content of European lead ores (England, Germany, Spain, Italy, Greece, Yugoslavia, Austria). The difference in the isotope ratios for samples from various sources can be more than 2%, with a maximum error of 0.3%. Thus new information about the origin of, and trading in, ancient lead objects can be obtained in extreme cases of isotope distribution in the object and in the ore. When no certain conclusion can be reached, the uncertainty can be reduced by additional determination of trace elements. / Z. Naturforsch. *21a*, 1167 (1966) / –Hz. [Rd 629 IE]

Metallic conductivity in supercritical mercury has been discovered by *E. U. Franck* and *F. Hensel*. The vapor pressure curve was obtained from the discontinuities in the temperature-conductivity curves at constant pressure (T_c = 1490 ± 15 °C; p_c = 1510 ± 30 bar). At temperatures below 1200 °C, the conductivity depends only slightly on pressure, but above this temperature it increases rapidly with pressure. At 1520 °C, compression from 1580 to 2100 bar leads to an increase in conductivity from $10^{-2}\ \Omega^{-1}\ cm^{-1}$ to $5 \times 10^{2}\ \Omega^{-1}\ cm^{-1}$. At higher supercritical temperatures, the pressure-dependence of the conductivity again decreases. As is characteristic of metals, the conductivity of supercritical mercury decreases with rising temperature. / Physical Rev. *147*, 109 (1966) / –Hz. [Rd 630 IE]

BOOK REVIEWS

Anwendungen der Schwingungsspektroskopie in der Anorganischen Chemie (Applications of vibrational spectroscopy in inorganic chemistry). By *H. Siebert*. Vol. VIII of the series "Anorganische und Allgemeine Chemie in Einzeldarstellungen" (Inorganic and general chemistry in monographs). Springer-Verlag, Berlin-Heidelberg-New York 1966. 1st Edit., 209 pp., 28 figures, cloth DM 39.60.

This book is a review of the applications of vibrational spectroscopy in inorganic chemistry and of the results obtained. It begins with an introductory chapter on the theory of molecular vibrations, their classification according to symmetry, and their quantum-mechanical treatment. However, this survey of the theory in only 37 pages will probably be insufficient for the reader approaching this subject for the first time; he would need to refer to the standard texts by *G. Herzberg* and *Wilson-Decius-Cross*.

The next three chapters present a summary of the frequencies of the normal vibrations and the force constants determined from these. Chapter II deals with molecules of the type X_mY_n, Chapter III with the other non-complex inorganic

compounds, and Chapter IV with coordination compounds. The book closes with a list of over 1000 references, as well as a substance index and a subject index.

This book should be useful to anyone interested in the application of IR spectroscopy to inorganic problems; it is particularly suitable for use as a reference work.

W. A. Bingel [NB 566 IE]

Chemistry and Cytochemistry of Nucleic Acids and Nuclear Proteins. By *G. Scholtissek et al.* Vol. V/3 of "Protoplasmatologia". Edited by *M. Alfert et al.* Springer-Verlag, Vienna-New York 1966. 1st Edit., iv, 236 pp., 67 figures, paper DM 81.–; subscr. DM 65.–.

The book contains four independent articles: – *C. Scholtissek*: "The Chemistry and Biological Role of Nucleic Acids" (47 pp.), *B. M. Richards*: "Cytochemistry of Nucleic Acids" (34 pp.), *R.* and *C. Vendrely*: "Biochemistry of Histones and Protamines" (76 pp.), and *D. P. Bloch*: "Cytochemistry of Histones" (51 pp.). These are good neviews with numerous references. The first article presents the textbook knowledge of the chemistry and functions of nucleic acids, and goes as far beyond this scope as is possible in 47 pages.

The other three artieles are more specialized; they are intended for those who wish to familiarize themselves with these fields or who are looking for specific data and references.

However, one must ask who will look for articles of this type in a "Handbook of Protoplasm Research", which is otherwise concerned with spherosomes, flagellae, vitamins, frost resistance, *etc.* In raising this question, it is not intended to cast doubt on the quality of any article, but only on the organization of the classical handbook system. However, the volume can be bought separately, and it should not be absent from the libraries of institutes concerned with these fields.

H. G. Zachau [NB 576 IE]

Organisch-chemische Experimentierkunst (Experimental organic chemistry) by *C. Weygand* and *G. Hilgetag*, in collaboration with *A. Martini*. Johann Ambrosius Barth Verlag, Leiozig 1964. 3rd revised Edit., xxiv, 11442 pp., 213 figures, DM 65.20.

This book, which first appeared more than 25 years ago, is now available in a completely revised edition. The former textbook has now become a reference work, the various chapters of which have been written by specialists. The arrangement of the contents have remained unchanged, the characteristic division into "Materials and Operations", "Reactions", and "Chemical and Physical Characterization" being retained. It was evidently again intended to provide a comprehensive work, from which the user could learn all he needed to prepare and characterize a product, in the order corresponding to the course of an organic-chemical operation. The aims of the book have remained those of a textbook. It suffers from the fact that the transition from a textbook to a handbook has not been consistent.

The first part (113 pp.) contains useful information about the most important chemical operations, particularly purification and separation processes. However, the treatment is not sufficiently detailed for a handbook, and hardly goes beyond that found in any good textbook of practical organic chemistry. It is essential that the next edition deal with ion-exchange chromatography and zone melting. The section on "Purification, Drying, and Testing of solvents" should include tetrahydrofuran and refer to the use of molecular sieves. The section on working with small quantities of substances is well written. The survey of equipment and apparatus is far from complete, and is also out of date in places. No mention is made of equipment that has long been regarded as indispensable. Users with access to other handbooks, such as Houben-Weyl-Müller, will hardly look up Weygand-Hilgetag on this topic.

The third part of the book (85 pp.) is of practically no value. One might ask why, in a book intended for preparative organic chemists, 44 pages are devoted to quantitative analysis. Among other things, *Unterzaucher*'s apparatus for the determination of oxygen is described in detail. Quantitative analysis, apart from the determination of a few functional groups, has long been a matter for the analytical specialist, who will scarcely seek advice in this book. The contents of the section on "Physical Characterization" are out of date. By far the most important physical methods for the characterization of organic compounds, *i.e.* the spectroscopic methods, are dismissed in three pages. IR spectroscopy is covered in 20 lines, and the 2 pages on UV spectroscopy are of little interest to preparative organic chemists. NMR spectroscopy, ESR spectroscopy, and mass spectroscopy are not even mentioned.

The main part of the book (896 pp.) deals with synthetic methods. Seventeen experts present a first-class survey of old and new reactions. A concise and informative chapter on organometallic compounds has been added. The reviewer has profited from a study of this part of the book; he knows of no single-volume work on preparative organic chemistry that provides a comparable wealth of information. The fact that a few methods have been omitted cannot detract from the positive overall impression. However, the following reactions should be included in the next edition: the Hansley-Prelog and Stoll acyloin condensation, Cope elimination, Haller-Bauer cleavage, Baeyer-Villiger oxidation, alkylation with Meerwein salts, the Bamford-Stevens reaction, the Forster reaction, and the formation of cyclobutadiene rings by cycloaddition. The value of the book is enhanced, and the practical experience of the authors demonstrated, by numerous references to advantages and disadvantages of the various processes and by many hints, *e.g.* on how to improve the yields or how notoriously stubborn reactions can be made to "go". The same is true of the more than 1200 "recipes", which are skilfully selected for their relevance as examples. Some 6000 carefully cited references enable the reader to consult the original publicatrons when necessary. This part of the book unquestionably contains numerous highlights. Unfortunately, many of these are not easy to find. The reviewer doubts whether the arrangement according to formation and cleavage of certain bonds is so well conceived as is asserted in the preface. The full value of the book will be enjoyed only by the few readers who work through it systematically like a textbook and then know where to find any given piece of information. Anyone whose theoretical knowledge is so immense as to enable him to plan his synthesis step by step on paper will also find the book excellent, since it will offer examples for each step. However, this will be true only if he is perfectly familiar with the Weygand key, and so knows what reactions to look for in chapters with headings such as "Formation of the C–O Bond by Exchange with Formation of further C–O Bonds". On the other hand, someone with no clear idea of the synthetic rule to follow and the starting materials to use will probably soon lay Weygand-Hilgetag aside and turn to a handbook arranged according to the class of substance.

U. Schöllkopf [NB 565 IE]

Handbuch der Kolorimetrie. Band III: Kolorimetrie in der Biologie, Biochemie und Medizin. 1. Organischer Teil. (Manual of colorimetry, Vol. III: Colorimetry in biology, biochemistry, and medicine, 1. Organic section.) By *B. Kakáč* and *Z. J. Vejdělek*. Translated by *E. Hachová*. Gustav-Fischer-Verlag, Jena 1966, 1st Edit., xiii, 857 pp., 77 figures. DM 74.–.

Volume I of this work[1] dealt with methods for the determination of substances of plant origin used in pharmacy by light absorption in the visible region. Similar methods for synthetics and substances of animal origin were discussed in Volume II[2]. Volume III now deals with methods for the determination of biochemically important substances. Long

chapters are devoted to amino acids, peptides and proteins, carbohydrates and their derivatives, sterines, and steroids. There follows a discussion of metabolic products, the determination of which is important in the study of biochemical processes or for diagnostic purposes, *e.g.* for the testing of organ functions or for the determination of pathological changes in function.

The majority of such problems involve the determination of compounds in organic materials of plant or animal origin. Consequently, if the isolation and purification operations are not to be too expensive, the specificity of the method plays an importance role. The critical notes in this connection, which also deal with sensitivity, reproducitivty, and possible errors of each individual method, therefore will be particularly valuable to the user. Furthermore, as in the previous volumes, an attempt is again made together in the course of the color reactions on which a determination is based. The literature is systematically covered up to the end of 1962, and "a number of important studies published in 1963 are also taken into account".

This volume of the manual again gives an impression of having been carefully compiled. The volume will be very welcome in all laboratories in which such investigations are carried out, since, by obviating the need for laborious literature searches, it greatly facilitates the choice of a method. *H. Böhme* [NB 554 IE]

Fortschritte der Arzneimittelforschung. Progress in Drug Research. Progrès des recherches pharmaceutiques, Vol. 9. Edited by *E. Jucker*. Birkhäuser Verlag, Basel-Stuttgart 1966. 1st Edit., 414 pp., numerous figures and tables, cloth DM 88.–.

The 9th volume of the series[*] again presents detailed reviews of important topics. *H. J. Melching* and *C. Streffer* report (118 pp.) on work on "The influence of drugs on the sensitivity of mammals to radiation". After a short introductory passage on the biochemistry of radiation damage, the various groups of active substances are critically discussed and a brief description of their action mechanism closes the section. A discussion of "Structural considerations on psychopharmaceutics: attempted correlation of chemical constitution and clinical effect" is presented by *K. Stach* and *W. Pöldinger* (61 pp.). The pharmacology and clinical use of the drugs, with particular reference to the tricyclic diphenylamine and diphenylmethane derivatives, and the relationships between chemical constitution and activity are discussed. Special mention is made of the difference between planar (chlorpromazine type) and twisted (imipramine type) ring systems. The article also contains sections on *Rauwolfia* alkaloids, benzoquinolizines, and butyrophenone and hydrazine derivatives. A report by *R. Hawking* on the "Chemotherapy of Filariasis" covers 27 pages. A concise description of the types of *Filaria* that are important in clinical research and of *in vitro* and *in vivo* evaluation methods precedes a discussion of the chemotherapeutic agents of proven activity in this field: diethyl-carbamazine, antimony, arsenic and cyanine compounds, suramin, and bisquinolinium compounds. A very comprehensive article on "3,4-Dihydroxyphenylalanine and related compounds" is presented by *A. R. Patel* and *A. Burger* (56 pp.). Comprehensive tables first give the physical and chemical properties of the intermediates and the yields in the synthesis of 3,4-dopa, its positional isomers, and a number of derivatives. This is followed by analytical and pharmacological data on dopa. Finally, the dopa decarboxylase inhibitors, particularly α-methyldopa are discussed and a brief section on 3,4-dihydroxyphenylserine concludes the article.

R. L. Smith contributes 54 pages on "The biliary excretion and enterohepatic circulation of drugs and other organic compounds." After a discussion of the mechanisms involved in biliary excretion, the fate of the excreted products in the intestines and their possible role as carcinogens are examined. The author goes on to give a survey of the classes of substances that are predominantly excreted with the bile and the constitutional factors involved. The article by *K. Wiesner* and *H. Fink* on "Activity and side effects of metronidazol in the treatment of trichomoniasis" presents a critical evaluation of all the existing literature. For the reader's guidance, the numerical data from the various publications are reproduced in tables (24 pp.).

The value of this work for orientation in the field of drug research is enhanced by an excellent subject index for the present volume and an author and article index for the nine volumes published so far. The presentation of the book is once again excellent. *O. Schaumann* [NB 557 IE]

Compilation of Mass Spectral Data. By *A. Cornu* and *R. Massot*. Published jointly by Heyden & Sons Ltd., London, and Presses Universitaire de France, Paris 1966. 1st Edit., xv, 617 pp., cloth £ 14.

Mass spectra, like IR spectra, are well suited to the characterization of organic compounds. Although many reference spectra have been compiled in recent years, these exist mainly in company collections and are not generally accessible.

In the present book, *Cornu* and *Massot* have compiled tables of the data required for the mass-spectroscopic identification of compounds (the intensity values of the ten highest peaks) from a total of some 5000 spectra taken from such collections and from the literature. It is easy to find a compound quickly, since the tables are arranged according to the empirical formula, the molecular weight, the strongest peaks, and the source of the spectra.

Unfortunately, no line representations of spectra have been taken into account in the compilation of the tables, though this is the type of representation almost exclusively used by organic chemists nowadays. Thus the collection does not contain a single spectrum from the hundred or so fundamental studies by *Djerassi*. On the other hand, the spectra published several times in the API catalogue of mass spectra also appear several times in the book for example, on pages 11B and 12B there are five spectra of cyclohexene, distinguished only by a slight difference in the intensity values. These differences are due to variations in equipment and experimental conditions and are of no great experimental importance. It was therefore unnecessary to give the intensity values to an accuracy of tenths of a percent, since such an accuracy cannot be achieved in comparative work with different instruments.

To summarize, it can be said that this collection of spectra is very useful for the identification of thermally stable compounds (*e.g.* hydrocarbons, esters, and aromatic compounds), the spectra of which could be recorded before 1960 by the methods usual at that time; however, the reader will search in vain for spectra of such compounds as have been analysed by mass spectrometry during the past five years. These spectra already form a large part of the available data. This defect could be overcome by the publication of a supplementary volume. *G. Spiteller* [NB 553 IE]

Light: Physical and Biological Action. Edited by *H. H. Seliger* and *W. D. McElroy*. Academic Press, New York-London 1965. 1st Edit., xi, 417 pp., several figures. $ 12.–.

The book is intended to give the beginner a general picture of the problems and the state of photobiology. The first part (Chapters 1 to 3) deals with the physical principles, and the second part (Chapters 4 and 5) with the biological phenomena.

In Chapter 1, an introduction on the nature of light is followed by a discussion of the measurement of light, the characteristics of various light sources, and the production of monochromatic light. This is followed, in Chapter 2, by a description of primary photophysical processes, starting with energy level diagrams and electronic states, then fluorescence and energy transport, and finally reactions in gases and in solution. The chapter ends with a discussion of the photographic process and examples of photochroism and photoisomeric reactions. Chapter 3 deals with chemiluminescence in gases and liquids, and Chapter 4 with luminescence in biological systems. After a description of biological structures, Chapter 5 discusses photosynthesis. This is followed by descriptions of the phenomenon of vision, photoperiodism, phototaxis, and the action of UV light on biological cells.

The book ends with seven appendices containing a number of data and descriptions of instruments including the laser.

In view of the range of material covered, the choice of examples is necessarily limited However, the selection of subject matter is often not very suitable. For example, it is superfluous to describe photographic processes and their sensitization or lasers in this context, when protolytic reactions, redox processes, and flash photolysis are not dealt with. On the other hand, a preparatory treatment of the problems of energy transport is presented in the first part although this phenomenon in photosynthesis is not even mentioned in the second part. A better correlation of the physical and biological parts is to be hoped for in the second edition.

The treatment of biological structures deals with ideas that were current in 1959, but not with the more recent results. The chapter on photosynthesis is too brief, and inaccurate in places. On p. 86, the energies of the emission bands are given incorrectly.

H. T. Witt [NB 551 IE]

Ligand Substitution Processes. By *C. H. Langford* and *H. B. Gray*. From the series "Frontiers in Chemistry". W. A. Benjamin, Inc., New York-Amsterdam 1965. 1st Edit., viii, 111 pp., numerous figures, $9.35.

At a time of rapid progress in the study of ligand exchange processes the appearance of this monograph, presenting a modern interpretation of "classical" results, is to be welcomed. An introductory chapter lays down a new principle for the classification of ligand exchange reactions in which both the mechanism established from kinetic studies and the molecular processes involved are taken into consideration. The applicability of this classification, as applied to the most thoroughly studied complexes of Pt(II) and of Co(III), is demonstrated in the two following chapters. More recent investigations on other metals are also briefly mentioned, but the methods of investigation are not discussed. Each chapter ends with a summary and a list of original publications (up to 1965)

In view of the small size of the book, some knowledge of coordination chemistry and reaction kinetics is presupposed by the authors. Nevertheless, the book is very clearly written and excellently illustrated, and can be recommended even as an introduction to this special field.

Th. Kruck [NB 569 IE]

Advanced Physical Chemistry. Molecules, Structure and Spectra, by *J. C. Davis jr.* The Ronald Press Company, New York 1965. 1st Edit., x, 632 pp., numerous figures, cloth $ 12.00.

Physical chemistry is not only an independent scientific discipline, but also serves as a link between physics and chemistry. One of the tasks of a textbook of physical chemistry is therefore to introduce the chemist to the physical methods that are important to him, including those of theoretical physics. A few decades ago, thermodynamics was undisputedly the most important field of theoretical physics as far as chemists were concerned; nowadays, however, a knowledge of molecular dynamics, quantum theory, statistical mechanics, and the theory of magnetism is becoming increasingly important in chemical research. Accordingly, at least half of the present textbook is a sort of "Theoretical Physics for Chemists". The adjective "advanced" in the title means only that the subject matter goes beyond the usual training in physical chemistry. No previous knowledge is required, apart from some experimental physics and as much mathematics as the average American reader might be expected to possess.

The principles of classical mechanics and of quantum mechanics are introduced in a rigorous form and are clearly interpreted. The reader should be able to gain an understanding of operator calculus from this textbook. One chapter is devoted to the fundamentals of statistical mechanics and its relation to thermodynamics. Further chapters deal with the theory of angular momentum, spin, and magnetic moments, the approximation methods of quantum mechanics, and the theory of the absorption and emission of light. Special attention is given to molecular rotation (also with respect to applications of microwave spectroscopy), the theory of molecular vibrations (but stopping before normal coordinate analysis), and the fundamentals of nuclear magnetic resonance spectroscopy. The treatment of the relationship between electronic structure and UV spectra is somewhat short, and the theory of chemical bonding us really only touched upon.

The book is well compiled from the didactic standpoint, logically arranged, and as lucid as possible in its reasoning. The main emphasis is always placed on the fundamental relationships. Special applications are presented for illustration rather than as ends in themselves. A wealth of interesting exercises (unfortunately the solutions are not given) enables the reader to check how much he has understood.

In many places the reader may notice a lack of absolute rigor or failure to mention details that are not unimportant. The transition from the Lagrange function to the Hamiltonian function should (like the transition from internal energy to enthalpy in thermodynamics) be substantiated. An important point in the derivation of the Planck radiation formula is that Bose statistics for light quanta are used. The derivation given for the Boltzmann velocity distribution is not quite rigorous. In Chapter 7, the term "hydrogen-like functions" is used in a very unconventional sense. The Dirac δ function is incorrectly defined on p. 504. The statement (p. 454) that VB functions are known as bond orbitals is also incorrect. On the other hand, one finds many critical comments on the concepts introduced. The author generally avoids oversimplified "proofs".

Anyone concerned with or interested in molecular spectroscopy or questions of molecular structure in general will find what theoretical principles he requires in this book.

W. Kutzelnigg [NB 561 IE]

Conformational Analysis. By *E. L. Eliel, N. L. Allinger, S. J. Angyal,* and *G. A. Morrison.* John Wiley & Sons, Inc., New York-London 1965. 2nd ed., xiii, 524 pp., numerous illustrations, paper $ 15.00.

The object of stereochemistry is to correlate the spatial arrangement of the atoms in molecules with the physical and chemical properties of the latter. This undertaking formerly met with only limited success, since the internal mobility of the molecules, which seemed excessively complicated, was disregarded. It is now accepted that it is unnecessary to consider all steric arrangements (*e.g.* conformations) of mobile molecules. Many "pure" substances simply consist of a few molecular species (mostly conformers), which (at present) cannot be separated owing to their rapid interconversion.

Conformational analysis consists in the determination of the composition of these mixtures by physical methods, and so

permits the correlation of the steric arrangement of the component molecules with their physical properties (*e.g.* energy). The intramolecular strains deduced from these properties are then used for the analysis of specifically arranged transition states, so that a direct relationship is found between molecular structure and chemical properties.

This work testifies to the fruitfulness and the wide applicability of this young discipline of organic chemistry.

The book deals with theoretical aspects of thermodynamics, kinetics, ultraviolet, infrared, microwave, and NMR spectroscopy, rotatory dispersion, and molecular refraction. It contains tables of rates, strain energies, equilibria, and rotation barriers. The different interests of the authors ensure a many-sided balance of subject matter, as is shown by the following randomly-chosen key phrases: conformational energy, kinetic determination of equilibria, isomerization of hydrocarbons (with methods), 2-, 3-, an 4-alkyl ketone effect, *gem*-dimethyl effect, 1,2-diaxial rearrangement, syn-axial interaction, medium and large rings, reflex effects, synthesis of cortisone from cholic acid, Δ^2-effect, anomeric effect in pyranosides, deformation of the cyclohexane chair, flexible form, entropy in equilibria, specific reactions of sugars, terpenoids, and steroids. The authors offer interesting rationalizations of a number of "rules", such as the von Auwers rule, the octant rule, the Brewster rule, and the phenylosotriazole rule.

A very large part of the book is concerned with the chemistry of cyclohexane and its derivatives, in which conformational analysis first took root, and in which it still finds its most successful applications. The reason for this is the small number of conformers involved and the depths of their energy minima.

It is regrettable that the designation of partial conformations by "*syn*-clinal (sc)", "*anti*-periplanar (ap)" *etc.* was not used consistently by the authors, since this together with the sequence rule (which is not mentioned) permits a simple and comprehensive description of any conformation.

Unfortunately, the four reactions given on pages 28–30 do not illustrate the Curtin-Hammett principle in a convincing manner. The first example is open to another interpretation (see footnotes on pp. 29 and 30), while the other three are really different cases of "steric" control of a reaction in which two "stereoelectronic" routes are possible. The 2:1 excess of the *erythro* product described on p. 34 scarcely can have resulted from the reaction of methylmagnesium bromide with 3-phenyl-2-butanone.

In spite of a few such minor shortcomings, the book by these four authors from the U.S.A., Australia, and England is an outstanding contribution to stereochemistry. The book is really absorbing in many places, and should not be missed by any diligent student or research worker. It gives a review, both panoramic and detailed, of the field of conformational analysis. The book also shows that the originally qualitative, and hence simple method has now entered a much complicated, but quantitative phase.

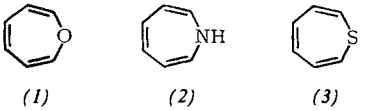
Benzene Oxide-Oxepin Valence Tautomerism

BY E. VOGEL AND H. GÜNTHER [*]



Dedicated to Prof. R. Criegee on the occasion of his 65th birthday

Benzene oxide and the potential 8π-electron system oxepin exist in valence-tautomeric equilibrium with each other, to which both components contribute to approximately the same extent. NMR spectroscopic measurements show that the equilibrium is rapidly established (activation energies of the forward and reverse reactions 9.1 and 7.2 kcal mole^{-1}, respectively). The present knowledge of the properties of oxepin justifies its classification as a "heterotropilidene". Benzene oxide-oxepin represents a system having fluctuating bonds, the equilibrium of which can be displaced from one extreme to the other by means of suitable substituents. The oxide component determines the reactions of the system with most agents.

With 1,6-oxido[10]annulene, which is formally a 2,7-bridged oxepin, the oxepin character is completely suppressed by the formation of a delocalized 10π-electron system extending over the C_{10} perimeter. The existence and aromatic character of 1,6-oxido[10]-annulene give rise to the conception of a homologous series of oxygen bridged annulenes (1,6;8,13-bisoxido[14]annulene, 1,6;8,17;10,15-trisoxido[18]annulene etc.), which, like the parent acenes, possess a (4n + 2)π-electron system. Molecular models demonstrate that a considerable flattening of the C_{4n+2} perimeter is achievable in the case of a syn or all-syn arrangement of the oxygen bridges, and that the requirement for aromaticity is thus satisfied. This is confirmed in a striking manner by the synthesis and properties of syn-1,6; 8,13-bisoxido[14]annulene.

I. Introduction

The discovery of the tropolones and the tropylium ion [1] resulted in the rapid development of the chemistry of carbocyclic aromatic seven-membered ring systems and an increased interest in the as yet unknown heterotropilidenes oxepin *(1)*, azepine *(2)*, and thiepin *(3)*, which are formally homologues of furan, pyrrole, and thiophene. *(1)*, *(2)*, and *(3)* are potential 8 π-electron systems, isoelectronic with the unstable cycloheptatrienyl anion [2] and cyclooctatetraene; thus they do not satisfy the Hückel rule, and therefore should not exhibit an electronic stability comparable with that of the tropylium compounds. Consequently, heterotropilidenes may provide an interesting test of the modern theories regarding the nature of aromaticity [3]. A knowledge of the heterotropilidenes above all promises valuable information on similarities and

differences in the properties of $4n$- and $(4n+2)$-π-electron systems.

Despite their simple structure, all attempts to synthesize oxepin and thiepin have so far been unsuccessful [4]; however, *N*-alkoxycarbonylazepines [5] and *N*-cyanoazepines [6] have become readily accessible by thermolysis of azidoformates and cyanazide in benzene and its derivatives. No detailed information is yet available concerning the parent compound 1*H*-azepine *(2)*, which, it is claimed, results from the alkaline hydrolysis of *N*-ethoxycarbonylazepine. It is evidently a very reactive substance, which rearranges rapidly into the tautomeric 3*H*-azepine [7,8]. *N*-Methylazepine, which is prepared from *N*-ethoxycarbonylazepine [7,9], and whose spectral properties should be very close to those of *(2)*, is also rather unstable; on standing for a short time it changes into a dimer [9].

The successful preparation of the *N*-methylated azepine suggested that, of the heterotropilidenes *(1)* to *(3)*, at least oxepin should be isolable. Like its analogues, this compound would be able to isomerize into the benzenoid system (formation of phenol); however, there is no possibility of tautomerization (such as exists with *(2)*) or of spontaneous elimination of the hetero atom (as is conceivable for *(3)*, *via* benzene sulfide).

Most of the earlier attempts to synthesize oxepin were patterned on *Willstätter*'s cycloheptatriene synthesis, *i.e.* attempts were made to introduce the missing double bonds into tetrahydro- or dihydrooxepins [10]. Critical examination of the results of these efforts suggests that no oxepin was formed in most cases. However, if the desired product had been formed in one of these reactions, it could have had little chance of survival because of the drastic conditions used.

In view of the difficulty of obtaining oxepin *via* partially hydrogenated derivatives, an attractive alternative method of preparation would seem to be the thermal rearrangement of strained valence isomers of oxepin [11]. The obvious choice of isomer is the hypothetical benzene oxide *(4)*, which was assumed, more intuitively than from thermodynamic considerations, to be less stable than oxepin. On the basis of this estimated stability relationship a ready benzene

(4) *(5)* *(6)*

oxide → oxepin isomerization could be envisaged, particularly since the disrotatory course of the reaction [12] and the geometry of the valence-isomeric system are matched to each other. In the case of the four-membered ring valence isomer 2-oxabicyclo-[3.2.0]hepta-3,6-diene *(5)*, on the other hand, the result of thermolysis is more difficult to predict. The cleavage of the cyclobutene ring in *(5)* does not conform stereochemically (conrotatory process) with the rearrangement to the oxepin [12,13], so that the isomerization temperatures required would almost certainly prove too high for the product. In the final case to be considered, *i.e.* the oxide of Dewar-benzene *(6)*, the conversion into oxepin would again appear promising, since the extremely high ring strain should allow homolytic cleavage of the bond common to the two four-membered rings, even at low temperatures. The sterically unfavorable synchronous isomerization of the cyclobutene ring would thus be bypassed.

II. Thermolysis of Epoxide C–C Bonds

The dehydrohalogenation of 1,2-epoxy-4,5-dibromocyclohexane *(17)* [14] provides a simple scheme for the synthesis of benzene oxide. However, according to investigations by *Meinwald* and *Nozaki* [15], only phenol can be isolated when *(17)* is heated with γ-collidine or sodium glycolate in an excess of ethylene glycol. Dehydrohalogenation experiments on *(17)* carried out simultaneously by our own research group [16] with a series of nitrogen bases were also unsuccessful.

The fact that dehydrohalogenation of *(17)* to benzene oxide under very mild conditions, as well as the benzene oxide-oxepin isomerization (which involved cleavage of an epoxide C–C bond), had to be regarded as unusual reactions at that time, may explain the reluctance to pursue further the above route to oxepin. However, following recent reports of the cleavage of the C–C bond in epoxides, it became almost certain that at least the second reaction step was feasible.

Braun's study [17] of the LiCl-catalysed pyrolysis of 1,2-divinylethylene carbonate *(7)* (mixture of *cis* and

[4] 3-Benzoxepin has become known through investigations by *K. Dimroth* [*K. Dimroth, G. Pohl,* and *H. Follmann,* Chem. Ber. *99*, 634 (1966); *K. Dimroth* and *G. Pohl,* Angew. Chem. *73*, 436 (1961)]; earlier papers deal with derivatives of 3-benzoxepin and its N and S analogues.

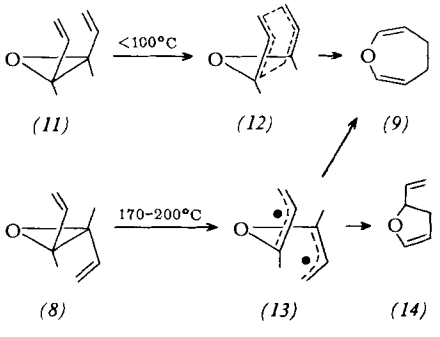
trans isomers) is particularly relevant to the benzene oxide-oxepin problem. This reaction, which requires a temperature of 200 °C, gives not only *trans*-1,2-divinylethylene oxide *(8)*, but also 4,5-dihydrooxepin



(7) *(8)* *(9)*

(10) *(8)* *(11)*

(9), the formation of which is probably due to a Cope rearrangement of initially formed *cis*-1,2-divinylethylene oxide *(11)*, facilitated by the strain in the epoxide ring. In order to avoid the pyrolysis of the carbonate, which is prohibitive to the isolation of *(11)*, *Stogryn, Gianni*, and *Passannante* [18] studied the action of alkali metal hydroxide on 3-chloro-4-acetoxy-1,5-hexadiene *(10)* (presumably a mixture of the two diastereoisomers). In this case, epoxide formation occurred at 40 to 50 °C, and it was possible to isolate *cis*-1,2-divinylethylene oxide. As expected, the *cis*-1,2-divinylethylene oxide undergoes the Cope rearrangement *(11)* → *(12)* below 100 °C, with quantitative formation of 4,5-dihydrooxepin *(9)*.

We investigated the thermal behavior of the relatively stable *trans*-1,2-divinylethylene oxide [19] and found that, at 170–200 °C, it also rearranged completely with cleavage of the epoxide C–C bond. As in the case of the *cis*-isomer, 4,5-dihydrooxepin was obtained; however, this was accompanied by a second product, which had escaped the earlier investigators, and which was identified as 2-vinyl-2,3-dihydrofuran *(14)*. Between 170 and 200 °C, the ratio of the quantities of seven-membered to five-membered ring ethers (30:70) is practically independent of the temperature and of the pyrolysis time. It is deduced from the relatively high isomerization temperatures and from the observed branching of the reaction that the rearrangement of *trans*-1,2-divinylethylene oxide *(8)* proceeds *via* the biradical intermediate *(13)*.

(11) *(12)* *(9)*

(8) *(13)* *(14)*

[19] *E. Vogel, R. Sundermann*, and *R. Schubart*, unpublished.

The mechanistic interpretation of the pyrolysis of *cis*- and *trans*-1,2-divinylethylene oxide, which is based largely on analogy with the thermal behavior of *cis,trans*-isomeric 1,2-divinylcycloalkanes containing strained rings [11, 20–24], was supported by a kinetic study. The isomerizations of the two compounds in the gas phase strictly obeyed the first-order rate law. The reaction of the *cis* oxide was not appreciably accelerated by an increase in surface area, whereas slight wall catalysis was observed in the case of the *trans* oxide. The activation parameters found for the rearrangement of the *cis* compound were $\Delta H^{\ddagger} = 24.6$ kcal mole^{-1} and $\Delta S^{\ddagger} = -11.3$ cal deg^{-1} mole^{-1}, while those for the *trans* compound were $\Delta H^{\ddagger} = 36.0$ kcal mole^{-1} and $\Delta S^{\ddagger} = -0.4$ cal deg^{-1} mole^{-1} [19].

Thus *cis*-1,2-divinylethylene oxide has a low activation energy and a highly negative activation entropy, whereas the *trans* compound has a relatively high activation energy and only a slightly negative activation entropy. If in addition one considers the nature of the rearrangement products, the essential criteria for a synchronous mechanism in the isomerization of the *cis* oxide and for a free-radical mechanism in the case of the *trans* oxide are satisfied. The difference of 11 kcal mole^{-1} in the activation energies for the concerted rearrangement of *(11)* and the free-radical cleavage of *(8)* is of the order of magnitude found for analogous cases [23–26].

Linn, Webster, and *Benson* [27] observed another example of the cleavage of an epoxide at the C–C bond, namely in tetracyanoethylene oxide *(15)*. This compound can undergo cycloadditions with olefins and acetylenes to form tetracyanotetrahydrofurans *(16)* and tetracyanodihydrofurans. Tetracyanoethylene oxide can add to aromatic systems with formation of tetracyanotetrahydroisobenzofurans.

(15) *(16)*

A kinetic investigation of the reaction of tetracyanoethylene oxide with styrene and *trans*-stilbenes [28] showed that the addition step is preceded by a thermal

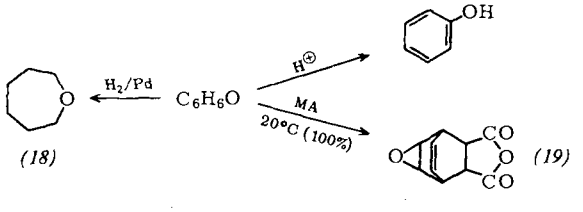
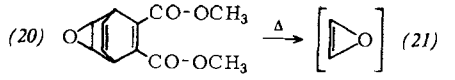
equilibrium between tetracyanoethylene oxide and an activated form thereof. When sufficiently reactive olefins, such as styrene, are used, the formation of excited tetracyanoethylene oxide becomes rate-determining. The addition taking place in the second step has the characteristics of a multi-center process.



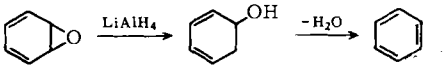
III. Benzene Oxide-Oxepin

The course of the thermolysis of *cis*- and *trans*-1,2-divinylethylene oxide gave new support to the concept of synthesizing oxepin *via* benzene oxide. The real problem was to find a suitable route to benzene oxide. Owing to the ready availability of the starting material, a reinvestigation of the dehydrohalogenation of 1,2-epoxy-4,5-dibromocyclohexane *(17)* [15,16] suggested itself. We found that the action of sodium methoxide on *(17)* in boiling ether gave an orange product C_6H_6O, (yield > 80 %) which was isomeric with phenol [29,30]. The question was whether this was benzene oxide, oxepin, or a valence-tautomeric mixture of benzene oxide and oxepin. As in the case of tropilidene [11], it turned out to be problematical to decide between these three possibilities by chemical means.



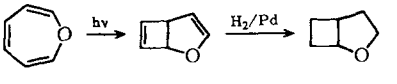
(17) *(4)* *(1)*

The substance C_6H_6O, which is stable at room temperature, readily isomerizes under the influence of Brönsted (proton) and Lewis-acids to form phenol; aromatization takes place, though only slowly, even in neutral aqueous solution. Distillation at normal pressure also leads to more or less complete rearrangement to phenol. Hydrogenation with palladium-charcoal produces mainly oxepane *(18)* (about 70 %)



(18) *(19)*

together with cyclohexanol and unidentified products. Reaction with maleic anhydride, even at 20 °C, leads within a few minutes to an adduct *(19)*, which must, according to its NMR spectrum and the absence of a UV-maximum above 220 mμ, be derived from benzene oxide. Dimethyl acetylenedicarboxylate gives an adduct *(20)* of the same type after a few days (20 °C). Attempts to fragment *(20)* by the Alder-Rickert method into acetylene oxide *(21)* and dimethyl phthalate have not so far yielded conclusive results.



The dehydrohalogenation product C_6H_6O can be reduced with lithium aluminum hydride to form the vacuum-distillable cyclohexa-1,3-dien-5-ol *(22)* ("hydrated benzene"), which undergoes wall-catalysed decomposition into benzene and water on standing. Methyl-lithium gives a mixture of the relatively stable *cis*- and *trans*-1-methylcyclohexa-2,4-dien-6-ols in which the *cis*:*trans* ratio is higher than 90:10.

(4) *(22)*

While the result of hydrogenation is equally compatible with either the benzene oxide or the oxepin formula, the relatively easy diene synthesis, the isomerization into phenol, and the reduction with lithium aluminum hydride can best be explained by the benzene oxide formula. On the other hand, the recently observed, almost quantitative photochemical conversion of the product C_6H_6O into 2-oxabicyclo[3.2.0]hepta-3,6-diene *(5)* is indicative of the presence of oxepin [31]. It seems unlikely that oxepin is formed from benzene oxide on irradiation, since a photochemical benzene oxide-oxepin isomerization should be forbidden according to the Woodward-Hoffmann rule [12]. The photoisomer *(5)*, the structure of which is proved mainly by the formation of 2-oxabicyclo[3.2.0]heptane *(23)* on hydrogenation [32], exhibits the anticipated thermal stability. At the temperature required to isomerize *(5)* back into oxepin (150–160 °C) the latter is no longer stable, and thus only phenol is obtained as the pyrolysis product.

(1) *(5)* *(23)*

Though the above chemical reactions point very strongly to the existence of a valence-tautomeric mixture of benzene oxide and oxepin, they do not constitute conclusive proof, since a change in structure caused by the agent in question cannot be ruled out. Consequently, spectroscopic methods must be used in an attempt to clarify the benzene oxide-oxepin problem.

The UV spectrum of the product (Fig. 1) shows an unusually strong dependence on the solvent. The absorption curves show an isosbestic point, a sure indication of the presence of two compounds, benzene oxide and oxepin, in equilibrium with each other. In order to assign the maxima and to obtain some information regarding the ratio of the components,

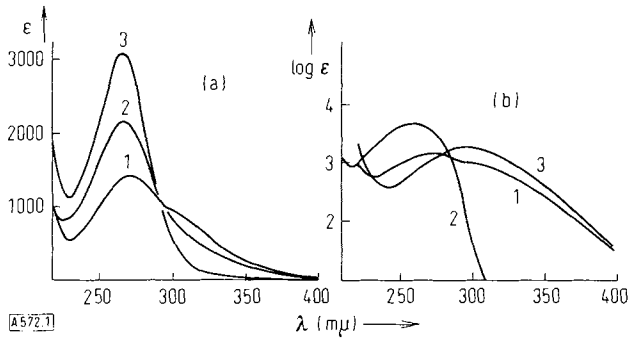
[31] A similar photoisomerization was observed for 2,7-dimethyloxepin by *L. A. Paquette* and *J. H. Barrett*, J. Amer. chem. Soc. *88*, 1718 (1966).

[32] *L. A. Paquette, J. H. Barrett, R. P. Spitz*, and *R. Pitcher*, J. Amer. chem. Soc. *87*, 3417 (1965).

we tried to derive the UV spectra of benzene oxide and oxepin with the aid of suitable reference substances.



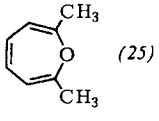


Fig. 1. (a) UV-Spectrum of benzene oxide-oxepin *(4)* ⇌ *(1)*.
1. in isooctane; 2. in methanol; 3. in water-methanol (85:15).
(b) UV-spectra in isooctane
1. benzene oxide-oxepin *(4)* ⇌ *(1)*; 2. 8,9-indan oxide *(24)*;
3. 2,7-dimethyloxepin *(25)*.

The model used for benzene oxide was 8,9-indan oxide *(24)*, in which the rearrangement into the oxepin isomer is blocked by the bracket effect of the trimethylene bridge (cf. Section IV. 5). The same principle had previously been used to fix the norcaradiene skeleton [33,34]. 8,9-Indan oxide *(24)* is colorless, and in isooctane possesses a UV spectrum of the cyclohexa-1,3-diene type with λ_{max} = 258 mμ (ε = 4900). A suitable reference substance for oxepin is its 2,7-dimethyl derivative *(25)*, in which the concentration of the oxide tautomer (if present) is below the detection limit of spectroscopic methods. The electronic spectrum of 2,7-dimethyloxepin contains a broad absorption band at λ_{max} (in isooctane) = 297 mμ (ε = 1800),

(24) 

(25)

which extends to about 430 mμ and gives the compound a yellow-orange color. Significantly, the UV spectra of both *(24)* and *(25)* are practically independent of the solvent.

These observations show that in the UV spectrum of the dehydrohalogenation product, the maximum at 271 mμ (ε = 1430) in isooctane is due to the benzene oxide component, whereas the shoulder at 305 mμ (ε = 900) corresponds to the oxepin maximum which must be located in this region. The position of the equilibrium cannot be accurately determined without knowledge of the extinction coefficients of the two valence tautomers, but it is estimated from comparison with the spectra of *(24)* and *(25)* that the benzene oxide concentration in isooctane is about 30 %, while that in water-methanol (85:15) is about 90 %. Concerning the solvent-dependence of the benzene oxide-oxepin equilibrium, which is presumably due to various factors, it is noteworthy that the proportion of benzene oxide increases with increasing dielectric constant of the solvent [30].

The existence of a benzene oxide-oxepin valence tautomerism with comparable concentrations of the components is clearly shown by NMR-spectroscopic investigations, which may also be used to deduce the thermodynamic and kinetic parameters of the equilibrium.

At room temperature, the ^{1}H–NMR spectrum of the product (Fig. 2) contains three groups of signals in the olefinic proton absorption region, the chemical shifts of which differ sufficiently to allow an assignment to the three pairs of protons of benzene oxide or oxepin purely on the basis of multiplicity. Thus the group of signals at τ = 4.8, which may be regarded to a first approximation as a doublet, must be assigned to the α-protons, while the multiplets at τ = 3.9 and τ = 4.4 can be assigned to the γ- and β-protons, respectively.

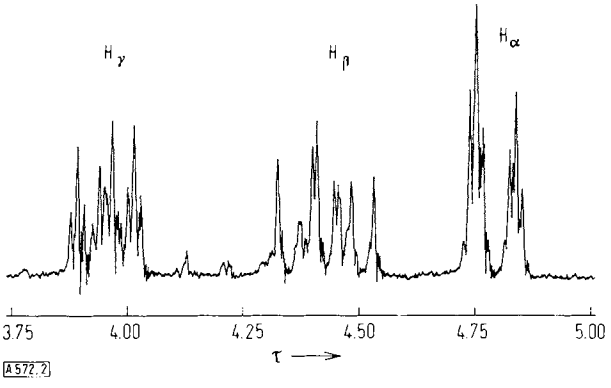

Fig. 2. ^{1}H–NMR spectrum of benzene oxide-oxepin at room temperature (in CS_2; 60 MHz; internal standard: tetramethylsilane).

The greatest difference in the spectra of benzene oxide and oxepin should be found for the position of the α-proton resonances. Taking cyclic enol ethers as a guide for oxepin, the α-protons of oxepin should absorb close to τ = 4.0. The resonance signals of the benzene oxide α-protons, on the other hand, would be expected to occur in the region of τ = 6.5 to 7.0, on the basis of experience with vinyl-substituted epoxides (Table 1).

[39] *P. Radlick* and *S. Winstein*, J. Amer. chem. Soc. *86*, 1866 (1964).

The observation that the α-proton resonance ν^{α} of the product lies between the expected values for benzene oxide and oxepin suggests a rapid valence tautomerism with comparable concentrations of the two forms, since for a rapid exchange ($k > 10^3$ sec^{-1}) of corresponding benzene oxide and oxepin protons, according to eq. (a), ν^{α} may be regarded as the average of the chemical shifts $\nu^{\alpha}_{(4)}$ and $\nu^{\alpha}_{(1)}$ ($p_{(4)}$, $p_{(1)}$ = mole fractions)[40]; the same is true of ν^{β} and ν^{γ}.

$$\nu^{\alpha} = p_{(4)}\,\nu^{\alpha}_{(4)} + p_{(1)}\,\nu^{\alpha}_{(1)} \qquad \text{(a)}$$

The assumption of an equilibrium of this type is confirmed by the temperature-dependence of the NMR spectrum[41] (Fig. 3).

The principal changes observed down to −80 °C are shifts of the resonance frequencies. The α-proton resonance undergoes a steady upfield shift, while the β-proton resonance is displaced in the opposite direction; the γ-proton resonance remains approximately constant. The same phenomena are observed in the room temperature spectra on changing the solvent from carbon tetrachloride to a polar medium such as methanol or dimethyl sulfoxide-water (cf. the solvent-dependence of the UV spectra, Fig. 1). The resonance shifts are therefore due to a displacement of the equilibrium. As can be deduced from the increasing shielding of the α-protons, the benzene oxide component is favored by a decrease in temperature, as well as by a change to a polar solvent.

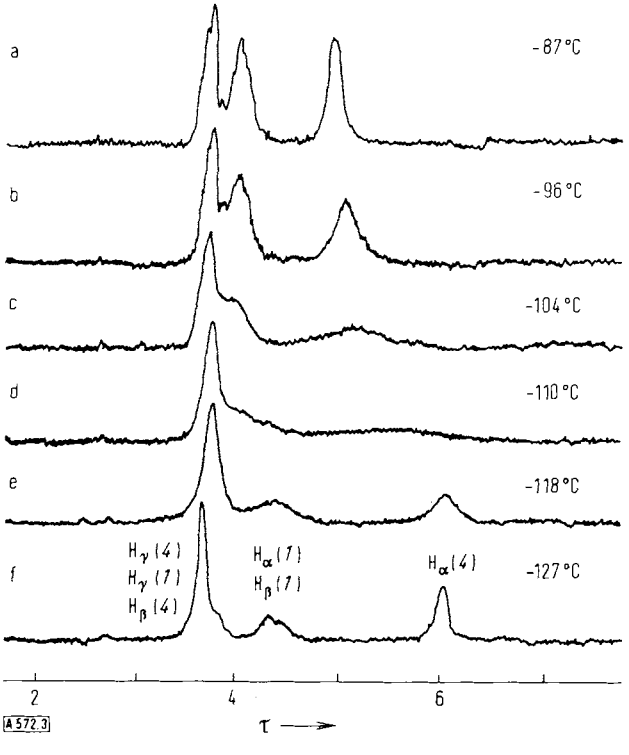

Fig. 3. ^{1}H—NMR spectra of benzene oxide-oxepin at various temperatures in CF_3Br/pentane (2:1) (60 MHz; internal standard: tetramethylsilane).

When the temperature is lowered below −80 °C, the exchange rate ultimately becomes so slow that the "average spectrum" is replaced by the individual spectra of the two equilibrium components (Fig. 3f). This process is shown particularly clearly by the α-proton signal, which reaches its maximum halfwidth at about −113 °C and then splits into two new absorptions which, as expected, are strongly separated, and which must be due to the α-protons in benzene oxide and oxepin.

In order to deduce the kinetics of the equilibrium *(4)* ⇌ *(1)* from the changes in the line shape of the spectrum, the assignment of the low temperature spectrum is essential. This can be made on the basis of the ratio of the signal areas and of the following considerations:

1. The resonance of the α-protons in benzene oxide must occur at the highest field strength[42].

2. The shift difference between the β- and γ-protons in benzene oxide must be small[43].

3. The shift difference between the β- and γ-protons in oxepin must be large[43].

The equilibrium constant K of the valence tautomerism *(4)* ⇌ *(1)* was determined below the coalescence temperature (−113 °C) from the ratio of the signal areas, and above this temperature from the resonance position of the α-proton signal. Its temperature-dependence gave a value of ΔH^0 ($=H^0_{(1)} - H^0_{(4)}$) = 1.7 ± 0.4 kcal mole^{-1} for the enthalpy of the isomerization *(4)* → *(1)*.

The lifetimes $\tau_{(4)}$ and $\tau_{(1)}$ of the valence tautomers, which must be known in order to find the activation parameters, are obtained from the halfwidths Δ' of the α-proton signal in the regions of slow and fast exchange (below −118 °C and above −110 °C respectively). Δ' was corrected for field inhomogeneity and coupling with the β-protons, whereas the long-range coupling with the γ-protons was not taken into account. For the limiting cases mentioned, the following relationships exist between the lifetime τ and the exchange broadening Δ_a of a resonance signal[40,44]:

$$\text{slow exchange: } 1/\tau_{(4)} = k_1 = \pi\Delta_a \qquad \text{(b)}$$

$$\text{fast exchange: } 1/\tau_{(4)} = k_1 = 4\pi p_{(4)}\, p^2_{(1)}\, (\delta\nu)^2/\Delta_a \qquad \text{(c)}$$

The rate constants k_1 ($=1/\tau_{(4)}$) and k_{-1} ($=1/\tau_{(1)}$) as found from equations (b) and (c) for ten different temperatures satisfy the Arrhenius equations:

$$k_1 = 10^{14.4 \pm 1.1} \exp\,[-(9100 \pm 800)/RT]\ (\text{sec}^{-1})$$

$$k_{-1} = 10^{12.1 \pm 1.4} \exp\,[-(7200 \pm 1000)/RT]\ (\text{sec}^{-1})$$

The ratio of the frequency factors gives the entropy difference ΔS^0 ($=S^0_{(1)} - S^0_{(4)}$) = 10.5 ± 8.3 cal deg^{-1} mole^{-1}. Using the equilibrium constant K for the calculation of ΔS^0 one obtains 11.0 ± 5.0 cal deg^{-1} mole^{-1}.

The favorable position of the equilibrium ($K < 20$) permits the observation and evaluation of the benzene oxide-oxepin valence tautomerism by NMR spectroscopy. According to these investigations the energy of benzene oxide is *ca.* 1.7 kcal mole^{-1} lower than that of oxepin. However, at room temperature the entropy gain associated with this rearrangement causes a considerable displacement of the equilibrium in favor of oxepin ($\Delta G \approx -1.3$ kcal mole^{-1}). Owing to the low activation energies of the forward and reverse reactions (9.1 and 7.2 kcal mole^{-1}, respectively), which

[42] This follows from the data of Table 1.

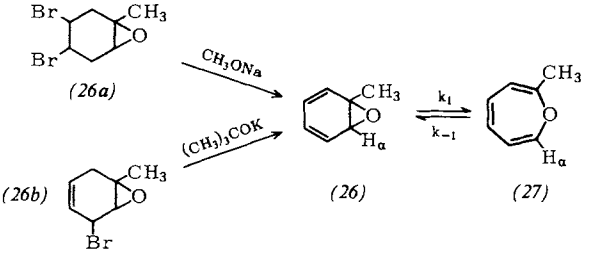
[43] This condition follows from the changes in the resonance frequencies in the average spectrum with temperature.

[44] *L. H. Piette* and *W. A. Anderson*, J. chem. Physics *30*, 899 (1959).

permit the isomers to be isolated at best by crystallization, benzene oxide-oxepin may be regarded as a system with fluctuating bonds (at 0 °C the valence isomerization of the benzene oxide-oxepin system proceeds approximately 10^4 times faster than that of bullvalene) [45].

How are the stability relationships of the benzene oxide-oxepin system to be interpreted? An enthalpy of formation of 29 kcal $mole^{-1}$ has been calculated for oxepin (three *cis*-CH=CH groups and one O group) by the method of Franklin [46]. A corresponding calculation for benzene oxide (two *cis*-CH=CH, two CH, and one O group) gives values of 21 and 35 kcal $mole^{-1}$, respectively, depending upon whether the value of 13 [47] or 27 kcal $mole^{-1}$ [48] is taken for the epoxide ring strain. The difference between the enthalpies of formation of oxepin and benzene oxide is therefore calculated as 8 or −6 kcal $mole^{-1}$, whereas the experimentally determined value is 1.7 kcal $mole^{-1}$. The conclusion to be drawn [49] from these considerations is that the stabilization energy of oxepin (with an epoxide ring strain of 13 kcal $mole^{-1}$) is at most of the order of magnitude of that of tropilidene (7 kcal $mole^{-1}$) [50].

A clearer indication of the expected non-aromatic character of oxepin is given by spectroscopic investigation of 2,7-dimethyl- and 2,7-pentamethylene-oxepin (cf. Section IV.2). These investigations indicate that oxepin possesses a nonplanar ring skeleton, which should correspond closely to that of tropilidene. It is thus justified to speak of oxepin as a heterotropilidene.



IV. Substituted Oxepins

The synthesis of oxepin described above is versatile, and has already been used for the preparation of a variety of substituted oxepins. The limiting factor of the method appears to be that the 1,4-cyclohexadienes used as starting materials are sometimes difficult to convert into 1,2-epoxy-4,5-dibromocyclohexanes, the immediate precursors of the arene oxide-oxepin systems. If the 1,4-cyclohexadienes are first converted into 1,2-epoxycyclohex-4-enes (instead of into dibromocyclohexenes), it can be advantageous to introduce the missing double bond by monohalogenation in the allyl position (with *N*-bromosuccinimide or t-butyl hypochlorite) followed by dehydrohalogenation, and not by bromination-dehydrobromination.

Owing to the sensitivity of the benzene oxide-oxepin equilibrium, it takes only small substituent effects to displace the position of the equilibrium from one extreme to the other. Substituents in the α-position would be expected, *a priori*, to favor the oxepin form electronically, and possibly sterically; the effects of substituents in the β- and γ-positions are more difficult to predict. A suitable model for the expected substituent-dependence of the equilibrium is the valence-tautomeric system bicyclo[4.2.0]octa-2,4-diene ⇌ cycloocta-1,3,5-triene [51], in which the components are also present in comparable quantities.

1. 2-Methyloxepin

2-Methyloxepin *(27)*, an orange liquid (b.p. 33.5 to 34 °C/11 mm Hg), has been obtained both from the dibromide *(26a)* and from the allyl bromide *(26b)* by dehydrobromination (with sodium methoxide and with potassium t-butoxide, respectively). It reacts with maleic anhydride to give a 1:1 adduct (m.p. 197 to 198 °C), the NMR spectrum of which indicates that it is derived from 1-methylbenzene oxide *(26)*.

According to NMR- and UV-spectroscopic studies, 2-methyloxepin, unlike 2,7-dimethyloxepin, still exists in "rapid" equilibrium with a considerable quantity of the corresponding arene oxide, *i.e.* 1-methylbenzene oxide [49].

The NMR spectrum, like that of oxepin, is temperature-dependent (Fig. 4). A decrease in temperature leads first to broadening and then to splitting of the signals (−113 °C); on further cooling (−119 °C), the individual spectra of *(26)* and *(27)* appear. The differences with respect to the spectrum at

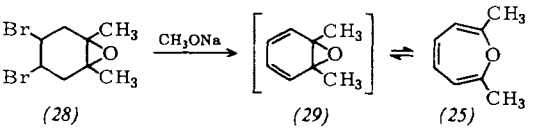
37 °C are particularly noticeable in the case of the methyl proton absorption. In the low-temperature spectrum the doublet (J = 0.8 Hz) at τ = 8.20 initially observed for these protons is split into two signals (τ = 8.09 and 8.45), the positions of which correspond to those of the methyl protons in *(27)* and *(26)*. The intensities show that, under these conditions, the two compounds are present in a molar ratio of 7:3. The new signal at τ = 6.26 must be assigned to the α-proton in *(26)*, whereas the doublet at τ = 4.22 must be due to the corresponding proton in *(27)*. This is compatible with the coupling of about 5 Hz found for the latter proton. The intensity ratio of these protons again shows that the oxepin form predominates.

The equilibrium constant K of the valence tautomerism *(26)* ⇌ *(27)* below the coalescence temperature (−113 °C) was derived from the intensities of the methyl proton signals, and above this temperature from the chemical shift of the methyl protons. The reaction enthalpy ΔH^0 of the 1-methylbenzene oxide → 2-methyloxepin isomerization as calculated from the temperature-dependence of K is 0.4 ± 0.2 kcal mole^{-1}, *i.e.* 1.3 kcal mole^{-1} lower than that of the corresponding reaction in the parent system. ΔS^0 is calculated to be 5.0 cal deg^{-1} mole^{-1}.

The activation parameters for the equilibrium were deduced in this case from the changes in the methyl proton resonances with temperature. The evaluation was carried out with the aid of the complete equation of the absorption curve [40,52], the coupling of the methyl protons with the adjacent olefinic protons in the oxepin form also being taken into account. The theoretical spectra were calculated by means of a Fortran II program. Fitting calculated and experimental spectra by variation of the exchange rate permitted the determination of the lifetimes τ of the isomers. In the regions of slow and fast exchange, the approximations (b) and (c) could also be used for the determination of the τ values (lifetimes).

The Arrhenius equations obtained by these methods for the valence tautomerism *(26)* ⇌ *(27)* are:



$$k_1 = 10^{14.2 \pm 0.9} \exp [-(9200 \pm 700)/RT] \text{ (sec}^{-1})$$

$$k_{-1} = 10^{13.1 \pm 0.9} \exp [-(8700 \pm 700)/RT] \text{ (sec}^{-1}).$$

In a comparison of the thermodynamic and kinetic quantities for the equilibrium *(26)* ⇌ *(27)* with those for the parent system, the decrease in the ΔH^0 value of the arene oxide-oxepin isomerization is particularly striking. Thus the introduction of the methyl group lowers the energy of the oxepin form in relation to that of the oxide form, either by hyperconjugation or by σ-bond stabilization [53]. The activation energy for the conversion of *(26)* into *(27)*, on the other hand, is practically the same as for the benzene oxide-oxepin rearrangement.

2. 2,7-Dimethyloxepin

In 2,7-dimethyloxepin *(25)* [29], which is obtained in high yield on dehydrobromination of 4,5-dibromo-1,2-epoxy-1,2-dimethylcyclohexane *(28)* with sodium methoxide, and which contains two α-methyl groups, the oxepin form is so strongly stabilized that the proportion of the oxide form in the equilibrium is below the spectroscopic detection limit (<5 %). However, 2,7-dimethyloxepin readily forms a maleic anhydride adduct derived from the oxide form. The strong displacement of the equilibrium to the oxepin side on α,α′-dimethyl substitution is undoubtedly not only the result of electronic interaction of the methyl groups with the double bond system in *(25)*, but is probably also due to the less favorable conformational situation in the oxide form (eclipsed *cis*-methyl groups).

(28) *(29)* *(25)*

The uniformity of 2,7-dimethyloxepin is shown in particular by the NMR spectrum (Fig. 5a). The positions of the methyl proton (τ = 8.19) and ring proton resonances ($H^{4,5}$: τ = 4.19, $H^{3,6}$: τ = 4.75) are in agreement with the triene structure *(25)*, as are the coupling parameters obtained by analysis of the AA′XX′-system of the ring protons. Practically the same couplings are found for the corresponding protons in 1,6-dimethylcycloheptatriene [54,55]. Comparison of the spectra of *(25)* and 1,6-dimethylcycloheptatriene (Fig. 5b) clearly shows the relationship between the two compounds. The NMR spectrum of *(25)* shows no sign of line broadening, even at −110 °C.

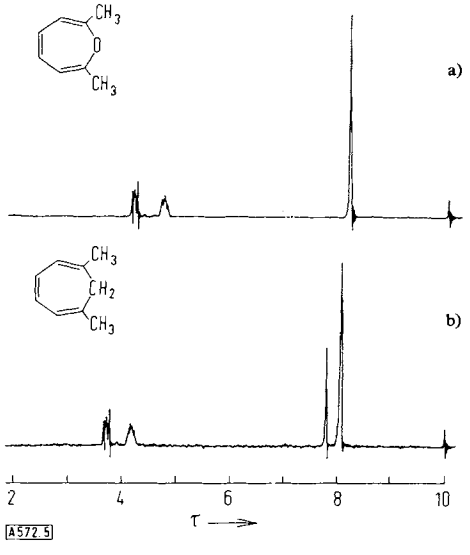


Fig. 5. ^{1}H—NMR spectra of a) 2,7-dimethyloxepin (in CS_2), b) 1,6-dimethylcycloheptatriene (in CCl_4) (60 MHz; internal standard: tetramethylsilane).

At the same time, the strong solvent-dependence of the UV spectrum observed for *(1)* and *(27)* is absent for *(25)*. Thus 2,7-dimethyloxepin appears to be best suited for physical studies on the oxepin system [56].

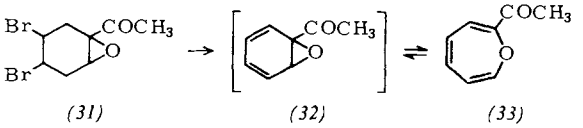
[54] *H. D. Roth,* Dissertation, Universität Köln, 1965.

[55] *H. Günther* and *H.-H. Hinrichs,* Tetrahedron Letters *1966,* 787.

[56] The IR spectrum of 2,7-dimethyloxepin contains an enol ether band at 1155 cm^{-1} and intense C=C stretching bands at 1655 and 1584 cm^{-1}.

Oxepin should have a conformation *(30)* similar to that of cycloheptatriene, *i.e.* the molecule should be in a boat form, presumably in equilibrium with its mirror-image conformer.



(30)

Evidence for such a nonplanar shape is provide by the coupling parameters of the olefinic protons of *(25)*, in conjunction with the UV spectrum of the 2,7-pentamethylene-bridged oxepin *(58)*. The coupling constant J_{34} (= J_{56}) should show a similar dependence on the dihedral angle to that observed for the analogous coupling in cycloheptatriene[57]. Thus it should be possible to deduce qualitatively the geometry of the triene part of *(25)* from the magnitude of J_{34}. The coupling constant J_{34} (5.5 Hz) is practically equal to the corresponding constants for cycloheptatriene and its 1,6-dimethyl derivative (5.5 and 5.4 Hz, respectively). It may therefore be taken as certain that the C_4–C_5 double bond does not lie in the plane of C-atoms 2,3,6, and 7. Owing to the good agreement between the UV spectra of *(25)* and of 2,7-pentamethyleneoxepin *(58)* (cf. Section IV.5), in which a deflection of the oxygen in relation to the triene part is forced by steric factors, it is likely that the oxygen atom also lies out of this plane.

3. 2-Acetyloxepin

An α-substituent that can enter into conjugation, *e.g.* an acetyl group, should be more effective than an α-methyl group in stabilizing the oxepin form. The red-brown 2-acetyloxepin *(33)* (b.p. 51 °C/0.4 mm)[59] obtained by dehydrobromination of 1-acetyl-1,2-epoxy-4,5-dibromocyclohexane *(31)* with 1,5-diazabicyclo[4.3.0]non-5-ene[58] (other bases always gave polymeric products) is uniform. This is shown by the NMR spectrum (complex multiplet for the olefinic protons between τ = 3.3 and 4.5, in which a doublet of triplets due to the proton H^7 is observed at τ = 4.06) and by the fact that the spectrum shows practically no change with temperature. The same conclusion can be drawn from the UV spectrum [λ_{max} (cyclohexane) = 222 mμ (ε = 10900), 315 mμ (2500), and 360 mμ (1200)] in conjunction with its weak solvent-dependence.

(31) *(32)* *(33)*

Though the oxide component *(32)* cannot be detected, it appears to determine the chemical reactivity, as in the case of 2,7-dimethyloxepin. 2-Acetyloxepin gives the adduct derived from the oxide form with maleic anhydride, and is aromatized by catalytic quantities of mineral acid, with formation of 2-hydroxyacetophenone.

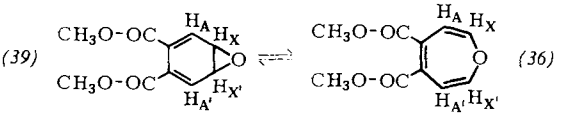
[59] *F.-G. Klärner,* Diploma Thesis, Universität Köln, 1965.



4. 4,5-Bis(methoxycarbonyl)oxepin

The γ,γ'-disubstituted oxepin *(36)* can be obtained from the oxide *(34)* of dimethyl 3,6-dihydrophthalate by allylic bromination with *N*-bromosuccinimide (NBS) and dehalogenation of the crude bromination product *(35)* with sodium iodide in acetone[60]. The same substance was very recently synthesized in an original manner by *Prinzbach, Arguëlles,* and *Druckrey*[61] from the Diels-Alder adduct *(37)* of furan and dimethyl acetylenedicarboxylate. Irradiation of the adduct yields the tetracyclic isomer *(38)*, which gives *(36)* on pyrolysis with cleavage of the indicated bonds in the three-membered rings.

(34) *(35)* *(36)* *(37)* *(38)*

The NMR spectrum of *(36)* consists of an AA'XX' system of the olefinic protons and a singlet due to the ester methyl protons. It is strongly temperature-dependent, so that a considerable proportion of the oxide tautomer *(39)* may be assumed to be present in the equilibrium. The changes in the τ- and *N*-values of the AA'XX' system when the temperature is lowered are shown in Table 2. The increasing shielding of

(39) *(36)*

Table 2. ^{1}H–NMR spectroscopic data for the system *(39)* ⇌ *(36)*.

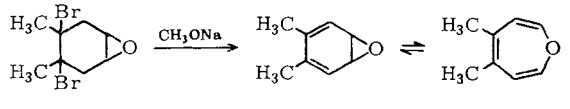
	τA	τX	τCH$_3$	$N = J_{AX} + J_{AX'}$ (Hz)
+33 °C	3.44	5.10	6.21	4.7_2
−10 °C	3.26	5.25	6.18	4.5_4
−30 °C	3.16	5.33	6.17	4.4_0
−56 °C	3.04	5.41	6.16	4.3_5

the α-protons (H_X and $H_{X'}$) and the simultaneous deshielding of the β-protons (H_A and $H_{A'}$) (owing to the conjugation position of these protons in relation to the ester group in the arene oxide *(39)*, their resonance frequency should occur at lower field strengths than in *(36)*) show that the decrease in temperature results in a displacement of the equilibrium in favor of the oxide.

The same conclusion can be drawn from the changes in the parameter *N*, which represents the sum of the coupling constants J_{AX} and $J_{AX'}$. $J_{AX'}$ is negligibly small in both isomers, so that in the present case *N* depends essentially on the coupling constant J_{AX}. Since *(39)* undoubtedly has the lower coupling constant, a decrease in *N* must correspond to an increase in the oxide concentration.

The UV spectrum of *(36)* is strongly solvent-dependent, again indicating a valence tautomerism with comparable

[60] *R. Schubart,* Dissertation, Universität Köln, 1967.



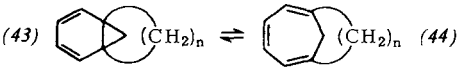
[61] *H. Prinzbach, M. Arguëlles,* and *E. Druckrey,* Angew. Chem. *78*, 1057 (1966); Angew. Chem. internat. Edit. *5*, 1039 (1966).

concentrations of the components. As in the parent system, a solvent change from cyclohexane to methanol causes a displacement of the equilibrium in favor of the arene oxide form.

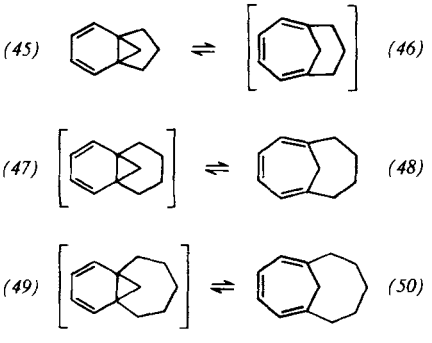
An NMR spectrum similar to that of *(36)* (even in its temperature dependence) is found for 4,5-dimethyloxepin *(42)*, which can be prepared from 1,2-epoxy-4,5-dimethyl-4,5-dibromocyclohexane *(40)*, but which has so far been obtained only in solution [60].

The room-temperature spectrum of the compound *(42)* shows an AA'XX' system for the olefinic protons with τ_A = 4.2 and τ_X = 5.68 and a methyl proton signal at τ = 8.16. The difference $\tau_X - \tau_A$ increases noticeably with decreasing temperature, while the position of the methyl proton signal, as expected, changes only slightly. The chemical shifts at −65 °C are τ_A = 4.0 and τ_X = 6.2, showing that under these conditions the system consists almost entirely of the oxide form.

In both 4,5-disubstituted oxepins therefore, as in the parent system, the arene oxide is the low energy component.



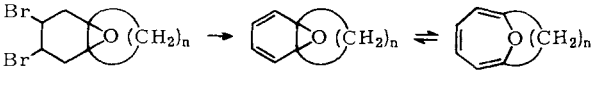
(40) *(41)* *(42)*



5. Fixed Arene Oxides

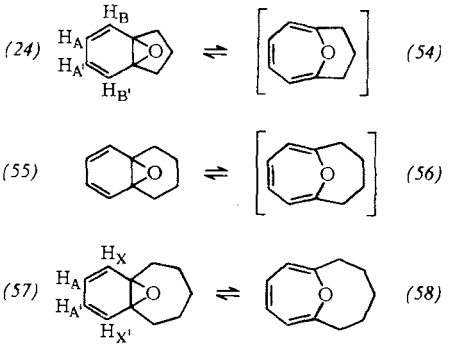
By bridging the oxepin in the 2,7-position with a methylene chain having a sufficiently small number of chain members *n*, it is possible, because of steric reasons, to achieve complete displacement of the arene oxide-oxepin equilibrium in favor of the arene oxide.

The influence of the number *n* of chain-CH_2 groups on the position of the equilibrium can be qualitatively estimated from the data for the corresponding bridged norcaradiene-cycloheptatriene systems *(43)* ⇌ *(44)* [33,54,62]. The strain imposed on the cycloheptatriene form *(46)* by a bridge having *n* = 3 is so great that the valence-tautomeric norcaradiene form *(45)* is frozen in. Surprisingly, however, a



complete reversal of the equilibrium is observed when *n* is as low as 4. Though the cycloheptatriene form *(48)* is still appreciably strained, as is clearly shown by its spectral data and by its reactivity toward maleic anhydride, the norcaradiene isomer *(47)* can no longer be spectroscopically detected. A chain of five methylene groups gives a cycloheptatriene form *(50)* that is almost strain-free, though its conformation is fixed by the bridge. *(50)* is in fact uniform, and is very similar in its spectral properties to 1,6-dimethylcycloheptatriene [54].

[62] *E. Vogel* and *J. Eimer*, unpublished.



Taking into account the different equilibrium positions in the parent systems norcaradiene-cycloheptatriene and benzene oxide-oxepin, it is to be expected from the above findings that the bridged arene oxide-oxepin systems will still contain measurable concentrations of the tricyclic isomers in the equilibrium at *n* = 4, and possibly even at *n* = 5.

The bridged arene oxide-oxepin systems *(52)* ⇌ *(53)* were synthesized by dehydrohalogenation of the dibromides *(51)* with potassium t-butoxide in ether [63]. *(51)* with *n* = 3 gives the uniform, colorless arene oxide *(24)* (8,9-indan oxide). The structure of the

n = 3, 4, 5 *(51)* n = 3, 4, 5 *(52)* n = 3, 4, 5 *(53)*

compound is shown by the similarity of its NMR spectrum to that of *(45)*. The spectrum shows an AA'BB' system of the olefinic protons at τ = 3.4 to 4.1 ($J_{AA'}$ = 6.0, J_{AB} = 9.3, $J_{AB'}$ = 0.7 and $J_{BB'}$ = 1.2 Hz) [64] and a multiplet due to the methylene protons at τ = 7.5 to 8.8 (intensity ratio 4:6). The values of the coupling constants are compatible with the assumed diene structure, but not with the triene structure (concerning the UV spectra, cf. Section III).

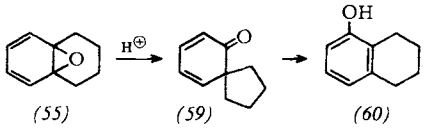
The product obtained from *(51)* with *n* = 4 was also found to be uniform, but the NMR spectrum in this case does not permit a definite assignment, since the olefinic proton absorption consists simply of a sharp signal at τ = 3.85. A decision in favor of the arene oxide structure *(55)* (9,10-tetralin oxide) is possible from the UV spectrum, since the maximum at 259 mμ (ε = 3900) corresponds exactly in its position (though the extinction is lower) to that of 8,9-indan oxide *(24)*.

The reaction product obtained from *(51)* with *n* = 5 differs from *(24)* and *(55)* even in its external appearance, in that it has the characteristic orange color of oxepins. Its spectral properties indicate the presence of an arene oxide-oxepin mixture with comparable concentrations of the components. Both the UV spectrum and the NMR spectrum are strongly solvent-dependent.

In cyclohexane, two UV maxima are observed at 276 and 300 mμ, both with ε = 1400; corresponding bands are observed in methanol at 270 and 300 mμ, but in this case

[63] *M. Wiesel*, Dissertation, Universität Köln, 1966.

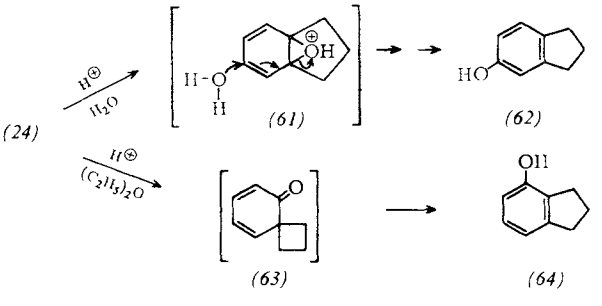
[64] *H. Günther* and *H.-H. Hinrichs*, Liebigs Ann. Chem., in press.



ε = 2100 and 1100. The oxide component, as in the parent system, is evidently favored in methanol. The changes in the NMR spectrum with the solvent are less pronounced, owing to the absence of α-protons, but point in the same direction. The olefinic protons absorb as an AA'XX' system, the N value ($J_{AX} + J_{AX'}$) of which is 7.2 Hz in cyclohexane and 8.1 Hz in methanol. Since a considerable amount of experimental evidence indicates that cyclic trienes have lower N values than the corresponding diene valence isomers [55], the increase in this quantity suggests an increase in the proportion of the oxide. The NMR spectrum shows no appreciable change when the temperature is lowered to −70 °C. This is not surprising, since the most pronounced changes are again associated with the presence of α-protons.

V. Chemistry of Arene Oxide-Oxepin Systems

Little investigation has been carried out on arene oxide-oxepin systems beyond the reactions mentioned in connection with the parent system. All the systems known are sensitive to Brönsted and Lewis acids, the action of which normally leads to aromatization. Unlike cycloheptatriene, these systems readily undergo Diels-Alder reactions, which yield the adduct derived from the arene oxide component. Another apparently general reaction is that with triphenylphosphine (at 120 to 150 °C), which leads to the hydrocarbon corresponding to the arene oxide. Removal of oxygen has also been observed under the action of carbonylchromium complexes [65], but in these cases the hydrocarbons were partly obtained as metal complexes. It is not yet known to what extent the addition of nucleophilic reagents can be achieved. Such additions are of interest, since as was shown by the formation of cyclohexa-1,3-dien-5-ol *(22)*, they would offer a possible route to 1,2-dihydrobenzene derivatives that are otherwise difficult to prepare.



In the study of the chemistry of arene oxide-oxepin systems, the important question is: which reactions can be ascribed to arene oxides and which to oxepins? Now that the benzene oxide-oxepin equilibrium has been established, the Diels-Alder reaction can be definitely ascribed to the oxide component. If, as is likely, arene oxides are also the reacting species in acid-induced isomerizations, nucleophilic additions, and other reactions, the chemical behavior of arene oxide-oxepin equilibrium systems should be similar to that of fixed arene oxides. It therefore seemed advisable that the properties of arene oxides such as 9,10-tetralin oxide *(55)* and 8,9-indan oxide *(24)* should be investigated in greater detail [66].

At room temperature in the presence of catalytic quantities of a proton acid (aqueous-ethereal medium), 9,10-tetralin oxide *(55)* undergoes an almost quantitative carbonium ion rearrangement into spiro[5.4]-deca-7,9-dien-6-one *(59)* [67]. At higher acid concentrations and when Lewis acids are used, complete aromatization takes place with formation of 5-tetralol *(60)*; formation of 6-tetralol was not detected. Since the spiro ketone *(59)* undergoes the dienone-phenol rearrangement [68] into 5-tetralol under comparable conditions, it may be assumed to occur as an intermediate in the aromatization of *(55)*.

(55) *(59)* *(60)*

8,9-Indan oxide *(24)* behaves differently toward Brönsted and Lewis acids. Rearrangement into a spiro ketone, *i.e.* *(63)*, is associated in this case with an energetically unfavorable contraction of the five-membered ring to give a four-membered ring, so that side reactions that are not encountered with *(55)* can prevail. Thus the aromatization product obtained in aqueous media is found to be pure 5-indanol *(62)*, and not the 4-indanol *(64)* that would be expected if the reaction proceeded *via* the spiro ketone *(63)*. The possibility that *(64)* is in fact formed *via* *(63)*, but undergoes a phenol-phenol rearrangement [69] into *(62)*, can be ruled out on the basis of control experiments. The OH group of *(62)* appears instead to be derived from the solvent by the route *(24)* → *(61)*, since an attempted isomerization in methanol gave the 5-methoxyindan corresponding to *(62)*, again in a uniform reaction. It should be possible to determine definitely the source of the OH group in *(62)* by labeling with ^{18}O. In the absence of prototropic solvents, the reaction sequence carbonium ion rearrangement – dienone-phenol rearrangement [*(24)* → *(63)* → *(64)*] can also be observed with 8,9-indan oxide *(24)*. The dienone *(63)* can be isolated as a dimer when the oxide is treated with catalytic quantities of a proton acid in ether. The tendency of *(63)* to dimerize is evidently even stronger than that of *(59)*, a property that protects it against the dienone-phenol rearrangement into *(64)* and allows its detection.

(24) *(61)* *(62)* *(63)* *(64)*

On the other hand, when Lewis acids such as zinc chloride are used instead of proton acids, the catalyst becomes fully effective, so that both the carbonium ion rearrangement and the dienone-phenol rearrangement are observed as in the corresponding experiment with *(55)*.

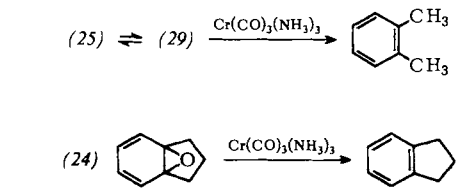
[69] *W. H. Hopff* and *A. S. Dreiding*, Angew. Chem. *77*, 717 (1965); Angew. Chem. internat. Edit. *4*, 690 (1965).

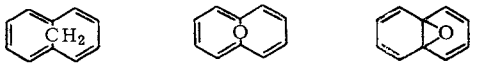
2,7-Dimethyloxepin *(25)*, which may be used for comparison purposes owing to its similarity of substitution, behaves toward dilute acids in much the same way as the two arene oxides *(55)* and *(24)*. The isomerization products obtained from *(25)* are 6,6-dimethylcyclohexadienone *(65)* and 2,3-, 3,4-, and 2,6-dimethylphenol [*(66)*, *(67)*, and *(68)*].



(65) *(66)* *(67)* *(68)*

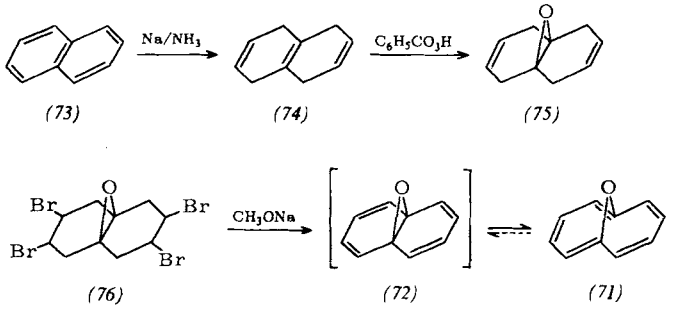
6,6-Dimethylcyclohexadienone[68] is much more resistant to acids than the spiro ketones *(59)* and *(63)*. This explains why 2,3-dimethylphenol, which is related to this compound *via* the dienone-phenol rearrangement, is present only to a very small extent. The formation of 3,4-dimethylphenol corresponds to that of *(62)* from *(24)*, and as in that case, is best rationalized by assuming that the OH group is derived from the solvent. Finally, 2,6-dimethylphenol, which [like 6,6-dimethylcyclohexadienone *(65)*] is probably formed from the mesomeric carbonium ion *(69)* derived from *(29)* by cleavage of the epoxide ring, can have no analogues in the case of *(55)* and *(24)*, since this would involve *meta*-bridging of the aromatic nucleus by a chain of only 4 or 3 methylene groups.

(69)



The similarity in the chemical properties of 2,7-dimethyloxepin *(25)* and of the above arene oxides also extends to the reactions with triphenylphosphine and $Cr(CO)_3(NH_3)_3$[65,70], in which both types of compounds lose oxygen and undergo aromatization. Finally, *(25)* resembles the arene oxides in that the oxygen can also be removed by catalytic hydrogenation (with platinum in ether at 0 °C)[71]; like the triphenylphosphine reaction, this hydrogenation leads to the corresponding aromatic hydrocarbons.

Though the comparative investigations of arene oxide-oxepin systems and fixed arene oxides have by no means been exhaustive, the results reported clearly indicate that the arene oxides are the more reactive components of the valence-tautomeric systems toward most reagents. The only chemical indication of the presence of the oxepins is the formation of 2-oxabicyclo[3.2.0]hepta-3,6-dienes[31,60] on photolysis.



VI. 1,6-Oxido[10]annulene

The synthesis and the aromatic nature of the cyclic conjugated 10 π-electron system 1,6-methano[10]-annulene *(70)*[72] directed interest toward the analogous 1,6-oxido[10]annulene *(71)*, which can also be regarded as a 2,7-bridged oxepin. That *(71)* might be unstable in comparison with the valence-isomeric 9,10-naphthalene oxide *(72)* [cf. the position of the equilibrium *(55)* ⇌ *(56)*] seemed unlikely in view of the properties of *(70)*, which indicate that the 10 π-electron system possesses considerable resonance energy. *(71)*

(70) *(71)* *(72)*

was synthesized simultaneously by *Sondheimer*[73] and by *Vogel et al.*[74] by dehydrobromination of the tetrabromo epoxide *(76)* with sodium methoxide in ether, *(76)* being obtained from 1,4,5,8-tetrahydro-4a,8a-oxidonaphthalene *(75)*[75] which in turn is readily available from *(73)* *via* *(74)*. Though a total of four moles of hydrogen bromide had to be eliminated in this step, *(71)* was formed in yields of up to 90 %.

(73) *(74)* *(75)*

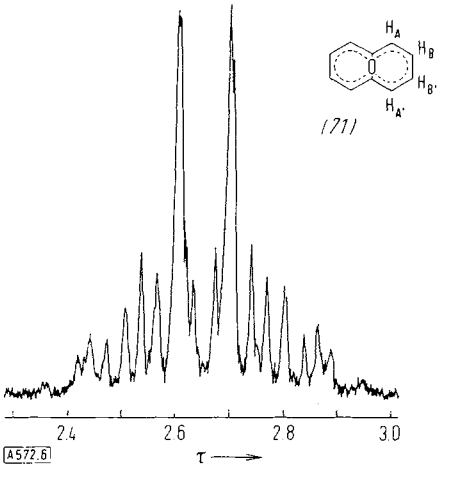
1,6-Oxido[10]annulene is a pale yellow crystalline substance (with an odor of naphthalene), which shows no tendency toward polymerization in air, despite the formal presence of five conjugated double bonds. The properties of the 10 π-electron system are evident from the spectra.

The ^{1}H–NMR spectrum (see Fig. 6) consists of an AA'BB' system with τ_A = 2.54 and τ_B = 2.74 and the coupling constants J_{AB} = 8.8, $J_{BB'}$ = 9.3, $J_{AB'}$ = 0.3, and $J_{AA'}$ = 1.1 Hz [76]. The absorption of the protons at relatively low field and the type of spectrum, according to which H^2 to H^5 and H^7 to H^{10} have identical NMR parameters, appear to be incompatible with a 1,6-oxido[10]annulene having localized double bonds. The NMR findings rather indicate that a ring current is present in the peripheral 10π-electron system, and hence that the compound has an aromatic structure [77]. Though the symmetry of the spectrum could likewise be explained by a molecule with rapidly fluctuating π-bonds, such a structure is not consistent with the position of the proton resonances.



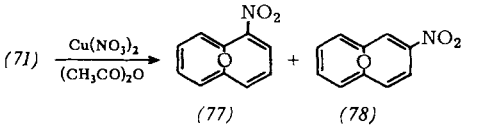


Fig. 6. ^{1}H–NMR spectrum of 1,6-oxido[10]annulene (in CCl_4; 60 MHz, internal standard: tetramethylsilane).

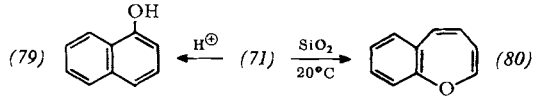
The coupling constants found for the AA'BB' system also fit into the above picture. This is particularly true of the vicinal couplings, which are almost identical, as is to be expected for a delocalized π-electron system in *(71)*. On the other hand, the vicinal coupling constants of olefinic protons in conjugated cycloolefins generally show considerable differences [57,64,78], which must be primarily due to the alternance of the bonds, if the double bond system is sufficiently planar [79]. It is interesting in this connection to note that the α-protons in *(71)* absorb at lower field strengths than the β-protons [80], *i.e.* the resonances occur in the opposite order to that found for the corresponding protons in oxepin and cycloheptatriene. In fact, the α-protons should be more strongly deshielded in *(71)* according to an estimate of the resonance positions using Pople's point-dipole model [81].



The electronic spectrum of 1,6-oxido[10]annulene contains three bands with maxima at 257 (ε = 74500), 302 (7100), and about 390 mμ (300), the last of these showing pronounced vibrational fine structure. 1,6-Methano[10]annulene gives a very similar spectrum. It may be concluded from this that there is no appreciable interaction between the free electron pairs on the bridge oxygen atom and the peripheral 10 π-electron system in the oxido compound. The habit of the spectra of *(71)* and *(70)* corresponds largely to that of the spectrum of benzene, and so points to a close relationship between the electronic structures of the π-systems in the 1,6-bridged [10]annulenes and in benzene [82].

In agreement with the symmetry shown by the NMR spectrum, the IR spectrum of 1,6-oxido[10]annulene contains relatively few bands. The C–C double-bond band at the unusually low frequency of 1538 cm^{-1}, which appears to be characteristic of the carbon skeleton, is reminiscent of C–C stretching vibrations of benzenoid compounds. This parallelism is also strongly suggested by the appearance of well-developed combination vibration bands in the range 1940 to 1580 cm^{-1}.

The aromatic nature of 1,6-oxido[10]annulene *(71)* is also apparent from its chemical behavior. The compound is not only relatively stable toward heat, oxygen, and light, but can also undergo substitution reactions with electrophilic reagents. Thus it can be nitrated with copper(II) nitrate in acetic anhydride, the nitro group being introduced into the 2- and 3-positions [*(77)* and *(78)*] [73,74].

However, the possibility of obtaining substituted products is considerably lower for 1,6-oxido[10]-annulene than for 1,6-methano[10]annulene, since the oxido compound and its derivatives, like the arene oxide-oxepin systems, are very sensitive toward proton and Lewis acids. 1,6-Oxido[10]annulene isomerizes to α-naphthol *(79)* under the action of proton acids in aqueous-ethereal media, while on silica gel in the presence of nonpolar solvents it rearranges almost uniformly into the intense yellow 1-benzoxepin *(80)* [74]. The formation of α-naphthol cannot involve *(80)* as an intermediate, since on treatment with acids *(80)* does not give α-naphthol, but products containing carbonyl groups; these indicate hydrolytic cleavage of the oxepin ring. The 1,6-oxido[10]annulene–1-benzoxepin rearrangement has also been observed with the 2-nitro

and 2-bromo derivatives of *(71)*. In the resulting nitro- and bromo-1-benzoxepins, the substituent is attached to the aromatic nucleus; its position has not yet been determined.

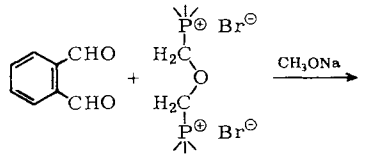
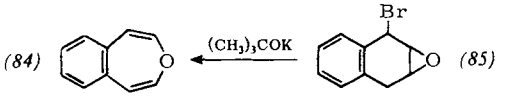
Concerning the mechanism of the acid-catalysed isomerization of 1,6-oxido[10]annulene into α-naphthol, there is as yet no evidence (unlike in the oxepin-phenol rearrangement) that the reacting species is the corresponding arene oxide, *i.e.* 9,10-naphthalene oxide.

An alternative is that the proton attacks the α-carbon atom of *(71)* and so initiates the structural rearrangement (cf. the formation of an arene oxide on bromination). The same difficulty is encountered in the interpretation of the surface-catalysed rearrangement of 1,6-oxido[10]annulene into 1-benzoxepin on silica gel.



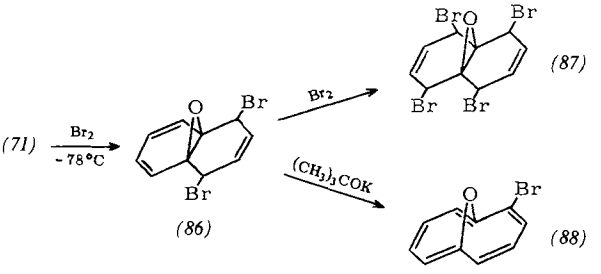
1-Benzoxepin is separated from its arene oxide valence isomer, 1,9-naphthalene oxide, by a relatively high energy barrier; consequently the oxepin character should be much more pronounced (though modified by the fused aromatic nucleus) than in the oxepin itself. As far as can be seen from the reactions studied so far,



(80) *(81)*

the chemical behavior of *(80)* corresponds to that of an enol ether. Like oxepin, *(80)* can be photochemically isomerized into a cyclobutene derivative *(81)* [83].

We have confirmed that the 1-benzoxepin obtained from *(71)* is free from the isomeric 3-benzoxepin *(84)*, which is also yellow, and which was first synthesized by *Dimroth* and *Pohl*[4] by a Wittig reaction of dimethylether-α,α'-bis(triphenylphosphonium) dibromide *(83)* with phthalaldehyde *(82)*. 3-Benzoxepin has recently also been obtained by reaction of 1-bromo-2,3-epoxy-1,2,3,4-tetrahydronaphthalene *(85)* with potassium t-butoxide in ether [84].

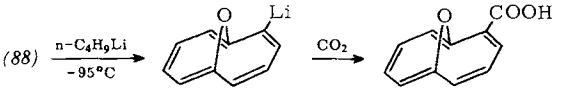


(82) *(83)*

(84) *(85)*

1,6-Oxido[10]annulene also resembles arene oxide oxepin systems in that the oxygen can be removed by triphenylphosphine (160 °C) or by $Cr(CO)_3(NH_3)_3$ (in boiling hexane) [65]; the reaction product is naphthalene. As a result of the resonance stabilization in 1,6-oxido[10]annulene, however, the reactivity towards dienophiles is drastically reduced.

A very close chemical relationship between 1,6-oxido-[10]annulene and arene oxides is established by addition-elimination reactions, a typical example of which is the bromination of the oxido compound [85]. Under the action of bromine in methylene chloride at −78 °C, 1,6-oxido[10]annulene gives a colorless dibromo adduct which can be isolated. This is identified spectroscopically as the benzene oxide derivative *(86)* with the bromine atoms *cis* to each other. Whereas symmetry of the NMR spectrum indicates that the position of the bromine atoms must be *cis*-2,5, but gives no further definite information (the protons of the double-bond system appear as a singlet), a conclusive decision between the benzene oxide and the oxepin structures is possible with the aid of the UV spectrum. As is to be expected for the benzene oxide structure *(86)*, the UV spectrum agrees closely with that of 8,9-indan oxide *(24)*, apart from



(71) *(86)* *(87)* *(88)*

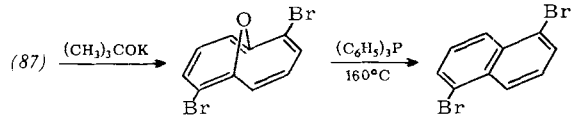
the high end-absorption of the adduct due to the bromine atoms. An oxepin, on the other hand, should give an absorption extending into the visible region. It is not yet certain whether the bromine attacks the ring from above or below relative to the oxygen bridge.

On further bromination, the dibromo adduct is converted into a tetrabromo adduct which, according to the NMR spectrum, has the structure *(87)* with *cis* bromine atoms in both cyclohexene rings; thus another *cis*-1,4 addition has taken place. The pairs of bromine atoms probably have *syn* and *anti* configurations with respect to the epoxide ring. *(71)* can be regenerated quantitatively from both the dibromo and the tetrabromo adduct on treatment with sodium iodide in acetone.

Attempted thermal dehydrohalogenation of the dibromo adduct *(86)* [86] has so far led only to unidentifiable decomposition products. However, if the dehydrobromination is carried out with bases such as potassium t-butoxide (in ether), the reaction leads smoothly to 2-bromo-1,6-oxido[10]annulene *(88)*, the NMR and UV spectra of which correspond to those of 2-bromo-1,6-methano[10]annulene [72]. Treatment of *(88)* with butyl-lithium (ether, −95 °C) yields 2-lithio-1,6-oxido[10]annulene *(89)*, from which it is possible to obtain 1,6-oxido[10]annulene-2-carboxylic acid *(90)* and other 2-substituted 1,6-oxido[10]-annulenes.

(88) *(89)* *(90)*

The reaction of the tetrabromo adduct *(87)* with potassium t-butoxide led to a dibromo substitution product of *(71)*, which was found to be pure 2,7-di-



[83] A derivative of 1-benzoxepin was recently described by *H. Hofmann* [Angew. Chem. 77, 864 (1965); Angew. Chem. internat. Edit. 4, 872 (1965)]; see also *H. Hofmann* and *H. Westernacher*, *ibid.* 78, 980 (1966); Angew. Chem. internat. Edit. 5, 958 (1966).

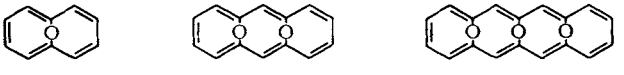
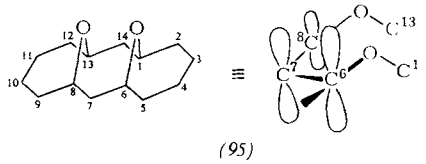
[86] The dibromo adduct of 1,6-methano[10]annulene, which still has the same carbon skeleton as the hydrocarbon, loses hydrogen bromide even below 0 °C.



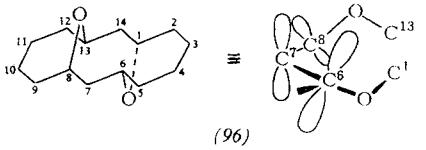
bromo-1,6-oxido[10]annulene *(91)*. This structure is based on a spectral comparison with 2,7-dibromo-1,6-methano[10]annulene[72], on the dipole moment[87], and on the formation of 1,5-dibromo-naphthalene *(92)* when *(91)* is heated with triphenylphosphine at 160 °C.

(91) *(92)*

VII. 1,6; 8,13-Bisoxido[14]annulene



The fact that the spectral and, to a large extent, the chemical properties of 1,6-oxido[10]annulene *(71)* are dominated by the 10 π-electron system of the C_{10} perimeter and not by the "oxepin structural unit" suggested the idea of a homologous series of bridged annulenes *(71)*, *(93)*, *(94)*, *etc.*, which, like the linearly fused aromatic hydrocarbons (the acenes) on which they are based, contain $(4n+2)$ π-electrons. According to calculations by *Dewar* and *Gleicher*[88] the Hückel rule may be regarded as valid for up to the 22 π-electron system; consequently the question of whether the aromaticity observed in the prototype *(71)* also extends to its nearest homologues should depend mainly on the geometry of the perimeter.



(71) *(93)* *(94)*

As soon as the number of bridges is greater than one, geometrical isomerism occurs, with the result that *(93)* can exist in a *syn* and an *anti* form, while *(94)* can exist in three forms (*syn-syn*, *anti-anti* and *syn-anti*). *Dreiding* and *Stuart-Briegleb* models of the homologues of *(71)* show that these molecules, unlike the flexible annulenes[89], have relatively rigid ring skeletons, and that substantial planarity of the perimeter is possible only in the *syn* and all-*syn* forms. The Stuart models indicate that there is no mutual steric hindrance of the *syn*-oxygen atoms, which would lead to bending of the carbon skeleton. Since the increase in the carbon perimeter from 10 to 14 or 18 C atoms is accompanied by an appreciable relief of strain in the C–O–C angle, the C skeleton can in fact be flatter in *syn-(93)* and *syn-syn-(94)* than in the parent compound *(71)*[90].

In the compounds in which we are interested, *i.e.* 1,6;8,13-bisoxido[14]annulenes, the $2p_z$-orbitals on C^6, C^7, and C^8 (like those on C^1, C^{14}, and C^{13}) can assume an approximately parallel position in the *syn* form *(95)*, whereas in the *anti* form *(96)* the $2p_z$-orbitals on C^6 and C^7 as well as those on C^7 and C^8 exhibit appreciable twisting in relation to each other. Thus the resonance stabilization should undoubtedly be highest in the *syn* form.

(95)

(96)

The qualitative validity of the views deduced from the Hückel rule and from molecular models concerning the homologues of 1,6-oxido[10]annulene *(71)* is demonstrated by attempts to synthesize *syn-* and *anti-*1,6; 8,13-bisoxido[14]annulene.

In view of the synthesis of *(71)* from 1,4,5,8-tetrahydronaphthalene, the most suitable starting compound for the synthesis of the two bisoxido[14]-annulenes *(101)* and *(105)* appeared to be 1,4,5,8,9,10-hexahydroanthracene *(97)*[91]. Reaction of the tetraene *(97)* with two equivalents of perbenzoic acid leads almost quantitatively to 1,4,5,8,9,10-hexahydro-4a,9a; 8a,10a-bisoxidoanthracene, which, according to the NMR spectrum, consists of the *syn (102)* and the *anti* isomer *(98)* (molar ratio approximately 60:40), since the central CH_2-protons give rise both to an AB-system (*syn* form) and to a singlet (*anti* form). The isomer mixture could be separated by fractional crystallization. Treatment of the *syn-* and *anti-*diepoxides *(102)* and *(98)* with bromine gives the corresponding tetrabromo adducts *(103)* and *(99)* (the configurational relationship between the remote bromine atoms is uncertain). The dehydrobromination of the two tetrabromides with potassium t-butoxide in tetrahydrofuran at 0 °C leads to a surprising result.

Whereas *(99)* lost four moles of hydrogen bromide to form the colorless bis(arene oxide) *(100)*, the reaction of *(103)* led directly to the desired *syn*-bisoxido[14]-annulene *(105)*, which was obtained as a stable carmine compound. Thus in the latter case the dehydrobromination was followed by dehydrogenation, evidently by atmospheric oxygen. The *syn* configuration of the bisoxido[14]annulene is shown, not only by the

[91] *J. Runge*, Z. Chem. *2*, 374 (1962); *A. J. Birch, P. Fitton, D. C. C. Smith, D. E. Steere*, and *A. R. Stelfox*, J. chem. Soc. (London) *1963*, 2209; *E. Vogel, M. Biskup, A. Vogel, U. Haberland*, and *J. Eimer*, Angew. Chem. *78*, 642 (1966); Angew. Chem. internat. Edit. *5*, 603 (1966).

synthesis [92], but also by the dipole moment of 3.25 D, which is of the expected order of magnitude [93]. In the meantime, it has been possible to detect spectroscopically the dihydro precursor of *(105)*. This is not the bis(arene oxide) corresponding to *(100)*, but the bisoxepin *(104)*.

The compound *(100)* has so far resisted all attempts to dehydrogenate it to *anti*-bisoxido[14]annulene *(101)*; this indicates that *(101)*, unlike the *syn*-isomer, has no appreciable resonance stabilization. A 1,6;8,13-bisoxido[14]annulene of unknown configuration [94], which was found to be identical with *(105)*, had been previously obtained from the mixture of *syn*- and *anti*-diepoxides *(102)* and *(98)* by reaction with *N*-bromosuccinimide and treatment of the crude bromination product with potassium t-butoxide in tetrahydrofuran.

A chemical proof of the structure of *syn*-bisoxido[14]-annulene *(105)*, which, however, does not take into account the configuration, is based on its reaction with $Cr(CO)_3(NH_3)_3$, which leads to deoxygenation and formation of anthracene in yields of up to 95 % [65]. This reaction should be useful in the determination of the structures of substitution products of *(105)*.

The NMR spectrum (Fig. 7) of *syn*-bisoxido[14]-annulene *(105)* shows a singlet at $\tau = 2.06$ (relative intensity 2) for the protons H^7 and H^{14} and an AA'BB' system ($\tau_A = 2.25$ and $\tau_B = 2.40$, relative intensity 8), which corresponds to the protons H^2 to H^5 and H^9 to H^{12}. The fact that the proton resonances occur at relatively low field strengths, together with the symmetry of the spectrum, points to a ring current in the peripheral 14 π-electron system. With 1,6-oxido[10]-annulene *(71)* as the reference substance, an estimate of the chemical shift from Pople's point-dipole model [81] gives $\tau_C = 1.92$, $\tau_A = 2.27$, and $\tau_B = 2.65$, in good agreement with the experimental values. The spin-spin interactions found for *(105)* are in remarkable agreement with those of *(71)* (cf. Section VI); $J_{AB} = 9.0$, $J_{BB'} = 9.2$, $J_{AB'} = 0.3$ and $J_{AA'} = 1.1$ Hz. Since the vicinal coupling constants J_{AB} and $J_{BB'}$ are practically identical, it is probable (as in the cases of *(70)* and *(71)* [90]) that the lengths of the C–C bonds in question do not differ appreciably.

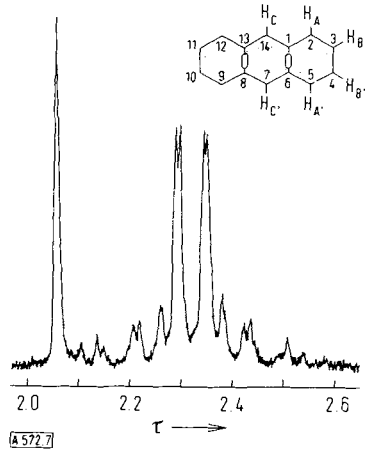

Fig. 7. ^1H–NMR spectrum of *syn*-1,6; 8,13-bisoxido[14]annulene (in $CDCl_3$; 60 MHz; internal standard: tetramethylsilane).

The electronic spectrum of *syn*-bisoxido[14]annulene *(105)* shows a four-band system, as is reported for the aromatic 14 π-electron system *trans*-15,16-dimethyldihydropyrene [95]. The maxima, which occur at slightly lower wavelengths than for the dihydropyrene derivative, are located at 306 (ε = 169000), 345 (14400), 382 (8500), and 555 mμ (775), the band at 555 mμ exhibiting vibrational fine structure. Though the C_{14} perimeter in bisoxido[14]annulene cannot become completely planar and electronic interaction of the oxygen atoms with the 14 π-electron system is not ruled out, the energy transitions calculated by the Pariser-Parr method for an unperturbed 14 π-electron system are surprisingly well satisfied. This is particularly true of the transition at the longest wavelength, whose expected value of 2.17 eV (≡ 572 mμ) corresponds to the band between 543 and 565 mμ [96].

[92] Oscillation of the bridge oxygen atoms through the peripheral C_{14} ring seems unlikely on steric grounds [the rotation of optically active methyl 1,6-methano[10]annulene-2-carboxylate remains unchanged even on prolonged heating at 240 °C (experiments by *W. Schröck*, unpublished)].

[93] According to measurements by *W. Bremser*, unpublished.

[94] *E. Vogel, M. Biskup, A. Vogel*, and *H. Günther*, Angew. Chem. *78*, 755 (1966); Angew. Chem. internat. Edit. *5*, 734 (1966).

[95] *V. Boekelheide* and *J. B. Phillips*, Proc. nat. Acad. Sci. USA *51*, 550 (1964); *F. Gerson, E. Heilbronner*, and *V. Boekelheide*, Helv. chim. Acta *47*, 1123 (1964).

[96] *H.-P. Blattmann, V. Boekelheide, E. Heilbronner*, and *J.-P. Weber*, Helv. chim. Acta, *50*, 68 (1967).

The IR spectrum, which contains relatively few bands owing to the symmetry of the compound, contains only one band at 1536 cm^{-1} in the C—C stretching region, which practically coincides with the analogous absorption of 1,6-oxido[10]-annulene (1538 cm^{-1}).

The aromatic character shown by the spectra of *(105)* is reflected in the considerable thermal stability of the compound and in its insensitivity to oxygen. Moreover, preliminary experiments indicate that *(105)* gives substitution products under the action of various electrophilic reagents.

The substantial similarity between the spectral and chemical properties of 1,6-oxido[10]annulene and *syn*-1,6; 8,13-bisoxido[14]annulene provides a firm experimental basis for the idea of an homologous series of bridged annulenes having aromatic character within the range of validity of the Hückel rule.

VIII. Procedures

Oxepin-Benzene Oxide:

A slurry of pulverized 1,2-epoxy-4,5-dibromocyclohexane *(17)*[14] (12.7 g, 50 mmole) in ether (25 ml) is added over a period of 10 min to a suspension of freshly prepared sodium methoxide (8.1 g, 150 mmole) in boiling ether (30 ml). After the reaction mixture has been refluxed for a further 5 min it is cooled in ice, and then 30 ml of water is added. The ethereal phase is washed with 2×20 ml of water and the combined washes extracted with 20 ml of ether (to recover any entrained oxepin-benzene oxide). The ethereal phase and the ether extract (from the washes) are then combined and dried over $MgSO_4$. The oxepin-benzene oxide is recovered by distillation using a 15 cm Vigreux column; the ether is distilled off first and the oxepin-benzene oxide finally recovered by distillation under vacuum (water pump). Yield: 3.85 g (80 %) of orange oxepin-benzene oxide (b.p. 27 °C/14 mm, 38 °C/30 mm; n_D^{20} = 1.5163). The product may be distilled under normal pressure (b.p. 124 °C) in an apparatus that has been treated with alkali.

2,7-Dimethyloxepin:

A solution of 4,5-dibromo-1,2-epoxy-1,2-dimethylcyclohexane *(28)* (20 g) (prepared from 1,2-epoxy-1,2-dimethylcyclohex-4-ene[97] and bromine in methylene chloride at −78 °C, m.p. 85—86 °C) in ether (30 ml) is added to a stirred suspension of sodium methoxide (14 g, 260 mmole) in boiling ether (30 ml). The reaction mixture is refluxed for 2 h, cooled on ice, and water (50 ml) is then added. The product is recovered as in the previous procedure. Yield: 7.3 g (84 %) yellow-orange 2,7-dimethyloxepin (b.p. 49—50 °C/11 mm; n_D^{20} = 1.5045).

8,9-Indan Oxide:

A solution of 5,6-dibromo-8,9-epoxy-4,7-dihydroindan *(51)*, $n = 3$, (14.8 g) (prepared from 8,9-epoxy-4,7-dihydroindan[98] and bromine in methylene chloride at −78 °C: m.p. 87 to 88 °C) in anhydrous ether (150 ml) is added to a stirred suspension of potassium t-butoxide (25 g, 220 mmole) in anhydrous ether (225 ml) at 0 °C over a period of 1 h.

After the reaction mixture has been stirred for 5 h at room temperature and then for 15 min at 40 °C, it is cooled on ice and 2 N KOH (40 ml) is added. Since the product is unstable towards water in neutral solution, it is washed twice with 2 N KOH (40 ml); it is subsequently recovered in the normal way. Yield: 5.7 g (85 %) of 8,9-indan oxide as a colorless liquid (b.p. 30—31 °C/0.4 mm; n_D^{20} = 1.5255).

Thanks are due to M. Biskup, R. Schubart, W. A. Böll, M. Wiesel, F.-G. Klärner, and R. Sundermann for their enthusiastic cooperation. We are grateful to H. Friebolin, Freiburg, for recording the low-temperature NMR spectra. Acknowledgment is also due to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their generous support of our work.

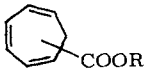
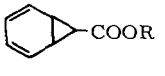
The Norcaradiene Problem



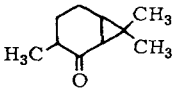
BY G. MAIER [*]

Dedicated to Professor R. Criegee on the occasion of his 65th birthday



Compounds having the norcaradiene structure are stable if one of the double bonds of the norcaradiene also belongs to a benzene ring or if C atoms 1 and 6 are fixed in position by a bridge. A similar effect that favors the norcaradiene form is produced by the incorporation of nitrogen atoms in positions 3 and 4. Cycloheptatriene and most of the simply substituted tropilidenes exist exclusively in the monocyclic triene form. It has been possible in some cases to detect a valence-tautomeric equilibrium between the norcaradiene and the cycloheptatriene ring system. Non-classical stabilization of compounds having norcaradiene or cycloheptatriene structure in the sense of a pseudoaromatic "homobenzene" is only very slight, if it occurs at all.

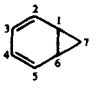
I. Introduction



Following a suggestion by his tutor *Curtius*[1], *Buchner*[2–10] attempted to identify the products formed in the thermal decomposition of diazoacetic ester in benzene. He found a mixture of esters ("Buchner esters") that appeared to contain the ester *(2)* of bicyclo[4.1.0]hepta-2,4-dienecarboxylic acid, as well as esters *(1)* of three isomeric cycloheptatrienecarboxylic acids (R = CH_3, C_2H_5).

(1)

(2)



(3)

The ester *(2)*, which is formed as the only product in the photolysis of diazoacetic ester in benzene[11,12] may be regarded as a three-, six-, or seven-membered ring derivative. Chemical proof was provided for all three ring systems: Oxidation of the carboxylic acid of *(2)* with potassium permanganate gave *trans*-cyclopropane-1,2,3-tricarboxylic acid[9]; the amide obtained by reaction of *(2)* with ammonia gave phenylacetic acid on treatment with concentrated sulfuric acid[9]; and the ester *(2)* could be converted into esters of three isomeric cycloheptatrienecarboxylic acids[5,7]. Because of its similarity to the structure of carone *(3)*, as established by *von Baeyer*[13], the carbon skeleton *(4)* on which the ester *(2)* is based was named norcaradiene.

The structure of the seven-membered ring esters *(1)* was established by hydrolysis and reduction to cycloheptanecarboxylic acid, which could be prepared independently from cycloheptanone[6].

Though the unsubstituted norcaradiene was unknown, *Willstätter*[14] obtained the isomeric cycloheptatriene *(5)* by an unambiguous route from cycloheptanone, and found it to be identical with the "tropilidene" obtained by *Ladenburg*[15] from atropine.

(4)

(5)

(6)

Thus both the norcaradiene and the cycloheptatriene ring systems were apparently capable of existing, and neither appeared to show any tendency to change spontaneously into the other. Compounds of the norcaradiene type, *e.g.* the ester *(2)*, were reported to undergo cleavage of the three-membered ring with formation of the cycloheptatriene derivative when heated[5–7,9] or when treated with bases[4,6,9].

This view was subsequently generally accepted as correct. It was only when *Meerwein* [16] and *Doering* [17, 18] studied the photolysis of diazomethane in benzene that doubts began to arise. While *Meerwein*, on the basis of hydrogenation experiments, regarded the reaction product as a mixture of cycloheptatriene and norcaradiene, *Doering* reported that the only product apart from a little toluene was cycloheptatriene, whereas norcaradiene *(4)* should have been formed by analogy with the formation of *(2)* from benzene and diazoacetic ester.

Doering repeated *Buchner*'s experiments and found [19] (see also [20, 21]) that all Buchner esters have the same basic structure, and may be regarded as the four positionally isomeric cycloheptatriene esters. Thus *Buchner* had not obtained a norcaradiene derivative.

II. Statement of Problem

Three basic limiting cases may be discussed for the relationships between the norcaradiene and the cycloheptatriene ring systems:

a) Both compounds with norcaradiene structures and compounds with cycloheptatriene structures can exist. These are to be regarded as independent entities; the energy barrier between the two systems is so high, that no interconversion takes place.

b) Norcaradiene and cycloheptatriene are related by a valence-tautomeric equilibrium similar to that known for some time for the system bicyclo[4.2.0]octa-2,4-diene/cycloocta-1,3,5-triene [22].

c) Norcaradiene is to be regarded as a pseudoaromatic planar compound [19], in which the 1,6 bond is fully uncoupled, and overlap of the orbitals of C-1 and C-6 with those of the two double bonds leads to the formation of a "homobenzene" *(6)* [23]. The structures *(4)* and *(5)* would then be resonance structures of the resonance hybrid *(6)*, the bond lengths and angles being assumed to be equal.

On the basis of the papers published up to 1960, strong arguments could be advanced for each of these three possibilities. The results of catalytic hydrogenation supported case a) [11, 16] (see also [24]), since compounds assumed to have the norcaradiene structure take up only two moles of hydrogen, while compounds having the cycloheptatriene structure take up three. The acid obtained by hydrolysis of the ester *(2)* reacted with bromine to give a tetrabromide, which was stable toward permanganate [9]. The ozonization of *(2)*, which is reported to give a diozonide, also supports the norcaradiene structure [25]. The NMR spectra of tropilidene and its simple substitution products, on the other hand, are indicative of a cycloheptatriene structure [26].

The fact that compounds to which a cycloheptatriene structure had been definitely assigned react in the bicyclic form in many reactions, *e.g.* in the Diels-Alder synthesis [11, 21, 27–29], could be taken as evidence of the existence of a valence-tautomeric equilibrium [case b)]. However, it is possible that transition into the bicyclic system takes place only under the influence of the attacking agent [30]. This view is supported by the fact that the enol esters of eucarvone, which, from their NMR spectra, must be monocyclic, give good yields of caronic acid on ozonolysis [31].

The NMR spectra of the Buchner esters and the value of about 7 kcal/mole found for the stabilization energy of tropilidene from heats of hydrogenation (based on the heat of hydrogenation of cycloheptene) [32, 33] led *Doering* to accept the pseudoaromatic structure *(6)* [case c)]. This view is compatible with *Winstein*'s concept of homoaromaticity [23, 34].

Further support for these considerations was provided by the analysis of the vibration spectra of tropilidene, which also indicates a planar, quasiaromatic structure, but does not discount the possibility that the methylene group lies slightly out of the plane of the ring [35]. In order to decide between the above alternatives, it will be necessary, not only to establish the general structure of the compounds in question, but also to clarify any relationships existing between the valence tautomers. The degree of delocalization of the 1,6 bond in compounds having the norcaradiene structure, or the degree of 1,6 overlap in substances having the cycloheptatriene ring structure, would also have to be known.

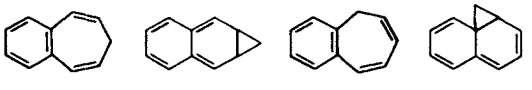
III. The Norcaradiene/Cycloheptatriene System

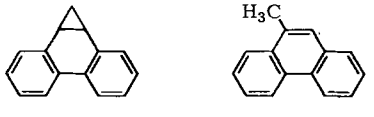
The easiest way to obtain more definite information would be by direct investigation of a system in which both the monocyclic cycloheptatriene form and the bicyclic norcaradiene form can exist, and in which both are present in sufficiently high concentrations. Until recently, however, this was not possible. More recent investigations have shown that cycloheptatriene and its simple substitution products exist entirely in the monocyclic form.

Compounds having an intact norcaradiene structure could be obtained only by the use of special expedients, either by inclusion of one of the two double bonds of the norcaradiene in an aromatic ring or by bridging of carbon atoms 1 and 6 with an additional ring.



a) Benzo Derivatives

Buchner [36] found that the decomposition of diazoacetic ester in naphthalene leads to the adduct *(7)* [30,37]. The transition into the cycloheptatriene derivative *(8)* involves dearomatization of the benzene ring. Consequently, the isomerization takes place only at high temperatures. On rearomatization, *(8)* is then converted into *(9)* with a hydrogen shift, which is probably rate-determining.



(7) *(8)* *(9)*

Conversely, if one of the double bonds of the cycloheptatriene also belongs to a benzene ring, only the triene form is found. It is therefore not surprising that the benzocycloheptatrienes *(10)* and *(12)* [39] do not change into the norcaradiene derivatives *(11)* and *(13)*, since this would involve the formation of a quinoid ring from a benzoid ring. On the contrary, compounds

(10) *(11)* *(12)* *(13)*

(14) *(15)*

of the type *(11)* or *(13)* isomerize spontaneously into the benzocycloheptatrienes [40].

Dibenzonorcaradiene *(14)* should be particularly stable toward isomerization into the cycloheptatriene system. It is found, in fact, that *(14)* does not form dibenzocycloheptatriene when heated, but yields 9-methylphenanthrene *(15)* instead [38,41,55]. The ease of conversion into the phenanthrene derivative is also indicated by the fact that *(14)* can transfer the methylene group to olefins under the action of light [42]. The adduct of dichlorocarbene and 9-methoxyphenanthrene loses methyl chloride when heated, with formation of a dibenzotropone [43]. The patterns outlined here are confirmed by the behavior of the adducts of methylene with anthracene [44].

Several highly condensed aromatic compounds have so far been converted into benzonorcaradienes. This is usually achieved by thermal decomposition of diazoacetic ester in the presence of the corresponding aromatic compound [30,36,37,41,45–53] (see also [40]); this method can sometimes be used with heterocyclic compounds [46,54]. The photolytic [37] or copper salt-catalysed [38,41,44,52,55] decomposition of diazo compounds, and even the addition of dihalogenocarbene in the case of activated aromatic compounds [43] have also been successfully used. These compounds cannot provide any information on the question of whether the norcaradiene system exists in a valence-tautomeric equilibrium with the cycloheptatriene system. The fused benzene rings can stabilize one tautomer to such an extent that no equilibrium can be detected at low temperatures.

The benzonorcaradienes also provide no indication of appreciable delocalization of the 1,6 bond of norcaradiene. This would lead to flattening of the ring, and, in the extreme case, the two geminal cyclopropane protons should give only one signal in the NMR spectrum. However, this is not so. The position and splitting in the NMR spectrum of the cyclopropane protons in the adduct of methylene and naphthalene [37] clearly indicate the structure *(16a)* ≡ *(16c)* [56]. However the two

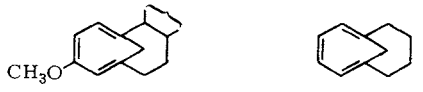
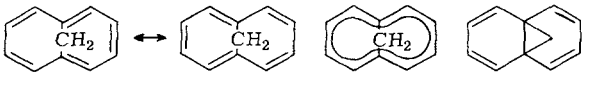
(16a) *(16b)* *(16c)*



geminal cyclopropane protons in *(16a)* give a single signal when this substance is heated to 180 °C. This is regarded as evidence that a valence-tautomeric equilibrium is established between the forms *(16a)*, *(16b)*, and *(16c)*. An equilibrium of this type is also suggested for a derivative of *(16a)* [57]. The activation energy of 19.4 kcal/mole found for this reaction [56] seems surprisingly low in view of the fact that the benzene ring must be dearomatized in the formation of *(16b)*.

b) Bridged Systems

The anhydride *(17)* prepared by *Eschenmoser* [58] in connection with his colchicine synthesis [59] and the hydrocarbon *(19)* described by *Vogel* [60] are examples of another, very elegant method of fixing the norcaradiene structure. In these compounds the carbon atoms 1 and 6 of the norcaradiene are held in position by an additional five-membered ring. In contrast to its anhydride *(17)*, the dicarboxylic acid exists entirely in the monocyclic form *(18)*. However, compounds containing a six-membered ring bridge, *e.g.* *(20)* [61,62], *(21)* [63], or their derivatives [64], must be regarded as derivatives of cycloheptatriene.



(17) *(18)* *(19)*

(20) *(21)*

In norcaradiene derivatives that are stabilized by a bridge, the two geminal three-membered ring protons are not identical, and very different τ values are found in the NMR spectrum, the higher τ value being assigned to the *endo* proton (see Section IVc). Information can also be obtained from the coupling between the methylene protons. While the absolute value for norcaradiene derivatives is 3–5 Hz, that for cycloheptatrienes is 7–12 Hz [60–71]. The UV spectra [60–71] and the ^{13}CH coupling constants [65,72] can also be used as evidence of structure.

An interesting bridged system is 1,6-methanocyclodecapentaene (1,6-methano[10]annulene) *(22)* [73]. All the properties of this compound [72], particularly the NMR spectrum, which shows 8 protons in the aromatic hydrogen atom region at $\tau = 2.5$–3.2 and a sharp singlet at $\tau = 10.5$ and which may be regarded as indicative of the existence of a ring current, suggest that the compound is best described by the two resonance structures *(22)* and *(23)* or by the formula *(24)*. The chemical properties, the ^{13}CH coupling constant of the methylene group, the UV spectrum, and the X-ray analysis of methanocyclodecapentaene-2-carboxylic acid [74], which showed that localized single and double bonds are not present although the perimeter is not quite planar, are all in agreement with this structure.

(22) *(23)* *(24)* *(25)*

There is no indication of any valence-tautomeric equilibrium with the norcaradiene form *(25)*. The same is true of the substitution products of *(22)* [64,65, 68,70,72,75], *anti*-1,6;8,13-bismethano[14]annulene [67], and the hydrocarbon *(26)* [66]. On the other hand compound *(28)* [69,71] and the adduct *(27)* [67] of *(22)* and dimethyl acetylenedicarboxylate exist in the norcaradiene form.

The four membered ring homologue *(29)* of *(22)* also has the tricyclic structure, probably for steric reasons [63,76].

The existence of the methylenenorcaradiene derivative *(30)* [77], which does not isomerize into *(31)*, even when heated at 275 °C, shows that norcaradiene struc-

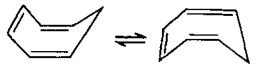
(26) (27) (28)

(29) (30) (31)

tures can be stabilized by other steric effects as well as by a "bracket effect".



A valence-tautomeric equilibrium between compounds having cycloheptatriene and norcaradiene structures coupled with a keto-enol tautomerization has been found between the alcohol *(32)* and the ketone *(33)* [68].

(32) (33)

c) The System Norcaradiene/Cycloheptatriene (Unsubstituted)

Tropilidene (cycloheptatriene) clearly has the monocyclic structure *(5)*. Hydrogenation yields cycloheptane [24], and oxidation with CrO_3/pyridine leads to tropone [78]. The NMR spectrum is particularly informative. At room temperature the two methylene hydrogen atoms give only one triplet signal; this could be regarded as evidence of a planar structure. In addition to the coupling constant for the geminal methylene protons, the coupling constants of the olefinic protons can also be used as evidence of structure [79,80]. Both methods indicate the monocyclic structure. The NMR spectrum is temperature-dependent, and the methylene protons give separate signals at −140 °C [81, 82]. This shows that cycloheptatriene has a boat configuration and undergoes a rapid ring inversion *(34a)* ⇌ *(34b)*.

(34a) (34b)

The boat form of cycloheptatriene is also indicated by IR-spectroscopic findings for [7-D]-cycloheptatriene [83], the microwave spectrum of cycloheptatriene [84], and the characteristic thermal [85,86] and photochemical [87,88] transannular hydrogen shifts of [D]-cycloheptatriene. The absolute proof is provided by electron diffraction diagrams [89]. According to X-ray analysis [90], the seven-membered ring in the tricarbonylmolybdenum complex of cycloheptatriene has a similar boat form, but in this case the six unsaturated carbon atoms lie almost in the same plane. In contrast to the angled structure of cycloheptatriene, the tropyl radical [95,96] and the tropilidene anion [97–99] have a highly symmetrical structure analogous to that of the planar tropylium ion [91–94].

No valence-tautomeric equilibrium has so far been detected between cycloheptatriene and norcaradiene. Even the dilatometric method used so successfully by *Huisgen* for the cyclooctatetraene/bicyclooctatriene system fails in this case [100]. The existence of an equilibrium with an extremely small quantity of norcaradiene, which cannot be detected directly, can only be indirectly deduced from the course of many chemical reactions of tropilidene, *e.g.* the Diels-Alder reaction [27,28,101–104] (many dienophiles also react with the triene form [105–107]) or the isomerization to form toluene [108,109], but mainly by analogy with the results obtained with substituted cycloheptatrienes (see next section).

While the thermal isomerization of cycloheptatriene into norcaradiene, according to *Woodward* and *Hoff-*

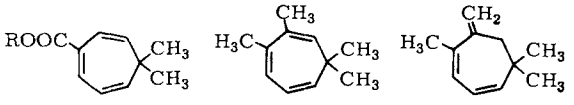
mann's rules [110], can be disrotatory and can therefore proceed very readily, the transition from cycloheptatriene to bicyclo[3.2.0]heptadiene *(35)* would require a greater activation energy for the thermal reac-

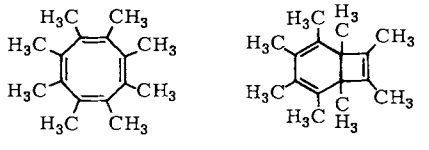


(5) *(35)*

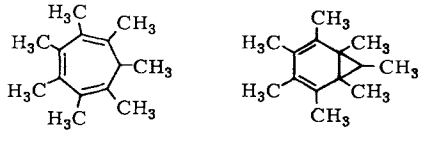
tion, but should proceed smoothly under the action of light. Cycloheptatriene can in fact be smoothly converted into *(35)* by exposure to light, but the thermal isomerization of *(35)* into cycloheptatriene takes place only under drastic conditions [111–114].

d) The System Norcaradiene/Cycloheptatriene (Substituted)

Most investigations on the norcaradiene problem have been carried out on simply substituted derivatives. Substituted cycloheptatrienes are best prepared by thermal [1–9, 24, 40, 115–124], photolytic [11, 16–18, 40, 123], or catalytic [125–128] decomposition of diazo compounds in the presence of aromatic compounds or from eucarvone [26, 29, 31] or tropylium salts [91, 129, 130]. Apart from diazo compounds, other sources of carbenes may also be used [131, 132].



The structures of the substituted cycloheptatrienes can again be determined from their chemical and spectral properties. The boat conformation is shown by X-ray analysis of a derivative of 7,7-dimethylcycloheptatriene-3-carboxylic acid *(36)* [133, 134], which is a typical cyclic polyolefin with alternating bond lengths. The 1,6 distance is 2.42 Å, so that a norcaradiene structure can be ruled out. A 1,6 overlap can occur, if at all, only "under the boat". Nevertheless, a value of 1/3 of the 2,3 overlap in butadiene is calculated for this overlap. The fact that the substituted tropilidene *(37)* is only 1.3 kcal/mole more stable than the isomer *(38)* shows that a 1,6 overlap, which is impossible in *(38)*, makes no appreciable contribution to the stabilization of *(37)* [135].



(36) *(37)* *(38)*

Compounds of the type *(37)* give an NMR spectrum that contains only one signal for the protons of the two geminal methyl groups. The derivative with a t-butyl group in position 2 gives two signals below −86 °C [136]. It was shown in this way for the first time that tropilidenes undergo a fast ring inversion at room temperature.

The question of the existence of a valence-tautomeric cycloheptatriene-norcaradiene equilibrium could not be answered until very recently. According to investigations by *Criegee*, an accumulation of methyl groups can favor bicyclic valence isomers rather than the monocyclic isomers. Thus octamethylcyclooctatetraene *(39)*, in contrast to the unmethylated parent compound [137, 138], can be converted into the bicyclic isomer *(40)* by heating [139, 140]. It therefore seemed pertinent to determine whether heptamethylcycloheptatriene *(41)* has a greater tendency than the unsubstituted cycloheptatriene to change into the norcaradiene derivative *(42)*. This isomerization did not

take place [124]; however, the increased rate of the Diels-Alder reaction compared with that of tropilidene indicates that the bicyclic form is more strongly favored. Heptaphenyltropilidene also has the monocyclic structure [141].

Investigations carried out by *Ciganek* show that a valence-tautomeric equilibrium can, in principle, be assumed for all these compounds. Whereas 7,7-bis(trifluoromethyl)cycloheptatriene *(43)* exists exclusively in the open triene form [122, 142], the UV spectrum indicating a somewhat flatter boat than in cycloheptatriene, only the bicyclic form *(44)* can be detected in the case of the corresponding dicyano compound [40]. The structure *(44)* is based on the chemical behavior and on the spectra. A detailed analysis of the NMR spectrum of *(44)* [143] and an X-ray analysis of the compound methylated in positions 2 and 5 [144] confirm the assignment of this structure.

(43) *(44)* *(45)* *(46)*

In view of these findings, it is not surprising that the temperature-dependence of the NMR spectrum of 7-cyano-7-trifluoromethylcycloheptatriene *(45)* indicates an equilibrium with the valence tautomer *(46)* [24].

Substituted tropilidenes undergo a variety of thermal rearrangements, depending on the conditions. The very readily induced ring inversion (activation energy about 6 kcal/mole [81, 82]) is followed at higher temperatures by the valence tautomerism mentioned above (calculated activation energy 11 ± 4 kcal/mole [145]); a further temperature rise leads to the 1,5 hydrogen shifts discussed earlier in connection with deuteriocycloheptatriene (E_A = 31 kcal/mole) [85, 86, 123, 146 to 152]. At sufficiently high temperatures, even the carbon skeleton can rearrange. Thus tropilidene isomerizes at 400 °C to give toluene (E_A = 51 kcal/mole [109]).

Berson studied the pyrolysis of 3,7,7-trimethyltropilidene *(47)* at 300 °C [145, 153]. Analysis of the pyrolysis products of 1,5-dideuterated *(47)* shows that the atoms 1 to 6 of the starting material always remain in their original sequence on pyrolysis, and that C-7, with its geminal methyl groups, is simply inserted between any two adjacent atoms of this sequence. The simplest explanation for this is that *(47)* and the two other tropilidenes that can result from rearrangement establish an equilibrium *via* the corresponding norcaradienes, the isopropyl residue formally migrating around a quasi-toluene ring as in *(48)*.

(47) *(48)*

Photolytically induced isomerizations into bicyclo[3.2.0]-heptatriene derivatives [155] and hydrogen shifts [87, 88, 123, 154] (which, according to *Woodward* and *Hoffmann*'s selection rules, must be either 1,7 or 1,3 shifts, in contrast to the thermally induced 1,5 shifts) as well as photolytically induced *Wagner-Meerwein* rearrangements [155] and rearrangements proceeding *via* tropylium ions (by primary removal of a hydride ion [146]) have also been observed with substituted tropilidenes.

IV. Systems Containing Hetero Atoms

a) Oxepin-Benzene Oxide

On the one hand the oxepins are of interest in connection with the norcaradiene problem, particularly because of the possibility of valence tautomerism with the corresponding bicyclic oxides, and on the other owing to their cyclic 8 π-electron system and the associated question of the aromaticity of these compounds [156]. The first oxepin derivatives, which became known mainly as a result of the work of *Dimroth*, were 4,5-benzoxepin *(49)* and its derivatives [157, 158-161]. 2,3-Benzoxepin has recently been synthesized [162]. The pigment flavanonol is also regarded as an oxepin derivative [163]. By analogy with benzocycloheptatriene *(10)*, compounds of the type *(49)* will have no great tendency to form the valence-tautomeric naphthalene oxides. Conversely, the norcaradiene-like form can again be stabilized by a "bracket effect", as in the compound *(50)* [164].

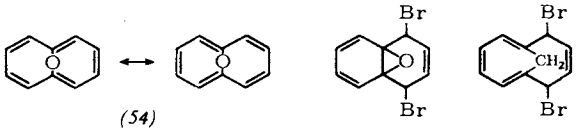
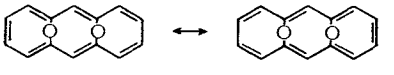
(49) (50) (51) (52)

It is possible that naphthalene oxides occur as intermediates in the isomerization of benzoxepins into phenol derivatives [161, 165]. A valence-tautomeric equilibrium has been definitely detected for the parent compound *(51)* and its methyl derivatives [164, 166]. These compounds are readily obtainable by double dehydrobromination of dibromides. Thus when 1,2-epoxy-4,5-dibromocyclohexane is treated with suitable bases, it forms a yellow oil, which clearly has the seven-membered ring structure *(51)* on the basis of its chemical properties (heating to 70 °C or treatment with acids yields phenol; catalytic hydrogenation leads to oxepane; the Diels-Alder reaction leads to adducts derived from benzene oxide) and its spectra [80, 164, 166]. Another synthesis of the oxepin system has been described by *Prinzbach* [166a].



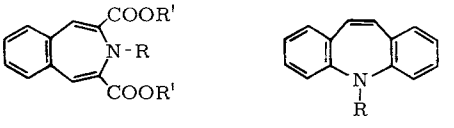
The temperature-dependence of the NMR spectrum of *(51)* and the solvent-dependence of the UV spectrum indicate a valence-tautomeric equilibrium between oxepin *(51)* and benzene oxide *(52)*, the position of the equilibrium being strongly dependent on the solvent (about 30% as benzene oxide in isooctane, and about 90% in water/methanol). The chemical and spectral properties of *(51)*, by analogy with those of cyclooctatetraene and in agreement with the Hückel rule, indicate that oxepin may be regarded as a typical polyolefin with no appreciable "aromatic" stabilization. The valence tautomerism *(51)* $\rightleftharpoons$ *(52)* is faster [164, 167] ($E_{A\ (51)\rightarrow (52)} = 7.2 \pm 1.0$; $E_{A\ (52)\rightarrow (51)} = 9.1 \pm 0.8$ kcal/mole) than that described for the system *(45)/(46)*. The analysis of the NMR spectrum [167] indicates that oxepin also exists as a boat form *(53)*; this fact suggests that there is again a very rapid interconversion between the two identical conformers *(53a)* and *(53b)*, and shows that there can be no delocalization, so that olefinic reactions are to be expected.



(53a) (53b)

Methyl groups in positions 2 and 7 favor the monocyclic form, probably because of steric repulsion. Thus 2,7-dimethyloxepin exists only as the triene; the monocyclic and bicyclic forms of 2-methyloxepin have almost the same energy [168].

On the other hand, 1,6-oxidocyclodecapentaene *(54)* could, according to the Hückel rule, be aromatic. In fact the NMR spectrum of *(54)* (A_2B_2 system, centered at $\tau = 2.5$ [162, 169]) indicates a ring current; the UV spectrum corresponds to that of 1,6-methanocyclodecapentaene. The chemical behavior of *(54)*, *e.g.* on electrophilic substitution, agrees with this. *(54)* reacts with bromine to form an addition product whose spectra indicate that it must have the benzene oxide structure *(55)* [64]. This is surprising, since the corresponding carbocyclic compound *(56)* exists in the cycloheptatriene form. Evidently the equilibrium can in general be displaced in favor of the norcaradiene form by an additional six-membered ring; however, this effect is not sufficiently strong in *(56)*, since the position of the valence-tautomeric equilibrium in the cycloheptatriene is too unfavorable. As in 1,6-oxido-[10]annulene *(54)*, a ring current must also be assumed to be present in 1,6;8,13-bisoxido[14]annulene *(57)* [170].



(54) (55) (56)

(57)

b) Azepine-Benzene Imine

The principle of "freezing" individual double bonds by incorporation in a benzene ring has also been used successfully in the azepine series. Typical examples are the monobenzo and dibenzo derivatives *(58)* [171–173] and *(59)* [174–176].

(58) (59)

The seven-membered ring in these compounds is probably again nonplanar, so that the 8 π coupling must be extremely small. It should be noted that *(58)*, R = Br, is very stable, and can probably be regarded as a derivative of the azatropylium ion. Mononuclear azepine derivatives are obtained by the thermal or photolytic decomposition of azido compounds in the

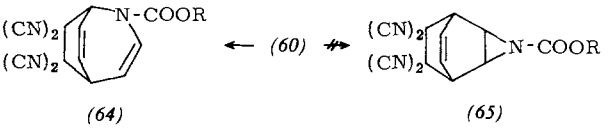
[176] *W. Schindler* and *H. Blattner*, Helv. chim. Acta *44*, 753 (1961).

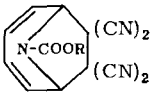
presence of aromatic compounds[177–179] (cf. the reaction with diazo compounds). Thus irradiation of ethyl azidoformate in benzene yields ethyl azepine-*N*-carboxylate *(60)*[180]. The same products are also obtained with ethoxycarbonylnitrene formed by α-elimination[181]. The chemical and spectral behavior clearly indicate the structure *(60)*. It is not yet clear whether or not *(60)* is in equilibrium with small amounts of the benzene imine derivative *(61)*. An electron-attracting substituent on the nitrogen appears to be essential to the stability of the azepine system; *N*-methylazepine *(67)*, which can be obtained from *(60)* by reduction with $LiAlH_4$, is thermally very unstable[182]. Thus azepine experiences only very little (if any) "aromatic" stabilization. This is supported by the fact that compounds that formally can enolize to form hydroxyazepines exist only in the keto form[57, 183, 184].

The azepines are sensitive to acids. Thus *N*-cyanoazepine *(62)*[179] rearranges in the presence of acids to form phenyl cyanamide. Isomerizations of this type may proceed *via* the azanorcaradienes, *e.g.* in this case *(63)*.



(60)  *(61)*

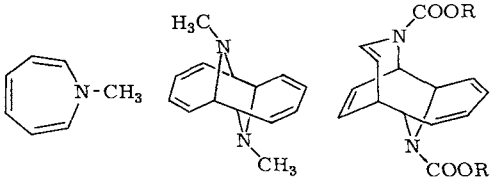
(62)  *(63)*



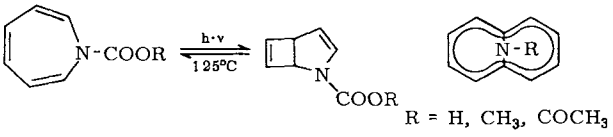
The same is true of the reductive elimination of nitrogen to form aromatic compounds[185].

On the other hand, it is surprising that the ester *(60)* of azepine-*N*-carboxylic acid does not give the adduct *(65)*, as would be expected by analogy with cycloheptatriene or oxepin, or the compound *(66)*, as was originally assumed[186], but that the compound *(64)* is formed instead[187–189].

The structure *(64)* is based on the X-ray analysis of its derivatives[190–191]. The formation of adducts of the type *(64)* can be explained by the assumption that the triene form is much more stable than the norcaradiene form in azepines. If this is so, the 1,4-addition to the triene form will predominate, whereas if the monocyclic and bicyclic tautomers are roughly equally stable, as in the case of the carbocyclic cycloheptatrienes, 1,4-addition to the norcaradiene form will take place[189].



(64) ← *(60)* → *(65)*



(66)

The yellow *N*-methylazepine *(67)* dimerizes rapidly above 0 °C to give *(68)*[182]. *(60)* and *(62)* give similar dimers when heated[192, 193]. According to the Woodward-Hoffmann rule, a 6 + 6 addition cannot take place directly[194], but must proceed in several steps. This is confirmed by the fact that a 4 + 6 addition product *(69)* has been found as an intermediate[192].

(67) *(68)* *(69)*

Like cycloheptatriene (Section IIIc) and 2,7-dimethyloxepin[190], *(60)* is converted by exposure to light into the valence-isomeric 2-azabicyclo[3.2.0]heptadiene derivative *(70)*, which in turn is reconverted into *(60)* by heating[190].

(60) *(70)* *(71)*

The spectra of the nitrogen-bridged cyclodecapentaenes *(71)*[162, 195] are in agreement with those of the methylene and oxygen analogues.

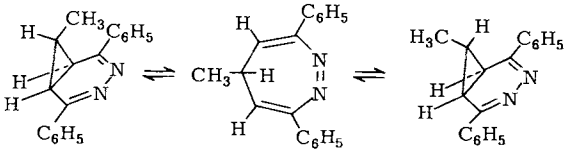
No compound having a definite benzene imine structure has so far been found, but there are indications of a valence-tautomeric equilibrium between *N*-methylazepine *(67)* and *N*-methylbenzeneimine [182].

c) 3,4-Diazanorcaradiene—3,4-Diazacycloheptatriene

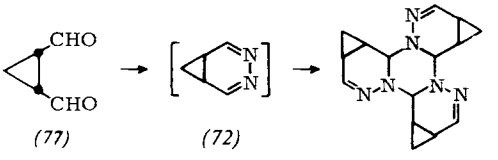


Norcaradiene derivatives can be stabilized, not only by "freezing" a double bond (by incorporation in an aromatic ring) or by the "bracket effect", but also by the incorporation of nitrogen atoms into the norcaradiene ring in positions 3 and 4. It can be calculated that in the system 3,4-diazanorcaradiene *(72)*/3,4-diazacycloheptatriene *(73)*, the bicyclic valence tautomer must be thermodynamically more stable than the monocyclic form.

(72) *(73)* *(74)*

In fact, 2,5-diphenyl-3,4-diazanorcaradiene *(74)*, R = H, and its substitution products are stable at room temperature [196–201]. The bicyclic structure is evidenced on the one hand by the spectra, and on the other by the chemical behavior of these compounds. Compounds of the type *(74)*, R = H, CH_3, COC_6H_5, form 4-alkyl-3,6-diphenylpyridazines when treated with acid, and reaction with manganese dioxide, ozone, or peroxy acids leads almost quantitatively to dibenzoylcyclopropanes [198, 199, 202]. Similar results were also obtained with the four-membered ring homologues of *(74)* [203–205].

The monocyclic triene form is present in such small concentrations in the diaza series that it cannot be detected directly. However, a valence-tautomeric equilibrium has been found between the diazanorcaradienes *(75a)* and *(75b)* and the diazacycloheptatriene *(76)*. As would be expected, *(74)* with R = CH_3 forms two *cis-trans* isomers *(75a)* and *(75b)*; in solution, the



(75a) *(76)* *(75b)*

equilibrium mixture contains equal amounts of the two compounds. This equilibration ($E_{A\ (75a)\rightarrow(75b)}$ = 22.0±2.5; $E_{A\ (75b)\rightarrow(75a)}$ = 24.5±2.5 kcal/mole [202]) is most easily formulated as proceeding *via* the triene *(76)*.

Delocalization of the 1,6 bond definitely does not take place in the diazanorcaradienes. This conclusion is based mainly on the NMR spectra: the three-membered ring protons of *(74)*, R = H, give an AB_2X spectrum (τ_A = 7.91, τ_B = 7.38, τ_X = 9.77; J_{AB} = 9.0, J_{BX} = 4.8, J_{AX} = 3.5 Hz). The great difference in the positions of the signals for the two geminal cyclopropane protons indicates that the three-membered ring is twisted well out of the plane of the six-membered ring. It can be deduced from the coupling constants that the proton corresponding to the high τ value lies above the dihydropyridazine ring.

The UV spectra of the diphenyldiazanorcaradienes differ markedly from those of suitable model substances, such as 3,7-diphenyl-1,2-diazacyclohepta-2,7-diene, and can be used for the identification of these systems.

As long as only 2,5-diphenyl-substituted 3,4-diazanorcaradienes are known, it will remain uncertain whether the stability of the bicyclic tautomers is really due to the nitrogen atoms, since it could also result from the conjugative effect of the phenyl groups. The same is true of diazanorcaradienes substituted in positions 2 and 5 by other groups containing double bonds (*e.g.* ester groups [201]).

(77) *(72)* *(78)*

Attempts were therefore made to prepare the unsubstituted parent compound *(72)*. Condensation of cyclopropane-*cis*-1,2-dicarbaldehyde *(77)* [206] with hydrazine leads not to *(72)*, but to a mixture of three isomeric substances, the composition and molecular weight of which indicate that they must be trimers of diazanorcaradiene. These can be separated chromatographically; each component, when treated with acid, yields the original mixture. The trimers of *(72)* presumably have the constitution *(78)* [206]. However, this structure indicates that in the diazanorcaradiene *(72)* postulated as the intermediate, the bicyclic valence tautomer is again more stable than the monocyclic form.

To avoid trimerization, attempts were made to synthesize 2,5-dimethyldiazanorcaradiene by preparation of *cis*-1,2-diacetylcyclopropane and *cis*-1,2-dimethyl-1,2-diacetylcyclopropane *(79)* and reaction of these with hydrazine [207]. *(79)* gave a compound having the correct empirical formula, but with double the expected molecular weight. The spectra of this compound show that a methyl group has reacted in the dimerization. The IR spectrum contains no NH band; therefore the methyl group has not added across the C=N double bond of a second molecule of *(81)* to give *(82)*. On the contrary, all the available evidence indicates that the dimer has the structure *(83)*. The same compound is formed in the reaction of pyridazinone *(80)* with methyl-lithium.

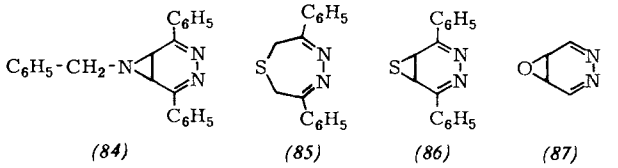
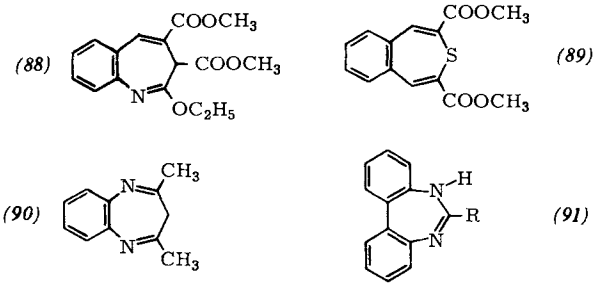
[207] *G. Maier* and *T. Sayrac*, unpublished.

Since one half of the molecule *(83)* contains the diazanorcaradiene ring system, it may be concluded that the stabilization of the bicyclic form is due to the nitrogen atoms, and that conjugation with the phenyl groups is of little importance.



The conjugation with the phenyl groups is the dominant factor when they are in the positions 1 and 6. In such systems the valence-tautomeric equilibrium is strongly in favor of the monocyclic form [207a].

(79) *(80)* *(81)* *(82)* *(83)*



d) Other Systems

The above conclusion remains valid even when an additional hetero atom is incorporated in position 7 of the diazanorcaradiene ring system. Like the compound *(74)*, the 3,4,7-triaza derivative *(84)* is also a relatively stable substance, which can again be detected only in the bicyclic form [208]. Though the *S*-analogue *(86)* has not yet been obtained, the easy elimination of the sulfur atom with formation of 3,6-diphenylpyridazine on bromination of *(85)* suggests intermediate formation of *(86)* [209]. A derivative of pyridazine oxide *(87)* has also been described in the literature [210]; however, doubt has recently been cast on the suggested structure [211].

(84) *(85)* *(86)* *(87)*

Mono- and dibenzo derivatives of azepine, thiepin, and the diazepines are known; examples are the compounds *(88)* [213], *(89)* [214], and *(90)* [212, 215–217] and compounds of the type *(91)* [218–219]. Since at least one of the double bonds in these compounds also belongs to an aromatic ring, valence tautomerization to form norcaradiene derivatives is hindered. However, the ease of elimination of the sulfur atom in *(89)* [220] does suggest a valence-tautomeric equilibrium.

(88) *(89)* *(90)* *(91)*

1,2-Diazepines appear to be stabilized even without condensation with a benzene ring, and exist in the monocyclic form [201]. It is interesting that these compounds, when their structures are such that tautomerization is possible (*e.g.* migration of the hydrogen from the carbon to the nitrogen), prefer the 3*H* form and not the 1*H* form; this is further evidence that the resulting 8 π-electron system is not appreciably stabilized. Quantum-mechanical calculations [221], according to which the 1*H*-azepine is less stable than the isomeric azatropilidenes with the nitrogen in the double bond, support this experimental evidence. The calculations also show that electron-attracting substituents on the nitrogen can stabilize 1*H*-azepines.

As in the carbocyclic norcaradienes (see Section IIIa), systems with hetero atoms should permit stabilization of the bicyclic tautomers by fixation of the double bond. This is so *e.g.* in the compound *(92)* [222], which in analogy to *(7)* can be transformed thermally to a benzodiazepine [222a]. The action of light on *N*-oxides of heterocyclic compounds should give compounds in which the norcaradiene system includes an oxaziridine ring. One of many compounds of this type [223, 224-226] is the product *(93)*, reportedly formed by the action of light on 2-phenylquinoline *N*-oxide. However, this compound is probably only an intermediate in the photolysis. The product isolated was benzoxazepine *(95)* [227], the formation

[227] *O. Buchardt*, Tetrahedron Letters *1966*, 6221.

of which can be explained by the isomerization of *(93)* into the norcaradiene derivative *(94)*, which immediately forms *(95)*.

The photolytically induced ring contraction of pyridine *N*-oxide to form pyrrole-2-carbaldehyde is also formulated as proceeding *via* primary formation of an oxazanorcaradiene derivative followed by valence tautomerization [228].

Stabilization by a condensed benzene ring does not occur with the azatropilidenes that are formed during the thermal or photolytic decomposition of aromatic azides in the presence of amines. Thus when phenyl azide is heated in aniline, "dibenzamil" is formed [229]; this was recognized as an azepine derivative [230, 231] having the structure *(96)* [186, 232]. The photolysis of phenyl azide in aniline yields the same substance, while the compound *(97)* is formed in diethylamine [233]. Trimethyl derivatives of this ring system can be obtained by ring expansion of 2,4,6-trimethylphenol [234]. In this case it is again found that the 3*H*-azepine system shows no tendency to change into the tautomeric 1*H*-azepine system. (1*H*-azepine structures are ruled out by the fact that the IR spectrum of compounds such as *(97)* does not contain an

NH band). A choice can be made between the six other possible structures on the basis of the NMR spectra. There is no evidence of a valence-tautomeric equilibrium, probably because the amidine resonance is lost on transition from *(96)* to *(98)*, $R^1 = H$, $R^2 = C_6H_5$. A 7-azanorcaradiene may occur as an intermediate in the formation of the compounds *(96)* and *(97)*. It is assumed [232, 235, 236] that the phenyl azide is converted *via* phenylnitrene into the dehydroazanorcaradiene *(99)*, which adds the base to give a 7-azanorcaradiene derivative *(100)*. *(100)* should then undergo valence tautomerization to form the 1*H*-azepine *(101)*, from which the final product is formed by hydrogen shift.

We are grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their generous support of our own work mentioned in this article.

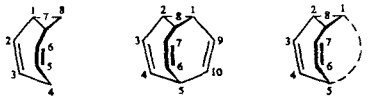
Recent Chemistry of Bullvalene[1]

BY G. SCHRÖDER AND J. F. M. OTH [*]

Dedicated to Professor R. Criegee on the occasion of his 65th birthday



The essential structural element of bullvalene is the homotropilidene system. Thus in any discussion of the chemistry of bullvalene, all bridged homotropilidenes must also be considered. The present article deals with new syntheses and with the thermal behavior of the homotropilidene system and of bullvalene. Emphasis is also placed on the syntheses and the NMR-spectroscopic behavior of complexed bullvalene, of monosubstituted, disubstituted, and fused bullvalenes, and of some benzobullvalene derivatives.

I. Introduction

The fundamental work of *Doering* and *Roth*[2] in the discovery of a fast and reversible valence isomerization (or a "degenerate Cope rearrangement") in bicyclo-[5.1.0]octa-2,5-diene *(1)*, which is also known as homotropilidene, together with the discussion of the fascinating properties of bullvalene *(2)*, is one of the milestones of organic chemistry and forms the basis of the present review.

Two years ago we published[3] our first review on molecules exhibiting fast and reversible valence isomerization, which are also described as molecules with fluctuating bonds. The present article is confined to only a part, though a very important part, of this class of compounds.

The essential structural element of bullvalene *(2)* is the homotropilidene system *(1)*. Consequently, all bridged homotropilidenes *(3)* are considered in the discussion of bullvalene.

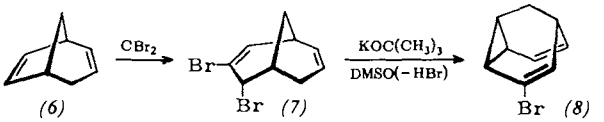
II. New Syntheses of the Homotropilidene System and of the Bullvalene Skeleton

a) Tricyclo[3.3.0.0^{2,8}]octa-3,6-diene ("Semibullvalene") [4]



The photolysis of a 1 to 2 % solution of barrelene *(4)* in isopentane, in the presence of 3 to 8 % of acetone as a sensitizer, leads to the formation of "semibullvalene" *(5)* and traces of cyclooctatetraene.

(4) *(5)*, 25-46% 1-2%

b) 3-Bromotricyclo[3.3.1.0^{2,8}]nona-3,6-diene [5]

The addition of dibromocarbene to bicyclo[3.2.1]octa-2,6-diene *(6)* under the conditions for the preparation of dibromocarbene (basic medium) yields the dibromide *(7)*, which loses HBr in the presence of a strong base to form *(8)*.

(6) *(7)* *(8)*

c) Tricyclo[3.3.1.0^{2,8}]nona-3,6-diene [6,7]

The Wolff-Kishner reduction of the tricyclic ketone *(9)*[6] or the base-catalysed decomposition of the tosylhydrazone *(11)*[7] leads *inter alia* to tricyclo-

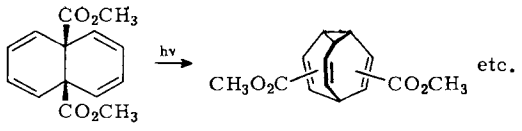
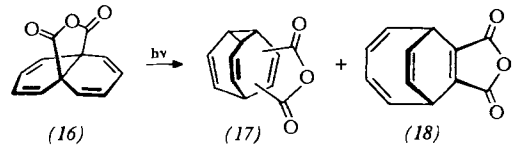
[3.3.1.$0^{2,8}$]nona-3,6-diene *(10)*. Following the mechanism of the Bamford-Steven reaction[8], *(11)* should give the cation *(11a)*, which is stabilized by loss of a proton to form *(10)*[7].

d) New Syntheses of Bullvalene

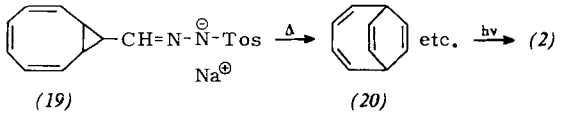


The two syntheses of bullvalene which were developed several years ago[9,10] may now be supplemented by the following additional syntheses:

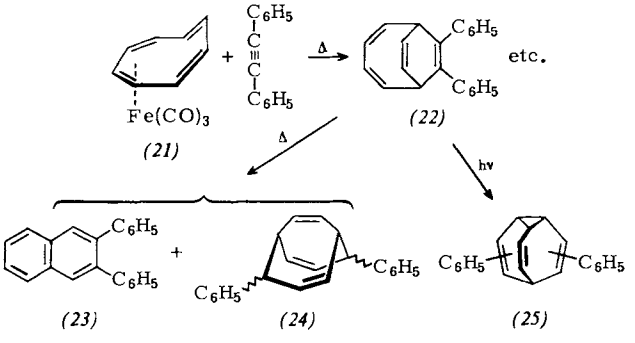


1. When 9,10-dihydronaphthalene *(12)* in deaerated pentane is irradiated by a low-pressure UV lamp at 0 °C, a mixture of four compounds is formed. One of these compounds is bullvalene[11].

As a result of theoretical considerations by *Hoffmann* and *Woodward*[12], the synchronous photochemical conversion of *(12)* into tetracyclo[4.4.0.$0^{2,10}0^{5,7}$]deca-3,8-diene *(13)* has now become understandable; *(13)* plays a part in speculations on the mechanism of this new synthesis of bullvalene [11,14b].



2. Almost simultaneously with the work of *Doering* and *Rosenthal*[11], *Vogel et al.*[13] reported work which was mechanistically closely related to the former, and which led to the synthesis of disubstituted bullvalenes. On irradiation of dimethyl *cis*-9,10-dihydronaphthalene-9,10-dicarboxylate *(14)* in methanol by a low-pressure mercury lamp, one of the products is a photoisomer, which must have the structure of a dimethyl bullvalenedicarboxylate *(15)*. The anhydride



(16) corresponding to *(14)* is converted by UV irradiation in ether solution into two photoisomeric anhydrides for which the structures *(17)* and *(18)* are proposed.

3. Bicyclo[4.2.2]deca-2,4,7,9-tetraene *(20)*, which is formed together with $C_{10}H_{10}$ isomers on thermal decomposition of the sodium tosylhydrazone *(19)*, is converted surprisingly smoothly into bullvalene on UV irradiation[14a].

4. Tricarbonylcyclooctatetraeneiron *(21)* reacts with alkynes at high temperatures (boiling mesitylene) to form derivatives of bicyclo[4.2.2]deca-2,4,7,9-tetraene[15]. Thus the products obtained with tolan include a hydrocarbon $C_{22}H_{18}$ (35 %) whose NMR spectrum is compatible with the structure *(22)*. *(22)* decomposes at about 180 °C to give mainly 2,3-diphenylnaphthalene *(23)* and diphenylbicyclo[3.3.2]deca-2,6,9-triene *(24)*. The evidence for the structure *(24)* is based essentially on the NMR spectrum of this compound. UV irradiation of *(22)* yields unchanged starting material, together with a viscous oil having the composition $C_{22}H_{18}$ and which gives temperature-dependent NMR spectra. The oil evidently contains diphenylbullvalene *(25)*.

Replacement of an isolated double bond in *(20)* by a cyclobutene ring leads to a hydrocarbon $C_{12}H_{12}$ *(27)*[16], which might, by analogy with the behavior of *(20)*, be expected to undergo isomerization to *(26)*[17] under the action of UV light.

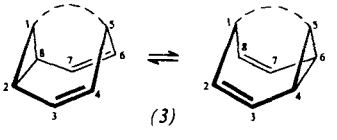
However, the result actually observed is ring contraction with formation of roughly equal quantities of the two isomers *(28a)* and *(28b)* [18]. This result is underlined by the fact that UV irradiation of bicyclo[4.2.1]nona-2,4,7-triene *(29)* leads *inter alia* to the *exo*- and *endo*-tricyclononadienes *(30a)* and *(30b)* [19].

Of the five known syntheses of the bullvalene skeleton, by far the highest yields are obtained by that based on the formation of a homotropilidene system on thermal dimerization of cyclooctatetraene [9]. This is the only synthesis that permits a relatively fast and simple preparation of bullvalene on the 100 g scale (assuming that cyclooctatetraene is readily obtainable in large quantities).



It is of interest in this connection to consider the mechanism of the dimerization of cyclooctatetraene. Earlier attempts [9b, 20] to explain this reaction were based on an incorrect structure for the dimer *(32)* and are consequently no longer tenable. In our new hypothesis, we assume that the first step is analogous to that of a 1,2/1,2 cycloaddition [21] and leads to the biradical *(31)*. Further reaction of *(31)* leads to branching. The activation required for the formation of the dimer *(32)*, which is a symmetrical tricyclic compound with an all-*cis* configuration of the cyclobutane ring [16], is relatively low; *(32)* is formed in preference to all other dimers [18]. *(31)* either decomposes reversibly into two molecules of cyclooctatetraene or undergoes irreversible rearrangement into *(35)*, presumably *via* the intermediates *(31a)*, *(33)*, and *(34)*. This interpretation agrees with the experimental observation that when pure *(32)* is heated to about 100 °C it forms (a) cyclooctatetraene, which under suitable reaction conditions (slightly reduced pressure) is removed from the reaction vessel immediately on formation, and (b) the dimer *(35)* [22]. This shows that *(32)* is at least one of the precursors of *(35)*.

III. Reversible and Irreversible Thermal Rearrangements of Molecules Containing the Homotropilidene System

The reversible thermal rearrangements of molecules containing the homotropilidene system have relatively low activation energies E_a (see Table 1) and have been described by the concept of fluctuating

Table 1. Kinetic parameters of the valence isomerization in bridged homotropilidenes *(3)*. (The values of $\log_{10}A$ and E_a were calculated by the method of least squares (Arrhenius equation). The errors correspond to the mean square deviations; the systematic errors were not taken into account. A = frequency factor.)

bonds [3]. The fast and reversible valence isomerizations in *(3)* (the broken line represents a bridge between C-1 and C-5) are generally fairly easily recognized from the temperature-dependence of the NMR spectra. The activation energies E_a for the bond shifts decrease with decreasing distance between C-1 and C-5 in *(3)*.

At higher temperatures (between 100 and 400 °C, depending on the molecular structure), the reversible reactions in *(3)* are replaced by irreversible reactions. In the examples a) to e) discussed here these irreversible reactions lead to definite secondary products.

a) Homotropilidene *(1)* undergoes an irreversible vinylcyclopropane → cyclopentene rearrangement [28] at about 305 °C to give bicyclo[3.3.0]octa-2,6-diene *(36)* [2].

b) In dihydrobullvalene *(37)*, on the other hand, the 1,5-homodienyl hydrogen shift predominates; the product is *(38)* [29].

c) Pyrolysis of *(39)*, a homotropilidene system bridged by a cyclobutene ring, leads smoothly to the isomer *(41)*, the formation of which is explained as follows: Valence isomerization in *(39)* (as indicated by the arrows) yields a vinylogue *(40)* of bullvalene, which subsequently undergoes a vinylcyclopropane rearrangement to form *(41)* [29].

d) The dimeric cyclooctatetraene *(35)* reacts readily with dienophiles [17]. In our opinion, this behavior is compatible only with an *anti* configuration on the cyclobutane ring. Thus consideration of models shows that if the configuration were *syn*, steric interactions in the resulting Diels-Alder adducts should lead to unusually high strain, which would greatly impede the formation of these products. At about 100 to 110 °C, *(35)* rearranges (yield $\geqslant$ 80 %) to form the known [30] dimeric cyclooctatetraene *(43)* [31]. A simple valence isomerization in *(35)* leads first to *(34)*, which, in principle, exists in equilibrium with *(35)* and *(42)*. However, the steric requirements for an intramolecular Diels-Alder reaction to form *(43)* are satisfied only in *(42)*.

e) Bullvalene *(2)*, which in the dissolved state can be described by 1.2×10^6 structurally equivalent valence isomers, and whose ten carbon atoms are continuously exchanging places and neighbors at room temperature [2], undergoes a thermally irreversible rearrangement at about 350 °C to form 9,10-dihydronaphthalene *(9)* [11]. Two mechanisms are at present under discussio for this reaction [11].

IV. New Bullvalene Derivatives

a) Bullvalene-Ag^+ Complexes

Bullvalene *(2)* forms complexes of various compositions with $AgNO_3$ and $AgBF_4$ [25]. The results of X-ray structural analysis of a complex $(C_{10}H_{10})_3AgBF_4$ *(44)* are shown in Figure 1 [32].

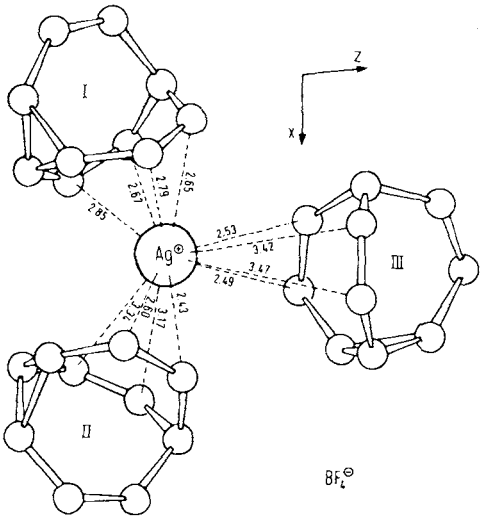

Fig. 1. Structure of an $Ag^+(C_{10}H_{10})_3$ unit. (Examined parallel to the *b* axis; the Ag^+—C(sp^2) distances are given in Å units).

The degree of complexing of the silver ion with the olefinic double bond varies. With each of the molecules II and III in *(44)*, we find a stronger (distance

[32] *M. G. Newton* u. *I. C. Paul*, J. Amer. chem. Soc. *88*, 3161 (1966).

2.51 Å) and a weaker (distance 3.35 Å) interaction between the silver ion and the double bonds; roughly equally strong complexing of two double bonds is found only in I. The structure *(44)* has the highest $Ag^{\oplus}$-olefin coordination number so far observed by X-ray crystallography. In the crystalline complex *(44)* [33], the fast and reversible valence isomerization in the bullvalene molecule appears to be frozen (diagram recorded at 4 °C).

In solution and in the presence of silver ions, bullvalene (0.32 g of bullvalene in 1 ml of 7.15 M $AgNO_3$ in D_2O) shows an apparent activation energy $E_a = 15.1 \pm 0.8$ kcal/mole for the valence isomerization in the homotropilidene system [25]. The value for uncomplexed bullvalene is about 2.3 kcal/mole lower [3, 23–25]. There are two explanations for this difference:

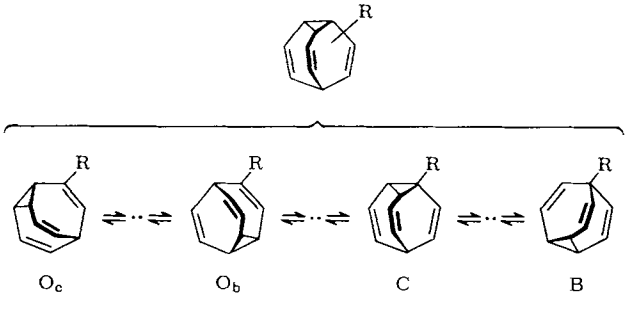
(i) The valence isomerization takes place only in uncomplexed bullvalene, which is formed by dissociation of the silver complex; the dissociation constant should be expected to increase with rising temperature.

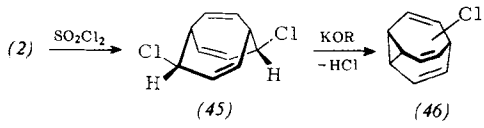
(ii) The valence isomerization takes place in the silver complex, but at a lower rate and with a higher activation energy than in free bullvalene.

It is possible that both of these mechanisms are involved [25].

b) Monosubstituted Bullvalenes

In principle, any substituted bullvalene represents a system of 1.2×10^6 valence isomers, but in contrast to the parent compound, these isomers are not all structurally equivalent. Thus for a monosubstituted bullvalene there are four possible positional isomers, which can be interconverted at room temperature. The equilibrium between these four positional isomers (cf. Fig. 2), which is dynamic at high temperatures, is frozen at very low temperatures [3, 34]. It was of interest to us





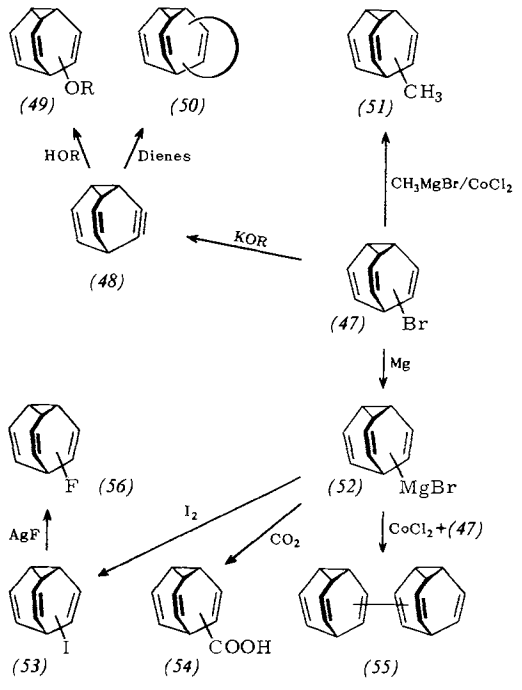


Fig. 2. The four positional isomers of monosubstituted bullvalenes [35].

to learn how the kinetic parameters of the valence isomerization, and hence also the equilibrium composition [34], could be influenced by variation of the substituent R.

The synthesis of chlorobullvalene *(46)* [36] proceeds by stereoselective chlorination of *(2)*. In the presence of KOR, HCl is eliminated from the bicyclic *trans*-dichloride *(45)* with reformation of the homotropilidene system; the product is *(46)*.

At present, bromination of bullvalene is still the best route to monosubstituted bullvalene derivatives. Bromobullvalene *(47)* can be obtained in good yields from the resulting dibromide by treatment with bases [34] and is the key substance for the preparation of other monosubstituted bullvalenes (see Scheme 1).

Scheme 1. Substituted bullvalenes prepared from bromobullvalene.

(47) reacts smoothly with potassium alkoxides to form alkoxybullvalenes *(49)* (60–90%) [34], the reaction proceeding *via* a didehydrobullvalene *(48)* [36], since Diels-Alder adducts *(50)* (17–80%) are formed in the presence of reactive dienes [36]. Methylbullvalene *(51)* can be obtained in moderate yields (32%) by treatment of *(47)* with CH_3MgBr in the presence of $CoCl_2$ [36]. Reaction with Mg turnings leads to the versatile Grignard compound *(52)*, which reacts (i) with *(47)* in the presence of $CoCl_2$ to form bibullvalenyl *(55)* (17%), (ii) with CO_2 to form bullvalene carboxylic acid *(54)* (40%), and (iii) with iodine to form iodobullvalene *(53)* (38%) [36]. *(53)* is in turn the starting material for the preparation of fluorobullvalene *(56)* (52%, in pyridine) [36]. *(56)* is remarkable in that the valence isomers in this case can be studied on the basis of two temperature-dependent NMR signals (H and F).

All substituted bullvalenes give temperature-dependent NMR spectra. The spectra recorded at high temperatures reflect the dynamic situation (*i.e.* the fast

[33] For the thermal behavior of crystalline bullvalene, see *J. D. Graham* and *E. R. Santee jr.*, J. Amer. chem. Soc. *88*, 3453 (1966).

[35] The meanings of the abbreviations are: C, substituent on the cyclopropane ring; O_c and O_b, substituent on the olefinic double bond nearer to the cyclopropane ring and nearer to the bridgehead respectively; B, substituent on the bridgehead; see also [34].

[36] *H. Röttele*, Dissertation, Technische Hochschule Karlsruhe, 1967.

and reversible valence isomerizations), while those recorded at low temperatures correspond to the static situation (*i.e.* the frozen equilibrium mixtures)[3]. Two examples are described below.

a) In bibullvalenyl *(55)*, $C_{20}H_{18}$, there are not four (the number for monosubstituted bullvalenes), but ten positional isomers to be considered (the second bullvalenyl residue, like the first, has four different positions). The temperature-dependent NMR spectra of *(55)* are shown in Fig. 3. At higher temperatures only one resonance signal is found for the eighteen protons,

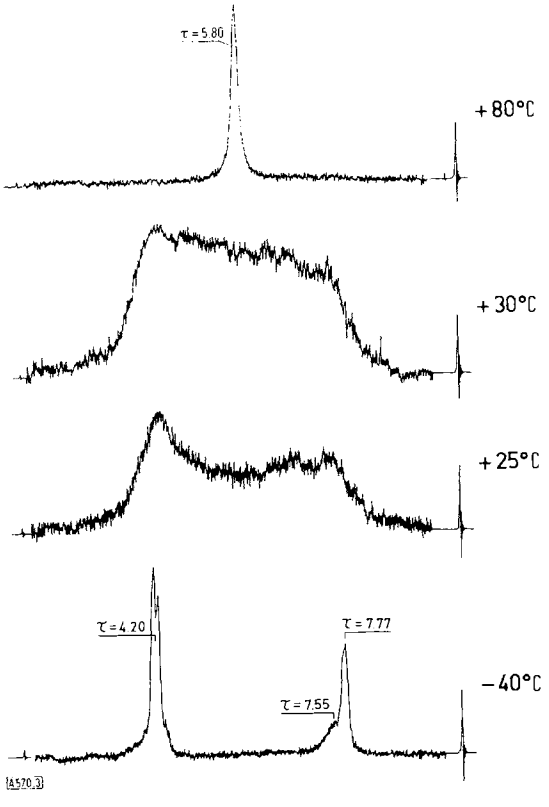

Fig. 3. ^{1}H—NMR spectra of bibullvalenyl *(55)* in CS_2. (Internal standard: tetramethylsilane, $\tau = 10$.)

i.e. the eighteen protons are all NMR-spectroscopically equivalent. In the bibullvalenyl molecule, the valence isomerizations in the two linked bullvalenyl residues proceed more or less independently of one another. The low-temperature spectrum (−40 °C) indicates a ratio of ten olefinic to eight aliphatic bullvalenyl protons, *i.e.* the equilibrium mixture (as was to be expected from earlier investigations on monosubstituted bullvalenes[3,34]) consists mainly of the isomers O_b–O_b, O_b–O_c, O_c–O_c in which the two halves of the molecule are joined *via* two olefinic C atoms.

In all the monosubstituted bullvalenes studied so far (see Table 2), with the exception of fluorobullvalene *(56)*, the substituent preferentially occupies an olefinic position (O_c and/or O_b). The low-temperature spectrum of *(56)* (Fig. 4) shows that an isomer with the substituent in an aliphatic position (B or C; see Fig. 2) predominates in the equilibrium mixture, since the ratio of olefinic to aliphatic bullvalenyl protons is 6:3.

The olefinic proton signal appears as a doublet at $\tau = 4.11$ in the low-temperature spectrum. At 20 MHz, this low-temperature resonance signal has the same habit, with no change in the splitting. Thus the doublet

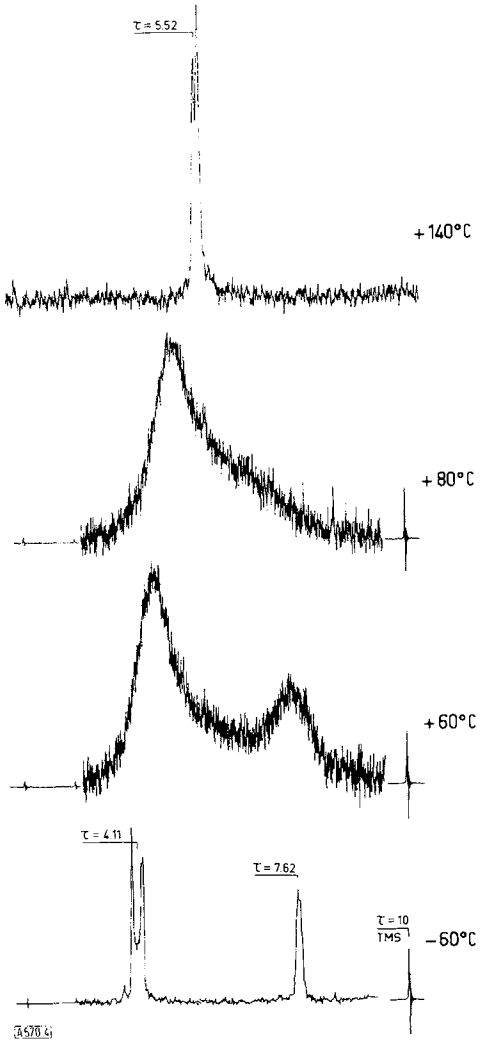

Fig. 4. ^{1}H—NMR spectra of fluorobullvalene *(56)* in $CDCl_3$. (Internal standard: tetramethylsilane, $\tau = 10$.)

is due to spin-spin coupling between the olefinic protons and the fluorine nucleus in the B position (see Fig. 2). The chemical shifts of the O_b and O_c protons and the coupling constants between these protons and the fluorine nucleus ($J_{FHO_b} \approx J_{FHO_c} \approx$ 14 Hz) are almost identical. The simple symmetrical signal of the aliphatic protons can again be explained only if the fluorine is in the B position. The high-temperature spectrum (+140 °C) consists of a doublet centered at $\tau = 5.52$. All the protons are now NMR-spectroscopically equivalent and coupled with the fluorine nucleus (mean value of the coupling constants $J_{HF} \approx 6$ Hz).

Figure 5 shows the ^{19}F—NMR spectra of *(56)* at −53 and 40 °C. At −53 °C, the spectrum contains a pseudoheptet centered at $\delta = -12.26$ (internal standard: C_6F_6). The multiplet loses its fine structure when the temperature is raised, and the spectrum also shows line broadening and a downfield shift.

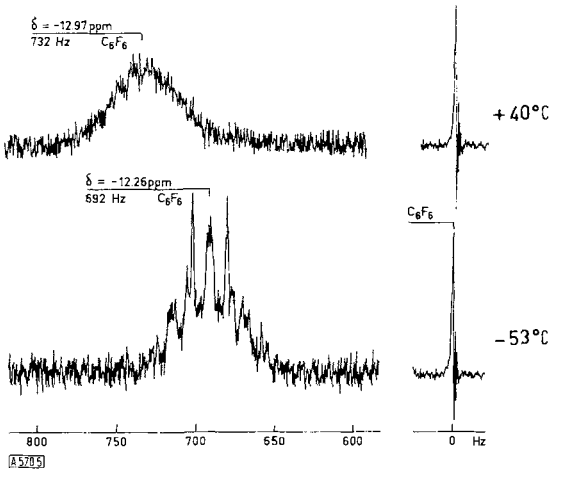

Fig. 5. ^{19}F—NMR spectra of fluorobullvalene *(56)* in $CDCl_3$. (At 56.4 Mc/s; internal standard: C_6F_6).

It is intended [37] to carry out a quantitative calculation of the ^1H and ^{19}F nuclear resonance spectra of fluorobullvalene *(56)*, which should contribute toward a deeper understanding of the dynamic equilibria.

Some important NMR-spectroscopic results for substituted bullvalenes are listed in Table 2. The second column shows the chemical shifts (τ scale) of the singlet observed for the bullvalenyl protons, and the third column gives the corresponding half-widths. All substituted bullvalenes exhibit greater half-widths than bullvalene itself. It may therefore be concluded that, on average, the bonds in substituted bullvalenes fluctuate more slowly than in bullvalene itself. It can be seen from the fourth column that, as expected, the O isomers are generally preferred [3, 34], except in fluorobullvalene, in which the B isomer is surprisingly found to have a lower energy than any of the other three.

c) Disubstituted Bullvalenes

Table 2 contains data for three disubstituted bullvalenes. For a disubstituted bullvalene with two identical substituents, there are twelve possible positional isomers (three of which correspond to pairs of antipodes) (cf. Fig. 6) and 27 isomerization processes. The twelve positional isomers can, in principle, be thermally interconverted under relatively mild conditions. This dynamism is peculiar to molecules having the bullvalene skeleton.

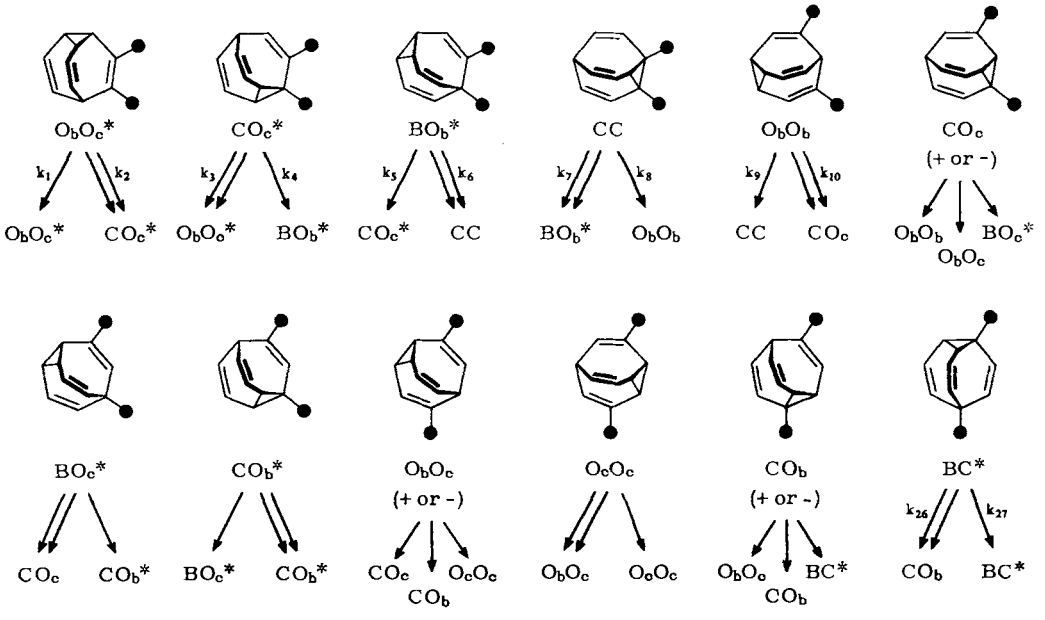

Fig. 6. Positional isomerism of disubstituted bullvalenes [38].

Table 2. ^1H—NMR-spectroscopic data for mono- and disubstituted bullvalenes (cf. Fig. 2 and 6).

Substituent R		τ at 80 °C	Δν [Hz] at 80 °C	Preferred isomer [38]

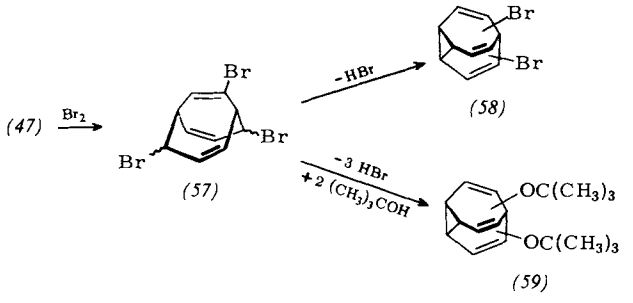
OCH_2CH_3	*(49)*	6.00	55.0	O_b
OCH_3	*(49)*	6.02	72.0	O_b
2 Br	*(58)*	5.69	35	O_bO_c and O_cO_c
2 $OC(CH_3)_3$	*(59)*	6.08	97	O_bO_c and O_cO_c
2 CO_2CH_3	*(15)*	5.25	24	O_bO_b

Dibromo- *(58)* and bis(t-butoxy)bullvalene *(59)* were synthesized and studied by our research group [40], and bis(methoxycarbonyl)bullvalene *(15)* by *Vogel* [13]. The bromination of *(47)* yields a tribromide whose NMR spectrum agrees with the structure *(57)*. Treatment of *(57)* with potassium t-butoxide in t-butanol/benzene leads to elimination of HBr and formation

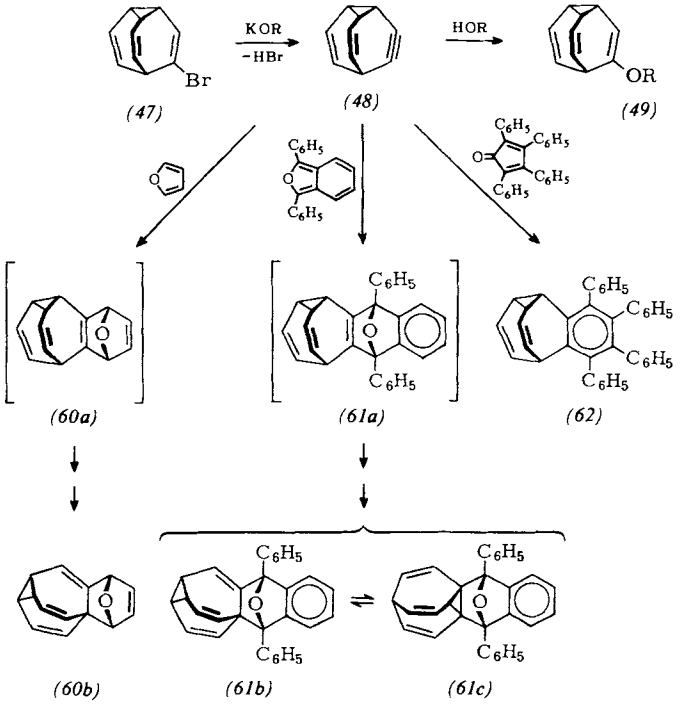
[37] *J. F. M. Oth* and *J.-M. Gilles*.



[38] The meanings of the abbreviations are as follows: C, O_c, O_b, and B as in [35]; the asterisk "*" denotes structures in which both substituents are situated on the same arm of the bullvalene skeleton. (An arm is a chain of bridgehead, olefinic, olefinic and cyclopropane carbon atoms.)

[39] *G. Schröder*, Angew. Chem. *77*, 682 (1965); Angew. Chem. internat. Edit. *4*, 695 (1965).

[40] *J. F. M. Oth, R. Merényi, G. Engel*, and *G. Schröder*, Tetrahedron Letters *1966*, 3377.

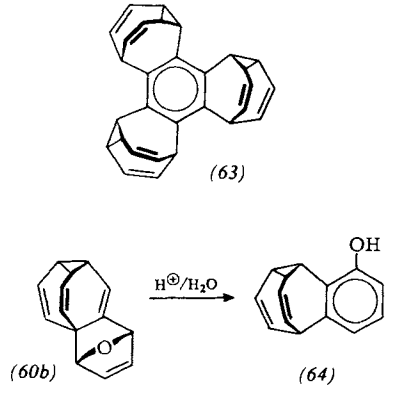


of the dibromide *(58)*, whereas dry potassium t-butoxide in benzene gives *(59)*.

As can be seen from Table 2, each of the three disubstituted bullvalenes gives a singlet (the half-widths being different) for the eight bullvalenyl protons at high temperatures. O,O-Isomers predominate in the equilibrium mixture.

d) Fused Bullvalenes, Benzobullvalenes [36,41]

Bromobullvalene *(47)* and potassium alkoxides react (preferably in dimethyl sulfoxide) to form alkoxybullvalenes *(49)* in good yields [34]. Extensive investigation of the preparation and behavior of 1,2-dehydrobenzene [42] and other cyclic dehydro compounds [43] suggest that these reactions should be formulated as proceeding by an elimination-addition mechanism. The decisive intermediate is 3,4-didehydrobullvalene *(48)* [44]. It is to be expected that *(48)* behaves as a reactive dienophile and reacts in the presence of dienes to form the corresponding adducts (see Scheme 2).



Scheme 2. Reactions of 3,4-didehydrobullvalene.

When the reaction of *(47)* with KOR is carried out in furan, the products include not only *(49)*, but also the furan adduct *(60)* (16 %) and small quantities of trimeric didehydrobullvalene *(63)* [36]. When the reaction of *(47)* with bases is carried out in benzene with the addition of 2,5-diphenyl-3,4-benzofuran, or in dioxane with the addition of tetracyclone, the adducts *(61)* and *(62)* can be isolated in yields of 76 % and 46 % respectively.

The evidence for the structures *(60)* to *(62)* is based particularly on the temperature-dependent NMR spectra. It is clear from these spectra that the adducts of *(48)* and the two furans do not have the structures *(60a)* and *(61a)* expected from a Diels-Alder reaction. This seems surprising at first sight, but can be explained as follows. The rapid bond shifts in the bullvalene skeleton allow the molecules to "collapse" into the structures having the lowest energy, *i.e.* into *(60b)* and into *(61b)* and *(61c)* [41]. The strain (Pitzer and/or Baeyer strain) in *(60b)* and in *(61b)* and *(61c)* is obviously less than in the corresponding isomers *(60a)* and *(61a)*.

In the light of *Wittig*'s work on the behavior of cyclohexyne [45] and 1,2-cyclohexadiene [46], we regard the formation of *(63)* as further evidence of the intermediate formation of *(48)*.

Hydrolysis of the furan adduct *(60b)* leads to smooth rearrangement with formation of 6-hydroxytetracyclo[6.3.3.$0^{2,7}0^{9,14}$]tetradeca-2(7),3,5,10,12-pentaene *(64)*.

α) NMR-Spectroscopic Behavior of Fused Bullvalenes [41]

The valence isomerizations in fused bullvalenes *(60)* and *(61)* are treated like those in disubstituted bullvalenes (cf. Fig. 6). Owing to ring strain, however, all

[41] *G. Schröder, H. Röttele, J. F. M. Oth*, and *R. Merényi*, Chem. Ber., in press; *J. F. M. Oth, R. Merényi, H. Röttele*, and *G. Schröder, ibid.*, in press.

[42] See, *e.g.*, *G. Wittig*, Angew. Chem. *77*, 752 (1965); Angew. Chem. internat. Edit. *4*, 731 (1965).

[43] For the detection of a dehydrocycloheptatriene derivative, see *W. Tochtermann, K. Oppenländer*, and *U. Walter*, Chem. Ber. *97*, 1318 (1964).

[44] The systematic name for bullvalene *(2)* is tricyclo[3.3.2.$0^{2,8}$]-deca-3,6,9-triene, corresponding to the numbering given on p. 414, and not tricyclo[3.3.2.$0^{4,6}$]deca-2,7,9-triene [2, 3]. We are grateful to Dr. *R. Cruse*, Freiburg, for pointing this out.

[45] *G. Wittig* and *U. Mayer*, Chem. Ber. *96*, 342 (1963).

[46] *G. Wittig* and *P. Fritze*, Angew. Chem. *78*, 905 (1966); Angew. Chem. internat. Edit. *5*, 846 (1966).

the isomers in Figure 6 except the first four must be ruled out. The two substituted carbon atoms are always *ortho* to each other, since k_8 (Fig. 6) is practically zero. The relatively complex temperature-dependent NMR spectra of *(60)* can be best explained by the valence isomerizations $BO_b^* \rightleftharpoons CC \rightleftharpoons BO_b^*$ as shown in Fig. 7, provided that the percentage of CC is assumed to be small [41].

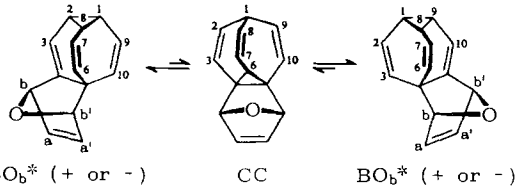


Fig. 7. Valence isomerizations in the 3,4-didehydrobullvalene-furan adduct *(60)*.

The adduct *(61)* in solution is in principle described by the same equilibria; the percentage of the two BO_b^* isomers is now about 54%, and that of the CC isomer is about 46% [41].

Since the valence isomerizations in the fused bullvalenes *(60)* and *(61)* are very limited, the eight bullvalenyl protons no longer give one singlet in the high-temperature NMR spectrum.

To illustrate this, let us consider the temperature-dependent NMR spectra of the furan adduct *(60)*

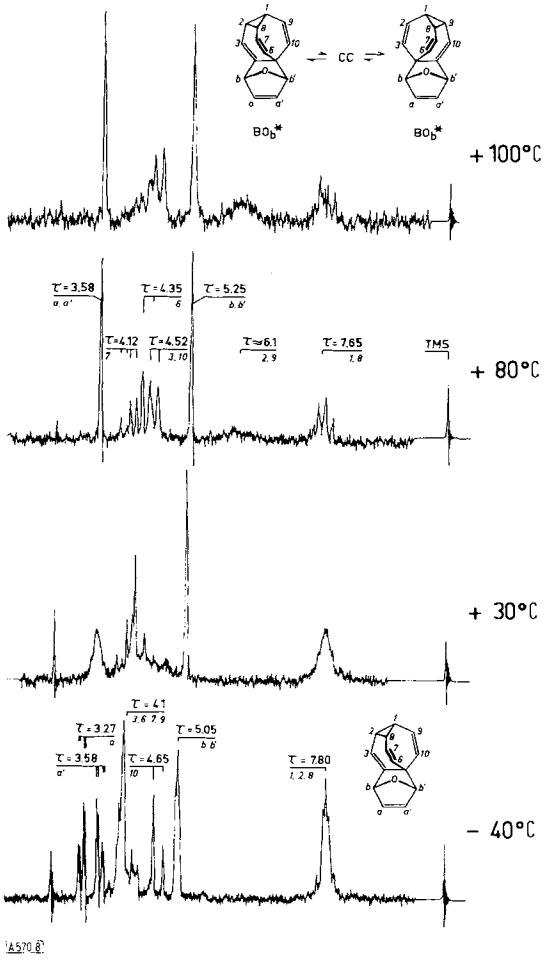

Fig. 8. ^1H—NMR spectra of the 3,4-didehydrobullvalene-furan adduct *(60)*.

(Fig. 8) in more detail. The low-temperature spectrum (−40 °C) shows three aliphatic and five olefinic bullvalenyl protons, the three aliphatic protons giving the signal centered at $\tau = 7.80$ and the five olefinic protons the signals between $\tau = 3.7$ and $\tau = 4.8$. The "non-bullvalenyl" olefinic protons aa′ give an AB quartet at $\tau_a = 3.27$ and $\tau_{a'} = 3.58$ ($J_{aa'} = 5.8$ Hz). Each of these signals is split into a doublet as a result of coupling with the protons b and b′ ($J_{ab} = 1.5$ Hz). The bridgehead protons bb′ appear as a pseudo-triplet at $\tau = 5.05$.

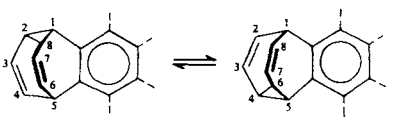
The ratio of three aliphatic to five olefinic protons and the habit of the resonance signals of the protons aa′ and bb′ show unmistakably that only the isomers BO_b^* and CO_c^* must predominate in the equilibrium mixture of *(60)*. However, the CO_c^* isomer can be ruled out, since it is not in agreement either with the changes in the NMR spectrum when the temperature is raised or with the high-temperature spectrum [41]. BO_b^* is the predominant isomer in the adduct *(60)*.

The bullvalenyl proton signals in the low-temperature spectrum of *(60)* are assigned as follows: The doublet centered at $\tau = 4.65$ represents proton no. 10 [47] ($J_{9,10} = 11$ Hz), protons 3, 6, 7, and 9 give the group of signals centered at about $\tau = 4.1$, and the aliphatic bullvalenyl protons 1, 2, and 8 give the signal at $\tau = 7.80$.

The temperature-dependence of the NMR spectra of *(60)* and the habit of the high-temperature spectrum can be best explained by the valence isomerizations $BO_b^* \rightleftharpoons CC \rightleftharpoons BO_b^*$ (see Fig. 7) (the two BO_b^* isomere are related as mirror images), provided that the percentage of CC is assumed to be small. It is then understandable why the resonance signal of the a and a′ protons at low temperatures represents an AB system and why the a and a′ protons are NMR-spectroscopically equivalent at higher temperatures (one resonance signal at $\tau = 3.58$). Similar considerations apply to the resonance signals of the b and b′ protons. The shape of the signals of the a, a′, b, and b′ protons corresponds to the calculated spectrum of an A_2X_2 system with $J_{AX} = J_{ab} = 1.5$ Hz, $J_{AA} = J_{aa'} = 5.8$ Hz, and $J_{AX'} = J_{XX'} = J_{ab'} = J_{bb'} = 0$ Hz. The presence of a band centered at $\tau = 6.1$ and having a relative intensity of 2 in the spectrum at +80 °C and +100 °C can also be explained on the basis of the same valence isomerization. This τ value approximately corresponds to the average of the chemical shifts of protons 2 and 9 ($\tau_{calc.} = 5.95$). It is also clear that protons 3 and 10 give a doublet centered at $\tau = 4.52$ ($J_{2,3} = J_{9,10} = 9$ Hz) and having a relative intensity of 2.

The signals of protons 7 ($\tau = 4.12$), 6 ($\tau = 4.35$) and 1 and 8 ($\tau = 7.65$) should be independent of temperature. The small changes in their chemical shifts can be explained by a temperature-dependent solvent effect. The percentage of the CC isomers in the equilibrium is certainly very small (< 5%), since a distinct shift of the signals due to protons 6 and 8 would otherwise be observed in the high-temperature spectrum. The low concentration of the CC isomer is also confirmed by the absence of two sharp bands for the a and a′ and the b and b′ protons (a and a′ as well as b and b′ are identical in the CC isomer) in the low-temperature spectrum.

Furthermore, the CC isomer can occur in two configurations, with either the oxygen atom or the double bond of the substituted dihydrofuran system situated above the cyclopropane ring of the bullvalene skeleton. The two CC isomers are described as CC_{endo} and CC_{exo}, corresponding to the position of the oxygen atom relative to the cyclopropane ring. Only the CC_{endo} isomer participates in the NMR-observed exchange process; this can be explained by steric effects. Valence iso-



[47] Numbering of the left-hand formula in Fig. 7.

merizations involving the CO_c^* and $O_bO_c^*$ isomers can be ruled out. If these isomers were involved, much stronger mixing of the bullvalenyl proton signals should occur.

β) NMR-Spectroscopic Behavior of Benzobullvalenes

In the benzobullvalenes, one double bond of the bullvalene is blocked by incorporation into a benzene ring. Thus we have a homotropilidene system bridged by a benzene residue. The temperature-dependence of the NMR spectra of the benzobullvalenes can only be explained by a valence isomerization involving two $O_bO_c^*$ isomers.

The spectra of *(62)*, *(63)*, and *(64)* at +70 °C are in fact similar to the high-temperature spectra of other bridged homotropilidene systems [3]. An important signal in this case, which is centered at $\tau = 6.1$ ppm, results from the averaging of the chemical shifts of two cyclopropyl (nos. 2 and 8) and two olefinic protons (nos. 4 and 6) (Fig. 9, left-hand formula).

Additions to the Activated CC Triple Bond

BY E. WINTERFELDT [*]

The possibilities of additions to the activated CC triple bond are discussed with the aid of a number of examples. The additions of donors that contain no active hydrogen are generally initiated via a dipolar primary complex, which can undergo stabilization by rearrangement, cyclization, or addition reactions. Preparative aspects of these reactions are also discussed. They offer routes for the preparation of heterocycles, particularly pyrrole and thiophene derivatives.

I. Introduction

The high reactivity of the CC triple bond toward nucleophilic reagents is of great significance in many preparatively interesting reactions and also in important industrial processes. This reactivity is even greater in conjugated polyynes. A survey of addition reactions of these compounds has already been published [1]. Since reviews have also appeared concerning their 1,3-dipolar additions [2] and on their diene reactions [3], the present article will deal only with nucleophilic additions to CC triple bonds activated by acceptor groups. Triple bonds polarized by functional groups of this type are very reactive, and are attacked, often surprisingly readily, by many nucleophiles. The adducts are obtained directly, when possible, and generally in very high yields. Otherwise the primary complex of the general type *(1)* is stabilized by rearrangement or cyclization, or by further reaction with a second mole of the acetylene derivative. This offers a simple route to a wide range of heterocyclic compounds.

II. Additions of Compounds containing Mobile Hydrogen

1. Addition of Alcohols

The addition of alcohols and phenols can be catalysed both by alkoxides [4] and by tertiary amines [5]; the addition is predominantly *trans* [4,6], and in the case of dimethyl acetylenedicarboxylate it leads to enol

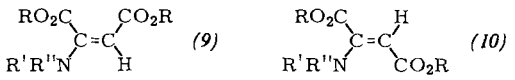
ethers of the type *(2)*. Thermal additions (≈ 180 °C), on the other hand, lead mainly to the *cis* derivative *(3)*. Similar results are obtained in additions to methyl

(2) *(3)* *(4)* *(5)*

propiolate. Dinitriles of the type *(5)* predominate in the products obtained from dicyanoacetylene and the corresponding primary or secondary alcohols even at room temperature [7]. Whereas t-butyl alcohol does not add to acetylenedicarboxylic acid, even under drastic conditions, the addition to dicyanoacetylene proceeds at room temperature in the presence of weak bases, *trans* addition to form the product *(4)* being predominant. The configurations in the diesters *(2)* and *(3)* can be established readily by NMR spectroscopy, since products of the type *(2)* show a distinctly negatively shielded proton at $\tau = 3.9$, while products of the type *(3)* give a signal at $\tau = 4.8-4.9$ [6]. In the nitriles, as measurements on *cis,trans*-isomeric compounds have shown [8], the resonance of the proton in compounds having the configuration *(4)* is shifted by only 0.1–0.2 ppm towards lower fields. Since this difference is in full agreement with the values found for other compounds, an assignment is again possible in this way.

These results suggest that the *trans*-addition product should predominate in the catalytic addition of alcohols; however, the sodium methoxide-catalysed addition of methanol to the diester *(6)* shows that this rule is not generally valid.



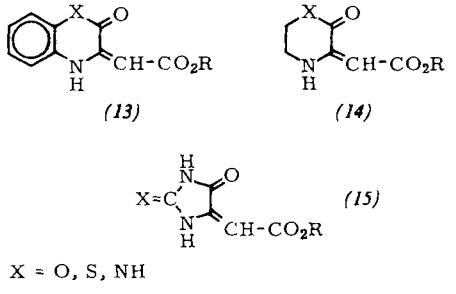
(6) *(7)* *(8)*

In this case the kinetically controlled reaction leads to equal quantities of the *cis,trans*-isomeric enol ethers *(7)* and *(8)* [7]. An unambiguous assignment of the configurations is again possible on the basis of NMR measurements.

2. Addition of Amines

The addition of primary and secondary amines proceeds extremely rapidly and smoothly with formation of enamines of the types *(9)* and *(10)* (R′ = H, R″ = alkyl or aryl, or R′ and R″ = alkyl or aryl).

(9) *(10)*



This *cis* addition plays a dominant role in these reactions [6,9,9a]. Though the proportion of the *cis* configuration is already very high in the case of primary amines, it is even higher for secondary amines. However, it is found that the steric course depends on many factors, including the constitution of the acetylene compound and of the amine, as well as on the manner in which the two reactants are brought together [7]. When the amine is added very slowly to the solution of the acetylene compound, the addition can proceed exclusively in the *cis* direction. This can be demonstrated for the dinitrile *(11)*, owing to the stability of the reaction products. Whereas a mixture of the dinitriles *(11)* and *(12)* is formed when the reactants are brought together rapidly, slow addition with cooling leads exclusively to the *cis*-addition product *(11)*. With the diester, it must be assumed that during slow addition, the very small quantities of *trans* adduct that are observed on direct combination in an NMR tube at low temperatures [9,9a,16] undergo very rapid isomerization.

The configuration can again be determined from the NMR spectrum; however, the IR spectra were also used for the adducts with primary amines, since the configuration *(10)* can be recognized by the presence of a hydrogen bond. The results of the NMR analysis of adducts with secondary amines are confirmed by dipole-moment measurements.

(11) *(12)*

o-Substituted aniline derivatives add readily to form products of the type *(13)* [10].

(13) *(14)* *(15)*

X = O, S, NH

This principle is generally applicable to the synthesis of six-membered heterocyclic compounds *(14)* [11]. Substituted imidazolidones *(15)* are obtained in this way by the use of guanidines as bifunctional components [12]. When the reaction with aniline is carried out in the presence of Cu(I), a mixture of *(16)* and *(17)* is obtained, depending on the conditions [13].

The addition of phenylhydroxylamine to dimethyl acetylenedicarboxylate follows a rather unusual course [14]. It proceeds *via* an intermediate *(18)* which,

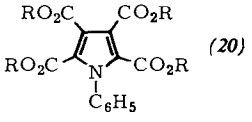
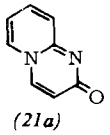
(16)



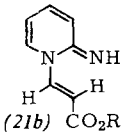
(17)

though unstable, can be isolated in the crystalline form; the stable end product obtained after two days at 35 °C is the 2:1 adduct *(19)*, the structure of which is confirmed by independent synthesis and conversion into the pyrrole derivative *(20)*.

(18) (19)

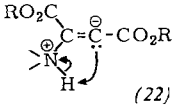


(20)



In the reaction with 2-aminopyridine, the ring nitrogen takes part in the addition, and the two products *(21a)* and *(21b)* [15] are obtained.

In connection with investigations on the mechanism of the addition of amines, *Huisgen* and *Herbig* examined the stabilities of *(9)* and *(10)*. The "maleic acid derivatives" of the type *(9)* are more stable than the "fumaric acid derivatives" of the type *(10)*; the isomerization is catalysed by protons [16]. A thorough investigation of the stabilities of the configurations was also carried out by *Reimlinger*, who demonstrated the *cis* addition of pyrazole to dimethyl acetylenedicarboxylate [17].

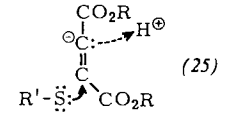


It has been suggested [6] that the direct, uncatalysed addition of amines (and alcohols) may proceed by an intramolecular cyclic proton shift from the primary complex *(22)*, and this was confirmed in a recent kinetic study by *Huisgen et al.* [16a] on the addition of ethylenimine to dimethyl acetylenedicarboxylate.

(21a)

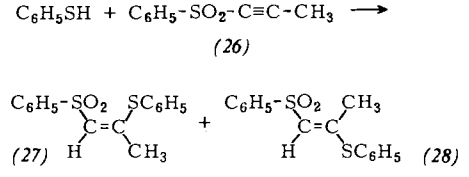
(21b)

(22)



3. Addition of Thiols

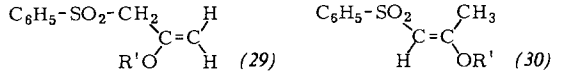
In a series of fundamental investigations, *Truce* [18] established the *trans*-addition mechanism for the catalysed addition of thiols. As in the addition of alcohols and amines, two configurations [*(23)* and *(24)*] are to be expected.



(23) (24)

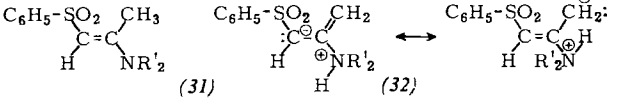
Truce was able to prove that the addition products have the "fumaric acid" configuration *(24)*, and he formulated the reaction as proceeding *via* the complex *(25)*, though it is not certain whether the alkylthioalkenyl ion exists as such for a definite period, or whether the proton capture takes place simultaneously with the addition of the thiolate ion.

(25)



The addition of thiols such as thiophenol to phenyl 1-propynyl sulfone *(26)* has also been studied [19, 19a], and in agreement with *Truce*'s results, *trans* addition to form *(27)* is again observed.

(26) (27) (28)



Products such as *(27)* can also be isomerized into the thermodynamically more stable compounds *(28)*. The reaction of sodium sulfinates R–SO–ONa with *(26)* also leads to the *trans*-addition product.

The additions of phenyl propadienyl sulfone, phenyl 1-propynyl sulfone, and phenyl 2-propynyl sulfone all give the same mixture, *i.e.* the compounds *(29)* and *(30)*.

(29) (30)

(29) is the product of the kinetically controlled reaction, and subsequently isomerizes to form *(30)*. Thus in this case isomerization is faster than addition, and the thermodynamically stable end product is *(30)*. The addition of amine, irrespective of the solvent, also leads almost exclusively to the *cis* adduct *(31)*, which is given by all three isomers as the only reaction product. However, *Truce* recently showed by NMR measurements at −25 °C that, because of the stabilization of the transition state, this reaction also proceeds as a pure *trans* addition, but that very rapid isomerization then ensues to give the thermodynamically stable product with the *trans* arrangement of the donor and acceptor groups [9a]. A considerable solvent-dependence is found, a very low reaction rate being recorded (as expected) in benzene, and a very much higher rate in methanol.

(31) (32)

Labeling with deuterium shows that the proton probably migrates after the addition of the amine [to form the primary betaine *(32)*]. With the primary amine benzylamine, the product is again a mixture of the *cis* and *trans* adducts, in which the *trans* adduct *(33)* predominates because it is stabilized by hydrogen bonding [19a].

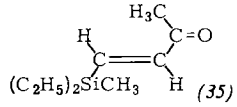
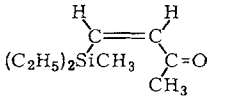
(33)



(34)

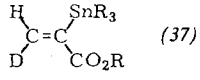
Additions of semicarbazide and phenylhydrazine yield the normal phenylsulfonylacetone derivative *(34)*.



4. Additions of Substances of the Type H-X

Kinetic studies on the addition of hydrobromic [20] and hydriodic [21] acids have also been recently carried out. It was confirmed that the adducts are in the "fumaric acid configuration"; the reaction is interpreted as nucleophilic addition.

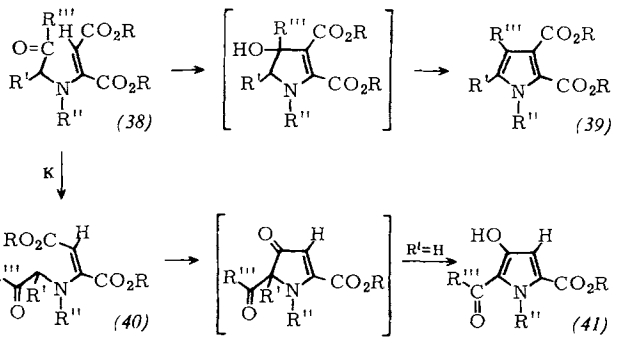
The addition of trialkylsilanes to butynone [22] yields a mixture of the *cis,trans*-isomeric addition products *(35)* and *(36)*.



(35)

(36)

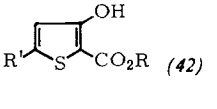
A kinetic study of the addition of deuterium trialkylstannates ($DSn(R)_3$) showed that the reaction with methyl propiolate proceeds by *trans* addition to give the compound *(37)*, and that the addition of the hydride ion is the rate-determining step [23]. Similar results were obtained in a study of the hydroplumbation of the activated CC triple bond [24].



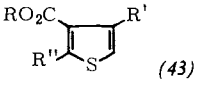
(37)

The addition of phosphines will be discussed in connection with the phosphorus derivatives.

5. Preparative Uses

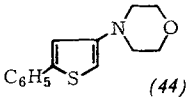


The main preparative application is the preparation of pyrroles and thiophenes by the addition of amines and thiols. Thus *Hendrickson* [25] described a general and smooth synthesis of pyrroles (Scheme 1), which was extended by *Pandit* and *Huisman* to polycyclic compounds [26].

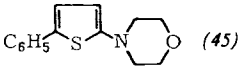


(38) (39) (40) (41)

After isomerization of *(38)* to *(40)*, however, the latter undergoes Dieckmann cyclization to form the hydroxypyrrole *(41)* [27].



Similar reactions can be used for the preparation of thiophenes. *Fiesselmann* and *Schiprak* reported the formation of esters *(42)* of hydroxythiophenecarboxylic acids by addition of methyl thioglycolates to dimethyl acetylenedicarboxylate [28]. This method was then used by other authors for the synthesis of other thiophene derivatives of this type [29]. *Bohlmann* and *Bresinsky* [30] showed that, depending on the conditions, it is possible to obtain either the thiophene derivatives *(42)* or (by direct artack on the carbonyl group of the ketone) the derivatives *(43)*.



(42)

(43)

(44)

(45)

The combined action of morpholine and sulfur on alkynyl ketones also leads to thiophene compounds. Thus 4-phenylbutynone gives a mixture of the two morpholinothiophenes *(44)* and *(45)* [31].

III. Additions of Donors containing No Active Hydrogen

1. Addition of Aromatic Tertiary Amines

Diels and *Alder* showed many years ago that aromatic amines, *e.g.* pyridine, react smoothly with dimethyl acetylenedicarboxylate to form adducts [32].

However, the structure of the products [*(48)* is formed as the stable end product *via* an unstable primary

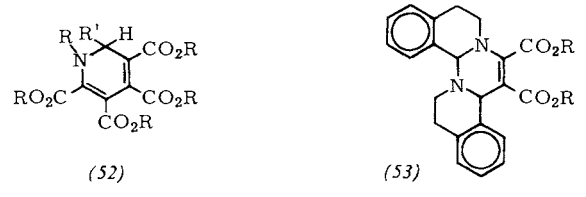
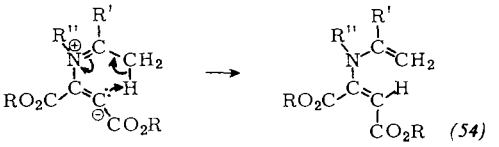
product having the structure *(47)*] was conclusively proved very much later [33]. The mode of formation of a by-product of this reaction ["Kashimoto compound" *(49)*] was also established recently [34].

(46) *(47)* *(48)* *(49)*



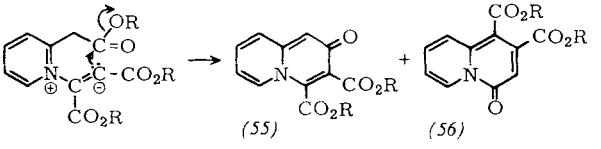
In connection with the mechanism of this reaction, apart from the work of *Jackmann et al.* [35], special mention should be made of the investigation of the interception of the enoxide ion in *(46)* with CO_2 by *Acheson* and *Plunkett* [36]. The products obtained are the *cis,trans*-isomeric betaines *(50)* and *(51)*.

(50) *(51)*



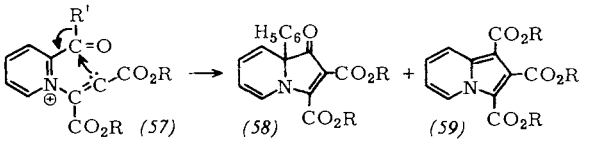
Pyridine and quinoline derivatives have also been used in this reaction [33]. An excellent survey of the spectral data for the resulting compounds has been published by *Acheson* [37].

Huisgen and *Herbig* have also used imines as donors, and have shown that the products *(52)* are formed [38]. The second addition step is classified by these authors as a 1,4-dipolar addition. In the presence of a suitable excess of the imine, the 1,4-dipole can also be intercepted by this component. Thus under these conditions dihydroisoquinoline gives the pentacyclic compound *(53)*.



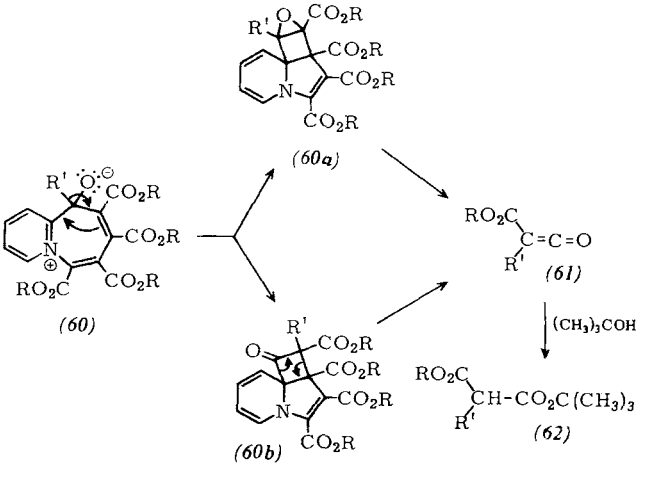
(52) *(53)*

In the reaction with ketimines (Schiff bases), the primary complex is stabilized by prototropy to form enamine derivatives of the type *(54)* if protons are available in the α position.



(54)

Attempts to stabilize the enoxide ion in the primary complex *(46)* by attack on the electrophilic center of a carbonyl group led, in the case of ethyl pyridylacetate, to the 2*H*- or 4*H*-quinolizones *(55)* or *(56)*, the main product in polar solvents being *(55)*, and in nonpolar solvents *(56)* [39].



(55) *(56)*

If the carbonyl group is directly attached to the ring, this reaction, with R′ = C_6H_5, yields the rearrangement product *(58)* *via* *(57)*, but the main product in every case is the indolizinetricarboxylate *(59)* and is completely independent of the residue R′.

(57) *(58)* *(59)*

The formation of these substances is explained by primary addition to give the 2:1 complex *(60)*. The simultaneous formation of the ketene *(61)* can be deduced from the fact that the mono-t-butyl ester *(62)* is obtained when the reaction is carried out in t-butanol.

(60a) *(60)* *(61)* *(60b)* *(62)*

It was not possible to decide whether *(60a)* or *(60b)* occurs as the intermediate, though the route *via* *(60b)* seems more plausible.

The addition products with aromatic heterocycles can be used for the synthesis of cycloazines. Thus *Acheson* showed that the "2nd stable adduct" obtained by *Diels* and *Möller* [40] from dimethyl acetylenedicarboxylate and *trans*-stilbazole results from the

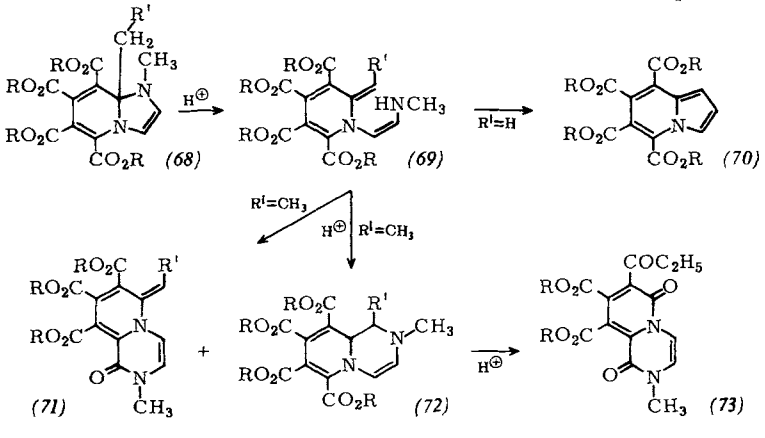
[40] *O. Diels* and *F. Möller*, Liebigs Ann. Chem. *516*, 45 (1935).

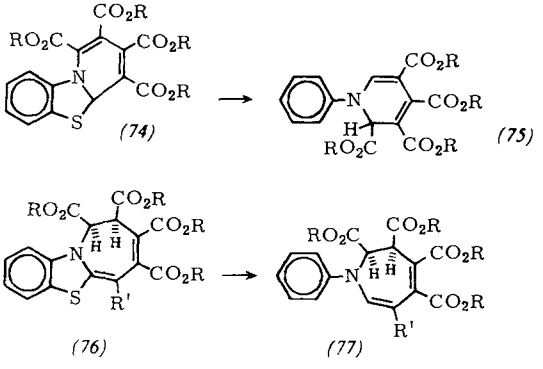
thermal isomerization of the "1st stable adduct" *(63)* and has the constitution *(64)* [41].



(63) *(64)*

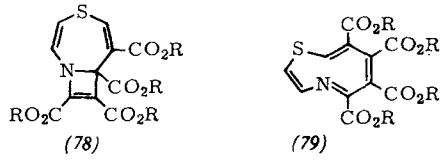
Gibson and *Leaver* converted the quinolizine derivative *(65)* into the tetracyclic product *(66)* (R′ = CO_2CH_3, R = CH_3) by addition of dimethyl acetylenedicarboxylate. This interpretation is supported by the fact that with the phenyl compound *(65)* (R = C_6H_5) and methyl phenylpropiolate, subsequent decarboxylation gave a compound *(67)*, the symmetry of which is apparent from its NMR spectrum [42].

(65) *(66)* *(67)*



The reaction with imidazoles and thiazoles, which had also been considered earlier by *Diels* and *Alder* [45] proceeds fundamentally in accordance with the same reaction scheme [43,44]. This was confirmed by *Crabtree* and *Johnson*, who also described interesting secondary reactions [47]. Thus it is found that the adduct *(68)* with R′ = H is converted *via (69)* into the indolizine *(70)* by the action of acids. A similar primary adduct is obtained when R′ = CH_3; however, it does not lose methylamine on treatment with acids, but recyclizes to form the compounds *(71)* and *(72)*. Both products give *(73)* when heated with concentrated hydrochloric acid.

(68) *(69)* *(70)* *(71)* *(72)* *(73)*



Thiazoles and oxazoles react similarly (for a survey of the spectral data see [46]).

The benzothiazole derivative *(74)* can be desulfurized with Raney nickel to give the dihydropyridine derivative *(75)*. 2-Alkyl derivatives of benzothiazole also add two moles of the ester to form the azepine derivatives *(76)*, which can be desulfurized with Raney nickel to give *(77)*.

(74) *(75)* *(76)* *(77)*

Similar results are also reported by a second research team, but it cannot be established whether the reactions of thiazole and its 2- and 4-methyl derivatives in dimethylformamide yield *(78)* or *(79)* [44].

(78) *(79)*

The simultaneous action of pyridine and CH acids on dimethyl acetylenedicarboxylate has also been studied in detail [47,48]. The first results were again reported by *Diels et al.* [49]; it was later found that the reaction with cyanoacetic ester leads to the blue salt *(81) via* the primary adduct *(80)*.

The primary adduct *(80)* can be protonated at room temperature to give *(82)*, with simultaneous hydration of the nitrile group. *(82)* cyclizes when heated to form *(83)*. The cyclopentadienone obtained by protonation of *(81)* is assigned a dimeric structure. The results obtained with malonodinitrile are completely analo-

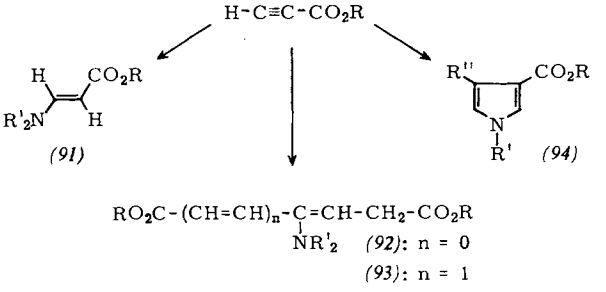
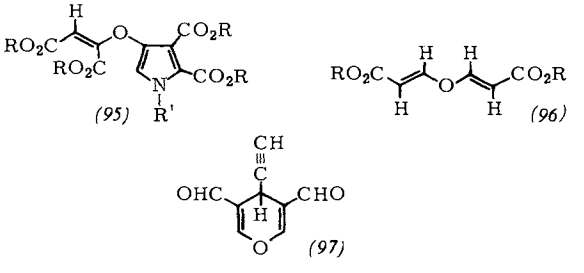
gous. An attempt to apply these reactions to methyl phenylpropiolate results in cleavage of the pyridine ring *via (84)*, with formation of *(85)*.

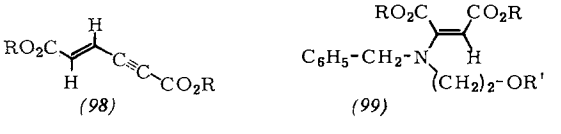
The reaction with diesters of malonic acid in the presence of pyridine leads to entirely different structures, *i.e.* to the cycloheptadienes *(86)* and *(87)*.



When heated with potassium acetate, these compounds lose the malonate component and form the potassium salt *(88)*. The acid of this salt is as strong as nitric acid. The formation of the anion is explained by deprotonation to form *(89)* followed by transannular Michael addition to give *(90)*, which is thought to undergo subsequent loss of the malonate component to form *(88)*.



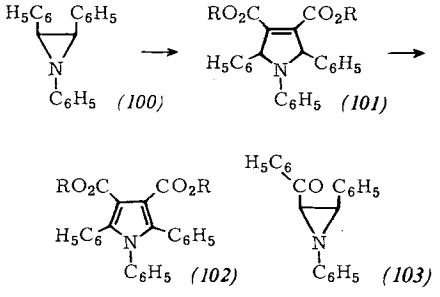
2. Addition of Tertiary Amines



Non-aromatic tertiary amines can also be made to react, but in this case it is necessary to use dilute solutions and low temperatures because of the higher basicity of these compounds. Thus the reaction of methyl propiolate with β-aminocarbonyl compounds leads to *(91)* by Hofmann degradation, that with esters of α-amino acids and their vinylogues to *(92)* and *(93)* by rearrangement and prototropy, and that with α-amino ketones in dimethyl sulfoxide to pyrroles *(94)* [5].

Analogous products are obtained with dimethyl acetylenedicarboxylate [50]. In this case, however, pyrrole derivatives are also formed in the reaction with esters of α-amino acids, but these immediately react further to yield *(95)* [27].

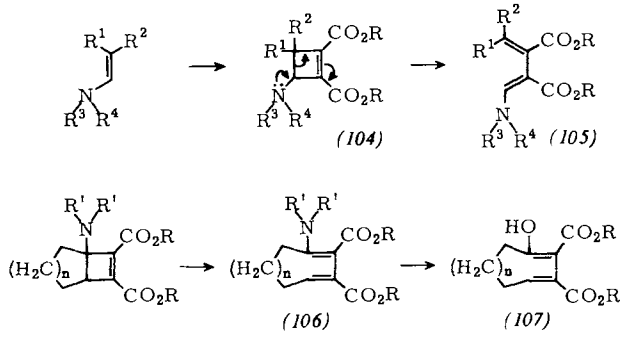
Trialkylamines add only in the presence of their salts to give esters of dialkylaminomaleic acid [51]. These tertiary amines can therefore be advantageously used as catalysts for additions to CC triple bonds. This permits the addition, not only of alcohols (see Section III 1), but also of water; in the case of methyl propiolate, double addition takes place with formation of *(96)*, while with propargyl aldehyde, addition and condensation leads to *(97)* [52]. The reaction of methyl propiolate with tertiary amines with rigorous exclusion of water leads to *(98)*.



Whereas the reaction of *N*-benzylaziridine with diethyl acetylenedicarboxylate in alcohol results almost exclusively in cleavage of the C–N bond and formation

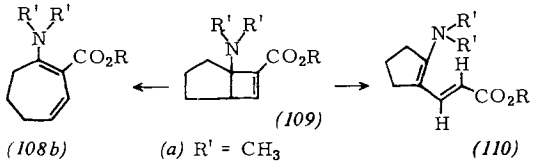
[50] *E. Winterfeldt*, unpublished.

[51] *R. J. Alaimo* and *D. G. Farnum*, Canad. J. Chem. *43*, 700 (1965).



[52] *E. Winterfeldt*, Chem. Ber. *97*, 1959 (1964).

of ethers of the type *(99)* [27], reactions involving the cleavage of the C–C bond have been reported for the substituted aziridines *(100)* and *(103)*. Thus the reaction of *(100)* in toluene yields the pyrroline *(101)*, which can be converted into the pyrrole *(102)* by treatment with chloranil [53]. *(103)* reacts similary [54].

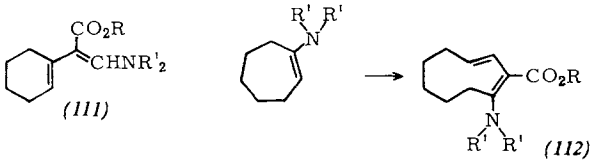


(100) *(101)* *(102)* *(103)*

The reaction of enamines with the activated triple bond was studied simultaneously by several research groups [55]. The reaction generally proceeds *via* the four-membered ring adduct *(104)*, which undergoes ring cleavage to form the dienamine *(105)*. Cyclic enamines undergo ring expansion *via* a similar intermediate, with formation of *(106)*.

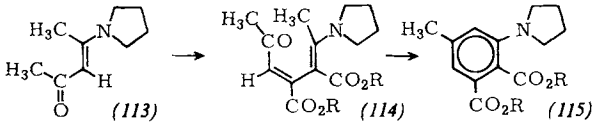
(104) *(105)* *(106)* *(107)*

The hydrolysis of this reaction product leads to the enol ester *(107)*. The cyclobutene structure of *(104)* has been confirmed, *inter alia*, by hydrogenation to form the corresponding cyclobutane [55c]. The reactions of enamines with methyl propiolate can also be explained by this scheme, but in this case *Brannock et al.* found a dependence on the ring size of the enamine and on the structure of the amine component [56]. Thus *(109a)* gives the Stork adduct *(110)* when simply allowed to stand at room temperature, while *(109b)* and *(109c)* are converted into the cycloheptadienes *(108b)* and *(108c)* when heated at 90 °C.



(108b) *(a)* R' = CH_3 *(109)* *(110)*

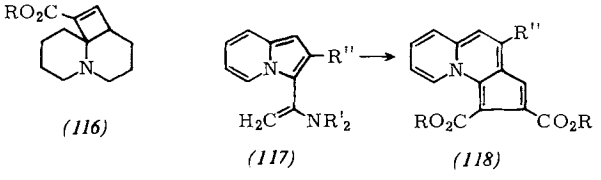
(108c) *(b)* R', R' = $-(CH_2)_4-$



(c) R', R' = $-(CH_2)_5-$

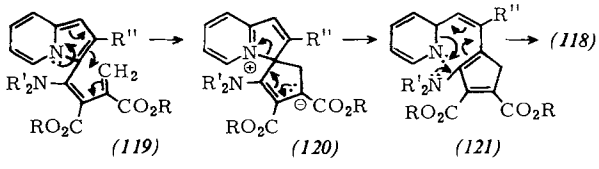
Whereas cyclohexenamines unexpectedly give the substituted aminoacrylates *(111)*, cycloheptenamine gives the normal ring-expansion product *(112)*.

(111) *(112)*



Enamines derived from β-dicarbonyl compounds, *i.e.* vinylogous amides and urethanes also undergo this reaction [55c]. Thus the pyrrolidinopentenone *(113)* first reacts normally to form *(114)*, which then undergoes spontaneous cyclization to form the aromatic compound *(115)*.

(113) *(114)* *(115)*



According to *Huebner et al.*, the addition of vinylogous urethanes also proceeds *via* a four-membered ring adduct, but the authors do not rule out the normal Michael reaction.

This reaction has been used *e.g.* for ring expansion in the steroid series [55a] and for the synthesis of a tricyclic ester *(116)* from 2,3,6,7,8,9-hexahydro-4*H*-quinolizine [57].

(116) *(117)* *(118)*

In one case of the attempted preparation of cycloazines, the indolizine derivative *(117)* gives the cyclopentaquinolizine derivative *(118)* [58]. This previously unknown indolizine-quinolizine rearrangement probably also proceeds *via* a cyclobutene derivative, since it is possible to isolate the primary adduct *(119)* at room temperature; *(119)* forms *(118)* when heated in toluene, *(120)* and *(121)* being proposed as intermediates.

(119) *(120)* *(121)* *(118)*

Alkynylamines also add smoothly to dimethyl acetylenedicarboxylate, and benzene derivatives of the type *(122)* are formed, even at room temperature [59].

An interesting reaction of acetylenedicarboxylic acid with ethynyl alkyl ethers has been described by *Arens*

[53] *H.W. Heine* and *R. Peavy*, Tetrahedron Letters *1965*, 2123.

[54] *A. Padwa* and *L. Hamilton*, Tetrahedron Letters *1965*, 4363.

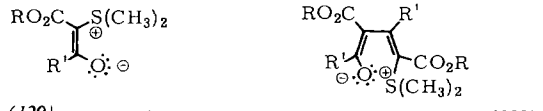
and *Cley*[60]. The ketene acetal *(123)* formed at −10 °C in diethyl ether rearranges spontaneously into the diketene *(124)*, which gives the anhydride *(125)* in the presence of water.

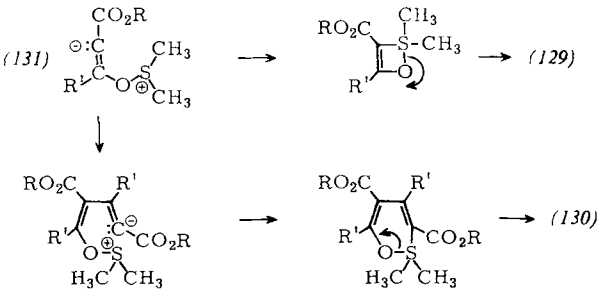
(122) *(123)* *(124)* *(125)*

Though the reaction of aromatic *N*-oxides with activated acetylene derivatives normally proceeds by 1,3-cycloaddition[61], *Takahashi* and *Kano* have described a case that does not fit directly into this scheme[62]. The reaction of the *N*-oxide *(126)* with methyl propiolate or dimethyl acetylenedicarboxylate in chloroform at room temperature yields a betaine, which is assigned the structure *(127)*, R′ = H or CO_2R, on the basis of the degradation products obtained on acid hydrolysis.



(126) *(127)* *(128)*

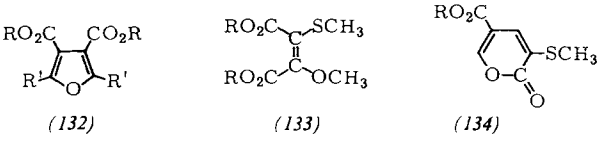
The structures have also been confirmed by independent synthesis. Since the authors were unable to isolate a cycloadduct even at −20 °C, they suggested the formation of *(127)* *via* the four-membered ring transition state *(128)*.



3. Addition of Sulfur Compounds

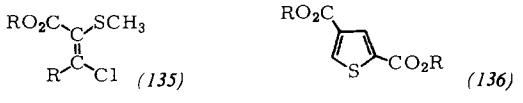
A similar transition state is required to explain the reaction of activated triple bonds with dimethyl sulfoxide. Both methyl propiolate and dimethyl acetylenedicarboxylate give the adducts *(129)* and *(130)* when heated in dimethyl sulfoxide[63].

(129) *(a)* R′ = H *(b)* R′ = CO_2R *(130)*



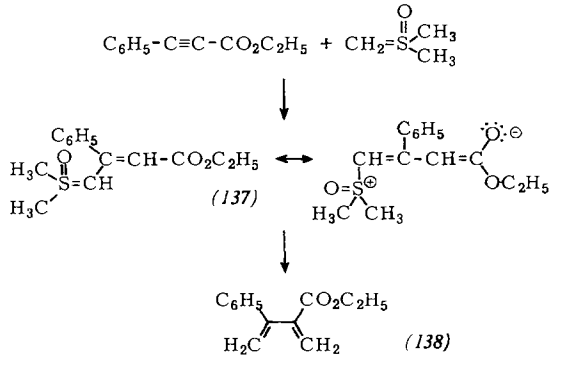
The formation of those products is explained by the assumption of a primary adduct *(131)*.

(131) *(129)* *(130)*



(129b) could be isolated as the main product, even at very high ester concentrations, whereas with methyl propiolate the reaction can be directed, and *(129a)* is the main product only at very high dilutions. Thus the reaction of methyl propiolate can be carried out in such a way as to obtain the 1:1 *(129a)* or the 1:2 adduct *(130a)*, as desired[27].

When heated further with methyl propiolate or dimethyl acetylenedicarboxylate, *(129a)* and *(129b)* give the furan derivatives *(132)*. When heated in the absence of the acetylene compounds, *(129b)* exhibits migration of the methyl group and formation of *(133)*. *(130b)* gives the tetraester of furantetracarboxylic acid as the main product, while *(130a)* gives the pyrone *(134)* and only very small quantities of dimethyl furandicarboxylate.



(132) *(133)* *(134)*

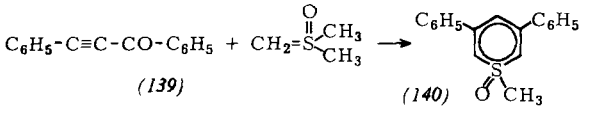
The compounds *(129a)* and *(129b)* react smoothly with acyl chlorides to form the thioethers *(135)*; under these conditions *(130a)* reacts surprisingly smoothly to give the dimethyl thiophenedicarboxylate *(136)*.

(135) *(136)*

The reaction of dimethylsulfoxonium methylide with acetylene compounds has also been studied by several authors[64]. Ethyl phenylpropiolate gives the crystalline ylide *(137)*.

(137) *(138)*

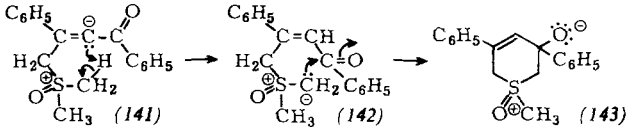
[60] *J. F. Arens* and *J. Cley*, Recueil Trav. chim. Pays-Bas *78*, 929 (1959).



[61] *R. Huisgen* and *H. Seidel*, Tetrahedron Letters *1963*, 2023, 2191.

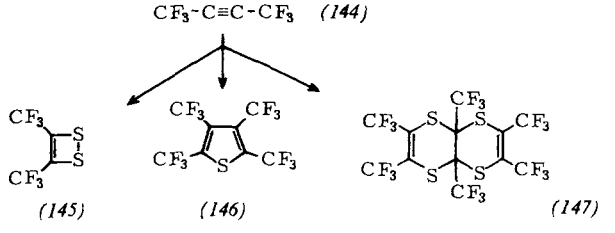
[62] *S.Takahashi* and *H.Kano*, J.org.Chemistry *30*, 1118 (1965).

[63] *E. Winterfeldt*, Chem. Ber. *98*, 1518 (1965).



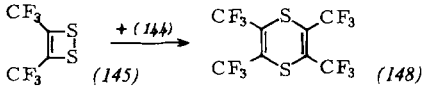
[64] a) *C. Kaiser, B. M.Trost, J. Beeson*, and *J. Weinstock*, J. org. Chemistry *30*, 3972 (1965); b) *J. Ide* and *Y.Kishida*, Tetrahedron Letters *1966*, 1787.

On treatment with triethylamine, this compound gives the interesting diene *(138)*. The same authors obtained only very unstable products in the reaction of dimethylsulfoxonium methylide with dimethyl acetylenedicarboxylate. In the reaction with the ketone *(139)*, *Hortmann* obtained the thiabenzene derivative *(140)* [65].



(139) *(140)*

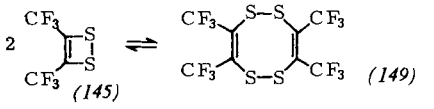
The reaction proceeds *via (141)*, *(142)*, and *(143)*.



(141) *(142)* *(143)*

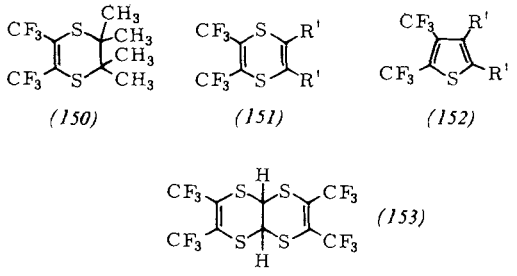
The action of elementary sulfur on the activated triple bond of hexafluoro-2-butyne *(144)* was studied by *Krespan* [66]. At high temperatures, the reaction yields the compounds *(145)*, *(146)*, and *(147)*.

(145) *(146)* *(147)*



The reaction of *(144)* with sulfur vapor gives *(145)* in 80% yield. Thus this dithiete may be regarded as the primary adduct, which, because of the strained disulfide bond, smoothly adds a second mole of the acetylene compound to form *(148)*.

(145) *(148)*

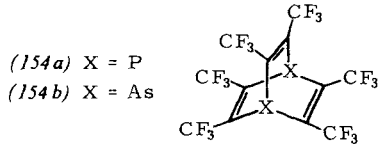


(148) may then either lose sulfur to form *(146)* or react with a second mole of *(145)* to give *(147)*. These views are strongly supported by the fact that when *(145)* and *(144)* are heated at 100 °C, they react to form *(148)*, which gives *(146)* as expected on further heating. *(146)* can be obtained as sole product by this reaction.

The ring strain in *(145)* is also shown by the smooth dimerization to form *(149)*. The equilibrium between *(145)* and *(149)* is demonstrated by the fact that *(149)* gives *(145)* when heated at 200 °C.

(145) *(149)*

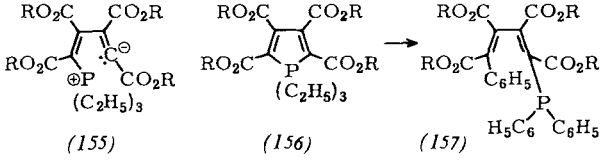
In agreement with the above reactions, *(145)* reacts with 2,3-dimethyl-1,3-butadiene to form *(150)* and with acetylene at 70 °C to give *(151)* (R′ = H) while the reaction with acetylene at 125 °C yields a mixture of *(152)* and *(153)*.



(150) *(151)* *(152)*

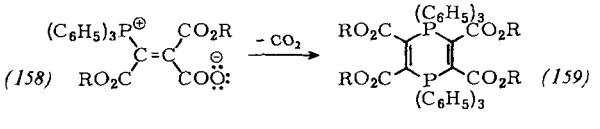
(153)

The reaction of *(145)* with dimethyl acetylene dicarboxylate leads only to the 1:1 adduct *(151)* (R′ = CO_2R). This compound loses sulfur when heated, and forms the thiophene derivative *(152)* (R′ = CO_2R). The acceptor groups on the double bond prevent further addition in this case.



The additions described are catalysed by iodine. Under pressure, phosphorus and arsenic can also be made to react under comparable conditions to give the 1,4-diphospha- *(154a)* or 1,4-diarsabarrelene structure *(154b)* [67].

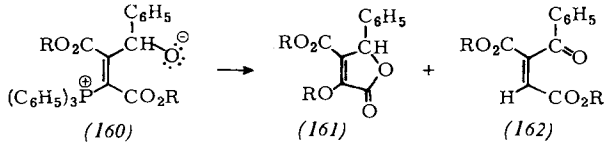
(154a) X = P
(154b) X = As



4. Addition of Phosphorus Compounds

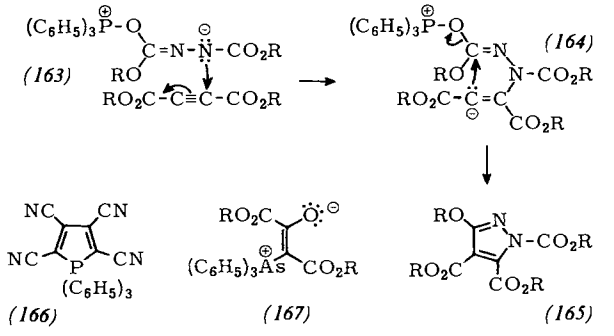
The addition of phosphorus compounds to the activated CC triple bond has also been studied from various points of view. *Horner* and *Hoffmann* reported the reaction of triphenyl- and triethylphosphines with dimethyl acetylenedicarboxylate. They formulated a 1:1 adduct with triphenylphosphine and the 2:1 adduct *(155)* with triethylphosphine [68].

(155) *(156)* *(157)*



The same formulation was given by *Johnson* and *Tebby* for the 2:1 adduct with triphenylphosphine, but it can also be shown that the adduct is stabilized by formation of *(157)* when heated [69]. The same product is obtained when the reaction is carried out in boiling ether. These authors were also able to intercept the 1:1 adduct with CO_2 as the betaine *(158)*, which is readily decarboxylated to form a product that is formulated as *(159)*.

(158) *(159)*

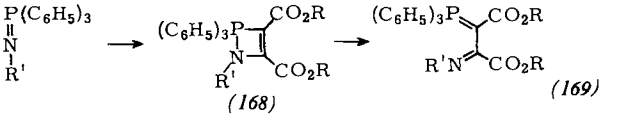


[65] *A. G. Hortmann*, J. Amer. chem. Soc. *87*, 4972 (1965).
[66] *C. G. Krespan*, J. Amer. chem. Soc. *83*, 3434, 3438 (1961).
[67] *C. G. Krespan*, J. Amer. chem. Soc. *83*, 2126 (1961).
[68] *L. Horner* and *H. Hoffmann*, Angew. Chem. *68*, 473 (1956).
[69] *A. W. Johnson* and *J. C. Tebby*, J. chem. Soc. (London) *1961*, 2126.

A similar interception reaction is possible with an excess of benzaldehyde; the stable end products *(161)* and *(162)* are obtained *via (160)* [27].

(160) *(161)* *(162)*

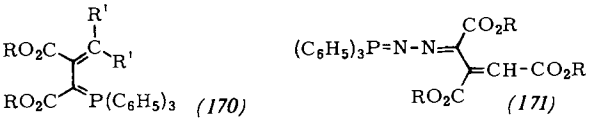
The reaction of triphenylphosphine with dimethyl azodicarboxylate and dimethyl acetylenedicarboxylate is also interpreted as an interception reaction, leading *via (163)* and *(164)* to the pyrazole *(165)* [70].



(163) *(164)* *(166)* *(167)* *(165)*

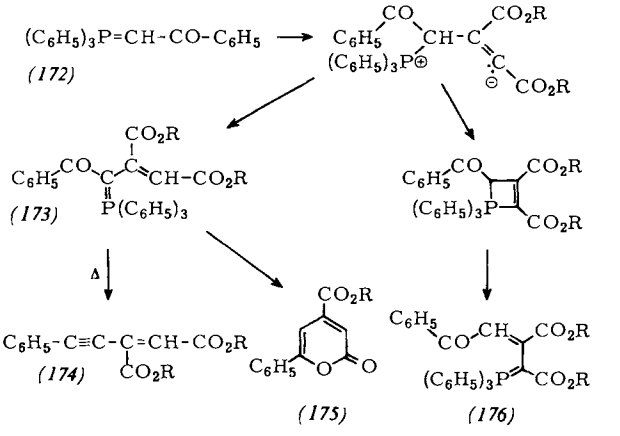
Hendrickson et al. [71] proposed the neutral structure *(156)* as the final formulation of the 2:1 adduct, since the conversion of *(156)* into *(157)* proceeds smoothly and quantitatively in acidic media, whereas an enoxide ion should be protonated under these conditions, and hence be unable to undergo rearrangement.

The product of the reaction of dicyanoacetylene and triphenylphosphine is also formulated as a phosphole *(166)* [72]. However, the adduct of dimethyl acetylenedicarboxylate and triphenylarsine, for which a similar structure was originally postulated, has been found to be the oxidation product *(167)* [71].



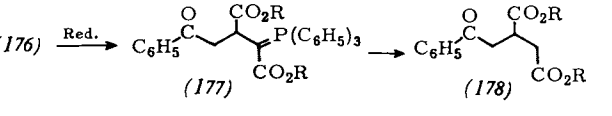
Phosphine imides react smoothly with the activated CC triple bond. The reaction proceeds *via* a four-membered ring adduct to yield the stable compound *(169)*, the structure of which has been established by X-ray analysis [73].

The unsubstituted phosphine imine, which could, in principle, enter into a Michael addition, also reacts *via* a four-membered ring [74].



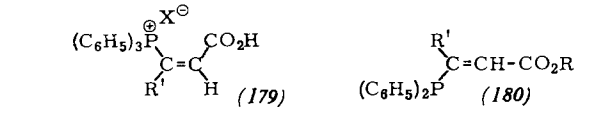
(168) *(169)*

A similar reaction of phosphoranes leads to products of the type *(170)* [75]. Phosphazines, on the other hand, react by Michael addition to give *(171)* [74].



(170) *(171)*

According to *Hendrickson*, the reaction of acylphosphoranes can proceed either *via* the four-membered ring or as a Michael addition, depending on the solvent [76]. Thus *(172)* in methanol gives the Michael addition product *(173)*, the structure of which is established by pyrolysis to form *(174)* and by conversion i..to the pyrone *(175)*.



(172) *(173)* *(174)* *(175)* *(176)*

The reaction in ether, on the other hand, yields *(176)*, the structure of which was established by spectral data and by reduction to *(177)*, which forms the keto acid *(178)* on treatment with alkali.

(176) *(177)* *(178)*

According to *Hoffmann* and *Diehr*, triphenylphosphine adds to propiolic acid in acidic media to form the *trans* adduct *(179)* (R′ = H); acetylenedicarboxylic acid yields the same product on subsequent decarboxylation [77].

(179) *(180)*

The *trans* addition follows from the fact that the adduct *(179)* (R′ = C_6H_5) obtained from phenylpropiolic acid gives *trans*-cinnamic acid on hydrolysis (provided that the configuration is stable during

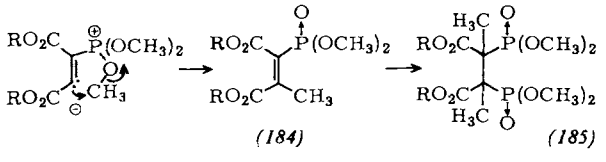
[74] *G.W.Brown*, *R.C.Cookson*, and *D.R.Stevens*, Tetrahedron Letters *1964*, 1263.

[75] *H. J. Bestmann*, Angew. Chem. *76*, 569 (1964); Angew. Chem. internat. Edit. *3*, 512 (1964).

[76] *J. B. Hendrickson*, *C. Hall*, *R. Rees*, and *J. F.Templeton*, J. org. Chemistry *30*, 3973 (1965).

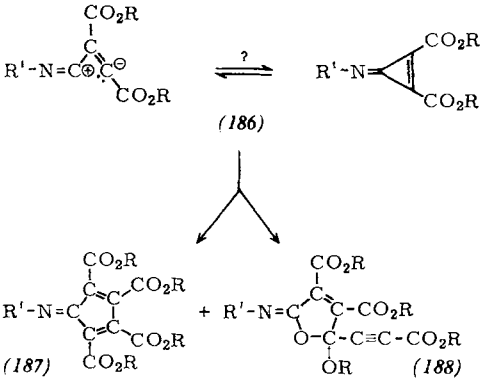
[77] *H. Hoffmann* and *H. J. Diehr*, Chem. Ber. *98*, 363 (1965).

hydrolysis). The addition of diphenylphosphine was also studied in this connection; the reaction leads smoothly to the adduct of the general structure *(180)*. An interesting course is found in the addition of trialkyl phosphites. In the case of compounds with non-activated triple bonds, the primary complex *(181)* can be stabilized in various ways.



(181)

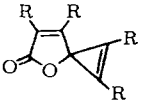
(182) *(183)*



For R' = C_2H_5 and n-C_4H_9, stability is achieved by a *cis* elimination, which leads, by elimination of the corresponding olefin, to the vinylphosphonates *(182)*. This route is not possible for R' = CH_3; *(181)* is therefore protonated by a second mole of the acetylene compound to give the quasiphosphonium salt *(183)*, which then also gives *(182)* by dealkylation.

Neither of these routes is possible in the reaction of trimethyl phosphite with dimethyl acetylene dicarboxylate. Nevertheless, the two components react very vigorously, and in etheral solution the compound *(185)* is obtained in 38 % yield[78]. The most likely course for this reaction is the primary formation of the vinylphosphonate *(184)* followed by further reaction in an analogous secondary step to form *(185)*.

(184) *(185)*



Finally, it should also be mentioned that isocyanides, as expected, react smoothly with dimethyl acetylenedicarboxylate[79]. The course of this reaction is very strongly dependent on the external parameters, and can be directed in such a way as to obtain various products. With a small excess of the ester and at low temperatures, it is possible to obtain good yields of the products *(187)* and *(188)*, the formation of which can be readily explained as proceeding *via* the primary adduct *(186)*.

(186)

(187) *(188)*

Breslow observed that a reaction similar to the formation of *(188)* takes place with a cyclopropenone derivative, which can be converted into the spirane *(189)*.

(189)

I am grateful for the industrious and imaginative cooperation of H. Preuss, H. J. Dillinger, and W. Krohn, who have attacked this problem with great enthusiasm and energy. Acknowledgment is due to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the ERP-Sondervermögen for their promotion of this work. Thanks are also due to Professor F. Bohlmann for his untiring support and his constant interest.

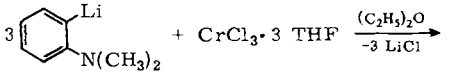
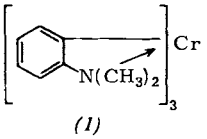
Sigma-Bonded Organochromium Compounds. Hydrogen Transfer Reactions

BY H. H. ZEISS AND R. P. A. SNEEDEN [*]

The preparation and properties of two classes of organochromium compounds and their interconversion have been studied actively in recent years. These are the σ-bonded organochromium compounds in which alkyl, aryl, or aralkyl groups are covalently bonded to chromium (II or III) and the π-arenechromium complexes in which "aromatic" nuclei are covalently bonded to chromium (0 or 1). From certain reactions of the σ-bonded organochromium compounds, evidence has accumulated which shows that the chromium atom acts not only as a coordination center, but also as a hub for hydrogen transfer and H/D exchange [1,2]. σ-Organochromium compounds may act as sources of radicals and carbanions. The present paper deals with the preparation and properties of σ-bonded organochromium compounds; particular attention is given to hydrogen transfer reactions and rearrangements to bis(π-arene)chromium complexes.



I. Preparation



Solvated σ-bonded organochromium compounds may be prepared by the action of certain organometallic compounds on chromium halides, *e.g.*, unsolvated $CrCl_3$ or $CrCl_3 \cdot 3$ tetrahydrofuran, provided particular attention is paid to solvent, temperature, and stoichiometry of the reaction. Phenyl-lithium [3] and phenylsodium [4], for example, react with chromium trichloride according to eq. (a) and (b) to give lithium- and sodium-containing organochromium complexes of varying composition. In some cases organolithium reagents give lithium-free complexes [5], *e.g. (1)*.

$$6\ LiC_6H_5 + CrCl_3 \xrightarrow{(C_2H_5)_2O} Li_3[Cr(C_6H_5)_6] \cdot 4(C_2H_5)_2O\ [2] \quad (a)$$

$$5\ NaC_6H_5 + CrCl_3 \xrightarrow[THF]{(C_2H_5)_2O} Na_2[Cr(C_6H_5)_5S] \cdot 2S \quad (b)$$

$S = (C_2H_5)_2O$, THF [4]

(1)

However, in the reaction between triphenylaluminum and chromium(III) chloride in tetrahydrofuran only one phenyl group is introduced, giving the complex *(2)* [6].

$$Al(C_6H_5)_3 + CrCl_3 \xrightarrow{THF} C_6H_5CrCl_2 \cdot 3\ THF + (C_6H_5)_2AlCl \quad (2)$$

The most convenient and perhaps cleanest route to σ-bonded organochromium compounds is by the action of organomagnesium halides on $CrCl_3 \cdot 3THF$ in tetrahydrofuran [2,7–10,13,14] or in diethyl ether [eq. (c)]. This is a general and most versatile method for the preparation of such compounds.

$$3\ RMgX + CrCl_3 \cdot 3THF \rightarrow R_3Cr \cdot xTHF + MgXCl \cdot yTHF \quad (c)$$

R = phenyl [7]; α- and β-naphthyl [8]; ethyl [9]; mesityl [10,14b]; allyl [11,12]; vinyl [13]; benzyl [2]; *p*-tolyl [14]; *p*-F-, *p*-Cl-, *p*-Br-, *p*-C_6H_5–C_6H_4 [14a]; *m*-Cl-, *m*-CH_3–C_6H_4 [14a]; 2-thiophenyl [14a]; *o*-tolyl [14b]; methyl [9].

By varying the stoichiometric ratios of the reactants, solvated organochromium compounds of the type, $R_nCrCl_{3-n} \cdot xS$ (n = 1,2 or 3) R = *e.g.* benzyl [2,15a],

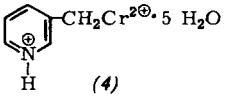
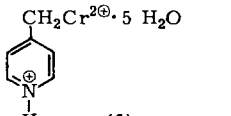
[15b,16,17] [*], phenyl [6], methyl [16], *p*-tolyl [16a], and mixed organochromium compounds RR'R''Cr·*x*S have become accessible.

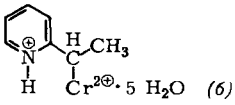


Another interesting route to organochromium species is based on the reaction of chromium(II) salts with certain organic halides [18,19] (eq. (d)). This reaction has been used to prepare the compounds *(3)–(6)* [20a–20c] as well as alkylchromium compounds [20d].

$$2\,Cr^{2+} + RCl \xrightarrow{H_2O} RCr^{2+}\cdot 5H_2O + CrCl^{2+}\cdot 5H_2O \qquad (d)$$



R = C_6H_5–CH_2, $CHCl_2$



(3)

(4)

(5)

(6)

More recently this method has been adapted to the preparation of the crystalline monoorganochromium compounds $RCrCl_2$·3pyridine (R = benzyl, *o*-chlorobenzyl and *p*-chlorobenzyl) [15b].

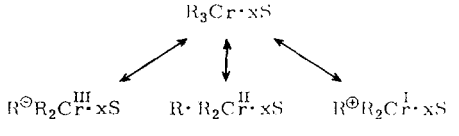
II. Properties

The monoorganochromium dihalides $RCrCl_2$·*x*S differ markedly in thermal stability. Whereas the phenyl and *p*-tolyl derivatives may be recrystallized from tetrahydrofuran (−10 to 20 °C), the benzyl and mesityl compounds decompose rapidly in this solvent at room temperature. Solutions of $C_6H_5CH_2CrCl_2$·*x*S in tetrahydrofuran can be diluted with water and stored at −20 °C. Alternatively $C_6H_5CH_2CrCl_2$·*x*THF may be extracted quantitatively into water from ethereal suspension. Properties of the aqueous solution [15b,17], *i.e.* reducing power towards $FeCl_3$, formation of benzaldehyde on oxidation, and the visible spectrum are the same as those of a complex $CrCl_2(C_6H_5CH_2)\cdot 5H_2O$ formed directly from benzyl chloride and chromous salts [18].

The thermal decomposition of the benzyl- and mesitylcompounds as in eq. (e) involves homolysis of the carbon-chromium bond giving 1,2-diphenylethane and bimesityl, respectively, and chromium(II) chloride. It has been reported that CH_3CrCl_2·*x*S can be recrystallized from warm tetrahydrofuran [16].

$$RCrCl_2\cdot xS \xrightarrow{\Delta} R{-}R + CrCl_2\cdot xS \qquad (e)$$

R = Benzyl, mesityl



The monoorganochromium dichlorides $RCrCl_2$·*x*S react with mercuric chloride in tetrahydrofuran [eq.(f)] to give the corresponding organomercuric chloride and $CrCl_3$·3THF.

$$RCrCl_2\cdot n\text{THF} + HgCl_2 \rightarrow RHgCl + CrCl_3\cdot 3\text{THF} \qquad (f)$$

Therefore, σ-bonded organochromium compounds can be regarded as sources of carbanions or of radicals:

$$R^{\ominus}\ldots\overset{\oplus}{Cr}Cl_2\cdot xS \leftrightarrow RCrCl_2\cdot xS \leftrightarrow R^{\bullet}\ldots Cr^{\bullet}Cl_2\cdot xS$$

The triorganochromium compounds, R_3Cr·*x*S, undergo both heterolytic and homolytic carbon-chromium bond cleavage. Thus, triphenylchromium is hydrolysed to benzene and reacts with mercuric chloride to give phenylmercuric chloride [7]. Triallylchromium is converted on warming to diallylchromium(II) and presumably 1,5-hexadiene [12]. Depending on the nature of group R and of the coordination, these substances may also be regarded as sources of carbanions, of radicals, and even of carbonium ions.

III. Reactions

1. Reactions with Ketones

Organochromium compounds differ from their organomagnesium counterparts in reactions with ketones. The latter may act either as a source of alkyl or aryl groups in forming tertiary carbinols or as conventional

organic bases in effecting self-condensation of ketones [21]. Organochromium compounds, on the other hand, may serve to do both simultaneously.

Triphenylchromium reacts with cyclohexanone [22] to give 1-phenylcyclohexanol, 2-cyclohexenylcyclohexanone and 2-phenylbicyclohexyl-1',2-diol *(7)*. Similarly, triethyl- and triphenylchromium with 3-pentanone give respectively 3-ethylpentan-3-ol and 3,5-diethyl-4-methylheptane-3,5-diol *(8)*, R = C_2H_5), and 3-phenylpentan-3-ol and 5-ethyl-4-methyl-3-phenylheptane-3,5-diol *(8)*, R = C_6H_5).

(7)

(8)

The formation of 2-cyclohexenylcyclohexanone from cyclohexanone and triphenylchromium is evidence of the organochromium compound acting as a coupling center. Finally, the formation of *(8)* (R = C_6H_5) in the same reaction is evidence that triphenylchromium acts simultaneously as a coupling center [*] and a phenylating agent.

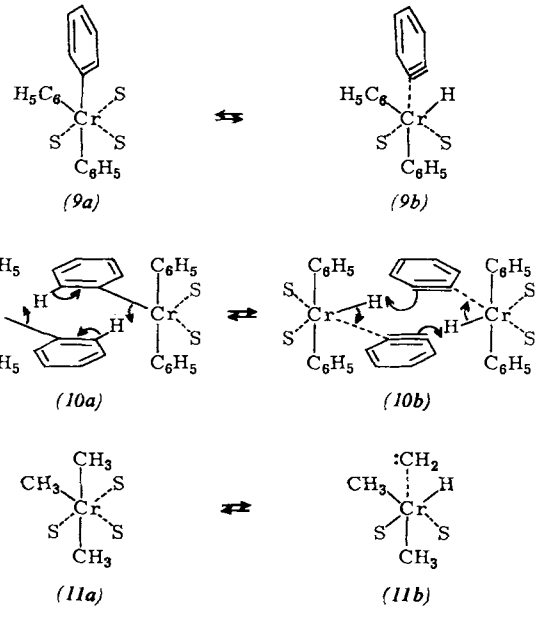
2. Reactions with Disubstituted Acetylenes and Olefins

Organochromium compounds act as coordination centers in their reactions with disubstituted acetylenes, *e.g.*, dimethyl- and diphenylacetylene [1]. In general, five main types of products are obtained:

1) Yellow, viscous polymers formed by the usual ionic polymerization of acetylenes.

2) Hexasubstituted benzenes, *e.g.*, hexamethyl- or hexaphenylbenzene, formed by trimerization of the acetylene component.

3) Tetrasubstituted cyclic products formed when two molecules of the acetylene combine with one of the groups attached to chromium with concomitant hydrogen abstraction (see Table 1).



4) Compounds which are formed when one molecule of the acetylene component combines with one or two of the groups bonded to chromium. For example, trimesitylchromium and dimethylacetylene give 2-mesityl-2-butene as well as hexamethylbenzene [10]. Bicyclo[2.2.1]hepta-2,5-diene is mono and diphenylated by triphenylchromium giving *exo*-5-phenylbicyclo-[2.2.1]hept-2-ene and *exo,exo*-2,5-diphenylbicyclo-[2.2.1]heptane [23].

5) Bis(π-arene)chromium complexes formed from trimers of types 2) and 3).

The isolation of compounds of type 3) (see Table 1) provided the first evidence that organochromium compounds promote hydrogen abstraction. Although no intermediates have been isolated yet, the first step may tentatively be represented by the following equilibrium:

$$R_3Cr{\cdot}xS \rightleftharpoons R\text{-}H \,.\,.\,.\,.\,.\,.\, R_2CrH{\cdot}xS$$

The mono- and dimeric forms of the triphenylchromium complex [*(9b)*, *(10b)*, and *(11b)* respectively] have been considered as rearrangement components.

In effect, the organochromium compound $R_3Cr \cdot xS$ can be regarded as a potential source of an aryne [*(9b)*, when R is an aryl group] or of a carbene [*(11b)* when R is an alkyl group]. In such species, rapid reaction with "two molecules of acetylene" would occur to give compounds of type 3).

This concept also implies that a σ-bonded organochromium(III) hydride *(12)* is either in equilibrium with, or can proceed to, the π-arenechromium(I) species.

3. Rearrangement

σ-Bonded arylchromium compounds undergo an unusual reaction in rearranging to π-arenechromium complexes; thus, on treatment with oxygen-free diethyl ether at 20 °C, $(C_6H_5)_3Cr \cdot 3THF$ [26] and $(p\text{-}CH_3C_6H_4)_3Cr \cdot 3THF$ [14] are converted into black intermediates which, on hydrolysis, give bis(π-arene)-chromium complexes. These complexes may be isolated as their tetraphenylborate salts, which are stable in air.

$$(p\text{-}R'\text{-}C_6H_4)_3Cr \cdot 3THF \xrightarrow[2)\ H_2O]{1)\ (C_2H_5)O} \{p\text{-}R'\text{-}C_6H_5\}_2\, Cr^{\oplus}B(C_6H_5)_4^{\ominus} \quad (14) +$$

$$R' = H, CH_3 \qquad \{p\text{-}R'\text{-}C_6H_5\}\ \{(p\text{-}R'\text{-}C_6H_4)_2\}\ Cr^{\oplus}B(C_6H_5)_4^{\ominus} \quad (15)$$

The same black intermediates can be prepared directly by the reaction of the arylmagnesium halide and $CrCl_3$ (molar ratio 3:1) in diethyl ether [14,26]. With *p*-tolylmagnesium bromide the final products are toluene and *p,p'*-dimethylbiphenyl, indicating that in this reaction, and probably in all cases involving arylchromium compounds, the "dimeric products" (both free and in the bis(π-arene)chromium complexes) arise by *para*-coupling of two aryl species within the confines of the organochromium compound.

The nature of the black intermediate [26a] and the mechanism by which σ-bonded arylchromium(III) compounds rearrange to bis(π-arene)chromium complexes remain unknown. Clearly both steric and electronic factors as well as solvent effects influence the rearrangement. Thus the early observation that solvated $(mesityl)_3Cr$ is stable and does not rearrange to a bis(π-arene) complex was taken as evidence that the two methyl groups *ortho* to the C–Cr bond impede the reaction [26b]. However, it has been shown that solvated $(o\text{-tolyl})_3Cr$, with only one methyl group *ortho* to the C–Cr bond, does rearrange to a bis(π-arene) complex. The electronic influence of substituents is illustrated by the observation that, under analogous conditions, the *ortho-*, *para-*, and *meta*-alkyl substituted compounds rearrange, whereas the *para-* and *meta*-halogen substituted compounds do not [14a,14b].

IV. Benzylchromium Compounds

1. Reactions

In pure tetrahydrofuran, the tetrahydrofuran adducts of $(CH_2C_6H_5)_3Cr$, $(C_6H_5CH_2)_2CrCl$, and $C_6H_5CH_2CrCl_2$ are readily accessible (see Section I). In pure diethyl ether, benzylmagnesium chloride and $CrCl_3 \cdot 3THF$, or $CrCl_3$, (molar ratio 1:1) react at temperatures lower than −10 °C to give monobenzylchromium dichloride which can be extracted into aqueous solution. With a reactant ratio of 3:1 and at −78 °C, the initial product is tribenzylchromium [2]. This compound is unstable in diethyl ether and at *ca.* 20 °C it rearranges to a black intermediate which, on hydrolysis, gives hydrogen, toluene, 1,2-diphenylethane, *o*-methyldiphenylmethane, and π-(*o*-methyldiphenylmethane)-π-toluenechromium(I).

Experiments have shown that when only 1,2-diphenylethane is formed (hydrolysis of THF/ether mixtures), little or no π-complex is formed. On the other hand, when *o*-methyldiphenylmethane alone, or together with 1,2-diphenylethane, is formed (hydrolysis of ethereal solutions), the bis(π arene)chromium complex is also formed. It appears, therefore, that there is a direct relationship between the formation of the bis(π-arene)chromium complex and that of *o*-methyldiphenylmethane.

Formation of *o*-methyldiphenylmethane indicates that in the original tribenzylchromium complex two benzyl groups have undergone *ortho*-coupling. This is in sharp contrast to the triaryl compounds, in which two aryl species undergo *para*-coupling (cf. Section III.3). Furthermore, in the case of tribenzylchromium, the formation of toluene and *o*-methyldiphenylmethane involves the acquisition of hydrogen by the benzyl group originally bonded to chromium. The bis(π-arene) complex can only arise by the acquisition of two hydrogen atoms by the intermediate formed in the coupling of two benzyl species within the tribenzylchromium complex. These hydrogen atoms may originate from the water used in the hydrolysis step or by internal transfer – their origin will be discussed in the following section.

2. Deuterolysis [27,28]

If the hydrogen is acquired during the simple hydrolysis of organochromium compounds or their rearrangement products, then the products of deuterolysis should be monodeuteriotoluene and monodeuterio-*o*-methyldiphenylmethane, both free and in the π-complex. However, the results of the deuterolysis experiments (Table 2 [27]; Section VI) indicate that other reactions take place besides those of simple deuterolysis. The hydrogen deuteride observed may arise from the deuterolysis of a chromium hydride

intermediate. The undeuterated toluene and *o*-methyldiphenylmethane can arise only by a process of internal hydrogen transfer.

The presence of two or three deuterium atoms in the toluene and *o*-methyldiphenylmethane, both free and in the bis(π-arene) complex, indicate an H/D exchange reaction.

Experiments in the presence of anthracene and dihydroanthracene (see Table 2 and [27]), established that at no stage during the reaction were benzyl radicals released into solution. Therefore, the processes of hydrogen abstraction and hydrogen transfer all occur within the confines of an organochromium complex. In order to establish that this applies also to the H/D exchange reaction, it was first necessary to establish that the latter is promoted neither by the presence of the bis(π-arene)chromium(0) or-(I) complex, nor by colloidal chromium.

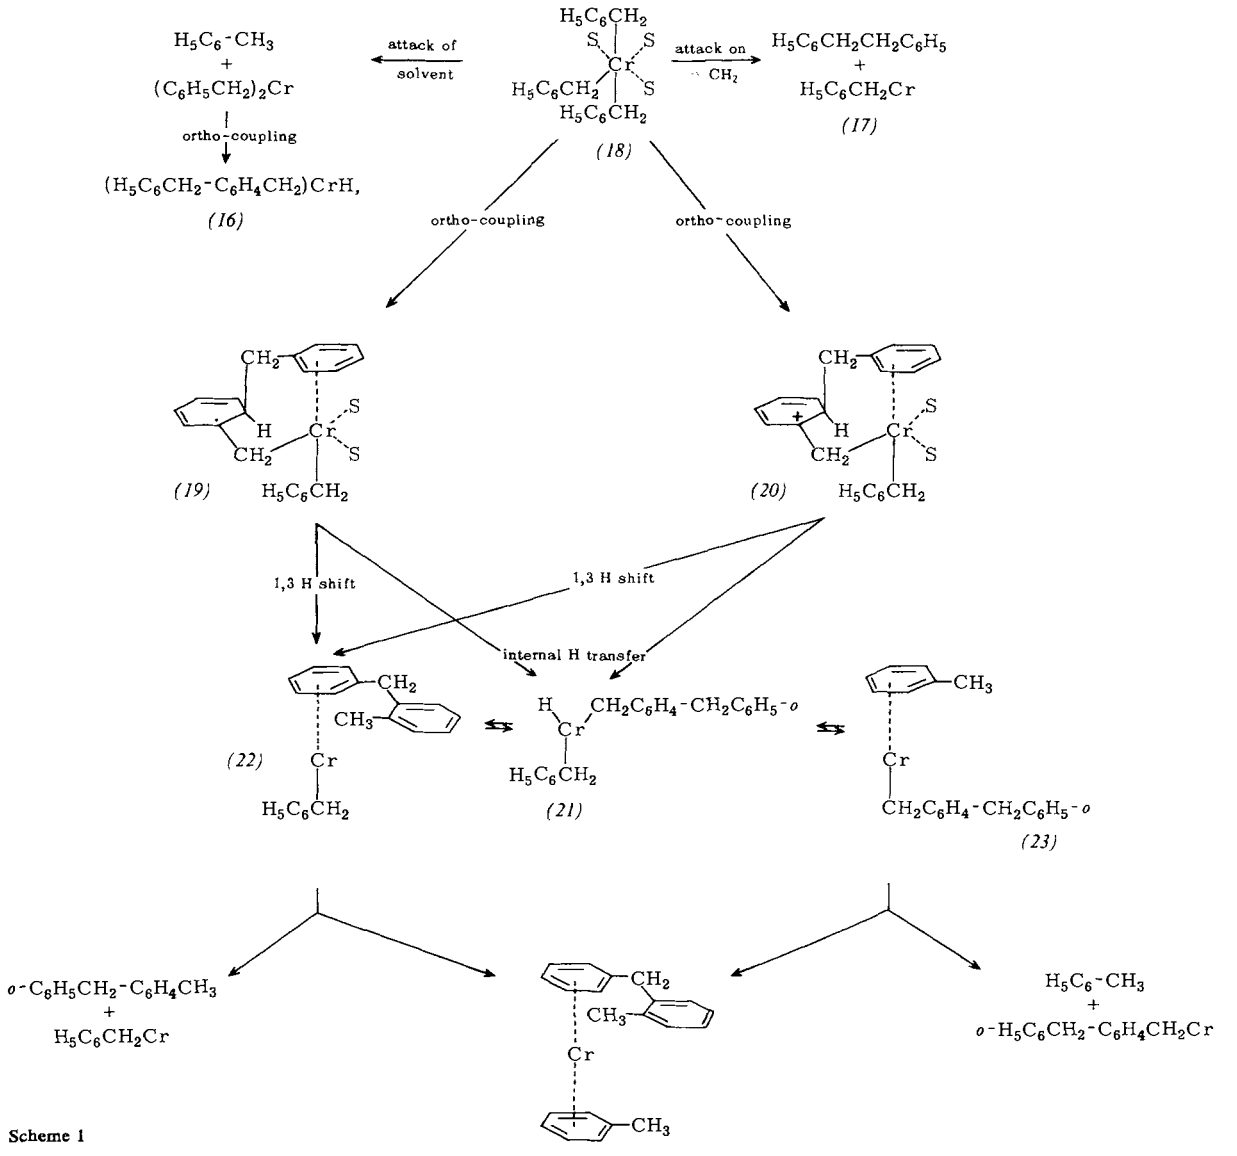
Thus it was found that when tribenzylchromium rearranges in diethyl ether solution in the presence of *p*-xylene and the reaction mixture is deuterolysed, the *p*-xylene recovered is deuterium-free (cf. Section VI). Furthermore, when a mixture of undeuterated π-(*o*-methyldiphenylmethane)-π-toluenechromium(0) and -(I) deuteroxide in benzene/D_2O is allowed to interact with D_2O/D_2, the toluene in the recovered bis(π-arene)chromium contains only traces of deuteriotoluenes (cf. Section VI).

An interpretation of these results must begin with a consideration of the behavior of tribenzylchromium. Replacement of the tetrahydrofuran in the initial tribenzylchromium complex by diethyl ether induces homolysis of the benzyl-chromium bond. The benzyl radical remains within the confines of the organochromium compound and reacts either with the solvate or with a σ-bonded benzyl group. This leads to the following considerations:

1. Hydrogen abstraction from a molecule of solvate (diethyl ether or tetrahydrofuran) gives undeuterated toluene and solvated dibenzylchromium(II). The *cis*-form of the latter can undergo *ortho*-coupling to (*o*-phenylmethylbenzyl)chromium hydride *(16)*.

2. Oxidative coupling of two benzyl groups bonded to chromium gives undeuterated 1,2-diphenylethane and benzylchromium(I) *(17)*.

$$(C_6H_5CH_2)_3Cr \cdot xS \longrightarrow C_6H_5CH_2CH_2C_6H_5 + C_6H_5CH_2Cr(I) \cdot xS \qquad (g)$$

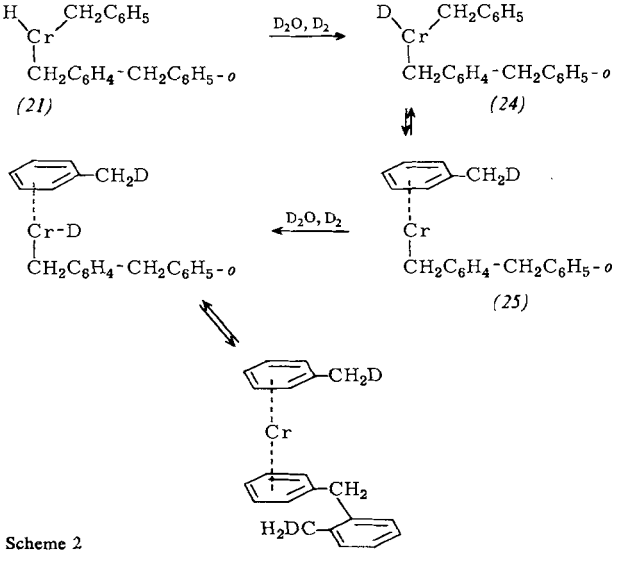


Neither of the reactions 1) or 2) leads directly to the bis(π-arene) complex, but both effectively reduce the amount of tribenzylchromium available for the ultimate formation of bis(π-arene) complex.

3. Two of the benzyl groups in tribenzylchromium *(18)* are suitably juxtaposed, for *ortho*-coupling to the radical *(19)* (see Scheme 1). This concept is supported by the recent observation that the pyridine molecules which are coordinated to chromium in $CrCl_3 \cdot 3$ pyridine are attacked by phenyl radicals, generated in solution, giving a mixture of 2-phenylpyridine (45 %), 3-phenylpyridine (19 %) and 4-phenylpyridine (36 %) [29]. Alternatively, ortho-coupling by an ionic mechanism gives the carbonium ion *(20)*. In both cases a 1,3-hydrogen shift produces undeuterated *o*-methyldiphenylmethane whereas hydrogen transfer to chromium leads to (*o*-phenylmethylbenzyl) benzylchromium hydride *(21)*.

Scheme 1 requires that some of the undeuterated toluene and *o*-methyldiphenylmethane be present in the reaction mixture before deuterolysis. This was confirmed by filtering the crude reaction mixture and deuterolysing separately the filtrate and residue. The toluene and *o*-methyldiphenylmethane found in the filtrate contain considerably more of the undeuterated species (see Table 2, reaction 6) than do those found in the residue.

The organic products, isolated after deuterolysis, always contain more toluene than the combined total of *o*-methyldiphenylmethane and 1,2-diphenylethane



[29] *R. J. Gritter* and *A. W. Godfrey*, J. Amer. chem. Soc. *86*, 4724 (1964).

Scheme 1

(cf. Table 2). The relative isotopic compositions of the toluene and *o*-methyldiphenylmethane are similar; this implies that they are formed from similar but not necessarily the same precursors. Previous experiments on the deuterolysis of benzylchromium(III) compounds[29a] exclude organochromium(III) compounds as possible precursors. Although no experimental evidence is available, reasoning from recent theory concerning H/D exchange reactions[30,31] suggests that either an organochromium(I) compound [*e.g.*, $C_6H_5CH_2Cr \cdot xS$ *(17)*] or an organochromium(II) hydride [*e.g.*, *o*-$C_6H_5CH_2CH_2CrH$ *(16)*] is likely.

The relative deuterium contents of the toluene and *o*-methyldiphenylmethane isolated on pyrolysis of the bis(π-arene) complex are very similar, indicating that the precursor to the π-complex in which the H/D exchange occurs, must contain both future arene parts. Such an intermediate is the organochromium(III)-hydride *(21)*, which is in equilibrium with or progresses to the "tautomeric"[32] arene forms *(22)* and *(23)* (Scheme 1). Thus the hydride *(21)* reacts with D_2O to

Scheme 2

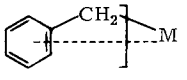
give the corresponding deuteride [Scheme 2, *(24)* and 2, *(25)*].

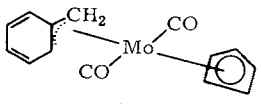
A series of H/D exchanges in a σ-bonded organochromium deuteride and a series of tautomeric changes account for the formation of the bis(π-arene) complexes.

V. Structure



Though it had been assumed that the organic groups are directly bonded to the chromium atom on the basis of indirect evidence (*e.g.*, deuterolysis, reaction with $HgCl_2$, *etc.*) there was no direct evidence for this assumption. This has now been supplied by single crystal X-ray structure determinations of $Li_3Cr(CH_3)_6 \cdot 3$ dioxane and $(p\text{-}CH_3C_6H_4)CrCl_2 \cdot 3THF$.

The data for the first compound [33] have not been refined but they show that all six methyl groups are octahedrally disposed around the chromium atom (C–Cr bond distance ≈ 2.15 Å). The data for $(p\text{-}CH_3C_6H_4)CrCl_2 \cdot 3THF$, summarized in Fig. 1 show: i) the *p*-tolyl group is bonded to the chromium atom through one carbon atom (C–Cr bond distance 2.104 Å ± 0.010 Å); ii) the length of the chromium oxygen bond *trans* to the σ-bonded *p*-tolyl group is significantly greater than the other two (2.214 ± 0.007 Å as against 2.045 ± 0.008 Å). This trans effect could account for the selective loss of and for the replacement of one tetrahydrofuran molecule from $(C_6H_5)_3Cr \cdot 3THF$ [34] (see Section IV. 2). Reference



has been made earlier to the striking differences in the reactions of the benzyl- and *p*-tolyl-chromium systems. In the case of the triorgano-chromium compounds, coupling of one of the benzyl groups occurs with the *ortho* position of another, whereas in the *p*-tolyl system one of the *p*-tolyl groups couples with another to give exclusively the *para* substituted product (cf. Section IV.1). In the case of the monoorganochromium compounds, the benzyl compound is stable towards water (< 0 °), reduces $FeCl_3$, and absorbs strongly in the visible region [15b], whereas the *p*-tolyl compound is rapidly hydrolysed, does not reduce $FeCl_3$, and absorbs weakly in the visible region [16a].

It follows therefore that there are certain special features associated with the benzyl-group when bonded to metal centers. In the case of chromium it has already been suggested [2] that the benzyl group, in analogy to the allyl group, can act as a bidentate ligand (cf. *(26)*). If such a situation pertains, the reactivity of the *ortho* position (and of the *ortho* hydrogen) will be considerably enhanced. This is reflected in the recent observations [35] that the reactivity of the *ortho* carbon atom in the benzyl Grignard compound is enhanced. Furthermore, in the case of molybdenum, two benzylmolybdenum complexes have recently been prepared [36], one $(C_6H_5CH_2)Mo(CO)_3(C_5H_5)$ has been formulated as a pure σ-bonded compound, the other $(C_6H_5CH_2)Mo(CO)_2(C_5H_5)$, formed by loss of one carbon monoxide ligand, has been formulated on the basis of NMR evidence as the π-benzyl compound *(27)*.

(27)

VI. Experimental

For general reaction conditions, product isolation techniques, and preliminary results of deuterolysis see earlier publications [2, 27].

a) *Reaction of Benzylmagnesium chloride with $CrCl_3 \cdot 3THF$ (ratio 3:1) and Deuterolysis of the Complex Formed*

Ethereal benzylmagnesium chloride (300 ml, 189 mmoles) was added, over 15 min, to a briskly stirred suspension of $CrCl_3 \cdot 3THF$ (23.6 g, 63 mmoles) in diethyl ether (150 ml) at −78 °C. After 30 min at this temperature, the dark reaction mixture was allowed to warm to 20 °C (Gilman Color Test No. 1, negative). After 3 h at 20 °C, pure, oxygen-free *p*-xylene (13.4 g, 126 mmoles) was added; the reaction mixture was stirred briskly and D_2O added. The final deuterolysis mixture was filtered through a sinter disc, under nitrogen pressure, the residue being washed with ether, water, and hot acetone until the washings were colorless. The combined etheral layers were dried with Na_2SO_4 and shown by gas chromatography to contain: tetrahydrofuran (150 mmoles), toluene (119 mmoles), *p*-xylene (118 mmoles), *o*-methyldiphenylmethane and 1,2-diphenylmethane (total 15.4 mmoles, corrected for 1,2-diphenylethane in the benzyl-Grignard solution). The more volatile components were separated by fractional distillation. The pure compounds, isolated by preparative gas chromatography, were shown by mass-spectroscopy [37] to have the compositions: tetrahydrofuran, C_4H_8O, 100 %; *p*-xylene, C_8H_{10}, 100 %; toluene (see Table 2,

[35] *R. A. Benkeser* and *T. E. Johnston*, J. Amer. chem. Soc. *88*, 2220 (1966).

[36] *R. B. King* and *A. Forzaglia*, J. Amer. chem. Soc. *88*, 709 (1966).

[37] We wish to thank Dr. *W. E. Koerner* and his associates of the Monsanto Company, Research Center, St. Louis, Mo., USA for determining the mass spectra.

reaction 4). The residue from the above distillation was further separated by column chromatography into 1,2-diphenylethane [m.p. and mixed m.p. 52–53 °C; δ(TMS) = 2.87 (CH_2)] and *o*-methyldiphenylmethane, [δ(TMS) = 3.91 (CH_2) and 2.18 (CH_3)]. On many columns the gas-chromatographic retention times of these two compounds are the same. NMR spectroscopy is thus the only reliable method of analysis. The isotopic composition of these compounds is given in Table 2, reaction 4. The aqueous layers were combined with the concentrated acetone extracts, filtered, and treated with $NaB(C_6H_5)_4$ (5.2 g, in H_2O 100 ml). The crude π-(*o*-methyldiphenylmethane)-π-toluenechromium(I) tetraphenylborate (2.26 g, 3.52 mmoles) was pyrolysed to give benzene and biphenyl (from the $^{\ominus}B(C_6H_5)_4$ anion), toluene, and *o*-methyldiphenylmethane. There was no trace of *p*-xylene or 1,2-diphenylethane. The isotopic composition of the toluene and *o*-methyldiphenylmethane [δ (TMS) = 3.91 (CH_2) and 2.18 (CH_3)], are given in Table 2, reaction 4.

b) *Benzylmagnesium chloride and $CrCl_3$·3THF (molar ratio 3:1), Filtration and Deuterolysis*

Ethereal benzylmagnesium chloride and $CrCl_3$·3THF, (molar ratio 3:1), were allowed to interact under the conditions described above. The reaction mixture was filtered though a sinter disc under nitrogen pressure. The residue was suspended in pure, dry, oxygen-free diethyl ether and the resulting suspension and the filtrate were deuterolysed. The products were isolated and estimated as described in the previous experiment. The distribution of toluene, 1,2-diphenylethane, and *o*-methyldiphenylmethane, and the bis-(π-arene) complex between the filtrate and the residue is given in Table 2. The isotopic composition of these products is also given in Table 2, reaction 6.

c) *(p-Tolyl)Cr(III) Cl_2·3THF*

Equimolar ratios of *p*-tolylmagnesium chloride and $CrCl_3$·3THF were allowed to react in tetrahydrofuran at −50 °C. On warming to 20 °C (3 h) the pink crystalline solid gradually dissolved, to give finally a clear green solution. This was cooled to −20 °C (24 h), and the yellow-green solid which had formed was removed by filtration under argon. Crystallization of this substance from tetrahydrofuran was carried out in a Schlenk tube, in vacuum, in the temperature range −30 ° to 20 °C. The results of elemental analysis, molecular-weight determination (found 425.2, based on measured density d_4^{20} = 1.315; calc., 430.4 [40]), and the paramagnetic nature of the compound (3.87 B.M. [38]) show it to be (*p*-tolyl)Cr(III)Cl_3·3THF. Optical data: λ_{max}(THF) 445 nm; ε_{max} 137.

d) *Attempted H/D Exchange in Bis(arene)chromium Complexes*

Crude π-(*o*-methyldiphenylmethane)-π-toluenechromium(I) hydroxide (5 mmoles) (from the benzyl Grignard compound and $CrCl_3$·3THF, ratio 3:1) was reduced in benzene (as the chromium(0) complex) with alkaline sodium dithionite [39]. The aqueous layer was replaced by D_2O (50 ml) and dry oxygen was bubbled through the system. The color passed from the benzene into the D_2O layer, indicating the formation of the chromium(I) deuteroxide. Metallic sodium was added cautiously until the color was evenly distributed between the benzene and D_2O. The apparatus was flushed with D_2, sealed, and left for 24 h at 20 °C. Dry oxygen was again bubbled through the system and the bis(π-arene) complex recovered quantitatively from the D_2O layer as its tetraphenylborate. The toluene, obtained by the pyrolysis of the crude salt, was isolated by preparative gas-chromatography and had the composition [37]: C_7H_8, 97.2; C_7H_7D, 2.6; $C_7H_6D_2$, 0.2 %.

Metalated Orthothioformates

By *D. Seebach* [*]

Dedicated to my tutor, Professor Rudolf Criegee, on his 65th birthday

Little is known about metalated orthothioformates [1]. By adding equimolar amounts of butyl-lithium [2] to the orthothioformates *(1a)* to *(1f)* in tetrahydrofuran at −78 °C [3,4], we obtained solutions of the lithium compounds *(2a)* to *(2f)*. Hydrolysis of the metalated compounds *(2)* with D_2O affords the deuterated orthoesters *(1a')* to *(1f')*. The compounds *(2)* are also formed conveniently from orthothiocarbonates *(3)* and butyl-lithium. (Previously, a carbon-sulfur bond cleavage of this kind had only been observed with sp-hybridized carbon [5].) Thus, the orthothioformate *(1d)* (b.p. = 74 °C/0.35 mm, n_D^{20} = 1.6180) is isolated in 70 % yield on cleavage of *(3d)* (m.p. = 32.3–32.7 °C [6]) and subsequent hydrolysis. We found the following order of decreasing thermal stability [1,7]: *(2a)* > *(2e)* ⋙ *(2d)* ~ *(2f)* > *(2c)* (cf. Table 1).

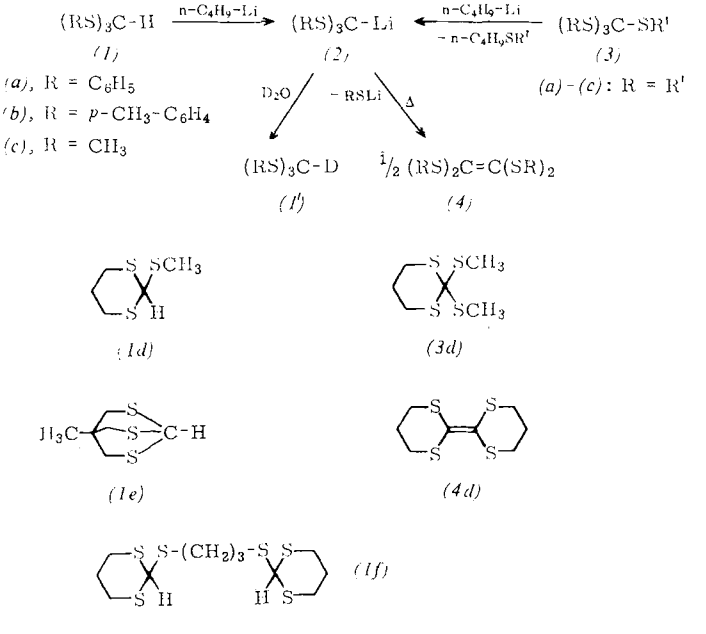

Table 1. Thermal decomposition of *(2)* to the ethylene derivatives *(4)* in tetrahydrofuran.

	(2) Conc. (mole/l)	Temp. (°C)	Time (h)	*(4)* M.p. (°C)	Yield (%)
(a)	0.2	20	24	154.5—155.0 ([1]: 153—154.5)	15
	0.2	65	12		70
(c)	0.3	−20	2	60.5—61.5 ([1]: 59—60)	80
(d)	0.1	−30	20	140.8—141.6	80
(e)	0.1	0	24	—	stable [a]
(f)	0.1	0	14	*(4d)* 140.0 — 141.0	60

[a] *(2e)* decomposes to an extent of *ca.* 60 % in 24 h at room temperature; the product of decomposition was not isolated.

With electrophiles the compounds *(2)* give good yields of products only if the reactions take place rapidly and well below the decomposition temperatures. Table 2 lists some of the products we obtained upon alkylation, hydroxyalkylation, acylation, thiolation, silylation, and oxidative dimerization. Because of its great stability and favorable stereochemistry the bicyclic *(2e)* gives the highest yields. Among the products $(RS)_3C-R^1$, the ethanes substituted by six RS-groups ($R^1 = C(SC_6H_5)_3$ and $R^1 = C(SCH_3)_3$) are of special interest, the first one being cleaved quantitatively above 150 °C (1 mm) to yield *(4a)* and diphenyldisulfide.

Table 2. Products $(RS)_3C-R^1$ of the reactions [a] of metalated orthothioformates *(2a)* [c].

Reagent	R^1 of product	Yield (%)	M.p. (°C)

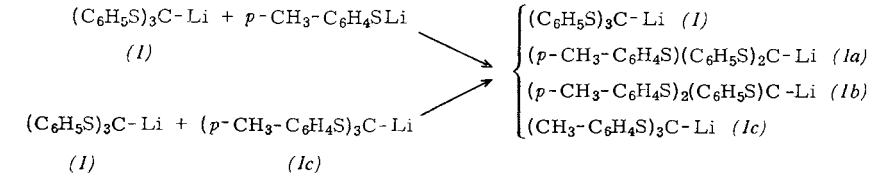
Bis(phenylthio)carbene



By *D. Seebach* [*]

Dedicated to my tutor, Professor Rudolf Criegee, on his 65th birthday

We have found evidence of the existence of a true equilibrium between a carbenoid (tris(phenylthio)methyl-lithium *(1)* [1]) and a carbene (bis(phenylthio)carbene *(2)*) in solution. The formation of tetrakis(phenylthio)ethylene *(4)* from the equilibrium mixture takes place either by dimerization of the carbene *(2)* or *via* the intermediate *(3)* [1]. Since the reaction is irreversible and very slow, even at room temperature, we were able to study the presumed equilibrium *(1)* ⇌ *(2)* conveniently [2]:

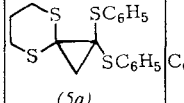
1. Addition of lithium thiophenolate drives the equilibrium towards *(1)*, thus decreasing the rate of formation of compound *(4)* (Table 1).

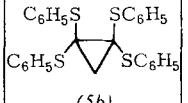
2. Addition of Li *p*-thiocresolate gives a mixture of *(1)*, *(1a)*, *(1b)*, *(1c)*, *i.e.* *p*-tolylthio groups are incorporated into the carbenoid *via (2)*; after a reaction time of 20 h at a temperature of −10 °C the mixture was hydrolysed with D_2O and H_2O and the formation of the lithium compounds *(1)* through *(1c)* proved by NMR analysis of the hydrolysates [3].

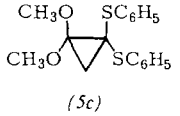
3. Under the same conditions the four products are obtained in a ratio of approximately 1:2:2:1 after mixing (1:1) solutions of *(1)* and *(1c)*.

4. Electrophiles (see Table 1) which cannot react easily with the bulky carbenoid *(1)*, but which can be attacked by the non-hindered thiophenolate without difficulty, trap C_6H_5S–Li, drive the equilibrium towards *(2)*, and increase the rate of formation of the ethylene *(4)*: three times as much *(4)* is obtained – under otherwise identical conditions – in the presence of 2 moles of propylene epoxide as in the absence of any "additive"; 1 mole of the higher substituted epoxide of cyclohexene traps thiophenolate so effectively that the yield of *(4)* becomes five times as high (Table 1). [In the first case the reaction products were, *(4)* (44 %), $(C_6H_5S)_3C-CH_2-CH(OH)CH_3$ (26 %) [1], and $C_6H_5S-CH_2-CH(OH)CH_3$ (30 %) b. p. 75 °C / 0.06 mm; $n_D^{20} = 1.5698$ [4]: b.p. 86 °C/0.35 mm; $n_D^{20} = 1.5705$). Similar results are obtained on alkylation (Table 1).]

Table 1. Yield of tetrakis(phenylthio)ethylene *(4)* from *(1)* in the presence of electrophilic reagents (0.2 M solution in tetrahydrofuran/n-hexane 10:1; 10 mmole scale; 24 h at 20 °).







Reagent (mole/mole *(1)*)	–	C_6H_5SLi 1	Propylene oxide 2	Cyclohexene oxide 1	CH_3I 2	$(CH_3)_2CHI$ 2
(4), Yield (%)	15	5	44	74 [a]	0	45 [b]

[a] In the presence of 1 mole of lithium *trans*-2-phenylthio-cyclohexanolate-1 we obtained 25 % of *(4)* from *(1)*.

[b] 10 % of *(4)* was isolated under identical conditions when *(1)* decomposed in the presence of 1 mole of LiI.

5. Certain nucleophiles remove the weakly electrophilic carbene [5] from the equilibrium. Thus, the cyclopropanedione derivatives *(5)* are obtained (at 20 ° after several days) with 1,1-bis(methylthio)- and 1,1-dimethoxyethylene (Table 2).

Table 2. Cyclopropanes obtained by adding 1 equivalent of activated ethylenes to the equilibrium mixture.

Starting material b.p. (°C/mm); n_D^{20}	2-methylene-1,3-dithiane 80/10; 1.6064	$(C_6H_5S)_2C=CH_2$ 138/0.75; 1.6484	$(CH_3O)_2C=CH_2$
Products	 *(5a)*	 *(5b)*	 *(5c)*
Yield (%)	66	78	15
M.p. (°C)	110.2–110.9	90.0–90.7	[a]
NMR signal of cyclopropane CH_2-protons, τ (ppm), CCl_4	8.26	8.12	8.51

[a] Oil after chromatographing twice on silica gel.

Addition of 1 mole of a phosphine gives (after 5 h at room temperature) the rather inert, isolable ylides *(6)* in more than 80 % yield.

$$(C_6H_5S)_2C{=}P(n\text{-}C_4H_9)_3 \xrightarrow[48h;\ 20°C]{THF/H_2O/KOH} (C_6H_5S)_2CH_2$$

(6a)

The NMR spectrum of *(6a)* (m.p. 79–81 °C; molecular weight cryoscopically in C_6H_6: 432) shows only peaks of aromatic and aliphatic protons, ratio 10:27; that of *(6b)* (C_6H_5 instead of n-C_4H_9 in *(6a)*; m.p. 170–172 °C; molecular weight cryoscopically in C_6H_6: 502) only aromatic protons. Ultraviolet spectrum of *(6a)*: λ_{max}(dioxane) = 256.5 nm (ε = 31000), of *(6b)*: λ_{max}(dioxane) = 253.5 nm (ε = 23000), ε_{300} = 7000, ε_{340} = 2500, ε_{380} = 950. Alkaline hydrolysis of *(6a)* gives bis(phenylthio)methane, the identity of which was established by comparison with an authentic sample [1].

Although one might discuss in some cases a reaction at the bulky, nondissociated carbenoid *(1)* [6], the observations 1.–5. described here suggest that the carbene *(2)* is present in the equilibrium mixture.

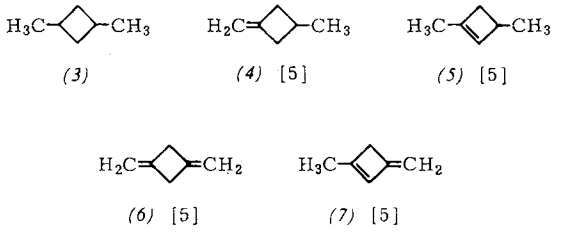
Synthesis of 1,3-Dimethylbicyclo[1.1.0]butane

By *K. Griesbaum* and *P. E. Butler* [*]

Dedicated to Professor R. Criegee on the occasion of his 65th birthday

1,3-Dimethylbicyclo[1.1.0]butane *(2)* was first synthesized in an approximately 3 % overall yield [1] by the tri-n-butyltin chloride catalysed reaction of diazomethane with 1,2-dimethylcyclopropane or with the latter's precursor 2-butyne [2]. We have been able to synthesize *(2)* in high yields by means of a new two-step synthesis. Addition of hydrogen bromide to allene and/or methylacetylene leads, in a one-step reaction, to a mixture of *cis*- and *trans*-1,3-dibromo-1,3-dimethyl cyclobutane *(1)* [3]. When this mixture *(1)* is added to a suspension of 2 % lithium amalgam in dioxane and then stirred for 48 h at room temperature 1,3-dimethylbicyclo-[1.1.0]butane is produced in over 85 % yield [4]. The compound *(2)* can be isolated by fractional distillation.



(1) *(2)*

The structural assignment of *(2)* is based on its NMR spectrum in dioxane (tetramethylsilane as internal standard, singlets at δ = 1.35 (CH_3), 1.04 (*exo*-CH_2), and 0.52 ppm (*endo*-CH_2), in the relative ratios 3:1:1, respectively) and on its time-of-flight mass spectrum (Table 1).

Analysis of the crude reaction mixture by capillary gas chromatography revealed the presence of three volatile by-

products having retention times very close to that of *(2)*. A combined analysis of the mixture by gas chromatography and time-of-flight mass spectroscopy in conjunction with an evaluation of the NMR spectra of samples in which the volatiles were substantially enriched suggested the structures *(3)* to *(7)*.

(3) *(4)* [5] *(5)* [5]

(6) [5] *(7)* [5]

Table 1. Volatile products from the debromination of 1,3-dibromo-1,3-dimethylcyclobutane with lithium amalgam.

Product	Retention time (min) [a]	Wt.-%	Molecular ion (*m/e*)	Characteristic fragment ions (*m/e*)
(3)	4.05	4.2	84 (C_6H_{12})	69 (M − CH_3); 56 (C_4H_8); 42 (C_3H_6)
(2)	4.10	87.5	82 (C_6H_{10})	81 (M − H); 67 (M − CH_3); 41 (C_3H_5)

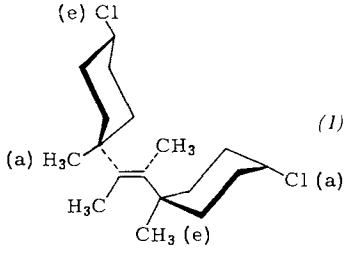
[4] Based on NMR analysis of the mixture before and after the reaction, using the solvent (dioxane) peak as internal standard. The result of this analysis (87 % of *(2)*) is remarkably close to that of the gas-chromatographic analysis (Table 1) which gave a value of 87.5 %.

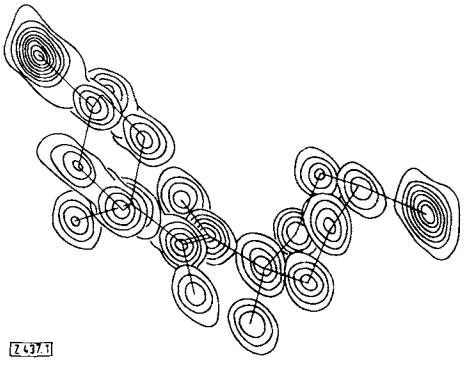


[5] The NMR spectrum of *(4)* showed a quintet for the CH_2 group at $\delta = 4.68$, downfield from TMS as internal standard. The NMR signal of the olefinic proton of *(5)* occurs at $\delta = 5.70$. The mixture of compounds *(6)* and *(7)* was identified by gas-chromatographic comparison with an authentic mixture.

Intramolecular Conformational Isomerism of the Cyclohexane Rings in Crystalline 2,3-Di-(*cis*-4-chloro-1-methylcyclohexyl)-*trans*-2-butene

By *D. Mootz* and *E. Mootz* [*]

2,3-Di-(*cis*-4-chloro-1-methylcyclohexyl)-*trans*-2-butene*(1)* [1] crystallizes from petroleum ether in a triclinic form having m.p. 97–98 °C.



The identity of the two cyclohexane rings that one would expect from the method of preparation is confirmed by X-ray analysis in respect of configuration and substitution. However, as shown by the electron density distribution (Figure), this identity does not apply to the conformation. Both rings are in the chair form, but in one ring the chlorine atom is equatorial and the methyl group axial and in the other ring this relation is reversed. The cause of this intramolecular conformational isomerism is to be sought in an energetically more favorable packing of the molecule into the crystal lattice.

(1)

The conformation of the bonds between the rings and the butene part of the molecule can also be determined from the electron density distribution; the methyl groups attached to the rings lie on the same side of the plane of the *trans*-butene group.

1719 independent structure amplitudes were collected for the structure determination. The reflection intensities (copper radiation, integrated Weissenberg photographs) were estimated visually.

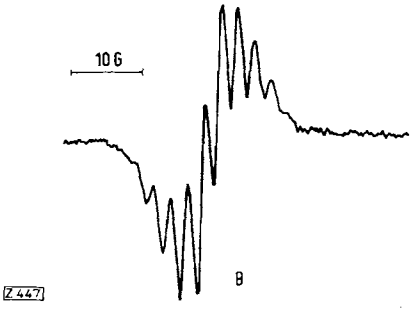
Stable Anion Radicals from 2,4,6-Triphenylphosphabenzene

By *K. Dimroth* and *F. W. Steuber* [*]

2,4,6-Triphenylphosphabenzene *(1)* gives stable radicals on oxidation [1] as well as on reduction. We here report three reduction stages, which are produced by the action of metallic potassium, as a potassium mirror, or of potassium/

sodium alloy on a solution of 2,4,6-triphenylphosphabenzene in tetrahydrofuran.



(1)

At first a solution is obtained that exhibits green fluorescence and whose ESR spectrum shows a doublet without fine structure; the phosphorus coupling constant a_P = 32.4 gauss (Fig. A).

If an equally concentrated benzene solution of the radical (a_P = 23.2 gauss) obtained by oxidation[1] is then added, the ESR signals of both radicals disappear. According to the UV spectrum, 2,4,6-triphenylphosphabenzene has been reformed.

On further action of potassium upon the radical anion (a_P = 32.4 gauss) in tetrahydrofuran the solution gradually becomes deep red and the ESR signal disappears. Further reaction with potassium then gives rise to a new signal (Fig. B).

Addition of 0.5 equivalent of a solution of unchanged 2,4,6-triphenylphosphabenzene then again gives a solution without an ESR signal, but addition of 2 equivalents leads to a solution with the above mentioned doublet in the ESR spectrum (a_P = 32.4 gauss).

Thus 2,4,6-triphenylphosphabenzene can take up three electrons stepwise. The reduction products can also release the electrons stepwise.

All three reduction stages (monoanion radical, non-radical dianion, and trianion radical) can be kept unchanged for several days if air is rigorously excluded.

Synthesis of a Germylsilylstannylamine

By *O. J. Scherer* and *D. Biller*[*]

As an adjunct to our studies of tri- and di-organometalylamines[1] we have achieved the first synthesis of an amine carrying the three carbon "homologues" silicon, germanium, and tin on the nitrogen atom.

On metalation with a solution of butyl-lithium in hexane at −78 °C, an ethereal solution of dimethyl[methyl(trimethylsilyl)amino]silylamine *(1)*[2] gives lithium dimethyl[methyl(trimethylsilyl)amino]silylamide *(2)*, which is readily soluble in this solvent mixture.

Treating this salt with chlorotrimethylgermane in ether at 0 °C gives a 50 % yield [calculated on *(1)*] of *N*-{dimethyl-[methyl(trimethylsilyl)amino]silyl}(trimethylgermyl)amine *(3)*. This amine is a clear, readily hydrolysable liquid of b.p. 45–47 °C/0.2 mm, and is readily soluble in proton-inactive organic solvents. Its ^{1}H–NMR spectrum (Varian A60, 60 MHz; 10 % solution in CCl_4; tetramethylsilane as internal standard) contains the expected signals with the calculated relative intensities τ = 9.95 [$(CH_3)_2Si$], 9.92 [$(CH_3)_3Si$], 9.74 (CH_3Ge), and 7.54 (CH_3N).

Further metalation of *(3)* with ethereal methyl-lithium solution at −78 °C gives lithium *N*-{dimethyl[methyl(trimethylsilyl)aminosilyl}(trimethylgermyl)amide *(4)*, which with chlorotrimethylstannane in ether at 0 °C affords *N*-{dimethyl[methyl(trimethylsilyl)aminosilyl}-*N*-(trimethylgermyl)(trimethylstannyl)amine *(5)*. The yield amounts to 60 % [calculated on *(3)*].

The amine *(5)* is a clear liquid that is readily hydrolysable and readily soluble in proton-inactive organic solvents, and can be distilled at 84–86 °C/0.2 mm without dismutation. Its composition follows from elemental analysis, molecular-weight determination, and ^{1}H–NMR spectrum (sharp signals at τ = 9.92 [$(CH_3)_3Si$ and $(CH_3)_2Si$], 9,73 (CH_3Sn), 9.69 (CH_3Ge), and 7.55 (CH_3N); $J_{117,119Sn-C-H}$ = 53.0 and 56.0 Hz; the relative intensities observed agree well with those calculated).

Synthesis of New Silazanes by Reaction of Silicon Tetrachloride with Ammonia [1]

By *U. Wannagat, P. Schmidt,* and *M. Schulze*[*]

If 2 mole equivalents of ammonia are passed, with stirring, into an ethereal solution of 1 mole equivalent of silicon tetrachloride at −78 °, a precipitate is formed having the approximate composition $Cl_4SiN_3H_9$ (A). It consists mainly of a mixture of hexachlorodisilazane *(1)*, oligomeric *(2)* and polymeric (–$SiCl_2$–NH–) units *(3)*, and ammonium chloride.

When (A) is heated at 80 °C/*ca.* 1 mm, the product *(1)* [2] first distils off. The oligomer *(2)* sublimes in low yield (*ca.* 3 %) onto a cold finger with the last portions of *(1)*.

Treating the residual $(Cl_2SiNH)_x/NH_4Cl$ mixture with HCl in ether leads to a further quantity of *(1)*, b.p. 174 °C, whose total yield may reach about 30 %.

Hexachlorotrisilazane *(2)* forms hexagonal platelets melting at 164 °C. The size of the ring is determined by mass spectroscopy and cryoscopy. The vibration spectra indicate a planar ring (symmetry D_{3h}) [3]. Dimethylamine converts *(2)* in high yield into hexakis(dimethylamino)cyclotrisilazane *(4)*, m.p. 94 °C, which contains the hitherto unknown Si_3N_9 skeleton. When the residue remaining after separation of *(1)* and *(2)* is treated with HBr in ether, surprisingly, octachlorotrisilazane *(5)*, b.p. 97 °C/1 mm, along with other products, is formed. Apparently the NH_4Cl present causes Cl/Br exchange in the primary products.

If the oligomeric portion of (A) is extracted with benzene and then treated with HBr in ether, 1,3-dibromotetrachlorodisilazane *(6)*, b.p. 57–58 °/2 mm, is formed.

The structures of the new compounds *(2)*, *(4)*, *(5)*, and *(6)* were proved by elemental analyses, determination of molecular weights, vibration spectra, and in some cases, NMR spectra.

Reactions of Hexachlorodisilazane [1]

By *U. Wannagat, P. Schmidt*, and *M. Schulze* [*]

Reactions of hexachlorodisilazane *(1)* have not been described previously. They can occur by exchange of a $SiCl_3$ group or by replacement of a Cl or H atom.

Treating *(1)* with trichloro(methyl)silane leads to a poor yield of pentachloro(methyl)disilazane *(2)*, b.p. 56–58 °C/10 mm. Yields are better if $(Cl_2Si{-}NH)_x$ is used instead of *(1)*.

The disilazane *(1)* is converted by dimethylamine into hexakis-(dimethylamino)disilazane *(3)*, b.p. 248 °C, in high yield. This product can be metalated by sodamide in benzene, giving sodium bis[tris(dimethylamino)silyl]amide *(4)*, m.p. *ca.* 160 °C (decomp.), which can be used to build up a tris-(silyl)amine with a Si_3N_{10} skeleton.

If *(1)* is treated with methyl-lithium in ether at −78 °C, a mixture of hexachloro-*N*-ethyldisilazane *(5)*, m.p. −14 °C, b.p. 205 °C, and *(7)* is formed. However butyl-lithium in petroleum ether at −78 °C converts *(1)* into lithium bis(trichlorosilyl)amide *(6)* in high yield.

The compound *(6)* is a white solid, moderately soluble in benzene but very hygroscopic and very reactive, and, according to its ν_{as}(SiNSi) stretching frequency (1135 cm^{-1}), has the greatest valence force constant of all SiN compounds known so far. When heated to 85 °C, compound *(6)* yields, without melting, decachloro-*N,N'*-bis(silyl)cyclodisilazane *(7)* almost quantitatively.

The size of the ring can be determined by mass spectroscopy and cryoscopy. The melting point (66 °C after repeated sublimation in a vacuum) is about 20 °C lower than that of a product (m.p. 84–86 °C) that was obtained from $SiCl_4$ and N_2 in a glow discharge [2]. The latter contains a Si:N:Cl ratio of 2:1:5 and corresponds to compound *(7)* in its cryoscopically determined molecular weight.

With silicon tetrafluoride at −78 °C compound *(6)* yields smoothly bis(trichlorosilyl)trifluorosilylamine *(8)*, b.p. 42 °C/15 mm. All attempts to prepare the $(Cl_3Si)_3N$ formed in a

glow discharge[2] analogously from silicon tetrachloride failed; even under mild conditions, only *(7)* was obtained.

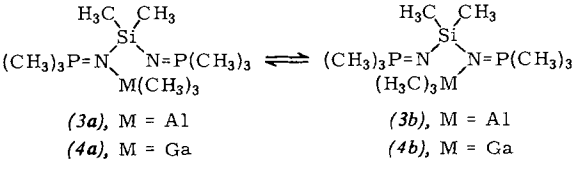
Coordination Compounds with Stationary and Oscillating Acceptors



By *H. Schmidbaur* and *W. Wolfsberger*[*]

If an acceptor molecule A with one free coordination position is confronted with a donor molecule containing two spatially proximate donor centers B[1], then the acceptor A may not form a bond to only one of the two donor positions B but may interact with both the basic centers alternately[2]. Bis-(trimethylphosphoranylideneamino)dimethyl silane *(1)* has now been found to be a bidentate ligand for which this phenomenon can be observed. The silane *(1)* is obtained from dimethylsilylene diazide and trimethylphosphine *via* the intermediate dimethyl(trimethylphosphoranylideneamino)silyl azide *(2)*. It forms stable 1:1 complexes *(3)* and *(4)* with trimethylaluminum and trimethylgallium, respectively.

The ^{1}H–NMR spectra of solutions of *(3)* and *(4)* in methylene dichloride or benzene at room temperature show only one signal each for the protons of the methyl groups attached to the silicon and to the metal atoms, and one doublet for the H_3C–P groups. When the temperature is lowered the $(CH_3)_3P$ doublet becomes broader and eventually splits to two doublets (see Table)[3].

Since the singlet nature of the $(CH_3)_2Si$ and $(CH_3)_3M$ signals is retained at all temperatures, this pheonomenon can be explained only by assuming a temperature-dependent exchange process in the sense *(3a/b)* and *(4a/b)*. The phenomenon is fully reversible and can be repeated *ad infinitum*. The activation energy of the interchange of positions can be estimated from the alteration in line widths and from the splitting temperatures as being 13.4 and 12.8 kcal/mole for *(3)* and *(4)*, respectively, in CH_2Cl_2. The values are solvent-dependent and are somewhat higher for benzene solutions[4].

(3a), M = Al *(3b)*, M = Al
(4a), M = Ga *(4b)*, M = Ga

It remains to decide whether the interchange of position of the metal atoms requires intermediate complete dissociation of the donor from the acceptor (within the solvent cage) or whether it can occur through a transition state containing pentacoordinated metal.

In contrast to *(3)* and *(4)*, the complex with trimethylindium *(5)* at temperatures down to –70 °C gives a temperature-independent NMR spectrum with one $(CH_3)_3P$ doublet only. Thus for this compound a fixed structure with a pentacoordinated metal atom or an extremely rapid exchange of positions can be considered. In the latter case the activation energy for the "jump" must be less than 8 to 9 kcal/mole. "Stationary" 1:1 complexes with tetracoordinated metal atoms are obtained from *(1)* and dimethylzinc or dimethylcadmium.

Preparation of (1):

$(CH_3)_3P$ (16.5 g) is added slowly from a cooled dropping funnel to $(CH_3)_2Si(N_3)_2$ (26.5 g) at room temperature. Reaction ensues immediately with evolution of nitrogen. Fractional distillation of the reaction mixture gives *(2)* (yield 33.3 g; 94 %). 33.2 g of this intermediate reacts with a further 16.5 g of $(CH_3)_3P$ in an autoclave at 110–130 °C to give *(1)*, which is purified by distillation (yield 40.1 g; 96 %).

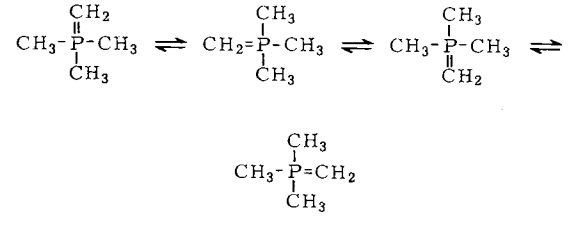
Trimethyl(methylene)phosphorane

By *H. Schmidbaur* and *W. Tronich*[*]

Trialkyl(alkylene)phosphoranes cannot be obtained by any of the synthetic procedures available for phosphorylides. Their properties are thus substantially unknown[1].



We have now synthesized pure trimethyl(methylene)phosphorane, which *Wittig* and *Rieber* had obtained as etheral solution as early as 1949 but were unable to isolate[2].

Our synthetic principle utilizes the notable readiness of formation of organosiloxanes to promote formation of the ylide. When trimethyl(trimethylsilylmethylene)phosphorane[3] is treated with silanols or alcohols such as trimethylsilanol or methanol, compound *(1)* is formed, even at 0 °C, in more than 90 % yield. The only by-products are hexamethyldisiloxane and methoxytrimethylsilane, respectively, which can readily be removed by distillation.

$$\begin{array}{l} \qquad\qquad + (CH_3)_3SiOH \qquad\qquad + (CHi_3(_3SiOSi(CH_3)_3 \\ (CH_3)_3Si{-}CH{=}P(CH_3)_3 \;\rightarrow\; (CH_3)_3P{=}CH_2 \\ \qquad\qquad + CH_3OH \qquad\quad (1) \qquad + (CH_3)_3SiOCH_3 \end{array}$$

Compound *(1)* can be distilled without decomposition at atmospheric pressure (b.p. 118–120 °C). It solidifies to colorless crystals (m.p. 14–15 °C) when cooled. *(1)* was shown cryoscopically to be monomeric in benzene solution. Decomposition with brown coloration occurs almost instantaneously on contact with oxygen or moisture.

The ^1H–NMR spectrum[4] of the pure compound *(1)* at room temperature shows well resolved doublets for the methyl and methylene protons (relative areas 9:2) at $\delta = -73$ Hz (CH_3P), $J(^1H{-}C{-}^{31}P) = 12.6$ Hz, and at $\delta = +45$ Hz (CH_2P), $J(^1H{-}C{-}^{31}P) = 6.9$ Hz. However, when the temperature is raised the signals become broader, resolution of the doublet becomes poor, and finally (> 100 °C) the two resonance signals merge to a singlet. This phenomenon may be reproduced repeatedly and can be interpreted only as the result of rapid proton exchange in *(1)*, whereby all 11 protons, and thus all four carbon atoms, are equilibrated at elevated temperatures:

On addition of a proton active species (*e.g.* a trace of methanol) the NMR equivalence of the methyl and methylene groups is brought about at room temperature by proton catalysis.

With hydrogen halides, compound *(1)* forms tetramethylphosphonium halides; with methyl iodide, ethyltrimethylphosphonium iodide is formed. On its addition to trimethylaluminum the zwitterionic compound *(2)* (m.p. 62 °C, b.p. 130–134 °C/1 mm) results; *(2)* is an isostere of bis(trimethylsilyl)methylene[5].

$$(1) + Al(CH_3)_3 \;\rightarrow\; \underset{(2)}{(CH_3)_3\overset{\oplus}{P}CH_2\overset{\ominus}{Al}(CH_3)_3}$$

Trimethylbis(trimethylsilyl)methylenephosphorane *(4)*[3] and *(1)* comproportionate to trimethyl(trimethylsilylmethylene)-phosphorane at 100 °C:

$$(CH_3)_3P{=}CH_2 + \underset{(4)}{[(CH_3)_3Si]_2C{=}P(CH_3)_3} \;\rightarrow\; 2\,(CH_3)_3Si{-}CH{=}P(CH_3)_3$$

Trimethylphosphine Imide: Synthesis and Reactions with Organometallic Compounds

By *H. Schmidbaur* and *G. Jonas* [*]

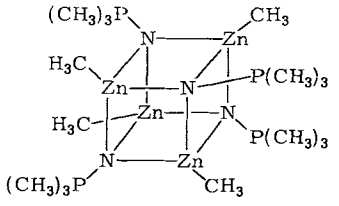
The few known methods for the preparation of triorganophosphine imides can be used only with difficulty[2], if at all[1], for the synthesis of trimethylphosphine imide *(2)*. Attempts to prepare other alkylmethylphosphine imides also met with serious difficulties[3].

We have now found that $(CH_3)_3P{=}NH$ *(2)* can be obtained in high yield by starting from trimethylphosphine and hydrogen azide; the reaction proceeding *via* the intermediate trimethylphosphine imidium azide *(1)*[4]. The imide *(2)* is formed, with sodium azide, on reaction of the azide *(1)* with sodium in liquid ammonia at −78 °C:

$$(CH_3)_3P + 2\,HN_3 \;\rightarrow\; N_2 + \underset{(1)}{[(CH_3)_3PNH_2]N_3}$$

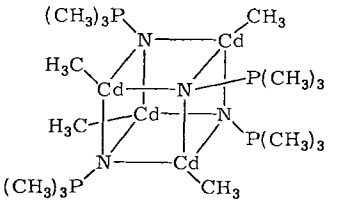
$$[(CH_3)_3PNH_2]N_3 + Na \;\rightarrow\; {}^1/_2\,H_2 + NaN_3 + \underset{(2)}{(CH_3)_3P{=}NH}$$

(2) is separated easily from NaN_3 by extraction with anhydrous benzene and can be purified (m.p. 59–60 °C) by sublimation (from 45 °C/1mm) or distillation (70 °C/1mm). It has the simple molecular weight in benzene (cryoscopy). The imide *(2)* is converted by an alkyl-lithium, in ether or in a hydrocarbon solvent, into lithium trimethylphosphine imide *(3)*, with loss of alkane:



$$(CH_3)_3P{=}NH + LiCH_3 \;\rightarrow\; CH_4 + \underset{(3)}{(CH_3)_3P{=}NLi}$$

This derivative is an involatile compound, very sparingly soluble in ether or benzene and, like its homologues of the type R_3PNLi[5], an extremely reactive component for the synthesis of new derivatives of trimethylphosphine imide.

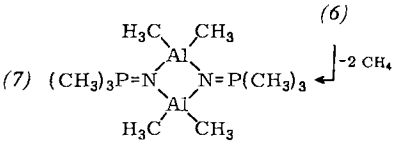


On treatment of *(2)* with dimethylzinc or dimethylcadmium in diethyl ether, methane is evolved and the organometallic derivative *(4)* or *(5)*, respectively, is formed:

$$\begin{array}{l} 4\,(CH_3)_2Zn + \qquad\qquad + [CH_3Zn{-}N{=}P(CH_3)_3]_4 \\ \qquad\qquad 4\,(CH_3)_3P{=}NH \;\rightarrow\; 4\,CH_4 \qquad (4) \\ 4\,(CH_3)_2Cd + \qquad\qquad + [CH_3Cd{-}N{=}P(CH_3)_3]_4 \\ \qquad\qquad\qquad\qquad\qquad\qquad (5) \end{array}$$

Determination of molecular weights and IR and NMR spectroscopic studies indicate a tetrameric cubanite structure for the inorganic skeleton of compounds *(4)* and *(5)*. This structure is confirmed by comparison of the X-ray diagrams of the homologous ethyl compounds with those of the isosteric methylzinc and methylcadmium triethylsilanolates for which the cubanite structure has meanwhile been proved[6, 7]. Compounds *(4)* and *(5)* decompose without melting at temperatures considerably above 200 °C; they can be sublimed in a high vacuum above 240 °C and 180 °C, respectively (with partial decomposition).

(4)



(5)

Trimethylaluminum and the imide *(2)* give first trimethylphosphine imidium trimethylaluminate *(6)* [which can be isolated; m.p. 44–46 °C (decomp.)] and then, on warming, form methane and dimeric trimethyl(dimethylalumino)phosphine imide *(7)*, which was recently prepared by two other methods[8]:

$$2\ (CH_3)_3P{=}NH + [Al(CH_3)_3]_2 \rightarrow 2\ (CH_3)_3P{=}\overset{\oplus}{N}H\text{-}\overset{\ominus}{Al}(CH_3)_3$$

(6)

(7)

The lithium imide *(3)* reacts with trimethyltin chloride with loss of LiCl, yielding trimethyltin trimethylphosphine imide[5], and with dimethylarsenic chloride to yield dimethylarsenic(III) trimethylphosphine imide *(8)*, b.p. 96–99 °C/12 mm, which is quaternized at the arsenic atom by methyl iodide, yielding *(9)*.

$$(CH_3)_3P{=}N\text{-}As(CH_3)_2 + CH_3I \rightarrow [(CH_3)_3P\cdots N\cdots As(CH_3)_3]^+I^-$$

(8) *(9)*

Compounds *(2)–(9)* are of interest because of their isoelectronic relationship to siloxane and silazane derivatives.

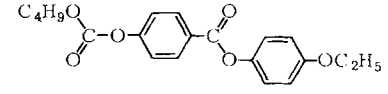
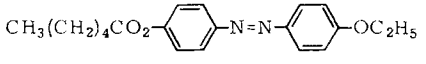
Low-Melting Nematic Phases for Determination of NMR Spectra of Orientated Molecules

By *H. Spiesecke* and *J. Bellion-Jourdan*[*]



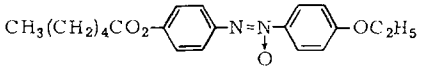
Measurement of the highly resolved nuclear magnetic resonance spectra of samples dissolved in the nematic phase of liquid crystals offers the possibility of determining the relative atomic distances, bond angles, anisotropy of chemical shift, sign of the scalar coupling constants, and intermolecular reactions of host and guest molecules[1].

The relatively high melting point (70 to 80 °C) of liquid crystals has hitherto, however, posed experimental difficulties. For instance, the orientation of the guest molecule in the nematic host substance – and thus the width of the NMR lines – is strongly temperature-dependent, which requires that the temperature around the sample be kept constant[2] (± *ca.* 0.1 °C). Further, at the temperatures necessary for transition into isotropic melts (>120 °C) low-boiling substances must be kept under too high a pressure. The spectra of simple gases, which would be most interesting on theoretical grounds, have therefore not been investigated experimentally because of these disadvantages.

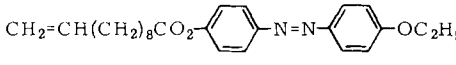


Components, 80:20 (mole-%)	M.p. (°C)	Clearing point (°C)
(1):*(2)*	41	108
(1):*(3)*	48	114
(1):*(4)*	39	91
(1):*(5)*	29	78
(1):*(6)*	44	114

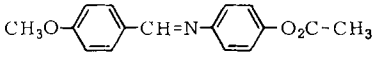
If, however, eutectic mixtures of liquid crystals (see Table) are used, the melting point can be lowered to 30 to 40 °C. Samples prepared in such host substances can be equilibrated in the usual thermostats and studied in the usual NMR sample head at 34 °C.



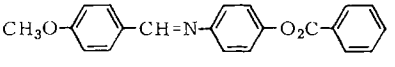
The following are suitable components for the eutectics[3]:



(1)

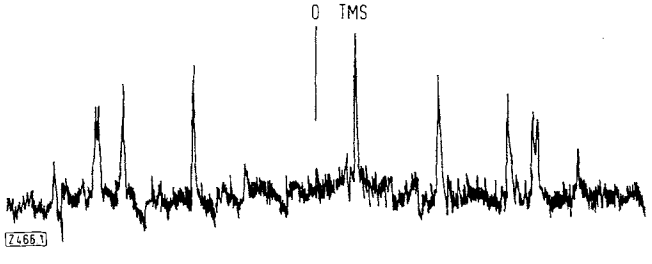


(2)



(3)

(4)



(5)

(6)

Except for the Schiff bases *(5)* and *(6)* all these compounds are relatively indifferent chemically, so that even reactive gases such as $H^{13}CN$, ethylene, and acetylene can be studied.

The 60 MHz spectrum of 20 mole-% of allene in a mixture of 60 mole-% of *(1)* and 20 mole-% of *(2)* (see Figure) may

serve as example (internal standard: tetramethylsilane). The rather high viscosity of the melt at 34 °C has no apparent disturbing effect on the line width (6 Hz for all lines). The

symmetrical spectrum contains five pairs of lines (distances from the centre: 901, 1414, 1591, 1613, 1922 Hz; TMS at 276 Hz).

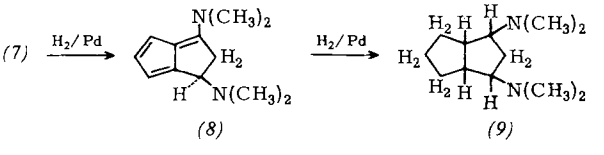
1,3-Bis(dimethylamino)pentalene

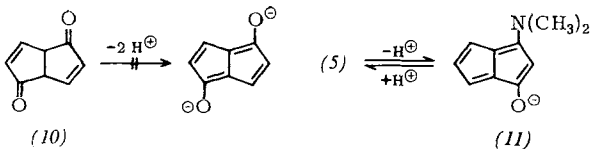
By *K. Hafner*, *K. F. Bangert*, and *V. Orfanos* [*]

Hitherto it has not been possible to synthesize pentalene or its simple derivatives[1]. Like fulvene, pentalene should be stabilized by electron donors in the 1- or 3-position[2]. Synthesis of the thermally stable 1,3-bis(dimethylamino)-pentalene *(7)* has now confirmed this hypothesis.



Cyclopentadienylsodium *(1)* in tetrahydrofuran reacts at 20 °C with the complex *(2)* (a yellow, viscous oil) obtained from tetra-*N*-methylmalonodiamide and triethyloxonium tetrafluoroborate, yielding the fulvene derivative *(3)* {yield 44 %; yellow leaflets of m.p. 135 °C; λ_{max} = 339 mμ (log ε = 4.45) in CH_3OH; $\nu_{C=O}$ = 1650 cm^{-1} (in $CHCl_3$); NMR spectrum (in $CDCl_3$): multiplet centered at τ = 3.75 (4 ring protons), singlets at τ = 6.30 (CH_2), 6.80 [$N(CH_3)_2$], and 7.05 as well as 7.15 [$N(CH_3)_2$]}. A by-product is compound *(4)*, which is separated from *(3)* by chromatography (neutral Al_2O_3 of activity III; eluent, ether/ethyl acetate) and forms red needles, decomposing above 140 °C (yield 2 %; λ_{max} = 219 mμ (log ε = 4.14), 285 (4.36), 399 (4.18), 455 (4.40) in CH_3OH; NMR spectrum in [D_6]dimethyl sulfoxide); multiplet centered at τ = 3.65 (7 ring protons), singlets at τ = 5.80 (CH_2) and 6.65 as well as 6.72 [$N(CH_3)_2$].

In boiling xylene (5 h) compound *(3)* loses dimethylamine, forming 3-(dimethylamino)-1(2*H*)pentalenone *(5)* in 63 % yield. This forms yellow needles of m.p. 225 °C and has λ_{max} = 247 mμ (log ε = 4.43), 371 (4.29) in CH_3OH, $\nu_{C=O}$ = 1675 cm^{-1} (in nujol), and an NMR spectrum (in [D_5]-pyridine)[3] with multiplets centered at τ = 3.13 (H-4, H-6) and 3.52 (H-5), and singlets at τ = 6.58 (CH_2) and 6.91 as well as 7.03 [$N(CH_2)_2$]. With dimethylammonium perchlorate in CH_2Cl_2/CH_3OH (3:1 v/v), compound *(5)* affords the immonium perchlorate *(6)* (yield 95 %) as yellow needles (from CH_3CN), decomp. > 150 °C, λ_{max} = 253 mμ (log ε = 4.47), 260 (4.48), 359 (4.11), 3.97 (4.30) in CH_3CN, NMR spectrum (in [D_6]dimethyl sulfoxide) 3 singlets at τ = 3.04 (3 olefinic ring protons), 5.43 (CH_2), and 6.50 [2 $N(CH_3)_2$].



Deprotonation of *(6)* by a strong base (*e.g.* isopropylmagnesium chloride) in ether leads to compound *(7)*, which is purified by sublimation in a high vacuum at 110 °C, or by recrystallization from acetone. This compound is obtained in 88 % yield as dark blue crystals of m.p. 163 °C (decomp.). Its UV spectrum [λ_{max} = 236 mμ (log ε = 4.21), 329 (4.42), 384 (4.04), 618 (2.56) in CH_2Cl_2] resembles that of hexaphenylpentalene[1] and agrees satisfactorily with the results of an SCF–CI calculation[4]. The NMR spectrum (in [D_6]-acetone) proves the structure of *(7)*, showing, besides the A_2B system of the unsubstituted five-membered ring [doublet centered at τ = 4.31 (H-4, H-6), triplet centered at τ = 4.66 (H-5, J_{AB} = 3.4 Hz)], a singlet for the protons of two equivalent dimethylamino groups at τ = 6.92, as well as a singlet shifted to high field (τ = 7.20) for the proton on C-2 (β-position of the quasidouble enamine system).

Compound *(7)* is stable towards atmospheric oxygen for several hours at 20 °C and dissolves in polar aprotic solvents to give deep blue solutions. It reacts with protic acids as an enamine, with protonation on C-2, regenerating *(6)*. Catalytic hydrogenation (20 °C, 760 mm, H/Pd) leads to absorption of one mol. equivalent of H_2 and formation of *(8)*, which is also obtained by reduction of *(6)* with $NaBH_4$ in H_2O and forms yellowish leaflets of m.p. 72 °C, λ_{max} = 319 mμ (log ε = 4.39) in n-hexane; its NMR spectrum (in $CDCl_3$)

has 3 multiplets centered at τ = 3.39 (H-5), 3.89 (H-4, H-6), 5.82 (H-1), singlets at τ = 6.76 and 6.81 [$N(CH_3)_2$ on C-3], a multiplet centered at τ = 6.92 (CH_2), and a singlet at τ = 7.72 [$N(CH_3)_2$ on C-1]. Further hydrogenation of *(8)*, which requires three moles of H_2, affords *(9)* as a colorless oil.

Whereas 1,4-pentalenedione *(10)* is not enolized in the presence of strong bases[5], compound *(5)* is readily converted by potassium t-butoxide in t-butyl alcohol into the blue enolate *(11)*, whose UV spectrum resembles as that of *(7)*. Hydrolysis of *(11)* regenerates *(5)*.

1,5-Cyclooctadienenickel Bromide and Iodide

By *L. Porri, G. Vitulli*, and *M. C. Gallazzi*[*]

We have prepared two new nickel complexes, namely, 1,5-cyclooctadienenickel bromide, $C_8H_{12}NiBr$, and iodide, $C_8H_{12}NiI$. A π-allylnickel halide is treated with 1,5-cyclooctadiene (20- to 30-fold excess) in n-heptane in the presence of norbornene (slight excess) at room temperature. The complex separates as well-formed crystals two to three hours after the beginning of the reaction, the yield being *ca.* 75 % after 15 hours.

The complex $C_8H_{12}NiI$ can also be obtained (about 80 % yield) directly by heating a solution of π-allylnickel iodide in 1,5-cyclooctadiene to *ca.* 80 °C and then slowly cooling the mixture. The less stable bromide could not be obtained in this way.

The two cyclooctadienenickel halides are very sensitive to air. They dissolve slightly (*ca.* 1.5 wt.-%) in cyclooctadiene and these solutions are stable in absence of oxygen. Both compounds dissolve in benzene, tetrahydrofuran, or ethanol; these solutions, however, decompose rapidly, even under nitrogen, with formation of metallic nickel, nickel halide, and 1,5-cyclooctadiene, but they are stable if small amounts (2–3 %) of free cyclooctadiene are added.

There is no band at 1667 or 1486 cm^{-1} in the IR spectrum of either compound, which indicates that both double bonds of the cyclooctadiene are coordinated to the nickel atom.

The magnetic moments of the solid complexes could not be determined because of the low stability. However, reaction with triphenylphosphine in benzene at room temperature gave the known[1] complexes $(C_6H_5P)_3NiX$, whose magnetic moments (*ca.* 1.9 B.M. for the bromide, *ca.* 1.98 B.M. for the iodide) correspond to an unpaired electron; the presence of nickel(I) in these complexes is thus indicated.

The $(C_8H_{12})NiX$ complexes react readily, even at room temperature, with benzonitrile, acrylonitrile, quinones, or esters of unsaturated carboxylic acids, with formation of new complexes in which the cyclooctadiene is replaced by another ligand. The $(C_8H_{12})NiX$ complexes catalyse polymerisation of butadiene, allene, or acetylene to linear polymers[2].

Radical Formation on Heating of Trityl-aluminum or -boron Compounds

By *H. Hoberg* and *E. Ziegler*[*]

Trityl-aluminum and -boron derivatives are accessible from the corresponding chlorides and triphenylmethylsodium in ether[**]:

$$X_2MCl + (C_6H_5)_3CNa \rightarrow X_2M{-}C(C_6H_5)_3 + NaCl$$

M = Al or B; X = Cl, alkyl, or phenyl

Diphenyltritylaluminum, $(C_6H_5)_2Al{-}C(C_6H_5)_3$, m.p. 205 °C (decomp.), can also be obtained by the action of diphenyldiazomethane on triphenylaluminum in anisole at 20 °C:

$$(C_6H_5)_2CN_2 + (C_6H_5)_3Al \rightarrow (C_6H_5)_2Al{-}C(C_6H_5)_3 + N_2$$

Like the central C–C bond of hexaphenylethane, the $M{-}C_{(trityl)}$ bond of trityl-aluminum and -boron compounds readily undergoes homolysis. For colorless diphenyltritylaluminum, this homolysis, which occurs at 130 °C in the solid state, is demonstrated by an intense yellow coloration and by development of the ESR signal of triphenylmethyl. Also, on pyrolysis in an aliphatic or aromatic hydrocarbon, aluminum separates after several hours' heating at 130 °C; deposition of aluminum is observed only above 240 °C for trialkylaluminums[1].

$$3\ X_2Al{-}C(C_6H_5)_3 \rightarrow [3\ X_2Al\bullet] + (C_6H_5)_3C\bullet \quad ([3\ X_2Al\bullet] \rightarrow 2\ AlX_3 + Al)$$

The aluminum radical can be trapped by a primary or secondary amine, the separation of aluminum being thus prevented.

$$R_2Al{-}C(C_6H_5)_3 + R^1_2NH \rightarrow R_2Al{-}NR^1_2 + (C_6H_5)_3CH$$

If pyrolysis is effected in the presence of pyridine bases[2], colored solutions containing radicals with Al–N bonds are formed whose ESR spectra (20 °C) are no longer identical with that of triphenylmethyl [the trityl radical reacts with the solvent at the reaction temperature (130 °C), yielding $(C_6H_5)_3CH$]. The hyperfine structure of these spectra is so little developed that the number and type of the nuclei (H, N, Al) concerned in the splitting cannot be determined. On pyrolysis of tritylaluminum dichloride in pyridine a deep blue solution is obtained whose ESR spectrum shows a hyperfine structure of 57 lines; the same spectrum develops on dehalogenation of $AlCl_3$ with sodium or on cathodic reduction in pyridine[3].

Pyrolysis of dialkyltritylboron in quinoline or isoquinoline also affords colored solutions containing radicals with B–N bonds. The ESR spectra show resolution into 10 equidistant HFS lines, with a relative separation of 4.10 or 4.17 gauss, that is interpreted as due to coupling of the electrons with

three equivalent ^{11}B nuclei[4]. Pyrolysis of diethyltritylboron in the presence of pyridine leads to a radical whose ESR signal, unlike that of the radical produced by dehalogenation[4], shows distinct 1:1 splitting of *ca.* 12.6 gauss. Homolytic fission of trityl-aluminum and -boron compounds can also be induced by photolysis, even at room temperature[5]; on irradiation of tritylaluminum dichloride in the presence of pyridine the 57-line hyperfine structure is again observed in the ESR spectrum.

A New Indolenine Synthesis

By *B. Zeeh*[*]

Müller and *Zeeh*[1] recently reported the formation of *t*-butylamides of cycloalkenylglyoxylic acids on treatment of cycloaliphatic ketones with t-butyl isocyanide. A Lewis acid such as boron trifluoride is required as catalyst.

Surprisingly this reaction takes a different course with aromatic isocyanides: the indolenine skeleton can be built in one step from phenyl isocyanide and cycloaliphatic ketones.

When a mixture of cyclohexanone and phenyl isocyanide is allowed to react in the presence of boron trifluoride for 1 h at 0 °C, subsequent chromatography (aluminum oxide, petroleum ether/benzene eluant) leads to isolation of spiro-[indolenine-3,1′-cyclohexane]-2-carboxanilide *(1)* in 40 % yield [m.p. 148–149 °C; λ_{max} = 228 (ε = 14600), 315 nm (12200) in ethanol].

(1), n = 5
(2), n = 6

Spiro[indolenine - 3,1′ - cycloheptane]-2-carboxanilide *(2)* (yield 30 %; m.p. 94–95 °C) is obtained analogously from cycloheptanone.

The IR spectra (in KBr) of *(1)* and *(2)* show characteristic bands at 3360 (NH), 1698 (C=N), 1680, 1603, and 1530 cm^{-1} (CO–NH). In the NMR spectra (in $CDCl_3$) signals are observed for 9 aromatic protons and respectively 10 or 12 aliphatic protons as multiplets, as well as the NH signal (τ = 0.53) as a singlet. Important structural indications are also provided by the mass spectrum (base peak: M–$CONHC_6H_5$).

The C=N double bond in *(1)* and *(2)* can be reduced either with $LiAlH_4$ or catalytically with platinum/hydrogen. The hydrogenation products [m.p. 132–133 °C from *(1)*; m.p. 152–153 °C from *(2)*] arise in almost quantitative yield. Their NMR spectra show the newly formed –NH–CH group as two doublets between τ = 5.7 and 6.0 (J = 5 Hz). The proton attached to the nitrogen undergoes exchange in D_2O, the doublet being thereby converted into a singlet (τ = 5.98).

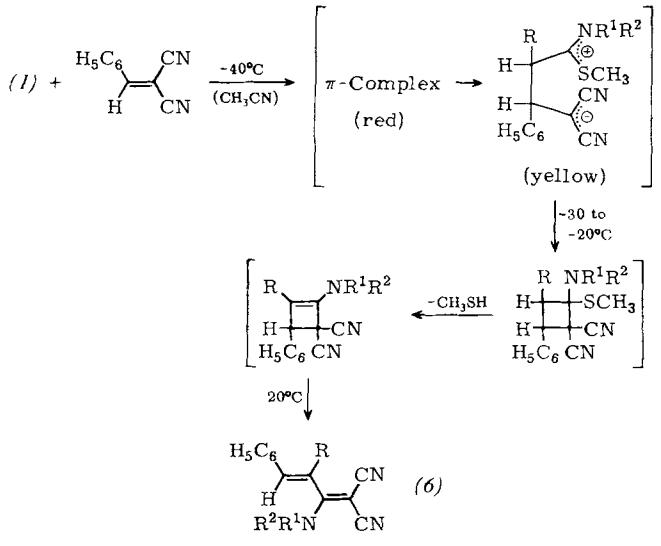
Stable 1,4-Dipolar Compounds from Ketene Acetals and Methylenemalononitriles[1]

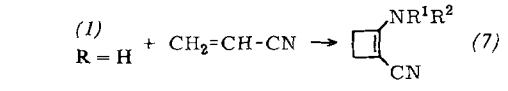
By *R. Gompper, W. Elser,* and *H.-J. Müller*[*]

Reaction of electron-rich with electron-deficient olefins gives 1:1 and 1:2 or 2:1 cyclo adducts (four- or six-membered rings), mechanistic alternatives being a synchronous and a two-stage process[2]. On treating ketene *S,N*-acetals *(1)* and ketene aminals *(2)* with methylenemalononitriles *(3)* we have been able to isolate the 1,4-dipolar compounds *(4)* and *(5)* for the first time, and to investigate their properties.



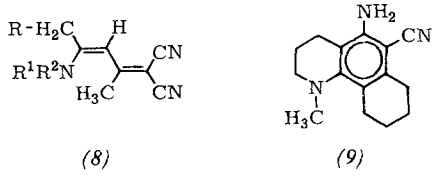
(1), X = SCH_3 *(3)*
(2), X = $N(CH_3)_2$, R = CH_3

(4), X = SCH_3
(5), X = $N(CH_3)_2$, R = CH_3



R = H, CH_3, C_2H_5, n-C_3H_7, or C_6H_5
$R^1 + R^2 = (CH_2)_{2-4}$
R^3 = C_6H_5, *p*-O_2N–C_6H_4, CF_3, or CN
R^4 = H, CF_3, or CN

On treatment of solutions of tetracyanoethylene in acetonitrile at *ca.* –50 °C with *(1)* or *(2)* there is immediate deep blue coloration (formation of π-complexes). When the temperature is raised to –20 to 10 °C, the blue color vanishes and yellow compounds crystallize which can be filtered off at room temperature and purified by washing with ether. Elemental analyses indicate that they are 1:1 adducts. Their structure as 1,4-dipolar compounds *(4)* and *(5)*, $R^3 = R^4$ = CN, follows from the IR spectra (in Hostaflon oil; νC≡N 2110, 2170 cm^{-1}; νC=N 1580–1610 cm^{-1}) and from the NMR spectra (in liquid SO_2)[**]. Particular stability is exhibited by the orange-red and the yellow 1,4-dipolar compounds resulting from *(1)* and *p*-nitrobenzylidene- and hexafluoroisopropylidenemalononitrile, respectively. In contrast to other 1,4-dipolar compounds, which can be preserved only at –20 to –40 °C, these compounds can be kept for a considerable time at room temperature; some of them begin to decompose only at 60 to 80 °C.



The yellow, crystalline 1,4-dipolar compounds formed from *(1)* and benzylidenemalononitrile are so unstable that, with one exception [*(4)*, R = CH_3, $R^1 + R^2 = (CH_2)_4$, $R^3 = C_6H_5$, R^4 = H], they react further to give butadiene derivatives *(6)* when attempts are made to isolate them.

We were not able to identify a 1,4-dipolar compound after reaction of *(1)* with acrylonitrile; the cyclobutene derivatives *(7)* were isolated.

Reaction of isopropylidenemalononitrile *(3)*, $R^3 = R^4 = CH_3$, with *(1)* does not give a 1,4-dipolar compound, but because of the activated methyl groups affords the butadiene de-

(8) *(9)*

rivatives *(8)*. Cyclohexylidenemalononitrile and *(1)*, R = CH_3, $R^1 + R^2 = (CH_2)_3$, afford the octahydrobenzo[*h*]-quinoline *(9)*, m.p. 119–120 °, in an analogous fashion.

PF_2 Bridges in Metal Complexes [1]

By *Th. Kruck* and *W. Lang* [*]

In a search for polynuclear metal complexes containing PF_n bridging groups ($n = 1$ to 3), we have established formation of the first trifluorophosphinemetal complex with PF_2 bridges by studying the cobalt(II) iodide/PF_3 (pressure) system, which has already been investigated extensively [2]. Bis(μ-difluorophosphino)hexakis(trifluorophosphine)dicobalt *(1)* was isolated and characterized; it is diamagnetic, has the noble-gas configuration, and is the first representative of a series of type $[(PF_3)_nM(PF_2)]_2$ that is to be expected especially with transition metals of odd atomic number.

It is formed in about 30 % yield, along with another binuclear complex, on reaction of anhydrous CoI_2 and Cu powder (molar ratio 1:10) with trifluorophosphine under 400 atm at temperatures above 170 °C (15 h). The oily, deep red liquid solidifies at 25 °C and can be distilled at *ca.* 50 °C/10^{-3} mm. It is soluble in polar and non-polar organic solvents and is stable for some days towards atmospheric oxygen. The thermal stability is noteworthy, for in a sealed tube the compound decomposes, with discoloration, only at temperatures above 200 °C.

The IR spectrum of the substance in pentane solution contains P–F stretching vibrations at 909 (m, sh), 901 (vs), 858 (w,sh), and 855 cm^{-1} (s) [3], *i.e.* in the region that has up to now been regarded as characteristic of terminal PF_3 groups. Although this does not establish the presence of PF_2 bridges, their existence has been proved, in particular, by mass spectroscopy and NMR studies [4].

The mass spectrum (Atlas-CH-4, 15–70 eV) indicates a molecular weight of 784 which, together with the analytical data (Co:P:F = 2:7.95:22.4), proves the molecular formula $Co_2P_8F_{22}$. Further, it was found that on excitation by electrons of not too high an energy, six PF_3 groups are lost stepwise, with formation of the ions $[(PF_3)_{6-n}Co_2(PF_2)_2]^{\oplus}$ ($n = 0$ to 6). The high relative intensity of a peak at 256 mass units also shows the notable stability of the $Co_2(PF_2)_2$ group.

In the ^{19}F–NMR spectrum (Spectrospin-KIS-2, 60 MHz, pure substance at 26 °C, CCl_3F as external standard) two groups of signals appear; one of these ($\delta = +13.2$ ppm) lies in a region characteristic of terminal PF_3 groups of trifluorophosphine-metal complexes, but the other is shifted by a further 33.8 ppm to higher field strengths. On account of their position and intensity the signals of the second group are assigned to F atoms of two PF_2 bridges. Studies of the hyperfine structure are in agreement with this, for they show that all the ^{19}F signals of the bridge fluorine atoms are split into septets owing to coupling with the P nuclei of the six terminal PF_3 ligands. The coupling constant $^3J_{P-F}$, (28 Hz) is of the order of magnitude found also for other systems; furthermore, the spectrum affords coupling constants $^1J_{P-F}$ for the terminal PF_3 groups of *ca.* 1330 Hz and for the PF_2 bridges of *ca.* 1230 Hz.

All these results indicate a molecule of structure *(1)* with an almost planar arrangement of the four-membered $Co(PF_2)_2Co$ ring. No certain information can yet be given about the position of the PF_3 ligands, but the low number of the P–F stretching frequencies indicates a high symmetry for the overall structure.

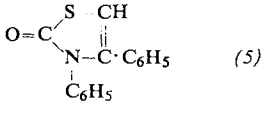
2-Imino-1,3-oxathioles [1]

By *G. Ottmann* and *H. Hooks jr.* [*]

N-Substituted *S*-chloroisothiocarbamoyl chlorides *(1)*, which are obtained by careful chlorination of isothiocyanates [3], react with aryl alkyl ketones to form derivatives of the unknown class of 2-imino-1,3-oxathioles *(3)*. In the case of



(1) *(2)* *(4)* *(3)*

R	R^1	R^2	*(3)* M.p. (°C)	*(3)* Yield [5] (%)	*(3)* Hydrochloride m.p. (°C)
C_6H_5	H	C_6H_5	137–138	52	210–212
C_6H_5	CH_3	C_6H_5	143–144	48	188–189
C_6H_5	H	p-$CH_3OC_6H_4$	159–160	59	193–194
C_6H_5	H	3.4-Cl_2-C_6H_3	169.5–170.5	40	192–194
C_4H_9	H	C_6H_5	60.5–61	64	143.5–144.5
C_4H_9	CH_3	C_6H_5	31.5–32	34	153–154

N-aryl substituted *S*-chloroisothiocarbamoyl chlorides the reaction proceeds directly, with hydrogen chloride elimination, to the hydrochlorides of *(3)*, not permitting isolation of a stable reaction intermediate [4]. In some instances, the reaction is accompanied by formation of substantial amounts of *S*-(2-chlorovinyl)thiocarbamates, *e.g.* *N*-phenyl-*S*-[2-chloro-2-(4-methoxyphenyl)vinyl] thiocarbamate *(4)* from *(1)* (R = C_6H_5) and 4-methoxyacetophenone. The simultaneous formation of *(3)* and *(4)* can be explained by elimination of hydrogen chloride from the hypothetical intermediate *(2)*. In the case of *(3)*, a simple β-elimination with a rupture of the C–Cl bond occurs, while HCl-formation and cleavage of the C(4)-O bond accounts for the formation of *(4)*.

The hydrochlorides of *(3)* are readily converted to the free bases by triethylamine under anhydrous conditions, or simply with water. Treatment of the hydrochlorides of *(3)* with alcohols, however, affects structural rearrangement and affords, besides sulfur-free by-products (mainly aniline hydrochloride), 1,3-thiazolin-2-ones, *e.g.* 3,4-diphenyl-1,3-thiazolin-2-one *(5)*, m.p. 121.5–123 °C from 5-phenyl-2-phenylimino-1,3-oxathiole hydrochloride and methanol.

(5)

The structures of compounds *(3)* are supported by elemental analysis, NMR, IR, and mass spectroscopy. The structure of *(4)* is evidenced by hydrolytic degradation to 2-chloro-2-(4-methoxyphenyl)vinylmercaptane *(6)*, m.p. 87.5-88 °C

$HSCH{=}C(Cl)C_6H_4OCH_3$

(6)

Experimental:

103 g of *S*-chloro-*N*-phenylisothiocarbamoyl chloride is added dropwise to a stirred solution of 75 g of acetophenone in 150 ml of ether at 40–45 °C. The reaction is accompanied by heavy HCl-evolution. The reaction mixture is stirred overnight, and the precipitate is then separated, washed with ether/pentane, and dried. Yield: 80 g (55 %) of 5-phenyl-2-phenylimino-1,3-oxathiole hydrochloride.

a) A solution of 17 g of triethylamine in 75 ml of ether is added to a stirred slurry of 47 g of the hydrochloride in 1000 ml ether over a period of 45 min at 10–15 °C. After 4 h at room temperature, the solid is separated and extracted with ether in a Soxhlet apparatus. 5-Phenyl-2-phenylimino-1,3-oxathiole is recovered from both ether solutions and recrystallized from methanol. Yield: 37 g (90 %).

b) 11 g of the above hydrochloride is added to 100 ml of water (~60 °C) in several portions with vigorous agitation. The precipitate of 5-phenyl-2-phenylimino-1,3-oxathiole is recrystallized from methanol.

c) 22 g of the above hydrochloride is mixed with 50 ml of methanol and slowly heated. At about 50 °C an exothermic reaction ensues and a clear solution is formed. The methanol is evaporated and the oily portion of the residue separated from aniline hydrochloride by extraction with ether. The ether was removed, and the remaining oil allowed to crystallize over several days. The crystals (8.5 g) are freed from contaminating oil and recrystallized from methanol and then from cyclohexane yielding 3.2 g of pure 3,4-diphenyl-1,3-thiazolin-2-one *(5)*.

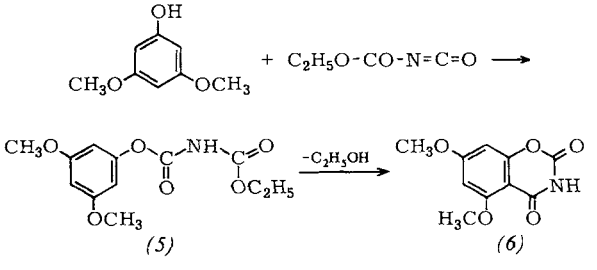
Reaction of Isocyanato- and Isothiocyanatoformates with Activated Phenols [1]

By *F. Effenberger* and *R. Niess* [*]

3,5-Bis(dialkylamino)phenols *(1)* [2], which are accessible from phloroglucinol and secondary amines, contain positive electromeric substituents in *meta*-position to one another, the effect of which is markedly displayed in an increased reactivity of the ring-carbon atoms towards electrophilic reagents.

Thus they react with isocyanatoformates *(2)*, X = O, and isothiocyanatoformates *(2)*, X = S, even at room temperature with exclusive *C*-acylation that yields the compounds *(3)* and *(3a)*, respectively. Acylation in the *para*-position could not be detected by ^1H–NMR spectroscopy.

(1) *(2)* *(3)* *(4)* *(3a)*



The compounds *(1)* and *(2)* were dissolved in anhydrous ether and mixed in the molar ratio 1:1 at 20 °C. After 2h at this temperature, the solution was cooled to −20 °C and after *ca.* 12h the crystals that had separated were collected by filtration.

R, R–N–	R¹	X	(3a) Yield (%)	(3a) M.p. (°C)	(4) Yield (%)	(4) M.p.
Piperidino-	CH_3	O	77.5	156–157	94	247–248
Piperidino-	C_2H_5	O	80	155–157	84.5	247–248
Piperidino-	C_2H_5	S	87	*ca.* 148	87	220–221
Dimethylamino-	CH_3	O	100	125–127	80	223–224
Dimethylamino-	C_2H_5	S	87.5	110–111	100	221–223

Whereas the aminophenols *(1)* are in the benzenoid form, spectroscopic results indicate that the acylation products have the tautomeric quinonemethide structure *(3a)*. According to the results of *Gompper et al.*[3] quinonemethides with ω,ω-hetero-substituents are relatively stable. It is possible that hydrogen bridges contribute further to the stabilization of *(3a)*.

Heating the acylation products *(3a)* above their melting points causes intramolecular removal of alcohol and formation of 1,3-oxazetidin-2-ones *(4)*, X = O, and 1,3-thiazetidin-2-ones *(4)*, X = S, whose structures are proved by elemental analysis, molecular-weight determination, and ^{1}H–NMR and UV spectra.

In contrast to the behavior of the bis(dialkylamino)phenols *(1)*, reaction of the less activated phloroglucinol dimethyl ether with *(2)*, X = O, R′ = C_2H_5, causes exclusive *O*-acylation with formation of the urethane *(5)*, which, when heated above the melting point, also loses alcohol and gives the benzoxazine derivative *(6)*.

Other phenols also react similarly to yield benzoxazines *(6)*.

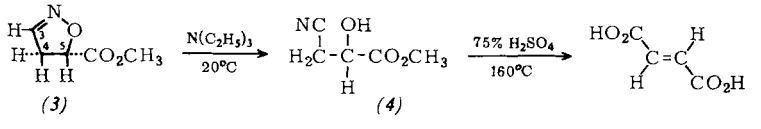
1,3-Dipolar Cycloadditions of Fulminic Acid

By *R. Huisgen* and *M. Christl*[*]

Quilico et al.[1,2] described cycloadditions of fulminic acid *(2)*, which was liberated from sodium fulminate by 20 % sulfuric acid or from formohydroximoyl iodide *(1)* by a base.

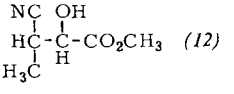


The rapid polymerization of *(2)* is responsible for the low yields of adducts. For instance, with acetylene only 3 % of isoxazole was obtained but 20 % of isoxazole-3-aldoxime (the adduct of dimeric fulminic acid)[1].

We converted mercuric fulminate into pure crystalline formohydroximoyl iodide *(1)* in 60 % yield with HI/KI without the detour through the sodium salt[3]. The fulminic acid is liberated by adding one equivalent of triethylamine dropwise and slowly to an ice-cooled, stirred solution of *(1)* in an excess of the dipolarophile (sometimes after dilution with ether). The low stationary concentration of *(2)* provides optimal conditions for the formation of 2-isoxazolines or isoxazoles from olefinic or acetylenic dipolarophiles, respectively.

(1) *(2)*

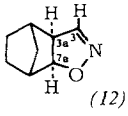
Methyl acrylate gives a 90 % yield of methyl 2-isoxazoline-5-carboxylate *(3)*, which is purified by high-vacuum distillation (b.p. 70–80 °C/0.001 mm) [NMR ($CDCl_3$): τ = 2.72 (H-3,t), J_{34} = 1.7 Hz; τ = 6.67 (H-4, q), J_{45} = 9.1 Hz; τ = 5.00 (H-5, t); τ = 6.20 (OCH_3,s)]. An excess of triethylamine converts *(3)* quantitatively into methyl 3-cyano-2-hydroxypropionate *(4)* [NMR ($CDCl_3$): τ = 5.48 (H-2, t), J_{23} = 5.5 Hz; τ = 6.12 (OCH_3, s); τ = 6.37 (OH, s, broad); τ = 7.12 (H-3, d): IR (film), 2248 (C≡N), 3400 cm^{-1} (OH)].



(3) *(4)*

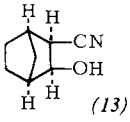
Methyl crotonate and *(2)* afford the adducts *(5)* and *(6)* in the proportions 62:38 (yield 36 %) and the 2:1 adducts *(7)* and *(8)* in the proportions 45:55 (31 % yield). Thus cycloaddition of *(2)* to give *(5)* and *(6)* is in competition with dimerization of *(2)* to hydroxyiminoacetonitrile oxide which combines with the dipolarophile to give *(7)* and *(8)*. Benzonitrile oxide and methyl crotonate provide *(9)* and *(10)* in the proportions 34:66[4].

(5), R = H *(6)*, R = H
(7), R = -CH=NOH *(8)*, R = -CH=NOH
(9), R = C_6H_5 *(10)*, R = C_6H_5



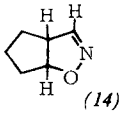
(12)

The adducts *(5)* and *(6)* can be separated by thin-layer chromatography (with benzene on silica gel PF_{254} + 366). NMR spectra indicate the structures. Ring opening of *(5)* to give *(11)*, catalysed by triethylamine, occurs even in the cold. NMR spectrum of *(11)* ($CDCl_3$): τ = 5.74 (H-2, d), J_{23} = 3.5 Hz; τ = 6.81 (H-3, octuplet); τ = 8.67 (4-CH_3, d), J_{34} = 7.3 Hz; τ = 6.11 (OCH_3,s); τ = 6.28 (OH, s, broad). IR (film): 2270 (C≡N), 3400 cm^{-1} (OH). The 2:1 adducts *(7)* and *(8)*, which distil only at 120–150 °C (bath)/0.001 mm, were analysed in admixture by NMR spectroscopy.



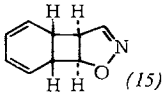
Methyl cinnamate affords analogously 1:1 (23 % yield) and 2:1 adducts (33 % yield). The 1:1 adducts contain the 4- and

5-carboxylic esters in the proportions 76:24 (70:30 on addition of benzonitrile oxide to cinnamic ester[4]).

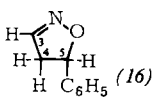


By virtue of the angular strain of its double bond, norbornene reacts with *(2)* to give 76 % of the adduct *(12)*, b.p. 65–75 °C/0.001 mm [NMR ($CDCl_3$): τ = 3.08 (H-3, d), J_{33a} = 1 Hz; τ = 6.85 (H-3a, q), J_{3a7a} = 8.2 Hz; τ = 5.61 (H-7a, d). The absence of coupling of H-3a and H-7a with the bridgehead hydrogen proves the *exo*-addition. Triethylamine converts *(12)* into the nitrile *(13)* [m.p. 35–38 °C; IR: 2270 (C≡N), 3450 cm^{-1} (OH)] in 93 % yield, but only after boiling for 12 h.

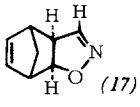
(12)



(13)



(14)

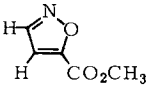


Cyclopentene and *(2)* give *(14)* in 8 % yield (b.p. 95–110 °C (bath)/10 mm). The adduct *(15)* of cyclooctatetraene, also isolated in 8 % yield, is derived from the bicyclo[4.2.0]-octadiene skeleton, as is shown by the ratio of vinyl-H to

(15)

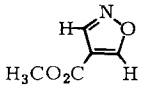
(16)

(17)



tertiary-5-Phenyl-2-isoxazoline *(16)* (b.p. 90–100 °C/0.001 mm) is formed in 70 % yield by cycloaddition of *(2)* to styrene. Its NMR spectrum ($CDCl_3$) proves the structure: τ = 2.91 (H-3, to J_{34} = 1.7 Hz; the CH_2 group on C-4 provides the expected 16-line signal (J_{gem} = −17.6 Hz). Ring opening to give the hydroxynitrile occurs only in boiling triethylamine.

The norbornadiene adduct *(17)*, which is isolated by distillation (b.p. 60–65 °C/0.001 mm) in 41 % yield and whose structure is proved by NMR and IR spectra, undergoes a retro-Diels-Alder reaction at 140–160 °C, which leads to cyclopentadiene and isoxazole (90 % yield). NMR spectrum of *(18)* ($CDCl_3$): τ = 1.66 (H-3, d), τ = 3.59 (H-4, t), and τ = 1.49 (H-5, d) with J_{34} = J_{45} = 1.5 Hz.



(18) R = H

(19) R = C_6H_5

(20)

(21)

Reaction of *(2)* with phenylacetylene gives a 51 % yield of 5-phenylisoxazole *(19)*. NMR ($CDCl_3$): τ = 1.72 (H-3, d) and τ = 3.52 (H-4, d) with J_{34} = 1.9 Hz.

Methyl propiolate adds fulminic acid in both directions. A 84:16 mixture of *(20)*, m.p. 47–50 °C[5], and *(21)* is obtained in 50 % yield. NMR spectrum of *(20)* ($CDCl_3$): τ = 1.47 and 2.93 (H-3 and H-4, d) with J_{34} = 1.8 Hz, τ = 5.98 (OCH_3,s). NMR spectrum of *(21)* ($CDCl_3$): τ = 1.30 (H-3, s), τ = 0.85 (H-5, s), and τ = 6.09 (OCH_3, s). Benzonitrile oxide reacts with methylpropiolate, giving the 5- and the 4-carboxylic ester in the ratio 72:28[4].

These cycloadditions are incompatible with the classical carboxime formula but agree with the formonitrile oxide structure of fulminic acid, thus supporting a recent assignment[6] based on IR spectroscopy.

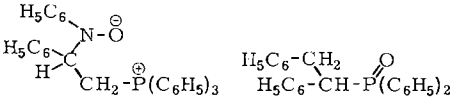
1,3-Cycloadditions of Nitrones to Methylenephosphoranes

By *J. Wulff* and *R. Huisgen*[*]

It has recently been shown that methylenephosphoranes are dipolarophiles and combine with nitrile oxides to give five-membered cycloadducts[1,2]. We have chosen azomethine oxides (nitrones) for further investigations since they represent a class of 1,3-dipoles that contain no double bond in their sextet structure[3].

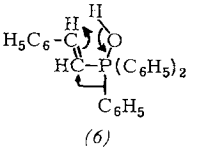
(1) *(2)* *(3)*

(a), R = R^1 = H



(b), R = R^1 = D

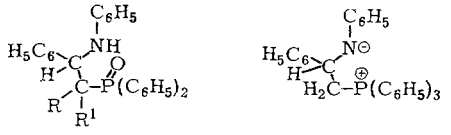
(c), R = C_6H_5, R^1 = H



(d), R = R^1 = CH_3

If one equivalent each of *C,N*-diphenylnitrone *(1)* and methylenetriphenylphosphorane *(2a)* are mixed in ether at 20 °C, the colorless, crystalline 1,2,5-oxazaphosphole derivative *(3a)* precipitates in 93 % yield (decomp. 136–137 °C); C, H, and N analyses and osmometric determination of the molecular weight give correct values for *(3a)* as well as for the other new compounds prepared. NMR spectrum ($CDCl_3$) of *(3a)*: H-4 and H-4′ as octuplets at τ = 6.36 and 6.93 with $J_{44'}$ = −16.3, J_{34} = 8.5, J_{45} = 12.0, $J_{34'}$ = 7.0, and $J_{4'5}$ = 12.4 Hz. The similarity of the couplings of H-3 (J_{35} = 8.1 Hz) leads to a quadruplet at τ = 5.30. The ^{31}P signal at +58.6 ppm ($CDCl_3$, 85 % phosphoric acid as external standard) indicates quinquecovalent phosphorus; if the phosphonium zwitterion *(4)* were present instead of the isomeric *(3a)*, then a large negative chemical shift would be observed[4].

The ^1H–NMR spectrum could be interpreted only by comparison with that of the 4,4-dideuterio compound *(3b)*. The compound *(2b)* is obtained from (trideuteriomethyl)-triphenylphosphonium bromide by reaction with sodamide in benzene[5] without D-exchange. NMR spectrum ($CDCl_3$) of *(3b)*: H-3 as broad doublet at τ = 5.32 with J_{35} = 8.1 Hz.



(4) *(5)*

(6)

Hydrolysis of *(3a)* in dioxane / water (5:1 v/v) at 100 °C gives (1,2-diphenylethyl)diphenylphosphine oxide *(5)* (yield 81 %) identified by comparison with an authentic specimen[6]. The *N*-phenylhydroxylamine that is also expected can be isolated

as *C,N*-diphenylnitrone if the hydrolysis is conducted in the presence of benzaldehyde. The reaction route leading to *(5)* [*(6)* is conceivable as intermediate] is as far from clear, as is the formation of *(5)* from a methyltriphenylphosphonium salt and benzaldehyde in the presence of sodium ethoxide in ethanol [7].

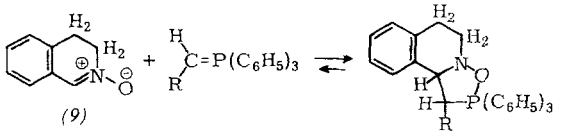
(7) *(8)*

(a), R = R^1 = H

(c), R = C_6H_5, R^1 = H

(d), R = R^1 = CH_3

Thermolysis of *(3a)* in boiling xylene, which occurs with formal loss of benzyne and formation of *(7a)* in 38 % yield, is also not understood; m.p. 204–205 °C; IR spectrum (KBr): 3320 (NH) and 1182 cm^{-1} (P=O). In an independent synthesis of *(7a)* (91 % yield), the zwitterion obtained from *(2a)* and *N*-benzylideneaniline in ether is hydrolysed.



Slow reaction of benzylidenetriphenylphosphorane *(2c)* with *(1)* in benzene at 60 °C for 24 h gives the cycloadduct *(3c)* in 39 % yield, (decomp. 146–147 °C). NMR spectrum ($CDCl_3$): τ = 5.13 (H-3, t) with $J_{34} = J_{35}$ = 6.5 Hz, and τ = 5.67 (H-4, q) with J_{45} = 10.0 Hz; the ^{31}P signal ($CDCl_3$) is at +57.9 ppm. Thermolysis of *(3c)* in xylene gives the phosphine oxide *(7c)* in 24 % yield, m.p. 228–229 °C; IR spectrum (KBr): 3360 (NH) and 1178 cm^{-1} (P=O).

Isopropylidenetriphenylphosphorane *(2d)* also adds *(1)* in ether at 20 °C. The adduct *(3d)* (yield 22 %, decomp. 142 to 143 °C), is isolated along with 15 % of triphenylphosphine. NMR spectrum ($CDCl_3$) of *(3d)*: τ = 9.09 (4-CH_3, d) with J_{45} = 21 Hz, τ = 8.37 (4'-CH_3) with $J_{4'5}$ = 18 Hz, and τ = 5.01 (H-3, s); ^{31}P signal ($CDCl_3$) + 46.3 ppm. Hydrolysis of *(3d)* in boiling dioxane/water (10:3 v/v), or pyrolysis in a high vacuum at 150 °C, leads to the same product *(7d)*. (2-Anilino-1,1-dimethylphenethyl)diphenylphosphine oxide melts at 217–219 °C and is identical with a product which was obtained from *(2d)* and *N*-benzylideneaniline with subsequent hydrolysis. NMR spectrum ($CDCl_3$) of *(7d)*: τ = 8.69 (CH_3, d) with *J* = 14 Hz, τ = 8.89 (CH_3, d) with *J* = 16 Hz, τ = 5.84 (tertiary H, d, broad) with *J* = 7.0 Hz, IR band (KBr) at 3320 cm^{-1} (NH).

N-Methyl-*C*-phenylnitrone reacts more slowly than *(1)* with methylenetriphenylphosphorane *(2a)* in ether. The resulting cycloadduct (analogous to *(3a)*, N–CH_3 instead of N–C_6H_5) melts at 134–135 °C; ^{31}P signal ($CDCl_3$): + 60.3 ppm. Hydrolysis with dioxane/water gives the same phosphine oxide *(5)* (yield 43 %) as is formed from *(3a)*.

1,3-Dipolar cycloaddition of 3,4-dihydroisoquinoline *N*-oxide *(9)* to ethyl crotonate at 100 °C is 43 times faster than that of *C,N*-diphenylnitrone *(1)* [8]. The nitrone *(9)*, however, combines more slowly with *(2a)* than does *(1)*; after a week in benzene at room temperature *(10a)* (73 % yield, m.p. 146–147 °C, ^{31}P signal ($CDCl_3$): +56.4 ppm) is isolated.

Hydrolysis of *(10a)* in boiling dioxane/water is accompanied by fragmentation to starting materials, yielding, alongside *(9)*, 78 % of methyldiphenylphosphine oxide which is a

(9) *(10)*

(a), R = H

(b), R = C_6H_5

known hydrolysis product of *(2a)*. If *(10a)* is heated in the presence of benzaldehyde in anhydrous ethanol, (1,2-diphenylethyl)diphenylphosphine oxide *(5)* is formed in 48 % yield by the route described by *Trippett* and *Walker* [7] *i.e. via (2a)*.

The *N*-oxide *(9)* can be recovered to the extent of 70 % after being boiled for three days with benzylidenetriphenylphosphorane *(2c)* in benzene. 81 % of the *(9)* consumed appears as the colorless cycloadduct *(10b)*, decomp. 150–152 °C; NMR spectrum ($CDCl_3$), τ = 5.24 and 5.80 (2 tertiary H, q); the ABX spectrum shows the *J* values 5.4, 15.0, and 15.5 Hz; ^{31}P signal ($CDCl_3$): +50.9 ppm.

A New Synthesis of Phosphabenzene Derivatives

By *G. Märkl*, *F. Lieb*, and *A. Merz* [*]

It is usually impossible to isolate the phosphonium salts that are formed from silylphosphines and alkyl halides since they readily decompose into alkylphosphines and halosilanes [1]. Thus the reaction of tris(trimethylsilyl)phosphine [2] *(1)* with pyrylium iodides (fluoroborates and perchlorates cannot be used because of the low nucleophilicity of the anions) gives iodotrimethylsilane and the bis(trimethylsilyl)phosphine *(2)* [3]; however, the latter is not isolated but cyclizes with separation of hexamethyldisiloxane and formation of the substituted phosphabenzene *(3)*.

[a] Shoulder.

In contrast with the synthesis of 2,4,6-triphenylphosphabenzene[4] from the pyrylium salt and tris(hydroxymethyl)-phosphine in boiling pyridine, no basic solvent is needed in this case. Water is not formed as a reaction product. Yields of the phosphabenzene derivatives are higher than in the tris(hydroxymethyl)phosphine synthesis in all cases.

2,4,6-Triphenylphosphabenzene:

2,4,6-Triphenylpyrylium iodide (1.1 g, 2.5 mmoles) in anhydrous acetonitrile (15 ml) is treated with tris(trimethylsilyl)phosphine (0.7 g, 2.8 mmoles) and boiled under reflux in an atmosphere of pure nitrogen for 20 h. After removal of the solvent by vacuum distillation, chromatographic separation of the reaction mixture with benzene on Al_2O_3 gives 365 mg of product, m.p. 172–173 °C after one recrystallization from chloroform/ethanol (1:3 v/v).

CONFERENCE REPORTS

Macromolecular Colloquium

This colloquium was held on March 9th–11th, 1967, at the Institut für Makromolekulare Chemie der Universität Freiburg (Germany).

From the lectures:

Secondary and Tertiary Structure of Transfer Ribonucleic Acid

By F. *Cramer*[*]

Transfer ribonucleic acids, which bring the amino acids into the genetically determined positions prior to incorporation, are the shortest definite nucleic acids known, since they contain only 70 to 80 nucleotide units. The sequences of four transfer ribonucleic acids have been established so far. In order to understand the function of the molecule, it is necessary to know its secondary and tertiary structure.

It was found earlier that monoperoxyphthalic acid oxidizes adenine units in nucleic acid only when these are not situated in base-paired regions.

Transfer ribonucleic acid is oxidized by monoperoxyphthalic acid at pH = 7. The course of reaction can be followed either by the change in the absorption spectrum as a result of the oxidation or by degradation of the nucleic acid and determination of the AMP 1-*N*-oxide units.

[*] Prof. Dr. F. Cramer
Max-Planck-Institut für experimentelle Medizin,
Abteilung Chemie
Hermann-Rein-Str. 3
34 Göttingen (Germany)

It is possible in this way to determine the number of non-base-paired A residues per molecule of RNA. The linear relationship between the oxidizability and the thermal hyperchromicity confirms that the A residues in transfer RNA are protected against oxidation as a result of the secondary structure (Watson-Crick base pairing). In this way, the thermal hyperchromicity can be calibrated with the aid of a chemical reaction. If the distribution of the A residues is assumed to be statistical, the number of base pairs in RNA can be calculated from hyperchromicity. It is found that the total s-RNA from yeast and *Coli* have 28 and 23 base pairs per molecule, respectively, at 20 °C. Of the 28 base pairs in yeast s-RNA, five disappear at 40 °C. These five base pairs are assigned to a tertiary structure (additional folding).

Dynamic Investigations on Oligo- and Polynucleotides

By *M. Eigen*, *G. Maass*, and *D. Pörschke*[*] (delivered by *G. Maass*)

It is known from the work of *Watson*, *Crick*, *Nirenberg*, *Khorana*, and many others that the program for the synthesis of proteins is contained in the sequence of the purine and pyrimidine bases A, G, T, and C in the double helix of the deoxyribonucleic acid (DNA) in the cell. The reading of the code is based on the complementarity between these

[*] Prof. Dr. M. Eigen, Dr. G. Maass, and
Dipl.-Chem. D. Pörschke
Max-Planck-Institut für Physikalische Chemie
Bunsenstr. 10
34 Göttingen (Germany)

nucleo bases. This complementarity depends on the specific hydrogen-bonding interaction between the bases. The main reason for the stability of the double helix of nucleic acid, apart from the hydrogen bonding, is the "stacking" interaction of the planar base pairs in the direction of the axis of the helix. To obtain an understanding of the elementary processes involved in the formation of the double helix and the nature of the complementary interaction in smaller code units (*e.g.* the codon–anticodon interaction), we studied the dynamic behaviour of synthetic polynucleotides and oligonucleotides of various chain lengths (from the trimer to the nonamer). The adenylic acid double helix was used as the model system.

The measurement of hypochromicity as a function of temperature gave results that agree with a statistical-thermodynamic theory developed by *Applequist* and *Damle* for the helix-coil transition of short-chain adenylic acids. The slopes of the melting curves at the T_m value and the dependence of the T_m value on the concentration gave reaction enthalpies of -7 to -8 kcal per mole of base pair.

Using the temperature jump relaxation method [1], it is shown that the helix-coil transition of oligoadenylic acids proceeds as a second-order reaction. The recombination rate constants for the helix formation are about 3×10^6 l mole^{-1} sec^{-1}, and are largely independent of the chain length. The dissociation rate constants are independent of the chain length for a constant melting range, but increase with increasing helix-coil transition. The results are discussed in relation to the denaturation kinetics of highly polymeric DNA and non-specific transfer RNA. The elementary steps in the helix-coil transition of adenylic acids, *i.e.* the formation and dissolution of base pairs, take 10^{-6} to 10^{-7} sec.

Quaternary Structure and Activity of Enzymes (Alcohol Dehydrogenase, Glutamic Dehydrogenase, Catalase)

By *H. Sund* [*]

The ageing of yeast alcohol dehydrogenase, which is accompanied by a decrease in the number of free SH groups (mainly as result of oxidation to disulfide groups) and in the enzyme activity as well as by partial dissociation into the polypeptide chains, does not affect all molecules to the same extent. In addition to fully active molecules (molecular weight 157000) and inactive polypeptide chains (molecular weight 40000), there are also inactive, or largely inactive, molecules that have not yet dissociated into polypeptide chains. These can be reactivated by incubation in the presence of mercaptoethanol and zinc ions. Even after dissociation into the polypeptide chains, a considerable degree of reactivation, with concurrent reassociation, has been accomplished by incubation at 0 °C in the presence of mercaptoethanol; the turnover number rises from 2500 to 28000 min^{-1} when the S_7 component (molecular weight 157000) is increased from 15 % to 85 % [2].

Glutamic dehydrogenase from ox liver dissociates into enzymatically active sub-units at low protein concentrations. To determine the size of these sub-units, the sedimentation coefficient was studied at protein concentrations down to 25 µg/ml. Extrapolation gave $s^0_{20,w} = 13.3$ S, corresponding to a minimum molecular weight of 260000 for the sub-unit. In the associated state (molecular weight 2×10^6), glutamic dehydrogenase probably contains eight sub-units [3].

To determine whether the structural information for the conformation of glutamic dehydrogenase is contained in the primary structure, the reactivation following the action of dodecyl sulfate was studied. In the presence of dodecyl sulfate, inactive sub-units ($s^0_{20,w}$ values of 5.8 S and 7.6 S), which probably consist of two and three polypeptide chains, are formed as well as the inactive polypeptide chains having a molecular weight of 50000. Substantial reactivation is possible after dissociation into the $S_{7.6}$ component. The extent of reactivation depends on the incubation time and on the protein concentration [4].

After succinylation and at pH = 12.5, ox-liver catalase (molecular weight 250000) dissociates under the influence of 5M guanidine hydrochloride (in the presence of mercaptoethanol) or sodium dodecyl sulfate to give four sub-units of equal size and having a molecular weight of 63000. In the absence of mercaptoethanol, denaturation by guanidine hydrochloride or urea, or incubation at pH = 3, leads to dissociation into two sub-units of molecular weight 125000. The four sub-units are held together in the native catalase molecule by non-covalent bonds. Electron micrographs show the catalase molecule as a flat parallelepiped having an edge length of about 80 Å and an altitude of about 35 Å; a symmetrical division into four is clearly discernible. It is assumed that each sub-unit having a molecular weight of 63000 contains an active center [5].

Synthesis of Polyarabinonucleotides with Esters of Polyphosphoric Acid

By *G. Schramm* [*]

A new type of polynucleotide has been obtained by polycondensation of uridylic acid with the aid of phenyl polyphosphate. Polyarabinonucleotides are formed with inversion of the 2′-hydroxyl group, poly-*O*^{2}-2′-cyclourydilic acid occurring as an intermediate. The polyarabinonucleotides are resistant to ribonuclease, and are only slowly hydrolysed by acid and alkali. This permits their separation from polyuridylic acid. Degradation with bacterial monophosphatase and snake-venom diesterase gave 9-β-D-arabinosyluracil. This substance ("spongouridine") has been isolated from sponges. In polyspongouridylic acid, the nucleotides are joined by 3′–5′ bonds, as in the natural nucleic acids. The condensation products were separated chromatographically according to their chain lengths, fractions containing up to 17 units being obtained. The polyarabinonucleotides are intermediate between RNA and DNA. Competitive inhibition of the degradation of DNA by deoxyribonuclease and RNA by ribonuclease was observed. Polyspongouridylic acid stimulates the adaptation of phenylalanine transfer RNA to ribosomes in the same manner as polyuridylic acid.

Synthesis of Insulin by the Merrifield Method [6]

By *H. Zahn, T. Okuda,* and *Y. Shimonishi* [**]
(delivered by *H. Zahn*)

Marglin and *Merrifield* [7] recently reported the syntheses of the A and B chains of ox insulin on chloromethylated polystyrene [8]. In co-operation with these authors, we have car-

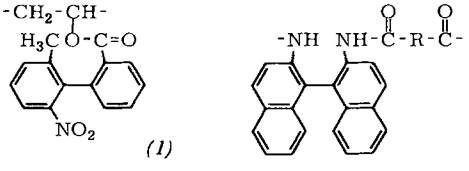
ried out similar work since October 1965 which has culminated in the synthesis of insulin chains in larger quantities than before[9]. Syntheses carried out included that of the A chain of human insulin and of the B chain of the ox (sheep) insulin. A new method used was the formation of peptide linkages on the amino group of threonine with the aid of *p*-nitrophenyl esters; in this method there is no need to protect the hydroxyl group of the threonine. The yields of analytically pure and partially protected chains, based on the C-terminal amino acid in the resin, were 23–34%. (This value includes the synthesis of the peptide chain, cleavage from the resin, double reprecipitation, and final purification by gel filtration.)



The partially protected insulin chains were converted into the *S*-sulfonates by reduction with sodium in liquid ammonia and oxidative sulfitolysis. The yields of electrophoretically homogeneous Bunte salts after purification by gel filtration and ion-exchange chromatography were about 10 to 15%, based on the protected chains. Combination of the synthetic human A chain with isolated ox B chain gave half-synthetic pig insulin in a yield of 1–2%. We obtained half-synthetic ox insulin with an insulin content of 1–3% from isolated ox A chain and synthetic ox B chain. Crystals were obtained from this preparation.

Though the Merrifield synthesis has increased the yields of protected insulin chains by several powers of ten, the preparation of crystalline insulin from the protected chains is still associated with extremely large losses.

Polymers with Atropisomeric Biphenyl Structural Units

By *R. C. Schulz* and *R. H. Jung*[*]
(delivered by *R. C. Schulz*)

In the course of investigations on optically active polymers, we have prepared polymers containing the units *(1)*–*(6)*; they contain atropisomeric biphenyl or binaphthyl groups either as substituents along the main chain or as components thereof.

Johann-Joachim-Becher-Weg 18
65 Mainz (Germany)

The polymers *(1)* and *(2)* are soluble *e.g.* in γ-butyrolactone, dimethylformamide, or tetrahydrofuran; *(4)* is soluble only in hexafluoroisopropanol, and *(5)* is also soluble in hexafluoroacetone sesquihydrate and hexamethyltriamidophosphoric acid. Only oligomers of *(3)* and *(6)* have so far been isolated. *(1)* softens at about 160 °C and *(5)* at 260 °C, while *(2)* and *(4)* do not soften below 300 °C.

The polymers *(1)*, *(2)*, and *(5)* have been obtained in optically active forms. The compounds *(7)*–*(12)* were used as model substances for the optical measurements.

(11)	190	+328.1 [a]	346	−786	305	+8650

[a] In tetrahydrofuran, $c = 0.5$; all others in dioxane, $c = 1$.

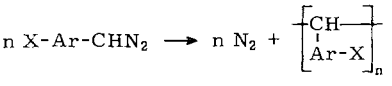
The polymers agree with the corresponding models in their rotatory dispersion and in their circular dichroism; however, on racemization considerable differences become apparent, which are due to the polymer structure.

Synthesis of Polyamides in the Fine-Grain Form from Diphenyl Esters and Diamines

By *W. Wolfes*[*]

Solutions of Diphenyl esters of dicarboxylic acids in aromatic hydrocarbons can be made to react with solutions of primary aliphatic diamines at low temperatures. The resulting polyamides precipitate out as fine powders. Polyamides having higher molecular weights are obtained by further condensation in suspension at higher temperatures (but below the melting point of the polyamide). The weight ratio of suspending medium to polyamide powder is about 4:1.

[*] Dr. W. Wolfes
Dynamit-Nobel AG.
521 Troisdorf (Germany)



The condensation plant consists of a steam-heated stirring reactor fitted with a distillation column, a centrifuge, a wash tower, and drying apparatus; all solvents and washing agents are recycled. The phenol liberated during the condensation is used again for the production of the diphenyl ester. The average molecular weight of the polyamide depends mainly on the condensation temperature. The particle size depends on the stirring speed, the reaction temperature, and the solvent or suspending medium. The condensation process described permits the incorporation of divided fillers such as glass fibers, copper powder, or graphite, in a very uniform distribution.

The process is suitable for the production of polyamides of aromatic dicarboxylic acids that have a high melting point and do not swell appreciably.

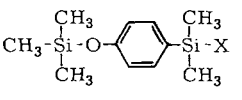
Polymers and Copolymers of Diazoalkanes

By *G. Smets*[*]

When aryldiazoalkanes are unsubstituted or carry substituents which are unreactive towards the diazoalkane function, polymerization can proceed with nitrogen evolution and formation of polyarylidenes.

Such a type of polymerization of diazoalkane can be achieved by a pseudo-cationic mechanism (*Bawn*), or catalytically on colloidal metal surfaces (*Nasini*).

It was found that several polyarylidene polymers are formed by decomposition of aryldiazoalkanes in the presence of an alcohol, either in an homogeneous benzene-alcohol solution, or in heterogeneous systems by alkaline thermal decomposition of N-tosylbenzalhydrazones in water-benzene-methanol. The presence of an alcohol is indispensable for polymer production although its structure is of secondary importance. The yield of polymer is always high (80 to 95 %). The degree of polymerization varies with the nature of the aryl group and of the substituent. The overall activation energy of polymerization of phenyldiazomethane is equal to 5.5 kcal/mol.



The fact that no polymerization takes place in the presence of peroxides, the failure of phenyldiazomethane to copolymerize with vinyl monomers, and the role of the alcohol are indicative of a reaction mechanism that involves the formation of an aryldiazoalkane methanol molecular complex (see reaction scheme) and which is based upon the low reactivity of diazoalkanes towards alcohol in the absence of any acid hydrogen. Copolymerization experiments were carried out in order to elucidate the nature of the reaction mechanism. The copolymerization parameters have been determined for the system phenyl-(M_1) and *p*-chlorophenyl-(M_2)-diazomethane (r_1 = 1.2; r_2 = 0.3) and the system phenyl-(M_1) and *p*-bromophenyl(M_2)-diazomethane (r_1 = 0.85 and r_2 = 0.4). These values are different from those for the corresponding ionic and radical polymerization of substituted styrenes. These copolymerization experiments agree therefore with the reaction mechanism through molecular complexes as suggested for the homopolymerization.

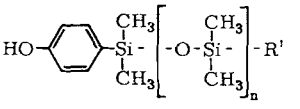
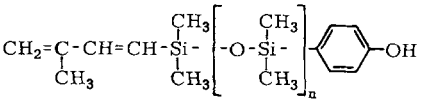
Louvain (Belgium)

Synthesis and Reactions of Siloxane-Substituted Phenols

By *G. Greber* and *D. Lohmann*[*] (delivered by *G. Greber*)

We synthesized the chlorosilane *(1)*, the phenol group of which is protected by a trimethylsilyl residue, by the Wurtz-Fittig reaction of *p*-chlorophenoxytrimethylsilane, dimethyldichlorosilane, and sodium, and by the reaction of the Grignard compound of *p*-bromophenoxytrimethylsilane with dimethyldichlorosilane. On hydrolysis with aqueous ammonia, *(1)* is converted into the silanol *(2)* without loss of the protecting group.





(1), X = Cl
(2), X = OH

(3), R = CH_3, n = 1–3
(4), R = Cl, *n* = 1–3
(5), R = H, *n* = 0–2
(6), R = C_6H_4–O–Si$(CH_3)_3$, *n* = 1–3

The reactions of the silanol *(2)* with trimethylchlorosilane or 1-chloropolysiloxanes lead to the siloxane-substituted phenols *(3)*, which are still protected. With an excess of dimethyldichlorosilane or ω,ω′-dichloropolysiloxanes, on the other hand, they give polysiloxanes *(4)* having a protected phenol group and a Cl–Si end-group ,which can be reduced to an H–Si group (in *(5)*) by $LiAlH_4$. Polysiloxanes having two protected phenol end-groups *(6)* are formed on condensation of the silanol *(2)* with *(1)* or with dimethyldichlorosilane or ω,ω′-dichloropolysiloxanes in a molar ratio of 2:1.

Siloxane-modified polymers can be obtained from the bisphenols *(8)* by reaction with bifunctional components.

(7), R′ = CH_3, *n* = 1–3
(8), R′ = C_6H_4OH, *n* = 1–3

(9), *n* = 1, 2

The compounds *(5)* containing H–Si groups add *e.g.* to the triple bond in isopropenylacetylene with H_2PtCl_6 as catalyst. Removal of the trimethylsilyl protecting groups yields *trans*-isoprene derivatives containing a *p*-hydroxyphenylsiloxane residue *(9)*, which copolymerize with a readiness similar to that of isoprene, and copolymerize *e.g.* with styrene to form products containing lateral free phenol groups.

The Mechanism of Formation of Polyesters from Cyclic Anhydrides and Cyclic Ethers with Cationic Initiators

By *K.-H. Reichert*, *J. Habermeier*, and *K. Hamann*[**] (delivered by *K. Hamann*)

Earlier investigations on the cationically initiated formation of polyester and poly(ester ethers) from cyclic ethers and dicarboxylic anhydrides[10] showed that the content of ether

[10] *J. Habermeier*, *K.-H. Reichert* and *K. Hamann*, J. Polymer Sci. *C*, in press; *A. Hilt*, *K.-H. Reichert*, and *K. Hamann*, Makromolekulare Chem. *101*, 246 (1967).

groups in the resulting polymer is strongly dependent on the reaction conditions, and particularly on the nature and concentration of the initiator.

The assumption that the reaction may be regarded essentially as a copolymerization with a coupled polymerization–depolymerization equilibrium of the ring ether was confirmed by comparative kinetic studies on the polymer formation and on model reactions. The rate of formation of the polymers is independent of the concentration of the monomers up to yields of about 60 wt-%. It is therefore concluded that the ring cleavage of the initially formed cyclic oxonium ion determines the rate of the overall reaction.

Model experiments on the rate of the acylation of n-butyl ether with succinic anhydride, the establishment of the polymerization–depolymerization equilibrium of polytetrahydrofuran by depolymerisation, and the rate of formation of polyesters or poly(ester ethers) from polytetrahydrofuran and succinic anhydride showed that under the normal copolymerization conditions, very little direct acylation of ether groups in the polymer chain is to be expected, whereas the ether content of the resulting polymers is certainly strongly influenced by the polymerization–depolymerization equilibrium of the corresponding polyether. The kinetic studies were carried out with two types of initiators having different effects on the course of the reaction. Whereas the copolymers of tetrahydrofuran and succinic anhydride obtained with $CH_3CO^{\oplus}SbCl_6^{\ominus}$ have a constant ether content over the entire range of yields, $C_4H_8\overset{\oplus}{O}-\overset{\ominus}{P}F_5$ leads to a decrease in the ether content as the reaction progresses. This is in agreement with the results of depolymerization of polytetrahydrofuran, according to which $CH_3CO^{\oplus}SbCl_6^{\ominus}$ causes faster equilibrium than $C_4H_8\overset{\oplus}{O}-\overset{\ominus}{P}F_5$.

Further experiments showed that the course of the copolymerization of cyclic ethers with dicarboxylic anhydrides under comparable conditions depends on the reactants. Thus the polymer yields and the ether contents indicate that the reactivity of a number of dicarboxylic anhydrides toward tetrahydrofuran decreases in the order: succinic anhydride > *cis*-hexahydrophthalic anhydride > maleic anhydride > phthalic anhydride. The reactivity of cyclic ethers toward succinic anhydride decreases in the order: tetrahydrofuran > 3-methyltetrahydrofuran > 2-methyltetrahydrofuran > oxepane > 1,4-dioxane > tetrahydropyran. The order of the cyclic ethers can be qualitatively explained by the combined effects of ring strain and the basicity of the ether oxygen.

Isoprene and Organolithium Compounds in Hydrocarbons and Ethers

By *H. Sinn, F. Bandermann, K. Trukenbrod*, and *G. Dobratz* [*] (delivered by *H. Sinn*)

Butyl-lithium and isoprene react in diethyl ether to form isoprenyl-lithium. Spectroscopic investigation of the reaction showed that the reactivity of butyl-lithium toward isoprene is about 1000 times as high as that of isoprenyl-lithium toward isoprene. Whereas isoprenyl-lithium is monomeric in ether, butyl-lithium is present in associates of approximately three molecules. These degrees of association were also found in the metalation of triphenylmethane with butyl-lithium and isoprenyl-lithium. In hydrocarbons, on the other hand, the two organometallic compounds are associated to approximately the same extent, and the reactivity of butyl-lithium towards isoprene is smaller by a factor of 250 than that of isoprenyl-lithium.

Since isoprenes from various sources differ in the content of polar impurities (in the ppm-range) even after careful purification, extremely reproducible time-conversion curves are obtained with isoprenyl-lithium. but not with butyl-lithium. This follows quantitatively from the above reactivity ratios, and can be experimentally confirmed by the addition of appropriate quantities of ether to very pure isoprene. As a result of these additions, the initiating reaction becomes faster than the propogation reaction.

Calculations for real reactors show that isothermal reactions are impossible owing to the finite rate of heat transfer (except with programmed temperature control). The temperature fluctuations are of the order of a few tenths of a degree. The calculation is carried out by means of the three differential equations:

$$-\frac{dV}{dt} = \frac{V-K_1}{K_1}(K_2 n_{LiBu} + K_3)$$

$$-\frac{V dn_{LiBu}}{dt} + \frac{n_{LiBu} dV}{dt} = K_4 (V-K_1) n_{LiBu}$$

$$\frac{dT}{dt} = \frac{1}{V}\left(K_5 \frac{dV}{dt} - K_6 T + K_7\right)$$

V = volume, n = number of moles, T = temperature, t = time, K = experimental constants.

It is interesting to note that with equations of this degree of complexity, the differences in the course of the time-conversion curves obtained by means of digital and analogue computers are greater than the experimental error.

The system involved in these studies are characterized by their conductivity and dielectric constant as functions of concentration and reaction time. The maximum ion concentrations are around 10^{-9} g-equiv./l. Their concentration-dependence cannot be correlated with the kinetic findings.

A Novel Method of Determing Reactivity Ratios in Copolymerization

By *V. Jaacks* [*]

The copolymerization of two monomers M_1 and M_2 is carried out with a sufficiently large excess of one of the monomers *e.g.* M_1, so that the copolymer contains only a few isolated M_2 units. The composition of this polymer is then determined almost entirely by the parameter $r_1 (= k_{11}/k_{12})$, and is independent of r_2. The copolymerization proceeds in accordance with the equation

$$\log [M_1]_0/[M_1]_t = r_1 \log [M_2]_0/[M_2]_t \quad (1)$$

A graph of $\log [M_2]_0/[M_2]_t$ against $\log [M_1]_0/[M_1]_t$ at various conversions gives a straight line whose gradient is equal to r_1. ($[M]_0$ and $[M]_t$ = concentrations of a comonomer at the beginning and at the end of copolymerization, respectively.)

The advantage of this method is that equation (1) is valid up to high conversions, provided that the excess of M_1 remains large enough. It is therefore no longer necessary to isolate and analyse the copolymer after small conversions in order to determine the consumption of the two monomers (it is well known that this involves analytical difficulties is many cases). The high monomer conversions can instead be measured

relatively accurately by gas-chromatographic determination of the monomers in the copolymerization mixture. This determination could not be carried out with sufficient accuracy in the usual method for the determination of reactivity ratios, which is restricted to low conversions.

The method described was first used for the copolymerization of trioxane (M_1) and styrene (M_2) ($r_1 = 0.025$, $r_2 \sim 10$, at 30 °C in methylene dichloride with $SnCl_4$). The determination of the relative reactivities of this pair of comonomers by the usual *Mayo-Lewis* method had been unsuccessful because of side reactions. The principle described above can also be applied to ter- and quaterpolymerizations. Quaterpolymerizations in which an excess of one monomer is present at any time will give three reactivity ratios for each monomer present in excess.

The Frequency Distribution of the Chemical Composition in Binary Copolymers

By *G. Markert*[*]

Mayo's copolymerization equation is valid for any mixing ratio of a pair of monomers (defined by the mole fraction), irrespective of copolymers that have already been formed. Thus the change in the chemical composition of the copolymers formed at any time with increasing conversion follows a single curve, irrespective of the initial mixing ratio of the monomers, which determines only the position of the zero point on the curve (the distance on the ordinate between the zero point and the end of the curve always corresponds to 100 % conversion).

However, such a "general conversion curve" is unsuitable in practice for a representation of the copolymerization process. The frequency distribution of the chemical composition is more readily accessible to generalization. From the general frequency curve (for a given pair of paremeters r) based on the frequency minimum, together with the copolymerization curve, it is possible to read off directly the frequency distribution in a copolymer of any overall composition. This type of plot is suitable for pairs of monomers with and without azeotropes.

Influence of the Anomalous Chain-Growth Reaction on the Copolymerization Kinetics

By *B. Erussalimskii, S. Lyubetskii, A. Goldenberg*, and *F. Duntov*[**] (delivered by *B. Erussalimskii*)

Some copolymers of ethylene are characterized by an appreciable content of anomalous sequences, $-CH_2CHX-CH_2CH_2-CHXCH_2-$[11]. A kinetic scheme that takes into account the formation and the reactions of the anomalously growing chains leads to a modified Mayo equation[12] the parameters of which can be determined in various ways. The calculated values agree satisfactorily with those found by measurement.

The existence of the anomalous growth reaction may be regarded as one of the reasons for the dependence of the φ factor (cross-termination constant) on the monomer ratio.

Attempts to Characterize the Catalytically Active Center in Homogeneous Ziegler-Natta Polymerization

By *G. Henrici-Olivé* and *S. Olivé*[*] (delivered by *G. Henrici-Olivé*)

Magnetic measurements (susceptibility, ESR) and determination of the rate of polymerization were combined in order to obtain information about the valence and ligands of the titanium ion in the active species of a Ziegler-Natta catalyst. The system dicyclopentadienyltitanium dichloride–ethylaluminum dichloride in toluene was used as the catalyst, with ethylene as the monomer.

A linear relationship was found between the rate of polymerization and the concentration of Ti(IV) that had not been reduced. It was also found that at least two Ti(IV)–Al compounds containing bridge bonds must be the source of the Ti(III) compounds whose ESR spectra were observed. Only one of the complexes proves to be catalytically active.

Isolation and Characterization of Cyclic Oligomers of Formaldehyde

By *K. Burg* and *H. D. Hermann*[**]

During product recovery from residues from the polymerization of trioxane, higher oligomers of formaldehyde could be isolated as well as trioxane and tetroxane. The pentamer was isolated with the aid of preparative gas chromatography, while zone melting could be used for the isolation of a ring containing 15 formaldehyde units. The acid-catalysed pyrolysis of polytrioxane also leads to higher cyclic oligomers of formaldehyde. Pyrolytic gas-chromatographic investigations indicated formation of pentoxane, and probably also of hexoxane.

The cyclic acetals isolated were characterized on the basis of their polymerizability, their melting points, and their IR, NMR, and mass spectra.

The Efficiency of Gel Permeation Chromatography

By *G. Meyerhoff*[***]

Gel permeation chromatography (GPC) has recently developed into a very important aid for the determination of the molecular weight distributions of polymers. This method gives the relationship between the polymer concentration and the elution volume V_e. The molecular weight distribution is found by conversion of V_e into the molecular weight M by means of a suitable function.

The transformation function is obtained empirically; a function of the form $\log M = A - BV_e$ can often be used for suitable column combinations. These and other calibration functions are used to find theoretical elution curves for polymers having the well-known Schulz distribution; deviations in behavior from the GPC curves are also determined.

Rather surprisingly, almost perfect agreement is found between the theoretical and recorded curves for a single GPC column provided that the column is suitable for the molecular weight range under investigation. On the other hand, the recorded

elution curves for the more efficient combinations of columns in groups of two or four correspond to a molecular weight distribution that is too narrow. This means that the separating efficiency is too high for a mixture of two polymers having very different average molecular weights. Analysis of this result is made difficult by the fact that the type of polystyrene gel and the elution velocity strongly influence the separation process.

The Influence of the Order in Polymer Solutions on Light Scattering

By *W. Burchard*[*]

For macromolecules that form a random coil in solution, plots of $c/i(\Theta)$ against $\sin^2 \Theta/2$ normally give straight lines (Θ = scattering angle, $i(\Theta)$ = scattering intensity).

On the other hand, solutions of polyvinyl carbanilate (PVCarb) in diethyl ketone shows an upward deflection of the curve at small angles. This means that the value of the shape factor $P(\Theta)$ at $\Theta = 0$ is not 1, but may be as much as 60 % lower.

This behavior shows that the angle-dependence is due not only to internal intereferences on one macromolecule, but also to external interferences on neighboring molecules.

The light-scattering measurements on PVCarb are evaluated by means of the equation given by *Zernicke* and *Prins*[13].

$$P'(\Theta) = P(\Theta) \left\{ 1 - 4\pi \frac{N}{X} \int_0^\infty [1-\rho(r,c)] r^2 \frac{\sin sr}{sr} \, dr \right\} \approx P(\Theta)$$

$$[1 + b\, c\, \bar{r}^{2\,3/2} \frac{N_L}{M} \Phi(\Theta)]^{-1}$$

$P'(\Theta)$ is the shape factor perturbed by external interference, $P(\Theta)$ the true shape factor, $\Phi^2(\Theta)$ the shape factor of a spherically symmetrical particle, $\rho(r,c)$ the probability of finding a macromolecule at distance r, M the molecular weight of the macromolecule, c the concentration, N_L the Loschmidt number, and b a constant, N the number of particles, V the volume, $\bar{r}^2$ the mean square radius.

A Guinier plot of $[P(0)/P'(\Theta)] - 1$ for PVCarb gives straight lines, the gradients of which are used to find the average distance to which two PVCarb molecules can approach each other. These results indicate strongly hindered penetration of the PVCarb coils in diethyl ketone. This hindrance is assumed to be due to a very firm and extensive solvation sheath.

Association of Macromolecules

By *H.-G. Elias, H. Dietschy, J. Gerber*, and *H. Lys*[**]

Association is a reversible combination of similar molecules. The limiting cases are open association ($2\,M_I \rightleftarrows M_{II}$, $M_{II} + M_I \rightleftarrows M_{III}$, *etc.*) and closed association ($N\,M_I \rightleftarrows M_N$). Equations for the relationship between the apparent molecular weight of unassociated molecules, the association equilibrium constants, multiplicity N, and concentration c for theta solutions have been derived for the two extreme cases. It is not possible to give closed equations that are valid for all solvents. The determination of the molecular weight of the unassociated molecules is difficult, particularly in the case of association in good solvents (2nd virial coefficient positive). Open association is exhibited by polyethylene glycols in benzene and carbon tetrachloride, and by "amorphous" polypropylene, *e.g.* in benzene, toluene, and cyclohexane. The association of polypropylene is probably due to desolvation. For ether-soluble polypropylene in CCl_4, association increases with the content of isotactic triads. Poly-γ-benzyl-L-glutamate obeys the laws of closed association in many theta solvents.

Electron-Microscope and X-Ray Investigations on the Structure of Drawn High Polymers

By *E. W. Fischer, H. Goddar*, and *G. F. Schmidt*[*] (delivered by *E. W. Fischer*)

The mechanical properties of drawn, partially crystalline high polymers depend largely on the mutual arrangement of the crystallites and on the conformation of the chains in the disordered regions. These two structural characteristics were studied for samples of polyethylene, polyoxymethylene, and polyethylene terephthalate by means of the electron microscope and with the aid of small-angle X-ray scattering, and compared with various models that have been proposed for the structure of the drawn polymers.

In the case of polyethylene, it is well known that the long period observed in X-ray studies is identical with the distance between lamellar crystallites in the direction of the fiber. However, the results reported here show that not only the positions of the reflections, but also the intensity distribution in the small-angle X-ray diagram can be explained with the aid of the structures observed by electron microscopy. For example, the investigations on cold drawn polyethylene showed that the four-point diagrams obtained with many high polymers are due to the oblique position of the lamellar crystallites with respect to the fiber direction.

To obtain further information on the structure of the disordered regions, the change in the small-angle intensity as a result of the infiltration of iodine into these regions was studied. It was concluded from these measurements that the difference in density between crystallites and disordered regions is caused by folding of some chains. Even in the case of oblique crystal layers (four-point diagram), chain folding must be assumed to occur on the boundary surfaces of the crystallites. It could be shown by this method that the difference in density between the amorphous and crystalline regions increases by a factor of 5 when the drawn sample is annealed. This is because the defects created in the crystallites during drawing diffuse out of the crystallites on heating, and take up an arrangement in layers transverse to the axis of the fiber.

The Influence of Chain Rigidity on the Crystallization Process in Macromolecules

By *H. Bittiger* and *E. Husemann*[**] (delivered by *H. Bittiger*)

The molecular mechanism of the crystallization process in polymers, *i.e.* the transition of the molecular coils into ordered solids, was investigated by electron microscopy for cellulosetricarbanilate and polyethylene. The influence of the proper-

ties of the molecules (molecular weight, chain rigidity, extension of the coils, chain diameter) on the crystallization behavior (formation of nuclei, monocrystals, and fibrils, *etc.*) was compared for polymer-homologous series of the very rigid cellulosetricarbanilate and of the flexible polyethylene, in order to determine the reason for the folding of chain molecules.

In the case of the very rigid cellulosetricarbanilate, it was possible to observe individual ordered molecules, nuclei, monocrystals, and fibrils, and to determine the conditions for their formation. On the other hand, the flexible polyethylene showed neither individual molecules nor fibrils, despite extreme variations of molecular weight and crystallization conditions.

The experimental results, particularly the temperature-dependence of the lengths of the folded chain segments and of the sizes of the nuclei, are compared with the predictions of *Lauritzen* and *Hofmann*'s kinetic theory of chain folding[14]. The deviations from the theory can be discussed in relation to the flexibility of the chains.

Examples of the Flow Birefringence of Viscoelastic Systems

By *H.. Janeschitz-Kriegl*[*]

Macromolecular liquids exhibit pronounced elastic properties. This is demonstrated by their partial recovery on removal of a load causing plastic deformation. The recoverable shear in the rotation viscometer (constrained recoverable shear) is found on removal of the shear stress required for stationary laminar flow. Normal stresses acting perpendicular to the boundary surfaces of the liquid play an important part as constraining forces. However, the only material properties are differences in the normal stresses, which one would like to determine as functions of the (stationary) shear gradient, but which cannot be measured directly without disturbing the flow. One method for the indirect measurement of $p_{11} - p_{22}$ (difference of the normal stresses in the flow direction and in the direction of the shear gradient) consist in the determination of the axial force (normal thrust) in the rheogoniometer. The present investigations arose from a desire to use the flow birefringence of macromolecular liquids for photoelastic investigations.

Comparison with the measurements carried out with the rheogoniometer showed that an investigation of this nature is quite feasible at low shear gradients. It was also confirmed that molten polymers having a wide molecular weight distribution have more pronounced elastic properties than those having a narrow distribution and having approximately the same viscosity. Two polypropylenes were studied[15].

Experiments were also carried out to determine whether results for polymer melts can be compared with those for dilute solutions. This is important in connection with the interpretation of the influence of the molecular weight distribution, since the known theoretical relationships are really valid only for dilute systems, for which good agreement with experiment has been found. The dimensionless stress quantities used lead to an excellent reduction with respect to molecular weight, temperature, and concentration for anionically polymerized polystyrenes. The reduction with respect to the concentration is subject to an interesting limitation. Using a technical polystyrene, it is shown that solutions of medium concentration are more elastic in relation to their viscosities than dilute solutions and melts, which correspond to each other.

Investigations on the Flow Behavior of Polymers in Relation to their Molecular Structure

By *H. H. Meyer* and *W. Ring*[*] (delivered by *H. H. Meyer*)

The flow behavior of polymers in the melt and in concentrated solution is mainly determined by the average molecular weight, the molecular weight distribution, and the degree of branching. To study these relationships, model substances were prepared by polymerization of butadiene in benzene with n-butyl-lithium as the catalyst. The reaction of these "living polymers" with alkylchlorosilane or $SiCl_4$ led to macromolecules with a defined degree of branching.

The pure substances and a series of mixtures were characterized by solution viscosity, osmometry, and light scattering, and in some cases by gel permeation chromatography. The Weissenberg rheogoniometer was used to determine the flow behavior in concentrated solution and in the melt at shear rates between about 10^{-3} and 10^3 sec^{-1}. The normal stresses were measured as well as the tangential stresses. The results were largely in agreement with those obtained by *Kraus* and *Gruver*[16]; however, we have found that for 10% solutions of polybutadiene branching in four directions and having molecular weights up to $\bar{M}_w = 700000$, the course of the viscosity-molecular weight line (logarithmic graph, gradient 3.4) is parallel to that for linear polybutadiene, the branched polybutadiene always having a lower viscosity than a linear polybutadiene of the same molecular weight. No intersection of the two curves is observed up to a molecular weight of $\bar{M}_w = 2.5 \times 10^6$. This in agreement with a theory recently proposed by *F. Bueche*.

The normal stress differences have been found to be proportional to the square of the shear rate in the low shear rate range for linear, narrow distribution polybutadiene of various molecular weights (10% solution). A reduced plot showed good superposition. Moreover, application of a recently published phenomenological theory of *Ninomiya* and *Ferry*[17], which allows calculation of the equilibrium compliance essentially from intrinsic viscosity data, and of a specific result from "second order" fluid theory[18] yielded normal stress differences in good agreement with those directly measured by the rheogoniometer.

Torsional Vibration Measurements on High Polymers in the Rubber-Elastic Range

By *E. E. Schäfer* and *G. Rehage*[**] (delivered by *E. E. Schäfer*)

The elastic properties of dry and swollen elastomers that are cross-linked *via* principal valences were studied above the glass transition point. Experiments were carried out to determine whether the theories derived from statistical thermodynamics for the entropy-elastic state of matter can be applied to torsional vibration measurements. These measurements should give the principal parameters for the description of the elastic behavior of real networks, the degree of cross-linking, and the energy-elastic component of the storage modulus G'.

For this purpose we constructed a torsional pendulum that permits the determination of the temperature-dependence of the storage modulus, even for highly swollen elastomers, with an accuracy of at least 0.5%.

der Technischen Hochschule
Adolf-Römer-Str. 2 A
3392 Clausthal-Zellerfeld (Germany)

The investigations were carried out on polymethyl methacrylate that had been cross-linked in bulk or in a chlorobenzene solution with ethylene glycol dimethacrylate, and on natural rubber cross-linked with dicumyl peroxide. After extraction for about three weeks with *m*-xylene, nearly all the specimens showed a linear increase in storage modulus G' with temperature over a wide temperature range.

The physically effective degree of cross-linking could be calculated from the slope of these straight lines. The result is independent of the swelling agent used for a given specimen.

The energy-elastic component G'_4 of the storage modulus was found from the intercept of the lines $G'(T)$ on the axis, which was determined both graphically and analytically. G'_U was based on the total storage modulus, since the errors arising in the determination of the dimensions of the specimen are then eliminated. The energy-elastic component of the storage modulus for the unswollen polymethyl methacrylate specimens is less than 5 %, *i.e.* these specimens are almost ideally rubber-elastic in this temperature range. The values for the dry rubber specimens were 21 to 32 %, depending on the degree of cross-linking. G'_4 always increases with the degree of cross-linking.

In every case, the energy-elastic component of the storage modulus increases with the degree of swelling at a constant degree of cross-linking. We assume that the networks studied by us contain not only chains whose contour length is so great that their behavior is entropy-elastic, but also short chains, which are braced by the swelling process and energetically loaded on deformation.

Thermodynamic (Maximum) Melting Points of Oligomeric and Polymeric Single-Component and Multi-Component System

By *H. G. Kilian*[*]

Formulae are given for the thermodynamic equilibrium melting points of oligomeric and polymeric single-component systems of linear, perfectly stereo-regular chains. Under these conditions the chains are always built into crystal lamellae of the same thickness in the extended state (molecular folding is impossible). According to *Flory* and *Vrij*, the melting point of such a system is partly determined by a characteristic additional entropy term, which takes into account the nematic mixing of the chains in an otherwise invariant crystal lattice. This additional term is also significant for eutectic, ideally athermic polymeric multi-component systems. In this case it is accompanied by the entropy of mixing, which is due to the mixing of chains of various lengths in the melt. In the fully-crystalline eutectic state, the chains of various lengths in the eutectic multi-component system are arranged according to chain length and built into the crystal lamellae in the extended state, the length of these lamellae being the same as that of the chains themselves.

However, complete fractionation of the chains of various lengths during crystallization can seldom be achieved. It must therefore be assumed that there is limited miscibility of the chains of various lengths in the solid state and a limited possibility of nematic translation of the chains of various lengths in the crystal. These deviations from the equilibrium outlined above can be theoretically taken into account by a single "internal" parameter at the maximum melting point. The limited miscibility in the solid state and the possibility of nematic translation raise the maximum melting point in relation to that of the equilibrium system, since the "total" entropy of melting is decreased.

The melting points of several n-paraffins, the melting points of several fractions of linear polyethylene (in which there is no molecular folding), and the maximum melting points of quasi-eutectic copolymers can all be quantitatively described by an invariable set of phenomenological constants with the aid of the formulae discussed here. The polymeric single-component systems have consistently higher melting points than the multi-component systems, while the maximum melting points of the quasi-eutectic copolymers with statistical length distribtions of the crystallizable sequences show higher melting point depressions than the fractions with gaussian length distributions.

Investigation of the Melting Behavior of Crystalline Polyethylene Produced by Degradation with HNO_3

By *K. H. Illers*[*]

Partially crystalline samples of linear and branched polyethylene, the crystallinities of which varied between 0.46 and 0.96; were treated with 100 % HNO_3 for up to 40 hours at 70 °C. According to *Palmer* and *Cobbold*[19], this leads to selective oxidation and breakdown of the amorphous regions. Investigations on the residual highly crystalline skeleton should provide information about the size, morphology, and properties of the crystalline regions in the partially crystalline starting material.

A differential calorimeter (DSC1, Perkin-Elmer) was used to find the melting point and the enthalpy of fusion as a function of the reaction time and rate of heating. The molecular weights $\overline{M}_n$ and $\overline{M}_w$ of the completely degraded samples were also determined, and electronmicroscope and X-ray measurements were carried out. The results can besummarized as follows:

1. The average crystal thickness in chain direction as calculated from the average molecular weights $\overline{M}_n$ and $\overline{M}_w$ of the degraded samples agree closely with the larger of the two X-ray periods. This shows that the dimension of the crystal in the chain direction is given by the larger X-ray period, and not by the smaller.
2. The molecular weight distributions of the degraded samples are very narrow, and probably approximately agree with the crystallite size distribution before degradation. The morphological structure of the original samples is evident in the molecular weight distribution of the degraded samples.
3. The melting point (position of endothermic peak extrapolated to a heating rate of zero) is not affected by treatment with HNO_3. On crystallization of the degraded samples from the melt, the melting point rises slightly for previously short crystallized chains, and falls for long chains.
4. The marked increase in the melting point of samples crystallized under high pressure with increasing heating rate ("superheating effect") is no longer observed after degradation.
5. The heat of melting increased with increasing reaction time, and reaches a limiting value after a time which decreases with increasing crystallinity of the original sample. The limiting value for annealed (130 °C) samples and samples crystallized under high pressure is 70 ± 1 cal/g. This value agrees with the heat of fusion of the infinitely large, 100 % crystalline polyethylene crystal, which could previously be determined only by extrapolations. In the case of branched and quenched linear polyethylene, a small amorphous fraction (15 and 10 % respectively) is still present even after the limiting value has been reached.
6. After degradation, the chains are crystallized in the extended state. When the degraded samples are subsequently crystallized from the melt, the heat of fusion again decreases, the decrease becoming more pronounced with increasing original crystal size. This is attributed to the combined influence of renewed chain folding and of the crystallite size. [VB 58 IE]

Oxidation Reactions of the Thioamide Group

By *W. Walter* [*]

On oxidation with H_2O_2, thioamides afford thioamide *S*-oxides *(1)*, which can be clearly differentiated from the isomeric thiohydroxamic acids. The vibrations of the C=S group of thioamides couple so strongly with other vibrations that they cannot be used for identification, but the S=O vibration of the >C=S=O system offers a key band for this group. The equilibrium between a thioamide and an imido thiol corresponds to the equilibrium between *(1)* and the iminomethanesulfenic acid *(2)* in the oxidation products.

$$R^1\text{-}\underset{\underset{S=O}{\|}}{C}\text{-}NHR^2 \rightleftharpoons R^1\text{-}\underset{SOH}{C}=NR^2$$

(1) *(2)*

Reactions of thioamide *S*-oxides have been found in which the form *(2)* takes part; in the thiourethane series compounds of structure *(2)* can be isolated, *e.g.* when R^1 = $-O-C_6H_4-C_6H_5$-*o*, and R^2 = $-C_6H_3(CH_3)_2$-*o,o'*. The hydrogen bond shown in *(1)* plays a part in the stability of compounds *(1)* and *(2)*.

Thioamides show *cis-trans*-isomerism at their partial C=N double bonds. One isomer of an *N*-benzyl-*N*-methylthioformamide has been isolated and the other has been enriched to the extent of 75 %; the activation energy for their interconversion has been determined as 25.16 ± 0.66 kcal/mole. Their respective structures were assigned on the basis of NMR and X-ray diffraction data.

N-Isobutylthioformamide is an equilibrium mixture of 82 % of the *trans*- and 18 % of *cis*-form, but after oxidation to the *S*-oxide only the *cis* isomer remains; thus the intramolecular hydrogen bond is so strongly stabilizing that the barrier to rotation cannot be overcome at room temperature.

Nicotinamide *N*-Oxide: A Biological Oxidant

By *S. Chaykin* [*]

Hog liver xanthine oxidase can catalyse the reduction of nicotinamide *N*-oxide [1]. Either reduced nicotinamide adenine dinucleotide (NADH), hypoxanthine, or xanthine can be oxidized by the *N*-oxide. Since the enzyme also catalyses reactions with oxidizing agents that can act only as electron acceptors, it has been generally assumed that oxidizing agents always function solely as electron acceptors in xanthine oxidation. Water would serve as an oxygen donor when required. Although the *N*-oxide certainly is an electron acceptor in the oxidation of NADH, the possibility existed that it might act as an oxygenating agent in the oxidation of hypoxanthine or xanthine. The latter reactions were therefore investigated using ^{18}O-labeled oxidants.

When xanthine is oxidized in an atmosphere of $^{18}O_2$ no oxygen-18 is found in the uric acid which is formed. If the reaction is carried out in $H_2^{18}O$ and an atmosphere of $^{16}O_2$ oxygen-18 is found in the uric acid. However, when ^{18}O-labeled nicotinamide *N*-oxide is used, direct transfer of oxygen to xanthine occurs and 0.67 g-atom of ^{18}O per mole of uric acid are found. The *N*-oxide also functions as an electron acceptor, but to a much lesser extent; on oxidation with unlabeled *N*-oxide in the presence of $H_2^{18}O$ 0.18 g-atoms of ^{18}O were incorporated per mole of uric acid.

Similar results were obtained with milk and liver xanthine oxidases. If the properties of nicotinamide *N*-oxide are representative of those of heterocyclic *N*-oxides in general, then these compounds can be classified as biological oxidizing agents and should be investigated as potential electrophilic hydroxylating agents.

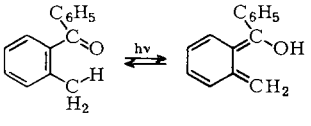
Photoreduction of Ketones and Ketimines

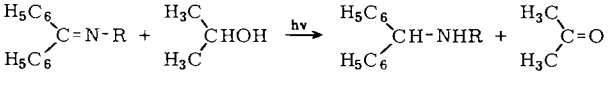
By *M. Fischer* [*]



On irradiation by UV light, benzophenone *(1)* is reduced by hydrogen donors such as alcohols and hydrocarbons to benzopinacol *(2)* [1]. The quantum yield for the photoreduction reaches an optimal 2.0 in 2-propanol since hydrogen is abstracted relatively easily from this solvent, and it is vanishingly small in benzene whose hydrogen atoms are more firmly bound [2]. Studies with quenchers [3] show that

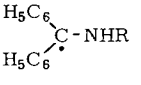
(1) *(2)*

the triplet state is the excited state responsible for the light-induced reaction.



2-Methylbenzophenone *(3)* cannot be reduced to the pinacol [4] because the excitation by light causes an intramolecular migration of hydrogen to give the dienol *(4)*, which spontaneously reverts to the ketone. Formation of the dienol *(4)* was demonstrated by Diels-Alder addition to dimethyl acetylenedicarboxylate.

(3) *(4)*



Photoreduction is also not observed with those benzophenones [2] that have substituents with electron-donor properties at the *o*- or *p*-position, since on irradiation electron shifts lead to a π,π^* triplet instead of the reactive n,π^* triplet.

Ketimines derived from benzophenone, *e.g.* benzophenone methylimine *(5)*, with R = CH_3, are reduced by 2-propanol under the influence of UV light to the corresponding amines *(6)* [5]. Quantum yield: 0.01 on irradation with light of wavelength 265 nm. Reaction conditions: Hanau immersion lamp TQ 81; Solidex filter; yield: 90%.

(5), R = CH_3, $C_6H_5CH_2$, C_6H_5 *(6)*

The aminodiphenylmethyl radical *(7)* is formed in the primary photochemical process, as could be shown by means of radical trapping agents and by isotope experiments.

(7)

Sensitizers such as xanthone with triplet energies of at least 62 kcal/mole sensitize the photoreduction of *(5)*.

Side-Chain Interactions in Polypeptides. Experiments with Donor-Acceptor Complexes

By *R. Schwyzer* [*]

Synthetic chemical work has shown that the information held in the amino acid sequences of biologically active polypeptides is grouped in individual words of specific biological meaning [1]. For angiotensin and adrenocorticotropin (the first protein hormone synthesized in a pure state [2]) it has been shown that the regions responsible for the receptor mechanism, for blocking and for qualitative and quantitative alternation of activity, for transport, and for antigenic properties lie next to one another and are spelled out with different amino acid sequences. These results are important in the development of drugs.

The conformational possibilities of the active materials and their binding to the receptor molecule play a large part in translation of the sequence information into biological activity ("2nd translation of biochemical genetics"). Sidechain interactions are particularly important in this respect. In order to obtain information on side chain interactions in solution, we are attempting to build such amino acids into synthetic polypeptides whose side-chains might, given favorable conformations, form electron-donor-acceptor (EDA) complexes with one another. Complex formation can be detected spectroscopically by appearance of charge-transfer (CT) bands.

Our present experiments concern the following questions:

1. Which amino acids can form EDA complexes? 2. What are the properties of their intermolecular complexes? 3. Can one establish the existence of intramolecular complexes and what are their properties?

Our preliminary findings can be summarized as follows:

1. Amino acids with donor sidechains are: pentamethylphenylalanine, *p*-dimethylaminophenylalanine, tryptophan.

2. Amino acids with acceptor side chains are: *p*-nitrophenylalanine, 2,4-dinitrophenylalanine, 2,4,6-trinitrophenylalanine, N^{ε}-(4-nitrophthaloyl)lysine, N^{δ}-(4-nitrophthaloyl)ornithine, N^{ε}-(tetrachlorophthaloyl)lysine, N^{δ}-(tetrachlorophthaloyl)-ornithine.

3. Some intermolecular EDA complexes of 4-nitrophthaloylglycine ethyl ester: *N*-(benzyloxycarbonyl)pentamethylphenylalanine (in ethanol, λ_{CT} = 370 nm, ε_{CT} = 500, K_{ass} = 2.3, distance between ring planes 3.4 Å); *N*-acetyl-*p*-dimethylaminophenylalanine ester (in ethanol, λ_{CT} = 460 nm, ε_{CT} = 664, K_{ass} = 0.54); *N*-(benzyloxycarbonyl)tryptophan (in ethanol, λ_{CT} = 355 nm, ε_{CT} = 712, K_{ass} = 1.56).

4. Some intramolecular EDA complexes of the simplest *N*-phthaloylamino acid type: *N*-(4-nitrophthaloyl)pentamethylphenylalanine ester, yellow crystals (in $CHCl_3$, λ_{CT} = 345 nm, ε_{CT} = 310; mean distance for electron transfer 3.85 Å); *N*-(4-nitrophthaloyl)-*p*-dimethylaminophenylalanine ester, violet crystals (in ethanol, λ_{CT} = 430 nm, ε_{CT} = 17); *N*-(4-nitrophthaloyl)tryptophan ester, orange-red crystals (in $CHCl_3$, λ_{CT} = 428 nm, ε_{CT} = 470).

Siderochromes, Iron-Containing Substances from Microorganisms

By *H. Zähner* [*]

When grown in an iron deficient environment, numerous microorganisms excrete compounds that can form iron complexes. Study of these products from different microorganisms disclosed a new group of natural compounds, the siderochromes. These are characterized by the presence of three hydroxamic acid groups per molecule, arranged in such a way that formation of a stable iron(III) complex is possible. Three types of complex can be distinguished on the basis of their biological activities:

a) *Sideramines.* Growth factors for various sideramine-heterotropic microorganisms (*Pilobolus kleinii*, strains of *Microbacterium lacticum*, *Arthobacter terregens*) and also antagonists of iron-containing antibiotics, namely the sideromycins. The group includes: ferrichrome, ferrichrysin, ferricrocin, ferrirubin, ferrirhodin, ferrioxamines A_1, A_2, B, C, D_1, D_2, E, F, and G, coprogen, and the terregen factor; probably also schizokinen.

b) *Sideromycins.* Iron-containing antibiotics that can be considered as antimetabolites of sideramines (albomycin, grisein, ferrimycin A_1 and A_2, succinimycin, A 22765, danubomycin).

c) *Siderochromes* without detectable biological activity, *e.g.* ferrichrome A.

All the sideramines from molds contain three ornithine units, their amino groups being hydroxylated and acylated. Varations in structure either consist in the mode of union of the three ornithine groups, *e.g.* through three glycine residues to a hexapeptide (here the glycine residues may be partially replaced by serine), or in the presence of different acid components (acetic acid or *cis*- or *trans*-anhydromevalonic acid).

The biological function of the sideramines is not yet clear. Hypotheses deal on the one hand with an influence on iron transport and on the other with a "coenzyme" action in the incorporation of iron into Fe-containing enzymes; but other possibilities cannot yet be ruled out.

The various hypotheses can be experimentally tested by means of the antagonism between sideramines and sideromycins. Iron-free ferrioxamin B is used as its methanesulfonate (Desferal®) for treatment of disturbance of iron storage. Formation of iron-free sideramines can be regulated by varying the amount of iron offered (deficiency of iron leads to increased production; with sufficient supply of iron no sideramine is produced). The mechanism and site of this control are unknown.

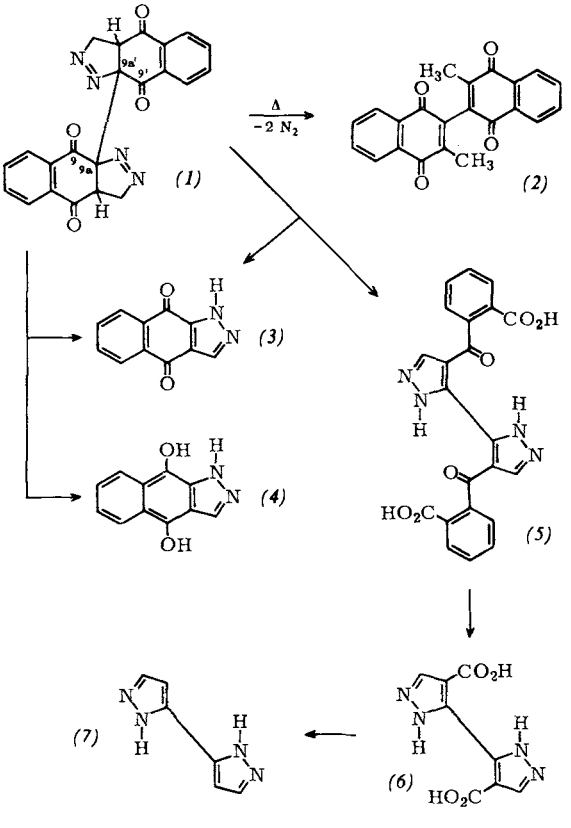
Oxidation and Elimination Reactions of the Diazomethane–2,2-Bi-(1,4-naphthoquinone) Adduct



By *A. Zeeck* [*]

Both half-molecules of 2,2′-bi-(1,4-naphthoquinone) react with diazomethane in a cycloaddition yielding the adduct *(1)* [1]. This compound can be stabilized in three ways, each of which involve attack on the bonds from C-9a and C-9′a and aromatization:

1. Warming the adduct in anhydrous toluene gives 3,3′-dimethyl-2,2′-bi-(1,4-naphthoquinone) *(2)* (thermal elimination of nitrogen).

2. In the presence of electrophilic agents disproportionating fragmentation occurs, yielding benz[*f*]indazole-4,9-quinone *(3)* and its hydroquinone *(4)*. The latter is rapidly oxidized by air to the former. *(3)* and *(4)* can be identified in admixture by means of acetic anhydride/pyridine (with exclusion of air) when the *N*-acetyl derivative of *(3)*, and the leucotriacetate derivative of *(4)* are obtained. In a side reaction, *(1)* loses half of its nitrogen before the two molecular fragements have separated; a nitrogenous quinone of molecular weight 352 but unknown structure results.

3. Oxidation in 2 to 4 N alkali hydroxide solution leads to (a) decoupling of the C-9a/C-9′a bond, yielding two molecules of *(3)*, or (b) fission of the C-9/C-9a and the C-9′/C-9′a bonds, yielding 4,4′-bis(2-carboxybenzoyl)-5,5′-bipyrazole *(5)*. Use of hydrogen peroxide as oxidizing agent gives mainly *(3)* [1], and use of potassium hexacyanoferrate(III) gives (energetically more favorable) mainly *(5)*. Both reactions are expected to occur by way of an dianion of *(1)* and a

radical anion, which either splits into two parts or, when attacked by hydroxide ions at C-9 or C-9′, initiates another reaction path (oxidative-hydrolytic scission of two C–C bonds).

The structures of *(5)* and some of its derivatives can be proved by IR, NMR, and mass spectrometry. The position of the hydrogen atom in the pyrazole rings cannot be determined by these methods. Since *(5)* contains the structural units of *o*-aroylbenzoic acids, ring-chain tautomerism also occurs. Reaction with diazomethane yields the normal dimethyl ester, whereas acetylation or reduction result in ring closure in both halves of the molecule to yield 1,1′-diacetyl-4,4′-bis(3-acetoxyphthalid-3-yl)-5,5′-bipyrazole or 4,4′-bis-(phthalid-3-yl)-5,5′-bipyrazole, respectively.

The parent of *(5)*, namely, 3,3′- or 5,5′-bipyrazole *(7)* (m.p. 259 °C) is obtained on decarboxylation of the dicarboxylic acid *(6)*; it is formed, with benzoic acid, in an alkali melt at 160 °C.

Commercial Processes for Antibiotic Fermentation

By *R. Kreutzfeldt* [*]

Industrial fermentation has recently achieved increased importance, principally by production of antibiotics. Some 1000 antibiotics have been discovered in the last 25 years, of which about 50 have acquired economic significance, notably the penicillins, tetracyclins, and streptomycins. About 3000 tons of antibiotics were prepared in USA in 1964 (*ca.* 50 % of the world production), at a value of *ca.* $ 400 million. The world production of penicillins can be estimated as about 1500 tons a year.

In spite of many years' experience, penicillin production remains one of the most difficult and most sensitive. *Fleming* achieved yields of 2–10 units/ml in his first fermentations: today 10000 units/ml are considered normal. The fermentations are carried out in a technically similar way for all antibiotics, and the technique for penicillin fermentation alone will be described more closely here.

The penicillin-forming mold is preserved as a permanent culture in the anhydrous state at about −5 °C in order to exclude any metabolism. From this permanent culture subcultures are made on the laboratory scale, and further cultures are grown in prefermenters. The amount of inoculum for the main fermenter is chosen to be between 2 and 20 % of the amount to be harvested; larger amounts of inoculum shorten the fermentation time.

The fermenters are fitted with an aeration system, a stirrer, and a cooling system that keeps the temperature constant within ± 0.5 °C. Provision of oxygen and formation of penicillin are closely related. Fermenters in commercial use today may have a capacity of 400 m³. Antibiotic fermentations must be carried out without admission of foreign infections: Only sterilization by steam (at least 120 °C for at least 20 min) comes into consideration for large-scale production.

Fermentation conditions: 7 Days at 25 ± 0.5 °C; 0.3 m³ of air per min per 1 m³ of liquor. The following are required for production of 100 kg (4.3 % yield) of penicillin-Na: 1200 kg of carbohydrate, 60 kg of animal and vegetable fats, 770 kg of corn steep liquor, 220 kg of inorganic substances (as buffer, and as source of sulfur and phosphorus), and 100 kg of phenylacetic acid for formation of penicillin G.

The material balance of penicillin production from these quantities (input 2350 kg of raw materials) is: 100 kg of penicillin-Na (4 wt-%), 825 kg of mould mycelium (35 %), 660 kg of residual substances in the culture solution (28 %), 765 kg of CO_2 (33 %).

The energy change of penicillin fermentation is as follows (heats of combustion of raw materials and of the metabolic products are compared: mechanical energy, *e.g.* heat generated by stirring of the culture liquor, is not considered):

Energy contained in	kcal	%
Penicillin-Na	586000	7
Mycellium	2805000	33
Residual substances in liquor	1923000	23
Heat of combustion evolved	3147000	37
Total consumption of energy of the raw materials	8461000	100

Further, every 100 kg of penicillin require: 3000 kWh of electrical energy (mainly for stirring), 4 tons of steam (sterilization and sealing), 50000 Nm^3 of crude air, 900 m^3 of cooling water (cooling of the sterilized solution, removal of the heat produced by stirring and by biochemical combustion).

Costs of penicillin production (exclusive of amortization) can be divided as follows: for raw materials 50 %, for energy 20 %, for repairs 10 %, personel costs 15 %, other costs 5 %. These complicated biological processes are very liable to disturbance and require detailed supervision and exact analytical control. Even with fermentation processes that have been well established variations of yield amounting to ± 15 % are to be expected. In general, the following factors are responsible for this: variation of the penicillium strain or of the quality of raw materials; infection by foreign molds; errors in servicing and technical disturbances. The quality of the raw materials is decisive for fermentation yields, and as these materials are mostly of natural origin they are subjected to analytical and biological control.

Electrochemical Oxidation of Formic Acid and Carbon Monoxide on Platinum Catalysts in Acid Electrolytes

By *H. Binder*, *A. Köhling*, and *G. Sandstede*[*]

Fuel cells containing acid electrolytes are advantageous for electrochemical oxidation of carbon-containing fuels because the resulting carbon dioxide is obtained as a gaseous combustion product, whereas in alkaline electrolytes it remains dissolved as carbonate. In addition to hydrocarbons and methanol, other carbon-containing fuels are carbon monoxide (which can be obtained mixed with hydrogen on conversion of hydrocarbons or coal) and also formic acid. Their use has hitherto been restricted because they poison platinum catalysts, the electrodes becoming strongly polarized and the output of the cells lowered. When the platinum surface is partially covered with sulfur, the anodic oxidation to carbon dioxide is greatly accelerated. This result could lead to development of fuel cells utilizing either carbon monoxide and hydrogen, or formic acid.

On a Raney platinum catalyst that is partially covered with a monatomic sulfur sorbate, carbon monoxide in 3 N sulfuric acid at 90 °C leads to a potential of 250 mV (at a current density of 200 mA/cm^2) against a hydrogen reference electrode in the same solution. Anodic oxidation of formic acid (the hydrate of carbon monoxide) is still more strongly accelerated, so that under similar conditions a current density of 200 mA/cm^2 is obtained, even at 30 °C. At 90 °C the current density reaches a stationary value of *ca.* 2 A/cm^2. At an untreated Raney platinum electrode, however, a current density of less than 1 mA/cm^2 is obtained.

The sulfur sorption layer can be easily placed on any platinum catalyst, including platinum black, *e.g.* by treatment with hydrogen sulfide. It is stable at anodic regions up to 600 mV; oxidation to sulfur dioxide begins only at higher potentials. The degree of coverage of the platinum surface has a large effect on the reaction rate of carbon monoxide or formic acid; the rate is a maximum when about one third of the total surface platinum atoms is covered with sulfur.

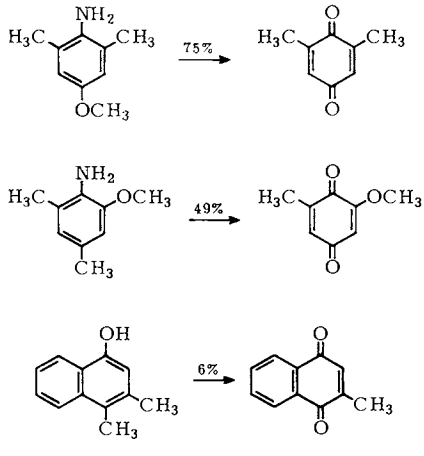
Specific Oxidation of Phenols by Dipotassium Nitrosobissulfate

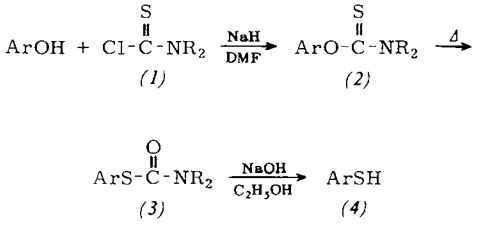


By *H.-J. Teuber*[*]

Reaction of 2,3-phenanthrenediol with dipotassium nitrosobissulfate, $ON(SO_3K)_2$, yields 3-hydroxy-1,2-phenanthraquinone, which is obtained as the colorless dimer *(1)*[1] whose UV spectrum corresponds substantially to that of 3,4-dihydro-1(2*H*)-phenanthrone but not to that of 2,3-dihydro-4(2*H*)-phenanthrone. The (dimeric) 2-hydroxy-3,4-phenanthraquinone is thus not formed.

(1)

In the formation of *p*-quinones from monohydric phenols, substituents may be eliminated from the *para*-position; not merely COOH, OCH_3, and Cl but even CH_3 may be eliminated, so that blocking of *para*-positions by methyl groups cannot always be reliably accomplished:

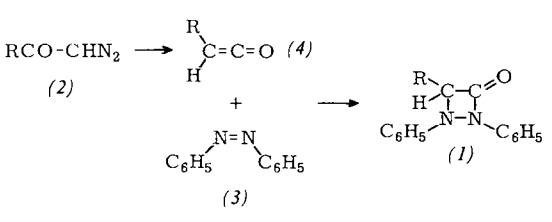


Formation of the *N*-methyliminobissulfate, $H_3C{-}N(SO_3K)_2$, during demethylating oxidations has been demonstrated.

Lecture at Hamburg on January 10th, 1967 [VB 59 IE]
German version: Angew. Chem. 79, 426 (1967)

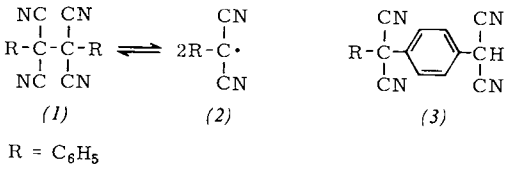
[*] Prof. Dr. H.-J. Teuber
Institut für Organische Chemie der Universität
Robert-Mayer-Str. 7/9
6 Frankfurt/Main (Germany)

[1] Cf. *H.-J. Teuber* and *G. Steinmetz*, Chem. Ber. *98*, 666 (1965); *H.-J. Teuber*, *P. Heinrich*, and *M. Dietrich*, Liebigs Ann. Chem. *696*, 64 (1966).



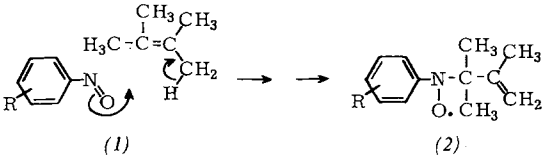
The conversion of phenols into thiophenols, according to *M. S. Newman* and *H. A. Karnes*, can generally be achieved by the reaction sequence *(1)–(4)*. The decisive step is the thermal rearrangement of *o*-aryl dialkylthiocarbamate *(2)* into *S*-aryl dialkylthiocarbamate *(3)*. This rearrangement proceeds

at 130–300 °C (depending on Ar) in high yields. The reaction has been used with numerous phenols and hydroxyheterocyclic compounds. 2- and 4-pyridyl esters can rearrange at 25 °C with acidic reagents. / 152nd Meeting Amer. chem. Soc. *1966*, p. 111 / –Ma. [Rd 608 IE]



The formation of cyanogen *N*-oxide, NC–C≡N→O *(1)*, from cyanoformhydroximyl chloride NC–C(Cl)=NOH with tertiary amines or aqueous organic bases has been detected by *Ch. Grundmann* and *H.-D. Frommeld* by means of typical 1,3-dipolar additions. Preparation of the oxide in the presence of active dienophiles such as styrene, acrylonitrile, 1,3-butadiene, phenylacetylene, and dimethyl acetylenedicarboxylate led to substituted 3-cyano-4,5-dihydro-1,2-oxazoles or 3-cyano-1,2-oxazoles. *(1)* forms an explosive solid polymer. Unlike cyanogen bis-*N*-oxide ONC–CNO, which is an unusually stable aliphatic nitrile oxide because of the large number of possible resonance structures, *(1)* is typically unstable. / 152nd Meeting Amer. chem. Soc. *1966*, p. 49 / –Ma. [Rd 612 IE]

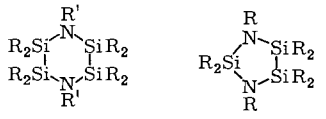
1,2-Diazetidinones *(1)* have been synthesized by *W. Fischer* and *E. Fahr*. These authors irradiated (high-pressure mercury lamp) diazoketones *(2)* in CH_2Cl_2 in the presence of azobenzene *(3)*. The initially formed aldoketenes *(4)* add to azobenzene. *(1)* are pale yellow or colorless substances,



which can be recrystallized from ethanol. Examples: R = *m*-$NO_2C_6H_4$, m.p. 125 °C, yield 43%; *p*-ClC_6H_4, m.p. 131 °C, 42%; α-naphthyl, m.p. 147 °C, 30%; *m*-CH_3O–C_6H_4, m.p. 142 °C, 57%. / Tetrahedron Letters *1966*, 5245 / –Ma. [Rd 613 IE]

Polycyano radicals such as *(2)* have been studied by *H. D. Hatzler*. The α,α-dicyanobenzyl radical *(2)*, which is formed from phenylmalodinitrile and t-butylperoxide or from symtetracyanodiphenylethane *(1)*, dimerizes to give *p*-(α,α-dicyanobenzyl)phenylmalodinitrile *(3)*. *(2)* reacts with NO_2, NO, Br_2, and 2,2-diphenylpicrylhydrazyl, but not with O_2. It abstracts hydrogen from THF, but does not initiate the polymerization of styrene. Radicals are also formed at room

temperature in solutions of 1,2-bis-(4-nitrophenyl)tetracyanoethane, sym-dicyanotetraphenylethane, and hexacyanoethane, and these can be intercepted with 2,2-diphenylpicrylhydrazyl. The reactions of polycyanoethylenes such as *(1)* are best interpreted by assuming easy homolytic dissociation. 9-Cyano-9-tricyanomethylfluorene undergoes homolysis much more slowly than the compounds mentioned above. / J. org. Chemistry *31*, 2654 (1966) / –Ma. [Rd 614 IE]



Very stable nitroxide radicals are formed from nitrosoaromatic-olefin adducts. Nitrosoaromatic compounds react with olefins in a Diels-Alder type of reaction, as indicated in *(1)*, to give *N,N*-disubstituted hydroxylamines, which are oxidized to the radical *(2)* by an excess of nitroso compound.

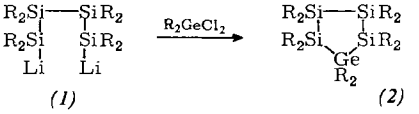
In order to obtain the simplest possible ESR spectra, *A. B. Sullivan* used 2,3-dimethyl-2-butene (0.01 N in benzene). The unstable nitroxide radicals could not be detected; however, *N*-(trimethylprop-2-enyl)aniline could be isolated by reduction with sodium in n-butanol. The radicals are formed in a second-order reaction. The coupling constants for a series of *m*- and *p*-substituted compounds (*e.g.* R = Cl, CH_3, OCH_3, OC_6H_5) can be linearly related to the Hammett σ values. The effects of the substituents on the ESR spectra are the same as for the nitrobenzene radical-anions. / J. org. Chemistry *31*, 2811 (1966) / –Bu. [Rd 622 IE]

The aromatization of cyclohexanecarboxylic acid to benzoic acid is catalysed by an enzyme which has been enriched from liver and liver mitochondria by *B. M. Babior* and *K. Bloch*. Cyclohexane carboxyl CoA is substrate, cyclohexene-1-carboxyl CoA is intermediate. All three isomers of cyclohexene carboxyl CoA are converted to benzoyl CoA. The reaction does not proceed *via* hydroxylation and dehydratation but has the character of an oxidation similar to acyl-CoA-dehydrogenation in fatty acid catabolism. FAD acts as coenzyme and is removable at lower pH, FAD addition then reactivates the enzyme. The aromatization requires oxygen, which, however, can be replaced by 5-methylphenaziniummethyl sulfate and iron(III) cyanide. The Michaelis constant for cyclohexane carboxyl CoA is 9.1×10^{-5}, for cyclohexene-1-carboxyl CoA 3.4×10^{-5} moles/l. The natural substrate is not known. / J. Biol. Chemistry *241*, 3643 (1966) / –Hö. [Rd 634 IE]

New five- and six-membered silicon-nitrogen ring systems have been reported by *U. Wannagat* and *O. Brandstätter*. The previously unknown 1,4-diazatetrasilacyclohexanes *(1)* (R′ = H, m.p. 1 °C; R′ = CH_3, m.p. 23 °C) were prepared by the reaction of ammonia or methylamine with 1,2-dichlorotetramethyldisilane.

(1) R = CH_3, R' = H, CH_3 *(2)* R = CH_3

The reaction of 1,2-dichlorotetramethyldisilane with *N,N'*-dilithiumbis(methylamino)dimethylsilane yields the new 1,3-diazatrisilacyclopentane derivative *(2)* (m.p. −12 °C). / Mh. Chem. *97*, 1352 (1966) / −WG. [Rd 635 IE]



A new reaction of geminal bis(ethoxycarbonyl) compounds is reported by *A. P. Krapcho, G. A. Glynn,* and *B. J. Grenon.* On heating *(1)* with at least one equivalent of NaCN to about 160 °C in dimethylsulfoxide for *ca.* four hours, the ester *(2)* is produced in good yield. This simple method is superior to the classical decarboxylation reaction.

$$\underset{(1)}{R^1R^2C(CO_2C_2H_5)_2} \xrightarrow[DMSO]{NaCN} \underset{(2)}{R^1R^2CHCO_2C_2H_5}$$

Examples: Diethyl 1,1-cyclobutanedicarboxylate → ethyl cyclobutanecarboxylate (yield 75 %); diethyl 1,1-cyclopentanedicarboxylate → ethyl cyclopentanecarboxylate (75 %); $CH_3-CH_2-CH(CO_2CH_5)_2$ → $CH_3CH_2-CH_2-CO_2C_2H_5$ (80 %). / Tetrahedron Letters *1967*, 215 / −Ma. [Rd 638 IE]

Gas chromatographic capillary columns of high resolution in direct combination with a mass spectrometer is the basis of a new technique reported by *J. A. Völlmin, I. Omura, J. Seibl, K. Grob,* and *W. Simon.* The apparatus permits of the routine operation of packed columns, as well as capillary columns, coupled to a single focusing mass spectrometer. The most important feature is the arrangement of the separator, glass connecting tubes, and stopcock, on a carrier which is screwed onto the ion source, and by means of which these parts may be removed from the rest of the mass spectrometer without breaking any glass joints. The system may be heated to a maximum temperature of 250 °C. The change from capillary to packed column can be accomplished without modifying the rest of the apparatus. Evaluation and interpretation, *e.g.* of the mass spectrum of the substances contained in cigarette smoke, can be carried out at least ten times faster than the conventional gas chromatographic characterization. / Helv. chim. Acta *49*, 1768 (1966) / −WG. [Rd 636 IE]

Tetrasilacyclopentanes containing an additional hetero atom in the ring have been prepared by *E. Hengge* and *U. Brychcy.* Members of this little investigated class of compounds may be synthesized in the following way: Cleavage of octaphenylcyclotetrasilane by halogens or by lithium yields bifunctional tetrasilanes, *e.g. (1)*, which further react with other bifunctional molecules to yield the desired heterocyclic compound

(1) *(2)*

R = C_6H_5

e.g. (2). Compound *(2)* contains a hetero atom which has no lone pair of electrons. The compound is of interest for purposes of spectral comparison. / Mh. Chem. *97*, 1309 (1966) / −WG. [Rd 637 IE]

BOOK REVIEWS

Dünnschichtchromatographie in der Aminosäure- und Peptidchemie (Thin-Layer Chromatography in Amino-acid and Peptide Chemistry). By *G. Pataki.* de Gruyter & Co., Berlin 1966. 1st ed., xviii, 250 pp., 128 illustrations, 52 tables, 1 fold-out table, bound DM 38.– (*ca.* $10.–).

Owing to the many applications of thin-layer chromatography, the number of publications has become so large that the need has arisen for a special treatise on thin-layer chromatography in amino acid and peptide chemistry. The author has provided a useful aid in the form of a handy (*octavo*) laboratory manual with clear working procedures.

After reading the short description of the technique and theory of thin-layer chromatography in the first part of the book, the reader can carry out and evaluate separations without referring to the original literature. In the second part, the chromatography and electrophoresis of amino acids and iodine-containing amino acids are discussed in detail, and brief hints on the separation of peptides and intermediates are offered. The third and most detailed part gives data on the thin-layer chromatographic separation of derivatives of terminal amino acids and on the "fingerprint" technique, as well as guidance in the determinatron of the amino-acid sequence of proteins and peptides. The last part describes the preparation ot starting materials for the analysis of amino acids and related compounds in biological materials.

The most important publications up to November 1964 are covered (457 references). The subject index could have been more detailed, and the quality of some photographs of instruments might have been better. The reader misses a description of molecular-sieve chromatography with the aid of the thin-layer technique, which yields information on the molecular weights of peptides and proteins too.

The publication of this (unfortunately expensive) laboratory manual will undoubtedly be welcomed by all amino acid and peptide chemists. *A. Arens* [NB 526 IE]

Handbuch für das Eisenhüttenlaboratorium. Bd. 2: Die Untersuchung der metallischen Stoffe (Handbook for the iron foundry laboratory. Vol. 2: The investigation of metallic substances). Edited by the Chemikerausschuß des Vereins Deutscher Eisenhüttenleute. Verlag Stahleisen, Düsseldorf 1966. 2nd Edit., xxiii, 441 pp., 117 figures, cloth DM 88.– [*].

This manual gives detailed analytical procedures for pig iron, steel, ferrous alloys, filler metals, metallic coatings, and (more briefly) cemented carbides and structural components. It also contains sections in which analytical methods (photoemission spectrometry, X-ray emission spectrometry, microchemical analysis) are discussed. The advisability of this division is not easy to judge.

Apart from numerous improvements in individual procedures, a number of important changes have been made to the first edition. The chapters entitled "Sampling and "The examination of metals and metal alloys" have been omitted, as have the procedures for the determination of the beryllium, thorium, and uranium contents, which are of little practical importance. The section on "Photoemission spectrometry",

however, has been enlarged and a chapter on "X-ray emission spectrometry" has been introduced. The latter is the only chapter that does not describe experimental procedures, but simply gives a description of the method and a list of references to applications in the steel industry.

The great value of the book lies in the description of proven analytical methods, incorporating the experience of numerous large laboratories of the steel industry. Rather surprisingly, however, relatively little or no mention is made of a number of more modern methods, such as polarography, X-ray analysis, and atomic absorption. Moreover, there may be some doubt as to the usefulness of the method given for the determination of selenium.

The updating of this work in the new edition is very welcome, and the book itself should take an important place in the library of any iron-foundry laboratory.

R. Bock [NB 558 IE]

[*] For a review of Vol. 1 see Chemie-Ing.-Techn. *36*, 569 (1964).

Advances in Structure Research by Diffraction Methods, Vol. 2 Fortschritte der Strukturforschung mit Beugungsmethoden, Bd. 2[*] Edited by *R. Brill* and *R. Mason*. Friedr. Vieweg & Sohn, Braunschweig – Interscience Publishers, a Division of John Wilev & Sons, Inc., New York-London-Sydney 1966. 1st Edit., iii, 166 pp., 73 figures, 11 tables, DM 34.–.

Progress reports of this nature fulfil a very important function in scientific literature. They present a summary of the latest results of special fields of research within a relatively short time of the publication of the original papers. The book contains four articles written by experts.

On pages 1 to 33, *G. E. Bacon* discusses the investigation of magnetic structures by neutron diffraction. Corresponding to the great technical interest of this topic, very many publications have appeared; the author presents a good general review.

An important question is discussed in the article by *R. Mason* and *G. B. Robertson* (Diffraction Methods and Quantum Chemistry). The authors show how accurate X-ray analyses (particularly accurate measurements of bond lengths and angles) can provide experimental bases for quantum-mechanical calculations.

The longest article (*D. C. Phillips*: Advances in Protein Crystallography) deals with one of the most modern aspects of X-ray structure analysis. It also shows how quickly articles of this type become out of date. For example, the latest work by *Phillips* on lysozyme is not included. However, it is still very valuable because of its discussion of methods.

The last, short article by *P. Corradini* (New Results of Structural Researches on High Polymers) deals mainly with recent work in the Italian high-polymer school.

W. Hoppe [NB 572 IE]

[*] Vol. 1, cf. Angew. Chem. *77*, 184 (1965); Angew. Chem. internat. Edit. *4*, 175 (1965)

Immunopathology. IVth International Symposium, Monte Carlo 1965. Edited by *P. Grabar* and *P. A. Miescher*. Schwabe & Co., Publishers. Basel-Stuttgart 1966. 1st. Edit., 467 pp., 153 figures, 1 color plate, DM 80.–.

The present volume IV of the series on immunopathology is a fit companion for the earlier volumes, and needs no special recommendation in expert circles.

The subjects discussed at this symposium were: The question of tumor-specific antigens, and the closely related problem of the histocompatibility antigens, the chemistry of which is still largely unknown. A second lecture cycle deals with immune globulins and "paraproteins" in the widest sense; finally light is thrown from various sources on autoimmunization, special emphasis being rightly placed on "immunovasculitis". The choice of lecturers is excellent, and the discussions are terse and trimmed to the essentials. It may be asked, however, whether it might not have been better to translate the French contributions, for example one as important as that by *Voisin*, into English. The overall presentation is such as to make the high price appear justifiable.

This book is more than mere leisure readin and it is recommended to the biochemist, who is nowadays faced to an increasing extent with immunobiological questions as integral parts of his own field. Some topics, such as immunochemical questions in the structure of proteins, will already be familiar to him, and these will encourage him to turn to the apparently complex "immunobiological" phenomena, which are presented here as a huge field of research.

G. Uhlenbruck [NB 575 IE]

The Amino Sugars. Vol. IIB: Metabolism and Interactions. Edited by *E. A. Balazs* and *R. W. Jeanloz*. From the series "The Chemistry and Biology of Compounds Containing Amino Sugars". Academic Press, Inc., New York-London 1966. 1st Edit., xvii. 516 pp., numerous figures and tables, $22.00.

The latest contribution on the amino sugars[1] contains 14 chapters (38–51 in the consecutive numbering system), which can be grouped according to subject. The first group (38–41) deals with metabolic processes of the monomeric amino sugars as well as of the polymeric compounds, the second (42–47) with the enzymatic and non-enzymatic degradation of glycosaminoglycanes, and the third (48–51) with the relationships between amino sugars or polymers containing amino sugars and various biological systems.

The individual topics discussed are: the metabolism of amino sugars *(E. A. Davidson)*, of glycosaminoglycans *(H. Boström, L. Rodén)*, of glycoproteins, glycopeptides, and glycolipids *(I. Yamashina)*, the influence of steroid hormones on the glycosaminoglycans of secondary sex characteristics *(J. A. Szirmai)*, hexosaminidases *(P. G. Walker)*, neuraminidases *(M. E. Rafelson jr., M. Schneir, V. W. Wilson jr.)*, glycosaminoglycan-degrading enzymes *(H. Gibian)* glycosaminoglycan sulfatases *(K. S. Dodgson)*, activation and inhibition of enzymes by polyanions containing amino sugars *(P. Bernfeld)*, chemical and physical changes of glycosaminoglycans and glycoproteins by redox systems and irradiation *(L. Sundblad, E. A. Balazs)*, interactions of polyanions with blood components *(P. Bernfeld)*, immunochemistry *(G. F. Springer)*, interactions between glycoproteins and viruses *(A. Gottschalk)*, and interactions between amino sugars or polymers containing amino sugars and viruses cells, and tissues *(E. A. Balazs, B. Jacobson*

The literature is generally covered up to 1963, and publications from 1964 and 1965 are listed as an appendix in some chapters. In the article on amino sugar metabolism, the data unfortunately do not proceed beyond 1963, though numerous papers on this topic were published after 1963, particularly in the bacteriological sector. *H. Gibian*'s chapter on glycosaminoglycan-degrading enzymes is particularly well documented (up to 1965). Many of the articles also contain additional literature surveys on individual problems (*e.g.* on the incorporation of ^{35}S into connective tissue and cartilage; p. 52).

Like its predecessors in the series, the present volume again demonstrates the importance of amino sugars in biological systems. The authors do not confine themselves to listing and discussing results, but present detailed information about the methods used and point out the advantages and disadvantages of certain techniques. (*Gibian*: hyaluronidase tests; *Walker*: working-up of hexosaminidases; *Springer*: immunological techniques).

The excellent article by *G. F. Springer* on the immunochemistry of substances containing amino sugars describes in detail the structure and immunology of the blood-group substances, but also deals with other immunologically interesting polymers from higher organisms, bacteria, and protozoa, and describes relationships between the various systems. Special mention should also be made of the article by *A. Gottschalk*, which clearly describes results on virus receptors, RDE, and analogies between the receptors and various glycoproteins.

The book is an important addition to the literature, and can be warmly recommended. *H. J. Risse* [NB 571 IE]

[1] Cf. Angew. Chem. *78*, 1027 (1966); Angew. Chem. internat. Edit. *5*, 979 (1966).

Advances in Free-Radical Chemistry. Vol. 1. Edited by *G. H. Williams*. Logos Press – Academic Press, London 1965. 1st Edit., xi. 291 pp., several figures and tables, $12.00; 75s.

The chemistry of free radicals has developed independently in physical chemistry (gas-phase reactions) and organic chemistry (solution reactions; stable radicals). It is to be hoped that the new series "Advances in Free-Radical Chemistry" will help to bring these two branches together.

In what is probably the most interesting article in the first volume, *A. F. Trotman-Dickenson* critically sifts and comments upon the literature on "The Abstraction of Hydrogen Atoms by Free Radicals". The articles by *N. J. Friswell* and *B. G. Gowenlock* ("Inorganic Hydrogen- and Alkyl-Containing Free Radicals") and by *E. S. Huyser* ("Solvent Effects in Free-Radical Reactions") are first interim reports on current research topics, the object of which is to describe new departures and to stimulate new work by formulations that are occasionally rather too subtle.

An important report on the little known but surprisingly smooth "Vapor-Phase Halogenation of Aromatic Compounds", which has been studied mainly in the author's own laboratory since 1957, is presented by *E. C. Kooyman*. *R. Kh. Freidlina*'s article on "Rearrangments of Radicals in Solution" emphasizes the Russian work, and particularly her own; this article therefore complements a recent review by *Ch. Walling*. However, the choice of subject matter is not always absolutely satisfactory. For example, the important 1,5-hydrogen shifts are discussed only on the basis of the earliest examples, while no mention is made of more recent reviews. "Free-Radical Reactions of Bridged Cyclic Systems" are discussed by *D. I. Davies* and *S. J. Cristol*. In contrast to the chemistry of the carbonium ions, these free-radical reactions show few unusual features; the article points out some useful relationships.

With a few exceptions, the literature is covered only up to 1964, and even for this period the coverage is unfortunately not always complete. The authors should have specified the completeness and the period covered. The presentation and the index are good, but the references might have been better inserted as footnotes. *C. Rüchardt* [NB 574 IE]

The Molecular Orbital Theory of Conjugated Systems, by *L. Salem*. W. A. Benjamin, Inc., New York-Amsterdam 1966. 1st Edit., xvi, 576 pp., numerous illustrations, cloth $ 22.50.

The MO theory of conjugated systems is probably the most extended and one of the most successful sectors of quantum chemistry. *Salem* makes a commendable attempt to present a methodically complete description of the theory in its present state.

This book should not be approached without a previous knowledge of the elementary theory of chemical bonding. The first chapter is a recapitulation of, rather than an introduction to, Hückel MO theory. Unfortunately, no serious foundation is given for the distinction between σ and π electrons nor for the fundamentally important σ–π separation. This is particularly regrettable since some aspects of σ–π separation are currently regarded as very doubtful, and since joint treatments of σ and π electrons (though within the framework of the σ–π separation) are becoming increasingly important. Among the basic assumptions for which no convincing justification is given are the "neglect of overlap" and of "differential overlap". The short section on electron correlation deals only with some aspects of this important concept.

The review of the refined methods in the second chapter is arbitrary rather than systematic. The strength of the book does not lie in the discussion of fundamental questions, but in the detailed description of the current and possible applications of the MO theory. The author goes into detail on the relationship between theoretical delocalization energies and resonance energies, the Hückel rule, and the semi-empirical calculation of dipole moments, bond lengths, force constants, and ionization energies. Special attention is given to the magnetic properties of π-electron systems, particularly to 'ring currents", the theory of "chemical shifts", and spin densities and their relation to ESR spectra. Further chapters deal with the theory of the chemical reactivity and that of the UV spectra of unsaturated molecules. The author makes extensive and profitable use of the simple rules derived by the "English school" for the Hückel MO's of alternant hydrocarbons, *e.g.* the scheme for obtaining the coefficients of a non-bonding MO without calculation.

The final chapter is devoted, apart from the Jahn-Teller effect, to a phenomenon on which the author himself has worked successfully, *i.e.* bond alternation in polyenes and other conjugated systems.

Though the book is quite extensive and includes treatments of some uncustomary problems, such as conjugated rings containing d electrons, the author has omitted the theory of a number of interesting unsaturated systems, *e.g.* that of the non-classical carbonium ions, as well as conjugation in non-planar systems. The main emphasis is placed on the treatment of alternant hydrocarbons. The reader experiences little of the special problems of the theory of heteroaromatic compounds.

The recent literature is abundantly cited, though sometimes the selection is somewhat arbitrary.

The rather high price of this book may preclude purchase by individuals, but chemical libraries should not do without the information it contains. *W. Kutzelnigg* [NB 560 IE]

Electron-Impact Induced Rearrangement Reactions of Organic Molecules [**]

BY P. BROWN AND C. DJERASSI [*]

Hydrogen migrations accompany many mass spectrometric fragmentation processes and a detailed study of these migrations, largely by means of deuterium labeling, has shed much light on electron-impact induced bond fissions. More recently, it has been found that groups other than hydrogen, such as alkyl, aryl, hydroxyl, etc., also can migrate after electron bombardment and the present article is concerned with a discussion of such molecular rearrangements among organic compounds. These observations are not only of intrinsic mechanistic interest, but a detailed knowledge of the occurrence of such migration reactions is crucial to the proper interpretation of mass spectra and to the avoidance of misinterpretations in "element mapping".

1. Introduction

One of the most significant developments in organic chemistry during this decade has been the very rapid acceptance and extremely wide use of mass spectrometry for the solution of structural problems. *Stenhagen*'s [1] prediction in 1961 "Es wird wahrscheinlich nicht lange dauern, bis der massenspektrometrischen Analyse bei Strukturbestimmungen in der organischen Chemie dieselbe Stellung zukommt wie jetzt z.B. der Infrarotspektrometrie und der magnetischen Kernresonanz" has become a statement of fact in less than five years. The pursuit of natural products chemistry without mass spectrometry has become unthinkable [2].

Whereas the rapid acceptance of UV, IR, and NMR spectroscopy or optical rotatory dispersion by the organic chemist was triggered to a large extent by the commercial availability of suitable instruments, this was not the case with mass spectrometry. Adequate mass spectrometers were available at least ten years prior to their extensive utilization for structural organic investigations and it seems that one of the principal motivating factors has been the recent "mechanistic" studies which led to the conclusion [3] that many fragmentation reactions of organic molecules induced by electron impact are interpretable in the every-day language of the organic chemist. To a certain extent, the word "mechanism" is a euphemism since the products of such fragmentations in the mass spectrometer are not isolable, but are only detected in terms of their mass and one is thus dependent on indirect evidence. For this purpose, the most useful technique is isotopic labeling [4], but recognition of metastable ions, high resolution mass measurements, and appearance potential determinations also play important roles.

Many of the bond fissions promoted by electron bombardment in the mass spectrometer are accompanied by transfer of one or more hydrogen atoms. Such hydrogen migrations shed considerable light on the probable fragmentation paths of organic molecules. Much of the work in our laboratory [5] has concentrated on detailed studies of such hydrogen migrations triggered by a variety of functional groups. As an example of the relevance of such hydrogen migrations to mass spectrometric fragmentation "mechanisms" one may cite the "McLafferty rearrangement" [6] of ketones such as n-dibutylketone *(1)*, which has been shown [7] by deuterium

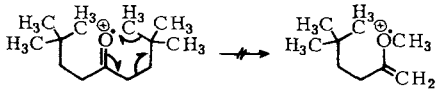
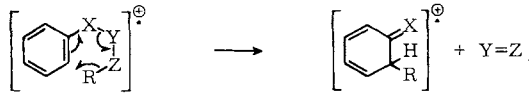
labeling to involve transfer of the γ-hydrogen and fission of the β-bond with production of the enol ion radical *(2)* [8] and a neutral olefin *(3)* [*]. The "McLafferty rearrangement" is thus the mass spectrometric equivalent of the well known "Type II" Norrish photochemical decomposition of ketones [9].

(1) *(2)* *(3)*



The frequent occurrence of hydrogen rearrangements raises the question whether other moieties are also prone to migrate after electron impact. Answers to this question are not only of intrinsic mechanistic interest, but they also have a crucial bearing on the scope and limitation of *Biemann*'s "element mapping" computer technique [10], which either requires that such rearrangements do not proceed to a significant extent or that their occurrence be predictable and hence discountable. The electron impact induced migration of alkyl, aryl, and other functional groups has attracted considerable attention during the past two years and apparently occurs with much greater frequency than has hitherto been realized. It is with this subject that the present review is concerned and for our purpose, we are principally concerned with the following process:

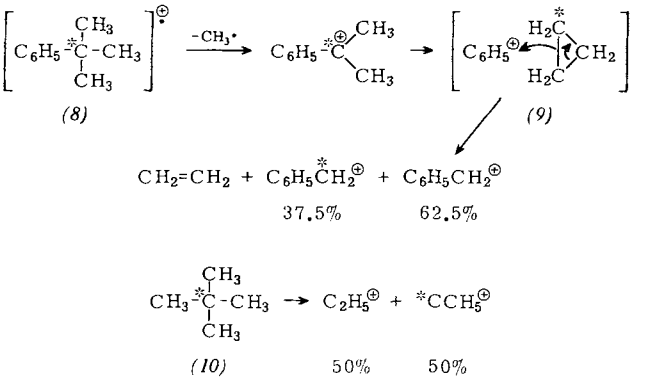
in which the migrating group C is at no time bound to the rest of the molecule by more than one σ-bond.



2. Simple Alkyl and Aryl Rearrangements

The first question that may be asked is whether alkyl rearrangements can take place in lieu of isotopically documented hydrogen migrations in substances where all implicated hydrogen atoms have been replaced by alkyl groups. The answer is decisively negative [11,12]. Thus 2,2,8,8-tetramethylnonan-5-one *(4)* is the completely methylated analogue of n-dibutylketone *(1)* and a "McLafferty rearrangement" of one of its methyl groups should then lead to an ion *(5)* of mass 142, which was not observed [11].

(4) *(5)*



Similarly, a variety of benzene derivatives of type *(6)* have been shown by isotopic labeling [13] to fragment by hydrogen transfer [*(7)*, R = H], but no analogous methyl migration [*(7)*, R = CH_3] was encountered [12] when the appropriate hydrogen atoms were substituted by methyl groups.

(6) R = H, CH_3; X = CH_2, O, S, NH; Y = CH_2, O; Z = CH_2, O

(7) R = H; X = CH_2, O, S, NH

These results would seem to offer a poor prognosis for the prevalence of methyl migrations. On the other hand, some of the early mass spectral results with ^{13}C-labeled hydrocarbons showed quite definitely that methyl migrations do occur, presumably through the intermediacy of cationated cyclopropanes [14]. Thus, the mass spectrum of t-butylbenzene *(8)* exhibits a peak at *m/e* = 91 (benzyl or tropylium cation) which in the ^{13}C-labeled analogue [see asterisked carbon atom in *(8)*] is distributed between *m/e* = 91 and 92 in the indicated proportions, thus supporting the suggestion that cyclopropane *(9)* is an intermediate. A similar conclusion [14] can be reached from the observation [15] that the C_2 species in the mass spectrum of neopentane *(10)* labeled with ^{13}C at the central carbon atom are equally represented by labeled and unlabeled fragments.

(8) *(9)*

$CH_2{=}CH_2$ + $C_6H_5\overset{*}{C}H_2^{\oplus}$ + $C_6H_5CH_2^{\oplus}$

37.5% 62.5%

(10) 50% 50%

Another type of methyl migration, which cannot really be subjected to the same type of experimental scrutiny as the above mentioned examples, is one

[8] The relevant evidence is summarized by *S. Meyerson* and *J.D. McCollum* in *C. N. Reilly*: Advances in Analytical Chemistry and Instrumentation. Interscience, New York 1963, Vol. 2, pp. 184–199.

[*] A single "fishhook" (cf. [2], Vol. II, pp. 1–2) denotes homolytic fission ($-\overset{\frown}{C}-C- \rightarrow C\bullet + \bullet C-$), while the conventional arrow refers to heterolysis ($-\overset{\frown}{C}-C- \rightarrow -C^{\oplus} + -C^{\ominus}$). Several of the fragmentations are indicated as concerted processes, but this is only done for the sake of convenience since no experimental method is available at the present time of differentiating between concerted or stepwise processes.

[9] *J. G. Calvert* and *J. N. Pitts jr.*: Photochemistry. Wiley & Sons, New York 1966. See also *P. J. Wagner* and *G. S. Hammond*, J. Amer. chem. Soc. *87*, 4009 (1965).

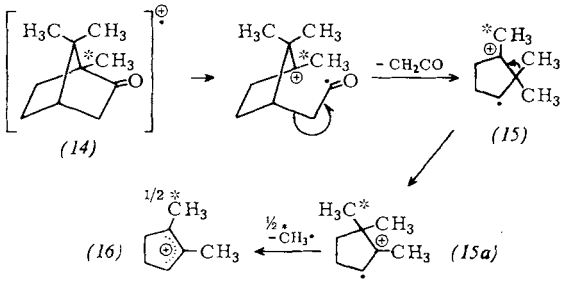
[12] *M. Fischer* and *C. Djerassi*, Chem. Ber. *99*, 750 (1966).

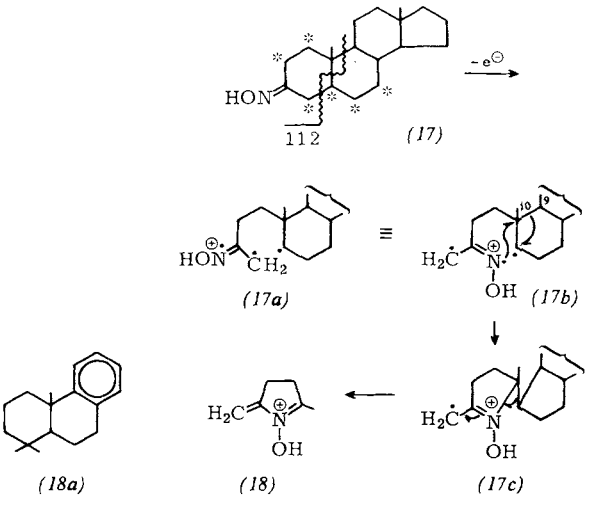
[13] For leading references see [12].

[14] *P. N. Rylander* and *S. Meyerson*, J. Amer. chem. Soc. *78*, 5799 (1956).



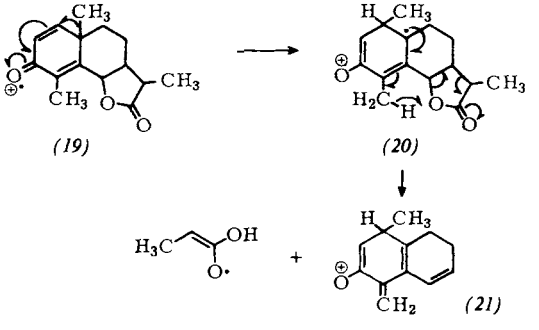
[15] *C. P. Johnson* and *A. Langer*, J. physic. Chem. *61*, 1010 (1957).

where only the observed fragmentation mode suggests its occurrence. For instance, the M − 43 peak (loss of CH_3CO) in 5α-pregnan-20-one *(11)* is much smaller than the corresponding one in Δ^{16}-5α-pregnen-20-one *(12)*, which is a surprising result since vinylic fissions are usually very unfavorable processes in mass spectrometry. Consequently, it has been suggested [16] that the expulsion of the acetyl radical in *(12)* is accompanied by concerted migration of the angular methyl group to furnish the highly stabilized carbonium ion *(13)*.



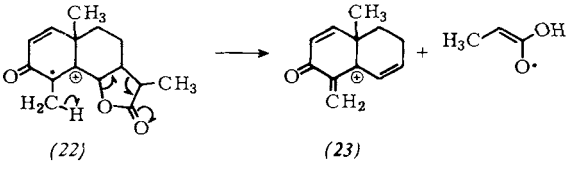
(11) *(12)* *(13)*

A similar case is provided by the mass spectrum [17] of camphor *(14)*, whose base peak occurs at $m/e = 95$ (C_7H_{11}) *(16)* owing to the loss of ketene and a methyl radical. As shown by isotopic labeling, nearly 50 % rather than the expected 33 % of the methyl loss originates from C-1. This is best interpreted by assuming that the fragment ion *(15)*, resulting from expulsion of ketene, first suffers methyl migration to *(15a)* (the driving force being the generation of an "ionized double bond") in which either the labeled or unlabeled methyl group would be expected to be lost to an equal extent.



(14) *(15)* *(16)* *(15a)*

Yet another example is provided by the most abundant fragment ion of mass 112 ($C_6H_{10}NO$) in the mass spectrum of 5α-androstan-3-one oxime *(17)*, which by deuterium labeling (see asterisked positions) was shown [18] to arise formally by the bond cleavages indicated by the wavy line in formula *(17)*. Such a formulation would require the very unfavorable fission of two bonds connected to one carbon (C-10) and it is for this reason that migration of the 9–10 bond [*] in the hypothetical intermediate *(17b)* was postulated [18], the final $C_6H_{10}NO$ fragment then being depicted as *(18)*, which is completely consistent with the deuterium labeling results.



(17) *(17a)* *(17b)* *(17c)* *(18)* *(18a)*

The postulation of such "undetectable" migrations typified by *(12)*, *(15)*, and *(17b)* is tempting and great caution should be exercised before resorting to such mechanistic rationalizations. An example of an unnecessary postulation of a methyl migration is provided by the recently proposed [19] reaction path *(19)* → *(20)* → *(21)* to account for the appearance of an ion of mass 173 in the spectrum of santonin *(19)*.

(19) *(20)* *(21)*

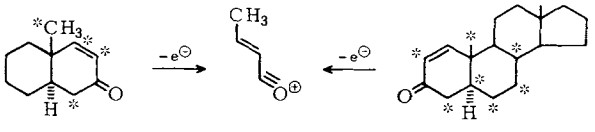
In fact a more plausible decomposition path can be formulated as *(22)* → *(23)*, which does not require the intervention of a methyl migration nor does it utilize the unfavorable electron sextet depicted in *(20)* and *(21)*, simply by assuming that the fragmentation is initiated by the molecular ion *(22)*.

(22) *(23)*

With the above material as background, it is now possible to consider recent authenticated cases of alkyl or aryl migrations. They may be divided into reactions

[16] *L. Tökés* and *C. Djerassi*, Steroids 6, 493 (1965).

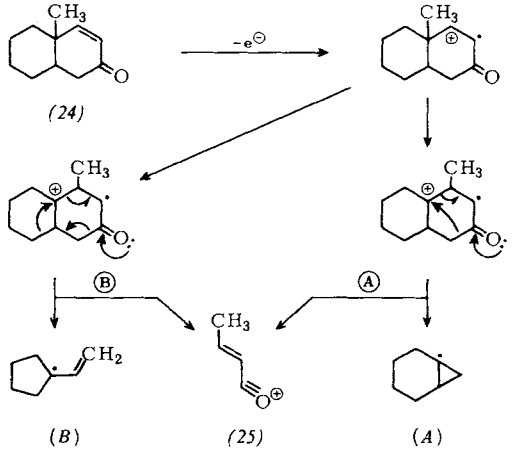
[17] *D. S. Weinberg* and *C. Djerassi*, J. org. Chemistry *31*, 115 (1966); *D. R. Dimmel* and *J. Wolinsky*, J. org. Chemistry *32*, 410 (1967).



[18] *D. Goldsmith*, *D. Becher*, *S. D. Sample*, and *C. Djerassi*, Tetrahedron, Suppl. 7, 145 (1966).

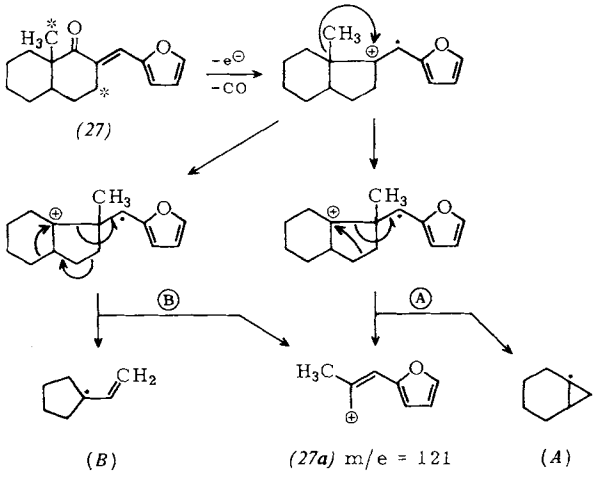
[*] A very similar rationale has been offered (see *H. E. Audier*, *S. Bory*, *G. Defaye*, *M. Fétizon*, and *G. Moreau*, Bull. soc. chim. France, *1966*, 3181) for the presence of an intense peak at m/e=117 in the mass spectrum of the diterpenoid hydrocarbon *(18a)*.

[19] *D.G.B. Boocock* and *E.S. Waight*, Chem. Commun. *1966*, 90.



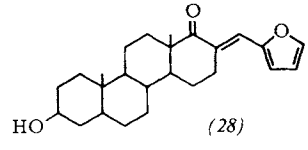
where the principal driving force appears to be the generation of favorable carbonium ion or radical intermediates and those where the migration is accompanied by the expulsion of a stable neutral molecule such as CO or CO_2. It is the latter type of rearrangement reaction that is most likely to lead to erroneous results in "element mapping" [10], unless its occurrence is readily recognized.

The first example of an authentic 1,2-alkyl migration is provided by the mass spectra of *trans*-Δ^3-10-methyl-2-octalone *(24)* and related bicyclic ketones, which exhibit an intense peak at $m/e = 69$ that was shown by high resolution mass measurements to correspond to the composition C_4H_5O. Isotopic labeling [20] (see asterisked positions in *(24)*) demonstrated that methyl migration had occurred and that the resulting fragment is probably best expressed in terms of *(25)*. Similar conclusions could be reached [21] from the mass spectrum of Δ^1-5α-androsten-3-one *(26)* and its labeled analogues.



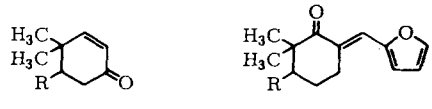
(24) *(25)* m/e = 69 *(26)*

Two plausible pathways to the rearrangement ion *(25)* are outlined below, the principal difference being the nature of the uncharged species which may result from either a 1,3-(path A) or two consecutive 1,2-(path B) [22] shifts.



(B) *(25)* *(A)*

A similar methyl migration process was discovered [23] through appropriate deuterium labeling (see asterisks in *(27)*) in 2-arylidene- and 2-furfurylidene-1-decalones *(27)* as well as analogous D-homo steroids *(28)*, whose mass spectra displayed the most intense peak at $m/e = 121$ *(27a)* and which was displaced by the appropriate mass increment in the various arylidene derivatives. Again two reaction paths (A and B) can be entertained [23] which are analogous to those proposed in the fragmentation of the octalone *(24)* or the steroid *(26)*.



(27) *(B)* *(27a)* m/e = 121 *(A)*

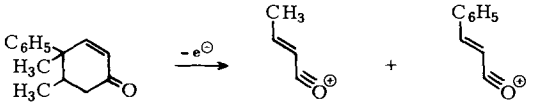
(28)

A possible distinction between paths A and B can be made by examining the minimum structural requirements for such methyl migration. The striking observation was made [24] that whereas 4,4-dimethylcyclohex-2-en-1-one *(29)* and 2-furfurylidene-6,6-dimethylcyclohexanone *(30)* exhibit practically no methyl rearrangement peaks in their mass spectra, introduction of an additional methyl substituent (see *(31)* and *(32)*) at the site of the original ring juncture restores again the proclivity towards methyl transfer observed in their bicyclic analogues (*(24)* and *(27)*). Since the presence of this additional methyl function in *(31)* and *(32)* should play no noticeable role in reaction path A, route B may be considered to be more plausible.

(29) R = H *(30)* R = H
(31) R = CH_3 *(32)* R = CH_3

Not only methyl groups, but other alkyl and aryl groups have also been shown [24] to participate in such rearrangements. These observations raise the question about the relative migratory aptitudes of various substituents in electron impact promoted rearrangements as compared to the migratory aptitudes of the same substituents in carbonium ion or free radical

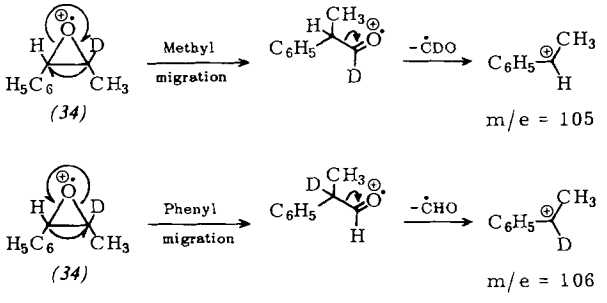
[20] *F. Komitsky jr.*, *J. E. Gurst*, and *C. Djerassi*, J. Amer. chem. Soc. *87*, 1398 (1965).



[21] *R. H. Shapiro* and *C. Djerassi*, J. Amer. chem. Soc. *86*, 2825 (1964), as well as unpublished high resolution mass measurements which showed that 70% of the m/e=69 peak in the mass spectrum of *(26)* corresponds to C_4H_5O.

[22] This possibility was first raised by Dr. *W. J. Richter* at the EUCHEM Conference on Mass Spectrometry, Sarlat (France) 1965.

[23] *C. Djerassi*, *A. M. Duffield*, *F. Komitsky jr.*, and *L. Tökes*, J. Amer. chem. Soc. *88*, 860 (1966).



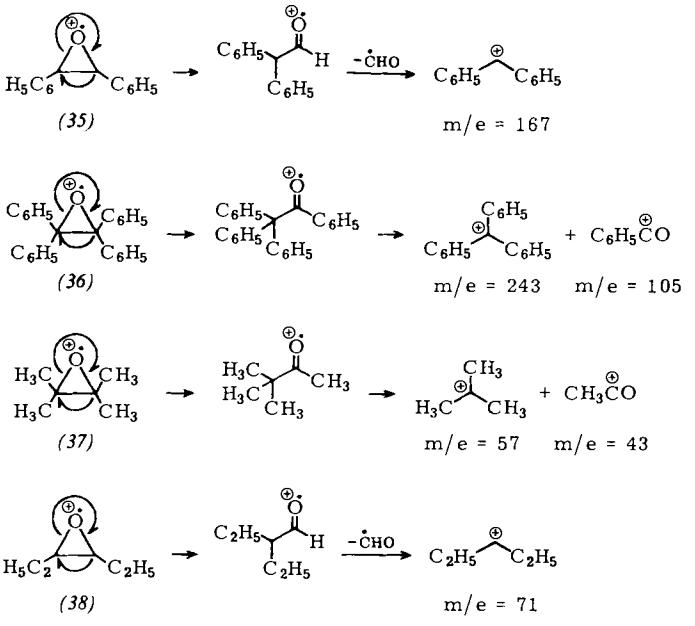
[24] *R. L. N. Harris*, *F. Komitsky jr.*, and *C. Djerassi*, J. Amer. chem. Soc., in press.

rearrangements[25]. Thus a comparison[24] of the relative intensities of the m/e = 69 and 131 peaks in the mass spectrum of 4,5-dimethyl-4-phenylcyclohex-2-en-1-one *(33)* indicates a ten-fold preference for phenyl as compared to methyl migration. Such a conclusion is only qualitative, since it presupposes an identical rate (or lack) of further decomposition of the rearrangement ions of mass 69 and 131.

(33) *(25)* m/e = 69 *(25a)* m/e = 131

A similar conclusion about the preference of phenyl over methyl migration can be reached by comparing the relative intensity of the hydrocarbon portion (C_8H_9) of the m/e = 105 peak in the mass spectrum[26] of [2-D]-1-phenyl-1,2-epoxypropane *(34)* with that of the m/e = 106 peak. The virtue of this comparison is that these two hydrocarbon species yield effectively the same ion and any difference in their subsequent decomposition would be relatively small since it would be only due to an isotope effect.

(34) *(34)*



Epoxides appear to be a relatively fertile field for encountering molecular rearrangements. Thus the presence of m/e = 167 and m/e = 243 peaks in the mass spectra[26] of stilbene oxide *(35)* and tetraphenylethylene oxide *(36)* demonstrates the occurrence of phenyl migrations, while high resolution and isotope labeling experiments[27] in dialkyl epoxides such as 2,3-dimethyl-2,3-epoxybutane *(37)* and 3,4-epoxyhexane *(38)* revealed the occurrence of ethyl and methyl migrations, respectively.

These skeletal rearrangements among epoxides would complicate or confuse the interpretation of "element maps"[10] were it not for the rather low abundance of such rearrangement peaks. However, much more substantial rearrangement peaks, which could affect conclusions from "element mapping"[10], have been encountered in other compounds and three such examples involving aryl or benzyl migration may be cited in this connection.

[25] See *e.g. E. S. Gould*: Mechanism and Structure in Organic Chemistry. Henry Holt and Co., New York 1959, pp. 607and 758.

[27] *P. Brown, J. Kossanyi*, and *C. Djerassi*, Tetrahedron Suppl.*8*. Pt. 1, 241 (1966).

(35) *(36)* *(37)* *(38)*

2,2-Diphenylchroman *(39)* exhibits in its mass spectrum[28] a significant peak at m/e = 195, which by high resolution mass measurements and isotopic labeling has been shown[29] to involve a phenyl migration resulting in the eventual expulsion of a benzyl radical, a moiety which is not present in the original molecule *(39)*. One plausible mechanism, though by no means the sole one[29], is depicted below:

(39) *(39a)* *(39b)* *(39c)*

A second case is illustrated by *Biemann*'s observation[30] that the tribenzylamine *(40)* mass spectrum contains an appreciable peak at m/e = 181 of composition $C_{14}H_{13}$. Since the parent amine *(40)* does not contain an uninterrupted sequence of fourteen carbon atoms, a benzyl rearrangement must have occurred in the genesis of the m/e 181 fragment.

$$(C_6H_5CH_2)_3\overset{\oplus\bullet}{N} \longrightarrow C_{14}H_{13}^{\oplus}$$

(40) $m/e = 181$

A third example is the production of a $C_9H_{10}N_2S$ ion (m/e = 178) from 3-(β-hydroxy-β-phenylethyl)-2-iminothiazolidine *(41)* (R = OH; R′ = H) in a one-step process (as shown by the presence of the appropriate metastable ion), which may be depicted[31] as a six-center phenyl migration, although the structural requirements for such a migration must be fairly specific since no such rearrangement is encountered[32]

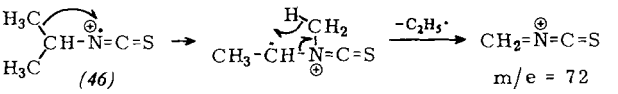
in the related pyrrolidone *(42)* nor in the ketone *(41)* (R = O; R′ = H) or various *N*-acetyl derivatives *(41)* (R′ = $COCH_3$; R = O or OH)[31].

(41) m/e = 178 *(42)*

It must be borne in mind that there are many skeletal rearrangements, which are mechanistically important and readily detectable by isotopic labeling, but where the occurrence of such a rearrangement, irrespective of its abundance, has no bearing on the interpretation of "element maps". Such isotopically documented examples include the loss of a propyl radical[33] encompassing carbon atoms 2, 3, and 4 of long chain fatty acid methyl esters *(43)*, the loss of ethylene[34] from positions 2 and 3 (22 %) or 3 and 4 (78 %) in isohexyl cyanide *(44)*, and finally the apparent ethyl migration[35] involved in the expulsion of a methyl radical in *N*-propylsuccinimide *(45)*.

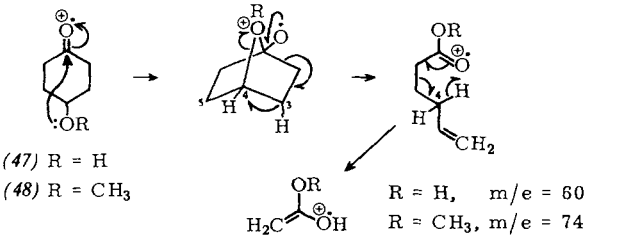


(43)

(44)

(44)

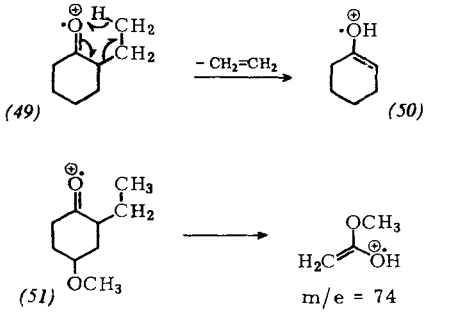
(45)



The expulsion of an ethyl radical[36] in 2-propylisothiocyanate *(46)* would be misleading in "element mapping", but fortunately it is of low abundance.

(46) m/e = 72

Alkyl or aryl groups are not the only molecular species that can suffer migration. When the migrating group contains a heteroatom, then it follows automatically that the composition of the resulting peak will afford misleading information in "element mapping". Whether such information will be fatal depends on the number of such rearrangement peaks in one such molecule, their relative abundance, and whether their occurrence can be pinpointed as a result of internal inconsistency of the computer-analysed data. The net result of such rearrangements, namely a combination in the fragment ion of heteroatoms and carbon atoms which is not present in the molecular ion, can also arise from the expulsion of neutral molecules such as carbon monoxide, formaldehyde, nitriles, *etc.* Before discussing them, it is worth while discussing some recent examples of oxygen rearrangements.



One of the most abundant ions in the mass spectrum[37a] of 4-hydroxycyclohexanone *(47)* corresponds to $C_2H_4O_2$ (*m/e* = 60). Similarly, the base peak in the spectrum of 4-methoxycyclohexanone *(48)* is associated with an ion of mass 74 ($C_3H_6O_2$). The presence of two oxygen atoms in a two-carbon fragment from *(47)* and in a three-carbon moiety from *(48)* requires the intervention of an oxygen rearrangement in each instance. By labeling all of the positions with deuterium, it was found[37a] that one of the hydrogen atoms at C-3 or C-5 becomes equivalent to the C-4 hydrogen atom, and a reaction path consistent with these data is depicted below.

(47) R = H
(48) R = CH_3

R = H, m/e = 60
R = CH_3, m/e = 74

These results raise the question of how general such transannular rearrangements might be and how they are able to compete with other fragmentation reactions. In this regard, it is relevant to point out that the second most intense peak in the mass spectrum of 2-ethylcyclohexanone *(49)* is due to a standard McLafferty rearrangement (see *(1)* → *(2)*) with loss of ethylene to give *(50)*, while in 4-methoxy-2-ethylcyclohexanone *(51)* this fragmentation is greatly

reduced [37a] at the expense of the transannular methoxyl rearrangement with eventual production of the $m/e = 74$ ion.

In the related cyclohexane diol system, rearrangement ions of composition CH_3O_2 ($m/e = 47$) and abundance $\Sigma_{35} = 1.1\ \%$ (70 eV) [*] have recently been reported [37b] for the 1,3- and 1,4-isomers, but no evidence for hydroxyl migration was found in the 1,2-compound [37b].

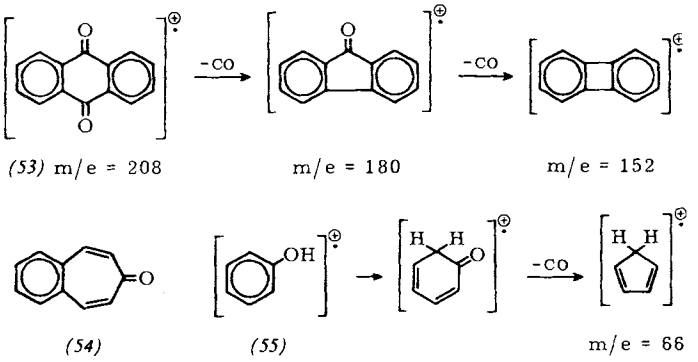
Methoxyl rearrangements have also been encountered in mass spectrometric investigations [38a] of permethylated sugars, an instructive example being the genesis of the $m/e = 105$ peak in the mass spectrum of methyl 2,3,4-tri-*O*-methyl-β-L-*arabo*-pyranoside *(52)*, as proved by appropriate deuterium labeling. An analogous acetoxy migration has been proposed [38b] in the fragmentation of pyranose penta- and hexa-acetates.

Rearrangements involving hydroxyl migration have been observed in benzoic acid [39,40], and in oximes of benzophenone [18] and acetophenone [41]; these examples are further discussed below.

3. Rearrangements Accompanied by Ejection of a Stable Neutral Molecule

Many of the skeletal reorganization processes encountered in mass spectrometry have in common the loss of a stable neutral moiety from a non-terminal position in the original molecule. The consequence of such rearrangements, especially if they occur to a significant extent, on the element map [10] of a particular compound is obvious. Entries will be recorded for ions comprising atoms that were not in fact bonded together as a contiguous chain in the original molecule, and may prove misleading unless the scope of these reactions is vigorously explored and delineated.

Kinetic methods [42,43] have so far proved inapplicable to the interpretation of the mass spectra of all but the simplest organic compounds; the role of thermodynamic considerations has consequently been enhanced. Thus one finds that major fragmentation pathways can almost always be rationalized (if not yet predicted) by stabilizing the positive charge (and radical, if present) at all intermediate stages, and by finally losing a stable neutral (or radical) species [44].



It is not very surprising then, to discover that a large proportion of electron impact induced skeletal rearrangements are accompanied by expulsion of such neutral entities as carbon dioxide, carbon monoxide, sulfur dioxide, formaldehyde, *etc.*, all of which have favorably negative heats of formation [45] (Table 1).

Table 1. Heats of formation (gas) at 298 °K.

Compound	ΔH_f^0 (kcal mole^{-1})	Compound	ΔH_f^0 (kcal mole^{-1})

a) Loss of Carbon Monoxide

In an important paper, *Beynon* [46] called attention to the ejection of carbon monoxide from *p*-benzoquinones, *e.g.* anthraquinone *(53)*, and from benzotropone *(54)* and phenol *(55)*. In each instance, major peaks result from such rearrangement.

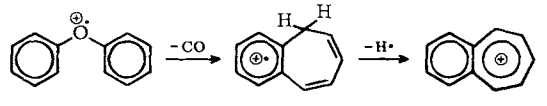
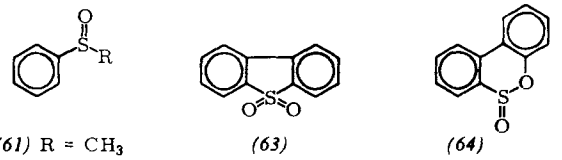
However, the elimination of a neutral molecule from a ring falls outside our definition of "group migration" (see Introduction). The term "migration" implies movement of a group from one site to another, accompanied by bond breakage and bond formation in the transition state. In many cases of expulsion of a stable, neutral species from a cyclic ion, recyclization is not a mechanistic necessity[47], although it is almost universally depicted as such in fragmentation schemes.

The perils inherent in assuming that loss of carbon monoxide from cyclic carbonyl compounds will generate a simple recyclized ion are apparent from a study[48a] of 2-pyrone *(56)* and its deuterated analogues *(57)* and *(58)*. If a symmetrical species such as *(59)* were formed, then the mass spectra of [3-D]-2-pyrone *(57)* and [6-D]-2-pyrone *(58)* would be identical. In fact they were not, gross differences being noted in the isotope distribution in ions formed by further decomposition of the M−CO species. However, the



(56) $R^1 = R^2 = H$
(57) $R^1 = H, R^2 = D$
(58) $R^1 = D, R^2 = H$



(59)

interpretation of these labeling results by *Pirkle*[48a] have recently been critically questioned[48b] and the intermediacy of a cyclic M − CO ion *(59)* in the fragmentation of 2-pyrone remains an open question.

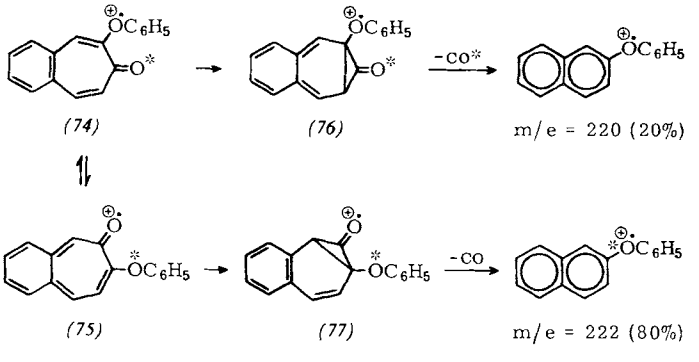
Elimination of carbon monoxide occurs somewhat unexpectedly in the mass spectra of diphenyl ether[46,49,50] *(60)* and various aryl substituted sulfones[51,52] and sulfoxides[52]. For example, methyl phenyl sulfoxide[52] *(61)*, diphenyl sulfoxide[52] *(62)*, and dibenzothiophene sulfone[51,52] *(63)* all display high intensity peaks, corresponding to operation of an M−CO process. It has been suggested[51,52] that isomerization of the molecular ion of *(63)* to that of the sulfinate ester *(64)* occurs prior to the ejection of

(60) m/e = 142 m/e = 141

(61) R = CH_3
(62) R = C_6H_5

(63) *(64)*

carbon monoxide. Skeletal rearrangements leading to M−CO ions were not encountered to any significant extent in dialkyl sulfones and sulfoxides[52,53].



Carbon monoxide loss has also been discerned in the spectra of acetylacetone[46,54,55] *(65)*, methyl and ethyl acetoacetate[54,56] *(66)* and *(67)*, isopropenyl acetate[57] *(68)*, distyryl ketone[54] *(69)*, phenyl styryl ketone[46,54] *(70)*, benzoic acid[39,40] *(71)*, benzophenone[49,50] *(72)*, and trichlorotrifluoroacetone[58a] *(73)* (Table 2), and a variety of other carbonyl compounds containing at least one additional site of unsaturation[58b].

Table 2. Rearrangement peaks involving loss of carbon monoxide.

[*] ^{18}O labeling showed [54] that principally the ketone carbonyl is lost as carbon monoxide.

The operation of a 1,4-phenyl migration associated with CO expulsion has been uncovered[59] by isotope labeling studies with 2-phenoxy-4,5-benzotropone *(74)*. Separate scrutiny of both the ^{18}O-labeled carbonyl compound and the ^{18}O-labeled ether analogue disclosed that in the formation of the two most important high mass peaks (M−OH, 26 %; M−CO, 60 %) both oxygen atoms are involved. In the carbon mon-

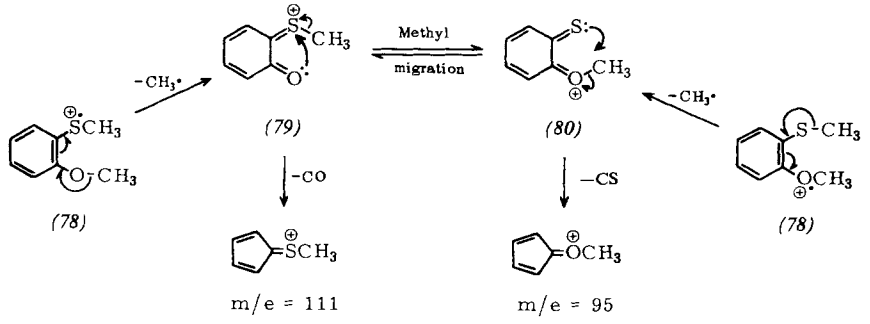
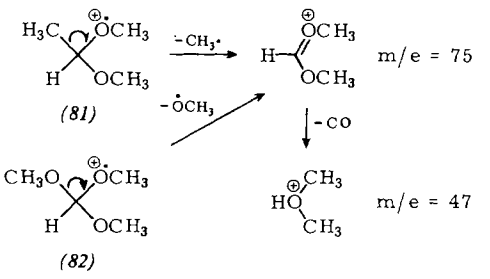
oxide loss (M−CO), 80 % of the oxygen involved derives from the ether position, which can be readily accounted for by consideration of the relative stabilities of the two postulated intermediates *(76)* and *(77)*.



In the loss of OH (M − 17) process, the oxygen originates to approximately equal extent from each position[59], implicating again 1,4-phenyl migration [*(74)* ⇆ *(75)*]. No thermal phenyl migration was observed in this system but other instances of photochemically induced phenyl shifts (1,5 in *cis*-dibenzoylethylene) to oxygen are on record[60,61].

(74) *(75)*

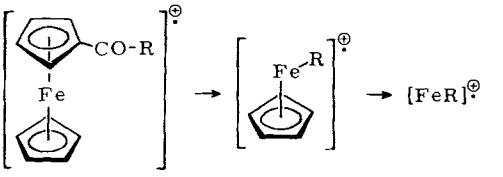
m/e = 231 (M-17)



A closely related methyl migration has been reported[62] in the electron impact induced fragmentation of 2-methoxythioanisole *(78)*. An appropriate metastable ion verifies the expulsion of carbon monosulfide from the M − 15 species *(80)*, furnishing an ion of mass 95. In the *S*-trideuteriomethyl analogue, approximately 65 % of *m/e* = 95 increases to *m/e* = 98, and again a corresponding metastable ion is observed, indicating that methyl migration between sulfur *(79)* and oxygen *(80)* precedes loss of carbon monosulfide.

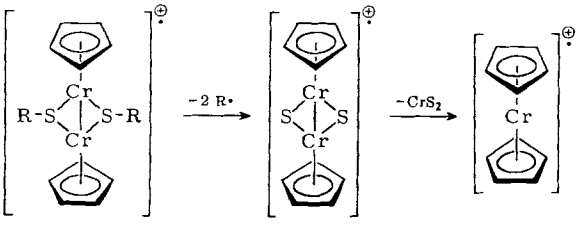
(78) *(79)* *(80)* *(78)*

m/e = 111 m/e = 95



A further example of carbon monoxide elimination attended by skeletal rearrangement is apparent in the fragmentation of dimethyl acetal[6,46] *(81)* and trimethyl orthoformate[63]

(81) *(82)*



(82) on electron impact. In both compounds, α-cleavage affords an ion of mass 75, which then expels carbon monoxide to give the rearrangement species at *m/e* = 47. The relative abundance of this peak is 8 % for *(81)* and 47 % for *(82)*.

Also falling in this category are the recent reports[64,65] of carbon monoxide loss from certain π-bonded organometallic compounds. For example, with the ferrocene derivatives

(83) R = CH_3, OH

(83), migration of the group R to the metal atom apparently occurs. This type of rearrangement is common to a wide range of suitably substituted π-complexes of Fe, Cr, and Mn[65].

(84) R = CH_3, C_6H_5 m/e = 298 m/e = 182

Another reorganization process in the mass spectra of some binuclear transition metal π-complexes has been observed by *Reed*[66]. Thus the chromium complex *(84)* decomposes to an ion of mass 298,

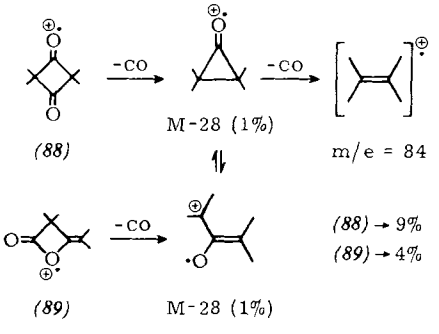
which in turn loses the elements of CrS_2. This behavior was also noted for the corresponding Fe and Ni analogues.

Skeletal rearrangement ions have also been observed [67] in the mass spectra of a variety of other transition metal complexes [*(85)*, *(86)*, *(87)*].

(85)



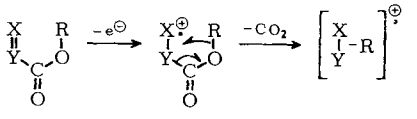
$$[(C_6H_5)_3SnMn(CO)_5]^{\oplus\cdot} \xrightarrow{-5\,CO} [(C_6H_5)_3SnMn]^{\oplus\cdot} \rightarrow [(C_6H_5)Mn]^{\oplus\cdot}$$

(86)

$$[(C_6H_5)SnFe(CO)_2(C_5H_5)]^{\oplus\cdot} \rightarrow [Sn(C_5H_5)]^{\oplus\cdot}$$

(87)

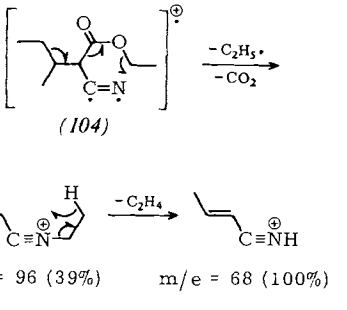
In the spectra of tetramethylcyclobutane-1,3-dione *(88)* and its photoisomer *(89)*, peaks [68] are seen which correspond to the sequential loss of two carbon monoxide molecules. Although the structures of the ions



depicted are no less tentative than those proposed in many mass spectral mechanistic schemes, nevertheless, carbon-carbon bond formation must accompany or precede the final ejection of carbon monoxide in order to furnish the ion of mass 84. The observation of a metastable peak for the decomposition of the molecular ion to $m/e = 84$ betrays the simultaneous operation of a concerted M−2CO process. Certain correlations between the electron impact induced and the photochemical behavior of ketene dimers such as *(88)* have been made [68].

b) Loss of Carbon Dioxide

Skeletal rearrangement accompanied by expulsion of carbon dioxide in the mass spectrometer is a well documented process, occurring particularly in certain types of esters, and closely related compounds (Table 3).



Significant rearrangement peaks have been noted in the mass spectra of all the compounds given in the table. For all the compounds listed, except the cyanoacetates *(94)*–*(97)* and the diethyl malonates *(98)*, an unsaturated system is in conjugation with the ester carbonyl group [69]. Effective localization of the charge on the adjacent group *(102)* would then provide an electron deficient site for alkyl migration [*(102)* → *(103)*], attended by simultaneous loss of carbon dioxide. Only the simpler alkyl groups (*e.g.* methyl, ethyl) give significant rearrangement peaks, probably due to the larger number of alternative reactions possible in the more complex groups.

(101) *(102)* *(103)*

However, although the migration of the alcohol R group in α-β unsaturated esters seems to be a fairly general process [73], only one case of the converse situation (*i.e.* a vinyl ester of a saturated acid) expelling carbon dioxide with concomitant alkyl shift has been reported [*(100)*, Table 3] [12]. Migration of the t-butyl group in phenyl pivalate is observed, but no corresponding methyl migration in phenyl acetate has been detected [12, 73].

The substituted cyanoacetates *(96)* and *(97)* are believed [70] to suffer synchronous γ-cleavage (to the carbonyl group), alkyl migration, and loss of carbon

(104)

m/e = 96 (39%) m/e = 68 (100%)

dioxide, as outlined for ethyl s-butylcyanoacetate *(104)*. Further elimination of ethylene from the rearrangement ion (mass 96) provides one route to the species (m/e = 68) responsible for the base peak in the spectrum.

Both alkyl and aryl group migrations have been described [74] in the electron impact induced decomposition of trimethylsilyl esters. Rearrangement peaks [M − (15 + 44)] were apparent in the spectra of the trimethylsilyl derivatives of octanoic, decanoic, and octadecanoic acids *(105)*, and also alanine. In the case of aromatic acid derivatives, support for the scheme *(106)* → M − 15 → M − (15 + 44) is provided by the presence of appropriate metastable peaks, and also by an increase in the intensity of the M − (15 + 44) peak relative to M − 15 as R is varied from an electron withdrawing to an electron donating group. In the mesitoic acid derivative, the rearrangement is still operative.

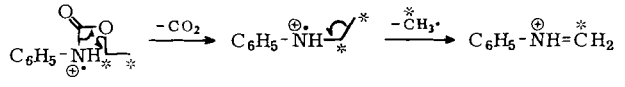
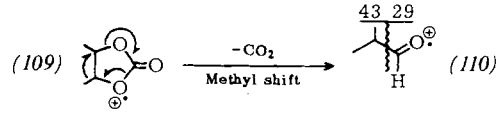
(105) M-15 M-(15 + 44)

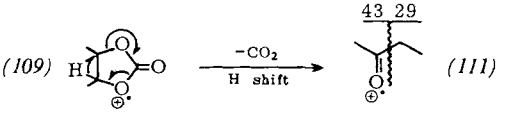


(106) M-15 M-(15 + 44)

Similar rearrangements have been noted [75,76] with *N*-substituted ethyl carbamates. Where α-cleavage to nitrogen is possible [*e.g.*, ethyl *N*-ethylcarbamate *(107)*], it apparently precedes ethyl migration and carbon dioxide loss. In instances where such cleavage is prohibited [*e.g.* ethyl *N*-phenylcarbamate *(108)*], the sequence of events appears to be reversed. Deuterium labeling studies [see asterisks in *(107)* and *(108)*] were undertaken in support of the proposed pathways.

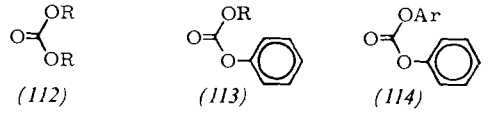


(107) m/e = 102 (M-15) M-(15 + 44)



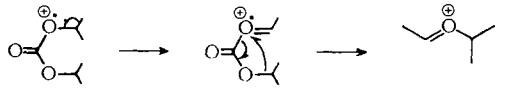
(108) m/e = 121 (M-44) M-(44 + 15)

Both hydrogen and methyl shifts accompanied by carbon dioxide elision are found [77] in the fragmentation of certain cyclic carbonates. Analogous rearrangements with loss of sulfur dioxide are also encountered [77] in the corresponding cyclic sulfites, further discussed below. As an example of the former, the two largest peaks in the mass spectrum of butane-2,3-diol cyclic carbonate *(109)* are at *m/e* = 43 (100 %) and *m/e* = 29 (38 %). Each peak is a doublet by exact mass measurements, indicating that both rearrangement species *(110)* and *(111)* are formed in approximately 1:3 ratio.



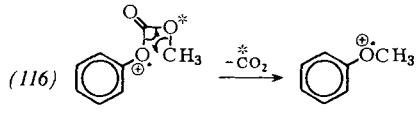
(109) (110)

(109) (111)



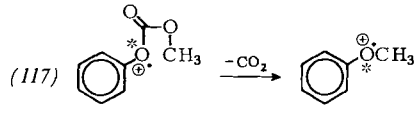
This type of rearrangement is also prevalent [78] in the mass spectra of symmetrical dialkyl carbonates *(112)*, alkyl phenyl carbonates *(113)*, and aryl phenyl carbonates *(114)*. The rearrangement peak is of high intensity for the methyl compounds *(112)* (R = CH_3, 53.2 % Σ_{40}) and *(113)* (R = CH_3, 11.8 % Σ_{40}), and likewise for the diphenyl compound *(114)* (Ar = C_6H_5,

(112) (113) (114)



R = CH_3, C_2H_5, n-C_3H_7, i-C_3H_7, n-C_4H_9, sec.-C_4H_9, i-C_4H_9, i-C_5H_{11} Ar = C_6H_5, *p*-$CH_3C_6H_4$

8.3 % Σ_{40}), but rapidly falls off with the larger R groups. Evidence was adduced [78] for a two stage decomposition of the dialkyl carbonates *(112)*, with alkyl migration and loss of carbon dioxide following initial α-cleavage (see *(115)*, diisopropyl carbonate). With the alkyl phenyl carbonates *(113)* (except for R = CH_3), both this decomposition path and the converse (initial loss of carbon dioxide, then α-cleavage) appear to operate, while the diaryl compounds *(114)* expel carbon dioxide [79], followed by carbon monoxide from the diaryl ether [46] rearrangement ion.



(115) m/e = 131 (M-15) m/e = 87 M-(15 + 44)

A more detailed study has since been undertaken [80a] in an attempt to clarify further the mechanism of methyl migration in methyl phenyl carbonate [*(113)*, R = CH_3]. Previous results [78] already indicated that migration was taking place to aryl oxygen, rather than to the *ortho* ring position, and two separate ^{18}O-labeling experiments [see asterisks in *(116)* and *(117)*]

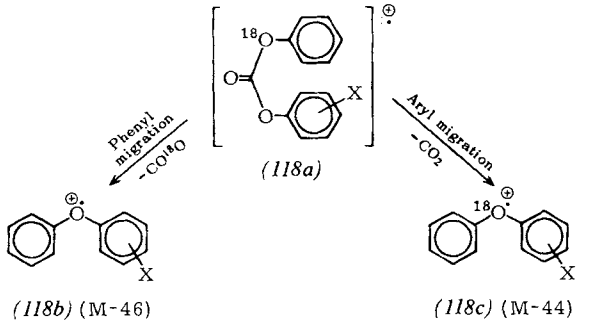
[79] The pyrolytic analogue of this rearrangement has been reported by *P. D. Ritchie*, J. chem. Soc. (London) *1935*, 1054.

[80a] *P. Brown* and *C. Djerassi*, J. Amer. chem. Soc. *89*, 2711 (1967).

verified[80a] that the aryl oxygen was indeed retained exclusively in the M – 44 rearrangement ion.



By variation of the *meta*- and *para*-substituents [X in *(118)*] in the aromatic ring, the propensity for rearrangement was expressed[80a] in kinetic terms[43], and a Hammett ρσ plot of positive slope obtained. A reasonable interpretation of these data is that methyl migration takes place in this system preferentially to the more positively charged site.

(118) M-44

In this connection, it is worth recalling that alkyl migration in dialkyl carbonates[78] *(112)* and ethyl *N*-ethylcarbamate[75] *(107)* occurs only after initial α-cleavage. This cleavage removes the inductively stabilizing effect of an alkyl group on the ion radical, and simultaneously generates a full positive charge on the "receptor site". Alkyl migration takes place in the molecular ion of methyl phenyl carbonate[78] [*(113)*, R = CH_3] and ethyl *N*-phenyl carbamate[75] *(108)*, where the phenyl substituent can inductively enhance the positive character of the "receptor site". The data for trimethylsilyl derivatives of substituted benzoic acids[74] *(106)* also support the hypothesis that the migrating group will be a nucleophilic species and the "receptor site" electrophilic in nature.

A substituent effect study has also been performed[80a] on the electron impact induced decarboxylation of aryl phenyl carbonates. In this reaction, phenyl migration [*(118a)* → *(118b)*] was distinguished from aryl migration [*(118a)* → *(118c)*] by ^{18}O-labeling. Thus relative migratory aptitudes of the aryl groups could be assigned (Table 4).

(118a)

(118b) (M-46) *(118c)* (M-44)

Table 4. Relative migratory aptitudes of aryl groups in the electron impact induced decarboxylation of aryl phenyl carbonates.

It was found that charge distribution in the molecular ion and the relative nucleophilicities of the migrating species are major factors controlling the overall migration tendencies. Very generally, electron withdrawing substituents on the aryl group favored phenyl migration, and electron releasing substituents produced more aryl migration. Correlation of these migratory aptitudes (1,3–O to O shift) with those obtained in solution chemistry for the pinacol rearrangement (1,2–C to C shift)[80b] is only qualitative (see Table 4).

As a logical extension of our previous work[78], we have studied[81] the relative ease of elimination of various possible neutral molecules from the series of

$H_3C{-}X{-}C(=Z){-}Y{-}C_6H_5$ $C_6H_5{-}X{-}C(=Z){-}Y{-}C_6H_5$

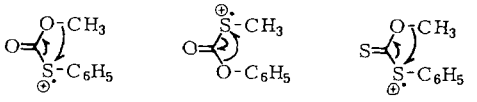
$C_6H_5S{-}CS{-}SC_6H_5$		0.7			1.5

isomerization of the molecular ion of compounds containing the part structure $C_6H_5O{-}CS$ was disclosed [see *(121)* → *(122)*]. This latter type of rearrangement has good analogy in the corresponding thermal process.



(121) X = O, S R = CH_3, C_6H_5 *(122)*

The observed eliminations (Table 5) can be rationalized by locating the charge at a favorable site, and assuming a relative migratory order of $CH_3 > OC_6H_5 > SC_6H_5 > C_6H_5$. In this way, neutral species with negative heats of formation are preferentially produced (see Table 1), but this factor alone does not exert the sole

[80b] *W. E. Bachmann* and *J. W. Ferguson*, J. Amer. chem. Soc. *56*, 2081 (1934).

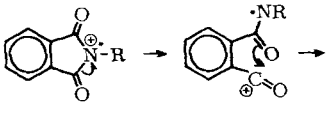
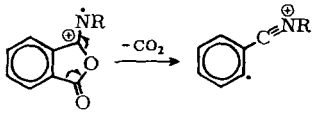
controlling influence. Thus in *(123)*, carbon dioxide is lost to a greater extent than carbonyl sulfide, whereas in *(124)* carbon monoxide loss prevails over that of carbonyl sufide or carbon dioxide, and in *(125)* only

(123) *(124)* *(125)*

elision of carbonyl sulfide is apparent. In the diphenyl series, *(126)* suffers loss of carbon monoxide rather than carbon dioxide or carbonyl sulfide, and *(127)* eliminates carbon monoxide rather than carbonyl sulfide.



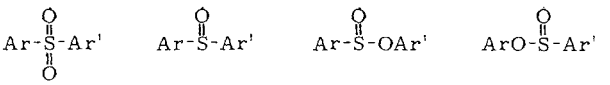
(126) *(127)*



In the course of this work [81], it was noted [77] that the spectrum of phenyl chloroformate *(128)* contains two rearrangement peaks, due to loss of carbon monoxide (4 % relative abundance), and of carbon dioxide (14 %).

C_6H_5–O–CO–Cl *(128)*

Two recent reports call attention to the expulsion of carbon dioxide from certain aromatic imides, *e.g. N*-methylphthalimide *(128a)*, R = CH_3 [82a] and the *N*-phenyl analogue *(128a)*, R = C_6H_5 [82b]. *(128a)*, R = C_6H_4-*p*-C_6H_5, also gives rise to carbon dioxide elimination, but an *o*-phenyl substituent *(128a)*, R = C_6H_4-*o*-C_6H_5, results in different fragmentation pathways [82b].



(128a)

M-44

c) Loss of Sulfur Dioxide and Sulfur Monoxide

The mass spectra of diaryl sulfones [52,83,84] *(129)* and sulfoxides [52,84] *(130)* have recently been published, and it is apparent (Table 6) that skeletal rearrange-

(129) *(130)* *(131)* *(132)*

ments in these compounds are more pronounced than in the dialkyl analogues [53]. In addition to the unexpected carbon monoxide expulsion discussed in one of the preceding sections, loss of sulfur dioxide from sulfones and sulfur monoxide from sulfoxides seems to require at least one aromatic ring (site of unsaturation) in the molecule. Analogous eliminations of sulfur dioxide from sulfones have been observed under radiolytic [85] and pyrolytic [86] (600–700 °C) conditions.

Table 6. Some rearrangement peaks in the mass spectra of sulfoxide and sulfones.

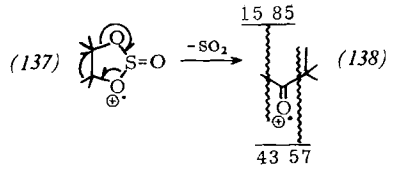
substituted aromatic nucleus was found to migrate preferentially in every case.

Loss of sulfur dioxide from sulfonamides on electron impact has also been reported [87] (Table 7). Since the intensity of the M – SO_2 peak increases as the basicity of Z increases (see *(133)* and Table 7), and taking into account steric considerations, a general scheme can be proposed *(133)* → *(134)* → *(135)*][87]. In support

(133)

(134) *(135)* M-SO_2

of this rationalization, it should be noted that 4-aminobenzosulfonamide (Table 6, R = H) exhibits no M – SO_2 peak, whereas with 4-nitrobenzosulfonamide, this process is responsible for the base peak.



More recently, an analogous expulsion of sulfur dioxide from *N*-n-butyl-*N'*-*p*-toluenesulfonylurea *(136)* has been detected [88]. By a combination of exact mass measurements and deuterium labeling techniques, two fragmentation pathways were established, the main process being identical to that described above for other sulfonamides[*(133)* → *(134)* → *(135)*]. At low ionizing voltage (19 eV), the relative importance of the rearrangement was enhanced.

p–CH_3–C_6H_4–SO_2–NH–CO–NH–C_4H_9 *(136)*

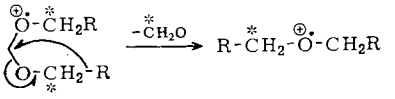
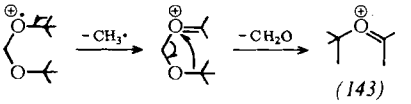
As previously mentioned,certain cyclic sulfites undergo alkyl migration accompanied by sulfur dioxide loss [77], analogous to the corresponding cyclic carbonates losing carbon dioxide [*(109)* → *(110)*]. For example, 2,3-dimethylbutane-2,3-diol cyclic sulfite *(137)* ap-



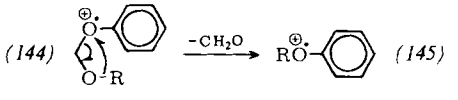
(137) *(138)*

pears to rearrange to the 3,3-dimethyl-2-butanone molecular ion *(138)*, in what may be described as an electron impact induced pinacol rearrangement. The peaks at *m/e*=43 and 57 have the compositions expected, and together comprise 52 % Σ_{40}.

d) Loss of Formaldehyde



One of the few well documented cases of skeletal rearrangement with formaldehyde expulsion taking place in the mass spectrometer has been described [89] for formaldehyde acetals. The primary alcohol derivatives *(139)* display low intensity M – CH_2O peaks



(139) *(140)* M-30

R = C_2H_5, i-C_3H_7, t-C_4H_9

(140), that surprisingly involve loss of the α-carbon of the alcohol. Acetals of secondary and tertiary alcohols, on the other hand, first suffer α-cleavage and then rearrangement [*(141)* → *(142)* → *(143)*], exactly as in the dialkyl carbonates *(112)*. Alkyl aryl acetals *(144)* eliminate formaldehyde directly from the molecular ion, again paralleling the behavior of the corresponding carbonates *(113)*, in which alkyl migration takes place preferentially to the most positive site. It should be noted that the analogous rearrangement process apparently does not operate in dithioacetals [90].

(141) *(142)* M-15 *(143)* M-(15 + 44)

(144) *(145)*

During the course of deuterium labeling studies on butyl acetate [91]*(146)*, a small but characteristic M – 30 peak was detected. Loss of formaldehyde from butyl acetate *(146)* and of acetaldehyde from 1-methyl-propyl acetate *(147)* was confirmed by precise mass measurements. Similar rearrangements occur with neopentyl esters of acetic, propionic, benzoic, and some substituted benzoic acids [92]. In an independent investiga-

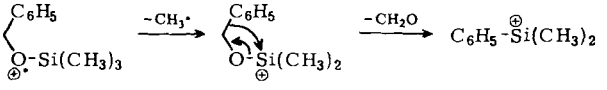
[92] *W. H. McFadden*, *K. L. Stevens*, *S. Meyerson*, *G. J. Karabatsos*, and *C. E. Orzech*, J. physic. Chem. *69*, 1742 (1965).

(146) $R^1 = CH_3$, $R^2 = H$, $R^3 = C_2H_5$ *(149)*
(147) $R^1 = R^2 = R^3 = CH_3$
(148) $R^1 = C_2H_5$, $R^2 = H$, $R^3 = C_2H_5$

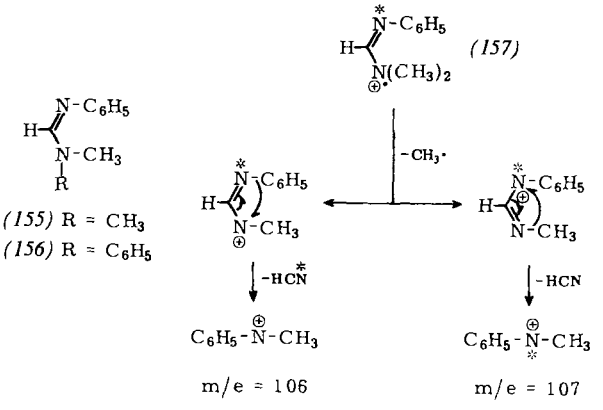


tion[93] using deuterium labeled esters, expulsion of formaldehyde from butyl propionate *(148)* was noted. The rearrangement ion was written as the ketone molecular ion *(149)*, since α-cleavage in *(149)* could then account simply for an otherwise anomalous peak (C_4H_7O) at *m/e* = 71.

It is noteworthy in this connection that thioesters[94] do not lose thioformaldehyde, but rather thiiranes *(153)*. The rearrangement peak corresponds to 3.8 % Σ_{40} for *(150)*, and 1.2% Σ_{40} for *(151)*.

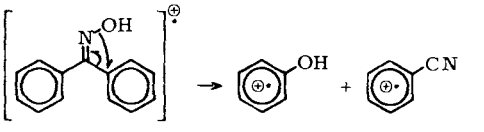
(150) $R^1 = CH_3$, $R^2 = C_2H_5$ *(152)* *(153)*
(151) $R^1 = R^2 = C_2H_5$

In a series of experiments designed to explore the feasibility of elimination of various neutral species (particularly formaldehyde) from trimethylsilyl derivatives of alcohols, a large rearrangement peak (62 % relative abundance) was detected[95] in the mass spectrum of the benzyl alcohol derivative *(154)*. This process is obviously closely related to the loss of



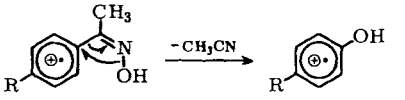
(154) M-15 M-(15 + 30)

carbon dioxide by trimethylsilyl derivatives of benzoic acid[74] *(106)*. A similar study of the effect of substituents in the aromatic ring on the migratory propensity of the aryl group in this system is in progress[95].



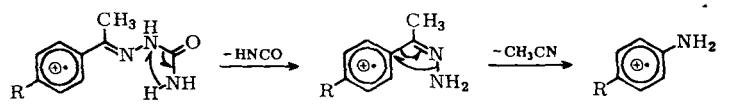
e) Loss of Hydrogen Cyanide and Nitriles

Skeletal rearrangement accompanied by elimination of hydrogen cyanide as a neutral species has been observed[96] in the spectra of certain amidines. In N^1,N^1-dimethyl-N^2-phenylformamidine *(155)*, the rearrangement peak appears at *m/e* = 106 [M − (CH_3 + HCN), 45 % relative abundance], and in N^1-methyl-N^1,N^2-diphenylformamidine *(156)* it is shifted to *m/e* = 168 [M−(CH_3 + HCN)]. By using the ^{15}N-labeled analogue [*(157)*, see asterisks], it was shown that both methyl and phenyl migrations are taking place, since some of the *m/e* = 106 peak moved to *m/e* = 107.

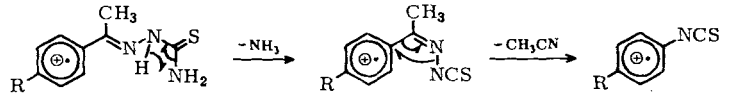


(155) R = CH_3
(156) R = C_6H_5
(157)

The occurrence of two rearrangement peaks at *m/e* = 94 and *m/e* = 103 in the mass spectrum of benzophenone oxime *(158)* has been attributed[18] to a hydroxyl migration, producing benzonitrile as one of the species. Operation of this scheme is supported by both precise mass measurements and observation of a metastable peak for the transition.

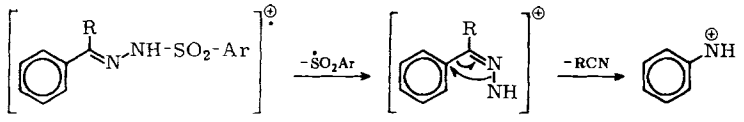


(158) m/e = 94 m/e = 103



Similar rearrangements have been claimed[41] in the spectra of oximes *(159)*, semicarbazones *(160)*, and thiosemicarbazones *(161)* of *p*-substituted acetophenones.

(159)
R = H, CH_3, OCH_3, Br, NO_2



(160)

(161)

A recent study[97] of the electron impact induced fragmentation of alkyl and aryl sulfonylhydrazones has uncovered some important rearrangement processes which fall in this category. For example,

[93] *C. Djerassi* and *C. Fenselau*, J. Amer. chem. Soc. *87*, 5756 (1965).
[94] *W. H. McFadden, R. M. Seifert*, and *J. Wasserman*, Analyt. Chem. *37*, 560 (1965).

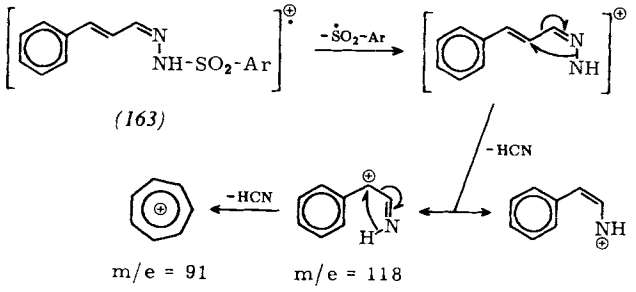
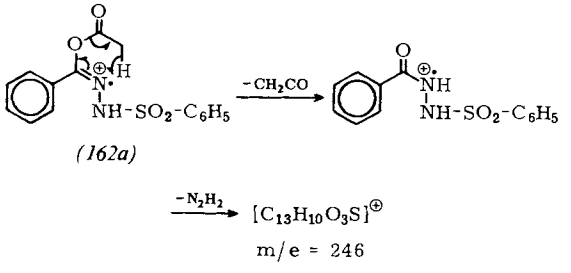
[97] *A. Bhati, R. A.W. Johnstone*, and *B. J. Millard*, J. chem. Soc. *C 1966*, 358.



(162)

R = H, CH_3, $OCOCH_3$, C_6H_5

m/e = 92



benzenesulfonylhydrazones and toluene-*p*-sulfonylhydrazones of aromatic aldehydes and ketones *(162)* generate characteristic peaks at *m/e* = 92. With the cinnammaldehyde derivatives *(163)* two rearrangement peaks are seen at *m/e* = 118 and *m/e* = 91, produced by successive eliminations of hydrogen cyanide. A further reorganization process has been

(163)

m/e = 91 m/e = 118

recognized in the acetyl derivative *(162a)*. After conventional cleavage of ketene, a subsequent loss of diimide apparently occurs, furnishing a rearrangement peak at *m/e* = 246.

(162a)

m/e = 246

f) Loss of Sulfur

Systematic studies on sulfides [53,62,84] and disulfides [84,98,99a] have clearly shown that many skeletal rearrangements with attendant sulfur loss are possible (Table 8). However, as with rearrangements involving carbon dioxide expulsion [69], it has been proposed [62,98] that an unsaturated site in the molecule is a necessary prerequisite for significant rearrangement. The absence of skeletal rearrangement peaks in the mass spectra of higher dialkyl sulfides [99b] may be cited in favor of this suggestion. Also, the much greater proclivity of methyl compounds (*e.g.* dimethyl sulfide [53], dimethyl disulfide [98], and thioanisole [62]) to undergo skeletal rearrangement compared with other alkyl substituted analogues has been attributed [62,98] to the lack of competing reactions possible with the simplest alkyl group.

Table 8. Skeletal rearrangement peaks in the mass spectra of sulfides and disulfides.

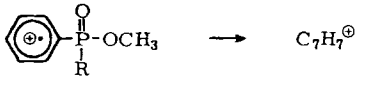
[99b] *S. D. Sample* and *C. Djerassi,* J. Amer. chem. Soc. *88,* 1937 (1966).

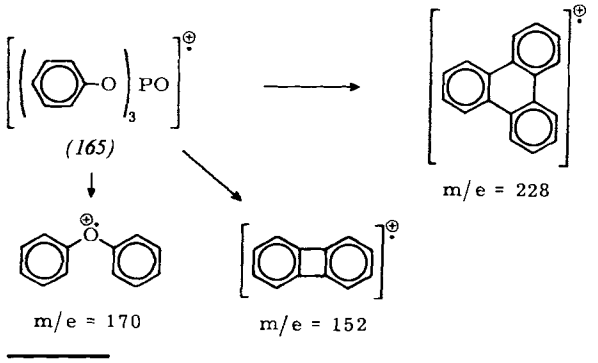
In phenyl substituted sulfides and disulfides, the $C_7H_7^{\oplus}$ ion of mass 91 is virtually ubiquitous, occurring for example to the extent (Table 8) of 25 % with thioanisole[62], and 12 % with phenyl allyl sulfide. It is also worth noting that although the M – CO process in diphenyl ether[46,49,50] *(60)* is a relatively favorable one (15–25 % relative abundance[46,49]), with diphenyl sulfide the corresponding M – CS peak is much less important (3 %, Table 8).

Thiuramdisulfides[99a] such as *(163a)* have small peaks corresponding to the loss of four sulfur atoms (Table 8), In addition, a more important (47 % relative abundance) rearrangement peak appears at $m/e = 109$, which can be most simply visualized as arising by phenyl migration to sulfur, followed by elimination of the elements of methyl isothiocyanate.



(163a)

m/e = 109



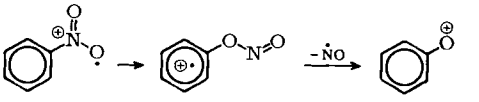
g) Miscellaneous Rearrangements

A rearrangement peak at $m/e = 91$, amounting to 20 % relative abundance, has been reported[100] in the mass spectra of a series of alkyl aryl phosphonates *(164)*.

(164) R = H, CH_3, C_2H_5 m/e = 91

Many relatively intense peaks in the spectra of triaryl phosphates[101] [*e.g.* triphenyl phosphate *(165)*] must involve complex skeletal rearrangements. For example, peaks at $m/e = 228$ (12 % relative abundance), $m/e = 170$ (40 %), and $m/e = 152$ (8 %) have been attributed[101] to the manifestation of such events. The trialkyl phosphates, on the other hand, fragment more predictably, with hydrogen transfer processes predominating.

(165)



m/e = 228

m/e = 170 m/e = 152

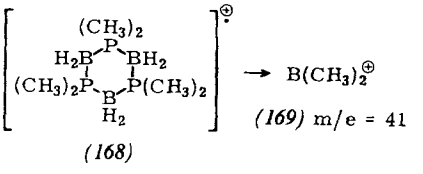
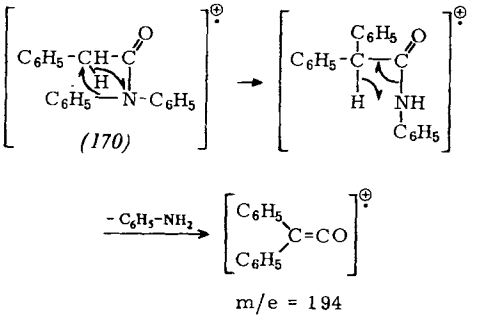
[101] *A. Quayle*, Advances Mass Spectrometry *1*, 365 (1959).



A significant peak (10 % relative abundance) at $m/e = 93$ (M – 30) in the mass spectrum of nitrobenzene *(166)* has been rationalized by the assumption[102] that prior isomerization of the molecular ion to that

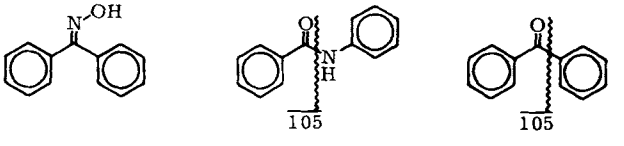
(166) *(167)* m/e = 93



of phenyl nitrite *(167)* occurs. No complementary rearrangement is apparent with aliphatic nitro-compounds[103].

In the spectrum of the triphosphatriboracyclohexane[104] *(168)*, the base peak appears at $m/e = 41$, which has been attributed to the formation of dimethylboron ion *(169)*. Interestingly, the appearance potential for this species is greater than 20 eV.

(168) *(169)* m/e = 41



A small peak (0.2 % Σ_{40}) at $m/e = 149$ detected[105] in the spectrum of *N,N*-diphenyl phenylacetamide *(170)* has been interpreted by invoking a phenyl migration, and substituent and deuterium labeling results (but no exact mass measurements) are cited as corroborative evidence.

(170)

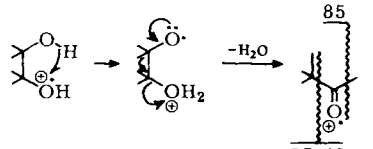
m/e = 194

In the same paper[105], an electron impact induced "Beckmann rearrangement" was claimed to operate in the fragmentation of benzophenone oxime *(158)*, due to the presence

(158) *(171)* *(172)*

of an otherwise anomalous peak at $m/e = 105$ (4 % Σ_{40}), which would be expected to result from cleavage in the Beckmann product benzanilide *(171)*. However, repetition of this

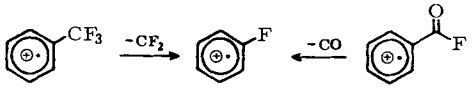
[102] *J. H. Beynon*, *R. A. Saunders*, and *A. E. Williams*, Ind. chim. belg. *1964*, 311.



[103] *R.T. Aplin*, *M. Fischer*, *D. Becher*, *H. Budzikiewicz*, and *C. Djerassi*, J. Amer. chem. Soc. *87*, 4888 (1965).

[104] *R. E. Florin*, *L. A. Wall*, *F. L. Mohler*, and *E. Quinn*, J. Amer. chem. Soc. *76*, 3344 (1954).

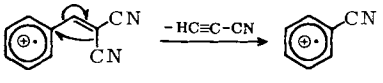
[105] *P.T. Funke*, *K. G. Das*, and *A. K. Bose*, J. Amer. chem. Soc. *86*, 2527 (1964).



work [18] suggests that the $m/e = 105$ peak probably originates from benzophenone *(172)* present as impurity in the oxime sample used.

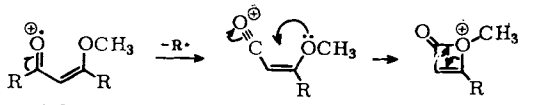
The more mechanistically feasible claim is also made [105] that pinacol *(173)* (and related 1,2-diols) may suffer an electron impact induced pinacol rearrangement. Thus peaks at M − 18, $m/e = 85$ (1.6 % Σ_{40}), $m/e = 57$ (2.5 %), and $m/e = 43$ (0.8 %) are observed in the spectrum of pinacol *(173)*, but apparently no precise mass determinations have been carried out.

(173) *(138)*



Migration of fluorine accompanied by skeletal rearrangement gives rise to major peaks in the mass spectra of perfluoroxylenes [106], trifluoromethyl substituted benzenes [107] [*e.g.*, *(174)*], and aroyl fluorides [107] [*e.g.*, *(175)*]. The enormous difference in

(174) *(175)*

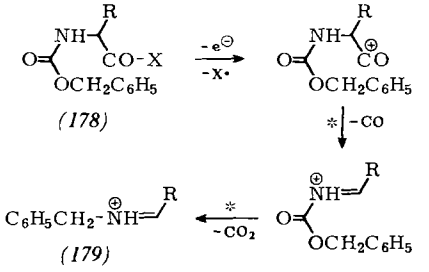


ease of elimination of CF_2 compared with CH_2 from organic compounds under electron impact has already been noted [108]. This trend is further illustrated by the rearrangement with CF_2 elimination which is suffered [109] by simple perfluorohydrocarbons.

A large peak (25 % relative abundance) in the spectrum of benzylidene malononitrile *(176)* at $m/e = 103$ has been attributed [110], on the basis of precise mass measurements, to the formal loss of the elements of cyanoacetylene from the molecular ion, accompanied by migration of a nitrile group.

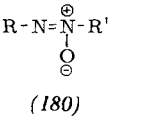
(176) m/e = 103

The base peak for a series of acyclic 1,3-diketone enol ethers *(177)* occurs [111] at $m/e = 59$, and is due to an ion of composition $C_2H_3O_2^{\oplus}$. Such a species requires formal migration of the methoxy function, and the presence of appropriate metastable peaks betray its origin as M − R fragments. The contribution of $C_2H_3O_2^{\oplus}$ to the total ion current decreases as the size of R increases.



(177)

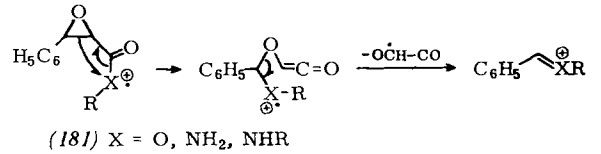
R	Σ_{30}
CH_3	11.1
C_2H_5	4.5
n-C_3H_7	3.6
n-C_4H_9	1.5



$CH_3O\overset{\oplus}{C}O$
m/e = 59

The occurrence of benzyl migrations in the mass spectra of benzyloxycarbonyl derivatives of certain amino-acid esters has been reported [112]. Important peaks (4–52 % relative abundance) were recorded for a series of mainly dipeptide methyl (X = CH_3), ethyl (X = C_2H_5), and phenylthio (X = C_6H_5S) esters, corresponding to rearrangement ions *(179)*. It seems very likely that the rearrangement step (loss of carbon dioxide) is closely related mechanistically to that occurring in ethyl carbamate derivatives [75,76].

(178) *(179)*



Extensive rearrangement in the molecular ion of a series of aromatic azoxy compounds *(180)* is indicated [113] by their proclivity to eliminate carbon monoxide followed by loss of nitrogen on electron impact. The rearranged ion in the case of *(180)* R = R′ = phenyl seems to be different from the molecular ion of *o*-hydroxyazobenzene, since this species expels nitrogen followed by carbon monoxide.

(180)

R = R′ = Phenyl
R = Phenyl, R′ = β-Naphthyl
R = β-Naphthyl, R′ = Phenyl
R = 2,4,6-Trimethylphenyl, R′ = Phenyl

An important rearrangement process, often generating the base peak of the spectrum, in glycidic esters and amides *(181)* has been noted [114], involving loss of C_2HO_2 from the molecular ion. As might be expected from the proposed mechanism, this rearrangement was not encountered [115] in 1,2-epoxyketones [*e.g.*, *(181)* X–R = alkyl).

4. Summary

In view of the relatively high incidence of electron impact induced skeletal rearrangements recognized during the past year, it seems highly probable that many additional examples await discovery in the near future. All such instances will be of intrinsic mechanistic interest, irrespective of the probability of the process, but only the more abundant peaks will be of serious consequence to the interpretation of "element maps".

Elimination of stable, neutral species (*e.g.* CO, CO_2, SO_2, HCN, CH_2O, *etc.*) from a non-terminal position in aromatic or other unsaturated molecules presently provides the largest collection of reorganization processes. In many cases, the migrating group may be visualized as a nucleophilic species, moving preferentially to the most positive site available. Operation of the same rearrangement in the molecular ion of the corresponding saturated analogues is usually markedly reduced, or even absent. Prior cleavage, in order to develop a full positive charge, is often necessary to induce a subsequent group migration. The most effective migrating groups appear to be those which have little tendency to suffer fragmentation, such as methyl and phenyl.

From a consideration of trends already apparent, it seems likely that thermal, photochemical, and acid catalysed rearrangements will act as important guides in the design of electron impact induced parallels. To date, it is a fairly safe assertion that good fortune has been involved in the detection of most, if not all, recorded mass spectral skeletal rearrangements. Critical comparison of such processes with free-radical and carbonium ion chemistry is required, and one avenue which may prove to be profitable in this connection, presently under active investigation, involves the study of relative migratory aptitudes.

Reactions with Molecular Oxygen

BY S. FALLAB [*]

Molecular oxygen is an important oxidizing agent both in industrial and in biological processes. In many of these processes, the O_2 molecule reacts preferentially with free radicals, which are frequently paramagnetic metal ions. Homogeneous systems of this type that are described in the literature are discussed, and an attempt is made to establish the factors that determine the course and mechanism of the reaction.

1. Introduction

According to its position in the electrochemical series, molecular oxygen is a powerful oxidizing agent. The calculated standard potential for the redox equilibrium (1) is +1.23 V [**]. However, reactions with molecular

$$O_2 + 4\,H^+ + 4e^- \rightarrow 2\,H_2O \qquad (1)$$

oxygen at room temperature generally proceed very slowly in the gas phase as well as in homogeneous solution. This is even more surprising in view of the fact that, in the ground state, the oxygen molecule possesses two unpaired electrons.

The stepwise course of the reduction (1) accounts in part for the slowness of reaction. The full redox potential is realized only when the oxidation can be carried out in a more or less synchronous four-electron step of the type that is assumed to play a part in enzymatic oxidations [1]. Such processes require a substrate with a specifically fixed steric position, and this is presumably possible only in a macromolecular environment.

If these conditions are not satisfied, the reduction of the oxygen molecule must take place in two-electron steps (2) and (3), or even in one-electron steps (4) to (7). Since the standard potential of reaction (2) is only +0.68 V [2], the O_2 molecule is a much weaker oxidizing agent when the structure of the substrate, or the medium, compels the oxidation to proceed in two-electron steps. The standard potentials assigned to the four one-electron steps (4) to (7) are −0.32, +1.68,

[*] Prof. Dr. S. Fallab
Institut für Anorganische Chemie der Universität Basel
Spitalstr. 51
Basel (Switzerland)

[**] The standard potentials of the following redox systems are of the same order of magnitude: Pb^{2+}/PbO_2: +1.46 V; Cl^-/Cl_2: +1.36 V; $Cr^{3+}/Cr_2O_7^{2-}$: +1.33 V; I_2/IO_3^-: +1.20 V; Br^-/Br_2: +1.07 V; VO^{2+}/VO_2^+: 1.00 V.

[1] *J. H. Wang* and *W. S. Brinigar*, Proc. nat. Acad. Sci. *46*, 958 (1960); *T. Nakamura*, Biochim. Biophysica Acta *42*, 499 (1960).

[2] *P. George*: Oxidases and Related Redox Systems. Wiley, New York 1965, p. 3.

$$O_2 + 2\,H^+ + 2\,e^- \rightarrow H_2O_2 \quad (2)$$

$$H_2O_2 + 2\,e^- + 2\,H^+ \rightarrow 2\,H_2O \quad (3)$$

$$O_2 + H^+ + e^- \rightarrow HO_2\cdot \quad (4)$$

$$HO_2\cdot + H^+ + e^- \rightarrow H_2O_2 \quad (5)$$

$$H_2O_2 + e^- \rightarrow OH\cdot + OH^- \quad (6)$$

$$OH\cdot + H^+ + e^- \rightarrow H_2O \quad (7)$$

+0.80, and 2.74 V respectively [2]. Thus the first step (4), which primarily determines the reactivity of the O_2 molecule, is thermodynamically very difficult in a mechanism divided into four steps. Consequently, before the energetically favorable later steps can take place, the energy threshold of the radical $HO_2\cdot$ must be crossed.

The unreactive nature is also partly due to the electronic structure of the molecule. The homonuclear diatomic structure leads to degeneracy of the molecular orbitals with π symmetry formed from the atomic orbitals $2p_x$ and $2p_y$ (z = molecular axis) [3]. Since the oxidizing action of the molecule is based on the tendency to complete the half filled antibonding orbitals π^*2p_x and π^*2p_y, the configuration of the transition state for such an electron transfer is fixed by the geometry of these orbitals, and the reactivity is restricted accordingly.

In a complete reduction of the O_2 molecule in accordance with equation (1), the O–O bond must be cleaved at some stage of the reaction. Since the energy required for the cleavage of the single bond is much lower in the peroxo group O_2^{2-} than in O_2, it may generally be assumed that the cleavage of the O–O bond takes place only after an electron transfer.

2. Oxidation Mechanisms

The autoxidation [4] of hydrated transition-metal ions is strongly dependent on the reaction medium. In a series of reactions of the type (8), the kinetics of which have been extensively studied, equation (8a) is valid at

$$4\,M^{\lambda+} + O_2 + 4\,H^+ \rightarrow 4\,M^{(\lambda+1)+} + 2\,H_2O \quad (8)$$

constant oxygen concentration. In weakly acidic solution, metal ions $M^{\lambda+}$ are hydrolysed to a greater or

$$d[M^{(\lambda+1)+}]/dt = k'[M^{\lambda+}]/[H^+] \quad (8a)$$

lesser degree in accordance with equation (8b). Replacement of $[M^{\lambda+}]$ in equation (8a) by the mass-action expression found from equation (8b) gives

$$M^{\lambda+} + H_2O \rightleftharpoons MOH^{(\lambda-1)+} + H^+ \quad (8b)$$

equation (8c). The apparent rate constant k'' now includes the hydrolysis constant of equation (8b), and

$$d[M^{(\lambda+1)+}]/dt = k''[MOH^{(\lambda+1)+}] \quad (8c)$$

it can be concluded from the empirical relationship (8a) that the actual reactive species is $MOH^{(\lambda-1)+}$, which is present in low concentrations.

This is true of the autoxidation of Fe^{2+} in weakly acidic solution [5], of U^{4+} in perchloric acid solution [6], of Ti^{3+} in hydrochloric acid solution [7], and of V^{3+} in perchloric acid

$$4\,MOH^{(\lambda-1)+} + O_2 + 4\,H^+ \rightarrow 4\,MOH^{\lambda+} + 2\,H_2O \quad (9)$$

solution [8]. The reaction kinetics found in all these cases correspond to a mechanism in which the first step, *i.e.* the reaction with the O_2 molecule itself (10), is rate-determining.

$$MOH^{(\lambda-1)+} + O_2 + H^+ \rightarrow MOH^{\lambda+} + HO_2\cdot \quad (10)$$

$$M^{\lambda+} + HO_2\cdot + H_2O \rightarrow MOH^{\lambda+} + H_2O_2 \quad (11)$$

$$M^{\lambda+} + H_2O_2 \rightarrow MOH^{\lambda+} + OH^- + OH\cdot \quad (12)$$

$$M^{\lambda+} + OH\cdot \rightarrow MOH^{\lambda+} \quad (13)$$

In any series of reaction steps, the rate of formation of the end product is determined mainly by the slowest step. Steps (11) to (13), which are reactions with H_2O_2 and with the reactive radicals $HO_2\cdot$ and $OH\cdot$, are relatively fast, and so influence the experimental kinetics only in that the concentration of $M^{\lambda+}$ is decreased fourfold per unit of time.

The scheme (10) to (13), which was first proposed by *Haber* and *Weiss* [9], provides a satisfactory explanation of the experimental findings. However, conclusive proof of the validity of this four-step mechanism for the reduction of O_2 is not yet available.

The results of kinetic studies on the autoxidation of Fe^{2+} and Pu^{3+} in strongly acidic solution suggest other reaction mechanisms. Under conditions that eliminate the formation of $FeOH^+$ or $PuOH^{2+}$, oxidation can evidently proceed by an alternative path (*via* a relative energy minimum). In addition to the linear dependence on the O_2 concentration exhibited by all the systems mentioned above, the reaction rate also depends on the square of the metal ion concentration [equations (14) and (15)]. *George* interprets this [10] as evidence

$$-d[Fe^{2+}]/dt = k[Fe^{2+}]^2[O_2] \quad (14)$$

$$-d[Pu^{3+}]/dt = k[Pu^{3+}]^2[O_2] \quad (15)$$

$$Fe^{2+} + O_2 \rightleftharpoons Fe^{II}O_2^{2+} \quad (16)$$

$$Fe^{II}O_2^{2+} + Fe^{2+} \rightarrow Fe^{III}O_2^{+} + Fe^{3+} \quad (17)$$

$$Fe^{III}O_2^{+} + 2\,H^+ \rightarrow Fe^{3+} + H_2O_2 \quad (18)$$

for the rate-determining reaction (17), which is preceded by the formation (16) of a presumably very unstable iron(II)-O_2 adduct. Reaction (17) leads first to electron transfer and formation of the iron(III)-peroxo

complex $Fe^{III}O_2^{2+}$, which then undergoes dissociation and protonation, to give H_2O_2 in accordance with equation (18). An analogous mechanism can be formulated for the oxidation $Pu^{3+} \rightharpoonup Pu^{4+}$ [11].

Thus in contrast to the Haber-Weiss mechanism (equations (10) to (13)) the reaction involves a two-electron step, which bypasses the energetically unfavorable step (4). This very plausible explanation is supported by information gained from autoxidation studies of V^{2+} and Cr^{2+}. In both cases it was possible to detect a binuclear oxidation product VOV^{4+} or $CrOCr^{4+}$, the formation of which is open to various interpretations, but which makes the Haber-Weiss mechanism appear unlikely.

According to *Swinehart* [12], the autoxidation begins with a two-electron step (19), which yields a vanadium(IV) species as an intermediate. VO^{2+} then reacts

$$V^{2+} + O_2 + H_2O \rightarrow VO^{2+} + H_2O_2 \quad (19)$$

$$V^{2+} + VO^{2+} \rightarrow VOV^{4+} \quad (20)$$

with unreacted V^{2+} to form VOV^{4+}, see equation (20). The formation of this binuclear product in accordance with equation (20) has been confirmed in an independent investigation [13]. VOV^{4+} absorbs at 425 nm, and can be unambiguously detected spectrometrically.

Thus the energetically unfavorable formation of the HO_2 radical is again avoided. A similar mechanism can be formulated for the autoxidation of Cr^{2+} [14]. However, the intermediate CrO^{2+} is much less stable than the corresponding vanadium compound. The reduction of the O_2 molecule (21) to (23) could conceivably take place in two successive two-electron steps, in which an adduct of O_2 with Cr^{2+}, formed in accordance with equation (21), reacts as shown in equation (22) with intermediate formation of a binuclear peroxo complex; this complex then undergoes homolytic decomposition in accordance with equation (23). ^{18}O-Tracer studies by *Gordon* and

$$Cr^{2+} + O_2 \rightleftharpoons Cr^{II}O_2^{2+} \quad (21)$$

$$Cr^{II}O_2^{2+} + Cr^{2+} \rightarrow Cr^{III}OOCr^{III4+} \quad (22)$$

$$Cr^{III}OOCr^{III4+} \rightarrow 2\,Cr^{IV}O^{2+} \quad (23)$$

Taube [15] have cast doubt on the Haber-Weiss mechanism proposed by *Halpern* and *Smith* [6] for the autoxidation of uranium(IV) salts. According to these studies, only one of the oxygen atoms in the final product UO_2^{2+} is derived from the O_2. On the other hand, when the reaction is complete, nearly all the labeled oxygen from the oxidizing agent O_2 is found in the bound form in UO_2^{2+}. This distribution would be incompatible with a mechanism (10) to (14) involving four one-electron steps. Thus two-electron steps are also more likely in this case: UOH^{3+} would react in the rate-determining step (24) to give a uranium(VI)-peroxo compound, which would then undergo a rapid secondary reaction with further UOH^{3+}.

$$UOH^{3+} + O_2 \rightarrow U(O_2)OH^{3+} \quad (24)$$

$$U(O_2)OH^{3+} + UOH^{3+} \rightarrow 2\,UO_2^{2+} + 2\,H^+ \quad (25)$$

Experiments with a chelate of vanadium(IV) with picolinic acid showed that partially hydrolysed metal ions are particularly readily autoxidized. The chelate bis(picolinato)oxovanadium(IV), VOZ_2 (Z = picolinate), which is formed in weakly acidic solution, is autoxidized only extremely slowly. In neutral solution, the chelate is hydrolysed to $V(OH)OZ_2^-$, with the hydroxo group *trans* to the vanadyl oxygen [16]. The autoxidation of this hexacoordinated species also proceeds very slowly, since the coordination sphere is fully occupied. Fast autoxidation takes place only on further hydrolysis to $V(OH)_2OZ^-$, with elimination of a picolinic acid ligand [17].

There now arises the question of the relationship between hydrolysis and autoxidizability. Since the more highly oxidized species of a redox pair $M^{\lambda+}/M^{(\lambda+1)+}$ will always be the more strongly hydrolysed, the redox potential must decrease with increasing OH^- concentration, *i.e.* $M^{\lambda+}$ apparently becomes a stronger reducing agent. Though the reactivity, which is determined by kinetic quantities, is in principle independent of the thermodynamic equilibrium position, various workers have found linear relationships between the free energy of activation $\Delta F^{\neq}$ and the total change in free energy ΔF° [18]. For a redox reaction of the type (8), the redox potential of $M^{\lambda+}/M^{(\lambda+1)+}$ is a relative measure of ΔF°. Under comparable conditions, the rates of autoxidation of V^{3+} and U^{4+} in acidic solution are 7×10^{-10} and 2.5×10^{-4} mole l^{-1} min^{-1} respectively. If the autoxidation reactions are assumed to proceed by the general mechanism (10) to (13), these experimental values give the rates of the bimolecular reaction steps (26) and (27). The standard potentials

$$VOH^{2+} + O_2 \rightarrow VO^{2+} + H^+ \quad (26)$$

$$UOH^{3+} + O_2 \xrightarrow{H_2O} UO_2^{2+} + H_2O_2 + H^+ \quad (27)$$

of the systems V^{3+}/VO^{2+} and U^{4+}/UO_2^{2+} (0.33 and 0.36 V, respectively) provide a relative measure of the equilibrium position for the redox steps (26) and (27). Comparison of the two pairs of figures shows immediately that the two potentials, which lie relatively close together, do not explain the enormous difference in the rates of reaction [19].

[18] *J. O. Edwards*: Inorganic Reaction Mechanism. Benjamin, New York 1964, p. 31.

[19] The hydrolysis constants of V^{3+} and U^{4+} that enter into the calculation have only a small effect on this comparison.

A second comparison of this type can be carried out for the systems Fe^{2+}/Fe^{3+} and Pu^{3+}/Pu^{4+}, which have the standard potentials $E^\circ = 0.77$ and 0.97 V respectively. The rate constants for the autoxidation [cf. equations (14) and (15)] measured under comparable conditions are 0.2 and 10^4 mole^{-1} l min^{-1} respectively; thus the autoxidation of the weaker reducing agent, Pu^{3+}, is 10^5 times as fast.

These two examples show that there is no parallelism between the reaction rate and the equilibrium position, and that the accelerating influence of the coordinately-bound hydroxo group must therefore be explained by specific kinetic factors.

The stereochemistry of reaction (26) is indicative of hydrogen transfer (Fig. 1a). This would readily explain

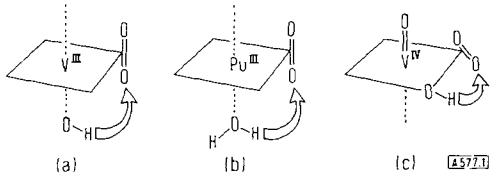

Fig. 1. Schematic representation of hydrogen-transfer mechanisms.

the influence of the hydroxo group on the reactivity toward O_2. The reaction of hydrated Pu^{3+} [11] could, in principle, also proceed by a hydrogen-transfer mechanism (Fig. 1b). The reaction step requiring the main part of the activation energy would then be the cleavage of an O–H bond, and since a monomolecular decomposition is strongly dependent on the vibration energy of the system, the reaction rates measured in H_2O and in D_2O should show a kinetic isotope effect. The theoretical ratio of the rate constants for the cleavage of O–H and O–D bonds at 25 °C is $k_H/k_D \approx 10$ [20]. Corresponding measurements on the autoxidation of $VO(OH)_2Z^-$ (Fig. 1c) gave $k_H/k_D = 0.92$. Values of between 1.2 and 1.3 were found for the autoxidation of Pu^{3+} [11]. Since the ratio k_H/k_D for both of these systems is only insignificantly different from 1, a hydrogen-transfer mechanism can be definitely ruled out.

Thus the reasonable and unrefuted mechanism for the general redox reaction (10) with molecular oxygen is electron transfer from the valence shell of the metal ion to the O_2 molecule. No definite information is available at present regarding the geometry of the transition state of such a reaction, but certain possibilities can be advanced on a purely theoretical basis. Thus from the electronic configuration of the O_2 molecule [3], it can be concluded that the reduction involves the transfer of an electron into an antibonding orbital having π symmetry. This is possible only if the corresponding atomic orbital of the electron donor has a matching symmetry.

Figure 2a shows a situation that favors the electron transfer [21]. The increase in the positive charge on the metal ion brought about by the redox reaction leads to

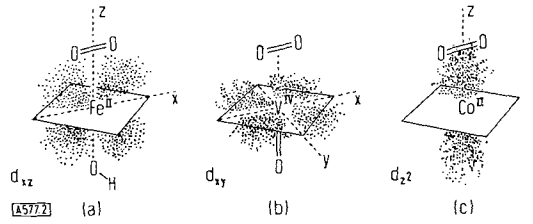

Fig. 2. Schematic representation of the orbitals of the central metal atom that might be used in electron-transfer mechanisms.

considerable reorganization of the coordination sphere: the lengths of the coordinate bonds become smaller, and the hydration sphere becomes larger. The electron transfer is very fast compared with these displacements of atomic nuclei, and after the activation energy for the reorganization has been supplied, an "energyless" electron transfer takes place from the high-spin d^6 configuration (from d_{xz} in Fig. 2a) to the O_2 molecule, which must also be favorably "prepared" by nuclear vibrations.

This hypothesis is confirmed by autoxidation experiments with VO^{2+} chelates [17]. According to calculations by *Ballhausen* [22], the one d electron of the vanadyl ion is localized in d_{xy} (Fig. 2b). Since bis(picolinato)oxovanadium(IV) must be assumed to have a square-pyramidal configuration [16], the attack by the O_2 molecule must take place exclusively in the *trans* position with respect to the vanadyl oxygen.

In the position shown in Figure 2b, the electron would have to enter a π^*2p_z or π^*2p_y antibonding orbital of the O_2 molecule. The maximum values of the function π^*2p_z lie in the xz plane, and coincide with a nodal plane of the d_{xy} orbital of vanadium. On the other hand, the overlap of d_{xy} with π^*2p_y should become important only when the O_2 molecule moves very close to the vanadium ion. An "energyless" electron transfer, such as occurs in the autoxidation of Fe^{3+} (Fig. 2a), is therefore impossible in this case.

The electron-transfer hypothesis is further confirmed by investigations on the influence of ligands on the rate of autoxidation. It was found in the autoxidation $Fe^{2+} \rightarrow Fe^{3+}$ that the transfer of the electron from Fe^{2+} to the O_2 molecule can be influenced by coordination of further ligands with Fe^{2+}, and that the nature of the coordinate linkage is evidently of decisive importance. Strongly basic ligand atoms, such as amino nitrogen, are σ bonded to the metal ion through their lone pair of electrons. σ-Donor properties predominate, so that the pair of bonding electrons that enters the position *trans* to the O_2 molecule in Figure 2a can directly influence only those d electrons of Fe^{2+} that have a high probability density along the z axis. However, it can be seen from Figure 2a that this is not the case for the d_{xz} electron. We have found [23] that N ligand atoms generally have little influence on the redox process, whereas O ligand atoms, particularly in the hydroxide and phenoxide anions, accelerate the electron transfer. In these cases the ligand atom has an additional non-bonding electron pair, which gives the base π-donor properties and exerts a direct repulsion on the d_{xz} electron of iron.

The above observations on the medium-dependence and kinetics of autoxidation relate exclusively to metal ions with an incomplete d or f shell. The mode of reaction of these metal ions contrasts in some respects with the behavior of Sn^{2+} and Cu^{+} [24]. The pH-dependence observed in these cases shows that the hydroxo group does not act in the same way as in the reactions discussed earlier. The rate of the reaction is not significantly affected by the hydrogen ion concentration. An increase in the acidity of the solution is accompanied by a small increase in reaction rate, the latter being relatively high for Cu^{+} and Sn^{2+} when compared with the rates of oxidation of metal ions having partially filled d and f shells. The influence of ligands Z on the rate of the reaction (28) has been studied for Cu^{+}. In contrast to the findings for Fe^{2+}, reaction (28) is only

$$4\,ZCu^{+} + O_2 + 4\,H^{+} \rightarrow 4\,ZCu^{2+} + 2\,H_2O \qquad (28)$$

slightly dependent on the nature of the ligand [25]. Cu^{+} and Sn^{2+} are spherically symmetrical ions having the configurations d^{10} and $d^{10}s^2$ respectively, and whose reactivities are evidently little affected by coordinately bound groups.

A recent kinetic study of autoxidation in accordance with equation (28) has revealed some interesting peculiarities [25a]. Cu^{I} is used in the form of $Cu(CH_3CN)_4ClO_4$, and solutions containing O_2 at definite concentrations are added; the rate $d[O_2]/dt$ or $d[Cu^{2+}]/dt$ is measured as a function of the concentrations of Cu^{I}, O_2, and complexing agents Z with the aid of an electrochemical oxygen analyser and a "stopped-flow" spectrophotometer, which is used to follow absorption changes in the millisecond range. For solutions in which the Cu^{I} is almost entirely in the form of the complexes $Cu(NH_3)_2^{+}$ and $Cu(Im)_2^{+}$, and which contain an excess of the buffer ammonia or imidazole, the kinetic equation (28a) is obtained. The rate constant k is of the order of 10^4 l^2 mole^{-2} sec^{-1}, and is approximately three times as great for NH_3 as for imidazole. Moreover, since the rate is independent of the pH, a partially hydrolysed species can be ruled out as the reactive species. The linear relationship with the

$$d[Cu^{2+}]/dt = k[Cu(NH_3)_2^{+}][O_2][NH_3] \qquad (28a)$$

concentration of the buffer base must be interpreted as indicating that the actual electron transfer takes place within a species $Cu(NH_3)_3 \cdot O_2^{+}$ or $Cu(Im)_3 \cdot O_2^{+}$, in accordance with Scheme (28b).

$$Cu(NH_3)_2^{+} \underset{\leftarrow}{\overset{NH_3}{\rightleftharpoons}} Cu(NH_3)_3^{+} \underset{\leftarrow}{\overset{O_2}{\rightleftharpoons}} Cu(NH_3)_3O_2^{+} \overset{NH_3}{\rightarrow} Cu(NH_3)_4^{2+} + O_2^{-} \qquad (28b)$$

The linear complexes $Cu(NH_3)_2^{+}$ and $Cu(Im)_2^{+}$ are evidently extremely unreactive toward O_2, and the system becomes redox-active only after the introduction of a third ligand which causes a change in steric configuration.

Special mention should be made of the autoxidation $Co^{2+} \rightarrow Co^{3+}$. Owing to the high standard potential of the system Co^{2+}/Co^{3+}, autoxidation of Co^{2+} in acidic aqueous solution is thermodynamically impossible.

$$Co(H_2O)_6^{2+} \rightleftharpoons Co(H_2O)_6^{3+} + e^{-} \quad E^{\circ} = 1.8\ V\ [26] \qquad (29)$$

$$Co(NH_3)_5H_2O^{2+} \rightleftharpoons Co(NH_3)_5H_2O^{3+} + e^{-} \quad E^{\circ} = 0.33\ V\ [27] \qquad (30)$$

$$Co(NH_3)_6^{2+} \rightleftharpoons Co(NH_3)_6^{3+} + e^{-} \quad E^{\circ} = 0.1\ V\ [28] \qquad (31)$$

The hydrated Co^{3+} is such a strong oxidizing agent ($E^{\circ} = 1.8$ V) that it can oxidize H_2O to O_2. However, in coordination compounds, particularly with nitrogen as the ligand atom, the Co^{III} stage is stabilized to such an extent, *i.e.* the standard potential is lowered to such an extent (see equations (30) and (31)), that reaction (32) becomes thermodynamically possible in the presence of complex formers such as NH_3.

Nevertheless, reaction (32) does not take place spontaneously (as *e.g.* in the case of Fe^{2+}), but only when the medium satisfies certain conditions. The coordination compound to be formed must be formed beforehand in the Co^{II} stage. With amines as the complexing

$$4\,Co^{2+} + 6\,NH_3 + O_2 + 4\,H^{+} \rightarrow 4\,Co(NH_3)_6^{3+} + 2\,H_2O \qquad (32)$$

agents, therefore, this is possible only at a relatively high pH; however, even in this basic medium, the rate of oxidation is very low. The activation step consists in a rearrangement of the starting complex, *i.e.* the electron transfer from Co^{2+} to the O_2 molecule can take place only when the Co^{II}-N bond lengths are reduced by nuclear vibrations to the length required for the final complex. Since all Co^{III}-amine complexes have the diamagnetic d^6 configuration, the rearrangement energy, and hence the activation energy, is relatively high [29]. Moreover, the rearrangement preceding the electron transfer imposes a charge distribution on the d^7 ion (Co^{II}) that corresponds to the low spin $d_\varepsilon^6 d_\gamma$ configuration. It follows that the electron undergoing transfer occupies a $d_{x^2-y^2}$ or d_{z^2} orbital in the initial state; this is again unfavorable to the electron transfer, on grounds of symmetry (cf. Fig. 2c).

These considerations are valid for an unperturbed octahedral ligand field. However, if the six coordination sites are not uniformly occupied by strong σ donors, the charge distribution in the starting complex undergoes a deformation that favors the electron transfer. Such a ligand effect has been observed in the autoxidation of 3-azapentylene-1,5-diaminecobalt(II) complex ions $Co^{II}Z^{\lambda+}$ [29], in which additional ligands having π-donor properties, such as PO_4^{3-}, $P_2O_7^{4-}$, and CO_3^{2-}, considerably favor the reaction with O_2.

[29] *B. Erdem* and *S. Fallab*, Chimia *19*, 463 (1965).

In this case the actual oxidation step (34) takes place in a binuclear complex, as is shown by the dependence of the reaction rate on the square of the cobalt concentration. The structure and composition of this oxygen complex, which is formed in accordance with equation (33), have also been established by numerous spectrophotometric investigations (see Section 3). It must be concluded from the reaction kinetics that a relatively stable cobalt(III)-peroxo complex is formed as a second intermediate. *Haim* and *Wilmarth* found a similar course for the autoxidation of $Co^{II}(CN)_5^{3-}$ [30].

$$2\,Co^{II}Z^{\lambda+} + O_2 \rightleftharpoons ZCo^{II}O_2Co^{II}Z^{2\lambda+} \quad (33)$$

$$ZCo^{II}O_2Co^{II}Z^{2\lambda+} \rightleftharpoons ZCo^{III}\text{–}O\text{–}O\text{–}Co^{III}Z^{2\lambda+} \xrightarrow{2H^+} 2\,Co^{III}Z^{(\lambda+1)+} + H_2O_2 \quad (34)$$

An unambiguous mechanistic interpretation of the autoxidation of organic substances is generally difficult [31], and a uniform reaction course can be observed only in exceptional cases, since the substance being oxidized generally offers several possible points of attack.

The behavior of most organic substances toward O_2 is similar in two respects: 1) the rate of oxidation increases as the reaction proceeds; 2) the course, yield, and rate are very sensitive to impurities, particularly traces of metals [32]. This behavior is typical of free-radical chain-reactions. The following reaction scheme is generally accepted for the autoxidation of hydrocarbons, alcohols, or aldehydes (RH)· Since a direct reaction (35) with O_2 is very improbable, a radical X· must be assumed, which may be produced by radiation or by added peroxide. X· reacts with RH in accordance with

$$RH + O_2 \rightarrow R\cdot + HO_2\cdot \quad (35)$$

$$X\cdot + RH \rightarrow R\cdot + XH \quad (36)$$

equation (36), with homolysis of the weakest C–H bond, and so initiates the chain reaction indicated in equations (37) and (38).

$$R\cdot + O_2 \rightarrow RO_2\cdot \quad (37)$$

$$RO_2\cdot + RH \rightarrow ROOH + R\cdot \quad (38)$$

The radical RO_2· and the peroxide ROOH can react further in various ways. For example, if RH is a secondary alcohol [33], RO_2· gives the corresponding ketone and HO_2·, which then reacts with RH to form H_2O_2 and another radical R·. The peroxide formed in accordance with equation (38) may decompose into new radicals [eq. (39)], which can then help to propagate the radical chain. The rate is determined mainly by the reaction leading to the radicals X·, *i.e.* the reaction that initiates the autoxidation. The rates of reactions (38) and (39), which provide new radicals, are also important. Thus if this general scheme is valid, the reactivity of the O_2 molecule itself is only of minor importance to the oxidation kinetics, since the direct attack (35) of O_2 on RH is so slow that it may be ignored [34], whereas the free-radical reaction (37) is extremely fast.

$$ROOH \rightarrow RO\cdot + OH\cdot \quad (39)$$

3. The Formation of Stable and Unstable O_2 Adducts

In the autoxidations described above, it is often assumed that the actual electron transfer is preceded by the reversible formation of an O_2 adduct. In most cases there is no direct evidence [36] for the existence of such adducts, which are not transition states, but true intermediates with a (relative) minimum in the energy-reaction coordinate diagram [35].

Thus there is only uncertain kinetic evidence of the occurrence of the species $Fe(OH)\cdot O_2^+$ (Fig. 1a) as an intermediate in the autoxidation in weakly acidic solution [cf. reaction (16)] [23]. Calculation of the activation energy from the temperature-dependence of the rate of reaction gives a surprisingly low value of about 5 to 6 kcal/mole. If one assumes a normal frequency factor of 10^{11} l mole^{-1} sec^{-1} [37], this gives an activation entropy of about -30 cal deg^{-1} mole^{-1}. This strongly negative activation entropy is not very plausible for a bimolecular reaction in which one of the reactants is uncharged [38]. The kinetic parameters are more in agreement with the intramolecular electron transfer (40) as the rate-determining step, and so indicate that the oxidation is preceded by the reversible formation of $Fe(OH)\cdot O_2^+$.

$$Fe(OH)O_2^+ \rightarrow FeOH^{2+} + O_2^- \quad (40)$$

The reversible formation of an O_2 adduct is also postulated for the autoxidation of NO. *Bodenstein* had already observed that the rate of oxidation depends on the square of the nitric oxide concentration, and had explained this observation by a two-step mechanism as shown in equations (41) and (42) [39]. This mechanism has been confirmed by more recent investigations [40]. The reversibly formed, unstable intermediate

$$NO + O_2 \rightarrow ON\cdot O_2 \quad (41)$$

$$ON\cdot O_2 + NO \rightarrow 2\,NO_2 \quad (42)$$

---

[30] *A. Haim* and *W. K. Wilmarth*, J. Amer. chem. Soc. *83*, 509 (1961). Cf. mechanism of the autoxidation of ethylenediaminetetraacetatocobalt(II) *R. G. Yalman*, J. physic. Chem. *65*, 556 (1961).

[31] *G. H. Twigg*, Chem. and Ind. *1962*, 4.

[32] The dependence on impurities is particularly noticeable in the autoxidation of acetaldehyde. The first observations on the aerobic oxidation of acetaldehyde were reported by *J. v. Liebig*, Liebigs Ann. Chem. *14*, 139 (1835). Doubts were later raised about whether very pure acetaldehyde is in fact autoxidizable: *H. Wieland* and *D. Richter*, Liebigs Ann. Chem. *495*, 284 (1932).

[33] In this case the free radical attacks the C atom carrying the hydroxyl group [31].

[34] In the autoxidation of n-decanal, *H. R. Cooper* and *H. W. Melville*, J. chem. Soc. (London) *1951*, 1994, obtained the bimolecular rate constant $k = 2.6 \times 10^{-7}$ mole l^{-1} sec^{-1} for equation (34). The activation energy was 15.6 kcal/mole.

[35] *S. Fallab*, Z. naturwiss. med. Grundlagenforsch. *1*, 366 (1963).

[36] In some cases it also follows from coordination-chemical considerations that the O_2 molecule must occupy a fixed position in the coordination sphere during the oxidation process.

$ON{\cdot}O_2$ is not identical with a species NO_3 that exists in the "nitrate form". Certain conclusions about the geometry of the activated complex can be drawn on the basis of calculations carried out by *Gerschinowitz* and *Eyring*[41]. These authors found good agreement between the rate of autoxidation of NO as obtained by purely theoretical calculations and the experimental values obtained by *Bodenstein* when they assumed that the activation energy for the combination (41) of the free radicals is negligible and that the transition state of (42) has the structure *(42a)*. The N.....O distance (5 Å),

(42a)

which is large in relation to the other interatomic distances, rules out the nitrate form for the intermediate NO_3.

Analogous intermediates $Cl{\cdot}O_2$ and $SO_3{\cdot}O_2^-$ have been postulated for the photoactivated autoxidation of chlorine[42] and for the autoxidation of sulfite[43].

An adduct of O_2 with the radical R· also plays an important part in the mechanism of the autoxidation of organic compounds [see eq. (37)]. No detailed information is available concerning the structure and stability of RO_2· and the reversibility of its formation. Investigations by *Cooper* and *Melville*[34] on the autoxidation of n-decanal have shown that the further reactions of RO_2· are extremely fast.

The suppression of fluorescence by O_2, *e.g.* in substituted anthracenes and more highly condensed aromatic hydrocarbons, is due to the tendency of the O_2 molecule to combine with particles possessing unpaired electrons[44]. A photoactivated molecule X* reacts reversibly in the triplet state with O_2 (43); the radiation quantum is converted into heat in the O_2 complex. Reaction (43) also forms the basis of the photosensitization discussed in Section 4.

$$X^* + O_2 \rightarrow X{\cdot}O_2^* \qquad (43)$$

The combination of the O_2 molecule with paramagnetic particles or with molecules in the triplet state is readily understandable in view of the free-radical character of both reactants. Rather surprisingly, however, O_2 can evidently also combine with otherwise inert components to form labile associates. Thus *Mulliken* interprets the small UV absorptions observed in basic organic solvents containing O_2 as charge-transfer bands of O_2-solvent complexes[45]. Similarly, *Heidt*[46] found that O_2 in aqueous solution forms hydrates in accordance with equation (44). Though from the

$$H_2O + O_2 \rightleftharpoons H_2O{\cdot}O_2 \qquad (44)$$

kinetic point of view these are undoubtedly only very labile collision complexes, their lifetime is still several orders of magnitude longer than the contact time in an elastic collision, since excitation to a charge-transfer transition is possible.

However, many extremely stable oxygen complexes are also known. A very limited number of paramagnetic metal complexes $ZM^{\lambda+}$, which are known as "oxygen carriers"[47], react reversibly with O_2 [see equation (45)] with partial or complete spin saturation. $ZM{\cdot}O_2^{\lambda+}$ undergoes practically no further reactions, or at most reacts only very slowly, and decomposes completely into the starting components in a different medium. It has not so far been possible to establish definitely

$$ZM^{\lambda+} + O_2 \rightleftharpoons ZM{\cdot}O_2^{\lambda+} \qquad (45)$$

the factors responsible for such substantial displacement of the equilibrium (45) in favor of the adduct. The electronic configuration of the metal ion is evidently of decisive importance, since only a few metals exhibit this complex formation[47].

Fe^{II} and Co^{II} are outstanding oxygen carriers when used in conjunction with certain polydentate complexing agents. A spectrophotometric study has shown[48] that O_2 is reversibly bound by Fe^{II} as a chelate with phthalocyaninetetrasulfonic acid. Cobalt(II) bis(salicylaldehyde imine) chelates were the first synthetic oxygen carriers. Extensive studies by *M. Calvin* (cf.[47]) have shown that the molar ratio of metal to oxygen is $Co^{II}:O_2$ or $Co_2^{II}:O_2$, depending on the structure of the ligand. The reversible formation of O_2 can be observed in the solid as well as in solution.

A plane-tetragonal Ir^{1+} complex[49] that reversibly binds O_2[50] in benzene solution in accordance with equation (46) was discovered in 1963. The entry of the

$$IrCO(P(C_6H_5)_3)_2Cl + O_2 \rightarrow Ir(O_2)CO(P(C_6H_5)_3)_2Cl \qquad (46)$$

O_2 molecule into the coordination sphere leads to rearrangement of the complex to an approximately trigonal-bipyramidal structure (see Fig. 3)[51]. On the basis of X-ray analysis, it was possible to confirm

what had formerly been assumed [52], *i.e.* that the O_2 dumbbell lies transverse to the bond axis. As a result of the coordinate bonding, the distance between the O atoms in the O_2 molecule is increased from 1.21 to 1.30 Å; it may be concluded from this that a charge transfer from the metal to O_2 has taken place.

A striking feature of the iridium-oxygen complex is that the ligands, with the exception of Cl^-, belong to the class of readily polarizable "soft" Lewis bases. According to *Pearson* [53], CO and phosphines PR_3 are typical "soft", weak proton acceptors, which tend to form coordinate bonds with d-metal ions having highly occupied valence shells in a low oxidation state. Their "softness" is due to the ability to accept electrons in low unoccupied π-orbitals. The oxygen molecule, which *Jørgensen* [54] includes among the "non innocent ligands", is also "soft" owing to its π-acceptor properties.

As was shown by *Jørgensen* [55], a certain similarity in the nature of the ligands is of decisive importance to the stability of a coordination compound. Thus a complex containing only "soft" ligands will be stabilized by a "symbiotic" effect. These considerations are in excellent agreement with observations on the iridium-oxygen complex. The oxygen-carrier properties of the Fe^{II} and Co^{II} chelates are also plausible on this basis. The hydrated Fe^{2+} and Co^{2+} ions cannot bind measurable quantities of O_2. However, a macrocyclic unsaturated ligand such as porphyrin or phthalocyanine changes the coordinative properties of the metal ion to such an extent, *i.e.* apparently makes it so "soft", that O_2 can be bound in measurable quantities.

In the case of Co^{II}, the metal ion can be caused to bind O_2, not only by polydentate unsaturated complex formers such as bis(salicylaldehyde imine), but also by monodentate ligands such as CN^- or NH_3 [56]. *Haim* and *Wilmarth* [30] found that $Co(CN)_5^{3-}$ reacts with O_2 in accordance with equation (47) to form a binuclear complex. The binuclear O_2 complex formed from bis(histidinato)cobalt(II) [57] was obtained in the crystalline form by *Sano* and *Tanabe* [58].

$$2\,Co(CN)_5^{3-} + O_2 \rightleftharpoons (CN)_5CoO_2Co(CN)_5^{6-} \qquad (47)$$

Chelates of cobalt(II) with the aliphatic polyamines 3,6-diazaoctylene-1,8-diamine (DODA), 3-azapentylene-1,5-diamine (APDA), and ethylenediamine (EDA) react in the same way [59]. In aqueous solution and in the absence of oxygen, these amines form the normal chelates $Co(DODA)^{2+}$, $Co(APDA)^{2+}$, and $Co(EDA)_2^{2+}$. The corresponding complex equilibria can be readily followed by pH measurements, since the free amines are partially protonated up to pH = 9, and protons are liberated by chelation. The absorption bands of these particles are very weak ($\varepsilon < 10^2$). Air-saturated solutions of these systems, on the other hand, give strong absorption bands in the region 300 to 500 mμ ($\varepsilon > 10^3$). Like chelation in the absence of air, this reaction is reversible. The absorption bands disappear on addition of strong acids or on flushing with N_2, and reappear when a suitable change is made in the medium. On the basis of quantitative evaluation of the dependence of the absorptions on concentration and on the medium, the reaction must proceed in accordance with (48) and (48a). The ratio of bound oxygen to cobalt(II) chelate was determined by colorimetric titration of 10^{-4} M solutions of $Co(DODA)^{2+}$ and $Co(EDA)_2^{2+}$

$$2\,Co(DODA)^{2+} + O_2 \rightleftharpoons Co_2(DODA)_2{\cdot}O_2^{4+} \qquad (48)$$

$$2\,Co(EDA)_2^{2+} + O_2 \rightleftharpoons Co_2(EDA)_4{\cdot}O_2^{4+} \qquad (48a)$$

$$2\,Co(APDA)^{2+} + APDA + O_2 \rightleftharpoons Co_2(APDA)_3{\cdot}O_2^{4+} \qquad (48b)$$

with air-saturated H_2O. For the ligand APDA, spectrophotometric investigation gives the stoichiometric composition $Co_2(APDA)_3{\cdot}O_2^{4+}$ [see eq. (48b)].

The reactions are fast. When the solution is saturated with O_2, the formation of the oxygen adducts in accordance with equations (48), (48a), and (48b) is complete after one minute. After a longer period of time (several hours in the cases of DODA and EDA, and about 10 minutes in the case of APDA) the reactions are followed by autoxidation to give the corresponding cobalt(III) chelates as indicated in reaction (34). These chelates were identified by synthesis and spectrophotometric comparison [60].

The ability of Co^{II} to bind O_2 as shown in equation (48) depends greatly on the structure of the complex ligands. If the polyamine is replaced by aminopolycarboxylic acids, *e.g.* nitrilotriacetic acid, ethylenediaminetetraacetic acid, or ethylenediamine-*N*,*N*-diacetic acid, the ability to bind O_2 is completely lost. On the other hand, the tridentate complexing agent iminodiacetic acid (IDA) in conjunction with EDA permits the formation of a species $Co(IDA)(EDA){\cdot}O_2$.

It appears from these experiments that at least three N-ligand atoms must be present in the coordination compound if the binding of O_2 is to be possible. In conjunction with other bidentate ligands such as glycine, EDA, or oxalate, $Co(APDA)^{2+}$ can react with O_2 to give $Co(APDA)(GLY){\cdot}O_2^{+}$, $Co(APDA)(EDA){\cdot}O_2^{2+}$, and $Co(APDA)(C_2O_4){\cdot}O_2$. On the other hand, the binding of O_2 again becomes impossible when the six coordination sites of Co^{II} are fully occupied. Thus Co(APDA)(IDA) no longer gives an O_2 complex. Similarly, no fixation of oxygen as indicated in equation (48b) is observed with $Co(APDA)_2^{2+}$. These experiments confirm that the O_2 molecule is directly bonded to Co^{II} in the innermost coordination sphere, and that there is a pronounced tendency toward the formation of binuclear complexes (cf. Fig. 4a. – the representation of $Co_2(APDA)_2{\cdot}O_2^{4+}$ is to be regarded as schematic; nothing is known as yet about the spatial arrangement of the ligands in the coordination octahedron). Ligand exchange experiments show that in the binuclear species $Co_2(APDA)_3{\cdot}O_2^{4+}$, two

[52] On the basis of stereochemistry and bonding theory, *A. A. Vlcek* postulated a similar structure for binuclear O_2 complexes of cobalt: Trans. Faraday Soc. *56*, 1137 (1960).

A 577.4a

$Co(APDA)^{2+}$ units must be linked by O_2 as a bridge ligand, and that the third molecule of APDA, which is very much more labile than the other two is also bound in the form of a bridge. A conjectural structure is shown in Figure 4b.

A 577.4b

The spatial position of the O_2 dumbbell in these oxygen complexes is not yet known [61]. However, experiments with cobalt-polyamine chelates show that the O_2 adducts, which have been well characterized by spectrophotometry, are not identical with corresponding cobalt(III)-peroxo complexes. This supports the theoretical considerations of *Vlceck* [52], according to which π bonding predominates, so that the O_2 group is transverse to the bond axis. The oxygen complexes formed in accordance with equations (48), (48a), and (48b) are kinetically stable, *i.e.* in contrast to normal cobalt(II) chelates, decomposition and ligand exchange reactions are slow enough to be measured. This observation suggests a low spin (d^6) configuration of the cobalt, which would be compatible only with a charge distribution $Co^{3+}O_2^{2-}Co^{3+}$. On the basis of the above mentioned reversibility of the reactions with O_2, however, the assignment of the Co^{II} valence state seems more correct.

4. Activation of the Oxygen Molecule

A possible mode of reaction that has not yet been discussed involves the low excited singlet states of molecular oxygen $^1\Delta$ or $^1\Sigma$ with paired electron spins. [see equation (49)], which differ from the triplet ground

$$^3O_2 + h\nu \rightarrow {}^1O_2 \qquad (49)$$

state by 0.977 and 1.63 eV respectively [62]. *Wexler* was able to show that in the oxidation of unsaturated hydrocarbons by singlet oxygen, which may be produced in a discharge tube or by reaction of H_2O_2 with sodium hypochlorite, the same products are formed as in the photosensitized autoxidation [63].

Investigations carried out by *Schenk* [64] have shown that the autoxidation of olefins is accelerated in the presence of dyes such as eosin, fluorescein, or anthracene. Excitation of the dye Y and reaction with $^3O_2$ [equation (50)] leads to the formation of the biradical $\cdot YO_2\cdot$, which then reacts with a substrate RH in accordance with equation (51).

$$Y^* + {}^3O_2 \rightarrow \cdot YO_2\cdot \qquad (50)$$

According to *Schenck* [64], the existence of a biradical $\cdot YO_2\cdot$ is confirmed by the facts that *e.g.* in the case of anthracene, irradiation in the absence of O_2 leads simply to dimerization, whereas in the presence of O_2, a substance having the composition YO_2 is formed; this can only be interpreted as a reaction of photochemically formed free radicals. The reaction sequence

$$\cdot YO_2\cdot + RH \rightarrow RO_2\cdot + H\cdot + Y \qquad (51)$$

(50) to (51), from which the sensitizer is recovered unchanged, is further confirmed by kinetic studies. The kinetics of corresponding unsensitized photooxidations show the typical characteristics of a chain reaction and quantum yields $\gg 1$ [48].

Wexler's experiments [63] indicate a different mechanism, in which $\cdot YO_2\cdot$ decomposes by path (52), and the resulting singlet oxygen reacts with the substrate RH in accordance with equation (53); $\cdot YO_2\cdot$ is therefore regarded as an extremely short-lived charge-transfer complex, which serves to transfer the excitation energy to the O_2 molecule.

$$\cdot YO_2\cdot \rightarrow Y + {}^1O_2 \qquad (52)$$

$$^1O_2 + RH \rightarrow RO_2\cdot + H\cdot \qquad (53)$$

Purely chemical activation of the oxygen molecule is also conceivable. The polarization of the electron sheath of O_2 as a result of a more or less labile linkage with an activator molecule A may be sufficient to facilitate reaction with an autoxidizable substrate RH.

$$A + O_2 \rightleftharpoons A^{\delta+}O_2^{\delta-} \qquad (54)$$

$$A^{\delta+}O_2^{\delta-} + RH \rightarrow A + R\cdot + HO_2\cdot \qquad (55)$$

Equations (54) and (55) show possible steps in the catalysis of autoxidation discussed in Section 5. It is also conceivable, in principle, that a strongly electropositive activator A causes heterolysis (56) of the O_2 molecule into highly reactive atomic particles [65]; however, such a reaction course has never been observed in practice.

$$A^{\delta+}O_2^{\delta-} \rightarrow A + O^+ + O^- \qquad (56)$$

[61] The X-ray analysis of $[(NH_3)_5CoO_2Co(NH_3)_5](NO_3)_5$ published some time ago, according to which the O–O axis is oblique to the line joining the Co nuclei, provides no definite indication of this, since the cobalt in this case is in a different oxidation state. *W. P. Schaefer* and *R. E. Marsh*, J. Amer. chem. Soc. *88*, 178 (1966).

[65] *A. Goudot*, C. R. hebd. Séances Acad. Sci. *251*, 722 (1960).

The autoxidation of unsaturated fatty acids in the presence of metal chelates is interpreted by *Uri*[66] as activation in the sense of equations (54) and (55). Co^{II} was particularly effective in conjunction with the macrocyclic complexing agents phthalocyanine and octamethyltetrazaporphin. In this case the activation results from the coordinative bonding of the O_2 molecule to the metal. *Kropf* postulated a similar activation mechanism for the autoxidation of cumene in nonpolar solvents in the presence of copper(II) phthalocyanine[67]. The activation energy is 6.7 kcal/mole lower than in the uncatalysed reaction, providing clear evidence in favor of mechanism (55). In studies on the mechanism of the autoxidation of *o*-phenylenediamine[68] in aqueous media, it was found (contrary to the results obtained by *Kropf*[67]) that copper(II) phthalocyaninetetrasulfonic acid is completely inactive as an autoxidation catalyst. This contradiction may be due to the fact that the *Kropf* activation mechanism is impossible in a polar medium[69].

The catalytic action of iron(II) salts in the hydroxylation of aromatic compounds in aerated solutions[70] could also be regarded as activation of oxygen in the widest sense. However, this effect is presumably due to reactions of the highly reactive intermediates H_2O_2 and OH· formed in the autoxidation of Fe^{2+} (cf. the Haber-Weiss mechanism equations (10) to (13)), since the reaction course and the oxidation products are substantially the same with the two systems Fe^{2+}/O_2 and Fe^{2+}/H_2O_2[71].

Hydroxylation with the system Fe^{2+}/O_2EDTA/ascorbic acid, which was investigated by *Udenfriend*, follows a different course[72]. With the aid of $^{18}O_2$, it could be shown that the oxygen of the hydroxyl group entering the aromatic system is derived mainly from the O_2 molecule. The mechanism (57)/(58) proposed by *Mason*[73] would correspond to true activation of O_2 in the sense of equation (54).

$$(EDTA)Fe^{II} + O_2 \rightleftharpoons (EDTA)Fe^{II}\cdot O_2 \quad (57)$$

$$(EDTA)Fe^{II}\cdot O_2 + ArH \rightarrow (EDTA)Fe^{IV}O + ArOH \quad (58)$$

The large number of reactive O_2 adducts formulated in Section 2 justifies the assumption that the relatively firmly bound O_2 molecule in the cobalt-polyamine chelates is also activated and capable of smooth reaction with oxidizable substrates. In particular it is to be expected that the binuclear O_2 adduct of 3-azapentylene-1,5-diamine-cobalt(II) (Fig. 4), in which "free" coordination sites (*i.e.* sites occupied by readily replaceable H_2O molecules) are still available, would be redox-active. Surprisingly, however, all attempts to promote reaction of the oxygen bound in this way have been unsuccessful[74]. No acceleration of autoxidation has been observed even with readily oxidizable substrates such as aromatic diamines and 4,4′-diamino-3,3′-dimethoxybiphenyl. It appears that the acceptor properties of the binuclearly bound O_2 molecule are in fact weaker than those of free oxygen. An activation mechanism in the sense of equation (54) would also be inconceivable on symmetry grounds (cf. Fig. 4).

5. Metal-Catalysed Autoxidation

The autoxidation of many organic substances can be catalysed by metal salts, the transition metals manganese, iron, cobalt, and copper as redox systems M^{2+}/M^{3+} or M^{+}/M^{2+} being particularly effective catalysts[75]. Whereas the mechanism of the uncatalysed autoxidations described above has been clarified in its broad outlines, there is still great uncertainty regarding the role of the metal ion.

The redox pair Co^{2+}/Co^{3+} can participate in various ways in the oxidation mechanism described in equations (35) to (39). Reaction with the peroxide formed in reaction (38) can lead in accordance with equations (59) and (60) to the accelerated formation of a further radical, with the result that the chain reaction is accelerated[76].

According to *Twigg*[31], the average chain length, which is defined as the number of O_2 molecules consumed per initial step (35), decreases with increasing

$$ROOH + Co^{2+} \rightarrow RO\cdot + OH^- + Co^{3+} \quad (59)$$

$$ROOH + Co^{3+} \rightarrow RO_2\cdot + H^+ + Co^{2+} \quad (60)$$

$$RH + Co^{3+} \rightarrow R\cdot + Co^{2+} + H^+ \quad (61)$$

metal ion concentration. The thermal decomposition of the hydroperoxide ROOH in accordance with equation (39) with formation of two free radicals is of decisive importance to the chain length, and the ROOH concentration is in fact lowered by reactions (59) and (60).

An important feature of the course of cobalt-catalysed autoxidation is that the induction period is considerably shorter than in the uncatalysed reaction[76]. The only possible explanation for this on the basis of the postulated catalysis mechanism is that the formation of the hydroperoxide ROOH that reacts with the catalyst is also accelerated, *e.g.* by the initial reaction (61). However, the overall oxidation could be appreciably accelerated by reaction (61) only if the reoxidation of Co^{2+} by O_2 were fast, and model experiments pro-

[69] Under certain circumstances, heterogeneous catalysis also plays a part here, since the non-sulfonated copper phthalocyanine is very sparingly soluble, and since the phthalocyanines tend to associate; cf. *K. Bernauer* and *S. Fallab*, Helv. chim. Acta *44*, 1287 (1961).

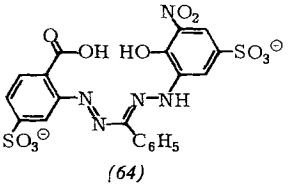
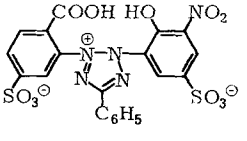
vide no evidence that this is so. It must therefore be admitted that the catalysis of autoxidation by metal ions is only incompletely explained by the mechanisms proposed so far.

The condition of fast reoxidation is satisfied in various Cu-catalysed autoxidations, and in these cases the reaction follows a very simple course described as a "two-stroke mechanism" [equations (62) and (63)][77].



$$RH + Cu(Pyridine)^{2+} \rightarrow R\cdot + Cu(Pyridine)^{+} + H^{+} \quad (62)$$

$$4\,Cu(Pyridine)^{+} + O_2 + 4\,H^{+} \rightarrow 4\,Cu(Pyridine)^{2+} + 2\,H_2O \quad (63)$$



In the first step, which is rate-determining, the substrate undergoes a one-electron oxidation (62) with Cu^{2+}, and the copper ion is then rapidly reoxidized (63) to the bivalent state. The induction period is completely eliminated; however, this catalysis is limited by the relatively low redox potential of Cu^{+}/Cu^{2+}. As has been shown in the autoxidation of *o*-phenylenediamine, pyridines can displace the thermodynamic equilibrium (62) in favor of the reaction products. A similar mechanism may be involved in the oxidative coupling of phenols and amines in the presence of copper salts [78].

For our purposes, the most important feature of the "two-stroke mechanism" is the absence of any direct interaction between the substrate to be oxidized and the oxidizing agent O_2, the catalyst ion acting as an intermediary.

Another obvious and plausible catalysis mechanism is one in which the metal ion brings the two reactants together in a ternary complex. Such a mechanism has been detected in the autoxidation of the formazan dye 1-(2-carboxy-5-sulfophenyl)-5-(2-hydroxy-3-nitro-5-sulfophenyl)-3-phenylformazan *(64)* to form the corresponding tetrazolium salt *(64a)*. The dye (FORM) reacts with Fe^{2+} in accordance with equation (65) to give a stable, planar Fe^{II} chelate, which binds O_2 in accordance with equation (65a). The redox process

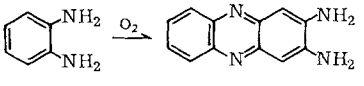
(64)

(64a)

$$Fe^{2+} + FORM \rightleftharpoons Fe^{II}(FORM) \quad (65)$$

$$Fe^{II}(FORM) + O_2 \rightleftharpoons Fe^{II}(FORM)\cdot O_2 \quad (65a)$$

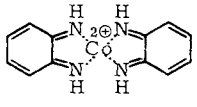
then takes place within this ternary complex. A "two-stroke mechanism" is definitely not valid in this reaction, since the oxidation of the formazan dye by Fe^{3+} proceeds very much more slowly in the absence of oxygen.



In this case the catalyst ion plays a more intimate role as an intermediary; on the one hand it fixes the reactants in a spatially favorable arrangement within its coordination sphere, and on the other it provides the redox components with a bridge for the electron transfer.

As expected, ternary complexes of this type can be detected only when the substrate to be oxidized exhibits complex-forming properties [80]. Thus it is unlikely that cobalt-substrate complexes occur in measurable concentrations in the Co-catalysed autoxidation of hydrocarbons, alcohols, and aldehydes. However, such a mechanism cannot be ruled out in advance, in view of the ability of Co^{II} particles to bind oxygen. The catalyst ion would then participate actively even in the first, radical-producing step in accordance with equation

$$Co\cdot O_2^{2+} + RH \rightarrow R\cdot + Co^{2+} + HO_2\cdot \quad (66)$$



(66). This would explain the observed shortening of the induction period in the presence of cobalt salts. It has not yet been possible to decide whether a ternary complex $Co(O_2)RH^{2+}$ occurs as an intermediate in reaction (66); however, a transition state would necessarily have the composition $Co(O_2)RH^{2+}$.

Spectroscopic studies on the autoxidation of *o*-phenylenediamine to give 2,3-diaminophenazine *(67)* show that reactive intermediates of this nature must occur in Co^{2+}-catalysed autoxidations. In the absence of

(67)

catalyst ions, the reaction takes place in neutral dilute aqueous solution (approx. 10^{-3} M) within several hours; the course of the reaction, which was followed by measuring the increase in the quantity of 2,3-diaminophenazine (λ_{max} = 415 nm), is characterized by a long induction period. In the presence of cobalt(II) salts in an NH_3 buffer, the reaction rate increases by a factor of about 10. Moreover, under these conditions a violet intermediate Z *(68)* is formed, the composition of which has been determined by quantitative experiments in dimethylformamide with H_2O_2 as the oxidizing agent [74]. Each ligand molecule has undergone a two-equivalent oxidation. The spectroscopic data yield no information about the further course of the

(68)

reaction leading from the intermediate *(68)* to the end product 2,3-diaminophenazine, but the kinetics of the formation of the intermediate Z provide an insight into the mechanism of the initial reaction with O_2. Equation (69) describes the dependence of the reaction rate

$$d[Z]/dt = k[Co^{2+}][o\text{-PHEN}][O_2] \quad (69)$$

[77] *K. Wüthrich* and *S. Fallab*, Helv. chim. Acta *47*, 1609 (1964).

[78] *E. Ochiai*, Tetrahedron *20*, 1831 (1964); *Y. Ogata* and *T. Movimoto*, *ibid. 21*, 2791 (1965).

[79] *K. Trefzer* and *S. Fallab*, Helv. chim. Acta *48*, 945 (1965).

[80] Cf. the mechanism of the Fe^{2+}-catalysed autoxidation of 1-hydrazinophthalazine: *D. Walz* and *S. Fallab*, Helv. chim. Acta *44*, 13 (1961).

d[Z]/dt on the concentration for reaction solutions containing a large excess of *o*-phenylenediamine (*o*-PHEN). The rate d[Z]/dt is also strongly dependent on the medium. The autoxidation is almost completely suppressed in phosphate buffer. On the other hand, if imidazole is added to NH_3 buffer, the oxidation exhibits significant further acceleration. In conjunction with the studies on cobalt(II)-oxygen complexes described in Section 4, these observations lead to the assumption that the first step consists in the reversible bonding of O_2 to the catalyst ion [see equation (70)]. Since the irreversible oxidation to the cobalt(III) stage (71) is very slow, the *o*-phenylenediamine cannot be oxidized by an initially formed cobalt(III) particle; on the contrary, a ternary complex must be formed in accordance with equation (72), the rate-determining redox step then taking place intramolecularly. Ligands L containing nitrogen displace the equilibrium to the right,

$$CoL_x^{2+} + O_2 \rightleftharpoons CoL_x \cdot O_2^{2+} \quad (70)$$

$$CoL_x \cdot O_2^{2+} \rightarrow CoL_x^{3+} + O_2^- \quad (71)$$

$$Co(o\text{-PHEN})L_x^{2+} + O_2 \rightleftharpoons Co(o\text{-PHEN})L_x \cdot O_2^{2+} \quad (72)$$

and this accounts for the specific effects of the buffer bases. The intramolecular redox step can, in principle, be based on a hydrogen-transfer or an electron-transfer mechanism. In the latter case the electron would have to be transferred to the O_2 *via* the coordinated amino group and *via* the d-metal ion. However, all the orbitals that the coordinately bound N atom can make available for the transport of electrons have bonding character and are fully occupied. The abstraction of a bonding electron from the amino group is energetically unfavorable, and a hydrogen-transfer mechanism (Fig. 5) is therefore more probable.

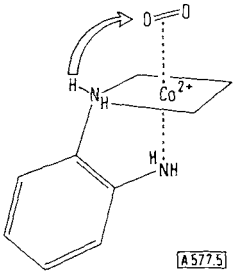


Fig. 5. Rate-determining step in the cobalt-catalysed autoxidation of *o*-phenylenediamine.

Separation of the Isotopes of Uranium by the Separation Nozzle Process

BY E. W. BECKER, K. BIER, W. BIER, R. SCHÜTTE, AND D. SEIDEL [*]

The separation nozzle process is based on the partial spatial separation of components of different mass in an expanding supersonic jet stream. The process is of especial interest for the separation of uranium isotopes. Details of a systematic experimental determination of the most favorable operating conditions for such a separation are given and the construction and testing of a closed circulation system, the basic unit of a ten membered pilot cascade separator for uranium isotope separation, is described. The optimum values of the specific cost factors obtained experimentally for the separation nozzle process are compared with the corresponding values estimated for the gaseous diffusion process.

Introduction

The light isotope of uranium, ^{235}U, required for the production of nuclear power, is currently enriched on a large scale by means of the gaseous diffusion process [1]. This method is based on the difference between the velocities with which $^{235}UF_6$ and $^{238}UF_6$ molecules migrate through porous membranes. It is also possible to separate the isotopes of uranium with gas centrifuges [2]; however, as far as is known, no such production facilities have as yet been constructed.

In the course of the past few years we have developed a process for the separation of the isotopes of uranium which avoids both the problems of the delicate membranes required by the diffusion process and also

those of the high mechanical stresses which occur in the centrifuge process [3–10]. This process is based on the partial spatial separation of the components of a gaseous mixture that takes place in an expanding supersonic jet. The separating effect of the jet may be explained qualitatively by the fact that the streamlines of an expanding jet are curved and, as in a centrifuge, the isotopic mixture is subjected to the action of a centrifugal acceleration, that is, to the pressure gradient which arises as a result of the centrifugal forces.

Figure 1a is a sketch of the arrangement which was used initially in the earlier experiments [3–5]. A convergent nozzle with either a circular or slit-shaped cross section was used in these experiments. A diaphragm, either conical or V-shaped, depending on the nozzle cross section, and having an aperture the same shape as that of the nozzle opening, was positioned directly in front of the nozzle. The diaphragm divided the jet emerging from the nozzle into two fractions, a core fraction and a peripheral fraction, which were then pumped off separately from the separating element. The peripheral gas fraction is enriched in the light component of the mixture when the streamlines are curved away from the axis of the jet. When a reversal in the curvature of the streamlines occurs, as is the case in the recompression region of an over-

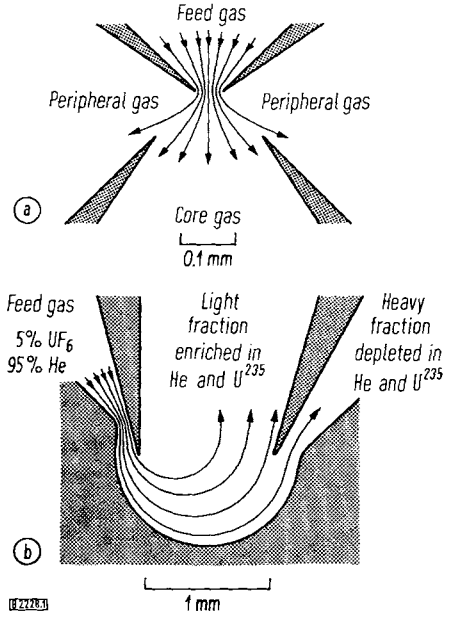

Fig. 1. Cross sections of the separation nozzle arrangements used in the earlier experiments (with a schematic representation of the streamlines):
a) a freely expanding jet from a circular or slit-shaped nozzle.
b) a UF_6 jet with helium as the auxiliary gas deflected by a curved wall.

expanded jet, the sign of the separation effect can also change [6].

Experiments with uranium hexafluoride as the process gas, using the arrangement pictured in Figure 1a, showed that the elementary separation effect for the nozzle process could, in fact, be somewhat larger than that for the gaseous diffusion process [5]. However, due to the higher expansion ratio required and to the appreciably lower absolute pressure which had to be used, the method, in this form, could only be economically competitive with the gaseous diffusion process in certain special cases.

A theoretical investigation of the separating processes taking place in supersonic jets [4, 7] indicated that the separation effect should increase if the angle through which the streamlines turn in the region between the nozzle and the diaphragm could be increased and if the Mach number of the jet could be increased.

An attempt to improve the economic potential of the process by increasing the angle through which the streamlines turn with the aid of a curved wall [8] met with little success. In the case of a mixture of argon isotopes alone, the mechanical deflection of the jet exhibited no clear economic advantages. This could be explained by the fact that, in this case, the increase in the angle of deflection of the streamlines which could be realized was relatively small, while, on the other hand, the decrease in the Mach number, caused by the entropy-producing effects associated with deflecting the jet, was relatively large.

An attempt to increase the Mach number of the isotopic mixture being separated by adding a light auxiliary gas in large molar excess was more successful [9]. The experimental arrangement used was that shown in Figure 1a. In the case of the argon isotopes, both the separation effect and the absolute pressure could be increased considerably, while the expansion ratio required could be decreased considerably. In spite of the necessity of compressing the light auxiliary gas along with the isotopic mixture, an appreciable improvement in the economic efficiency of the process was obtained.

However, when it came to the separation of the isotopes of uranium, the use of a light auxiliary gas with the experimental arrangement of Figure 1a appeared to be of questionable merit. Although the specific cost factors (defined below) which reflect the investment costs of the process could be reduced by more than a factor of four by the addition of 400 mole per cent of helium to the UF_6, the energy requirement increased by about the same factor [10]. This result could be explained by the fact that the large separation that occurred between the isotopic mixture and the light auxiliary gas caused a decrease in the angle of deflection of the streamlines of the isotopic mixture.

Thus, in the case of deflecting the jet with a curved wall, the advantage of the greater angle of deflection could only be obtained along with the accompanying disadvantage of having a smaller Mach number; while, in the case of adding a light auxiliary gas without deflecting the jet, the advantage of the larger

Mach number of the isotopic mixture was counteracted by the accompanying disadvantage of a smaller angle of deflection. It therefore appeared promising to combine the two types of operation. With the type of operation shown in Figure 1b, it was, in fact, possible to achieve a considerable decrease in the investment costs for separating the uranium isotopes without an appreciable increase in the operating costs [10]. Further development work was therefore concentrated on the method combining the use of a light auxiliary gas with the mechanical deflection of the jet.

In order to obtain criteria for the optimum shape of the separating system without performing time consuming separation experiments, Schlieren investigations were carried out using an experimental arrangement corresponding to that shown in Figure 1b [11]. It was assumed that a deflection of the jet as free as possible from disturbances would be the optimum for the separation process. Figure 2 shows examples of the formation of a jet, using nitrogen as a test gas, produced in one case by a convergent nozzle and in the other case by a curved Laval nozzle. It is evident from the figure that in the case of the convergent nozzle both shock waves and boundary layer separation occurred, while the curved Laval nozzle, on the other hand, produced an essentially disturbance-free, curved jet.

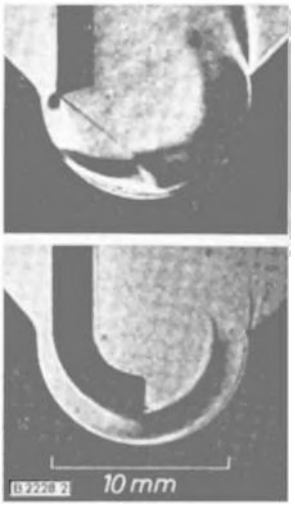

Fig. 2. Schlieren photographs of a nitrogen jet deflected through 180° produced by a convergent nozzle (above) and by a curved Laval nozzle (below). Inlet pressure, $p_0 = 258$ mm Hg; Expansion ratio, $p_0/p_M = 12.3$.

1. Determination of the Optimum Operating Conditions

On the basis of the Schlieren investigations and preliminary experiments with $He-UF_6$ mixtures, the separating elements shown in Figure 3 were selected for further experimentation. The two elements have essentially the same shape, but differ by a factor of two in the characteristic dimensions of the nozzle and of the deflecting surface (see Table 1).

Table 1. The characteristic dimensions of the separating systems investigated. The effective length of the nozzle slit (perpendicular to the plane shown in Figure 3) was 10 mm for both systems.

System	Width of nozzle at throat, a (mm)	Width of nozzle at mouth (mm)	Radius of curvature of the deflecting surface (mm)
X	0.40	0.60	1.5
XIII	0.20	0.30	0.75

1.1. Apparatus and Method of Evaluation

The separation experiments for the determination of the most favorable operating conditions were carried out with the apparatus shown schematically in Figure 4.

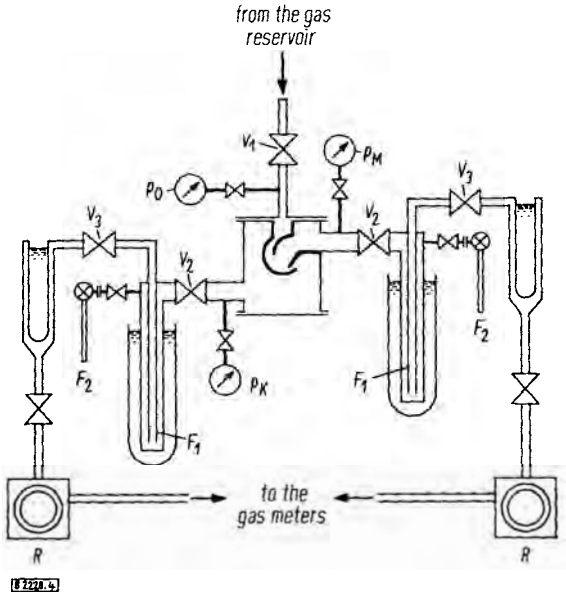

Fig. 4. Schematic diagram of the separation apparatus
F, cold traps; R, rotary pumps; V, valves.

The mixture of UF_6 and auxiliary gas which had been charged to the gas reservoir flowed through the regulating valve, V_1, to the nozzle of the separating system. The pressures, p_M and p_K, of the light and

heavy fractions, respectively, were adjusted to the desired values by means of the valves, V_2. Three diaphragm-type manometers were provided for the measurement of the pressures, p_0, p_M, and p_K. The UF_6 portions of the light and heavy gas fractions were precipitated out in the cold traps, F_1, which were cooled with liquid nitrogen. The cold traps could be isolated from the rotary pumps, R, by means of the valves, V_3.

The cut of the auxiliary gas (of the helium, for example), defined by

$$\theta_{He} = \frac{\text{flow rate of He in the light fraction}}{\text{flow rate of He in the feed gas}}, \quad (1)$$

was determined by means of gas meters installed on the high pressure side of the pumps. The cut of the UF_6 gas,

$$\theta_{UF_6} = \frac{\text{flow rate of } UF_6 \text{ in the light fraction}}{\text{flow rate of } UF_6 \text{ in the feed gas}}, \quad (2)$$

was determined by weighing the two UF_6 fractions which had been collected in the cold traps, F_1, and then reprecipitated in the pipettes, F_2.

The separation factor between the helium and the UF_6, A, was obtained from the cuts defined above by means of the relationship:

$$A = \theta_{He}(1-\theta_{UF_6})/\theta_{UF_6}(1-\theta_{He}) \quad (3)$$

The elementary separation effect for the uranium isotope separation, ε_A, is defined by

$$\varepsilon_A = [n_M(1-n_K)/n_K(1-n_M)]-1, \quad (4)$$

where n_M and n_K are the mole fractions of the light uranium isotope in the UF_6 isotopic mixture in the light and heavy fractions, respectively. The concentrations, n_M and n_K were determined mass spectrometrically [*].

1.2. Bases for the Optimization

In order to make practical use of the process, the elementary separation effect must be multiplied by connecting a large number of separating elements together to form a separation cascade. The elements should be connected in such a way that only streams with the same isotopic abundance ratio are mixed together in the cascade [12]. A separation of the auxiliary gas, accomplished, for example, by first enriching it with several stages of the separation nozzle process itself and then by freezing out the remaining UF_6, will be required only where the gas throughput changes, that is, only at the end of each square section in the cascade. The auxiliary gas which is separated at the top of a cascade section can be recycled and added to the UF_6 at the bottom of the cascade section.

Since a square cascade section consists, in practice, of many identical separating elements connected in series, the cost of separating the auxiliary gas, which needs to be done only at the top of the section, can be neglected in comparison with the other cascade costs. The economic efficiency of the process, using a light auxiliary gas, can therefore also be characterized by the previously defined "specific cost factors" [4,9].

Since, in the experimental work described in this report, the suction pressures, p_M and p_K, of the light and heavy fractions were always equal, the following simplified expressions could be used:

1) the specific ideal isothermal work of compression,

$$E_s = (1/\delta U)\, LRT \ln(p_0/p_M), \quad (5)$$

2) the specific suction volume,

$$V_s = (1/\delta U)\, LRT/p_M, \quad (6)$$

3) and the specific slit length,

$$l_s = (1/\delta U)\, l, \quad (7)$$

where δU is the separative power [12], given by

$$\delta U = \frac{L^*}{2}\varepsilon_A^2\, \theta_{UF_6}\, (1-\theta_{UF_6}), \quad (8)$$

L is the throughput of the gas mixture, L^* is the UF_6 throughput, and l is the slit length of the separating element.

The quantity, E_s, is a measure of the power requirement of the process; the quantity, V_s, is a measure of the investment costs of the compressors, piping, and valves; and the quantity, l_s, is a measure of the investment costs of the separating elements. From an investigation of the dependence of these three cost factors on the experimental parameters, the most favorable operating conditions for the process can be determined to within reasonable limits.

1.3. Experimental Results

The following parameters were varied during the experiments: the type of auxiliary gas, the mole fraction of the UF_6 in the mixture, the inlet pressure, the size of the separation system, the expansion ratio, and the distance between the knife edge and the curved wall (see Figure 1b or 3).

1.3.1. Type of Auxiliary Gas

Nitrogen, neon, and helium were tried as the auxiliary gas using separation system X (see Table 1). The UF_6 concentration was 10 mole per cent in these experiments. First, by varying the inlet pressure, p_0, with the expansion ratio, $p_0/p_M = 4$, held constant, the inlet

[*] Mass Spectrometer, Type 21–220 A, manufactured by CEC, Pasadena, California (U.S.A.).

[12] *K. Cohen*: The Theory of Isotope Separation as Applied to the Large Scale Production of U^{235}. McGraw-Hill Book Co., New York 1951.

pressure which yielded the minimum specific suction volume was determined for each of the three mixtures. The optimum values obtained for p_0 were: 16 mm Hg for the nitrogen-UF_6 mixture, 24 mm Hg for the neon-UF_6 mixture, and 32 mm Hg for the helium-UF_6 mixture. Next, the expansion ratio was varied with the inlet pressure held constant at its optimum value. From the results of the series of experiments presented in Figure 5, it can be seen that the smallest values of the specific cost factors were obtained with helium as the auxiliary gas. For this reason, only helium was used as the auxiliary gas in the experiments which followed [*].

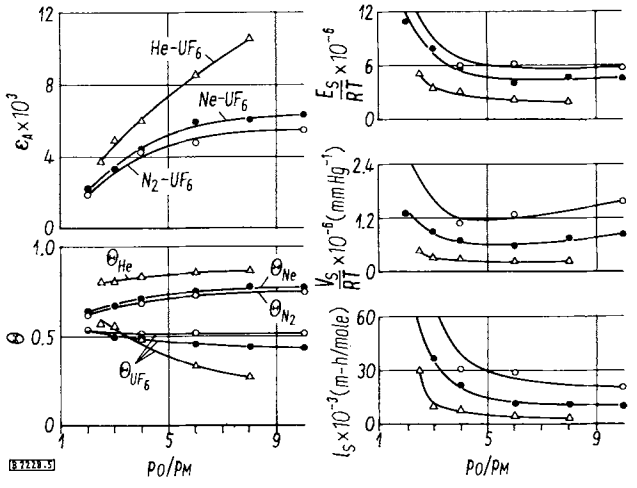

Fig. 5. The effect of different auxiliary gases on the specific cost factors. Inlet pressure: p_0 = 16 mm Hg for the N_2—UF_6 mixture, p_0 = 24 mm Hg for the Ne—UF_6 mixture, and p_0 = 32 mm Hg for the He—UF_6 mixture; Separation system X; Distance between the knife edge and the curved wall: 0.19 mm for the He—UF_6 mixture and 0.29 mm. for the N_2—UF_6 and the Ne—UF_6 mixtures; The UF_6 concentration was 10 mole per cent in all cases.

1.3.2. UF_6 Mole Fraction

Mixtures containing 3, 5, and 10 mole per cent UF_6 were investigated using separation system X. The optimum inlet pressure for each of the three mixtures was again determined first by varying the inlet pressure, p_0, with the expansion ratio, p_0/p_M = 4, held constant. The optimum values obtained for p_0 in these cases were: 60 mm Hg for the 3 % UF_6 mixture, 48 mm Hg for the 5 % UF_6 mixture, and 32 mm Hg for the 10 % UF_6 mixture. Next the expansion ratio was again varied with the inlet pressure held constant at its optimum value. It is evident from the results shown in Figure 6 that the specific suction volume, V_s, and the specific slit length, l_s, decrease monotonically with decreasing UF_6 content in the region investigated. However, as can be seen, the gain in going from the 5 % mixture to the 3 % mixture is rather slight. Therefore, since the 5 % mixture exhibits a somewhat smaller specific work of compression, E_s, the subsequent experiments were carried out using a 5 % UF_6 mixture.

[*] More favorable results can be obtained with hydrogen as the auxiliary gas. However, since H_2 and UF_6 can react chemically with each other, the advisability of using hydrogen as the auxiliary gas is questionable.

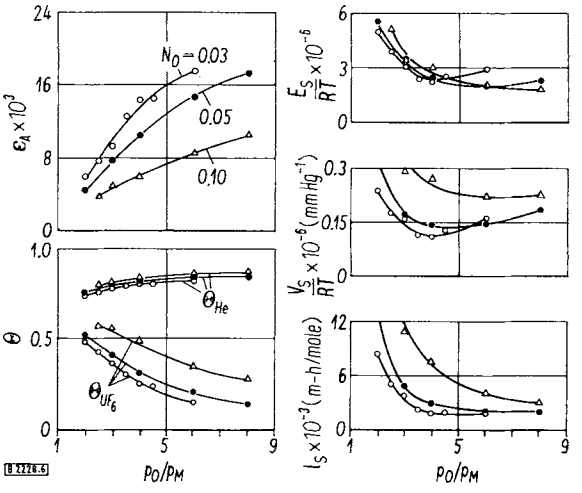

Fig. 6. The effect of the UF_6 mole fraction, N_0, on the specific cost factors.

Helium-UF_6 mixtures; Inlet pressure: p_0 = 60 mm Hg for the 3 % UF_6 mixture, p_0 = 48 mm Hg for the 5 % UF_6 mixture, and p_0 = 32 mm Hg for the 10 % UF_6 mixture; Separation system X; Distance between the knife edge and the curved wall: 0.19 mm.

1.3.3. Inlet Pressure and Size of the Separation System

The effect of the inlet pressure was investigated using separation systems X and XIII with the expansion ratio, p_0/p_M = 4, held constant. It can be seen from Figure 7, where the abscissa is the product of the inlet pressure, p_0, and the nozzle width, a, that both separation systems attain their optimum separating properties at about the same value of the p_0a product. The minimum values of E_s and l_s for both systems are

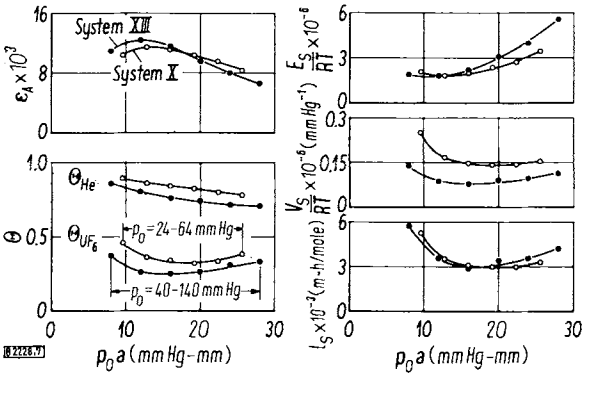

Fig. 7. Effect of the inlet pressure, p_0, and the size of the separation system on the specific cost factors.

Separation system X: width of nozzle at throat, a = 0.4 mm, distance between the knife edge and the curved wall = 0.19 mm.

Separation system XIII: width of nozzle at throat, a = 0.2 mm, distance between the knife edge and the curved wall = 0.11 mm.

Expansion ratio: p_0/p_M = 4; Helium-UF_6 mixture containing 5 mole % UF_6.

essentially the same. However, the minimum specific suction volume for the smaller system, which occurs at a higher value of p_0, is only about one half as large as it is for the larger system. For this reason further work was carried on with the smaller separation system.

1.3.4. Expansion Ratio

The effect of varying the expansion ratio with the inlet pressure held constant at the value which yielded the minimum specific suction volume, p_0 = 80 mm Hg, is shown in Figure 8. It can be seen that the minimum

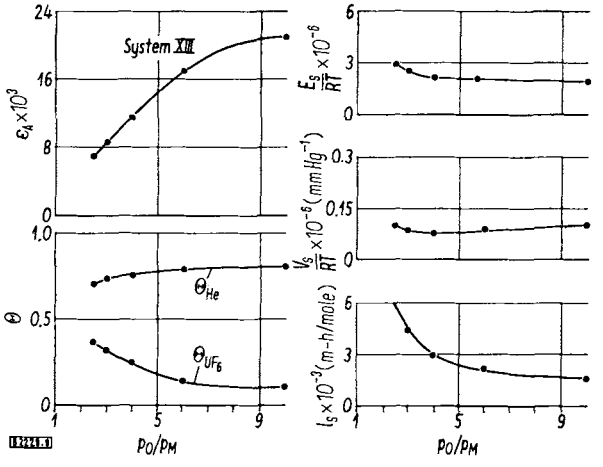

Fig. 8. The effect of the expansion ratio, p_0/p_M, on the specific cost factors.
Inlet pressure: p_0 = 80 mm Hg; Separation system XIII; Distance between the knife edge and the curved wall: 0.11 mm; Helium—UF_6 mixture containing 5 mole% UF_6.

values of E_S and V_S are obtained at an expansion ratio equal to about four. The specific slit length, l_S, continues to decrease with further increases in p_0/p_M. However, since the contribution which l_S makes to the cost of product seems to be of less importance than the contributions of the other two specific cost factors, the expansion ratio, $p_0/p_M \approx 4$, can be regarded as an optimum value.

1.3.5. Distance between the Knife Edge and the Curved Wall

It has already been mentioned that in an isotope separation cascade only streams with the same isotopic concentration should mix. In order for this condition to be satisfied, a different type of cascade connection is required for each different value of the UF_6 cut [1]. Economically satisfactory cascade arrangements are to be expected only when θ_{UF_6} can be expressed as the ratio of two small integers. The value, $\theta_{UF_6} = 1/2$, is a particularly good one as it is associated with the simplest type of cascade connection.

In the experiments described above, the minimum values of the specific cost factors were determined without regard to the θ_{UF_6} value which occurred. The cut, $\theta_{UF_6} = 1/2$, was obtained, if at all, only with relatively unsatisfactory values of the specific cost factors. In order to obtain the minimum values of the specific cost factors in conjunction with practical values of the cut, the effect of the expansion ratio was once again investigated, with the inlet pressure, p_0 = 80 mm Hg, again held constant, but with the distance between the knife edge and the curved wall a variable. The curves for constant values of θ_{UF_6}, shown in

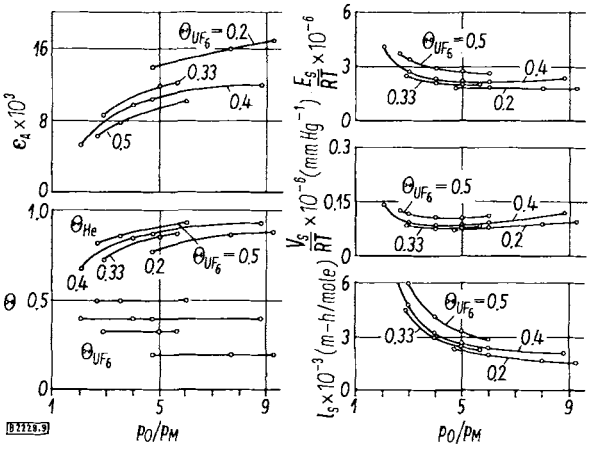

Fig. 9. The effect of the UF_6 cut, θ_{UF_6}, on the specific cost factors. The curves were obtained by varying the distance between the knife edge and the curved wall and interpolating between the measured results. Inlet pressure: p_0 = 80 mm Hg; Separation system XIII; Helium—UF_6 mixture containing 5 mole% UF_6.

Figure 9, were obtained by interpolating between the measured values. It can be seen that the smallest values of the specific cost factors were obtained at the smallest value of the cut which was investigated (θ_{UF_6} = 0.2). Between θ_{UF_6} = 0.2 and θ_{UF_6} = 0.33, the cost factors increase only slightly; on the other hand, between θ_{UF_6} = 0.33 and θ_{UF_6} = 0.5, they increase by a factor of about 1.4. Since the cost of piping and valves should be only slightly greater for a cascade operating with the cut, θ_{UF_6} = 0.33, than for a cascade operating with a cut of one half, the value, θ_{UF_6} = 0.33, will be assumed to be the optimum value of the cut for the separation nozzle process.

The optimum values of the specific cost factors resulting from the investigations described above and the associated operating conditions are compared in Table 2 with the corresponding, previously published values [10]. It can be seen that the specific work of compression and the specific suction volume have been reduced by almost a factor of two by the improvement of the separating element. The decrease in the optimum value of the compression ratio from 10 to 4 is also advantageous since it reduces the number of stages required in the compressors. The increase in the optimum suction pressure, $p_M = p_K$, from 12 to 20 mm Hg should also serve to reduce the relative pressure losses in the cascade piping.

Table 2. Comparison of the optimum values of the specific cost factors and associated operating conditions obtained with the improved separating system with the corresponding values from the previous investigation [10]. In both cases the UF_6 content of the He—UF_6 mixture was 5 mole per cent and the radius of the curved deflecting wall 0.75 mm. A temperature of 295 °K was assumed for the calculation of E_S and V_S.

	Present results	Previous results [10]
Specific work of compression, E_S (kWh/mole)	14.4×10^2	26.6×10^2
Specific suction volume, V_S (m³/mole)	1.40×10^6	2.61×10^6
Specific slit length, l_S (m-h/mole)	3.0×10^3	3.2×10^3
Compression ratio, p_0/p_M	4	10
Suction pressure, $p_M = p_K$ (mm Hg)	20	12
Elementary separation effect, ε_A	10.6×10^{-3}	10.6×10^{-3}
UF_6 cut, θ_{UF_6}	0.33	0.31

2. Testing the Process in a Closed Test Loop

In a separation cascade, the process gas containing the UF_6 which is expanded in one separating element must be recompressed by UF_6-resistant compressors before entering the neighboring elements. It must be demonstrated that such a cascade will be gas dynamically stable. Since a theoretical treatment of this problem is not sufficient for the design of large installations, a ten stage pilot plant is currently under construction in our institute. The construction and testing of the prototype unit for this pilot plant are described below.

2.1. Separating Element

Figure 10 shows a cross section of the separation nozzle system used and gives the nominal values of the pressures, p_0, p_M, and p_K, for these experiments. L moles per hour of a gaseous mixture consisting of 5 mole per

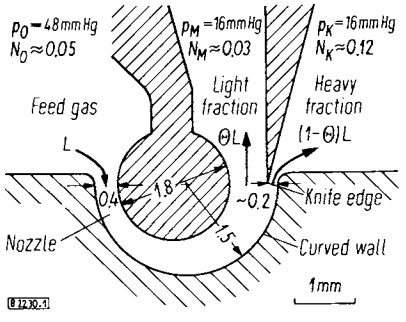

Fig. 10. Cross section of the separation nozzle system used in the closed test loop.

N_0, N_M, and N_K are the mole fractions of the UF_6 in the helium-UF_6 mixture used as the process gas; L is the molar flow rate of the process gas; Θ is the process gas cut.

cent UF_6 and 95 mole per cent helium were expanded through the curved Laval nozzle. The nozzle inlet pressure, p_0, was 48 mm Hg. The nozzle consisted of a curved wall with a radius of curvature, r = 1.5 mm, and a solid cylinder, eccentric to the wall, 1.8 mm in diameter. This model of the curved Laval nozzle has the advantage, compared with the nozzles investigated in detail in Section 1, of a simpler fabrication process for producing the longer separating systems. The width of the nozzle at its narrowest point, or throat, was 0.40 mm. The gas mixture expanded in the nozzle to the pressure, p_M = 16 mm Hg. These dimensions and operating conditions were fixed on the basis of the experiments described in Section 1 and from a consideration of the capability of the compressors which were available. The nozzle had a length of 100 mm in the direction perpendicular to the plane shown and was therefore ten times as long as the nozzles used in the earlier investigations.

The details of the assembly of the individual parts can be seen from Figure 11. In order to carry out all the testing desired, a scheme of construction was chosen which offered extensive possibilities for adjusting and changing all of the parameters affecting the geometry of the jet. The plate (b) bearing the nozzle cylinder (c) and the plate (f) terminating in

the knife edge were bolted securely to the machined surfaces of the brass cylinder (a). The plates (b) and (f) were fabricated from hardened tool steel (90 MnV8) and were, as was the brass cylinder (a), nickel-plated after the final machining. The positions of the nozzle cylinder (c) and of the knife edge (g) with respect to the curved wall (d) could be changed either by shifting the plates on their supporting surfaces or by extending the slotted brass cylinder (a) by means of the screws (e) provided for this purpose[*].

The separating element was bolted, by means of a blank flange (h) and the bolts (i), to the cover flange (n) of a cylindrical chamber, not shown, which surrounded the separating element. The sealing between the plane ground surfaces was accomplished with 0.1 mm thick teflon film (k). The light fraction passed between the nozzle plate (b) and the knife edge plate (f) into the chamber surrounding the element and was pumped off from there.

2.2. Compressor

In the construction of a plant utilizing the separation nozzle process, only compressors of the axial or centrifugal type ought to be considered. However, in making the choice of the type of compressor for the pilot plant, it had to be kept in mind that the plant should operate at the lowest practicable throughput in order to keep the cost of the installation low. A reasonable compromise was achieved with the use of Roots compressors. They can be constructed to have the desired, relatively small gas flow rate of about 100 m^3/h without much additional development work being required, and the dependence of their operating characteristics on the composition and physical prop-

[*] In practice, separating systems in which the critical dimensions are fixed at sufficiently close intervals along the length of the system would be used.

erties of the process gas is similar to that for centrifugal and axial compressors.

The Roots compressor used in these investigations has vacuum-tight shaft seals in the form of sealing chambers which are closed off by mechanical, radial-face seals at each end and through which flows a UF_6-resistant sealing oil. The compressor is provided with a built-in gas cooler. Additional internal cooling of the impellers is also possible. The compressor was developed in cooperation with the firm, E. Leybolds Nachfolger, Köln-Bayental, from the commercial Roots compressors designated "Ruvac E 126" [*]. All special elements in the construction were tested in our institute under process conditions and brought step by step to their final form.

The welded compressor housing is closed off on both sides by two face plates which contain four individual bearing assemblies which support the two impellers of the compressor. In each of the four bearing assemblies are a pair of the radial-face seals. They form four sealing chambers through which flows a sealing agent (KEL-F oil) which is maintained at a pressure higher than the surroundings. A water-cooled, spiral-tube cooler is built into the square-cornered gas outlet. If needed, the sealing oil can be conducted from one face plate to the other through the cooling chambers of the impellers to provide additional cooling. The compressor is driven by a three phase electric motor which turns at 2900 rpm. At this speed the compressor has a geometrical suction volume of 380 m^3/h.

The impellers are of stainless steel No. 4571. The face plates, the welded compressor housing, and all of the other parts which come into contact with the process gas were fabricated from stainless steel No. 4541. The sealing between the metal parts exposed to the process gas was accomplished with O-rings of Viton, a fluoroelastomer, which were inserted into slots provided for that purpose.

The radial-face seals have a layer of Stellite on their sliding surfaces. During the life testing of the compressor, values between 0.5 and 1.8 cm^3/d per compressor were obtained for the amount of sealing oil entering the process gas space. This inleakage is drawn off into a water-cooled oil collector. A vapor seal is used to prevent entry of the sealing oil vapor into the process gas region of the compressor.

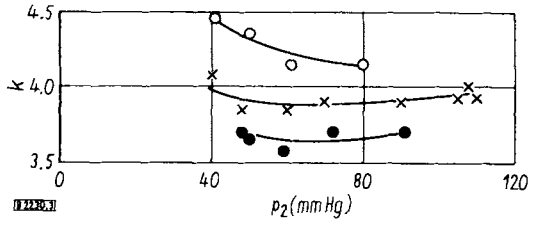

Fig. 12. The dependence of the compression ratio, $k = p_2/p_1$ of the Roots compressor on the discharge pressure, p_2, with the molar throughput, L, as a parameter.

Gas cooler with a cooling water flow rate of 2 l/min;
○ ○ L = 28 mole/h; × × L = 43 mole/h; ● ● L = 60 mole/h;
Helium-UF_6 mixture containing 5 mole% UF_6.

In order to evaluate the performance of the process compressors, the dependence of the throughput, L (moles/h), and of the compression ratio, $k = p_2/p_1$, on the discharge pressure, p_2, was measured using a UF_6-helium mixture containing 5 mole per cent UF_6. The measurements were made after the steady state temperature distribution was attained throughout the compressor. It can be seen from Figure 12 that at the specified operating point, that is, at a throughput of 60 moles/h and at 48 mm Hg discharge pressure, the compression ratio exceeds the required value of 3 by more than 20 per cent.

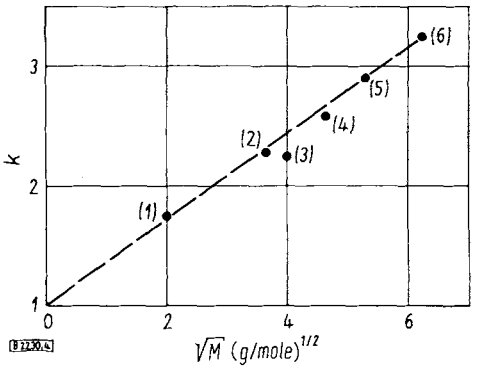

Fig. 13. The dependence of the compression ratio, k, on the square root of the molecular weight, M, of the process gas. Roots compressor without gas cooler;

Discharge pressure: p_2 = 50 mm Hg;
Molar throughput: L = 60 mole/h;
Data points: (1) He, M = 4
(2) 2.7 mole %UF_6—97.3 mole % He, M = 13.5,
(3) CH_4, M = 16,
(4) 5 mole % UF_6—95 mole % He, M = 21.4,
(5) N_2, M = 28,
(6) 10 mole % UF_6—90 mole % He, M = 38.8

Measurements of the throughput, made with an earlier model compressor without a gas cooler, for various process gases of different densities, showed a linear relationship between the square root of the average molecular weight of the gas and the compression ratio, k, which the compressor achieved at a given molar throughput, L, and discharge pressure, p_2. The measured results for L = 60 moles/h and p_2 = 50 mm Hg are shown in Figure 13.

2.3. Process Test Loop

The construction of the process test loop can be seen from Figure 14. The heavy and light fractions are removed from the separation chamber through separate lines and are pumped off simultaneously through the valves (c) and (b), respectively, by the Roots compressor (h). The compressed gas is returned to the separating element (i) through valve (e). Sample withdrawal reservoirs (k) are connected in parallel with the process gas lines. Their volumes were so determined that they contain, under operating conditions, a sufficient amount of UF_6 (about 0.1 g) for isotopic analysis with a mass spectrometer. During an experiment, they were swept out with process gas and then isolated from the system before the withdrawal of the sample. The samples were pumped from these reservoirs through cold traps (not shown) in which the UF_6 was frozen out. The UF_6, after being weighed, was then subjected to isotopic analysis. The UF_6 concentration in the UF_6-helium mixture was determined from the weight of the UF_6, the pressure, and the volume of the sample withdrawal reservoirs.

In order to facilitate a longer period of operation with frequent sample withdrawal, a 1000 l reservoir (l) can be connected to the system to increase its volume. Without the

reservoir, the volume of the test loop was 20 l. The reservoir also makes it possible to change the operating pressure without removing or adding process gas. When valve (e) is closed, the compressor pumps gas through the open valves (f) and (g) against the reservoir pressure, p_3. The nozzle fore-pressure, p_0, can then be regulated to values between the reservoir pressure, p_3, and the suction pressure of the compressor, p_1, by throttling the flow with valve (a). The pressures of the light and heavy fractions, p_M and p_K, can be adjusted by means of valves (b) and (c) to values between p_0 and p_1. The suction pressure, p_1, is regulated by means of the by-pass valve (d). The discharge pressure, p_2, of the compressor is normally identical to the reservoir pressure, p_3, and changes only slightly when the operating pressures of the separating element are changed due to the large volume ratio between the reservoir and the test loop. The pressures were measured with direct reading aneroid type and membrane type manometers as well as with electrical pressure transducers[*]. A self-stabilizing electromagnetic pressure balance with a linear response in the region from 0 to 760 mm Hg served as a standard[**]. For measurements in the region below 1 mm Hg, an electrostatic membrane micromanometer with a maximum sensitivity of 10^{-3} mm Hg per scale division was used. All of these instruments are suitable for direct measurements in UF_6 or in other fluorinating gases at room temperature. In addition, thermal conductivity and ionization pressure gauges were used for the control of the evacuation processes and for the measurement of the final vacuum in the different parts of the installation. These instruments were separated from the process gas space during operation with UF_6.

The test loop can be emptied by means of the liquid nitrogen-cooled UF_6 condenser (m). The helium can be pumped off with a rotary pump. A mercury diffusion pump is provided for the production of a high vacuum. It is protected against corrosive gas residues by two liquid nitrogen-cooled traps (n, o).

Austenitic steels, Nos. 4541, 4550, and 4571, were used for the construction of the test loop. All valves have a bellows or membrane type seal around the valve stem. Viton or, in special cases, teflon was used as gasket material. The maximum inleakage rate permitted was 5×10^{-6} mm Hg-l/s for the entire test loop, including the instrumentation and compressor, but excluding the 1000 liter reservoir. Before filling with UF_6, the entire test loop was baked out under high vacuum and passivated with a mixture of chlorine trifluoride (ClF_3) and nitrogen.

2.4. Isotope Separation Experiments

Although, according to the results of the experiments described in Section 1, a value of the UF_6 cut, θ_{UF_6}, equal to 0.33 would be expected to lead to the economically most favorable cascade arrangement, the ten stage pilot plant, because of the simpler interstage connections required, was designed to operate with a value of θ_{UF_6} equal to 0.5.

In practice, the value of θ_{UF_6} can only be set within a certain limit of error by the choice of a particular distance between the knife edge and the curved wall of the Laval nozzle. Since providing a means for

[*] Manufacturer: Appleby & Ireland, Basingstoke (England), Type 101 and 533.

adjusting the position of the knife edge during operation would be quite expensive, it seemed reasonable to utilize the dependence of θ_{UF_6} on the expansion ratio as a method for making fine adjustments in the value of the UF_6 cut.

For this reason, several series of isotope separation experiments were carried out with the test loop in which the variation of the separation effect and of the cut as a function of the expansion ratio, p_0/p_M, were of particular interest. At the same time these experiments served the purpose of life-testing the entire installation.

The compressor operated against the reservoir pressure, p_3, which was somewhat greater than the nozzle fore-pressure, p_0 = 48 mm Hg, so that a sufficiently large excess of gas was available in the installation for the withdrawal of samples. The expansion ratio was regulated with the by-pass valve (d) and the nozzle fore-pressure, p_0, with valve (a) (see Figure 14). The pressures of the light and heavy fractions, p_M and p_K, were always equal.

The dependence of the UF_6 mole fractions, N_0, N_M, and N_K in the feed gas, the light fraction, and the heavy fraction, respectively (obtained from the gas analysis), as well as that of the elementary separation effect, ε_A, for the uranium isotopes (defined by equation (4)) on the expansion ratio, p_0/p_M, is shown in Figure 15. The cuts, θ and θ_{UF_6}, were calculated from the relationships:

$$\text{Total cut, } \theta = (N_0 - N_K)/(N_M - N_K) \tag{9}$$

$$UF_6 \text{ cut, } \theta_{UF_6} = N_M\theta/N_0 \tag{10}$$

Inlet pressure: p_3 = 48 mm Hg; $p_K = p_M$;
Helium-UF_6 mixture containing 5 mole % UF_6.

The dependence of the specific cost factors, defined by equations (5) through (7), on the expansion ratio is also shown in Figure 15.

The values for the separation effect and for the specific cost factors obtained in the test loop with the separation nozzle system 100 mm in length agree within the limits of error with those obtained in the corresponding earlier experiments with the 10 mm long nozzle system.

All of the experimental results presented in Figure 15 were obtained with the distance between the knife edge and the curved wall of the nozzle equal to 0.20 mm. Within the limit of error of the measurements, the curve for θ_{UF_6} as a function of the expansion ratio passes through the specified operating point (θ_{UF_6} = 0.5 at p_0/p_M = 3). From a different series of measurements, it was observed that, at this value of the expansion ratio, a decrease in the distance between the knife edge and the nozzle wall of 0.01 mm caused the UF_6 cut to increase from 0.50 to 0.54. The θ_{UF_6} curve presented in Figure 15 shows that a deviation from the design point of this magnitude can be compensated for by an increase of about 10 per cent in the expansion ratio.

One of the series of measurements was repeated after an interval of more than four months. In the interim, suction volume measurements were made and the endurance-testing of the Roots compressor was undertaken. During the entire time the installation was filled with the helium-UF_6 mixture, and for about 1100 hours it was maintained under operating conditions. The results from both experiments were in agreement. This signified that the properties of the separating element did not change measurably during the many months of experimental operation.

3. Comparison of the Specific Cost Factors of the Separation Nozzle Process and the Gaseous Diffusion Process

For the purpose of judging the economic potential of the separation nozzle process, one can compare the optimum values obtained for the specific cost factors with the corresponding values for the gaseous diffusion process. Since the operating conditions employed in the gaseous diffusion process and the value of the elementary separation effect which has been attained in practice are not known, the values of the specific cost factors for the diffusion process can only be estimated.

According to theory, the upper limit for the elementary separation effect for the gaseous diffusion process for uranium isotope separation, using UF_6 as the process gas, is given by

$$\varepsilon_A(\max) = 0.00429\,(1-p_M/p_0)\,\frac{1}{\theta}\ln\frac{1}{1-\theta}, \tag{11}$$

where again p_0 is the pressure in the gas entering the separating element and p_M is the pressure in the light fraction. The cut, θ, is the fraction of the feed stream which is pumped from the separating element as the light fraction at the pressure, p_M. One can safely

assume that in the gaseous diffusion process θ is equal to 0.5. The optimum value of the pressure ratio, p_0/p_M, for the gaseous diffusion process, will be assumed to lie in the neighborhood of four, as is the case for the separation nozzle process.

Thus one obtains:

$$\varepsilon_A \text{ (max)} = 4.45\times10^{-3}.$$

This maximum value for the elementary separation effect can only be attained in practice when the mean free path of the UF_6 molecules is large compared to the diameters of the pores in the membrane and when no local depletion of the light isotope occurs on the high pressure side of the membrane. However, in order to decrease the investment costs of the diffusion process, one would choose a gas pressure as high as practicable and thereby accept in the bargain a certain decrease in ε_A due to the smaller ratio of the mean free path to the pore diameter. Moreover, in practice, the mixing in the gas on the high pressure side of the membrane in the direction perpendicular to the membrane surface is not complete. If it is assumed that in practice only 60 per cent of the theoretical maximum value of ε_A is attained, one obtains for the effective elementary separation effect:

$$\varepsilon_A(\text{eff}) = 2.67\times10^{-3}.$$

The specific ideal isothermal work of compression is given by the ratio of the ideal isothermal work of compression performed per unit time to the separative power, δU, defined by equation (8). The resulting expression is

$$E_s = \frac{1}{\delta U}\,\frac{L^*}{2}\,RT\,(\ln\frac{p_o}{p_M} + \ln\frac{p_o}{p_K}). \qquad (12)$$

With $\varepsilon_A = 2.67\times10^{-3}$, $p_0/p_M = 4$, an estimated pressure drop for the heavy fraction, $p_0/p_K = 1.2$, and an estimated operating temperature, $T = 330\,^\circ\text{K}$ (see below), it follows that

$$E_s \text{ (diffusion)} = 6.8 \times 10^2 \text{ kWh/mole}.$$

The optimum value, $E_s = 14.4\times10^2$ kWh/mole, obtained for the separation nozzle process with the improved separating system and with $\theta_{UF_6} = 0.33$, is therefore still higher by a factor of 2.1 than that estimated for the diffusion process. In addition, it should be kept in mind that the compressor efficiency to be expected with the $He-UF_6$ mixture is somewhat lower than that with pure UF_6 because of the smaller molar heat capacity of the mixture.

In the estimate for the diffusion process it was assumed that the heavy fraction is pumped off at an appreciably higher pressure than the light fraction. This implies that each separation stage is provided either with two compressors or with a single compressor of a special type which pumps gas simultaneously at the pressures, p_M and p_K. It could be of advantage, at least when processing the higher ^{235}U concentrations, to avoid this complication by expanding the heavy fraction to the pressure, p_M [13]. In this case the difference between the specific work of compression for the gaseous diffusion process and for the separation nozzle process would almost disappear.

In order to estimate the specific suction volume, one must make an assumption regarding the absolute pressure at which the diffusion process operates. An upper limit, assuming that sufficiently fine-pored membranes are available, is given by the vapor pressure of UF_6. At room temperature the vapor pressure of UF_6 is about 100 mm Hg, and at 53 °C it reaches 1 atm. Since the operating temperature of the plant is probably not much above 50 °C, and since it must be maintained at a safe distance from the condensation point, one can take 0.5 atm to be a reasonable value for the operating pressure. With this value for p_0 and the values for the other variables as given above, one obtains from the equation for the specific suction volume,

$$V_s = \frac{1}{\delta U}\,\frac{L^*}{2}\,RT\left(\frac{1}{p_M} + \frac{1}{p_K}\right), \qquad (13)$$

that for the diffusion process:

$$V_s \text{ (diffusion)} = 1.59\times10^5 \text{ m}^3\text{/mole}.$$

The optimum value, $V_s = 1.40\times10^6$ m³/mole, obtained for the separation nozzle process with the improved separating system, is therefore higher by a factor of 8.8 than that estimated for the gaseous diffusion process.

When judging the economic consequences of the larger specific suction volume, one must bear in mind that the separation nozzle process, operating with a UF_6 cut of 0.33, requires only about 1/2.7 times as many stages as the diffusion process [*]. For a given separation job the suction volume per stage will therefore be greater than that for the gaseous diffusion process by the factor, 8.8 times 2.7, *i.e. ca.* 24. Results obtained in the French gaseous diffusion plant studies indicate that the variation of the investment costs per stage with the size of the stage is given by a constant times $L^{0.38}$, where L represents the throughput of the stage [14]. If one assumes the same dependence and the same constant for the separation nozzle process, and postulates that changes in the volume throughput due to changing the pressure affect the investment costs in exactly the same way as changes in the molar throughput, one obtains the result:

[13] *H. Kronberger* and *G. R. H. Geoghegan*: Proceedings of the International Symposium on Isotope Separation, Amsterdam 1957. North Holland Publ. Co., Amsterdam 1958, p. 517.

[*] The concentration change between adjacent stages in a cascade is equal to $^1/_3$ of the elementary separation effect, ε_A, defined by equation (4), when $\theta_{UF_6} = 0.33$, and is equal to $\varepsilon_A/2$ when $\theta_{UF_6} = 0.5$.

[14] *C. Frejacques* and *R. Galley*, Third International Conference on the Peaceful Uses of Atomic Energy, Geneva 1964, Paper 28/P/89.

$$\left.\begin{matrix}\text{Investment Costs for the}\\ \text{Separation Nozzle Process}\end{matrix}\right\} = \frac{24^{0.38}}{2.7} (= 1.2) \left\{\begin{matrix}\text{Investment Costs for the}\\ \text{Gaseous Diffusion Process.}\end{matrix}\right.$$

Thus, in spite of the fact that, according to the estimate above, the specific suction volume is greater by a factor of 8.8 one would not expect an appreciably greater investment cost for the separation nozzle process than for the gaseous diffusion process.

It is expected that the separation nozzle process will have a real advantage compared to the gaseous diffusion process with respect to the equilibrium time of a separation cascade. By the term, equilibrium time, one refers to the time required between the start-up of a cascade and the attainment of the product concentration, *i.e.* the time during which no product can be withdrawn. The equilibrium time for cascades which enrich ^{235}U to medium or high concentrations can be so long that they may not be neglected in the economic considerations. For a given separation job, the equilibrium time is directly proportional to the average residence time of a UF_6 molecule in a stage and inversely proportional to the square of the elementary separation effect [12]. Since the average residence time will be at least no greater, and probably appreciably less, in the separation nozzle process than in the diffusion process, one can expect that the equilibrium time will be shorter by at least an order of magnitude in the former owing to the larger elementary separation effect.

We wish to thank G. Frey for his assistance in the development of the Roots compressor and the test loop as well as Miss B. Gebauer and J. Dröge, W. Mannherz, and G. Schüler for their help in carrying out the experiments. We also wish to thank Dr. von Halle for valuable discussions and for the translation of this report.

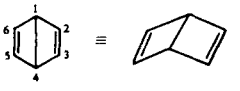
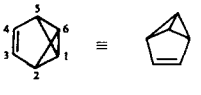
Hexamethyl(Dewar Benzene) (Hexamethylbicyclo[2.2.0]hexa-2,5-diene)



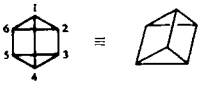
BY W. SCHÄFER AND H. HELLMANN [*]

Dedicated to Professor Friedrich Asinger on the occasion of his 60th birthday



Hexamethyl(Dewar benzene) was first obtained by bicyclotrimerization of 2-butyne in the presence of aluminum chloride. This preparation provided a basis for a comprehensive study of the chemical reactivity of Dewar benzene derivatives. Interesting information concerning the reactivity of the permethylated Dewar benzene system can be deduced from its behavior on hydrogenation and oxidation, and, in particular, from the addition of H-acidic compounds and from the substitution and elimination reactions of the resulting adducts.

1. Introduction



Dewar benzenes, benzvalenes, and prismanes, derivatives of the three non-planar "valence isomers" of benzene, are now, 100 years after Kekulé's conception of his benzene formula, emerging from the ranks of the esoteric organic compounds (see also [1, 2]). Fears that the unstable valence-isomeric forms would readily isomerize into benzene derivatives, because of their steric strain, are now recognized as being almost groundless. Derivatives of all three "valence isomers" have been prepared in recent years; these compounds can be handled without difficulty in the absence of

Dewar benzene (*Dewar*, 1867)[**]
Bicyclo[2.2.0]hexa-2,5-diene [3]

Benzvalene (*Hückel*, 1937)

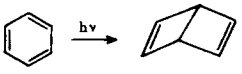
[2] *H. G. Viehe*, Angew. Chem. *77*, 768 (1965); Angew. Chem. internat. Edit. *4*, 746 (1965).

[**] The name "Dewar benzene" rather suggests a resonance structure of benzene. A trivial name, similar to benzvalene and prismane, has not been assigned to this compound although the structure and unsaturated character are well described by the name "tectadiene" (latin, tectum = roof).

[3] Concerning nomenclature, cf. *J. Meinwald* and *J. K. Crandall*, J. Amer. chem. Soc. *88*, 1300 (1966).



substituted Dewar benzene [4, 4a], which is less stable than its derivatives (half-life 2 days at 20 °C).

From the point of view of preparation, the Dewar benzene derivatives occupy a special place among the derivatives of the valence isomers of benzene, since all the preparations of prismanes yet accomplished are based on the photochemical excitation of Dewar benzene derivatives.

Dewar benzenes can be synthesized by the following five methods.

1.1. Photoisomerization of Benzene Derivatives

A benzene derivative is irradiated with high frequency UV light.

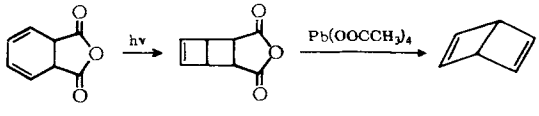
(a)

The first Dewar benzene derivative was synthesized by *van Tamelen* and *Pappas* [5], who obtained 1,2,5-tri-t-butyl(Dewar benzene) by photoisomerization of 1,2,4-tri-t-butylbenzene in ether. 1,2,3,5-Tetra-t-butyl(Dewar benzene) was obtained, together with the corresponding benzene derivative, by irradiation of 1,2,4,5-tetra-t-butylbenzene [6]. The photochemical rearrangement of hexafluorobenzene to hexafluoro(Dewar benzene) proceeds particularly smoothly (60 % yield) [7, 8]; octafluorotoluene, on the other hand, gives a mixture of 1- and 2-trifluoromethylpentafluoro(Dewar benzenes) [8].

Van Tamelen and *Pappas* chose 1,2,4-tri-t-butylbenzene as starting material because they deduced that the steric interaction of the bulky t-butyl groups situated *ortho* to each other ("aromatic destabilization", cf. *e.g.* [9]) would favor the Dewar form, in which these groups are farther apart.

However, the success of the photoisomerization is not tied to steric conditions of this nature [10], as is shown by the photoisomerizations of hexafluorobenzene and octafluorotoluene, as well as by a number of reactions in which the intermediate formation of Dewar benzenes has been postulated in order to explain the structure of the products. An example of such a reaction was described by *Kaplan et al.* [11], who obtained [1,2,4-$^{14}C_3$]trimethylbenzene *via* Dewar benzenes on photolysis of [1,3,5-$^{14}C_3$]trimethylbenzene; the course of this reaction also shows that the migration of the methyl groups does not involve free radicals.

The irradiation of a 20 vol.-% solution of cyclobutene in benzene with UV light (λ = 2537 Å) at room temperature gave rise to a novel cycloaddition. The reaction afforded the tetracyclic hydrocarbon $C_{10}H_{12}$ (50 % yield), the formation of which can be explained by the addition of cyclobutene to the Dewar benzene that is formed as an intermediate [12] (eq. (b)).



(b)

On the other hand, no Dewar benzene derivative can be isolated on irradiation of the "aromatically destabilized" *o*-di-t-butylbenzene; the product is in fact a mixture of *m*- and *p*-di-t-butylbenzenes in a ratio that depends on the irradiation time [13, 14], a result that can again be explained by the formation of Dewar benzene and prismane intermediates.

1.2. Degradation of Bicyclo[2.2.0]hex-5-ene-2,3-dicarboxylic Anhydride with Lead Tetraacetate

UV irradiation of *cis*-1,2-dihydrophthalic anhydride in ether yields bicyclo[2.2.0]hex-5-ene-2,3-dicarboxylic anhydride, which has been converted into the unstable Dewar benzene in 20 % yield by degradation with lead tetraacetate under mild conditions [4].

(c)

1.3. Addition of Cyclobutadiene *in situ* to Dihalogenomaleic Anhydride, Esterification, and Dehalogenation

Criegee and *Zanker* [15] have obtained dimethyl tetramethyl(Dewar phthalate) *(1)* in accordance with equation (d). The last step is reminiscent of a method used for the preparation of a Dewar anthracene derivative [16] [*].

(1) can be converted into another Dewar benzene derivative, namely, octamethylbicyclo[2.2.0]hexa-2,5-diene-2,3-dimethanol, by reaction with an excess of methylmagnesium iodide [17].

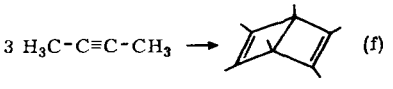
1.4. Addition of Cyclobutadiene *in situ* to Acetylenes



All attempts to isolate cyclobutadiene or its derivatives as such have so far been unsuccessful. However, there are a number of stable cyclobutadienemetal complexes [18] of which tricarbonylcyclobutadieneiron, which can be prepared [19] in 40% yield by the reaction of *cis*-3,4-dichlorocyclobutene with $Fe_2(CO)_9$, can be used for the synthesis of Dewar benzenes [20]. When the complex is decomposed by oxidation with salts of Ce(IV) in the presence of acetylene derivatives, the resulting cyclobutadiene is intercepted to form the Dewar benzene system (eq. (e)).

1.5. Bicyclotrimerization of Acetylenes

The formally most simple method for the preparation of Dewar benzenes is the bicyclotrimerization of acetylenes in accordance with equation (f).

In 1964, *Viehe et al.* [2,23] reported a spontaneous trimerization of the extremely reactive compound t-butylfluoroacetylene. 1,2,6-Tri-t-butyl-3,4,5-trifluoro-(Dewar benzene) and 1,3,6-tri-t-butyl-2,4,5-trifluorobenzvalene were formed in a yield of 33 % each. The trimerization of t-butylfluoroacetylene proceeds *via* dimeric intermediates, which can be intercepted with an excess of acrylonitrile or styrene. The origin of small quantities of tetramers observed in the oligomerization of t-butylfluoroacetylene can also be traced back to the dimerization of the dimeric intermediates. *Viehe* explained the reaction as proceeding formally *via* biradicals (eq. (g) and (h)) [24].

2. Synthesis of Hexamethyl(Dewar Benzene) *(3)*

It can be seen from the above survey that the preparation of Dewar benzenes requires the use of processes involving several steps. In the photochemically induced valence isomerizations, the yields and the uniformity of the reaction course generally leave much to be desired.

Early in 1966, we discovered a new synthesis that is free from these disadvantages, *i.e.* the bicyclotrimerization of 2-butyne in the presence of aluminum chloride to form hexamethyl(Dewar benzene) *(3)* [25]; the reaction proceeds formally in accordance with equation (f).

Optimization experiments showed that the synthesis is best carried out at 35–40 °C in benzene or methylene chloride. The catalyst is added in the proportion of about 5 wt-% (based on the 2-butyne), and the reaction time at 35 °C is 5–7 hours. The brown reaction mixture is poured onto ice and washed with dilute alkali, and *(3)* is isolated in a very pure state by fractional distillation of the organic phase. The conversion of 2-butyne is about 80 %, and the yield is 60 to 70 %, based on the reacted 2-butyne. Hexamethylbenzene and an approximately equal quantity of a dark oil are formed as by-products. Longer reaction times give higher conversions, but the yield of *(3)* decreases in favor of hexamethylbenzene *(5)*. This suggests that *(3)* is an intermediate and that *(5)* is the true stable end product of the $AlCl_3$-catalysed trimerization of 2-butyne. *(5)* can be obtained in yields of up to 85 % by trimerization of 2-butyne with $AlCl_3$ in boiling benzene. Even at low temperatures, the reaction leads exclusively to *(5)* when the reaction time is sufficiently long.

The course of the reaction is formally as shown in equation (i).

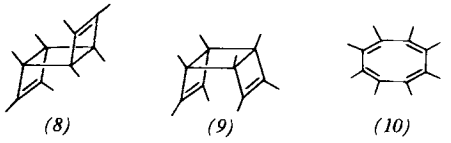
[25] *W. Schäfer*, Angew. Chem. *78*, 716 (1966); Angew. Chem. internat. Edit. *5*, 669 (1966).

(i)

When *(3)* is brought into contact with $AlCl_3$, it reacts extremely vigorously to form *(5)*. Quantitative exothermic rearrangement into *(5)* takes place when *(3)* is added dropwise to a slurry of $AlCl_3$ in benzene. It must therefore be concluded that in the bicyclotrimerization of 2-butyne the reaction mixture does not contain free $AlCl_3$, at least so long as the concentration of 2-butyne is sufficiently high.

2-Butyne reacts immediately with $AlCl_3$ to form a brown complex, which is readily soluble in methylene chloride but only slightly soluble in benzene. The UV, IR, and NMR spectra of *(2)* are very similar to the spectra of the 4-chloro-1,2,3,4-tetramethylcyclobutenyl cation *(6)*, which was prepared by *Gold* and *Katz* [26] by the action of $AlCl_3$ on 3,4-dichloro-1,2,3,4-tetramethylcyclobutene in methylene chloride.



(6) *(7)*

By analogy, therefore, the cationic part of the solvated polar complex intermediate *(2)* can be formulated as *(7)*. Thus *(2)* is not comparable to the stable cyclobutadiene complexes, which have a central d^8 ion of Fe^0, Co, Ni^{II}, or Pd^{II} [18].

Since the reaction mixture contains an excess of 2-butyne, $AlCl_3$ is slowly displaced from *(2)*, with immediate formation of fresh *(2)* and liberation of the unstable tetramethylcyclobutadiene, which is also instantaneously intercepted in a diene synthesis with 2-butyne to form hexamethyl(Dewar benzene).

In addition to hexamethyl(Dewar benzene) *(3)* (60–70 %) and hexamethylbenzene *(5)* (12–18 %) (yields based on reacted 2-butyne in both cases), the trimerization of 2-butyne also yields about 2 % of a crystalline mixture, which separates out (contaminated with hexamethylbenzene) from the very non-homogeneous residual oil (10–15 %) on cooling. Repeated fractional crystallization of this mixture gives three isomeric hydrocarbons $C_{16}H_{24}$, which have been identified as *syn- (9)* and *anti*-octamethyltricyclo[4.2.0.$0^{2,5}$]octa-3,7-diene *(8)* and octamethylcyclooctatetraene *(10)*.

(8) *(9)* *(10)*

M.p. 127 °C M.p. 196 °C M.p. 113 °C

These hydrocarbons had previously been obtained by *Criegee* [27] as dimeric products formed by secondary reaction of the unstable tetramethylcyclobutadiene. We regard their formation in the $AlCl_3$-catalysed bicyclotrimerization of 2-butyne as important evidence of the occurrence of tetramethylcyclobutadiene as an intermediate.

Finally, reaction scheme (i) raises the question of how the course of the reaction is affected by the presence of hexamethylbenzene, which also forms an addition complex *(4)* with $AlCl_3$. To solve this problem an excess of hexamethylbenzene was added to the slurry of aluminum chloride in benzene, and 2-butyne was then introduced. The reaction proceeded normally, showing that 2-butyne decomposes the complex *(4)* with formation of *(5)* and *(2)*.

The bicyclotrimerization of 2-butyne is catalysed not only by $AlCl_3$, but also by other aluminum compounds particularly alkylaluminum dichlorides (alkyl = ethyl, n-propyl, n-hexyl, s-butyl). The reaction time required is several times as long, and the amount of catalyst used must be increased to correspond to the increased molecular weight. $AlBr_3$ and alkylaluminum dibromides also gave positive results. On the other hand, dialkylaluminum chlorides are catalytically inactive, as are other Lewis acids (*e.g.* $FeCl_3$, $TiCl_4$, $SnCl_4$, $ZnCl_2$, or BF_3).

3. Reactions with Hexamethyl(Dewar Benzene)

The bicyclotrimerization of 2-butyne made it possible for the first time to prepare a Dewar benzene derivative on the kg scale by a simple one-step reaction. Apart from its ready availability, hexamethyl(Dewar benzene) has two properties that favor an investigation of its chemical reactivity: its appreciable thermal stability (when heated for 48 hours at 100 °C, the hexamethylbenzene content is less than 1 %) and the fact that it carries only methyl substituents. Consequently, in chemical changes in the Dewar benzene system, there is no need to take into account the effects of different substituents. On the other hand, the chemical reactivity of hexamethyl(Dewar benzene) cannot be regarded *a priori* as typical of Dewar benzenes carrying fewer substituents.

The physical constants of hexamethyl(Dewar benzene) are listed in Table 1.

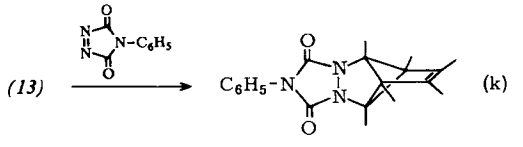
3.1. Valence Isomerization

Hexamethyl(Dewar benzene) *(3)* can be quantitatively isomerized to hexamethylbenzene *(5)* by $AlCl_3$ (cf. Section 2). This isomerization can also be brought about by other Lewis acids, such as $FeCl_3$, $SbCl_5$, $TiCl_4$, or, on gentle heating, by $SbCl_3$, $SnCl_4$, and $ZnCl_2$.



Irradiation of hexamethyl(Dewar benzene) with a low pressure UV lamp again leads mainly to hexamethylbenzene; however, in this case, the main product is accompanied by a 20–25 % yield [based on reacted *(3)*] of a second valence isomer, hexamethylprismane *(13)*, m.p. 91 °C [28,29].

Thus three prismane derivatives are now known [30,31], though *(11)* has so far been obtained only in a purity of 82 %. They were all obtained by irradiation of the corresponding Dewar benzenes with UV light of wavelength ≈ 254 nm.

(11) *(12)* *(13)*

When heated, *(13)* is converted into hexamethyl(Dewar benzene) *(3)* and hexamethylbenzene *(5)* [28,29]. It reacts with the strong dienophile 4-phenyl-1,2,4-triazoline-3,5-dione in strongly polar solvents to give *(14)* (*e.g.* (k)) [28].

3.2. *endo*-1,2,3,4,5,6-Hexamethylbicyclo[2.2.0]hex-2-ene [32]

Hydrogenation of hexamethyl(Dewar benzene) *(3)* to form *endo*-1,2,3,4,5,6-hexamethylbicyclo[2.2.0]hex-2-ene *(15)* proceeds smoothly under normal pressure on Pt/active charcoal at room temperature, or in an autoclave at 50 °C and 20 atm with Raney nickel as the catalyst when ethyl acetate is used as the solvent. When the reaction is carried out without solvent, the temperature and pressure must be increased (60–100 °C/100 atm).

(3) *(15)* *(16)* (1)

The physical constants of the compounds *(15)* to *(45)* are listed in Table 2.

Small quantities of *(15)* had already been obtained by another route by *Criegee et al.* [33]. The thermal rearrangement of *(15)* into hexamethylcyclohexa-1,3-diene *(16)* had also been studied in the course of kinetic investigations on the valence isomerization of cyclobutenes [34], though the compound was not isolated. The rearrangement of *(15)* into *(16)* in a stainless steel (V4A) autoclave at 200 °C takes 3 hours; at 250 °C, hexamethylbenzene *(5)* is also formed.

When the pyrolysis of *(15)* is carried out at 250 °C in a sealed glass tube, pentamethylbenzene and methane are formed as well as *(16)*. Thus the course of the pyrolysis is influenced by metal ions.

Table 2. Physical constants of the products formed by secondary reactions of hexamethyl(Dewar benzene) *(3)*.

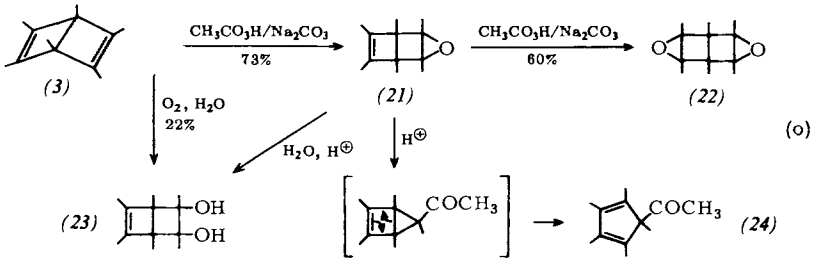
[34] *R. Criegee*, *D. Seebach*, *R. E. Winter*, *B. Börretzen*, and *H.-A. Brune*, Chem. Ber. *98*, 2339 (1965).

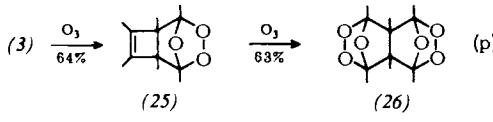
Ozonization of *(15)* in methylene chloride at 50 °C leads quantitatively to the distillable ozonide *(17)*, reductive cleavage of which gives 1,2,3,4-tetramethyl-1,2-diacetylcyclobutane *(18)*. *(18)* is also formed directly from *(15)* in low yields by oxidation with $KMnO_4$.

(15) can be epoxidized with perbenzoic acid in benzene (76 % yield) or with peracetic acid in methylene chloride in the presence of anhydrous sodium carbonate (65 % yield).



Treatment of the epoxide *(19)* with 1 % sulfuric acid in dimethyl sulfoxide leads, not to hydrolysis, but to isomerization to 1,2,3,4,5-pentamethyl-3-acetylcyclopentene *(20)*.

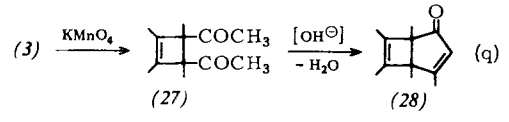
3.3. Oxidation Reactions with Hexamethyl(Dewar Benzene) *(3)* [35]



Hexamethyl(Dewar benzene) *(3)* is autoxidizable, and is therefore best stored under an inert gas. Old, partially oxidized samples, which give an acidic reaction, are washed with aqueous alkali before distillation, since rearrangement into hexamethylbenzene *(5)* may otherwise take place, sometimes very violently. When *(3)* is allowed to stand in air, colorless crystals of hexamethylbicyclo[2.2.0]hex-2-ene-5,6-diol *(23)* separate after only 1–2 days (yield ≈ 20 %). *(23)* is also formed from hexamethyl-5,6-epoxy-bicyclo[2.2.0]hex-2-ene *(21)* by hydrolysis *e.g.* with an ether-water mixture in the presence of $H^{\oplus}$ ions. The formation of *(23)* on autoxidation of *(3)* presumably also proceeds *via* the monoepoxide.

The epoxide *(21)* is obtained by the action of perbenzoic acid on an equimolar quantity of *(3)*. Peracetic acid (in the presence of anhydrous sodium carbonate) may also be used.

The epoxidation is accompanied by a side reaction, in which proton-catalysed ring contraction followed by valence isomerization leads to the formation of pentamethyl-5-acetylcyclopentadiene *(24)*. Similar acid-catalysed rearrangements to form three-membered rings have been observed with epoxycyclobutanes [36, 37]. *(21)* gives good yields of hexamethyl-2,3;5,6-bisepoxybicyclo[2.2.0]hexane *(22)* on reaction with perbenzoic or peracetic acid. *(22)* is stable under the conditions used for the hydrolysis of the monoepoxide *(21)*.



When the stoichiometric quantity of ozone is passed into a solution of *(3)* in CH_2Cl_2 at −50 °C, the monozonide *(25)* is formed, while a further mole of O_3 gives the diozonide *(26)*.

Unlike *(25)*, *(26)* is insoluble in methanol (separation method), and is so stable thermally that it melts without decomposing. The hydrogenative cleavage of *(26)* proceeds non-uniformly, and leads mainly to tetramethylfuran and acetic acid.

On oxidation of *(3)* with $KMnO_4$ in aqueous alkaline butanol at 0 °C, the main product was the steam-volatile 1,4,5,6,7-pentamethylbicyclo[3.2.0]hepta-3,6-dien-2-one *(28)* (yield 50 %), which is formed by intramolecular aldol condensation of the primary product, tetramethyl-3,4-diacetylcyclobutene *(27)*, in the alkaline solution.

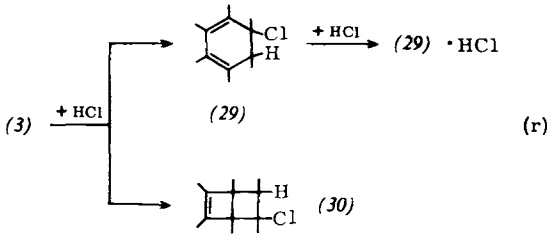
If the oxidation of *(3)* is carried out with $KMnO_4$ in aqueous acetone and with the addition of $MgSO_4$ to intercept the $OH^{\ominus}$ ions, *(27)* can be isolated in good yield in the form of colorless crystals (m.p. 57 °C).

3.4. The Action of H-Acidic Compounds on Hexamethyl(Dewar Benzene) *(3)* [38]

The literature contains several references to the sensitivity of Dewar benzenes to acids. In fact this lability does exist, but the Dewar benzenes should not be expected to isomerize exclusively to the benzene derivatives.

The action of HCl on hexamethyl(Dewar benzene) *(3)* in methylene chloride at −30, 0, or +40 °C leads to a

[35] *H.-N. Junker*, *W. Schäfer*, and *H. Niedenbrück*, Chem.Ber., in press.

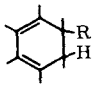


[36] *R. Criegee* and *K. Noll*, Liebigs Ann. Chem. *627*, 1 (1959).

[37] *J.-L. Ripoll* and *J.M. Conia*, Bull. Soc. chim. France *1965*, 2755.

[38] *H. Meister*, *W. Schäfer*, and *U. Sage*, unpublished.

new vacuum-distillable compound (yield 80–85 %; b.p. 110–112 °C/19 mm), elementary analysis of which shows that *(3)* has taken up 1 mole of HCl. The products also include a lower-boiling isomer having m.p. 62–64 °C, which is formed in a yield of 0–15 %, depending on the reaction conditions. Only a small amount of hexamethylbenzene is formed. The addition of HCl to *(3)* can also be carried out with concentrated HCl, though the yields obtained are lower.



The lower-boiling HCl adduct is hexamethyl-5-chloro-6*H*-bicyclo[2.2.0]hex-2-ene *(30)*, while the higher-boiling adduct is hexamethyl-5-chloro-6*H*-cyclohexa-1,3-diene *(29)*. The course of the reaction is as indicated in equation (r).

(r)

(29) can add a further mole of HCl to form a colorless, salt-like compound, which is moderately stable at low temperatures only, and which readily decomposes into HCl and *(29)*.

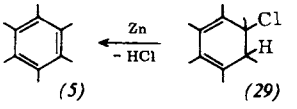
Addition in accordance with equation (r) is not confined to hydrogen chloride, though it proceeds particularly uniformly and smoothly in this case. We were even able to add carboxylic acids to *(3)*.

	Compound	R	Yield (%)
	*(31)*	Br	65
	(32)	OOCH	50
	(33)	$OOCCH_3$	26
	(34)	$OOCCH_2Cl$	64
	(35)	$OOCCHCl_2$	65
(31)-(36)	*(36)*	OCH_3	45

The addition of acids is always accompanied by a deep violet coloration of the reaction mixture, indicating an ionic mechanism. It is interesting to note that even methanol reacts with hexamethyl(Dewar benzene) *(3)* when the reactants are refluxed for several days in an atmosphere of nitrogen. After 48 hours, 45 % of *(36)* and 15 % of *(5)* could be isolated. *(3)* also reacts with methanol at room temperature, but the reaction is much slower. The reaction is completely suppressed by a few drops of sodium hydroxide solution.

3.5. Elimination and Substitution Reactions with Hexamethyl-5-chloro-6*H*-cyclohexa-1,3-diene *(29)* [39]

In our attempts to find chemical proof of the structure of the readily obtainable compound *(29)*, we obtained a series of unexpected reaction products. The formation of these products can be explained by the equilibrium of the carbonium ions A, B, C, and D as shown in equation (s). These ions can be formed either by protonation of *(3)* or by elimination of $Cl^{\ominus}$ from *(29)*.

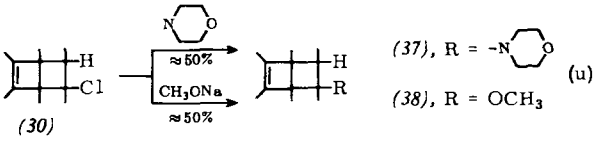


The questions of whether stabilization takes place by substitution or by deprotonation and whether the product is a derivative of A, B, C, or D depend on the

reaction conditions and on the nature of the attacking reagent.

3.5.1. Hexamethylbenzene

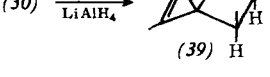
The structure of *(29)* can be deduced not only from spectral data, but also from the dehydrochlorination by Lewis acids such as $ZnCl_2$ or $AlCl_3$. Hexamethylbenzene *(5)* is obtained in quantitative yield even under very mild conditions. Gentle heating with zinc dust or iron powder leads to the same result.



(t)

(29) can take part in diene syntheses, *e.g.* with maleic anhydride or tetracyanoethylene; the reactions proceed at temperatures up to 40 °C.

3.5.2. Bicyclo[2.2.0]hex-2-ene Derivatives

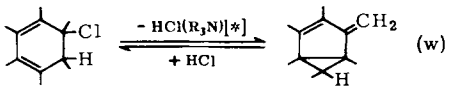


When *(30)* is refluxed for several hours with morpholine, the substitution product hexamethyl-5-morpholino-6*H*-bicyclo[2.2.0]hex-2-ene *(37)* and a mixture of elimination products, including hexamethylbenzene, are obtained in a yield of about 50 % each.

(u)

(30) behaves in a similar manner on treatment with methanolic sodium methoxide solution; hexamethyl-5-methoxy-6*H*-bicyclo[2.2.0]hex-2-ene *(38)* is formed in a yield of about 50 %, while the remainder of the products includes hexamethylbenzene.

Treatment of *(30)* with $LiAlH_4$ results in replacement of the chlorine atom by H to give *exo*-1,2,3,4,5,6-hexamethylbicyclo[2.2.0]hex-2-ene *(39)*.



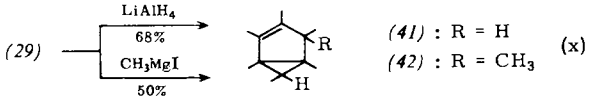
(v)

3.5.3. Bicyclo[3.1.0]hex-2-ene Derivatives

The action of amines on *(29)* leads to dehydrochlorination. Two isomeric hydrocarbons $C_{12}H_{18}$ may be formed, depending on the pK_b value of the amine.

[39] *H. Meister* and *W. Schäfer*, unpublished.

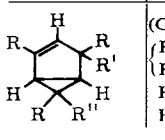
Primary, secondary, and tertiary amines having pK_b values lower than 8 give only pentamethyl-4-methylene-6*H*-bicyclo[3.1.0]hex-2-ene *(40)*. Examples of suitable strongly basic amines are [yields of *(40)* in brackets]: morpholine (86 %), cyclohexylamine (76 %), piperidine (80 %), diethylamine (77 %), *N*-methylmorpholine (72 %), triethylenediamine (1,4-diazabicyclo[2.2.2]-octane) (75 %), and ethylenediamine (79 %). To obtain *(40)*, *(29)* is heated with the amine for several hours at 60–200 °C, if necessary with the addition of an inert solvent (dioxane).



(29) *(40)* (w)

[*] R_3N = strongly basic amine.

It should be noted that this elimination can be reversed by the introduction of HCl gas into a solution of *(40)* in CH_2Cl_2 at 0 °C. *(29)* is formed in 80 % yield.



Substituted bicyclo[3.1.0]hex-2-ene derivatives are obtained when *(29)* is refluxed for several hours with $LiAlH_4$ or CH_3MgI in ether.

(41) : R = H
(42) : R = CH_3 (x)

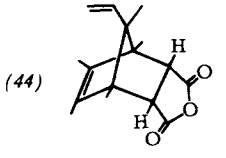
A reaction product of analogous structure is obtained by reaction of sodium methylate on (*29*) in methanol. By reaction of silver oxide with (*29*) a bicyclo[3.1.0]hex-2-ene derivative is obtained which readily dehydrates to give (*40*).

The addition of alcohols and acids to benzene or tri-t-butylbenzene on photochemical excitation with a low-pressure UV lamp has recently been reported[40,41]. The reaction products were assigned a bicyclo[3.1.0] structure.

	R	R′	R″	Ref.
	$(CH_3)_3C$	OCH_3	H	[40]
	H	OCH_2CF_3	H	[40]
	H	H	OCH_2CF_3	[40]
	H	$OOCCH_3$	H	[41]
	H	OH	H	[41]

The authors assumed that the H-acidic compounds added to benzvalene, which was formed as an intermediate, with opening of the three-membered ring. Our results suggest that the photochemical excitation leads preferably to the Dewar benzene, the protonation of which would also lead, *via* the carbonium ion equilibrium (s), to the observed results.

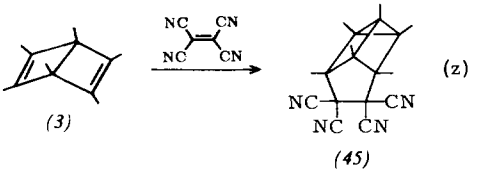
3.5.4. Cyclopentadiene Derivatives



Stable derivatives of carbonium ion D (eq. (s)) are to be expected only under reaction conditions that offer the ions a "chance of survival". Such conditions prevail *e.g.* during the action of weak amines on *(29)*. A suitable amine is dimethylformamide; when the components are refluxed for about 8–10 hours, possibly in the presence of an inert solvent (toluene), the dehydrochlorination product pentamethyl-5-vinyl-cyclopentadiene *(43)* is formed in 85–90 % yield.

The dehydrochlorination can also be effected, though in lower yields, by *e.g.* formamide, quinoline, pyridine, or urea. The purely thermal dehydrochlorination of *(29)* (3 hours at 180–205 °C) in an atmosphere of N_2 proceeds in the same direction, but less uniformly. About 50 % of *(43)* and about 40 % of hexamethylbenzene *(5)* are obtained.

(43) can be also obtained in almost quantitative yield from the methyl ester *(36)* by refluxing with DMF hydrochloride (cf. eq. (y)).



Further possibilities can be predicted from the equilibrium (s) and confirmed by experiment. Thus *(43)* is obtained in very good yields when the bicyclic compounds *(30)* and *(40)* are heated with DMF or DMF·HCl. Even *(3)* can be isomerized to *(43)* in a single-vessel reaction by heating with DMF·HCl in DMF, the product then being extracted with ligroin. The structure of *(43)* is established *e.g.* by the very smooth diene synthesis with maleic anhydride, in which the adduct *(44)* is formed in 90 % yield.

No substitution product derived from D (eq. (s)) has so far been isolated.

3.6. Action of Dienophiles on Hexamethyl(Dewar Benzene) *(3)*

The reactions of *(3)* discussed in the foregoing sections are only selected examples. It should finally be mentioned that *(3)*, by analogy with norbornadiene, may be able to add to strong dienophiles. *Lemal* and *Lokensgard*[28] reported that *(14)* could be obtained, not only from the prismane derivative *(13)* (cf. Section 3.1), but also directly from *(3)*.

(3) *(45)* (z)

We obtained the compound *(45)* (m.p. 268–269 °C) by reaction of *(3)* with tetracyanoethylene.

Polymerization of Trioxane[**]

BY K. WEISSERMEL, E. FISCHER, K. GUTWEILER, H. D. HERMANN, AND H. CHERDRON[*]

A survey of the possible modes of polymerization of trioxane is followed by a discussion of current ideas concerning the course of the polymerization. The polymerization, which involves ring cleavage, is characterized by a number of side reactions of the growing polyoxymethylene cations, such as chain transfer, transacetalization, and hydride shift. These reactions not only determine the nature of the end groups and the molecular weight of the resulting polyoxymethylenes, but are also responsible for their chemical and molecular uniformity. Special emphasis is placed on the role of the monomeric formaldehyde formed during the polymerization of trioxane.

1. Polymerization of Trioxane

Polyoxymethylenes, *i.e.* macromolecules consisting of CH_2O structural units, were intensively studied during the 1920's by *Staudinger* and *Kern*[1]. They can be prepared either from formaldehyde or from its cyclic oligomers, such as trioxane (1,3,5-trioxacyclohexane) or tetroxane (1,3,5,7-tetraoxacyclooctane). Whereas formaldehyde can be polymerized either anionically or cationically, only cationic polymerization takes place in the case of trioxane; free-radical polymerization has not so far been detected in either case. Finally, formaldehyde can undergo polycondensation in the aqueous phase to form polyoxymethylenes[***], but trioxane cannot.

The polymerization of trioxane can be initiated by cationic initiators such as protonic acids, ansolvo acids (complexes of organic acids with inorganic salts), and compounds that form cations[2,3] (for special initiators, see Sections 3.2.2. and 3.2.3). These initiators differ not only in their activity, but also in their influence on termination and side reactions. Trioxane can also be induced to polymerize by high-energy radiation, as was shown first by *Rösinger*[4] and, a little later, by *Okamura*[5] (see also Section 2.1.2.).

The polyoxymethylenes obtained by the cationic polymerization of trioxane are similar in structure to those obtained by the cationic polymerization of formaldehyde, but differ markedly in certain respects from the polyformaldehydes prepared by anionic polymerization. This is due to the introduction of special end groups, and possibly to branching, during cationic polymerization (see Section 3.4).

The ease of polymerization of trioxane also extends to copolymerization, in which compounds of many classes, such as cyclic ethers[6], cyclic acetals[6,7], cyclic esters[8], and vinyl compounds[8,9] may be used as comonomers.

The copolymerization of trioxane is of considerable industrial importance, since it offers an elegant means of suppressing the thermal and alkaline degradation (unzip depolymerization) that generally occurs in homopolyoxymethylenes with terminal hemiacetal groups (the degradation process begins at the end groups). Even random cleavage of the polymer chains (*e.g.* by oxidation or acid hydrolysis) causes much less breakdown in copolymers of trioxane than in homopolyoxymethylenes, since the degradation of the copolymer by successive removal of formaldehyde stops when the sequence of CH_2O units is interrupted by a comonomer unit, *i.e.* a C–C bond. The copolymerization of trioxane, which has already been described in detail[10–13], will be discussed in the present article only in connection with the side reactions (see Section 3.4.), which lead to deviations from the normal copolymerization kinetics.

2. Methods for the Polymerization of Trioxane

Trioxane can be polymerized in the solid state, in the melt, in the gas phase, in suspension, and in solution (precipitation polymerization). Not only do these methods differ in their execution, but some also lead to different products, since the polymerization conditions determine the importance of the side reactions.

2.1. Bulk Polymerization

2.1.1. Melt Polymerization

Trioxane polymerizes very readily in the molten state, *i.e.* above 62 °C, in the presence of cationic initiators. For example, it is completely polymerized within a few minutes at 70 °C with 10^{-4} mole of boron trifluoride per mole of monomer [14,15]. It is sometimes difficult to distribute the initiator uniformly in the melt, since the polymerization begins almost instantaneously under suitable conditions. However, initiators are also known that first dissolve very rapidly in the monomer, and only then initiate the polymerization [15,16]; these are particularly suitable for use in kinetic studies [17], *e.g.* for the investigation of transfer reactions [18].

During the bulk polymerization of trioxane above its melting point, the reaction mixture very rapidly becomes turbid, because of the insolubility of the polymer in the monomer, and the final product is a solid white block. The polymerization is accompanied by a volume contraction due to the difference between the densities of molten trioxane (d_4^{70} =1.13) and polytrioxane (d_4^{20} = 1.42).

Despite the low thermal conductivity of the polymer, the dissipation of the heat of polymerization (about 4 kcal/mole) presents no problems in small-scale experiments. With larger quantities of starting materials, on the other hand, the heat liberated is sufficient to vaporize some of the trioxane (b.p. 115 °C/760 mm) and to heat the reaction mixture almost to the ceiling temperature of 126 °C (see Section 3.1.), beyond which polymerization is no longer possible.

2.1.2. Polymerization in the Solid State

Numerous articles have been published on the polymerization of trioxane in the solid state. A simple example is polymerization in the presence of boron trifluoride [19]. The trioxane crystals are first charged with gaseous boron trifluoride at room temperature, and are then slowly heated. It can be readily established with the aid of the hot-stage microscope that polymerization becomes appreciable only at 50–55 °C, when needle-shaped polymer crystals [20] grow very rapidly from the surfaces of the trioxane crystals into the interior. The molecular weights of the resulting polytrioxanes are roughly double those of the polymers obtained under comparable conditions in the melt; viscosity numbers η_{sp}/c of up to 3.5 were obtained (0.5 g of polymer in 100 ml of γ-butyrolactone +2 % of diphenylamine at 140 °C).

Similar observations were made by *Okamura et al.* in the cationic suspension polymerization of trioxane below its melting point [21,22].

The action of high-energy radiation on crystalline trioxane also leads to polymerization [4,5,23–32a], very probably by a cationic mechanism. It is interesting to note that this radiation-induced polymerization of trioxane takes place only in the solid state, and not in the melt; the rate of polymerization reaches a maximum just below the melting point [24,25].

Particularly high yields and high molecular weights are obtained when solid trioxane is irradiated at low temperatures and is then heated to a temperature just below its melting point [26]. The polytrioxane prepared by radiation-induced polymerization is frequently obtained in the form of long filamentous crystals ("whiskers") [27–29].

It is not known why polymerization does not take place when pure trioxane is irradiated in the liquid phase. However, in the presence of an electron acceptor such as maleic anhydride [32], trioxane polymerizes even in the molten state when irradiated.

2.1.3. Polymerization During Phase Transitions

Trioxane exhibits a pronounced tendency to polymerize during gas-solid and liquid-solid phase transitions. The polymerization of trioxane on sublimation was first observed by *Hammick* and *Boeree* [33]. According to *Kohlschütter* and *Sprenger* [34], this polymerization takes place at the surface of the trioxane crystals and *Jaacks* and *Kern* [35] found that it is initiated by formaldehyde. Much higher polymerization rates are reached when trioxane vapor is allowed

to crystallize on a cooled surface in the presence of cationic initiators such as boron trifluoride [14] or sulfur trioxide [36]. Polymerization under the action of high-energy radiation also takes place particularly readily during the gas-solid phase transition [4].

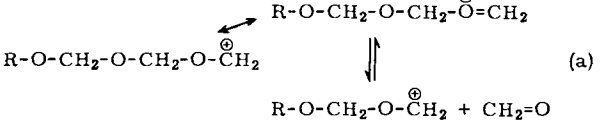
Similarly, trioxane polymerizes on crystallization from the liquid phase, and the polymerization can again be initiated by radiation [4] or by cationic initiators. The catalytic homopolymerization and copolymerization of trioxane during the liquid-solid phase transition are particularly interesting, since high conversions can be attained even with very small quantities of initiators (10^{-6} mole/mole of trioxane) [37]; on the other hand, practically no polymerization takes place under the same conditions in the melt. Another surprising observation is the increase in conversion when 1,3-dioxolane is added as a comonomer. This increase is also observed in radiation-induced polymerization [38]. The conversion can be further increased if, after the crystallization, the reaction mixture is twice heated to 70 °C and then cooled again. Similar results were obtained by *Baccaredda et al.* in the polymerization of trioxane in suspension or in solution on liquid-solid phase transition [39–41]. No explanation for these observations has so far been found.

2.2. Suspension Polymerization

The suspension polymerization of trioxane, in which the heat of reaction can be dissipated much more easily than in bulk polymerization, and in which the polymer is obtained, not as a solid block, but in a finely divided form, can be carried out in various ways. These include the polymerization of solid or molten trioxane with cationic initiators in the presence of suspending agents [14, 22] and the radiation-induced polymerization of solid trioxane in the presence of suspending agents [42]. Suitable suspending media include hexane, cyclohexane, heptane, and high-boiling hydrocarbons; since the monomer is soluble to a limited extent in these media, the suspension polymerization of trioxane is always accompanied by solution polymerization (precipitation polymerization).

2.3. Solution Polymerization (Precipitation Polymerization)

The solution polymerization of trioxane proceeds much more slowly than polymerization in bulk or in suspension. Benzene, halogenated hydrocarbons, nitroaliphatic compounds, and nitroaromatic compounds have been suggested as solvents [14, 43–45]. Since polytrioxane is insoluble in these solvents, the polymer precipitates right at the beginning of the polymerization (precipitation polymerization).



Accurate kinetic studies can be carried out on the polymerization of trioxane in solution [11], but the results are not directly applicable to bulk polymerization; this is particularly true of the copolymerization of trioxane, since the dilution effect of the solvent can prevent important reactions between the polymer molecules (transacetalization, see Section 3.4.2.), so that the copolymers obtained in solution are chemically less uniform.

3. Course of the Polymerization of Trioxane

3.1. The Role of Monomeric Formaldehyde

Monomeric formaldehyde, which is split off from the ends of the growing chains in accordance with eq. (a), plays an important part in the cationic polymerization of trioxane. It can affect the polymerization in many ways. Some of the reactions involved will therefore be considered before we proceed to discuss the course of the polymerization.

The cationic polymerization of trioxane is characterized by an induction period [46], during which no macromolecular products, but only monomeric formaldehyde and its oligomers are formed. During this period, monomeric formaldehyde is split off from the carbonium ion formed in the primary step of the polymerization until a temperature-dependent equilibrium concentration (ceiling concentration) of monomeric formaldehyde has been reached; it is only then that the polymerization begins.

(a)

In the homopolymerization of trioxane in solution, the ceiling concentration at 30 °C is 0.06 mole of CH_2O/l. As the temperature is raised, the equilibrium is displaced in favor of monomeric formaldehyde until, at the ceiling temperature of 126 °C, the polymer is no longer formed. The situation is more complicated in the case of copolymerization [47].

An induction period is no longer observed if a quantity of monomeric formaldehyde corresponding to the equilibrium concentration is introduced before the addition of the initiator. On the other hand, the induction period is lengthened if the formaldehyde formed is intercepted.

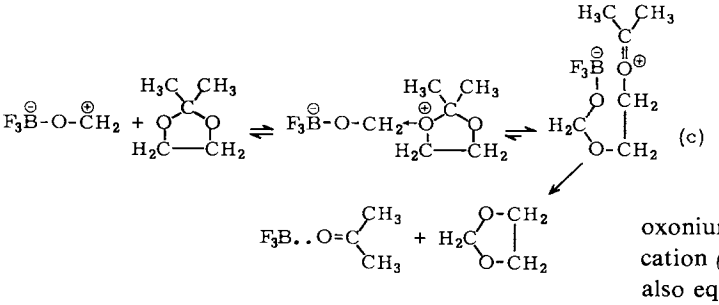
[46] *W. Kern* and *V. Jaacks,* J. Polymer Sci. *48,* 399 (1960).

[47] *K. Gutweiler,* unpublished.

Examples of the interception of the formaldehyde are found in the copolymerization of trioxane with ethylene oxide or of trioxane with 2-substituted 1,3-dioxolanes [48]. In the copolymerization of trioxane with ethylene oxide, the boron trifluoride-formaldehyde adduct *(1)* attacks the oxirane oxygen with formation of the cyclic oxonium salt *(2)*. The product rearranges *via* the open form *(3)* into the cyclic oxonium salt *(4)* which reacts with formaldehyde to give 1,3-dioxacyclopentane or dioxolane *(5)* [*]. Copolymerization of *(5)* with trioxane (eq. (b)) then takes place.



$$F_3B + O{=}CH_2 \longrightarrow F_3\overset{\ominus}{B}\text{-}O\text{-}\overset{\oplus}{C}H_2 \quad (1)$$

(b)

(2) *(3)* *(4)* *(5)* *(1)*

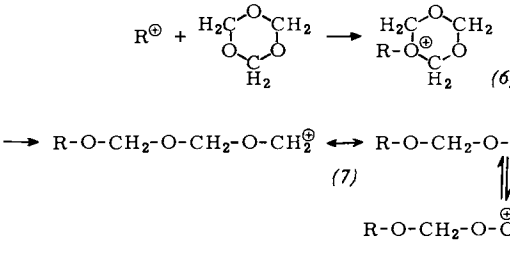
In the copolymerization of trioxane with 1,3-dioxolanes having one or two substituents in position 2, the carbonyl compound is displaced from the dioxolane derivative by formaldehyde with transacetalization and elimination to form the unsubstituted 1,3-dioxolane; it is only when this reaction is complete that monomeric formaldehyde can accumulate in the reaction mixture up to the ceiling concentration, so ultimately enabling the polymerization to proceed (eq. (c)).

(c)

The part played by formaldehyde in the initiation reaction can also be illustrated by another example. The less reactive compound tetrahydrofuran undergoes $Al(C_2H_5)_3$/epichlorohydrin-initiated polymerization to form high molecular weight products [49]. One would expect that the much more reactive trioxane would also polymerize with the same initiator system; however, this is not so, since formaldehyde immediately reacts with $Al(C_2H_5)_3$ to form aluminum alkoxides, which do not initiate cationic polymerization.

Finally, a number of observations suggest that the formaldehyde formed during the induction period takes part in the initiation step, and probably acts as a co-catalyst. This is understandable, since formaldehyde is more strongly nucleophilic than oxacycloalkanes; consequently, reaction (d) appears possible as the initiation step.

$$F_3B + O{=}CH_2 \longrightarrow F_3\overset{\ominus}{B}\text{-}O\text{-}\overset{\oplus}{C}H_2 \xrightarrow{+\ \text{trioxane}} F_3\overset{\ominus}{B}\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}\overset{\oplus}{C}H_2 \quad (d)$$



The co-catalysis is extremely difficult to detect, since polymerization is induced by initiator concentration as low as 4×10^{-5} mole/mole of trioxane, and the concentration of water in highly purified trioxane is also at least of this order of magnitude. The water could cause co-catalysis, by formation of a protonic acid from an ansolvo acid.

3.2. Initiation Reaction

It can be seen from the above discussion that the initiation reaction is subject to several influencing factors and therefore cannot be definitely formulated. The following possibilities have been proposed.

3.2.1. Classical Meerwein Mechanism

The initiation of the polymerization of trioxane by protonic acids, Lewis acids, or cation-forming components can be formulated in accordance with an oxonium ion/carbonium ion mechanism proposed by *Meerwein* [50] for the cationic polymerization of tetrahydrofuran (eq. (e)). Addition of an initiator cation to an oxygen atom of the trioxane first leads to an oxonium ion *(6)*, which gives a resonance-stabilized cation *(7)* by cleavage of one of the $^{\oplus}O-C$ bonds (see also eq. (a)).

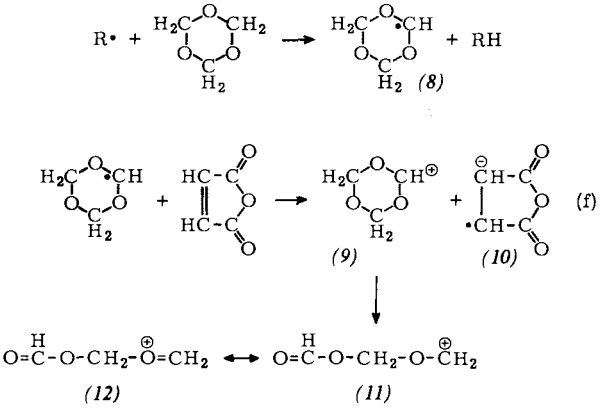
(e)

(6) *(7)*

The possibility of resonance stablization undoubtedly contributes to the ease of cleavage of the trioxane ring. In spite of the resonance stabilization, however, the resulting cation *(7)* is sufficiently active for an electrophilic attack on the next trioxane ring, *i.e.* for the propagation of the reaction chain.

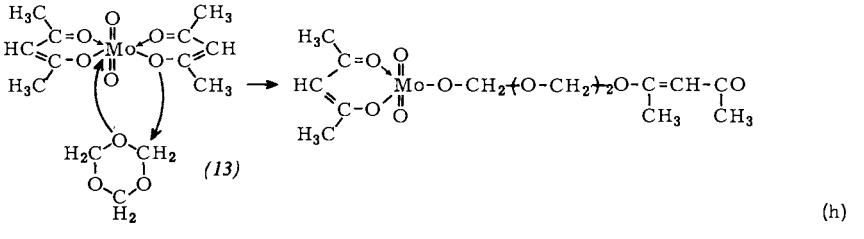
3.2.2. Initiation by Trioxane Cations

According to *Okamura et al.* [32], trioxane can be polymerized with peroxides, provided that an electron acceptor (*e.g.* maleic anhydride) is also present. The



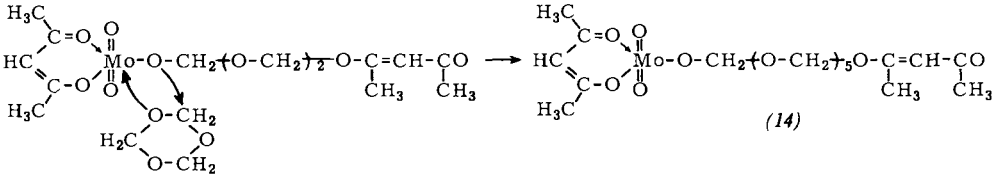
[48] *H. D. Hermann, K. H. Burg,* and *K. Weissermel,* Makromolekulare Chem., in press.

[*] As well as dioxolane, larger cyclic compounds and linear prepolymers are formed from formaldehyde and ethylene oxide in a similar way.

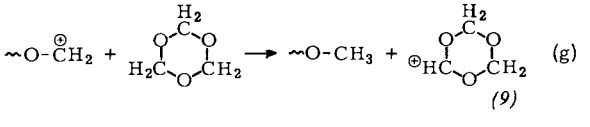


[49] *K. Weissermel* and *E. Nölken,* Makromolekulare Chem. *68,* 140 (1963).

[50] *H. Meerwein, D. Delfs,* and *H. Morschel,* Angew. Chem. *72,* 927 (1960).



reaction may be assumed to adopt the following course. A free radical formed by the decomposition of the peroxide abstracts a hydrogen atom from a trioxane molecule as in an RH reaction, with the result that a trioxane radical *(8)* is formed. This radical then gives up an electron to maleic anhydride, with formation of a trioxane cation *(9)* and the maleic anhydride radical-anion *(10)*. The trioxane cation may initiate the polymerization of trioxane either directly or after ring cleavage to form the carbonium ion *(11)*, which is mesomeric with the oxonium ion *(12)* (eq. (f)).



Initiation by trioxane cations *(9)* gives a polymer with ortho-ester end groups, while initiation by carbonium ions *(11)* gives formate end groups.

(h)

However, trioxane cations can also be formed from the monomer by hydride abstraction (see Section 3.4.3) without the formation of a free-radical intermediate: the hydride abstraction may be effected *e.g.* by the initiator or by a polyoxymethylene cation.

The polymerization again proceeds either *via* the cyclic cation *(9)* or *via* the carbonium ion *(11)* (cf. reaction (f)), and again yields polymers with ortho-ester or formate end groups.

The existence of trioxane cations is supported by mass-spectroscopic evidence. Cyclic acetals frequently give a peak corresponding to mass M – 1 [51]. It has also been suggested [52,53] that oxacycloalkane cations are formed during the polymerization of tetrahydrofuran.

3.2.3. Insertion Mechanism

A number of experimental observations suggest that trioxane also polymerizes by a mechanism similar to that of the polymerization of α-olefins. *Kennedy et al.* [54] postulated that the polymerization of trioxane in the presence of molybdenyl acetylacetonate proceeds by a non-cationic mechanism, in which coordination of the trioxane to the central atom of the chelate is followed by ring cleavage and ligand exchange to form oxymethylene units having acetylacetonate end groups (eq. (h)).

However, the possibility that the polymerization still ultimately proceeds *via* cations cannot be discounted.

The work of *Weichert* [55] on the MgI_2-initiated polymerization of cyclic formals also fits into a similar scheme. The initiation by MgI_2 is surprising, since no complex acids of this compound, *e.g.* of the form $H[MgI_3]$ or $H_2[MgI_2(OH)_2]$, are known. Concentrated aqueous solutions are neutral, and no hydrolytic formation of HI is observed. Consequently, the factor responsible for the initiation of polymerization is probably again the strong tendency of MgI_2 toward complex formation, in which the central atom can attain a maximum coordination number of 6 with compounds containing oxygen.

If the coordination sites are blocked by water or alcohol, polymerization does not take place.

3.3. Chain-Growth Reaction

The chain-growth reaction in the cationic polymerization of trioxane can be explained by the alternating oxonium ion/carbonium ion mechanism described by *Meerwein* [50] for the polymerization of tetrahydrofuran. The resonance-stabilized, but still sufficiently active ion *(7)*, which is formed by ring cleavage from the oxonium ion *(6)* formed in the primary step, adds

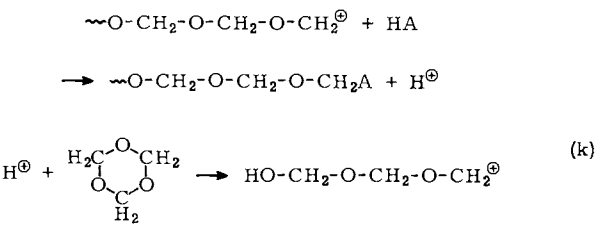
(i)

to a further molecule of trioxane. The resulting oxonium ion *(15)* is in turn converted into a resonance-stabilized cation *(16)*, which reacts once again with trioxane (eq. (i), see also eq. (e)).

The course of this chain reaction is undoubtedly strongly influenced by the cation and the solvent. The stability of the cation not only influences the chain length by retardation or acceleration of the chain termination, but evidently also suppresses side reactions of the end of the growing chain, *e.g.* transfer reactions, transacetalizations, and hydride shifts. The solvent must also be taken into account, since it can accelerate or retard the polymerization. Retardation is observed in the presence of dialkylethers. The cation *(18)* and the dialkyl ether *(17)* evidently exist in equilibrium with a very stable oxonium ion *(19)*. This ion *(19)* is cleaved to a small extent to form an alkyl cation *(20)* that has a very high energy and can carry on the reaction chain.

(j)

The cationic polymerization of formaldehyde, on the other hand, is not retarded by dialkyl ethers. In this case the growing carbonium ion *(18)* reacts much more rapidly with the nucleophilic formaldehyde than with the dialkyl ether, so that the normal chain reaction is not appreciably hindered.

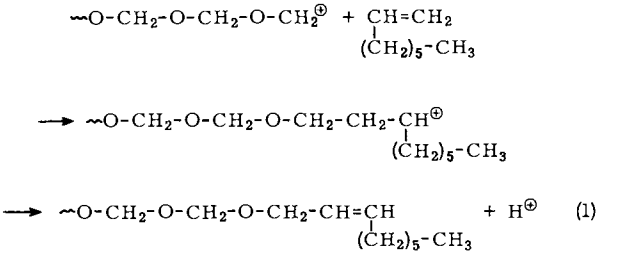


3.4. Side Reactions in the Polymerization of Trioxane

The growing polyoxymethylene cation can not only split off monomeric formaldehyde (cf. Section 3.1), but can also react with polar compounds, which may for example be present as impurities in the monomeric trioxane, with the result that the molecular weight of the resulting polymer is reduced (transfer reaction). However, polyoxymethylene cations can also react with oxygen atoms or methylene groups of the same or of adjacent polymer chains. Combination with oxygen atoms yields oxonium ions, which then decompose with chain cleavage (transacetalization); the reaction of polyoxymethylene cations with methylene groups, on the other hand, leads to the removal of hydride ions (hydride shift, cf. reaction (g)).

These side reactions are not merely of theoretical interest, since they have a decisive influence on the molecular weight, the molecular and chemical uniformity, and the stability of the resulting polyoxymethylenes.

3.4.1. Transfer Reaction



The transfer of the polymerization of trioxane by polar compounds containing mobile hydrogen atoms proceeds in accordance with eq. (k).

(k)

A = Anion

The anion A may for example be a hydroxide, alkoxide, or carboxylate ion. An extremely active compound HA is water [56,57], though alcohols and carboxylic acids are also very effective. Certain aromatic compounds, such as *m*-xylene, mesitylene, or anthracene, also react readily as transfer agents [18]. As in the transfer of the cationic polymerization of styrene [58], the aromatic compound first becomes attached to the polymer cation; this is followed by removal of a proton, which carries on the polymerization. The chain transfer by olefins probably also proceeds in a similar manner [59].

(l)

In addition to compounds with mobile hydrogen atoms, many other transfer agents are known, *e.g.* esters, orthoesters, anhydrides of carboxylic acids, and halogenohydrocarbons [60]; however, the activity of these compounds is relatively low. Very active transfer agents belonging to this group are esters of boric acid, peroxides [18], and in particular linear acetals, which react in accordance with eq. (m).

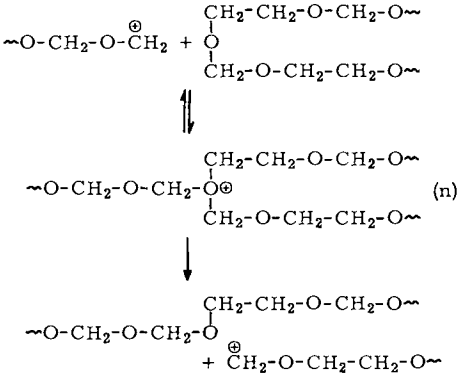
[60] *V. Jaacks, H. Baader*, and *W. Kern*, Makromolekulare Chem. *83*, 56 (1965).

(m)

Finally, mention should also be made of polymeric compounds containing chain transferring groups, *e.g.* polyvinyl acetate and polyvinyl butyral [10,61], which permit the preparation of block and graft copolymers of trioxane by transfer copolymerization.



The importance of chain transfer agents in the polymerization of trioxane is not confined to the reduction of the molecular weight of the polymer and the preparation of block copolymers. They also have a particularly interesting effect on the stability of the polymer. Proton-donating transfer agents always strongly favor the formation of hemiacetal end groups, which decompose on heating, particularly in the presence of alkali. This decomposition leads to the complete breakdown of the macromolecule [1]. A particularly interesting group of transfer agents consists of those that give polymers with two stable end groups. Thus by transfer of the polymerization of trioxane by means of dimethyl formal, *Jaacks*, *Baader*, and *Kern* [60] obtained polymers having predominantly methoxy end groups, and which therefore contain a fraction having a high thermal stability. However, complete etherification of the end groups by chain transfer is not possible, since the much more active proton-donating transfer agent water cannot be completely excluded from the polymerization, and since the exclusive formation of stable end groups is prevented by hydride shift (cf. Section 3.4.3).

3.4.2. Transacetalization

In chain transfer with low molecular weight acetals, the polyoxymethylene cation attacks an acetal oxygen atom with formation of an oxonium ion, which then decomposes; a similar reaction should, in principle, also be possible between a polyoxymethylene cation and an oxygen atom in a polyoxymethylene chain. This special type of transfer reaction has been detected in the copolymerization of trioxane with ethylene oxide, and is described as transacetalization [10]. The transacetalization may be either intermolecular or intramolecular, and it has consequences that will be discussed below.

Intermolecular transacetalization involves the continuous cleavage and reconstitution of polyoxymethylene chains, and is formulated as indicated in eq. (n) for trioxane/ethylene oxide copolymers.

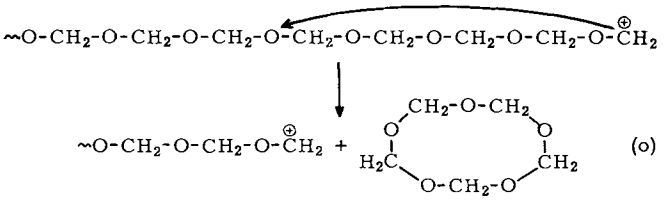
This side reaction competes with the chain growth reaction, and owing to constant cleavage and reconstitution, the polymers obtained are chemically and molecularly very uniform. The chemical uniformity is particularly clear *e.g.* in the copolymerization of trioxane with ethylene oxide. During the induction period, which is appreciably longer than in the homopolymerization of trioxane, a copolymer that is soluble in trioxane is formed; though this copolymer already contains all the comonomer in the form of mono-, di-, and triethylene oxide units [10], the product obtained on complete conversion does not consist of a mixture of high ethylene oxide copolymer and homopolymer or of a block copolymer, but of a

(n)

random copolymer, in which the ethylene oxide units are roughly uniformly distributed over the polyoxymethylene chains [*]. Thus the prepolymer formed during the induction period is later cleaved and incorporated in a rather random manner into the growing polyoxymethylene chain; it is therefore equivalent to a comonomer that takes part in the polymerization throughout the entire reaction time. Consequently, the copolymerization equation proposed by *Mayo* and *Lewis* cannot be applied to the copolymerization of trioxane, *i.e.* the calculation and discussion of copolymerization parameters is meaningful only if the transacetalization can be completely suppressed.

Additional possibilities for the modification of polyoxymethylenes are offered by the fact that linear prepolymers can also be used as "comonomers" for copolymerization with trioxane [10].

Intermolecular transacetalization also affects the molecular uniformity of homopolymers or copolymers of trioxane. Since the growing chains are continuously reacting with completed polymer molecules, cationically polymerized polyoxymethylenes have a relatively narrow molecular weight distribution corresponding to the Schulz-Flory normal distribution [62] with a ratio $Pw/Pn = 2$, such as also occurs *e.g.* in polycondensations. Thus this is a special case, in which the molecular weight distribution of a step reaction (transacetalization) is superimposed on the molecular weight distribution of a chain reaction (polymerization). In fact, polytrioxanes prepared under conditions in which transacetalization is suppressed have a much broader molecular weight distribution [**].



[61] *V. Jaacks* and *W. Kern*, Makromolekulare Chem. *83*, 71 (1965).

[*] A particularly suitable method for the determination of the sequence-length distribution is pyrolytic gas chromatography. See *K. H. Burg*, *E. Fischer*, and *K. Weissermel*, Makromolekulare Chem., in press.

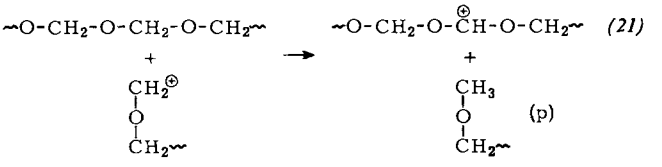
[62] *H. L. Wagner* and *K. F. Wissbrun*, Makromolekulare Chem. *81*, 14 (1965).

[**] Unpublished results.

Intramolecular transacetalization in accordance with (o) leads to cyclic oligo- and/or polyoxymethylenes by reaction of the growing cation with an oxygen atom of the same macromolecule.

(o)

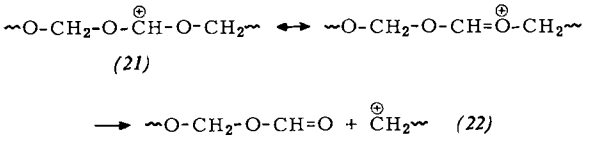
In addition to the lower members of the homologous series of cyclic oligomers of formaldehyde, such as tetroxane (1,3,5,7-tetraoxacyclooctane), pentoxane (1,3,5,7,9-pentaoxacyclodecane) and hexoxane (1,3,5,7,9,11-hexaoxacyclododecane), rings containing 15 CH_2O units have also recently been isolated and characterized [51]. Similarly, intramolecular transacetalization during the copolymerization of trioxane yields new cyclic formals of various ring sizes.



The transacetalization can be controlled within certain limits by variation of the reaction conditions. Since it proceeds *via* oxonium ions, it is temperature-dependent and so takes place particularly readily at high temperatures, both in the melt and in the solid state; it has not so far been detected at very low temperatures. Under comparable conditions, it is slower in solution polymerization than in bulk polymerization. Finally, the rate of transacetalization increases with increasing initiator concentration.

3.4.3. Hydride Shift

Transfer and rearrangement reactions involving the migration of a hydride ion have been observed in the cationic polymerization *e.g.* of styrene [63], 3-methyl-1-butene [64], and tetrahydrofuran [52,53]. The first indication of an initially inexplicable transfer reaction in the polymerization of trioxane was the observation that in most cases the number of initiator molecules does not correspond to the number of polymer molecules formed. One initiator molecule often leads to the formation of more than 20 polymer molecules [3], even when impurities that could cause transfer are carefully excluded [18].



Further evidence was found during the quantitative investigation of the thermally stable polymer fraction, which amounts to up to 25 wt-% in the melt polymerization of trioxane. This discovery can be explained only by the presence of stable end groups in the polymer. Analytical studies finally showed that polytrioxane prepared in the absence of impurities contains approximately the same number of formate and methoxy end groups. The transacetalization that accompanies the polymerization ensures that these end groups are randomly distributed over the polymer molecules. It is therefore to be expected that polymer chains having two stable methoxy end groups will also be formed [18]. Polymers of this nature are stable even above 230 °C in the absence of oxygen, whereas polymers having formate end groups have only limited stability at high temperatures [60] and are readily degraded by alkali.

The results of these and other experiments strongly suggest the occurrence of a hydride shift during the polymerization of trioxane [18]. Thus an electrophilic attack by the polyoxymethylene cation leads to the removal of a hydride ion from a methylene bridge of its own or of an adjacent macromolecule (eq. (p)).

(21) (p)

The new cation *(21)* is resonance-stabilized and can be cleaved.

The hydride ion may be removed from any methylene bridge, *e.g.* from the middle of an adjacent polymer molecule, from the end of the same molecule, or even from trioxane. The predominant formation of the cation *(22)* may be regarded as verified by the observed decrease in the molecular weight and by the occurrence of formate end groups. However, it is also conceivable that the polymerization is directly initiated by the cation *(21)*; in this case, branched molecules containing ortho-ester groups should be formed.

Investigations on the stability of polyoxymethylenes under various conditions indicate that such ortho-ester groups could exist [65]; however, this grouping has not so far been detected, and its presence would be difficult to demonstrate.

3.5. Termination Reactions

According to the results obtained so far, no termination takes place in bulk polymerization of trioxane in the absence of reactive impurities, *i.e.* the polymer contains "living" polyoxymethylene cations. The evidence for this includes the fact that the hydride shift can be observed in the finished polymer even several hours after completion of the reaction.

We are grateful to Dr. K. H. Burg, Dr. K. H. Häfner, Dr. K. Küllmar, and Dr. C. Schott for years of helpful collaboration.

Eliminations in Cyclic *cis-trans*-Isomers

BY W. HÜCKEL and M. HANACK [*]

Dedicated to my friend Georg Wittig on the occasion of his 70th birthday – (W. H.)

Solvolytic E1 eliminations from cis-alkylated p-toluenesulfonates of cycloalkanols (particularly menthols and decalols) lead almost exclusively to "Saytzeff hydrocarbons"; this fact is accounted for by the increase in the rate of solvolysis that results from the participation of the tertiary trans-hydrogen. The corresponding trans-alkylated compounds give mixtures. The solvolysis of these compounds is compared with the deamination of stereoisomeric primary amines and with the proton-catalysed dehydration of tertiary alcohols. E2 reaction of vicinally alkylated cycloalkane derivatives involves attack on the secondary hydrogen, and in the case of the trans isomers leads to pure "Hofmann hydrocarbon"; with the cis-isomers, competition occurs between the E1 and E2 reactions. The fact that the tertiary hydrogen is not attacked is explained by its anionic character. Reference is made to the competition of E1 and E2 reactions in exhaustive methylation.

Introduction

The first article dealing with the solvolysis of *p*-toluenesulfonates and chlorides of the menthol and decalol series [1] contained important information (from the preparative point of view) on the relationship between substitution and elimination processes, and it was recognized that E1 reactions and E2 reactions lead to fundamentally different results. Observations on this topic are scattered throughout the literature, with the result that many have been overlooked by various authors and their general significance has not been appreciated. The present review is an attempt to correct this situation.

All systematic investigations on E1 and E2 reactions have been based on comparison of the two contradictory elimination rules propounded by *Saytzeff* [2] and by *Hofmann* [3]. According to these rules, the course of elimination depends on the number of hydrogen atoms on the neighboring atoms.

The Saytzeff rule states that hydrogen is eliminated from the neighboring atom carrying the smallest number of hydrogen atoms, while according to the Hofmann rule elimination takes place from the neighboring atom with the largest number of hydrogen atoms [2, 3, 3a].

Other workers have tried to find a theoretical interpretation of this. We, on the other hand, have started by merely noting which of the two rules is obeyed. In certain cases it has been possible to gain an insight into the underlying principles on the basis of the reaction mechanism.

We have restricted our investigations to experiments with alicyclic compounds of known configuration and, in most cases, known conformation. The preferred carbon skeleton is the saturated cyclohexane ring, particularly in the menthane and decalin series. The standard substituents are an esterified hydroxyl group in the solvolysis experiments and an amino group in the deamination and exhaustive methylation experiments. The substituent is always situated on a secondary carbon atom, and may be eliminated either with a hydrogen atom from one of two CH_2 groups that are structurally not quite equivalent or with a hydrogen from either a CH_2 group or a CH group.

In previous investigations in the aliphatic series, a substituent on a secondary or tertiary carbon was usually given a choice of elimination with H from a CH_3 or from a CH_2 group. We decided to use cyclic compounds with five-, six-, or seven-membered rings; this has the advantage that the problem of simultaneous formation of *cis*- and *trans*-olefins does not arise. Moreover, in the comparison of stereoisomers, differences in electromeric and inductive effects, which might affect the rate and direction of elimination, are avoided.

I. E1 Reactions and Substitutions in the Absence of a Neighboring Substituent

The difference between the rates of elimination in two alternative directions is smallest when the substituent is immediately flanked by two CH_2 groups, so that any dissymmetry is due only to more distant atoms. The relatively small importance of dissymmetry of this type when the configurations differ can be seen in the methanolysis of the *p*-toluenesulfonates *(1a)* to *(1d)* of the four stereoisomeric β-decalols. Substitution, which leads mainly to the methyl ether *(4)* having the opposite configuration [4], is accompanied by elimination to form a mixture of the Δ^1- and Δ^2-octalins *(2)* and *(3)* in a yield of 42 to 76.5%.

The total extent of elimination is greatest for the axial isomer *(1b)* of the *trans*-decalin series, though this is closely followed by the equatorial "extreme" *cis* form *(1c)* of the *cis*-decalin series. The hydrocarbon mixture contains more of the Δ^2-octalin in the *trans* series, as well as in the case of the *cis* isomer *(1d)* (though the preference for the Δ^2-octalin is less pronounced in this instance); *(1c)* gives more Δ^1-octalin. No relationship can be observed between the ratio Δ^1-octalin: Δ^2-octalin and the position (axial or equatorial) of the hydroxyl group.

cis	*(1c)*	105	$2^e9^c10^c$ (e)	65 : 35	73	*(4c)*	27	98
	(1d)	18/31	$2^t9^c10^c$ (e)	44 : 56	63	*(4d)*	37	98

[*] e = hydroxyl group equatorial; a = hydroxyl group axial.

In 3-methylcyclohexyl *p*-toluenesulfonate *(5)*, the esterified hydroxyl group is again flanked by two CH_2 groups. On methanolysis, more cycloolefin is obtained from the *trans* isomer, which has an axial *p*-toluenesulfonate group, than from the *cis* isomer in which the *p*-toluenesulfonate group is equatorial. In both cases the methyl group directs the double bond into the Δ^3 position, but the effects differ in strength. The methyl ether *(8)* is again formed in an S_N2 reaction with the solvent [4], mainly with Walden inversion (Table 2).

This may be compared with the E1 deamination of the structurally analogous 3-methylcyclohexylamines by nitrous acid [7]. *trans*-3-Methylcyclohexylamine, in which the amino group is axial again gives more (and in this case much more) cycloolefin than the *cis* isomer, which has an equatorial amino group. However, the ratio of 3-methylcyclohexene *(6)* to 4-methylcyclohexene *(7)* is approximately the same (≈ 1:2); this suggests that the methylcyclohexenes are formed *via* the same planar ion.

The results of side reactions, which occur only to a small extent, are shown in Table 2. "Anomalous" substitution takes place only in the case of *trans*-3-methylcyclohexylamine, and leads mainly to the tertiary 1-methylcyclohexanol *(11)*. In normal substitution to form 3-methylcyclohexanol *(10)*, *trans*-3-methylcyclohexylamine gives 70% retention of configuration, and the *cis* isomer gives 90% retention.

In the deamination of β-decalylamines, elimination to form the octalin (except for one isomer $2^t9^c10^t$, axial, m.p. −1 °C)) is a minor side reaction, and has not yet been studied in any detail [7a].

II. E1 Reactions and Substitutions by Solvolysis in the Presence of an Adjacent Alkyl Group

Apparently anomalous substitutions and double bond shifts occur so regularly in vicinally alkylated *p*-toluenesulfonates *(12)* that it is necessary to extend

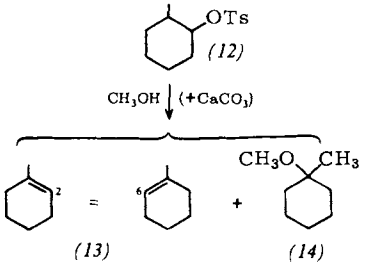
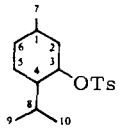
[7a] *W. Hückel*, Liebigs Ann. Chem. *533*, 15 (1937).

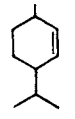


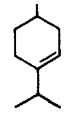
the scheme proposed by *Hughes*[8] for (E1 + S_N1) reactions in order to take into account, not only the neighbor C_β of the substituted C atom, but also the next atom but one, C_γ.

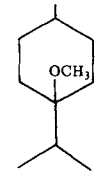
Extended Hughes scheme of E1 elimination and anomalous substitution on C_β.

With the aid of the extended Hughes scheme, it is possible to predict, not only normal substitution on C_α and the normal positioning of the double bond between C_α and C_β, but also the anionic migration of a β-hydrogen atom, with a consequent shift of the double bond into the position between C_β and C_γ.









A hydride shift in accordance with the extended Hughes scheme is normally observed only with a tertiary β-hydrogen, and is recognized by the formation of a tertiary substitution product (substituent on C_β). Thus methanolysis of the *p*-toluenesulfonate of *cis*-2-methylcyclohexanol *(12)* gives a 27% yield of methyl ether, 85% of which is *(14)*. The principal methanolysis product (72%) is 1-methylcyclohexene *(13)*, and only 1% of 3-methylcyclohexene *(6)* is formed[9].

It is not known how much of the $\Delta^{1(2)}$-methylcyclohexene *(13)* is formed in the normal manner and how much is $\Delta^{1(6)}$-methylcyclohexene formed *via* the tertiary ion by migration of the double bond.

The course of the hydride shift can be determined in the menthane series. The tertiary 4-menthyl cation, like the 1-menthyl cation, is optically inactive. It can be formed from the 3-menthyl cation by hydride shift. A proton may be removed from C-3 or C-5 to give racemic Δ^3-menthene *(17)*, or from C-8 to give $\Delta^{4(8)}$-menthene *(18)*. (The corresponding $\Delta^{1(7)}$-methylenecyclohexane is not obtained from the *p*-toluenesulfonate of 2-methylcyclohexanol.) However, on solvolysis of all four menthyl *p*-toluenesulfonates *(15a)* to *(15d)*, the amount of *(18)* formed is always small. The quantity of tertiary ether *(19)* is greater, but only slightly so (maximum 13%, as the only S_N1 product from neomenthol). Thus evidence of the hydride shift is provided by the formation of *(18)* and *(19)* as well as of racemic *(17)* (Table 3).

Table 3. Methanolysis of the *p*-toluenesulfonates of the four stereoisomeric menthols [10].

	 *(15)* Tosylate of:	Configuration	Menthene : Methyl ether ratio	 *(16)* *cis* and *trans*	:	 *(17)* (Degree of racemization)	:	 *(18)* (%)	 *(19)* (%) [c]

a] No secondary ether. [b] 4% of secondary ether. [c] Based on the total quantity of ether.

The connection between anomalous substitution and racemization in the menthane series was first recognized in the deamination of neomenthylamine, and was interpreted as resulting from a hydride shift[1]. The course of the reaction is admittedly more complicated[11] than was originally assumed.

The importance of the steric structure with regard to the direction of the E1 elimination from cyclic compounds can already be seen from the examples in the menthane series. From the behavior of many aliphatic halides and onium compounds *Ingold*[12] concluded that the Saytzeff rule is generally valid[14]. He explained this as resulting from a predominance of the electromeric over the inductive effect. *Ingold* further specified the "driving force" for the E1 elimination in accordance with the Saytzeff rule by formulation of hyperconjugation in the transition state[13]. Both the rule and the explanation have been accepted as generally valid[14].

It may, however, be objected that the Saytzeff rule was deduced empirically from observations on a structur-

ally unbalanced selection of compounds. The direction of elimination from halides was established only for tertiary halides in which there was a choice between adjacent CH_3 and CH groups; nearly all the secondary halides studied gave yields of less than 10% of an olefin, which was not examined further. The halides selected by *Ingold et al.* do not include the structural type $X-CHR-CH_2R$ corresponding to the secondary cycloalkanols with vicinal alkyl groups studied by us (Tables 4 to 8). Since many esters of secondary cycloalkanols do not obey the Saytzeff-Ingold rule, neither this rule nor its electronic interpretation can be universally valid, since *cis-trans* isomers would otherwise behave in the same manner, to a first approximation. Their fundamentally different solvolytic behavior, in elimination and in some substitution reactions, can be seen from a quick glance at Tables 4 to 8.

1. Vicinally *cis*-Alkylated Cycloalkyl *p*-Toluenesulfonates

All *cis*-alkylated cycloalkyl *p*-toluenesulfonates give more cycloolefin on solvolysis than the *trans* isomers, the cycloolefin being almost entirely that predicted by the Saytzeff rule. The mixture of cycloolefins obtained from *trans* *p*-toluenesulfonates contains two isomers, frequently in roughly equal quantities. This gives a *cis*-configuration rule for the solvolysis of vicinally alkylated cycloalkyl *p*-toluenesulfonates with adjacent alkyl groups. The hydride shift with simultaneous substitution is much more marked for *cis* than for *trans* isomers, as can be seen from the amount of tertiary ether formed (cf. Tables 5 and 7).

The α-decalols show that this *cis* rule depends on the configuration, and not on the conformation in the ground state. The equatorial *p*-toluenesulfonate of the "*cis*" alcohol *(20a)* from the *cis*-decalin series, like the axial *p*-toluenesulfonate of the "*cis*" alcohol *(20c)* from the *trans*-decalin series, gives almost exclusively

the Saytzeff hydrocarbon $\Delta^{1(9)}$-octalin *(22)*, which, together with the $\Delta^{9(10)}$-octalin *(23)* formed by hydride shift, amounts to > 99% of the total cycloolefin.

The *p*-toluenesulfonate of the normally equatorial "*trans*" alcohol *(20b)* of the *cis*-decalin series gives a 90% yield of cycloolefin, with unusually pronounced hydride-shift. This is an exception among the vicinally *trans*-alkylated cycloalkyl *p*-toluenesulfonates, for which there is no general rule. This is probably due to the flexibility, and the resulting variable conformation, of the *cis*-decalin skeleton, since the rigidly equatorial "*trans*" alcohol *(20d)* of the *trans*-decalin series behaves normally on solvolysis of its *p*-toluenesulfonate. It gives a mixture of $\Delta^{1(2)}$- and $\Delta^{1(9)}$-octalins, *(21)* and *(22)*, in a ratio of about 2:1; the principal reaction is a normal S_N2 reaction with inversion to form the secondary ether *(24)*, and S_N1 reaction with hydride shift to form the tertiary ether *(25)* takes place only to a very small extent. With the other isomers, the ether fraction consists mainly (66 to 100%) of the tertiary ether, of which two stereoisomers can be formed.

The vicinally *cis*-alkylated cycloalkyl *p*-toluenesulfonates are characterized, not only by the result of solvolysis, *i.e.* the formation of a large quantity of cycloolefin (of which 92 to 100% is Saytzeff hydrocarbon) accompanied by a largely anomalous S_N1 reaction, but also by the high rate of solvolysis, which is 20 to 100 times that of the isomeric *trans* *p*-toluenesulfonate[15]. This suggests that the solvolysis mechanisms are different.

It must be borne in mind that the formation of the Saytzeff hydrocarbon corresponds to *trans* elimination from *cis* *p*-toluenesulfonates and *cis* elimination from *trans* *p*-toluenesulfonates. In the case of the *cis* *p*-toluenesulfonates, it is independent of whether the tertiary hydrogen is axial or equatorial in the ground state, as has been known for some time for the *cis* alcohols of the *cis*- and *trans*-decalin series. The "extreme" *cis* form *(20a)* has an equatorial hydroxyl group, so that the vicinal tertiary hydrogen atom is *trans* and equatorial (*meso-trans* according to *Bredt*[17]); in the "*cis*" alcohol of the *trans* series, on the other hand, the two groups to be eliminated are axial. Both *(20a)* and *(20c)* solvolyse rapidly. Further examples were discovered later[18].

According to *Winstein*[19], the high solvolysis rate of vicinally *cis*-alkylated cycloalkyl *p*-toluenesulfonates

[19] *S. Winstein et al.*, J. Amer. chem. Soc. *74*, 1113 (1952).

is due to "participation" [*] of the adjacent hydrogen atom, though no details of the reaction products are given. This is illustrated for *trans*-elimination from neomenthyltosylate (formula *(26)*).

Nevertheless, *Winstein*'s view can also be interpreted on the basis of the reaction products. In the case of neomenthyltosylate, however, the formation of partially racemized Δ^3-menthene must be explained. Thus it is necessary to distinguish between the routes that lead to optically active menthene on the one hand and to the racemate on the other [20].

Winstein's model can be used directly for the route to optically active menthene. One need only assume that the electron pair that binds the tertiary hydrogen to C-4, and which assists in the removal of the acid residue from C-3, is fixed in the double bond between C-3 and C-4 (see formula *(27)*).

In the route leading to the racemate, the hydrogen atom is released together with its bonding electrons, and immediately attacks C-3 from the side opposite to the *p*-toluenesulfonate group, so assisting the release of the latter, while it is itself bound by S_N2 substitution. This yields the optically inactive 4-menthyl ion, which is stabilized either by loss of a proton from C-3 or C-5 to form racemic Δ^3-menthene, or by the solvent, which loses a proton, to form a derivative of 4-menthanol (cf. formula *(28)*).

(27) *(28)*

In *Winstein*'s model of neomenthyl *p*-toluenesulfonate, the arrangement of the leaving groups is *trans*-diaxial. This coplanar arrangement of the atoms taking part in the reaction, which satisfies the requirements for a four-center reaction [21], is not absolutely essential to intramolecular assistance of the elimination, *i.e.* to the formation of the optically active and the racemic Δ^3-menthene. The only requirement is that anionic hydrogen or a pair of electrons can attack C-3 from the rear. This is also possible in a *meso-trans* arrangement, but not in a *cis* or *meso-cis* arrangement such as exists in the *trans p*-toluenesulfonates.

The Saytzeff rule is almost always obeyed by the reactions of vicinally *cis*-alkylated *p*-toluenesulfonates of the cyclohexane series, since the solvolysis is intramolecularly assisted, and hence very fast. In the case of five-membered and seven-membered rings, the rates of hydrolysis of the vicinally *cis*-alkylated esters are only about seven times as fast and twice as fast, respectively, as those of the *trans* esters. The formation of the Saytzeff (Δ^1) hydrocarbon is again strongly favored, though less so than in the six-membered ring compounds [15].

2. Vicinally-*trans*-Alkylated Cycloalkyl *p*-Toluenesulfonates

Vicinally *trans*-alkylated cycloalkyl *p*-toluenesulfonates show no special preference for either of the two possible elimination routes (Table 6). The extent of anomalous substitution to give tertiary ethers with migration of a hydride ion always remains within reasonable limits (Table 7). The special position of the α-decalol *(20b)* has already been mentioned (Section II.1); this affects only the products, and not the kinetics. Except in the case of the *p*-toluenesulfonate of *(20b)*, the ratio of elimination to substitution products is always lower than with the *cis p*-toluenesulfonates. In many cases the frequencies of elimination of the hydrogen atom from the tertiary and from the secondary β-C atoms are approximately the same. Though the ratio of Δ^1- to Δ^2-hydrocarbon is occasionally as high as 72:28, one cannot say that the reaction follows the Hofmann rule, since the corresponding ratio of the reaction rates lies between 2:1 and 3:1 [*].

The formation of the Saytzeff hydrocarbon from *trans p*-toluenesulfonates must result from *cis*-elimination (cf. Section II.1) [**]. The *p*-toluenesulfonyl group is generally equatorial, while the *meso-cis* hydrogen is axial, and is therefore removed from the axial position. When secondary hydrogen is eliminated with roughly the same frequency as tertiary, it seems reasonable to assume (though there is no proof of this) that the secondary hydrogen is also removed from the axial position. In any case, statistical preference for the hydrogen of the CH_2 group rather than that of the CH group, which would favor elimination in accordance with the Hofmann rule, is of no importance.

In the solvolysis of the *trans p*-toluenesulfonates, the hydride shift involves the migration of the neighboring *cis*-hydrogen, together with its bonding electrons, from the tertiary carbon of the carbonium ion onto the adjacent carbon atom; this process is comparable with the anionic migration of a *cis*-methyl group in the Nametkin rearrangement [21a]. Hydrogen attached to a secondary carbon atom is not sufficiently anionic for

[*] *Winstein*'s term "participation" is generally used as synonymous with "assistance"; no exact definition is given for either of the two terms.

[20] *W. Hückel* and *C.-M. Jennewein*, Liebigs Ann. Chem. *683*, 100 (1965).

[21] For a detailed discussion of the applicability of the four-center principle, see *W. Hückel et al.*, Liebigs Ann. Chem. *624*, 142 (1959).

[*] For a long time, the only known solvolysis of a *trans*- *p*-toluenesulfonate was the ethanolysis of menthyl *p*-toluenesulfonate [1], which gave about 70% of Δ^3-menthene. This was described by *Winstein* as "a typical Saytzeff result" ([19], p. 1132), and *Ingold* also regarded this as characteristic of a solvolytic E1 elimination. However, even methanolysis gives only 54% of Δ^3-menthene.

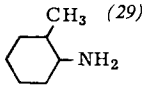
[**] *Ingold* gives a plausible model, with a substantially planar carbonium ion, for a *cis*-elimination from the *meso-cis* position ("*syn*" position according to *Ingold*) on the cyclohexane ring.

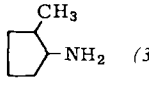
[21a] *S. Nametkin*, Liebigs Ann. Chem. *432*, 207 (1923); *S. Nametkin* and *L. Brüssoff*, *ibid. 459*, 144 (1927); *J. Houben* and *E. Pfankuch*, *ibid. 489*, (1931); *J. Bredt*, J. prakt. Chem. [2] *131*, 145 (1931); *S. Nametkin*, Chem. J. Ser. A general. Chem. (Russ.) *4*, (66), 847 (1934); *J. J. Ritter* and *G. Vlases jr.*, J. Amer. chem. Soc. *64*, 583 (1942).

migration; thus there is no transition from the menthol to the carvomenthol series or *vice versa.*

The anomalies that are sometimes observed in eliminations from *trans* *p*-toluenesulfonates, which do not fit into the extended Hughes scheme (see Section I) [18], cannot be discussed in any detail at present, since too little is known about them.

Only a few solvolyses of *cis-trans* isomeric, vicinally alkylated cycloalkyl *p*-toluenesulfonates containing five-membered and seven-membered rings have been studied so far, and the results are shown in the tables. Mention should be made of the special case of *trans*-2-methylcyclopentyl *p*-toluenesulfonate, which differs from the other *trans* *p*-toluenesulfonates in that it gives only the Δ^1-cycloolefin together with appreciable quantities of tertiary ether.





III. E1 Reactions in Deaminations

It was hoped that the deamination (by nitrous acid in dilute acetic acid) of cyclic primary amines having a neighboring substituent might yield more information than solvolysis about the direction of E1 eliminations from secondary ions because in this case the solvent is not directly involved in the ionization.

This hope was not fulfilled, since hydride shifts and similar anionic carbon shifts generally occur in the secondary ion before it is stabilized by loss of a proton to the solvent [22]. The only cases in which rearrangements do not take place, or occur only to a small extent, are those of the 2-methylcyclohexylamines *(29)* and the 2-methylcyclopentylamines *(30)*.

In addition to the Δ^1-hydrocarbon formed in accordance with the Saytzeff rule, the *cis* amines give not only the Δ^2-hydrocarbon, but also small quantities of isomers that have only been partly elucidated. *trans*-2-Methylcyclohexylamine *(29b)* yields 7% of ethylidenecyclopentane and a trace of vinylcyclopentane together with 72% of Δ^2-methylcyclohexene (cf. also Table 9). A comparison of the deamination of vicinally alkylated cycloalkylamines with the methanolysis of the *p*-toluenesulfonates of the alcohols having the same configuration shows that the hydride shift in the carbonium ion and the stabilization of the latter by loss of a proton to form the cycloolefin merely exhibit certain common features, but are in fact quite different. This is not surprising, since the solvation and energy conditions during the reaction are different. The small extent to which hydride shift takes place in the reactions of *trans*-2-methylcyclohexylamine *(29b)* and *trans*-2-methylcyclohexyl *p*-toluenesulfonate is surprising; the structure of the initially formed *trans*-2-methylcyclohexyl cation must be unfavorable for a hydride shift, since a considerable quantity of tertiary alcohol is obtained from all the other amines.

IV. Proton-Catalysed E1 Reactions of Tertiary Alcohols

Tertiary alcohols are dehydrated by traces of concentrated sulfuric acid (about 0.001 wt-%) [24]. This reaction has been systematically studied only for dimethylcycloalkylcarbinols with three- to six-membered rings. The main product (90 to 97%) in every case is the isopropenyl compound. Thus in the stabilization of the intermediate carbonium ion by deprotonation, the proton is removed almost exclusively from a methyl group, *i.e.* in accordance with the Hofmann rule; practically no attack takes place on the tertiary hydrogen atom, and hydride shift occurs to only a small extent. Thus 1-cyclohexyl-1-methylethanol gives a 90% yield of 2-cyclohexylpropene *(31)* in accordance with the following E1 mechanism (3% of the products are isopropylidenecyclohexane, and 7% are endocyclic 1-isopropylcyclohexene formed by hydride shift).

(31)

There are one tertiary and six primary hydrogen atoms available for elimination from the carbonium ion; the corresponding statistical ratio of the reaction rates, *i.e.* 6:1, would correspond to 86% of the Hofmann hydrocarbon.

However, this calculation does not take into account the anionic migration of the tertiary hydrogen to $C^{\oplus}$. This makes the direct removal of the tertiary hydrogen as a proton even more difficult, and explains why the elimination is substantially in accordance with the Hofmann rule.

V. E2 Eliminations from Cycloalkyl *p*-Toluenesulfonates

In the study of E2 eliminations [25] leading to unsaturated hydrocarbons, we concentrated mainly on the elimination of a strong acid from its esters by strong bases, particularly by alkoxides. The results were compared with those of E1 eliminations during alcoholysis, and in some cases with exhaustive methylation and other eliminations, such as pyrolyses, which are not E2 reactions.

The bimolecular reaction begins with an attack by the base on a hydrogen atom. The removal of this hydro-

[24] *R. van Volkenburgh, K. W. Greenlee, J. M. Derfer*, and *C. E. Boord*, J. Amer. chem. Soc. *71*, 172 (1949); *G. Chiurdoglu* and *S. van Walle*, Bull. Soc. chim. belges *66*, 612 (1957).

[25] See [12a], p. 420, 421; *C. K. Ingold*, Proc. chem. Soc. (London) *1962*, 265; *J. Caspilla*, Chimia *18*, 37 (1964); [14].

gen atom as a proton is coupled with the release of the acid residue as an anion. This bimolecular process may occur in competition with other first and second order reactions. In eliminations with alkoxide in alcoholic solution, the competing reactions are solvolytic E1 elimination and S_N2 substitution. The accuracy of kinetic measurements is often not sufficient to distinguish simultaneously between bimolecular and monomolecular processes. Except in preliminary experiments, therefore, we made no attempt to detect competing reactions by determination of the reaction order.

We were able to compare and distinguish E2 and E1 reactions in the following cases. In the elimination of *p*-toluenesulfonic acid from vicinally alkylated cyclohexyl *p*-toluenesulfonates, the ratio of the isomeric hydrocarbons formed depends on the reaction conditions, which determine whether E2 or E1 elimination takes place or whether both reactions proceed simultaneously (see Table 10).

Table 10. Competition between E1 and E2 elimination in vicinally alkylated cycloalkyl *p*-toluenesulfonates. The amount of "Hofmann hydrocarbon" (3-alkylcycloolefin or Δ^1-octalin) is given as a percentage of the total amount of hydrocarbon.

[*] The values in brackets signify wt.-%Na metal in methanol or isopropanol.

[**] With C_2H_5ONa (13 wt.-% Na in methanol).

The higher the alkoxide concentration, the higher is the ratio of Hofmann hydrocarbon to Saytzeff hydrocarbon; the proportion of Hofmann hydrocarbon can be as high as 100% in the case of the slowly solvolysing vicinally *trans*-alkylated cycloalkyl *p*-toluenesulfonates. It is therefore very probable that the E2 elimination, involving the adjacent CH_2 group, leads exclusively to the Hofmann hydrocarbon. The competing E1 elimination by alcoholysis and the S_N2 ether formation (cf. Section I [4]) become less important with decreasing ionizing power and dielectric constant of the alcohol ROH (replacement of CH_3OH by ROH). In order that the E2 reaction may be favored as strongly as possible in relation to the E1 reaction, the alkoxide concentration must be high and the alkyl group of the alkoxide must be as large and as highly branched as possible. Thus for E2 reactions, the order of preference is methanol < ethanol < isoamyl alcohol [26] ≈ isopropyl alcohol < t-butanol < 2-n-butylcyclohexanol [27]. By suppression of the E1 reaction, it is sometimes possible to avoid isomerization of intermediate carbonium ions.

The E2 reaction of slowly solvolysing esters of sulfonic acids at high alkoxide concentrations may be accompanied by cleavage of the O–S bond, with regeneration of the cycloalkanol:

$$\text{>C-O-SO}_2\text{R} \xrightarrow{\text{NaOR'}} \text{>C-OH} \xrightarrow{\text{HOR'}} \text{NaOH}$$

Even at high alkoxide concentrations, rapidly-solvolysed esters give the Saytzeff hydrocarbon as well as the Hofmann hydrocarbon. However, the quantity of the Hofmann hydrocarbon formed is so large as to indicate practically uniform E2 elimination, while the formation of the Saytzeff hydrocarbon is due to the solvolytic E1 elimination, which is not quite suppressed. The *p*-toluenesulfonate of the α-decalol having the configuration $1^c9^c10^t$ shows a surprising change in the direction of elimination by alkoxide. Even with only 0.9% of isopropoxide in isopropyl alcohol, the proportion of the Hofmann hydrocarbon ($\Delta^{1(2)}$-octalin) formed on solvolysis jumps from 1% to 67% [28], though the structure of the $1^c9^c10^t$-α-decalol is ideal for a diaxial *trans*-elimination of the tertiary hydrogen from C-9. The same alkoxide concentration is not sufficient to change the direction of elimination from the *p*-toluenesulfonate of $1^c9^c10^c$-α-decalol (m.p. 93 °C), which is solvolysed twice as rapidly as the $1^c9^c10^t$ isomer [28]. It is possible that in this case the E2 elimination affects the exposed equatorial tertiary hydrogen; however, the equatorial position of the ester group may be so unfavorable for the E2 elimination of secondary hydrogen that the fast E1 solvolysis still predominates (see below). E2 eliminations from other equatorial "*cis*" alcohols have not been studied as yet.

The *p*-toluenesulfonate of neomenthol, which has an axial *p*-toluenesulfonate group, gives 45% of *trans*-Δ^2-menthene with 8% of isopropoxide, while neomenthyl chloride with ethoxide gives only 25%. The partial racemization of the principal product, Δ^3-menthene, indicates that it is formed by an E1 reaction. The E2 mechanism is generally assumed to involve *trans*-elimination; however, this cannot be deduced from the formation of the Hofmann hydrocarbon. *Hückel* [1] explained the *trans*-elimination as being due to electrostatic repulsion of the alkoxide ion by the electronegative substituent, which hinders the approach of the ion on the *cis* side. Where *trans*-elimination is impossible, as in the case of β-hexachlorocyclohexane, a much higher activation energy is required for the *cis*-elimination [29].

Ingold[30] used the four-center principle to explain the *trans* E2-elimination. In the case of cyclohexane derivatives, this means that the leaving group must be coplanar with the *trans* β-hydrogen atom, which is attacked by the proton acceptor.

The tertiary β-hydrogen is *trans* in neomenthol and *cis* in menthol; it is therefore eliminated from neomenthol to give the Saytzeff hydrocarbon, but not from menthol. Thus in menthol, the attack is directed exclusively toward the secondary *trans* hydrogen, which can assume a position that satisfies the requirements of the four-center principle[12b], though only in the energetically very unfavorable a,a,a conformation. As can be seen from molecular models, however, the axial position of the ester group and the β-hydrogen atom in molecules that can undergo E2 elimination can be so unfavorable energetically that this type of elimination cannot occur; examples are the α-decalols having the configurations $1^c9^c10^c$ (m.p. 93 °C) and $1^t9^c10^t$ (m.p. 62 °C). Thus the four-center principle cannot be regarded as a universal condition for an E2 reaction.

In any case, *trans*-elimination is facilitated by coplanarity of the appropriate groups, since in cases where the model shows that coplanarity is very unlikely, the molecule tries to evade the E2 reaction. In $1^c9^c10^c$-α-decalol, in which the axial hydroxyl group is hemmed in and sterically hindered by hydrogen atoms on more remote C atoms, the fast E1 elimination is not accompanied by E2 elimination, as it is in the reaction of $1^c9^c10^t$-α-decalol, in which the groups to be eliminated occupy the normal diaxial position. The hydroxyl group in the rigid $1^t9^c10^t$-α-decalol is equatorial; it can become axial only if at least one ring has the energetically unfavorable boat form, in which the hydroxyl group is also hindered by more distant hydrogen atoms[30a]. Since the *p*-toluenesulfonate is very stable to solvolysis, competition by the E1 reaction is less important in this case. However, the compound evades E2 elimination in 0.9% isopropoxide solution by undergoing cleavage of the O–S bond, with regeneration of the α-decalol (42% yield). Hydrocarbons are formed in a yield of only 58%, in which the proportion of the Hofmann hydrocarbon (Δ^1-octalin) has risen only to 77%, as against 61% in methanolysis (E1 reaction).

The same side reactions are observed with the *p*-toluenesulfonate of all-*cis*-3,5-di(t-butyl)cyclohexanol, in which the *p*-toluenesulfonate group is equatorial and is flanked by two CH_2 groups. In this case the two *cis*-t-butyl groups make a coplanar arrangement of the ester group and the *trans*-hydrogen impossible[31].

Ingold did not restrict his considerations to an E2 elimination from diaxial positions. The scheme given can be readily modified in such a way that it can also apply to elimination from the *meso-trans* position. Moreover, *Ingold* also gives another scheme for *cis*-E2-elimination, which is explicitly considered to be possible[32, 32a].

Our own observations indicate that E2 elimination always involves the secondary hydrogen; there is no reliable evidence of any attack on tertiary hydrogen. If there are two neighboring CH_2 groups available, more remote atoms have very little directing influence on the elimination, as in solvolysis. Accordingly, the addition of alkoxides in the β-decalol series has a very small, but definite effect on the ratio of Δ^1- to Δ^2-octalin during solvolysis; however, the E1 and E2-eliminations cannot be distinguished in this case (see Table 11). The result of the pyrolysis of the acetates, *i.e.* an intramolecular *cis*-elimination, which is not specific in a structural sense, is also shown for comparison.

Table 11. Elimination reactions of the *p*-toluene sulfonates and acetates of β-decalols. The proportions Δ^1-: Δ^2-octalin are listed [33].

	Configuration	Tosylate		Acetate Pyrolysis (550 °C)
		E1 with CH_3OH	E2 + (E1 ?) with i-C_3H_7ONa (10%)	
(1a)	$2^c9^c10^t$ (e)	29:71	25:75	57:43
(1b)	$2^t9^c10^t$ (a)	25:75	33:67	43:57
(1c)	$2^c9^c10^c$ (e)	65:35	72:28	56:44
(1d)	$2^t9^c10^c$ (e)	44:56	23:77	56:44

Though 10% isopropoxide solution leads almost exclusively to an E2 mechanism, this has a noticeable effect only in the *cis*-decalin series, where the Δ^1-: Δ^2-octalin ratio given by the *trans p*-toluenesulfonate is practically the reciprocal of the ratio obtained from the "extreme" *cis* isomer. On the other hand, no difference is found between these two isomers in the pyrolysis of the acetates, whereas a similar inversion of the ratio is found for the two isomeric *trans*-octalins. In the α-decalol series, the acetate of the "extreme" *cis* isomer (m.p. 93 °C), which has no *cis*-hydrogen in position 9, gives Δ^1-octalin in 100% yield. On the other hand, the acetate of *trans*-α-decalol (m.p. 62 °C), which has a *cis*-hydrogen on each side, gives a mixture of Δ^1- and $\Delta^{1(9)}$-octalin in the ratio 41:59; thus the tertiary hydrogen on C-9 is only slightly favored in relation to the secondary hydrogen on C-2.

Thus where there is no neighboring group to determine the direction of an elimination, this direction cannot be predicted since the effects of more distant atoms are largely unknown, though a steric effect can still be recognized.

VI. Exhaustive Methylation

Exhaustive methylation was long regarded as a typical E2 reaction, involving an attack by the hydroxide ion of the tertiary base on the *trans*-hydrogen of a β-C atom. It was discovered only a few years ago, by deter-

[33] Earlier results, which appear to indicate that E2 eliminations in general proceed in a single direction ([1], survey on pp. 209–210), are superseded by these data [5].

mination of the order of the reaction [34], that a competitive E1 reaction may also take place, in which the trimethylamine is first split off. A proton is then removed from the remaining cation in a second step. This possibility had actually been considered previously [35]. Another competing reaction is α,β-elimination [36], but since this is a rare event, it will not be discussed here. The thermal decomposition of quaternary ammonium salts is very similar to that of sulfonium salts [37].

The E2 mechanism of exhaustive methylation causes vicinally *trans*-alkylated amines of the cyclohexane series to react mainly in accordance with the Hofmann rule, in analogy to E2 eliminations from esters by alkoxides. On the other hand, vicinally *cis*-alkylated cyclohexylamines react mainly by an E1 mechanism, and give the Saytzeff hydrocarbon. The E1 and E2 reactions again compete with each other.

Table 12. Results of the exhaustive methylation of vicinally alkylated amines of the cyclohexane series.

trans-Amine	Hofmann hydrocarbon (%)	
trans-2-Methylcyclohexylamine [37]	3-Methylcyclohexene	94
Menthylamine [39]	*trans*-Δ^2-Menthene	96
Isomenthylamine [39]	*cis*-Δ^2-Menthene	99
α-Decalylamine ($1^t9^c10^t$) [40]	*trans*-Δ^1-Octalin	100
cis-Amine	Saytzeff hydrocarbon (%)	
cis-2-Methylcyclohexylamine [38]	1-Methylcyclohexene	94–97
Neomenthylamine [39]	Δ^3-Menthene	89
Neoisomenthylamine [39]	Δ^3-Menthene, considerable excess	

More detailed investigations have been carried out only on menthylamine and neomenthylamine [34]. If the solution is sufficiently alkaline, the quaternary ammonium base formed from menthylamine gives 30% of *trans*-Δ^2-menthene by a bimolecular reaction, while 70% of the base escapes by cleavage into *N,N*-dimethylmenthylamine and methanol. The thermal decomposition of the quaternary iodide in water is first order and yields menthenes (Δ^2-: Δ^3-menthene = 32:68), following the Saytzeff rule.

The quaternary ammonium base from neomenthylamine undergoes a first-order decomposition to give a Δ^3-menthene that is 10% racemized, and which contains only 2% of Δ^2-menthene. Addition of hydroxide or alkoxide leads to an increase in the yield of Δ^2-menthene, but without an abrupt transition to the E2 mechanism. The rate constant of the E2 reaction can be extrapolated from the formation of menthene (which is not strictly second order), and the fraction of the neomenthylamine that reacts by an E2 mechanism can be calculated; this gives a Δ^3-menthene content of 88% of the total menthene when $OH^{\ominus}$ is added (1.36 M), and 65% when $OC_2H_5^{\ominus}$ is added (0.1 M). Thus the normal Hofmann hydrocarbon (Δ^2-menthene) content of 11% is the result of a competing E2 reaction, which unlike the cleavage of esters by alkoxide, does not proceed uniformly (if the calculation based on the extrapolated values is reliable).

The similarity of the direction of elimination from quaternary ammonium bases and *p*-toluenesulfonates having the C^3–C^4-*trans* configuration (cf. *(15)*) is the more remarkable in that the *p*-toluenesulfonates cannot have the same conformation as the ammonium bases, the $(CH_3)_3N^{\oplus}$ group of which is practically equivalent to a t-butyl group in its bulk and its low polarizability, and must therefore be equatorial. Consequently, coplanarity of the *trans* positions, which would favor the elimination, is impossible. This explains why the escape reaction accounts for 70% of the total conversion.

The bulk of the $(CH_3)_3N^{\oplus}$ group has not yet been taken into account in any of the discussions of exhaustive methylation. It necessitates modification of the explanation given by *Hughes* and *Wilby* [34] for the E1 elimination from the quaternary ammonium base of neomenthylamine, though the basic idea need not be entirely abandoned. This takes into account the intramolecular pressure exerted by the $^{\oplus}N(CH_3)_3$, which is assumed to be axial, on the adjacent axial hydrogen atoms. However, this pressure must also act in the equatorial position, for which the axial isopropyl group, which is *meso-cis* in neomenthyl derivatives, tends to eject trimethylamine. Though the isopropyl group in the quaternary base of menthylamine is also close to the $(CH_3)_3N^{\oplus}$ group, the *meso-trans* groups can move aside from one another as a result of intramolecular movements such as occur when the cyclohexane ring "flips", whereas *meso-cis* groups come closer together.

The reaction may be further facilitated by the electron pair bonding the tertiary hydrogen, which, as in the solvolysis of neomenthyl *p*-toluenesulfonate, is responsible for the Δ^3-double bond, provided that this leads to optically active Δ^3-menthene. This would be compatible with the small degree of racemization of the menthene, which, nevertheless, indicates moderate hydride shift.

In any case, *Hughes* appears to be correct in his basic idea that neomenthyltrimethylammonium hydroxide reacts in stages, the trimethylammonium group leaving first as a neutral molecule, and the tertiary hydrogen then being removed from the resulting cation by a proton acceptor. Nevertheless, it will be necessary to investigate the exhaustive methylation of vicinally *cis*-alkylated cyclohexylamines other than neomenthylamine in order to elucidate the competing reactions, particularly in connection with the calculation of the proportion of Saytzeff hydrocarbon on separation of the E1 and E2 reactions. Thus the attack of the proton acceptor on the tertiary hydrogen would be a process that has no parallel in

E2 eliminations from esters. Moreover, *cis-trans* isomeric amines with rigid five-membered rings and with flexible seven-membered rings, the exhaustive methylation of which has not been studied as yet, should also be used for comparison purposes.

VII. The Saytzeff and Hofmann Rules

Examination of the E1 and E2 eliminations described above in order to determine whether they obey one of the two rules shows that the relationships that have until now been regarded as generally valid [41] do not hold. E1 eliminations do not all follow the Saytzeff rule, nor do E2 eliminations from halides and esters of sulfonic acids, and the Hofmann rule in the E2 mechanism is not predominantly restricted to onium compounds. However, the behavior of the cycloalkane derivatives clearly shows that the steric structure of a molecule in the ground state can have a decisive effect on the mode of reaction.

The Saytzeff rule follows from those E1 eliminations that proceed rapidly with participation of tertiary hydrogen. When the steric conditions for the participation of tertiary hydrogen are not satisfied, the Saytzeff rule may still be more or less strictly obeyed if a hydride shift in the initially formed ion leads to a tertiary carbonium ion. The stabilization of this ion by loss of a proton to give a trisubstituted or tetrasubstituted "ethylene" then competes to a greater or lesser degree with stabilization of the initially formed primary or secondary carbonium ion by deprotonation, which leads to an olefin having a less highly alkylated double bond. For thermodynamic reasons, eliminations leading to equilibria obey the Saytzeff rule.

[41] See [14], p. 733, top of the left-hand column.

The Hofmann rule is obeyed with statistical probability when all the hydrogen atoms available for elimination are equally suitable; in the least favorable case, *i.e.* when there is a choice between a CH_3 and a CH_2 group, 2/3 of the product is Hofmann hydrocarbon. The relative yield of the Hofmann hydrocarbon can be higher if the reactivity increases with the number of protons on a group. This is so *e.g.* in the case of tertiary hydrogen, which has an anionic character owing to the inductive effect; this hydrogen remains intact in E2 eliminations, which are induced by a proton acceptor, and even in E1 reactions it may be taken up by the solvent to a smaller extent than "primary" or "secondary" hydrogen. Thus vicinally *trans*-alkylated and vicinally *cis*-alkylated cycloalkyl *p*-toluenesulfonates undergo *trans* E2-elimination involving the secondary hydrogen, even when the tertiary *trans*-hydrogen occupies the sterically favorable coplanar positions (see Section V).

If there is a choice between secondary and primary hydrogen, no generalizations can be made in view of the small statistical superiority of the primary hydrogen. The attack on a given hydrogen atom may be facilitated or hindered by steric factors; the elimination will be accelerated or retarded, depending on whether the hydrogen and the leaving group are more or less coplanar. The importance of electronic effects as compared with steric effects is unknown, since the steric factors can only be roughly estimated in general. The importance of bulk in E2 reactions in the aliphatic series has been discussed by *H. C. Brown* [42].

The Chemistry of Bunte Salts

BY H. DISTLER [*]

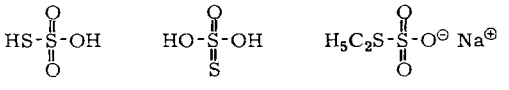
Bunte salts can be obtained, not only from alkyl halides and sodium thiosulfate, but also from compounds containing activated multiple bonds, and sodium thiosulfate. The Bunte salts prepared by the new method, contrary to earlier observations, are cleaved by alkalis into the unsaturated starting compounds and sodium thiosulfate. This reaction, which is used for the fixation of unsaturated compounds (e.g. to cellulose), and other reactions of the Bunte salts are discussed. The industrial applications and biological properties of the Bunte salts are also mentioned.

1. Introduction

Alkali metal *S*-alkylthiosulfates and *S*-arylthiosulfates are known as "Bunte salts". Since sodium *S*-ethylthiosulfate [1] was first prepared by *Bunte* (1874), many articles dealing with the chemistry of this class of substances have been published [2].

When *Bunte* synthesized sodium *S*-ethylthiosulfate, which he obtained by heating an aqueous solution of sodium thiosulfate with ethyl bromide, his main

[*] Dr. H. Distler
Badische Anilin- & Soda-Fabrik AG., Oxyd-Abteilung
67 Ludwigshafen (Germany)



[1] *H. Bunte*, Chem. Ber. *7*, 646 (1874).

[2] *B. Milligan* and *J. M. Swan*, Rev. pure appl. Chem. *12*, No. 6, p. 72 (1962).

object was to find conclusive proof of the constitution of thiosulfuric acid, which was still very uncertain at

$$C_2H_5Br + Na_2S_2O_3 \longrightarrow C_2H_5S_2O_3Na + NaBr \qquad (a)$$

that time. Of the possible isomeric forms *(1)* and *(2)*, the synthesis and chemical behavior of sodium *S*-ethylthiosulfate are compatible only with a derivative

(1) *(2)* *(3)*

of the structure *(1)*. This is shown in particular by *Bunte*'s observation that sodium *S*-ethylthiosulfate gives ethylthiol on acid hydrolysis.

$$\underset{(3)}{H_5C_2S_2O_3Na} + H_2O \xrightarrow{H^{\oplus}} NaHSO_4 + H_5C_2SH$$

The structure *(3)* was confirmed by a series of syntheses and secondary reactions, and also agrees with the results of UV [3], Raman, and IR measurements [4, 108].

The thiosulfate anion should contain different nucleophilic centers, and the nucleophilic strength should be greatest on the sulfur atom. It seemed desirable to check this experimentally, since it is well known that many nucleophiles, *e.g.* thiolate, add smoothly to compounds containing activated double bonds. The addition of thiolate ion to vinylsulfonic acid derivatives may be cited as an example [eq. (b)] [5].

$$R'-O-SO_2-CH=CH_2 + RS^{\ominus} \longrightarrow [R'-O-SO_2-\overset{\ominus}{C}H-CH_2-S-R] \xrightarrow{+H^{\oplus}} R'-O-SO_2-CH_2-CH_2-S-R \qquad (b)$$

We found that, in general, the addition of thiosulfate ions to vinylsulfonic acid derivatives proceeds smoothly and almost quantitatively in accordance with equation (c), to give Bunte salts *(4)* that crystallize well from water. The same reaction conditions were then used in an attempt to add thiosulfate ion to other

$$R'-O-SO_2-CH=CH_2 + S_2O_3^{2\ominus} \longrightarrow [R'OSO_2-\overset{\ominus}{C}H-CH_2-\overset{\ominus}{S_2O_3}] \xrightarrow{H^{\oplus}} \underset{(4)}{R'OSO_2-CH_2-CH_2-S_2O_3^{\ominus}} \qquad (c)$$

compounds containing activated double bonds, such as acrylic and methacrylic acids and their derivatives, as well as methyl vinyl ketone. *Kerber* and *Starnick* [6] carried out an independent study of the direct addition of sodium thiosulfate to compounds containing activated double bonds and obtained identical results.

[3] *H. Ley* and *E. König*, Z. physik. Chem. *B 41*, 379 (1938).

[4] *A. Simon* and *D. Kunath*, Chem. Ber. *96*, 157 (1963).

[5] *H. Distler*, Angew. Chem. *77*, 291 (1965); Angew. Chem. internat. Edit. *4*, 300 (1965).

[6] *R. Kerber* and *J. Starnick*, Tetrahedron Letters *1966*, 3007.

These authors ultimately extended the method to compounds containing activated triple bonds, which give Bunte salts *(5)* containing a C–C double bond.

$$R-CO-C\equiv CH + S_2O_3^{2\ominus} \longrightarrow [R-CO-\overset{\ominus}{C}=CH-\overset{\ominus}{S_2O_3}] \underset{OH^{\ominus}}{\overset{H^{\oplus}}{\rightleftharpoons}} \underset{(5)}{R-CO-CH=CH-S_2O_3^{\ominus}} \qquad (d)$$

In the study of the reactions of Bunte salts obtained by the direct addition of thiosulfate to activated multiple bonds, a surprising result was obtained on cleavage with aqueous alkali. Acid hydrolysis of Bunte salts yields thiols [1], alkaline degradation was reported to yield sodium sulfite [7, 8], alkylsulfenic acids, alkylsulfinic acids, disulfides, thiocarboxylic acids [9, 10], *etc.* However, we have found that Bunte salts obtained by direct addition of thiosulfate to activated multiple bonds are converted back into the

$$R-CH_2-CH_2-S_2O_3^{\ominus} \xrightarrow{OH^{\ominus}} [R-\overset{\ominus}{C}H-CH_2-\overset{\ominus}{S_2O_3}] + H_2O \longrightarrow R-CH=CH_2 + S_2O_3^{2\ominus} \qquad (e)$$

unsaturated starting compounds on treatment with aqueous alkalis. This behavior is particularly interesting and significant for the fixation of unsaturated compounds on fibers, *e.g.* cellulose.

2. Methods for the Preparation of Bunte Salts

a) Bunte Salts from Alkyl Halides and Alkali Metal Thiosulfate

The original method [1] for the synthesis of sodium *S*-alkylthiosulfates consists in the reaction of alkyl halides with sodium thiosulfate in aqueous solution at high temperature [see equation (f)].

$$RX + Na_2S_2O_3 \longrightarrow R-S_2O_3^{\ominus}Na^{\oplus} + NaX \qquad (f)$$

This method, which was frequently used (see [1, 2, and 11–18]), was extended to the preparation of Bunte salts

[7] *A. Gutmann*, Chem. Ber. *40*, 2818 (1907).

[18] *B. Milligan* and *J. M. Swan*, J. chem. Soc. (London) *1961*, 1194.

from secondary alkyl halides [19,13,20–22]. Tertiary alkyl halides apparently do not react with sodium thiosulfate. *Lecher* and *Hardy* [23] found it advantageous to use thallium(I) thiosulfate instead of sodium thiosulfate, since the isolation of the readily soluble Bunte salt is facilitated by the low solubility of the thallium chloride formed.

Even alkyl halides RX with a very wide variety of substituents in the residues R react with sodium thiosulfate – generally without side reactions. For example, alkyl halides that also contain primary [23–27], secondary [22,28], or tertiary amino groups [16,27,20,22,23] can be converted into Bunte salts. These can sometimes be isolated as inner salts *(6)* [160].

$$Cl{-}CH_2{-}CH_2{-}NH_3Cl + Tl_2S_2O_3 \longrightarrow \underset{(7)}{H_3\overset{\oplus}{N}{-}CH_2{-}CH_2{-}S_2O_3^{\ominus}} + 2TlCl$$
(6)

Betaine-like compounds can also be obtained from pyridine, chloroepoxypropane, and sodium thiosulfate [29].

Halogenated fatty acid derivatives of amines [30,31,15] also undergo this reaction. This class of substances was extensively studied in connection with the synthesis of thioctic acid (lipoic acid) [32–35] and its intermediates [36–39]. Dyes containing thiosulfate groups, which may carry various substituents, are being produced on the industrial scale [40–60]. It is reported [61] that sodium thiosulfate reacts only with terminal halogen atoms in polychlorinated hydrocarbons. Chlorinated ethers [62–65] and thioethers [66,67] as well as various substituted benzyl halides [68,69] also react under the classical conditions of the synthesis of Bunte salts.

The alkyl halide is made to react with aqueous sodium thiosulfate solution, usually in the presence of a solubilizing agent such as methanol or ethanol. The reaction is usually complete after one or more hours under reflux. Dioxane may also be advantageously used as the solvent in some cases [70]; aqueous acetic acid has been recommended in particular for aminoalkyl halides [20]. Prolonged heating should be avoided. The reaction mixture generally becomes homogeneous when the reaction is complete. The course of the reaction can be readily followed by determination of the thiosulfate. Isolation of the product is occasionally hindered by the sodium chloride formed in the reaction. The Bunte salts can be purified conveniently by hot extraction with alcohol, in which most of them are readily soluble.

b) Bunte Salts from Disulfides and Alkali Metal Bisulfite

The reaction of a disulfide with sulfite is reversible, as indicated in equation (g) [71–73].

$$R{-}S{-}S{-}R + SO_3^{2\ominus} \rightleftharpoons RS^{\ominus} + R{-}S_2O_3^{\ominus} \qquad (g)$$

The equilibrium can be displaced in favor of the formation of Bunte salts by the addition of oxidizing agents.

$$R{-}S{-}S{-}R + 2\,SO_3^{2\ominus} \xrightarrow{-2e^{\ominus}} 2\,R{-}S_2O_3^{\ominus}$$

This reaction is utilized in the determination of cysteine and cystine with "Folin's reagent", a phosphorus-tungsten heteropolyacid [74].

Bunte salts have also been prepared from aromatic disulfides and in particular from amino-substituted disulfides and sodium or potassium bisulfite [75, 76]. Nitro-substituted aromatic disulfides are reported to react similarly and to give excellent yields; depending on the oxidation potential of the intermediate thiol, sodium bisulfite itself can act as the oxidizing agent, promoting almost complete Bunte-salt formation. The course of the reaction can be explained to some extent by the scheme proposed by *Lecher* and *Hardy* [23],

$$4\,R{-}S{-}S{-}R + 4\,KHSO_3 \quad 4\,RSH + 4\,R{-}S_2O_3K \qquad (h)$$

$$4\,RSH + 2\,KHSO_3 \rightarrow 2\,R{-}S{-}S{-}R + K_2S_2O_3 + 3\,H_2O \qquad (i)$$

$$2\,R{-}S{-}S{-}R + 6\,KHSO_3 \rightarrow 4\,R{-}S_2O_3K + K_2S_2O_3 + 3\,H_2O$$

in which the bisulfite, as the oxidizing agent, is brought into the correct relationship with the thiol in equation (i). This would readily explain the very good yields of Bunte salts in the reaction of aromatic disulfides with bisulfites, even in the absence of air [23].

c) Bunte Salts from Thiols and Alkali Metal Sulfites in the Presence of an Oxidizing Agent

The reaction of thiols with sulfurous acid in the presence of an oxidizing agent, *e.g.* elementary iodine, gives the desired Bunte salts only in poor yields [77].

$$RSH + SO_3^{2\ominus} \xrightarrow{-2e^{\ominus}} R{-}S_2O_3^{\ominus} + H^{\oplus}$$

In reactions with aromatic thiols, *Bernthsen* [78] used air as the oxidizing agent. "Oxidative sulfitolysis", *i.e.* the reaction of sulfurous acid with thiols or disulfides [71, 72], has been studied in protein chemistry with particular reference to the quantitative colorimetric determination of cysteine and cystine with Folin's reagent [74].

d) Bunte Salts from Thiols and Chlorosulfonic Acid, Sulfur Trioxide, or SO_3-Pyridine Complexes

Aliphatic thiols, preferably with long (C_8–C_{18}) branched or unbranched chains, react at low temperatures with chlorosulfonic acid in the presence of an inert diluent such as ether in accordance with reaction (j). Subsequent neutralization with alkali metal hydroxide or ammonium hydroxide yields Bunte salts having surface-active properties [79].

$$RSH \xrightarrow[-HCl]{+\,ClSO_3H} R{-}S_2O_3H \xrightarrow{MOH} R{-}S_2O_3M + H_2O \qquad (j)$$

When sulfur trioxide is used instead of chlorosulfonic acid as the sulfating agent, compounds of the same type are obtained at −78 °C in difluorodichloromethane [80]:

$$RSH + SO_3 \longrightarrow R{-}S_2O_3H$$

At higher temperatures the thiol is oxidized [81] to the disulfide, *e.g. (8)*.

$$2\,C_6H_5SH + SO_3 \longrightarrow (C_6H_5S)_2 + SO_2 + H_2O \qquad (8)$$

SO_3-pyridine complexes [82] give quantitative yields of pyridinium *S*-arylthiosulfates such as *(9)* [83, 114].

$$C_6H_5SH + SO_3{\cdot}C_5H_5N \longrightarrow C_6H_5{-}S_2O_3^{\ominus}C_5H_6N^{\oplus} \qquad (9)$$

e) Bunte Salts from Sulfenyl Chlorides or Amides and Sulfurous Acid

Amides of aromatic sulfenic acids react with sulfurous acid to form *N*-substituted ammonium *S*-arylthiosulfates *(10)* [84].

$$Ar{-}S{-}NRR' + H_2SO_3 \longrightarrow Ar{-}S_2O_3^{\ominus}\,{}^{\oplus}NH_2RR' \qquad (10)$$

In most cases it is sufficient merely to digest the amide in concentrated aqueous sulfurous acid with gentle warming. The Bunte salts are readily obtainable by treatment of the ammonium salts *(10)* with alkali metal hydroxides.

Aromatic sulfenyl chlorides [85] react with alkali metal sulfite in aqueous media to form Bunte salts *(11)*.

$$C_6H_5S{-}Cl + Na_2SO_3 \longrightarrow C_6H_5S_2O_3Na + NaCl \qquad (11)$$

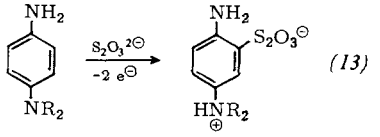
[84] *H. Z. Lecher* and *E.M. Hardy*, US.-Pat. 2706200 (1953).

[85] *Geigy*, Dissertation, Universität München, 1923.

The method is not generally applicable, and is restricted to relatively stable sulfenyl chlorides.



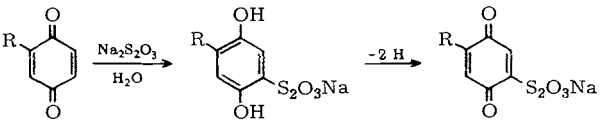
9-Anthryl dithiochloride, which is similar in structure, and which is readily obtainable from anthracene and sulfur monochloride, is converted by aqueous sodium sulfite solution into the sodium salt of *S*-(9-anthryl)-thiosulfuric acid *(12)*, with separation of elementary sulfur [86].

(12)

f) Bunte Salts from Aromatic 1,4-diamines and Thiosulfuric Acid in the Presence of an Oxidizing Agent

Bernthsen [78] observed that in the presence of aluminum thiosulfate and dichromate in acid solution, *p*-dimethylaminoaniline reacts to form *S*-(2-amino-5-dimethylammoniophenyl)thiosulfate *(13)*.

(13)



R = CH_3

The same inner salt is obtained by the reaction of 4-nitroso-*N*,*N*-dimethylaniline with aqeous thiosulfuric acid. In this case the nitroso group evidently brings about the substitution of the aromatic amine by thiosulfate [87,88].

The Bernthsen method has been studied for a number of 1,4-phenylenediamines, and has also been extended to related amines [89–92]. Di- and tetrathiosulfates of 1,4-phenylenediamine can be prepared by addition of the oxidizing agent and thiosulfate [93] in a suitable excess.

g) Addition of Thiosulfate to Quinones

p-Quinones add sodium thiosulfate in the presence of aqueous acetic acid [88,94,95] to give the sodium salts of substituted *S*-(2,5-dihydroxyphenyl)thiosulfuric acids *(14)*.

(14)

The reaction is applicable to quinones in general [96], including 1,4-naphthoquinones [88]. The Bunte salts *(14)* can be dehydrogenated under mild conditions to quinonethiosulfates [88].

h) Addition of Thiosulfate to Divinyl Sulfone

Sodium thiosulfate adds to divinyl sulfone in aqueous bicarbonate solution [97,98].

$$O_2S(CH{=}CH_2)_2 \xrightarrow[H_2O]{Na_2S_2O_3} O_2S(CH_2{-}CH_2{-}S_2O_3Na)_2$$

(15)

Because of the sensitivity of the Bunte salt *(15)* toward alkali, the reaction is best carried out in the presence of carbon dioxide. Dyes with vinyl sulfone residues have recently been converted into Bunte salts under similar conditions [99]. Under conditions analogous to those suggested by *Stahmann et al.* for the formation of Bunte salts from divinyl sulfone [97], aromatic vinyl sulfones can be converted into arylsulfonylethylthiosulfuric acids or their alkali metal salts [100]. They are much more stable toward alkalis than the sulfates of similar structure.

i) Reaction of Epoxyalkanes with Sodium Thiosulfate

Whereas 1,2-epoxyalkanes generally react with sodium bisulfite or thiosulfate with ring cleavage to form derivatives of 2-hydoxyethanesulfonic acid (isethionic acid) [101,102], cases have also been reported in which epoxyalkanes react with thiosulfate in the neutral or weakly alkaline range to give *S*-(2-hydroxyalkyl)thiosulfates [103,104]. An example of such a reaction is shown in equation (k).

$$H_2C\text{-}CH\text{-}CH_2Cl \xrightarrow[H_2O]{Na_2S_2O_3} ClCH_2\text{-}\underset{OH}{CH}\text{-}CH_2\text{-}S_2O_3Na \qquad (k)$$

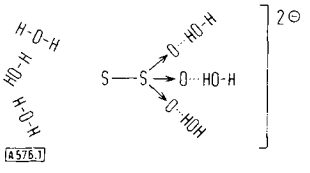
j) Addition of Thiosulfate to Activated Multiple Bonds

With few exceptions, *e.g.* the preparation of *S*-2,2,2 - trifluoro - 2 - (trifluoromethyl)ethylthiosulfate $[(F_3C)_2CH-S_2O_3Na]$ [105], which was obtained from hexafluorothioacetone and sodium bisulfite, the methods described in Sections 2a–2i for the synthesis of Bunte salts have been in use for some time.

We have discovered a new, simple method for the preparation of Bunte salts *i.e.* the addition of thiosulfate in aqueous solution to compounds containing activated double bonds, in accordance with reaction (l).

$$R-CH=CH_2 + S_2O_3^{2\ominus} \underset{aq.}{\rightleftharpoons} [R-\overset{\ominus}{C}H-CH_2-S_2O_3^{\ominus}] \underset{OH^{\ominus}}{\overset{H^{\oplus}}{\rightleftharpoons}} R-CH_2-CH_2-S_2O_3^{\ominus} \quad (l)$$

The discovery of this method resulted from consideration of the reactivity of the thiosulfate ion. It had been recognised even by *Bunte* [1] that thiosulfate must contain centers of differing reactivity, since only *S*-alkyl thiosulfates are obtained with alkyl halides [*]. A simple model shows that the four nucleophilic centers of the thiosulfate ion differ in their hydration sheath in aqueous solution (Fig. 1).



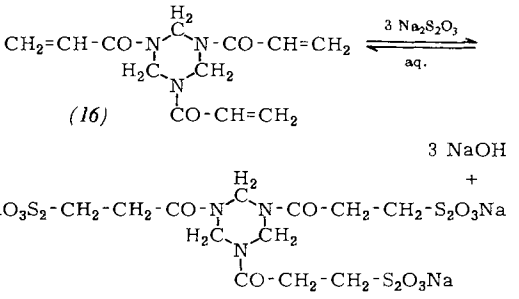


Fig. 1. Model representation of the solvation of the thiosulfate ion.

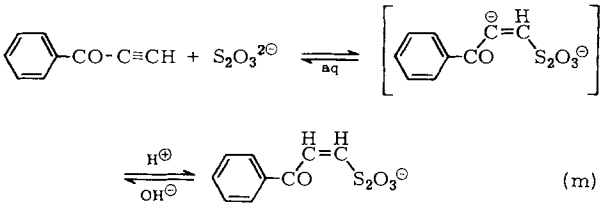
Whereas the oxygen atoms of the anion form hydrogen bonds with the water molecules, so that a structured and relatively stable solvation sheath is built up in the neighborhood of the three oxygen atoms, only a labile hydration sheath is found in the vicinity of the sulfur, owing to the low tendency of the latter to form hydrogen bonds. Thus reactions will take place preferentially on the S atom, where the hydration sheath is most easily stripped off.

Consequently, in nucleophilic substitutions such as equation (a) or in the nucleophilic addition of the thiosulfate ion to activated multiple bonds [*e.g.* equations (c) and (d)], the sulfur atom of the solvated anion reacts preferentially.

Examples of compounds containing activated double bonds that give Bunte salts on reaction with thiosulfate are derivatives of acrylic and α-methacrylic acids, vinylsulfonic acid, and methyl vinyl ketone. The applicability of the method has already been confirmed with a large number of monomers [107]. Polyunsaturated compounds such as the hexahydrotriazine derivative *(16)* [147] or the resorcinol ester of bisvinylsulfonic acid [5] also add on one or more thiosulfate ions. The solubility of *(16)* ("triacrylformal") in water is greatly improved by the introduction of one, two, or three thiosulfate groups.



(16)

The reaction is generally carried out at pH = 3–9, and preferably in neutral solution at 60–100 °C. Since one mole of alkali is liberated for every mole of thiosulfate used, preparations are carried out at pH = 6–8, this pH value being maintained by the addition of an acid.

At lower pH values and at temperatures between 60 and 80 °C, the thiosulfate begins to decompose. If the addition of the thiosulfate is not controlled by introduction of an acid, the reaction immediately stops. It has been found very advantageous to use a weak acid such as acetic or propionic acid, since it is then possible to work in acetate buffer, in which both thiosulfate and the Bunte salt are stable. Solvents such as methanol or ethanol can be advantageously used for the reaction of compounds that are sparingly soluble in water. The reaction can also be carried out in fused hydrated sodium thiosulfate, in the absence of water or other solvents. Iodometric titration may be used to follow the course of the reaction (time 1–2 hours).

According to *Kerber* and *Starnick* [109], the addition of thiosulfate to compounds containing activated triple bonds can be carried out under similar conditions. The reaction of 1-phenyl-2-propyn-1-one *(17)* may be assumed to proceed in accordance with equation (m).

(m)

The resulting Bunte salts occur mainly as *cis* compounds, and are remarkable in that they contain the first known example of a thiosulfate group directly attached to an olefinic C-atom (cf. [2], page 74). *Kerber* and *Starnick* observed no further reaction of the unsaturated Bunte salts with thiosulfate.

3. Reactions of Bunte Salts

The principal reactions of Bunte salts have been described in detail by *Milligan* and *Swan* [2]; the present discussion will therefore be confined to more recent work. Bunte salts resulting from the nucleophilic addition of thiosulfate to activated multiple bonds exhibit a particularly interesting behavior in alkaline media. These rections have been studied in detail; they offer new possibilities, primarily in connection with the fixation of unsaturated organic compounds *e.g.* to cellulose, leather, and polypeptides.

[106] *M. Schmidt, A. Bauer,* and *H. Rampf,* Angew. Chem. *70,* 399 (1958).

[*] *O*-Substituted esters of thiosulfuric acid cannot be obtained in this way. *O*-Alkyl thiosulfates are extremely unstable substances, which can be obtained, *e.g.* by the reaction of free thiosulfuric acid with diazomethane in ether at *ca.* −50 °C [106].

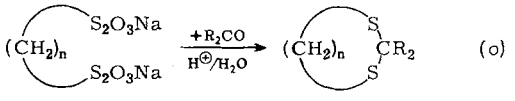
a) Behavior of Bunte Salts toward Acids



The hydrolysis of sodium *S*-ethylthiosulfate by aqueous acid was correctly recognized by *Bunte*[1] [eq. (n)].

$$C_2H_5{-}S_2O_3Na + H_2O = NaHSO_4 + C_2H_5SH \qquad (n)$$

The salt must generally be heated for several hours with dilute acid for complete hydrolysis. Except in special cases (the reaction of sodium benzoylmethylthiosulfate with acid gives 2,5-diphenyl-1,4-dithiin), the method is suitable for the preparation of thiols[15,17,23,110,111].

A particularly interesting use of Bunte salts is for the preparation of thioacetals and thioketals[14,112], which are obtained from carbonyl compounds and thiols. The Bunte salts are hydrolysed with acid in the presence of aldehydes or ketones.

Cyclic thioacetals and thioketals can be obtained in this way by the use of the α,ω-alkylenebis(thiosulfates) and formaldehyde or acetone respectively[12,113] [eq. (o)].

(o)

n = 2,3; R = H, CH_3

b) Behavior of Bunte Salts toward Alkalis

According to the literature, the alkaline degradation of Bunte salts is very complex[86]. On the basis of the degradation products (sulfenic acids[7,8,114,115], disulfides, carboxylic acids, thiocarboxylic acids, sulfurous acid, thioethers, and sulfinic acids), several reaction mechanisms, in some cases strongly contradictory, have been proposed[9,10,116,117]. On the other hand, a clear and unambiguous reaction course was found for *S*-alkylthiosulfates, resulting from the addition of thiosulfate to compounds containing activated multiple bonds. In 1946 *Stahmann et al.*[97] observed that the Bunte salt *(15)* of divinyl sulfone partially decomposes into a substance that readily takes up iodine. In 1961, *Tesoro et al.*[118,98] assumed that the divinyl sulfone is reformed in accordance with equation (p) during the reaction of the divinyl sulfone

$$(NaO_3S_2{-}CH_2{-}CH_2)_2SO_2 + 2\ NaOH \longrightarrow \underset{(15)}{} SO_2(CH{=}CH_2)_2 + 2\ Na_2S_2O_3 + 2\ H_2O \qquad (p)$$

Bunte salt with cellulose in alkaline media. Bunte salts of vinyl sulfones are reported to behave in a similar manner[119].

So far as we know, no definite proof of the course of the reaction is as yet available, presumably because divinyl sulfone is immediately hydrated in accordance with equation (q) in the presence of aqueous alkali[118]. The resulting bis(β-hydroxyethyl) sulfone *(17)* reacts with divinyl sulfone under the catalytic influence of hydroxide ions to form a water-insoluble adduct having a high molecular weight.

$$(CH{=}CH_2)_2SO_2 + 2\ H_2O \xrightarrow{(OH^{\ominus})} \underset{(17)}{SO_2(CH_2{-}CH_2OH)_2} \qquad (q)$$

The Bunte salts of aryl vinylsulfonates such as *(18)*, which crystallize very readily, can be quantitatively, converted back into the unsaturated starting compounds by treatment with aqueous alkali [equation (r)].

$$p\text{-}O_2N{-}C_6H_4{-}OSO_2{-}CH_2{-}CH_2{-}S_2O_3Na \xrightarrow{NaOH} \underset{(18)}{} p\text{-}O_2N{-}C_6H_4{-}OSO_2{-}CH{=}CH_2 + Na_2S_2O_3 + H_2O \qquad (r)$$

No hydration of the resulting vinylsulfonate under the influence of the hydroxide ions could be observed. Thus the degradation of these Bunte salts *(18)* in alkaline media is the reverse of their formation [see eq. (1)]. This cleavage evidently takes place with all Bunte salts formed by the addition of thiosulfates to activated CC multiple bonds. Deviations from this rule are to be expected only as a result of secondary reactions, such as hydration of the double bond under the influence of strong alkali[118].

c) The Alkaline "Fixation" of Bunte Salts on Cellulose and Other Fibers

In the fixation of dyes and unsaturated compounds on fabrics, the functional groups of the fiber react as nucleophiles, *e.g.* OH groups of cellulose, amino and thiol groups of wool, or amide groups in synthetic polyamides.

Whereas reactive dyes undergo a reaction with cellulose that may be regarded as nucleophilic substitution or as nucleophilic addition[159,120], "Bunte salt dyes"[121] do not react with the fiber. Suitable pretreatment with condensing agents such as sodium sulfide solution is followed by a polycondensation to give a water-fast bond *via* disulfide bridges [cf. eq. (s)].

$$2\ R{-}S_2O_3Na + Na_2S \longrightarrow R{-}S{-}S{-}S{-}R + 2\ Na_2SO_3 \qquad (s)$$

$$R{-}S{-}S{-}S{-}R + Na_2SO_3 \xrightarrow{(Na_2S)} R{-}S{-}S{-}R + Na_2S_2O_3$$

[111] *T. S. Price* and *D. F. Twiss*, J. chem. Soc. (London) *95*, 1725 (1909).

[112] *G. G. Stoner* and *G. Dougherty*, J. Amer. chem. Soc. *63*, 987 (1941).

[113] *Y.G. Mazover*, Ž. obšč. Chim. *19*, 843 (1949); Chem. Abstr. *44*, 3436 (1950).

[114] *A. Dornow*, Chem. Ber. *72*, 568 (1939).

[115] *K. Fries*, Chem. Ber. *45*, 2965 (1912).

[116] *E. Fromm* and *F. Erfurt*, Chem. Ber. *42*, 3816 (1909).

[117] *T. S. Price* and *D. F. Twiss*, J. chem. Soc. (London) *97*, 1175 (1910).

[118] *G. Tesoro*, *P. Linden*, and *St. B. Sello*, Textile Res. J. *31*, 283 (1961).

[119] *G. Tesoro* and *A. Oroszlan*, Textile Res. J. *33*, 93 (1963).

[120] *O. A. Stam*, J. Soc. Dyers Colorists *80*, 416 (1964).

[121] *K. Schimmelschmidt*, *H. Hoffmann*, and *E. Baier*, Angew. Chem. *74*, 975 (1962); Angew. Chem. internat. Edit. *2*, 30 (1963).

Since "Bunte salt dyes" in general must contain two or more *S*-alkylthiosulfate groups per molecule, it is understandable that condensation with sodium sulfide on the cellulose will lead to a highly cross-linked polydisulfide. Similar highly cross-linked polysulfides were obtained by *Tabushi et al.*[122] with Bunte salts that were prepared *via* chloromethylated polystyrene and sodium thiosulfate and then condensed with sodium sulfide.

Unlike cellulose, wool should react directly with the "Bunte salt dyes" by means of its free SH groups to give disulfides[120,123].

Bunte salts formed by nucleophilic addition to activated multiple bonds should be particularly suitable for "fixation" in alkaline media. This must be assumed to involve 1,2-elimination of thiosulfate ions in the aqueous alkali [eq. (t)].

$$R\text{-}CH_2\text{-}CH_2\text{-}S_2O_3^{\ominus} \xrightarrow{OH^{\ominus}} [R\text{-}\overset{\ominus}{C}H\text{-}CH_2\text{-}S_2O_3^{\ominus}] + H_2O$$
$$\xrightarrow{\text{stabilization}} R\text{-}CH{=}CH_2 + S_2O_3^{2\ominus} \qquad (t)$$

R = *e.g.* COOR′, COOH, $CO\text{-}NH_2$, $SO_2\text{-}OR'$, CO-R′, SO_2NH_2, $SO_2\text{-}NR'_2$

The vinyl derivative can again undergo nucleophilic additions. Nucleophilic reagents in general, such as thiols and alcohols, amines, *etc.*, are suitable for this reaction. The compound is then fixed on cellulose in the usual manner. R′SH, $R'NH_2$ and R'_2NH add on in the same way.

$$R\text{-}\overset{\delta\ominus}{C}{=}\overset{\delta\oplus}{C}\text{-} \underset{-R'O^{\ominus}}{\overset{+R'O^{\ominus}}{\rightleftharpoons}} R\text{-}\overset{\ominus}{C}\text{-}C\text{-}OR' \underset{-H^{\oplus}}{\overset{+H^{\oplus}}{\rightleftharpoons}} R\text{-}\underset{H}{C}\text{-}C\text{-}O\text{-}R'$$

R = $COOR''$, COOH, $CONH_2$, SO_2OR'', $CO\text{-}R''$, $SO_2\text{-}NH_2$, $SO_2\text{-}NR''_2$

It is possible in principle to fix many unsaturated monomers that have recently become readily available, and which are often sparingly soluble in water, by masking as Bunte salts as described above. When the Bunte salts derived *e.g.* from 1,3,5-tris(vinylcarbonyl)-hexahydro-*s*-triazine *(16)* (triacrylformal)[124] or resorcinol bis(vinylsulfonate)[5] are used, cross-linking effects occur.

d) Behavior toward Oxidizing Agents

The oxidation of *S*-alkylthiosulfates yields disulfides, sulfonic acids, or their derivatives, depending on the oxidizing agent and the reaction conditions. On oxidation of *S*-ethylthiosulfate with nitric acid, *Bunte*[1] obtained ethanesulfonic acid and sulfuric acid. Hydrogen peroxide leads mainly to disulfides[68,103,125–127], as does iodine in hot aqueous ethanol[68,103,127–129,125]. Oxidation with bromine water yields both disulfides[18,19,30] and sulfonic acids[130].

e) Behavior toward Halogens in the Presence of Water

In 1936 *Johnson et al.* found[131,132] that sulfur compounds in general can be converted into sulfonyl halides *(19)* by halogenation in water.

$$R\text{-}S\text{-}R' \xrightarrow[2\ H_2O]{3\ Cl_2} R\text{-}SO_2Cl + 4\ HCl + R'Cl$$
(19)

Bunte salts can be converted similarly into the corresponding sulfonyl halides[133–136]. For analytical purposes[137], bromine water is used instead of chlorine water, so that not only *S*-alkylthiosulfates, but also thiols, disulfides, thiocyanates, and similar sulfur compounds can be converted into sulfonyl bromides. These react with a cyanide to liberate cyanogen bromide, which can then be determined colorimetrically.

f) Reduction of Bunte Salts

The reduction of *S*-alkylthiosulfates with conventional agents, such as sodium amalgam[77], zinc and acid[78,89,93,94,138], or alkaline sodium arsenite solution[7,8] leads to thiols. However, this method is of little importance for the preparation of thiols, which can be obtained much more elegantly by cleavage of *S*-alkylthiosulfates with acid.

g) Reaction with Cyanides

S-Alkylthiosulfates are smoothly converted into thiocyanates in the presence of aqueous alkali metal cyanide solution, even at room temperature[76,139].

$$R\text{-}S_2O_3Na + NaCN \longrightarrow RSCN + Na_2SO_3$$

Dyes containing *S*-alkylthiosulfate residues can be readily converted into thiocyanates in this manner; these can sometimes undergo ring closure with ad-

[139] *H. B. Footner* and *S. Smiles,* J. chem. Soc. (London) *1925*, 2887.

jacent groups [121]. For example, *S*-phenylcarbamoylmethylthiosulfate gives 2-imino-3-phenyl[1,3]thiazolidin-4-one *(20)*, ("3-phenylpseudothiohydantoin"), presumably *via* a linear thiocyanate [30].

(20)

h) Reaction with Iodides, Thiocyanates, and Thiourea

Bunte salts react with iodides, and with thiocyanates as pseudohalides, in the acidic range to form disulfides. Thiourea is reported to behave similarly [2].

i) Reaction with Thiols and Alkali Metal Sulfides

Thiols react with *S*-alkylthiosulfates in alkaline solution to form disulfides [139].

$$RS^{\ominus} + R'-S_2O_3^{\ominus} \rightleftharpoons R-S-S-R' + SO_3^{2\ominus}$$

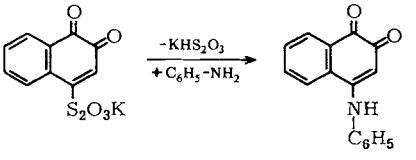
When R and R′ are the same, the resulting disulfides are symmetrical. Systems in which R and R′ are dissimilar do not yield unsymmetrical disulfides, but give equimolar mixtures of the symmetrical disulfides. However, high yields of unsymmetrical disulfides are reported to be obtained when the reaction is carried out in weakly acidic solutions [140].

The reaction of sulfide ions with Bunte salts in aqueous solution is very complex. Hydrodisulfides together with sodium sulfite [141] as well as disulfides [78] or trisulfides [19] have been suggested as intermediates and/or reaction products. The behavior of dyes containing *S*-alkylthiosulfate residues toward aqueous sulfide solutions is of industrial importance. The reaction leads mainly to water-insoluble aliphatic disulfides, which, unlike aromatic disulfides, are stable toward sulfide ions [121] (cf. Section 3c); the following reactions probably occur:

$$2\ R-S_2O_3Na + Na_2S \longrightarrow R-S-S-S-R + 2\ Na_2SO_3$$

$$R-S-S-S-R + Na_2SO_3 \xrightarrow{Na_2S} R-S-S-R + Na_2S_2O_3$$

Bunte salts formed by nucleophilic addition of thiosulfate to activated double bonds react differently. The hydroxide ions probably split the Bunte salt into thiosulfate and a compound containing an activated CC double bond. The much more nucleophilic thiolate ion then competes with the thiosulfate ion to form the thioether *(21)* [5, 142] in accordance with equation (u).



$$R-CH_2-CH_2-S_2O_3^{\ominus} \xrightarrow{OH^{\ominus}} [R-\overset{\ominus}{C}H-CH_2-S_2O_3^{\ominus}] + H_2O \longrightarrow R-CH=CH_2 + S_2O_3^{2\ominus} \quad (u)$$

$$R-CH=CH_2 + R'S^{\ominus} \longrightarrow [R-\overset{\ominus}{C}H-CH_2-S-R'] + H^{\oplus} \longrightarrow R-CH_2-CH_2-S-R' \quad (21)$$

R = *e.g.*, $COOR''$, $CONH_2$, SO_2OR'', COR'', SO_2NH_2, $COOH$

j) Reaction with Amines

S-Alkylthiosulfates generally react with amines to form disulfides [2]. An exception was found with Bunte salts of quinones, which undergo nucleophilic substitution with aromatic amines to give the arylaminoquinone, *e.g. (22)* [143].

(22)

A number of marked deviations from normal behavior are observed in the reaction of Bunte salts with amines. These have been extensively studied, particularly by *Swan* and *Milligan* [30, 144].

4. Properties and Use of Bunte Salts

a) General Characteristics

Owing to the presence of the NaS_2O_3 groups, the *S*-alkylthiosulfates are mostly very readily soluble in water, methanol, ethanol, and other polar solvents. The Bunte salts can be purified by recrystallization from alcohol or alcohol-water mixtures. The salts are occasionally obtained with one molecule of water of crystallization per molecule. Neutral aqueous solutions are frequently decomposed within a few minutes at 100 °C, as can be seen from the turbidity of the solution. Salts of alkali metals or, less commonly, of alkaline earth metals can be used for their isolation. Lead and silver salts are occasionally suitable for the characterization of a compound. It should be noted that *S*-alkylthiosulfates, which crystallize excellently from *e.g.* alcohol, do not have a true melting point, but rather a sort of sintering point, at which the salt agglomerates like a glass. Dry heating [1, 145] frequently leads to decomposition above 100 °C. According to *Bunte* [1], sodium *S*-ethylthiosulfate decomposes into diethyl disulfide, sulfur dioxide, and sodium sulfate.

$$2\ CH_3CH_2-S_2O_3Na \xrightarrow{>100\,^{\circ}C} SO_2 + (C_2H_5)_2S_2 + Na_2SO_4$$

[140] *J. M. Swan*, Nature (London) *180*, 643 (1957).
[141] *A. Gutmann*, Chem. Ber. *48*, 1162 (1915).
[142] *H. Distler*, unpublished.
[143] *G. Heller*, J. prakt. Chem. *108*, 257 (1924).
[144] *B. Milligan* and *J. M. Swan*, J. chem. Soc. (London) *1961*, 1184.
[145] *A. Purgotti*, Gazz. chim. ital. *20*, 25 (1890).

Further characterization is possible by the reaction of the *S*-alkyl-thiosulfates in aqueous alkali with Hg(II) chloride solution, which leads after brief warming to mercaptides such as *(23)* [11].

$$CH_3CH_2-S_2O_3^{\ominus}Na^{\oplus} + HgCl_2 + H_2O \longrightarrow C_2H_5SHgCl + HCl + NaHSO_4$$

(23)

b) Spectra of Bunte Salts

Kunath [146] and *Simon* [108] found a number of characteristic absorption bands for Bunte salts in the regions 640–660 cm^{-1}, 1040–1050 cm^{-1}, and 1190 to 1250 cm^{-1}. We have been able to confirm these data for a large number of Bunte salts [148]: the bands are generally situated at 648–650 cm^{-1}, 1040–1048 cm^{-1}, and 1210–1215 cm^{-1}.

c) Biological Action

Sodium *S*-ethylthiosulfate exhibits a striking synergic effect when used with the bacteriostat 2-mercaptobenzothiazole and its derivatives against *Staphylococcus aureus* [149]. A similar synergic effect was observed with sodium *S*-ethylthiosulfate and 2-mercaptobenzothiazole against the tubercle bacillus [150].

Sodium *S*-(3-nitrophenyl)thiosulfate is reported to have a particularly strong preventative and curative action against fowl coccidiosis [23]. According to our own observations, Bunte salts obtained *e.g.* by addition of thiosulfate to aryl vinylsulfonates have a considerable effect on *Aspergillus niger* [151]. Other adducts of thiosulfate with acrylic acid derivatives have a systemic-nematocidal action [151].

d) Industrial Use

Most patents dealing with the production and the use of Bunte salts are concerned with the textile industry. The "Bunte salt dyes" [121] have attracted particularly wide industrial interest in this field. Bunte salts derived from divinyl sulfone have recently found industrial use in the finishing of textiles, and particularly of cotton [161, 152, 153], in the Stevenset Super-Crease Process developed by *J.P.Stevens* (U.S.A.) [162].

The hydrophilic Bunte-salt group gives long-chain hydrophobic compounds a surface activity comparable with that of the sulfation products of fatty alcohols [154, 28, 155–158, 62–64].

I am grateful to Dr. Lützel for perusal of this article. I should like to thank Dr. Feichtmayr for stimulating discussions, particularly on the reactivity of the thiosulfate anion.

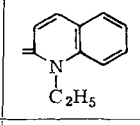
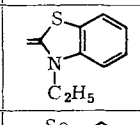
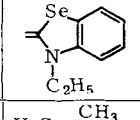
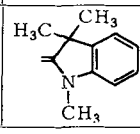
The Cyclobutenediylium Cation, a Novel Chromophore from Squaric Acid

By *H.-E. Sprenger* and *W. Ziegenbein* [*]









Dedicated to Professor F. Asinger on his 60th Birthday

Tertiary amines [1] and azulenes [2], like active pyrroles and phenols [3], condense smoothly with squaric acid (dihydroxycyclobutenedione), giving products that contain the structural element of cyclobutenonolate. Although these compounds are deeply colored it is problematical whether they are to be regarded as cyanine dyes [4]. In agreement with the conceptions of aromatic character and the results of other authors [5], structure *(1)* can be assigned to these dyes.

We have introduced, as nucleophilic components, the bases obtained by elimination of HI from 2-methyl-substituted quinolinium, benzothiazolium, and benzoselenazolium iodide. These also yield crystalline, intensely colored, betaine-like dyes *(2)*, which were hitherto unknown. The Fischer base reacts analogously with squaric acid giving the condensation

thiazolium iodides. Under the same conditions malonodinitrile gives a 92% yield of the deep yellow salt *(4)* [λ_{max} (in water): 380 mμ (ε = 34000), 265 (12000), 226 (15400)].

The structures of compounds *(2)* to *(4)* were proved by elemental analysis and UV, IR, and NMR spectra[**]. Dyes of types *(2)* and *(4)* can be differentiated by thin-layer chromatography.

Preparation of (2b): *N*-Ethyl-2-methylbenzothiazolium iodide (305.3 g) and squaric acid (57 g) are boiled in a mixture of butanol (1500 ml), benzene (600 ml), and quinoline (129 g) for *ca.* 20 h with simultaneous removal (azeotropic distillation) of the water formed. After cooling, the crystals (with a green metallic sheen) are filtered off and, when washed with ether and dried, are analytically pure. Compounds *(2a)*, *(2c)*, and *(2d)* are obtained analogously, compound *(2d)*, however, without use of quinoline.

Preparation of (3a): *N*-Ethyl-4-picolinium iodide (24.9 g, 100 mmoles) and diethyl squarate (8.5 g, 50 mmoles) are dissolved in butanol (200 ml) and heated to the boiling point. Sodium butoxide solution (50 ml, containing 5.5 wt-% of sodium) is added dropwise and the whole is heated under reflux for a further 10 min. Subsequent cooling yields crystals which are filtered off, boiled with a methanol/water mixture (1:1 v/v; 100 ml), washed several times with methanol and ether, and recrystallized from dimethylformamide. Compounds *(3b)* to *(3e)* were obtained analogously.

Preparation of (4): Malonodinitrile (6.6 g, 100 mmoles) and dibutyl squarate (11.3 g, 50 mmoles) are dissolved in butanol (100 ml) and heated under reflux. A sodium butoxide solution (50 ml, containing 5.5 wt-% of sodium) is added dropwise and the whole is stirred for a further 2 h under reflux. The crystals formed are removed by filtration. After being washed with methanol and ether and dried for two days in a vacuum over phosphorus pentoxide at 50 °C the product is analytically pure.

A New Synthesis of the Adamantane Ring System

By *H. Stetter* and *H. G. Thomas*[*]

Dedicated to Professor B. Helferich on his 80th Birthday

The synthesis of bicyclic ring systems by the action of dimethyl γ-bromomesaconate on enamines of cyclic ketones was recently reported[1]. Starting from this observation we have developed a new, prolific synthesis of the adamantane ring system whose value lies in the fact that it provides a route to adamantane derivatives that cannot be obtained by direct substitution.

The starting material is diethyl 4-oxocyclohexane-1,1-dicarboxylate *(1)*, which is accessible from malonic ester and 3-bromopropionic ester in one step and in high yield[2]. This is converted by pyrrolidine into the enamine *(2)*. Refluxing *(2)* with ethyl 2-(bromomethyl)acrylate[3] in ethanol/acetonitrile (1 : 1) for six hours and subsequent fractionation under

vacuum affords diethyl 2,6-dioxoadamantane-1,3-dicarboxylate *(4)*, b.p. 203–206 °C/3 mm, m.p. 113–114 °C, directly. Wolff-Kishner reduction of this product to the known adamantane-1,3-dicarboxylic acid[4] serves as a proof of structure. We assume that triethyl 9-oxobicyclo-[3.3.1]nonane-3,3,7-tricarboxylate *(3)* is formed as intermediate in the reaction *(2)* → *(4)* and then undergoes cyclizing ester condensation.

Ethylene glycol converts the ketone *(4)* into the monoketal *(5)*, m.p. 118 °C, whose structure is proved by formation of a pyrazolone *(6)*, m.p. 183–184 °C, with *p*-nitrophenylhydrazine. Catalytic hydrogenation of *(5)* afforded the hydroxy ketal *(7)*, m.p. 99 °C, from which diethyl 2-hydroxy-6-oxoadamantane-1,3-dicarboxylate *(8)*, m.p. 111–112 °C, is formed on hydrolysis. 2-Hydroxyadamantane-1,3-dicarboxylic acid *(9)*, m.p. 229–230 °C, was obtained by Wolff-Kishner reduction of *(8)*.

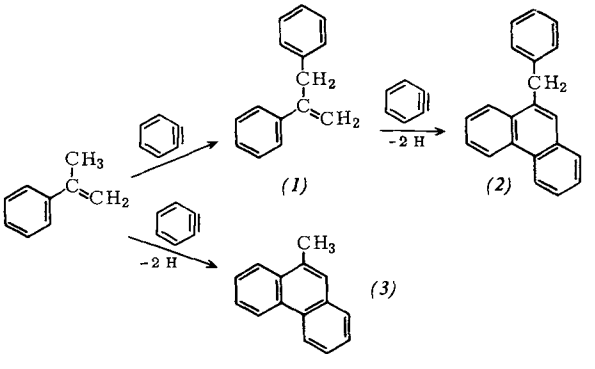
Reaction of Benzyne with α-Methylstyrene

By *E. Wolthuis* and *W. Cady*[*]

Dedicated to Professor G. Wittig on the occasion of his 70th birthday



Benzyne reacts with isosafrole and isoeugenol by normal 1,4-addition to give substituted phenanthrenes[1]. We have found that benzyne reacts with α-methylstyrene by substitution as well as by addition.

Solutions of 0.1 mole of anthranilic acid in tetrahydrofuran (THF) and 0.19 mole of isoamyl nitrite in THF were added simultaneously to a solution of 0.1 mole of α-methylstyrene in THF at 55–60 °C. The solvent was subsequently removed under vacuum and the residue was dissolved in benzene. The benzene solution was extracted with dilute sodium hydroxide to remove dark, acidic material, including acridone, and finally evaporated to dryness. The residue was dissolved in hexane, filtered to remove any precipitated acridone, and chromatographed on a column of alumina. Elution with hexane, and finally with hexane containing up to 20% benzene, gave the following products, in the order in which they are listed.

2,3-Diphenylpropene *(1)*[2], 6.19 g (32%), b.p. 100–105 °C/1 mm, 293 °C/750 mm. Its identity was established by its NMR spectrum, by hydrogenation, and by bromination.

9-Benzylphenanthrene *(2)*[3], 4.70 g (17.5%), m.p. 155 to 156 °C; picrate, m.p. 120.5–121 °C. Its structure was confirmed by NMR and UV spectroscopy.

9-Methylphenanthrene *(3)*[4], 0.75 g (4%), m.p. 93.1 to 93.6 °C; picrate, m.p. 154.5–156 °C. The structure was confirmed by NMR and UV spectroscopy.

Compound *(3)* is the expected product from a normal Diels-Alder reaction followed by aromatization with loss of hydrogen. The intermediate dihydro compound was sought but not detected; presumably the hydrogen was captured by benzyne, but our efforts to detect the formation of benzene by gas chromatography failed.

Compound *(1)* is formed apparently by substitution of the reactive allylic hydrogen by a phenyl group. The yields of *(1)* and *(3)* indicate that this substitution competes well with the 1,4-addition reaction.

Compound *(2)* is formed from *(1)* by further 1,4-addition reaction with benzyne. Evidence for this is the fact that when

benzyne was generated in a solution of *(1)* in THF, the only product isolated was *(2)*.

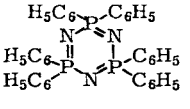
The Thermal Decomposition of Some Diphenylphosphinothioic Amides. A New Route to Arylcyclophosphazatrienes

By *R. A. Shaw* and *E. H. M. Ibrahim* [*]

Dedicated in sincere admiration to Professor Georg Wittig on the occasion of his 70th birthday

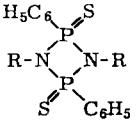
We recently described some novel reactions [1] in the thermal decomposition of phenylphosphonothioic diamides. We now report an even more diverse behavior in the thermal decompositions of diphenylphosphinothioic amides *(1)*.

The parent compound *(1a)* decomposes at 280 °C with evolution of ammonia to give the linear dimer bis(diphenylphosphinothioic)amide *(2a)* (yield 68 %, m.p. 213 °C). Two



$(C_6H_5)_2P(S)NHR$ — $(C_6H_5)_2P(S)-NR-(S)P(C_6H_5)_2$

(1a), R=H — *(2a)*, R=H

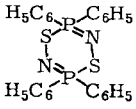


(1b), R=CH_3

(1c), R=C_6H_5 — *(2c)*, R=C_6H_5

side reactions also occur leading to 2,2,4,4,6,6-hexaphenylcyclotriphosphazatriene *(3)* (yield 7 %, m.p. 232 °C) and the cyclic dimer, 2,4-diphenylcyclodiphosphazane 2,4-bissulfide *(4a)* (yield 17.3 %, m.p. 242 °C) with the elimination of the elements of hydrogen sulfide and benzene respectively. We have proved structures of *(2a)*, *(3)*, and *(4a)* by elemental analyses, molecular-weight determinations, infrared spectroscopy, and for *(3)* by mixed melting point, and for *(2a)* and *(4a)* by hydrolytic degradation.

(3)



(4a), R = H

The thermal decomposition of *(1b)* (300–310 °C, *ca.* 1/2 h) yields *(3)* as the major product. A new compound bis(diphenyl-*N*-methylimidophosphinic) thioanhydride *(5b)* (yield 2.5 %, m.p. 169–170 °C) and the methyl ester of diphenyl phosphinodithioic acid *(6b)* (yield 12.6 %, m.p. 85 °C) are also obtained. The structure of *(5b)* was established by elemental analysis, molecular-weight determination, infrared and ^1H-NMR spectroscopy.

$(C_6H_5)_2P(NCH_3)-S-(CH_3N)P(C_6H_5)_2$ — $(C_6H_5)_2P(S)-SR$

(5b) — *(6b)*

The thermal decomposition (310–320 °C, *ca.* 1/2 h) of *(1c)* takes yet another course. The products are the linear dimer *(2c)* (yield 43 %, m.p. 220 °C) and a 3,3,6,6-tetraphenyl-1,4,2,5,3,6-diazadithiadiphosphorine *(7)* (yield 36 %, m.p. 265 °C), which is also obtained in the thermal decomposition of phenylphosphonothioic dianilide [2]. The structure of *(7)* was evidenced by elemental analysis, molecular-weight determination, and hydrolytic degradation to diphenylphosphinic acid [1].

(7)

All compounds have satisfactory elemental analyses.

Since the yield of *(3)* decreases rapidly in the series *(1b)* > *(1a)* > *(1c)*, *i.e.* R = CH_3 > R = H > R = C_6H_5, the electron supply to the nitrogen atom of the amide *(1)* seems to be an important factor in the formation of the cyclotriphosphazatriene *(3)*.

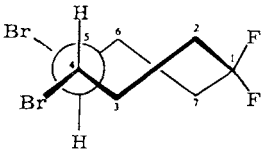
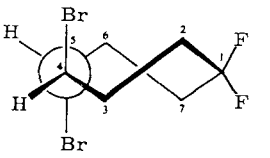
Ring Inversion in Cycloheptane and in Cycloheptene Derivatives

By *R. Knorr, C. Ganter,* and *J. D. Roberts* [*]



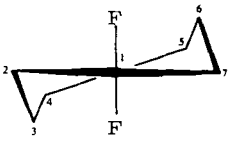
Dedicated to Professor G. Wittig on the occasion of his 70th birthday

Rapid pseudorotation [1] causes interconversion of substituent groups between "above" and "below" positions in cycloheptanes even at −150 ° [2] unless restrictions are imposed by bulky groups [2b, 3]. An especially interesting example of cycloheptane conformational preferences and rates of cycloheptane-ring inversion is provided by 4,5-*trans*-dibromo-1,1-difluorocycloheptane (m.p. = 52–54 °C). This substance was prepared from 4-cycloheptenone *via* several steps.

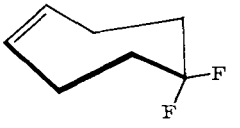


The ^{19}F-NMR spectrum of a 15 % solution of the substance in dimethyl ether was recorded (56.4 MHz; proton decoupling) at temperatures between *ca.* 25 ° and −126 °C. At temperatures below −118 °C two single lines (in the intensity ratio 74:26) were observed at 348 Hz and 550 Hz upfield from internal trifluoroacetic anhydride. These lines collapsed above −114 °C to a single line at the weighted center, 400 Hz.

The two resonances at 348 and 550 Hz are best ascribed to the separate conformations *(1a)* and *(1b)*, respectively. In each of these conformations of the twisted chair *(1)*, which has C2 symmetry, the fluorines are equivalent and will not show F–F coupling. Inspection of molecular models suggests that severe repulsive interactions occur in most of the other possible conformations and that *(1a)* is likely to be a little more flexible than *(1b)*.



The equilibrium ratio *(1b)*/*(1a)* = 0.35 was found to be temperature independent (signal weighted center constant at 400 Hz) from +25 to 126 °C in the same way as has been reported for 1,2-*trans*-dibromocyclohexane [4]. Exchange life times of τ_a and τ_b ($\tau_a : \tau_b$ = 74 : 26) were obtained by comparison with computer-simulated line shapes; at −114 °C, the coalescence point, τ_a = 0.0077 sec. The Eyring activation parameters determined for *(1a)* → *(1b)* between −126 °C and −77 °C were $\Delta H^{\ddagger}$ = 9.8 ± 0.3 kcal mole^{-1} and $\Delta S^{\ddagger}$ = +15 ± 3 e.u. The relatively high positive entropy of



(1a), 74%

(1b), 26%

(1)

(2)

activation suggests that the transition state for the process by which the fluorines become equivalent may be for conversion to the flexible boat form rather than for pseudorotation, which would be expected to proceed by way of highly strained intermediate conformations.

5,5-Difluorocycloheptene was prepared from *trans*-4,5-dibromo-1,1-difluorocycloheptane by debromination with zinc dust. The ^{19}F–NMR spectrum of a 10 % solution in propene (with the protons decoupled) showed a single AB system from −147 °C to the coalescence point of −92 °C, above which a single line was obtained at 4080 Hz. The A and B chemical shifts below −115 °C were 3280 Hz and 4882 Hz (upfield from internal standard bromotrifluoromethane) and the coupling constant J_{FF} was 248 Hz. At −92 °C, the half life was 0.00023 s. The Eyring activation parameters calculated for all points between −147 °C and −44 °C, $\Delta H^{\ddagger} = 7.4 \pm 0.1$ kcal/mole, $\Delta S^{\ddagger} = -0.2 \pm 2$ e.u., were comparable to those reported for some related systems [5,6].

The results are in accord with the assumption that the molecule exists in the chair conformation *(2)* and that the fluorines become equivalent by a ring-inversion process analogous to that which occurs with 1,1-difluorocyclohexane [2b].

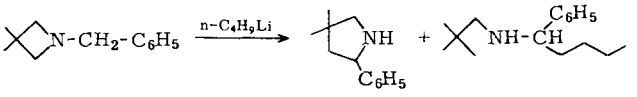
The Wittig Rearrangement of a Tertiary Amine[1]



By *A. G. Anderson* and *M. T. Wills* [*]

Dedicated to Professor G. Wittig on the occasion of his 70th birthday

The rearrangement of ethers induced by the action of strong bases was discovered by *Wittig* and *Löhmann* [2] twenty-five years ago and has since been studied extensively [3].

We have now found that treatment of 1-benzyl-3,3-dimethylazetidine *(1)* with a three molar excess of butyl-lithium in ether solution (0.13 M) under reflux for 24 h gives a Wittig rearrangement product, 4,4-dimethyl-2-phenylpyrrolidine *(2)* (18.6 %, n_D^{25} 1.5200) and *N*-(2,2-dimethylpropyl)-1-phenylpentylamine *(3)* (16.7 %, n_D^{25} 1.4837). Most of the starting material (> 60 %) is recovered unchanged. The formation of both *(2)* and *(3)* from *(1)* can be interpreted in terms of each of the various mechanisms (ion-pair, S_Ni, radical) which have been proposed [5] for the Wittig ether rearrangement.

The products gave spectra (see data below) and elemental analyses in agreement with the assigned structures, and *(2)* was also synthesized, for comparison, from β,β-dimethyl-γ-nitrobutyrophenone, by hydrogenation to the corresponding amine, cyclization to 4,4-dimethyl-2-phenyl-1-pyrroline and finally, reduction with lithium aluminum hydride.

(1) *(2)* *(3)*

The metalation of several different tertiary benzylamines with butyl-lithium has been examined by *Hauser et al.* [4], and evidence was obtained that ortho metalation occurred directly and that this was the exclusive reaction in the case of benzyl-dimethylamine. In contrast, our results indicate the formation of a 2-lithio intermediate in an amount not less than that represented by the total yields of *(2)* and *(3)*.

Spectral data:

Compound *(2)*: IR bands at 3.3, 3.4 (s), 3.5, 6.2 (w), 6.7, 6.85 (doublet) (s), 7.3 (s), and 14.3 (s) μ.

^{1}H–NMR peaks (δ in ppm relative to tetramethylsilane in carbon tetrachloride) at 1.09 (4-methyls), 2.77 (pair of doublets for 5-methylene), 4.2 (pair of doublets for 2-methine), 7.2 (multiplet for 2-phenyl), and multiplet centered at 1.6 for 3-methylene and N–H.

Compound *(3)*: IR bands at 3.3, 3.4 (s), 3.5, 3.6, 6.2 (w), 6.7, 6.85 (doublet) (s), 7.2., 7.35 (s), 8.45, 8.95 (s), and 14.3 (s) μ. ^{1}H–NMR peaks (δ in ppm relative to tetramethylsilane in carbon tetrachloride) at 0.85 (methyl groups), 2.1 (methylene bonded to N), 3.4 (triplet for methine), and 7.1 (phenyl).

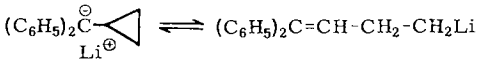
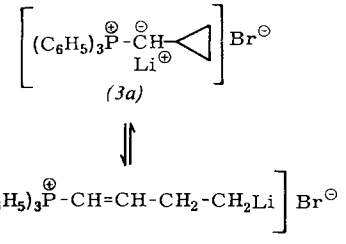
(Cyclopropylmethylene)triphenylphosphorane[1]



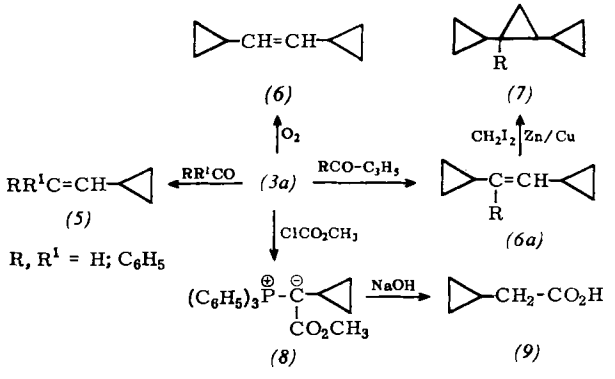
By *A. Maercker* [*]

Dedicated with respect and gratitude to Professor G. Wittig on his 70th Birthday

Wittig reagents that are prepared from phosphonium salts and phenyl-lithium differ significantly from ylides that are free from lithium salt [2] and are therefore often formulated as metalated phosphonium salts *(1)* [3].



(1)

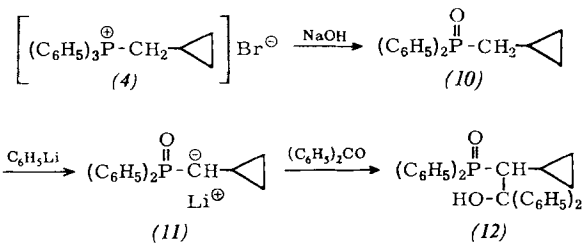


(2a) (2b)

To obtain information about the nature of the lithium-carbon bonding in these ylides we have prepared compound *(1)* with R = cyclopropyl. Our experiments with the system *(2a)* ⇌ *(2b)* [4] had shown that the open-chain form was present when the lithium-carbon bond was covalent (in ether) but that the cyclopropylmethanide *(2a)* was present when the bond was ionic (in tetrahydrofuran); thence it was expected that the ylide *(3a)* should be stable if the lithium-carbon bond is more strongly ionized than in *(2a)*, otherwise rearrangement to *(3b)* should take place.

(3a) (3b)

(Cyclopropylmethyl)triphenylphosphonium bromide *(4)*, which is obtained (77 % yield; m.p. 175–177 °C) by boiling triphenylphosphine and cyclopropylmethyl bromide for 10 days in benzene, reacts with ethereal phenyl-lithium to yield the yellowish-red ylide *(3a)*, which affords cyclopropylethylene derivatives *(5)* (see Table) by Wittig reactions [5] with carbonyl compounds even at room temperature.



(6) (7) (5) (3a) (6a) (8) (9)

R, R¹ = H; C_6H_5

Cyclopropylethylene derivatives *(5)* prepared (12 h in ether at room temperature).

R	R¹	Yield (%)	B.p. (°C/mm)
C_6H_5	C_6H_5	67	95/0.01
C_6H_5	H	90	99/13
C_6H_5	Cyclopropyl	86	65/0.01

When *(3a)* is autoxidized [6] or is treated with cyclopropyl ketones in ether at room temperature, 1,2-dicyclopropylethylene derivatives *(6a)* are formed, which are converted into tercyclopropanes *(7)* by the Simmons-Smith reaction [7]. On reaction with methyl chloroformate in ether, *(3a)* undergoes transylidation [8], leading to the yellow (cyclopropylmethoxycarbonylmethylene)triphenylphosphorane *(8)* (yield 41 %; m.p. 133–137 °C), which on hydrolysis affords cyclopropylacetic acid *(9)* (84 %) and triphenylphosphine oxide (98 %). On no occasion was ring opening to give *(3b)* observed, so that the lithium-carbon bond in *(3a)* must be largely ionized [9].

(4) (10) (11) (12)

Boiling the phosphonium bromide *(4)* with 2 N NaOH yields the phosphine oxide *(10)* (yield 95 %; m.p. 134–136 °C). The methanide *(11)* that is obtained therefrom by treatment with phenyl-lithium in ether is also stable and does not rearrange even when converted into the magnesium salt. However, the system *(2a)* ⇌ *(2b)* with magnesium as cation is present in the open-chain form, *i.e.*, is covalent, even in hexamethylphosphoric triamide. Benzophenone and *(11)* afford the alcohol *(12)* (yield 80 %; m.p. 218–218.5 °C), which gives 2-cyclopropyl-1,1-diphenylethylene *(5)*, (R = R¹ = C_6H_5) (55 %) and diphenylphosphinic acid (50 %) when boiled with potassium t-butoxide in benzene [10]. The oxide *(10)* is also converted into the olefin *(5)* directly when boiled with potassium t-butoxide and benzophenone [10], but the yields are not so good.

Testosterone as Protective Agent of the Water Beetle Ilybius [1]

By *H. Schildknecht*, *H. Birringer*, and *U. Maschwitz* [*]

Dedicated to Professor G. Wittig on his 70th Birthday

From the edges of South German lakes and pools we have caught, among other Dytiscidae (water beetles), two species of the genus *Ilybius*, *I. fenestratus* and *I. fuliginosus*. By carrying out our preparations in insect Ringer solution we were able to isolate the pygidial bladders lying at the posterior

end of the body and the prothoracic protective bladders in the anterior portion (see Fig. 1). The substances produced in the glands act as protective agents for the beetles against microorganisms and cold-blooded vertebrates.

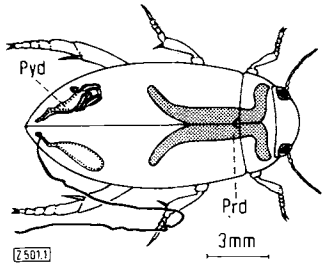

Fig. 1. *Ilybius* with prothoracic (Prd) and pygidial bladders (Pyd).

If the prothoracic bladders are compressed in methanol, a yellow solution is obtained which can be separated into components by thin-layer chromatography [silica gel GF_{254} (Merck); cyclohexane/ethyl acetate (1:1)]. On repeated chromatography we were able to isolate the main component as a viscous oil, which crystallized after several days. We began analysis of all the active constituents of *Ilybius* immediately after their isolation.

Main component: An enone chromophore was indicated by a UV absorption maximum at 241 mμ and was recognized also in the IR spectrum at 1660 ($\nu_{C=O}$) and 1610 cm^{-1} ($\nu_{C=C}$). An OH group indicated by its band at 3360 cm^{-1} was more accurately characterized by a ν-C–OH vibration at 1055 cm^{-1}, since this lies in the expected region for alicyclic secondary alcohols with five- or six-membered rings. A band at 3020 cm^{-1} indicated one or more hydrogen atoms on the C=C double bond. The molecular weight, determined by mass spectrometry, was 288. Experience gained in the analysis of the protective secretions of other water beetles[2,3] enabled us to identify the main component of this protective secretion as testosterone (17β-hydroxy-4-androsten-3-one). For further characterization we converted the natural product by reaction with acetic anhydride/pyridine into an acetate whose melting point (after thin-layer chromatography) was 134.5–136 °C (lit.: 135 to 138 °C). The IR spectra of this substance and of a comparison sample were identical.

The fact that *Ilybius*, like other Dytiscidae, ejects a milky secretion from the prothoracic glands when touched indicates that we are dealing here also with protective substances. To demonstrate this we fed *I. fenestratus* to toads (of the families *Bufonidae* and *Pelobatidae*) and grass frogs. The results were impressive. A hungry toad (*Bufo bufo*) that had eaten four beetles within 5 min was, after 20 min, obviously in pain and brought up two living beetles covered in a bloody slime. The spadefoot toads (*Pelobates fuscus*) and frogs also became severely ill after such meals and some of them brought up living water beetles. After one or two such meals of *Ilybius* these animals would eat no more beetles, even when hungry. Thus these dytiscidae seem to be excellently protected against the amphibia that live in the shore regions.

To test the effectiveness of testosterone as a component of the secretion we placed goldfish in an aqueous testosterone solution (10 mg/ml). Within a few minutes excitation and muscular weakness were observed. After 25 min the fish could no longer equilibrate and finally lay senseless on the bottom of the aquarium, but they recovered completely when placed in fresh water. It is thus shown that testosterone, like other steroids examined by us[2–4], is stupificient for fish. It is surprising that testosterone causes the same symptoms as cortexone although for vertebrates the former acts as male sex hormone and the latter as corticosteroid.

Ochs[5] has reported that water beetles, and in particular *Gyrinus*, are used in the Alps as an aphrodisiac for cattle and horses. According to our observations to date, *Gyrinus*, which belongs to another family of beetle, does not produce steroids. It seems probable that the local farmers confused *Gyrinus* with *Ilybius* since they have the same habitat and similar appearance.

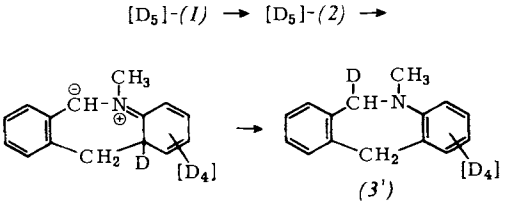
The Mechanism of the Wittig Rearrangement of *N*-Methyl-*N*-phenylisoindolinium Iodide

By *P. P. Gaspar* and *T. C. Carpenter*[*]

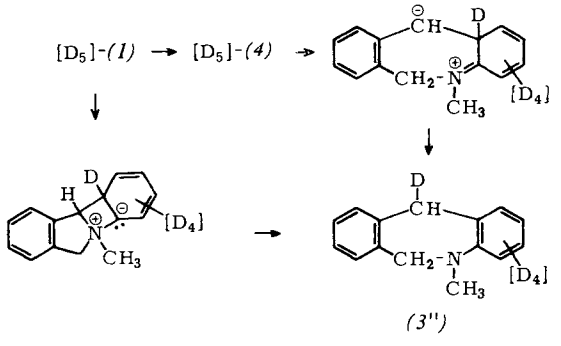
Dedicated to Prof. Georg Wittig on the occasion of his 70th birthday



Wittig, *Closs*, and *Mindermann* interpreted the formation of *N*-methyl-1-aza-2,3;5,6-dibenzocycloheptadiene-(2,5)*(3)* from the reaction of *N*-methyl-*N*-phenylisoindolinium iodide with phenyl-lithium[1] as resulting from the ylide rearrangement (a).

Other possible mechanisms include α-elimination to a carbene (b) and a variant of a Sommelet rearrangement (c).

The conversion of a sample of *(1)* whose *N*-phenyl group is labeled with deuterium into *(3)* permits a distinction between mechanism (a) and mechanisms (b) and (c).



When *N*-methyl-*N*-phenylisoindolinium iodide containing 68.4 % deuterium was treated with phenyl-lithium in ether, (3′) was obtained containing 1.27 ± 0.03 protons in the

7-position and 2.01 ± 0.02 protons in the 4-position, as determined from the NMR spetrum, *i.e.* the deuterium content of the 7-position is 0.73 ± 0.05 atom and that of the 4-position is 0.00 ± 0.05 atom. Mechanism (a), as proposed by *Wittig et al.* is thus confirmed by the observation that product *(3)*, or *(3')*, is formed in yields greater than 73 %.

The methylene NMR resonances of *(3)* at −4.26 and −4.07 ppm with respect to tetramethylsilane (in CS_2) were assigned by comparison with the NMR spectrum of *(3)* containing deuterium in the 4-position only. [4−D]-*(3)* was prepared by metalation of *(3)* with phenyl-lithium (proved by *Wittig et al.*[1] to occur exclusively at the 4-position) followed by quenching with heavy water.

Had mechanisms (b) or (c) been operative, *N*-phenyl ring deuterium would have been incorporated into the 4-position, and loss of label due to metalation would have occured. This would have yielded product *(3'')* with significantly lower deuterium content than that of the labeled starting material. Intervention of a benzocyclobutene, formed by a Stevens rearrangement of *(1)* in mechanism (a) and subsequently opening to *(2)*, is considered unlikely because of the known stability of 1-aminobenzocyclobutene[2,3]. Further experiments to trap the intermediate *(2)* are underway.

1-Methyl-3,3,5,5-tetraphenyl-1-thia-3,5-diphospha^{V}-2,6-diazine[1]

By *R. Appel* and *D. Hänssgen*[*]

Dedicated to Professor Georg Wittig on his 70th Birthday

N,N'-Dihalogeno derivatives of dialkylsulfur diimides (sulfur diimines) *(1)* react with phosphines by nucleophilic substitution, the halogen leaving as anion and two new phosphorus-nitrogen bonds being formed[2]. Application of this reaction to ditertiary diphosphines has made possible the synthesis of new ring systems that contain the elements P, S, and N as well as methylene groups. Reaction of the diimide *(1)* with methylenebis((diphenylphosphine) *(2)* in benzene/acetonitrile (75:100 v/v) gives the dibromide *(3)* and heating this at 110–120 °C in a high vacuum leads to loss of one molar equivalent of methyl bromide with formation of the monobromide *(4)*. A proton can then be removed from the methylene group of *(4)* by means of liquid ammonia, leading to the uncharged 1-methyl-3,3,5,5-tetraphenyl-1-thia-3,5-diphospha^{V}-2,6-diazine *(5)*.

(1) *(2)* *(3)* *(4)* *(5)*

	M.p. (°C)	Ratio $H(C_6H_5)$: $H(CH_3)$: $H(CH_2)$ and (CH)
(3)		20 : 6 : 2
(4)	255–257 (decomp.)	20 : 3 : 2
(5)	140–142	20 : 3 : 1

The structures of compounds *(3)* to *(5)* are evidenced by elemental analyses, ionic equivalents of *(3)* and *(4)*, the molecular weight of *(5)*, and the behavior of the various types of proton (NMR spectra). Conductivity measurements and conversion of the cyclic bromides into nitrates and picrates by double decomposition prove the ionic structure of compounds *(3)* and *(4)*.

The salts *(3)* and *(4)* are soluble in polar organic solvents such as alcohols and dimethyl sulfoxide, but insoluble in ether and hydrocarbons. *(5)* dissolves readily in benzene and chloroform.

Complexes of Alkoxy(dialkylamino)carbenes and Hg^{2+} Obtained from Dicarbamoylmercury Compounds

By *U. Schöllkopf* and *F. Gerhart*[*]

Dedicated to Professor G. Wittig on his 70th Birthday

Fischer and *Maasböl*[1] obtained metal-carbene complexes from carbonyl-metal π-complexes. We have investigated the question whether carbonyl-metal σ-compounds can also be transformed into metal-carbene adducts.

After we had treated biscarbamoylmercury compounds *(1)*[2] in methylene chloride at room temperature with 2 mol. equiv. of trimethyl- or triethyl-oxonium fluoroborate and had concentrated the solutions, we obtained crystalline compounds[3] that we formulate as adducts of alkoxy(dialkylamino)carbenes with Hg^{2+} ions *(2)*.

(1) *(2)*

	R^1	R^2	R^3	M.p. (°C)	NMR (τ) [c] $\diagdown N-CH \diagup$	$-O-CH \diagup$
(2a)	C_2H_5	C_2H_5	CH_3	207 [a]	5.99 (q); 6.21 (q)	5.43 (s)
(2b)	C_2H_5	C_2H_5	C_2H_5	202 [a]	6.02 (q); 6.25 (q)	5.14 (q)
(2c)	CH_3	$CH_2C_6H_5$	C_2H_5	228 [b]	5.06 (s); 6.37 (s)	5.02 (q)

[a] Reprecipitated from methylene chloride or nitromethane by ether.

[b] One of the possible isomers (12 %), obtained crystalline by reprecipitating the crude product from nitromethane by ether.

[c] In CD_3NO_2 or CD_3OD.

The NMR spectra are in good agreement with this structure. The non-equivalence of the *N*-alkyl groups indicates hindered rotation about the C–N bond; it might also result from hindered rotation about the Hg–C bond, with free rotation about the N–C bond, but then the two groups R^3 would be non-equivalent. Further study is needed to decide how much weight attaches to the mesomeric limiting structure with a mercury-carbon double bond, *i.e.*, how far it is justified to describe the compounds as metal-carbene adducts.

That the complexes react with hydroxide ions was shown by treatment of *(2b)* with aqueous sodium hydroxide, which led to mercury, *N,N*-diethylurethane, diethylformamide, and ethanol. This reaction can be used for their quantitative determination. The reaction can be formulated as attack by the base on one of the two carbon atoms. Lithium perchlorate or perchloric acid precipitates the corresponding perchlorate [$ClO_4^{\ominus}$ in place of $BF_4^{\ominus}$ in *(2b)*] from an aqueous solution of *(2b)*.

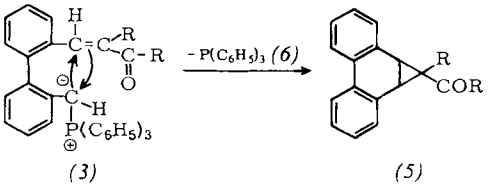
A New Route to Dibenzonorcaradiene Derivatives



By *H. J. Bestmann* and *H. Morper* [*]

Dedicated to Professor G. Wittig on his 70th Birthday

Reaction of the bisylide *(1)*, readily obtained from 2,2'-bis-(bromomethyl)biphenyl [1,2], with 1,2-dicarbonyl compounds *(2)* in benzene or dioxane gives dibenzonorcaradiene derivatives *(5)*, triphenylphosphine oxide *(4)*, and triphenylphosphine *(6)*.

(a), R = C_6H_5
(b), R = CH_3

We assume that compound *(3)* is first formed by a Wittig reaction and is then converted into *(5)* by intramolecular nucleophilic attack by the ylide on the double bond [3] with formation of the cyclopropane ring and loss of triphenylphosphine. We can as yet make no statement about the steric arrangement of the substituents R and R–CO in compounds *(5)*.

(5a): Yield 60 %; m.p. 157 °C; mass spectrum, M^+ at *m/e* = 372. Proton resonance, singlet for the two protons of the cyclopropane ring at τ = 6.08, multiplets for the aromatic protons at τ = 3.34, 2.71, and 2.39; UV spectrum (in cyclohexane), λ_{max} 217 nm, 236 (shoulder), 245 (shoulder), 270, 278 (shoulder), 301, 313; IR spectrum, λ_{max} 6.1 μ.

(5b): Yield 25 %; m.p. 129 °C; mass spectrum, M^+ at *m/e* = 248. Proton resonance, one singlet for the protons of each methyl group at τ = 9.32 and 7.72, a singlet for the cyclopropane protons at τ = 6.77, and multiplets for the aromatic protons at τ = 2.72 and 2.09; UV spectrum, λ_{max} 223 nm, 241, 272, 280 (shoulder), 299, 312; IR spectrum, λ_{max} 5.96 μ. Elemental analysis gave the expected results for compounds *(5)*.

Preparation of (5)

Compound *(2)* is added to a solution of *(1)* [the bisphosphonium salt from which *(1)* is obtained must be dried carefully in a high vacuum over P_2O_5] in anhydrous benzene or dioxane and the whole is boiled until the red color of the ylide has disappeared. An excess of methyl iodide is then added and the reaction mixture boiled for an hour; the triphenylmethylphosphonium iodide that has separated is subsequently filtered off. The solvent is next distilled off and the residue taken up in hot ethanol. Compound *(5)* crystallizes on cooling.

Mössbauer Spectrum of the Iron in Glauconite

By *U. Hofmann, E. Fluck*, and *P. Kuhn* [*]

Dedicated to Professor G. Wittig on his 70th Birthday

Glauconite is closely related to the micaceous clay mineral illite and is almost identical with seladonite [1]. These three minerals are colored more or less green because of their iron content. Seladonite is used as a green pigment under the name Veronese Green. These minerals are layer silicates. Their ideal formula

$$K\,(Al_2,\ Fe^{III}_2,\ Fe^{II}_3,\ Mg_3)\ (OH)_2\ [Si_3AlO_{10}]$$

octahedral layer — tetrahedral layer

corresponds to the formula of mica, but the potassium content is often rather lower than that of the ideal formula.

The green color has been assumed to be due to Fe(II) ions, since so far as we know there is only one oxygen-containing compound that is colored green by Fe(III) ions, namely, an olive-green modification of $NaFeO_2$ [2]. All other Fe(III) compounds are colorless, yellow, brown, or red.

Since chemical analysis does not give reliable results for FeO, the Mössbauer spectrum of the ^{57}Fe in glauconite has been measured[3].

Several glauconites gave Mössbauer spectra that were insufficiently resolved, probably because they contained too little iron. However, from Rosenthaler Formsand Ia, supplied by Firma Bongsche Mahlwerke, Süchteln/Rheinland, we were able to slurry a material which contained only 2 % of quartz and 0.3 % of calcite in addition to glauconite. Its iron content was 15.5 % (calculated as Fe_2O_3), which was bound in the glauconite lattice, as well as 0.6 % of free Fe_2O_3. Chemical analysis gave 0.9 % of FeO and 15.4 % of Fe_2O_3.

For iron-containing silicates at −130 °C the isomeric shift in the spectrum, referred to $Na_2[Fe(CN)_5NO]\cdot 2\ H_2O$, is for Fe(III)ions at +0.5 to +0.75 mm/sec, and for Fe(II) ions at +1.3 to 1.6 mm/sec[4]. The center of the observed doublet (see Fig. 1) is at +0.72 mm/sec and thus shows Fe(III).

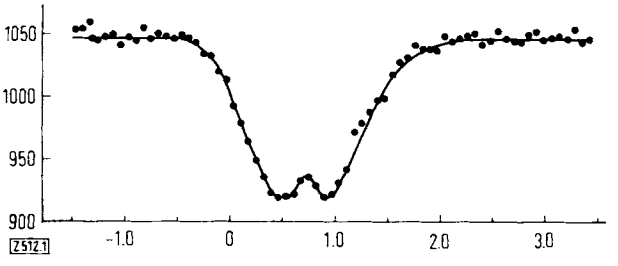

Fig. 1. Fe-Mössbauer spectrum of a glauconite.
Ordinate: Counts (arbitrary units).
Abscissae: Velocity (mm/sec).

The small content of Fe(II) found analytically does not appear in the Mössbauer spectrum.

For iron(III) silicates the quadrupole splitting of the doublet amounts to up to 1 mm/sec. For the glauconite examined it was 0.57 mm/sec. Our Mössbauer spectrum indicates approximately the same coordinative environment for all the iron ions. This means that almost all the Fe(III) ions lie in the octahedral layer of the lattice and not in the tetrahedral layer.

Since, according to the Mössbauer spectrum and the chemical analysis, only a very small amount of Fe(II) is present, the green color of the glauconite is apparently caused by Fe(III) ions in an octahedral environment. The same should be true for seladonite and, in general, for layer silicates that contain iron in the lattice.

Synthesis and Template Properties of Deoxyoligonucleotides with Repeating Triplet Sequences[1]

By *F. Cramer, W. Frölke*, and *H. Matzura*[*]

Dedicated to Professor G. Wittig on his 70th Birthday

For the synthesis of higher oligonucleotides the hitherto customary procedure of stepwise addition of one nucleotide at a time must be replaced by methods in which relatively short oligonucleotides are joined to larger units (block condensation). We have condensed trinucleotides of the type pXpTpC[2] to give oligonucleotides $(pXpTpC)_n$. The protected dinucleotide pTpC *(1)*[3] was treated with the 2-cyanoethylnucleotides *(2)*. In contrast to the procedures used hitherto, synthesis was effected in such a way that a free OH

(a), B = Thymine
(b), B = *N*-*p*-Anisoylcytosine
(c), B = *N*-Benzoyladenine

group on C-3′ of the mononucleotide reacted with a phosphate group on C-5′ of the dinucleotide.

For preparation of the dinucleotide components *(1)*, thymidine 5′-(2-cyanoethyl phosphate) was treated with *N*-*p*-anisoyl-3′-*O*-acetyldeoxycytidine 5′-phosphate in the molar ratio 1:1. After partial hydrolysis with 1 N NaOH the yield of pure 5′-*O*-phosphorylthymidylyl-(3′ → 5′)-*N*-*p*-anisoyldeoxycytidine was 38 to 40 %[3]. Then followed acetylation of the free 3′-hydroxyl group of the dinucleotide with acetic anhydride. Compound *(1)* was next treated with a 2-molar quantity of the mononucleotide *(2)*. For preparation of the 2-cyanoethyl esters of the mononucleotides and of the di- and tri-nucleotides, the corresponding pyridinium salts were treated with dicyclohexylcarbodiimide (DCC) in anhydrous pyridine; the reaction time for condensation of 2-cyanoethanol with the mononucleotides was 24 h at room temperature, but in the synthesis of the di- and tri-nucleotides a reaction time of 3 days gave the best results. After removal of the 2-cyanoethyl and acetyl protecting groups the reaction mixtures were separated on DEAE-cellulose columns (carbonate form), elution being in a triethylammonium hydrogen carbonate gradient at 3 °C. Yields of only *N*-protected trinucleotides amounted to 49.9 % *(3a)*, 44.5 % *(3b)*, and 45.2 % *(3c)*.

0.05 Mole of each trinucleotide *(3a)*–*(3c)* was condensed as pyridinium salt by a three-fold excess of 2,4,6-triisopropylbenzenesulfonyl chloride[4] in anhydrous pyridine for 12 h at room temperature, giving hexa-, nona-, dodeca-, and in part higher polynucleotides. The yields after removal of the protecting groups and paper-chromatographic purification in 1-propanol/conc. aq. NH_3/water (55:10:35) are shown in Table 1.

Table 1. Percentage product distribution after block condensation of the trinucleotides *(3)*.

Trinucleotide used	Distribution of the products [a]				
	Cyclic trinucleotide	$n = 1$	$n = 2$	$n = 3$	$n \geqslant 4$
(3a)	24.4	22.2	17.9	16.3	19.7
(3b)	23.2	24.6	22.2	12.4	17.5
(3c)	23.5	18.7	18.2	13.2	26.4

[a] n = Number of trinucleotide units per oligonucleotide chain.

The oligomers from dodecanucleotide upwards were used as single-strand templates for RNA-polymerase (E.C. 2.7.7.6)[5]. The introduction of nucleoside triphosphates (of which in each case one was labeled with ^{14}C in parallel experiments) into RNA was monitored for periods up to 2 h and corresponded to the ratio of bases in the DNA templates (Table 2).

Table 2. Introduction of nucleotides into RNA with synthetic templates.

Template	Introduction (nmoles) after 90 min		
	A	U	G
$(CTC)_{n\geqslant 4}$	4.65	—	9.50
$(ATC)_{n\geqslant 4}$	4.20	4.10	3.90
$(TTC)_{n\geqslant 4}$ [a]	24.30	—	12.20

[a] In this experiment a 2.5-fold amount of enzyme was used. Reactants: 0.25 ml at 20 °C. 0.03 M tris-acetate buffer (pH = 7.9), 0.13 M NH_4Cl, 0.03 M Mg acetate. — 10^{-3} M GTP and 0.5×10^{-3} M ATP, or ATP, GTP, and UTP (all three 10^{-3} M), or 10^{-3} M ATP and 0.5×10^{-3} GTP. — 0.01 M Phosphoenol pyruvate, 20 µg/ml pyruvate kinase, 1.0 O.D. unit of templates, 100 µg of protein (enzyme activity 200 units/mg protein).

Synthesis of Tetrakis(trimethoxyphosphine)nickel(0) [1]

By *Th. Kruck* and *M. Höfler* [*]

In studies of the complex chemistry of trifluorophosphine we have repeatedly observed that polar solvents (water, alcohols, primary and secondary amines) cause a characteristic rapid solvolysis of the phosphorus-fluorine bonds while the metal-phosphorus bonds remain intact. We therefore tried to effect planned P—F fissions with formation of new P—X bonds in order to obtain new species of phosphine complexes of transition metals without alteration of the type of compound. We have now effected exchange reactions of the type:

$$M{-}PF_3 + n\ M'X \rightarrow M{-}PF_{3-n}X_n + n\ M'F$$

(M' = alkali metal; X = OR, R, NR_2, *etc.*; $n = 1$ to 3)

for several trifluorophosphine-metal complexes (M = Ni, Pt, Fe, and Cr).

Particular interest centers on reactions in which an excess of M'X is used and complete exchange of fluorine leads to homogeneous phosphine complexes. An example is the synthesis of tetrakis(trimethoxyphosphine)nickel(0), which had not been isolated previously[2]:

$$Ni(PF_3)_4 + 12\ NaOCH_3 \rightarrow Ni[P(OCH_3)_3]_4 + 12\ NaF$$

This compound is formed quantitatively. It is a colorless non-electrolyte that crystallizes well and is readily soluble in the usual solvents except cold petroleum ether. The ^{31}P—NMR spectrum[3] (Spectrospin-KIS-2, 30 MHz, saturated solution in petroleum ether, 26 °C, 80 % H_3PO_4 as external standard) contains a signal at −164.3 ppm broadened to *ca.* 28 Hz by P—H coupling.

Experimental:

A solution of sodium (4.0 g, 174.5 mg-atoms) in methanol (50 ml) is added dropwise, with stirring, to a solution of $Ni(PF_3)_4$ [4] (5.4 g, 13.2 mmoles) in methanol (10 ml). The mixture is then boiled for 3 h under reflux and, after cooling, the methanol is distilled off in a vacuum. The viscous residue is extracted with four portions, each of 30 to 50 ml, of petroleum ether. The united extracts are freed from petroleum ether. If the crude product still contains P—F bonds (IR spectrum) it is treated again with an excess of $NaOCH_3$. Recrystallization from petroleum ether gives odorless, colorless crystals that melt at 132 °C and decompose only slowly above 220 °C with formation of a brown color and separation of metal.

Synthesis of 1,2,5-Selenadiazole and some of its Derivatives

By *V. Bertini* [*]

Weinstock et al.[1] have recently synthesised 1,2,5-selenadiazole *(1)*[2] in 7 % yield. We have now succeeded in preparing this compound [b.p. 142 °C/770 torr, $n_D^{25} = 1.6179$, $\lambda_{max} = 282$ nm[3] (log ε = 3.85) in isooctane] in 43 % yield.

A solution of 0.045 moles of ethylenediamine in 30 ml of *N,N*-dimethylformamide was added slowly to 0.135 moles of SeO_2 in 110 ml of *N,N*-dimethylformamide and the reaction mixture maintained at 120 °C under reflux for 40 minutes. The product was separated by steam distillation.

Under similar conditions, 0.030 moles of propylenediamine and 0.090 moles of SeO_2 yield 3-methyl-1,2,5-selenadiazole *(2)*[2] [b.p. 162 °C/770 torr, $n_D^{25} = 1.5807$, $\lambda_{max} = 287$ nm (log ε = 3.83) in isooctane] in 35 % yield.

(1), $R^1 = R^2 = H$
(2), $R^1 = H$, $R^2 = CH_3$
(3), $R^1 = R^2 = CH_3$

We have also found that *vic* dioximes, like aliphatic *vic* diamines, react with SeO_2 to give 1,2,5-selenadiazole derivatives. Thus, 3,4-dimethyl-1,2,5-selenadiazole *(3)*[2] [m.p. 87 °C, $\lambda_{max} = 287$ nm[3] (log ε = 3.88) in isooctane] has been prepared in 45 % yield by refluxing 0.006 moles of dimethylglyoxime and 0.030 moles of SeO_2 in 30 ml of

N,N-dimethylformamide for 45 minutes. The solid product, obtained by steam distillation of the reaction mixture, was purified by crystallization from n-pentane.

Compounds *(1)*, *(2)* and *(3)* have also been prepared by using Se_2Cl_2 instead of SeO_2; in this case the reaction is very exothermic and the addition of reagents must be carried out at about 5–10 °C; yields are also somewhat lower.

Compounds *(1)*, *(2)*, and *(3)* form complexes with $CdCl_2$ which are sparingly soluble in water and in most organic solvents. These complexes offer a useful method for purification of the heterocycles because steam distillation of the complex readily regenerates the 1,2,5-selenadiazole ligand.

When the compounds *(1)*, *(2)* and *(3)* are reduced with H_2S at room temperature, elemental selenium is formed rapidly in stoichiometric amounts along with ethylenediamine, propylenediamine, and 2,3-butylenediamine, respectively.

Spectroscopic Substituent Constants of Phosphorus-containing Groups[1]

By *G. P. Schiemenz* [*]

The spectroscopic constants $\delta\lambda_0$ of the Doub-Vandenbelt equation (a)[2] describe approximately the mesomeric effect of a substituent. Values of $\delta\lambda_0 = 41.1$ to 42.0 and 44.5 to 45.7 for the phosphinyl- and phosphonium-phosphorus, respectively, in the dimethylanilines *(1a)* to *(4a)* containing such substituents can be calculated by means of eqn. (a) from the position of the primary band in the required solvent water[2] with $\delta\lambda_0^{N(CH_3)_2} = 61.1$[3]; the values obtained indicate a $-M$ effect approximately the same as for cyano ($\delta\lambda_0 = 43.9$) and the carboxylate group ($\delta\lambda_0 = 44.7$)[2]. These values, however, being obtained from the spectra of only a few compounds, are not very certain.

It should be possible to obtain more reliable results, as has been done for the Hammett constants[4], by a least squares calculation on the data of a series of phosphine oxides and phosphonium salts substituted systematically by +M groups. However, the monofunctional derivatives *(1)* and *(2)* cannot be used for this purpose because with "electronically weak" substituents X the absorption of the group p-X–C_6H_4 is masked by that of the two phenyl groups[5]. This disturbance does not occur with the trisubstituted compounds *(3)* and *(4)*. Although, within the series *(3)* and *(4)*, the group $-P(O)Ar_2$ (or $-P^{\oplus}(CH_3)Ar_2$) that is regarded as substituent in the compound X–C_6H_5 does not remain constant, we have found previously[3,5] that the absorption of a p-X–C_6H_4 group is only slightly dependent on the presence of even "electronically strong" substituents on other aromatic rings.

p-X–C_6H_4–$P(O)Ar_2$ p-X–C_6H_4–$P^{\oplus}(CH_3)Ar_2$ $Hal^{\ominus}$

(1), Ar = C_6H_5 *(2)*, Ar = C_6H_5

(3), Ar = p-X–C_6H_4 *(4)*, Ar = p-XC_6H_4

When $\delta\lambda_0$ of the substituents X is plotted against λ_{max} of the primary band of compounds *(3)* and *(4)*, the experimental points all fall close to a straight line, only those for phenolates diverging appreciably (in those cases probably because of the accumulation of charged substituents[2]). After approximation (by the method of least squares) the remaining values give the "excellent"[4] equations (b) and (c), which give $\delta\lambda_0^{PO} = 40.0$ (at $\lambda_0 = 183.1$ nm) and $\delta\lambda_0^{P\oplus CH_3} = 47.1$ (at $\lambda_0 = 175.9$ nm). On normalization to $\lambda_0 = 180$ nm[2] one obtains $\delta\lambda_0^{PO} = 43.1$ and $\delta\lambda_0^{P\oplus CH_3} = 43.0$.

($\delta\lambda_0'$, $\delta\lambda_0''$ are spectroscopic substituent constants, $k = 24.05$, $\lambda_0 = 180$ nm in equation (a)).

$$\lambda_{max} = (\delta\lambda_0' \, \delta\lambda_0'')/k + \lambda_0 \quad (a)$$

$$\lambda_{max} = 1.661 \, \delta\lambda_0^{PO} + 183.1 \quad (b)$$
($r = 0.995$, $s = \pm 2.5$ nm)

$$\lambda_{max} = 1.959 \, \delta\lambda_0^{P\oplus CH_3} + 175.9 \quad (c)$$
($r = 0.998$, $s = \pm 1.8$ nm)

X	$\delta\lambda_0^X$	Phosphine oxide	λ_{max} (nm) in H_2O	Phosphonium salt	Hal	λ_{max} (nm) in H_2O

Tetrachlorophosphonium and Chloro(phenyl)-phosphonium Perchlorates and Hexachloroantimonates

By *A. Schmidpeter* and *H. Brecht* [*]

With many metal and non-metal chlorides PCl_5 gives addition compounds that are to be regarded as tetrachlorophosphonium salts of chloro acids. PCl_4^+ salts of pure oxo acids were, however, previously unknown and were considered incapable of existence[1].

We have found that PCl_5 reacts smoothly with perchloric acid in methylene chloride to yield PCl_4ClO_4; chloro(phenyl)-phosphonium perchlorate was obtained in the same way[2]:

$$(C_6H_5)_nPCl_{5-n} + HClO_4 \rightarrow HCl + [(C_6H_5)_nPCl_{4-n}]ClO_4$$
(1)

$[(C_6H_5)_nPCl_{4-n}]X$		$n = 0$	$n = 1$	$n = 2$	$n = 3$
(1)	M.p. (°C) (decomp.)	95	[a]	117	189
X = ClO_4	^{31}P (ppm) [b]	−87.1	−103.0	−93.2	−65.7 [c]
(2) X = $SbCl_6$	^{31}P (ppm)	[7] −87.9	−102.9	−93.2	−65.0

[a] Decomposes explosively at 70 °C.
[b] ^{31}P shifts in nitromethane or nitroethane with respect to 85 % H_3PO_4.
[c] In methylene chloride.

The products are colorless, crystalline compounds that do not decompose over a considerable period of time at −20 °C but are unstable at room temperature. When heated they decompose more or less violently; the phenyl compounds deflagrate with formation of much soot.

The ^{31}P–NMR signals are shifted downfield compared with the corresponding chlorophosphoranes. When plotted against the number of phenyl groups the values lie to a good approximation on a parabola with its minimum at $n \approx 1.2$. They agree with those of the hexachloroantimonates $[(C_6H_5)_nPCl_{4-n}]SbCl_6$ *(2)* which were prepared for comparison. The position of the ^{31}P signal of a solution of PCl_4ClO_4 in nitromethane is comparable[3] with the signals of $[PCl_4]AlCl_4$ (−86.5 ppm)[4], of $[PCl_4]^+$ in crystalline PCl_5 (−96, −92 ppm)[5,6], and of PCl_2F_3 (−95 ppm)[6]. Compounds *(1)* are thus to be considered as chlorophosphonium perchlorates.

Chlorophosphonium perchlorates:

An equivalent amount of an approximately 1 M solution of anhydrous $HClO_4$ in CH_2Cl_2 is stirred into a solution or suspension of a chlorophosphorane $(C_6H_5)_nPCl_{5-n}$, $n = 0$ to 3, in CH_2Cl_2 at 20 °C. The perchlorates crystallize spontaneously or after cautious concentration. The solubility increases greatly with increase in n.

Chlorophosphonium hexachloroantimonates:

Equimolar amounts of the chlorophosphorane and $SbCl_5$, both in CH_2Cl_2, are combined and the solution is concentrated, if necessary.

Synthesis of Phospha- and Diphospha-1,3,5-triazines by Cyclizing Transamination with Aminophosphazenes [1]

By *A. Schmidpeter* and *J. Ebeling* [*]

The methods previously described for the synthesis of diphospha-1,3,5-triazines[2] are not suitable for the preparation of the series *(4)* unsubstituted at position 6. We have now prepared the latter by treating 4-aminodiphosphazenes *(2)* with *N,N'*-diphenylformamidine.

The structure of *(4)* is proved by the NMR spectra [**]: As a result of coupling with the two equivalent phosphorus atoms the signal of the proton at position 6 is split into a triplet with an unusually high coupling constant (see table; the coupling constants J_{PH} of phosphinylmethylamides with the same arrangement of atoms P–N–C–H are between 9 and 15 Hz). The signal is shifted either slightly negatively or positively with respect to the formyl-proton in *(3)* (δ^1H = −8.23). On the other hand, the signal of the proton at position 2 of pyrimidine is at $\delta = -9.26$, although this can be shifted to −7.9 for pyrimidine derivatives. Thus the measured shifts cannot be used to draw conclusions about ring currents.

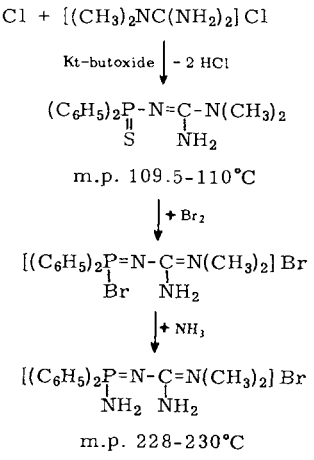
	M.p. (°C)	$\delta^{31}P$	Ring proton		Methyl protons	
			δ^1H	J_{PH} (Hz)	δ^1H	J_{PH} (Hz)
(4a)	242–243	−14.4	−8.43	40.3	—	—
(4b)	121–122 sublimes at 40 °C/0.01 mm	−27.1	−7.57	40.0	−1.40 doublet	14.0

Compound *(4b)* is hygroscopic and dissolves exceedingly readily and without decomposition in water. The solution reacts alkaline (pH = 9).

Compounds *(2a)* (m.p. 182–185 °C, $\delta^{31}P$=−17.7 in methanol) and *(2b)* can be obtained from the reaction of their hydrochlorides[3] with sodium methoxide; this reaction is remarkable insofar as *(2)* are aminophosphazyl-diaryl- and -dialkylphosphine imines and yet triorganylphosphine imines cannot be prepared in this way[4].

Phospha-1,3,5-triazines have hitherto been described only in the form of their imidophosphate or imidothiophosphate tautomers [5]. We obtained 4-dimethylamino-2,2-diphenylphospha-1,3,5-triazine *(6)* by cyclizing transamination with the guanylphosphazene *(5)*.

NMR spectrum of *(6)* in CH_2Cl_2: phosphorus, $\delta = -26.4$, doublet, J_{PH} = 35–40 Hz; ring proton, δ=−8.04, doublet, higher resonance masked by the multiplet of the phenyl protons, J_{PH} = 38 Hz; methyl protons, $\delta = -3.07$, signal broadened by unresolved hyperfine structure.



Derkatsch et al. have prepared other phospha-1,3,5-triazines from phosphorus isocyanates[6].

Diphospha-1,3,5-triazines:

A methanolic solution of *(1)* is treated with an equivalent amount of sodium methoxide, filtered from NaCl, and evaporated. The residual *(2)* is melted with an equivalent amount of *(3)* in a vacuum, whereby 2 mol. equiv. of aniline are distilled off. Purification is by recrystallization from benzene or sublimation in a vacuum. Yield: 70–80 %.

4-Dimethylamino-2,2-diphenylphospha-1,3,5-triazine (6):

The hydrobromide of *(5)* is obtained by the stages:

Product recovery is as described for diphospha-1,3,5-triazines. Compound *(6)* crystallizes, from benzene or ether, in flakes, m.p. 146.5–147 °C (yield 78 %).

A Simple Synthesis of Alkyl Formimidates

By *R. Ohme* and *E. Schmitz* [*]

We have found that alkyl formimidate hydrochlorides *(2)* may be prepared by the simultaneous action of benzoyl chloride and alcohol on formamide:

(1)

(2)

The mixed acid anhydride *(1)* may be an intermediate in the reaction since a compound of presumed structure *(1)* has been obtained on reaction of benzoyl chloride with formamide [1]. Such compounds are readily alcoholysed to *(2)* and benzoic acid.

Alkyl formimidate hydrochlorides *(2)* have indefinite melting points. Their structure follows from elemental analysis, thermal decomposition to formamide and alkyl chloride (identified by gas chromatography), and from the following characteristic reactions [2]: (i) with an excess of alcohol they undergo alcoholysis to form the trialkyl orthoformates and ammonium chloride; (ii) treatment with ammonia or amine leads to formamidines in good yields; and (iii) on heating in the presence of tri-*n*-butylamine the 1,3,5-triazines *(3)*, which are useful for many syntheses [3], are obtained in 79 % yield. Compounds *(2)* and *(3)* have hitherto been obtained from anhydrous hydrogen cyanide [4,5] but now become appreciably more easily accessible.

Attempts to carry out the above reaction in which the benzoyl chloride is replaced by other acid halides (*e.g.* sulfonyl chlorides, acetyl chloride, inorganic acid chlorides) proved unsuccessful; either no reaction took place or alcoholysis of the acid halide occurred. Ethanol could be replaced by other primary or secondary alcohols, whereby the corresponding formimidic ester hydrochlorides *(2)* were obtained with the following yields [6]: R = *n*-C_3H_7, 80 %; R = *iso*-C_3H_7, 60 %; R = *n*-C_4H_9, 79 %; R = CH_3, 70 %.

Ethyl formimidate hydrochloride:

A mixture of formamide (45 g) and ethanol (46 g) is added dropwise, and with stirring (over a 45 min period), to a solution of benzoyl chloride (140.6 g) in anhydrous ether (700 ml) at 10 to 20 °C. The whole is stirred for a further, 15 min, and the precipitated hydrochloride is filtered off, washed with anhydrous ether (200 ml), and dried over phosphorus pentoxide. Yield, 109 g (99 %). 1 mole of benzoic acid can be isolated from the filtrate.

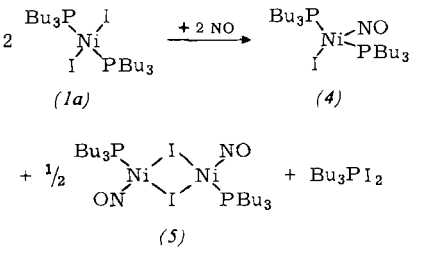
Reaction of Halogeno(phosphine)nickel Complexes with Nitric Oxide

By *H. Brunner* [*]

The reaction of nitric oxide with halogeno(tri-n-butylphosphine)nickels *(1)* is determined by the nature of the halogen. If NO is passed through a solution of $(Bu_3P)_2NiCl_2$ [1] in petroleum ether, benzene, or methylene chloride at room temperature, the IR spectrum of the solution exhibits a band at 2220 cm^{-1}, *i.e.* in the absorption region of the free NO^+ cation. The product, which is also formed in the non-solvating solvent, hexane, would appear to be best formulated as *(2)*. The weak intensity of the NO^+ band indicates that the equilibrium *(1)* ⇌ *(2)* lies largely on the side of *(1)*. When N_2 is passed through the reaction solution the NO bound in the complex is removed along with the dissolved NO, and the starting material *(1)* is recovered.

The IR spectrum of a hexane solution of $(Bu_3P)_2NiBr_2$ [2] that has been treated with NO contains, as well as a band at 2215 cm^{-1}, a further band at 1720 cm^{-1} corresponding to a coordinately bound NO group. Thus, in the case of the bromide, addition of the NO^+ cation follows a rapid reversible electron transfer, yielding *(3)*.

The magnetic moment of 2.0 B.M. found for *(3)* in cyclohexane by the NMR method [3] proves that in *(3)* the noble-



(1) (2) (3)

gas configuration of the Ni is exceeded by one electron. In an attempt to isolate *(3)* NO was lost and *(1)* was re-formed.

The complexes *(1)*, Hal = Cl and Br, cannot indefinitely undergo reversible addition of NO because on prolonged action of NO they are converted into the oxidation products $(Bu_3PO)NiHal_2$ [4].

On reaction of $(Bu_3P)_2NiI_2$ [2] with NO the presence of the intermediates *(2)* and *(3)* cannot be demonstrated although, as the products *(4)* and *(5)* show, they probably represent steps in the reaction.

(1a) (4)

(5)

If the reaction is carried out in hexane, Bu_3PI_2 is precipitated and can be isolated. The IR spectrum of the mixture of *(4)* and *(5)* contains three NO bands, of which one is assigned to *(4)* and the two others to the *cis,trans* isomers [5] of *(5)*. The analytical results and molecular weight of the mixture lie between those of *(4)* and *(5)*.

Chromatographic separation of *(4)* and *(5)* has not been accomplished because of the instability of *(5)*. However, *(5)* is readily converted into *(4)*: if the mixture of *(4)* and *(5)* is treated with PBu_3 the I bridges in *(5)* are broken and after removal of the excess of PBu_3 in a high vacuum at 90 °C analytically pure *(4)* is obtained in 95 % yield (calculated on the $(Bu_3P)_2NiI_2$ *(1)* used). Iodonitrosylbis(tri-n-butylphosphine)nickel *(4)* is a violet compound that is liquid at room temperature and dissolves as the monomer in benzene. Its properties closely resemble those of the compounds $[(C_2H_5)_3P]_2Ni(NO)NO_3$ [4] and $[(C_6H_{11})_3P]_2Ni(NO)I$ [5] which have been prepared by other methods.

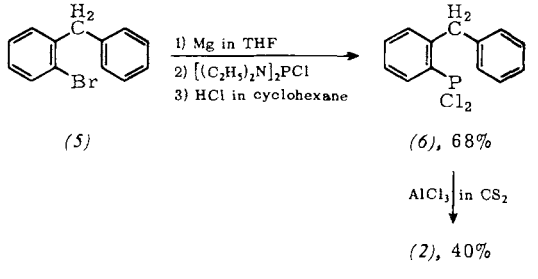
Dibenzo[*b*,*e*]phosphorin

By *P. de Koe* and *F. Bickelhaupt* [*]

With phosphorus, as with other elements of Period 3, the tendency to formation of p_π-hybrid bonds is very slight. Only very recently have derivatives of tervalent phosphorus with coordination number 2 been prepared [1]. We set ourselves the task of synthesizing dibenzo[*b*,*e*]phosphorin (9-phosphaanthracene) *(1)*, the phosphorus analogue of acridine, by removal of HCl from 5-chloro-5,10-dihydrodibenzo[*b*,*e*]-phosphorin *(2)* [2].

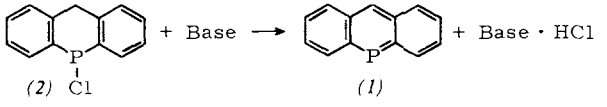
We worked out two new methods of preparing *(2)*:



a) A solution of the di-Grignard compound from bis(*o*-bromophenyl)methane *(3)* in tetrahydrofuran was added dropwise to a solution of dichlorodiethylaminophosphine (molar ratio *ca.* 1:1) in tetrahydrofuran at −80 °C. After evaporation of the solvent the residue was extracted with cyclohexane, filtered, and gaseous HCl was passed into the filtrate. The crude product obtained on subsequent evaporation was sublimed and recrystallized from toluene; m.p. (after sublimation) 102–109 °C (lit.: 78–86 °C [2]). To confirm its structure, the product *(2)*, which is very sensitive to hydrolysis, was oxidized in sodium hydroxide solution to *(4)* [2] by hydrogen peroxide.

(3) (2), 47 %

(4)



b) Analogously, interaction of the Grignard compound from (*o*-bromophenyl)phenylmethane *(5)* and chlorobis(diethylamino)phosphine in tetrahydrofuran at −80 °C and treatment of the reaction mixture with cyclohexane and HCl as described in a) affords *o*-benzylphenyldichlorophosphine *(6)*, b.p. 142–143 °/0.01 mm, $n_D^{20} = 1.6298$, in 68 % yield. When boiled for 10 h with a slight excess of aluminum chloride in carbon disulfide *(6)* gave *(2)* in 40 % yield [3].

(5) (6), 68%

(2), 40%

Experiments to remove HCl from *(2)* were carried out with various degrees of success with tritylsodium, ethyldicyclohexylamine, triethylamine, and 1,5-diazabicyclo[4.3.0]non-5-ene *(7)* [4] in various solvents, the appearance of the characteristic UV spectrum being considered as indicating formation of *(1)*. We found that a slight excess of *(7)* in toluene or dimethylformamide gave the best results: 76.9 mg of *(7)* was added to 126.5 mg of *(2)* in 10 ml of anhydrous, degassed toluene at −196 °C, the reaction vessel was sealed in a high vacuum, and the mixture allowed to warm to room temperature. The product *(1)* is formed slowly (several hours) in toluene, and the solution obtained is stable for several days. In dimethylformamide formation of *(1)* occurs within an hour but the solution is largely decomposed (UV spectrum) after one day.

(2) (1)

The following observations indicate the formation and structure of *(1)*: When the components are warmed from −196 °C to room temperature the solution gradually becomes

pale yellow; after a short time a white precipitate separates (but not from dimethylformamide), which contains 60–75 % of the hydrochloride of the base. The filtrate gives the UV spectrum reproduced in Fig. 1.

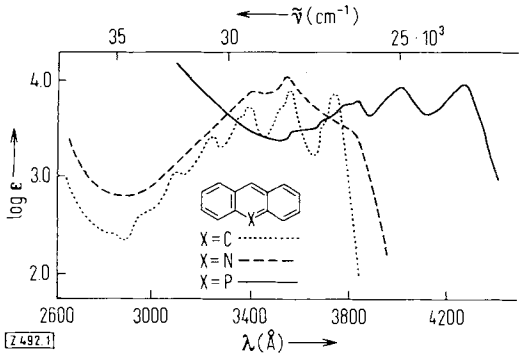


Fig. 1. UV spectra of anthracene (in cyclohexane), acridine (in 95 % ethanol), and *(1)* (in toluene). [The vertical position of the curve for *(1)* is selected arbitrarily.]

Surprisingly, the UV spectrum of the new compound resembles that of anthracene more closely than that of acridine. Apart from the bathochromic shift[1] (long-wave absorption at $\lambda = 429$ mμ, ε unknown) the separations and relative intensities of the maxima show strong analogies to the fine structure of the ^1L_A band of anthracene, possibly owing to the fact that phosphorus and carbon have almost identical electronegativities ($\chi_P = \chi_C = 2.5$)[5], in contrast to the more electronegative nitrogen ($\chi_N = 3.0$).

It has not yet been possible to isolate *(1)*. The UV spectrum disappears immediately on admission of atmospheric oxygen, very rapidly on addition of sodium hydroxide or anhydrous HCl, and slowly on addition of dilute acid or, depending on the solvent, on standing. On either evaporation or cooling to −196 °C the solution appears to decompose (irreversible weakening of the UV bands; evaporation of a filtered solution and washing of the residue with toluene gives an inhomogenous product).

HCl is also very easily split off from *(2)* (molecule ion at $m/e = 232$, intensity 43 %) under the conditions of mass spectroscopy; this gives a stable ion $(1)^+$ ($m/e = 196$, intensity 100 %), which in turn loses phosphorus to give (9-fluorenyl)$^+$ ($m/e = 165$, intensity 57.7 %; corresponding metastable ion at $m/e = 139.1$)[6]. Appearance of $(1)^{2+}$ ($m/2e = 98$, intensity 34 %) is noteworthy.

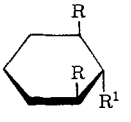
Synthesis of Cyclic 1,2,3-Triamines by the Reaction of Dialdehydes with Nitromethane and Benzylamine [1]

By *F. W. Lichtenthaler*, *T. Nakagawa*, and *A. El-Scherbiney* [*]

The Mannich reaction of 1,4- or 1,5-dialdehydes with primary amines and methylene compounds activated by carbonyl or carboxyl groups gives products of type *(1)* (Robinson-Schöpf synthesis[2]). We have found that cyclic nitrodiamines *(2)* are formed when nitromethane is used as the methylene component – analogous to its double aminomethylation[3].

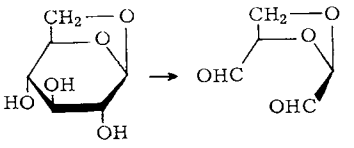


(1) *(2)*

Thus reaction of glutardialdehyde (25 % aqueous solution) with nitromethane and benzylamine in the molar ratio 1:1.5:4 (1 h at 0 °C, 12 h at room temperature) gives all-*trans*-N^1,N^3-dibenzyl-1,3-cyclohexanediamine *(3)* (m.p. 84 to 85 °C) in 60 % yield. The product is precipitated by addition of water and purified by recrystallization from methanol.

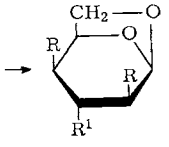
If the reaction is carried out stepwise (*i.e.* the nitromethane cyclization product *(4)*[4] is prepared first and then treated with benzylamine) compound *(3)* can be isolated in 75 % yield (calculated on the dialdehyde used).

Catalytic hydrogenation (3 h) of *(3)* over Raney nickel in water gives N^1,N^3-dibenzyl-*trans*-*trans*-1,2,3-cyclohexanetriamine *(5)*, which was isolated as trihydrochloride, m.p. 217–220 °C. On hydrogenation over 10 % palladium/charcoal in methanol/1 N acetic acid (1:1), reduction of the nitro group is accompanied by hydrogenolysis of the *N*-benzyl groups and thus formation of the all-*trans*-cyclohexanetriamine, which was characterized as trihydrochloride *(6)*, m.p. 330 °C, and triacetate, decomp. pt. 329–330 °C.



(3), R = C_6H_5-CH_2-NH, R^1 = NO_2
(4), R = OH, R^1 = NO_2
(5), R = C_6H_5-CH_2-NH, R^1 = NH_2
(6), R = R^1 = $NH_2 \cdot HCl$
(7), R = R^1 = NH-CO-CH_3

The all-*trans* configuration of the products *(3)* and *(5)* through to *(7)* is demonstated by the NMR spectra: *(3)* gives a triplet of intensity 1:2:1 at $\tau = 5.93$, which must be assigned to H-2 because of its chemical shift, and whose coupling constant of $J = 10$ Hz proves the axial orientation of the ring protons H-1, H-2, and H-3, *i.e.* the equatorial orientation of the substituents; the CH_3 groups of the triacetate *(7)* give only one signal, at $\tau = 8.10$ (9 H), which proves the steric equivalence of the acetamido groups and their equatorial orientation.



The principle of the reaction can be applied to sugar dialdehydes. Thus the dialdehyde *(9)* that is obtained on oxidation of levoglucosan *(8)* by periodate gives, on reaction with nitromethane and benzylamine (molar ratio 1:2:4), 2,4-bis-(benzylamino)-2,3,4-trideoxy-3-nitro-β-D-idosan *(10)* [yield 53 %, m.p. 121–123 °C, $[\alpha]_D^{20} = 73.5°$ ($CHCl_3$)] which can be isolated by virtue of its insolubility in water and purified by recrystallization from methanol.

Catalytic hydrogenation of the nitro compound over 10 % palladium/charcoal in water (18 h) affords 2,3,4-triamino-2,3,4-trideoxy-β-D-idosan as the trihydrochloride *(11)* [m.p. 189–190 °C (decomp.), $[\alpha]_D^{20} = -48.3°$ (H_2O)], which is converted into the triacetate *(12)*, m.p. 257–258 °C, $[\alpha]_D^{20} = -50°$ (in $CHCl_3$), by warming in acetic anhydride. The D-*ido* configuration of the triamino-anhydro-sugar is shown by the NMR spectrum of *(12)* in [D_6]dimethyl sulfoxide: The anomeric proton gives the expected doublet at $\tau =$

4.76 with a small coupling constant ($J_{1,2}$ = 2 Hz), and the CH_3 groups give a signal at τ = 8.17 whose position proves the presence of three equatorial acetamido groups.

(8) (9)

(10), R = C_6H_5-CH_2-NH, R^1 = NO_2
(11), R = R^1 = $NH_2 \cdot HCl$
(12), R = R^1 = NH-CO-CH_3

Methylamine and aniline are less suitable than benzylamine as amine components, but phenylhydrazine reacts analogously to benzylamine with *(4)*, yielding 2-nitro-*N*^{2},*N*$^{2'}$-diphenyl-*trans*-*trans*-1,3-cyclohexanedihydrazine, m.p. 130 °C (yield 15 %), which can also be obtained (yield 57 %) by treating *(3)* with phenylhydrazine.

Ability to vary the methylene component is shown by reaction of glutardialdehyde with nitroethane and benzylamine to afford *N*^{1},*N*^{3}-dibenzyl-2-methyl-2-nitro-1,3-cyclohexanediamine (yield 56 %, m.p. 98–99 °C) which is also formed (yield 83 %) from benzylamine and the cyclization product of nitroethane and glutardialdehyde [5].

It seems reasonable to classify this reaction, which proceeds similarly to a Mannich condensation, as a three-step process consisting of nitromethane cyclization, dehydration and Michael addition of the amine. Although the easy formation of the nitrodiamine from the nitrodiol, *(4)* → *(3)*, suggests this course, other mechanisms cannot be disregarded (*e.g.* nitromethane cyclization of the double Schiff base formed from dialdehyde and amine or, in certain circumstances, direct displacement of the OH group by the NHR group). Variations in the CH acidity and changes in the reaction conditions could account for the formation of fundamentally different products (compounds of type *(1)*) when carbonyl- or carboxy-activated methylene components are used in the reaction.

Simple Methods of Preparing Acetylacetonates

By *G. Stöckelmann*, *A. Kettrup*, and *H. Specker* [*]

Metal acetylacetonates are important in analytical and technical chemistry. We have found that commercial metal salts of 2-ethylhexanoic acid are cheap and excellent starting materials for the preparation of many metal acetylacetonates.

Metal naphthenates and stearates are also suitable. The advantage of these salts, and particularly of the ethylhexanoate, is their good solubility in organic solvents such as petroleum ether, benzene, and chloroform. Consequently the pH control, which is often difficult during synthesis of metal chelates in water or strongly polar solvents, is no longer necessary.

The metal acetylacetonates are precipitated in crystalline form, even at room temperature, on mixing of the β-diketone with the solution of the metal ethylhexanoate in benzene or petroleum ether. We have prepared Fe^{III}, Co^{II}, Co^{III}, Mn^{II}, Zr, Al, Ca, Zn, and Cu acetylacetonates in this way.

The methyl ethylhexanoates were mostly used in their commercial form (solutions in petroleum ether, metal content 8 %). They can, however, also be conveniently obtained from the metal acetates or oxides and the free acid; the acetic acid is removed by distillation and the metal ethylhexanoate, which is usually very viscous, is dissolved in hot petroleum ether; unchanged acetate is filtered off.

Cobalt(II) acetylacetonate:

0.1 mole of cobalt(II) 2-ethylhexanoate is stirred with 0.2 mole of acetylacetone in 100 ml of benzene for 5 min at room temperature under nitrogen. The pink complex is precipitated as crystal flakes in 80 % yield. If the mixture is heated under reflux for 30 min without use of a nitrogen atmosphere, dark green cobalt(III) acetylacetonate is obtained in 70 % yield.

Synthesis of Pentacarbonyldicyclopentadienyldivanadium and New Carbonylphosphinecyclopentadienylvanadium Compounds

By *E. O. Fischer* and *R. J. J. Schneider* [*]

We have prepared $Na_2[C_5H_5V(CO)_3]$ *(1)* [1] more simply than before, and in 83 % yield, by shaking a solution of $C_5H_5V(CO)_4$ *(2)* [1] in tetrahydrofuran with 1 % sodium amalgam. If this product is treated with 2 N hydrochloric acid, vigorous evolution of gas occurs and a flocculent green precipitate is formed. Extraction of the precipitate with hexane, chromatography on silica gel, and recrystallization from benzene/hexane (1:1) affords dark green crystals of pentacarbonyldicyclopentadienyldivanadium, $(C_5H_5)_2V_2(CO)_5$ *(3)*, m.p. 99 °C (decomp.), in 78 % yield. No hydride was found.

The ^{1}H–NMR spectrum, the IR spectrum, and the low dipole moment ($\mu_{25\,°C}$ = 1.0 ± 0.1 Debye, in cyclohexane) indicate a binuclear structure with *cis*-configuration, one vanadium-vanadium bond, and one bridging and four terminal CO ligands, as in *(3)*.

(3)

The molecular ion [3] corresponding to the molecular formula $C_{15}H_{10}O_5V_2$ appears in the mass spectrum at *m/e* = 372. Further, the fragment ions arising on stepwise loss of all five CO groups can be detected; an intense peak occurs at *m/e* = 232 $[(C_5H_5)_2V_2^+]$.

If the divanadium compound *(3)* is stirred with tri-*n*-butylphosphine at room temperature for about 20 min, subsequent

(8)	$(C_5H_5)_2V_2(CO)_4P(C_6H_5)_3$	5.38 [c] 5.98 [b]	–	–	2.85	2	1932, 1871, 1819, 1773 [f]

[a] In C_6D_6 with tetramethylsilane as internal standard. — [b] sharp singlet. — [c] doublet. — [d] triplet. — [e] middle of signal. — [f] in benzene.

distillation of the excess of phosphine in a high vacuum and chromatography on neutral Al_2O_3 with hexane as eluent affords yellow-orange crystals of $C_5H_5V(CO)_3P(C_4H_9)_3$ *(4)* (m.p. 78 °C) and red crystals of $C_5H_5V(CO)_2[P(C_4H_9)_3]_2$ *(5)* (m.p. 68 °C) in a 1:1 ratio and 34 % yield. The structures of both products were proved by IR, NMR, and mass-spectroscopic measurements[3].

$C_5H_5V(CO)_3P(C_4H_9)_3$ can also be prepared, analogously to $C_5H_5V(CO)_3P(C_6H_5)_3$[2], by UV irradiation of a solution of *(2)* and tri-n-butylphosphine in benzene at about 10 °C.

Further, diethylphenylphosphine cleaves *(3)* with formation of yellow $C_5H_5V(CO)_3P(C_2H_5)_2C_6H_5$ *(6)* and red $C_5H_5V(CO)_2[P(C_2H_5)_2C_6H_5]_2$ *(7)*.

However, if *(3)* is stirred with triphenylphosphine in benzene for 70 h, then chromatography on Al_2O_3 with hexane as eluent and crystallization from benzene/hexane (2:1) affords dark green crystals of $(C_5H_5)_2V_2(CO)_4P(C_6H_5)_3$ *(8)*. IR and NMR spectra show that one terminal CO group of *(3)* has been replaced by $P(C_6H_5)_3$. The compounds $C_5H_5V(CO)_3P(C_6H_5)_3$ and $C_5H_5C(CO)_2[P(C_6H_5)_3]_2$ were also formed, but only in traces.

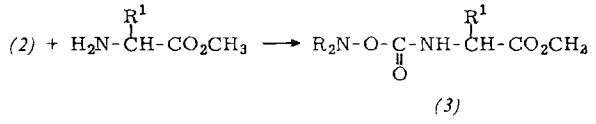
N,N-Disubstituted Derivatives of *O*-Chloroformylhydroxylamines as Reagents for Peptide Synthesis

By *H. Gross* and *L. Bilk*[*]

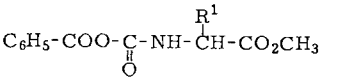
Derivatives *(2)* of *O*-chloroformylhydroxylamine can be obtained in good yields by treatment of alkali or trialkylammonium salts of *N*-hydroxysuccinimide *(1a)* or *N*-hydroxyphthalimide *(1b)* in CH_2Cl_2 or CCl_4 with an excess of phosgene at 0 to −5 °C.



$$R_2NOK + COCl_2 \rightarrow R_2N{-}O{-}COCl$$
(1) *(2)*

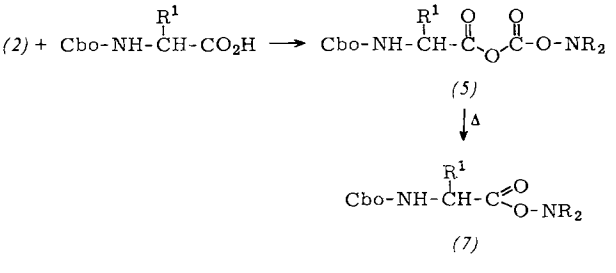
(a), $R_2 = OC{-}(CH_2)_2{-}CO$

(b), $R_2 = o\text{-}OC{-}C_6H_4{-}CO$



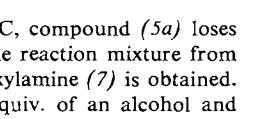
The rather unstable succinimide derivative *(2a)* is isolated as an oil from the filtered solution after removal of the solvent in a vacuum, whereas the stable phthalimide derivative *(2b)* can be obtained in crystalline form.

Amino acid esters react with *(2)* and triethylamine in dioxane at −5 to 0 °C, giving aminooxycarbonyl derivatives *(3)*, which are isolated on evaporating the solvent. Purification may be effected by dissolution of the residue in ethyl acetate, removal of acid and alkaline impurities, evaporation, and recrystallization from ethyl acetate/petroleum ether or methanol/water. These derivatives are relatively stable in both acid and alkaline media. When heated with Na benzoate in dioxane/



(3)

water (2:1) at 100 °C (90 min) they give the *C*-benzoylurethanes *(4)* in about 75 % yields [isolation and purification as described for *(3)*].



(4)

Acylamino acids with equimolar amounts of *(2)* and triethylamine in tetrahydrofuran afford, within 1 h at −10 °C, good yields of the mixed anhydrides *(5)*, which, on filtration and evaporation of the solution *in* a vacuum, are isolated as crystalline, relatively stable compounds in admixture with triethylammonium chloride. Aminolysis of the succinimide derivative *(5a)* with L-Tyr-OCH_3 in dioxane/water (25:1) gave, within 24 h at −10 to +20 °C, an 81 % yield of Cbo-L-Val-L-Tyr-OCH_3 *(6)*, which was obtained crystalline by the procedure described for *(3)* and recrystallization from ethyl acetate/ether [m.p. 151–153 °C, $[\alpha]_D^{20} = 53.5°$ ($c = 1.07$ in $CHCl_3$); lit.[1], m.p. 144–147 °C, $[\alpha]_D^{24} = 54 \pm 4°$]. The phthalimide derivative *(5b)* reacts analogously with L-Tyr-OCH_3, giving *(6)* in 86 % yield. The mixed anhydrides of type *(5)* do not need to be isolated in these reactions.

(5)

(7)

When warmed for 30 min at 130 °C, compound *(5a)* loses CO_2 and, on recrystallization of the reaction mixture from isopropyl alcohol, the *O*-acylhydroxylamine *(7)* is obtained. Finally, treatment of *(2)* with 2 equiv. of an alcohol and 1.1 equiv. of pyridine in CH_2Cl_2 at −5 to +20 °C gives, within 12 h, 65 to 73 % yields of the *O*-alkoxycarbonylhydroxylamine derivatives *(8)*, which are obtained pure by extraction of the reaction mixture with water, evaporation of the solvent, and recrystallization from ethyl acetate/petroleum ether.

[c] $c = 2$ in isopropyl alcohol.

$$(2) + R^1\text{-OH} \longrightarrow R_2N\text{-O-C}\overset{O}{\underset{OR^1}{}}$$

(8)

When warmed (95 °C) for 2 h with amino acids in dioxane/0.5 M Na_2CO_3 solution (2:1), these products afford, as was shown by Frankel and co-workers [3] for *(8a)* and *(8c)*, alkoxycarbonylamino acids which are obtained in high yield by evaporation of the solution in a vacuum, adjustment of the pH to 3, extraction with ethyl acetate, and evaporation of the solvent. *(8d)* reacts in the same manner. BOC-amino acids, which are of particular preparative importance, are thus obtained more conveniently than by way of the BOC-hydrazide.

CONFERENCE REPORTS

Organometallic and Hydrogen Compounds of Some Transition Metals

By *B. Sarry* [*]

In the absence of air and moisture, anhydrous halides of transition metals react in various ways with ethereal solutions of phenyl-lithium.

Nickel and cobalt halides are reduced to catalytically active metal powders:

$$MX_n + n\ LiPh \longrightarrow M + n\ LiX + \frac{n}{2}\ Ph_2 \qquad (1)$$

Organometallic compounds are not formed, nor are hydrides or hydrido complexes of the metals obtained in the presence of hydrogen. Hydrogen leads merely to the formation of lithium hydride:

$$LiPh + H_2 \longrightarrow LiH + C_6H_6 \qquad (2)$$

This reaction is accelerated by cobalt, whereas nickel acts as catalyst for concurrent hydrogenations.

Tungsten, niobium, and tantalum pentabromides are reduced by phenyl-lithium only as far as the oxidation state +2. Diphenyl derivatives of the metals are formed, which react with the excess of phenyl-lithium present to form organometallic complexes.

$$MBr_5 + 9\ LiPh \xrightarrow{(C_2H_5)_2O}$$

$$[MPh_2(LiPh)_4]\cdot n\ (C_2H_5)_2O + 5\ LiBr + \frac{3}{2}\ Ph_2 \qquad (3)$$

These products are dark brown to black, finely crystalline substances, which are extremely susceptible to oxidation and hydrolysis and are insoluble in petroleum ether, somewhat soluble in ether, and readily soluble in benzene or dioxane. The solvate ether ($n = 3.5$ to 4) is so firmly bound that it is retained even on recrystallization of the complexes from benzene.

Ethereal or benzene solutions of these compounds react with elemental hydrogen – the tungsten compound appreciably faster than the niobium compound – to form organometallic hydrido complexes. This reaction gives the black $WH(LiPh)_2$, which is initially soluble in ether, but which becomes insoluble on precipitation by hydrocarbons. The niobium compound has, so far, yielded two similarly insoluble complexes containing one or two hydride hydrogen atoms, repectively, per niobium atom.

In accord with the position of iron in the Periodic Table, iron(II) chloride can react in either way. Above 0 °C reduction occurs in agreement with equation (1), yielding a mixture of very finely divided pyrophoric iron and ether-insoluble lithium chloride. Reaction at about −15 °C leads to an ether-soluble product which, after separation from the lithium chloride formed simultaneously and from the excess of

phenyl-lithium, can be precipitated by petroleum ether as a dark reddish-brown, powder which is extremely sensitive to air and moisture.

When a phenyl-lithium solution (from bromobenzene) containing lithium bromide is used, the products has the composition $Fe(LiPh)_5 \cdot LiBr$, but when a solution (from diphenylmercury) free from lithium bromide is used the composition is $Fe(LiPh)_5$. It is formed according to the equation:

$$FeCl_3 + 8\ LiPh \longrightarrow Fe(LiPh)_5 + 3\ LiCl + \frac{3}{2} Ph_2 \qquad (4)$$

A small amount of an hydridoiron complex is formed simultaneously which, after isolation, is insoluble in ether. The hydride hydrogen is provided by oxidation of phenyl-lithium to biphenylylenedilithium.

Chemistry and Stability of Lead(IV) Compounds

By *F. Huber* [*]

The stability and structural relations of Pb(IV) and Pb(II) compounds cannot be explained by means of completion of the 6s orbitals [1,2] ("inert electron pair"). In the third and fourth main groups the decrease in stability of the maximal valency can be correlated satisfactorily with the decrease in covalent bond strength [3] only for the chlorides. A more generally valid rule can be derived by assuming Pb(IV) compounds to provide an intramolecular redox system and by attending more strictly to the ionic contribution to the valence [4].

In contrast to PbF_4, $PbCl_4$ cannot be obtained by direct halogenation of Pb(II) halides; chlorine oxidises only complex-bound $PbCl_2$, presumably in accord with $PbCl_3^{\ominus} + Cl_2 \rightarrow [PbCl_5]^{\ominus}$ and $PbCl_4^{2\ominus} + Cl_2 \rightarrow [PbCl_6]^{2\ominus}$. $PbCl_4$ is then obtained from the isolated hexachloroplumbates(IV), preferably from $[(C_2H_5)_3NH]_2[PbCl_6]$. $PbBr_4$, PbI_4, $M_2[PbBr_6]$, and $M_2[PbI_6]$ (M = cation) have not been prepared; the compounds described in the literature as $[C_9H_7NH]_2[PbBr_6]$ and $[C_9H_7NH]_2[PbI_6]$ [5] are in fact halogenoplumbates(II), which are formed by addition of halogen (set free in the "oxidation" of $Br^{\ominus}$ or $I^{\ominus}$ by Pb(IV)) to the quinolinium cation $C_9H_7NH^+$. $PbCl_4$ forms complexes $PbCl_4 \cdot 2Z$, which are more stable than $PbCl_4$, provided that Z is not susceptible to oxidation [Z = pyridine, quinoline, or $(C_6H_5)_3PO$]. Complexes with amines, $(C_6H_5)_3P$, ethers, *etc.*, decompose more or less rapidly, and partially even below 0 °C. Similar relations between stability and susceptibility of the cation to oxidation can be demonstrated for hexachloroplumbates(IV). Aminolysis of $PbCl_4$ occurs through an intermediate, for which the formula $[NH_4]_2[PbCl_4(NH_2)_2]$ has been derived. $PbCl_4$ reacts with PCl_5 to give $[PCl_4]_2[PbCl_6]$, and with $SbCl_5$ to give a complex, presumably $[PbCl_2][SbCl_6]_2$.

The ease of preparation and the stability of organolead complexes depend on the number and nature of the anionic groups X bound to Pb, and on the nature of the organic groups R. Donor-acceptor complexes of PbR_4 are unknown, and those of R_3PbX are unstable; nevertheless, complexes of various compositions can be obtained from R_2PbX_2, *e.g.* with pyridine, ethylenediamine, and 3-azapentamethylenediamine. The coordination number (CN) 6 is usual in these cases, and CN 5 is unusual; there are indications of CN 8, *e.g.* in the complex $[(C_6H_5)_2Pb(en)_3]I_2$.

The compound $R_2PbHal_2 \cdot 4\ C_5H_5N$ can be regarded as the ionic complex $[R_2Pb(C_5H_5N)_4]Hal_2$.

Stereoisomeric chelates $R_2Pb(ox)_2$ (Hox = 8-hydroxyquinoline) can be prepared from R_2XPbox by reaction with NH_3 or with NH_3 and Hox. In R_2XPbox the coordination number depends on the nature of the ligands, on the concentration, and on the temperature; in solution CN is often 5, and in the solid state presumably 6.

The compounds $RPb(ox)_3$ avoid CN 7 since two of the ox groups are bidentate and the third one is unidentate. Attempts to obtain compounds of the type $M[R_2PbX_3]$ gave halogenoplumbates(II) $M[PbX_3]$, with elimination of the alkyl group R as ethane (R = CH_3) or alkane/alkene mixtures (R = C_2H_5 *etc.*).

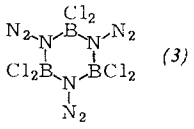
Boron Azides and Boron Imides

By *P. Paetzold* [*]

Thermal or photolytic decomposition of diorganylboron azides leads to the formation of rearrangement products in high yields. The decomposition may be formulated as in eq. (a), where $n = 2$ for R = aromatic ligand; or $n = 3$ for R = aliphatic ligand; $(RNBR)_n$ = rearrangement product.

$$R_2BN_3 \longrightarrow N_2 + \frac{1}{n} (RBNR)_n \qquad (a)$$



The tetraaryl-1,3,2,4-diazadiboretidines *(1)*, $n = 2$, which are isoelectronic with cyclobutadienes, are extremely sensitive to oxidation. Kinetic measurements of the decomposition of diarylboron azides show that they are the more stable the better electron-donors the aryl groups are, although *Saunders* and *Ware* observed the opposite relation for decomposition of triarylmethyl azides [1]. On decomposition of azides of the type $(C_6H_5)RBN_3$ the aryl group R migrates the more readily (relative to the C_6H_5 group) the more strongly it attracts electrons and the bulkier it is according to the following series: *m*-trifluoromethylphenyl > *o*-tolyl > α-naphthyl > phenyl > *p*-chlorophenyl > *p*-tolyl. The kinetic measurements and the migratory tendencies accord with a synchronous mechanism for the diorganylboron azide rearrangement.

Bis(dialkylamino)boron azides are more stable thermally than the diorganylboron azides; when heated to 270 °C they give indefinite resins. Photolysis leads, in accord with eq. (b), to the formation of rearrangement products in good yields, namely, to tetrakis(dialkylamino)-1,3,2,4-diazadiboretidines *(2)* that are susceptible to oxidation and on hydrolysis give, *inter alia* 1,1-dialkylhydrazines.

$$2\ (R_2N)_2BN_3 \longrightarrow 2\ N_2 + (R_2N{-}BN{-}NR_2)_2 \qquad (b)$$

Its vibrational spectra indicate that trimeric dichloroboron azide has a structure with a planar BN six-membered ring *(3)* and contains *N*-diazonium groups. When this compound is

heated in the absence of a solvent at *ca.* 200 °C, Cl migrates from B to the N_α atom of the N_3 group, N_2 is split off, and hexachloroborazole is formed.

(3)

If diphenylboron azide is heated with benzonitrile phenylimide as 1,3-dipolar agent, the phenylboron phenylimide, $C_6H_5-B\equiv N-C_6H_5$, that is formed as intermediate, acts as a dipolarophile and undergoes a 1,3-dipolar cyclization to yield a B-containing five-membered ring compound (1,2,4,5-triazaboroline); this reaction provides the first evidence for occurrence of a boron imide.

Boron imides stable at room temperature are obtained when aromatic amines such as *p*-anisidine, *p*-thioanisidine, or 2,4,6-trimethylaniline are treated with pentafluorophenylboron dichloride in boiling toluene [reaction (c)]. These compounds undergo a 1,3-dipolar reaction with benzonitrile *N*-oxide or phenyl azide, even at room temperature, which

$$F_5C_5-BCl_2 + ArNH_2 \longrightarrow C_6F_5-B\equiv N-Ar + 2\ HCl \qquad (c)$$

leads to heterocyclic five-membered ring compounds (1,2,4,5-oxadiazaborolines; tetrazaborolines) in almost quantitative yield. The BN stretching vibrations are IR-inactive but appear as intense bands in the Raman spectrum just above 1700 cm^{-1}. Unexpectedly, $C_6H_5BCl_2$ and $C_6H_5NH_2$ yield a monomeric boron imide with an IR-inactive but Raman-active BN stretching vibration at 1658 cm^{-1}.

New Compounds with Apatite or Garnet Structure

By *H. Schwarz* [*]

Ternary compounds $M^{II}_3(X^VO_4)_2$ have the same structure when M^{II} = Sr or Ba and X^V = P, As, V, or Cr. Isomorphous replacement of the cations, in accordance with a general formula $M^{II}_{3-x}M^{I}_x(X^VO_4)_{2-x}(X^{VI}O_4)_x$, leads, when $x = 2$, to double compounds of the type $M^{II}M^{I}_2(X^{VI}O_4)_2$ which, without exception, have the structure of the parent when X^{VI} = Cr, Se, or S, M^I = K, NH_4, Rb, or Tl, and M^{II} = Sr, Pb, or Ba (Ba only when X^{VI} = Cr) [1]. The compounds can generally be obtained by a thermal route or by precipitation from very concentrated $M^I_2X^{VI}O_4$ solutions. In agreement with this it was found for some more extensively studied $M^I_2X^{VI}O_4/M^{II}X^{VI}O_4$ systems that only the 1:1 double salts exist and that there are no regions of solid solution.

A second type of coupled replacement leads, from $Sr_3(PO_4)_2$, to a series of unusual apatites. If the P^{5+} in the parent $Sr_3(PO_4)_2$ is replaced by Si^{4+} and at the same time Sr^{2+} is partially replaced by La^{3+} $[Sr_{9-x}La_x(PO_4)_{6-x}(SiO_4)_x]$, a surprising change in structure occurs. From $x = 4.5$ $[Sr_{4.5}La_{4.5}(PO_4)_{1.5}(SiO_4)_{4.5}]$ to $x = 6$ $[Sr_3La_6(SiO_4)_6]$ only a single phase, which has the apatite structure, occurs; when $x = < 4.5$ the products are a mixture of $Sr_3(PO_4)_2$ and the apatite phase for $x = 4.5$. $Sr_3La_6(SiO_4)_6$ itself is the $y = 0$ member of a mixed-crystal series $Sr_{3-y}La_{6+2y/3}(SiO_4)_6$ that exists from $y = 1$ to $y = -1$. Here are for the first time compounds of apatite structure that have defects in the cation part of the lattice. Similar compounds *(1)* and *(2)* exist in the binary system La_2O_3/SiO_2, but here there are long series of mixed crystals of type *(1a)* and *(2a)* that extend up to the ternary silicate apatites *(1b)* and *(2b)* having filled cationic

(1)	$La_{8\frac{2}{3}}(SiO_4)_6O$
(1a)	$Sr_{4-y}La_{6+2y/3}(SiO_4)_6O$; $4 \geqslant y \geqslant 0$
(1b)	$Sr_4La_6(SiO_4)_6O$
(2)	$La_{9\frac{1}{3}}(SiO_4)_6O_2$
(2a)	$Sr_{2-y}La_{8+2y/3}(SiO_4)_6)_2$; $2 \geqslant y \geqslant 0$
(2b)	$Sr_2La_8(SiO_4)_6O_2$

parts of the lattice. In sum the ternary system $SrO/La_2O_3/SiO_2$ contains an extensive region of mixed crystals with the apatite structure.

Except for the natural berzeliites [2], the garnets *(3)* have hitherto presented no example with a quinquevalent element in the tetrahedral sites, which is surprising since in other respects there are many relationships between silicates and phosphates, arsenates, and vanadates. After unsuccessful experiments with various phosphate systems, we were able to prepare a series of arsenate *(3a)* and vanadate *(3b)* garnets, and our first attempts with fluoride systems led to synthesis of the cryolithionite *(3c)*. At higher temperatures the products decompose in various ways; for instance, after formation of a tetragonal phase at 850 °C, $Na_3Fe_2As_3O_{12}$ decomposes at 900 °C with loss of As_2O_3 and O_2 and formation of α-Fe_2O_3 and Na_3AsO_4.

(3)	$\{A_3\}$	$[B_2]$	(C_3)	O_{12}	
(3a)	$\{NaCa_2\}$	$[M^{II}_2]$	(As_3)	$O_{12}\}$	M^{II} = Mg, Co, or Ni
	$\{M^{II}Ca_2\}$	$[LiM^{III}]$	(As_3)	$O_{12}\}$	
	$\{Na_3\}$	$[M^{III}_2]$	(As_3)	$O_{12}\}$	M^{III} = Fe or Cr
(3b)	$\{Na_3\}$	$[M^{III}_2]$	(V_3)	$O_{12}\}$	
	$\{Ca_2In\}$	$[Li_2]$	(V_3)	O_{12}	
(3c)	$\{Na_3\}$	$[Al_2]$	(Li_3)	F_{12}	
(4)	$\{M^{III}_3\}$	$[M^{III}_2]$	$(\square_3)$	$(OH)_{12}$	
(4a)	$\{Ca_3\}$	$[M^{III}_2]$	$(\square_3)$	$(OH)_{12}$	M^{III} = Al or Cr
(4b)	$\{Sr_3\}$	$[M^{III}_2]$	$(\square_3)$	$(OH)_{12}$	M^{III} = Al, Ga, Fe, or Cr

To set alongside calcium hydroxoaluminate $Ca_3[Al(OH)_6]_2$ which was earlier recognized as a defect garnet structure *(4)* [3], we have obtained a series of further "hydrogarnets" *(4a)* and *(4b)* by two methods; precipitation from solution can generally be used; but the second method, in which anhydrous oxometalates $3M^{II}O.M^{III}_2O_3$ are treated with steam under pressure gives purer products. As an example of the often complex process of thermal decomposition of such "hydrogarnets" we may mention the decomposition of $Ca_3Al_2(OH)_{12}$ which affords $3CaO{\cdot}Al_2O_3$ only above 900 °C and by way of two intermediate stages.

New Results in the Chemistry of Chromium

By *H. L. Krauss* [*]

1. Chromium peroxides

$CrCl_3$ or $CrCl_3$·aq in tetrahydrofuran reacts with an excess of concentrated H_2O_2 to form first $CrCl_3$·3THF and then a deep blue chromium(VI) peroxide. The blue compound is spectroscopically identical with "CrO_5", which is quite stable in THF. The substance shows the same broad absorption maximum at 580 nm in water, ether, alcohol, and THF.

Electrophoresis of "CrO_5" in $THF/H_2O/H_2O_2$ with $LiClO_4$ as conducting salt showed, surprisingly, that the blue compound is anionic. It is assumed that the anions CrO_6H^- and CrO_5X^- [1,2] are present, their absorption being identical with that of CrO_5 (at the same pH).

Decomposition of "CrO_5" in water (pH = 1) with an excess of H_2O_2 [eq. (a)] or of chromate [eq. (b)] gives different amounts of oxygen but with the same rate of reaction:

$$Cr_2O_7^{2-} + 5\ H_2O_2 + 8\ H^+ \rightarrow 2\ Cr^{3+} + 9\ H_2O + 4\ O_2 \quad (a)$$

$$Cr_2O_7^{2-} + 3\ H_2O_2 + 8\ H^+ \rightarrow 2\ Cr^{3+} + 7\ H_2O + 3\ O_2 \quad (b)$$

The rates of reactions (a) and (b) are determined by attack of the protons; the rate of decomposition is thus dependent on the proton concentration. The apparent catalytic decomposition of H_2O_2 is explained by a redox reaction between chromium peroxide and hydrogen peroxide.

2. Surface Chemistry of Chromium

In continuation of work concerned with chromium(VI) and chromium(III) compounds on the surface of amorphous aluminum silicates with various Si/Al ratios the magnetic and the optical behavior have been studied at various temperatures, oxygen partial pressures, and concentrations. In all cases it was possible to distinguish chromium chemisorbed on the surface from that retained in capillaries.

Only the surface chromium has catalytic activity, *e.g.* for polymerization of ethylene. With corresponding supply of oxygen and on "activation" at 400 to 600 °C the oxidation number of surface chromium always lies between 5 and 6, the highest value (5.95) being achieved on pure SiO_2·aq. Comparison of quantitative ESR measurements with the analytical findings shows that the paramagnetic components appearing in surface chromium cannot be identical with chromium(V). It is assumed that the ESR-active species consists of chromium(III) ions in special crystal environments; the band form leads to the same conclusion.

The redox reactions were studied optically by use of a high-temperature cell for reflection measurements in the visible and near-IR region. This work gave complete agreement with the analytical results concerning the reduction-reoxidation sequence in the activation process. Chromium(VI) is present as dichromate in the active material. The catalytic reaction with ethylene was also studied optically. The initial step clearly consists in reduction of the surface chromium(VI), which leads to formation of the catalytically active centers.

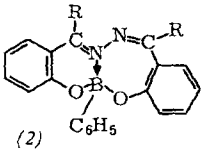
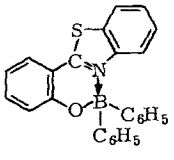
Reactions of Boron Compounds with Metal Chelates and Chelating Agents



By *F. Umland* [*]

Phenylboric acids, Ph_2BOH and $PhB(OH)_2$, react with chelating agents to form chelate rings with quadri- or triligating boron. From consideration of the bond angle between the ligands on the boron and the bond angle in the ring it is to be expected that quadriligating boron will be favored in five-membered ring chelates because of the tetrahedral angle (≈ 105 °; cf. bond angle in the ring 108 °), whereas triligating boron (120 °) should be favored in six-membered-ring chelates. Five-membered diphenylboron chelate rings occur with, *e.g.*, 8-hydroxyquinoline or nitrosophenylhydroxylamine [1]. Quasiaromatic systems, however, always lead to great stability, independently of the bond angles. Thus the diphenylboron chelate of *o*-aminophenol splits off benzene, with formation of 2-phenyl-1,3,2-oxazaboroline *(1)*.

Very stable quasi-aromatic six-membered ring compounds of Ph_2BOH are obtained with chelating agents such as salicylaldehyde or the corresponding azomethines [2]. The hydroxydiphenylboron-salicylaldehyde chelate is suitable as a reagent for primary amines; NH_3, NH_2OH, and NH_2NH_2 also react. Loss of benzene and formation of boric acid derivatives occur only when a more condensed ring system can be obtained, *e.g.*, with hydrazine, giving *(2)*. Free boric acids also give chelates of these types [3].



(1)

(2)

However, when *o*-aminothiophenol is used as amine component, a diphenylboron chelate *(3)* of the benzothiazole is formed with evolution of hydrogen.

(3)

The Ph_2B^+ group may replace the proton of metal chelates of the bis(dimethylglyoxime)nickel(II) type, $Ni(DMGH)_2$, containing an intramolecular hydrogen bridge [4]. A special study was made of whether analogous cationic complexes with triligating boron can be prepared. So far the following types are known: $[Ni(DMG)_2(BOH)_2]_3[B_3O_6]_2$ with a boroxole anion, $[Ni(DMG)_2Py_2(BOH)_2]Cl_2$, and $[Ni(DMG)_3(BPh)_2]$. Attempts to introduce elements other than boron into $Ni(DMGH)_2$ succeeded with Sn^{VI}, the trinuclear complex [(HDMG)Ni(DMG)$SnCl_2$(DMG)Ni(DMGH)] being formed.

Optical Behavior of Solutions of Sodium in Ammonia at High Pressures

By *U. Schindewolf*[*]

Solutions of Na in NH_3 have a lower density and a greater compressibility than pure ammonia. This is attributed to the solvated electrons that are formed on dissociation of the Na ($Na \rightarrow Na^+ + e^-_{sol}$). The solvated electrons are situated inside cages formed of NH_3 molecules. The apparent molar volume of the dissolved Na (60 to 70 ml/mole; cf. pure Na 23 ml/mole) gives a value of 3.25 Å for the radius of the solvated electrons.

The dilute solutions are deep blue (absorption maximum at 1.5 μ; maximal extinction coefficient 4×10^4 l mole^{-1} cm^{-1}) owing to strong light absorption in the red to near infrared spectral region. The absorption is attributed to transition of the electrons from the 1s to the 2p state in a hydrogen-like potential, paralleling the light absorption of F-centers (electrons at anion sites in ionic crystals). The transition energy is, to a first approximation (square well potential), inversely proportional to the square of the radius of the cage containing the electrons. Quantum mechanical calculation using the radius given above for the solvated electron is in agreement with the transition energy found.

The increase in compressibility of the solutions suggests that solvated electrons are more compressible than pure ammonia. Because of the relation between the radius of the solvated electrons and the energy of the electron transition it should be possible to estimate their compressibility from the increase in shift of the absorption maximum towards shorter wavelengths with increasing pressure.

The absorption spectra of dilute $Na-NH_3$ solutions at pressure up to 2000 atm and at temperatures −60 and +20 °C were studied by using a high-pressure cell. Owing to the strong absorption of the solutions the light path was kept below 10^{-2} cm.

The results of these investigations confirm the hypotheses: compression of the solvated electron by pressure shifts the absorption maximum towards shorter wavelengths (1000 Å/1000 atm); on the other hand, increase in temperature shifts the absorption maximum towards longer wavelengths (1000 Å/40 °C). The latter shift can be interpreted as due to thermal expansion of the solvated electrons.

These measurements lead to values of the compressibility (6.5×10^{-5} atm^{-1}) and thermal expansion (3.0×10^{-2} deg^{-1}) of the solvated electrons that are greater than those of pure ammonia (4.0×10^{-5} atm^{-1} and $1\times9\cdot10^{-2}$ deg^{-1}, respectively). Solvated electrons thus contrast with normal solvated ions, whose compressibilities and thermal expansions are smaller than those of the solvating medium.

Biosynthesis of Aromatic Systems

By *G. Billek*[*]

Aromatic natural products are formed almost exclusively by (i) condensation of acetate and malonate units (polyacetate rule[1]) or (ii) through intermediate stages of carbohydrate metabolism, by way of shikimic, chorismic, and prephenic acid (shikimic acid route[2]). Examples of the latter are the aromatic amino acids phenylalanine and tyrosine and their deamination products cinnamic and *p*-coumaric acid. It has been found for stilbenes of vegetable origin that both routes can contribute together to the formation of aromatic natural products.

More than half of the 14 stilbene derivatives that are now known as constituents of higher plants have been studied in regard to their biosynthesis[3]. The syntheses proceed along analogous routes in very different types of plant, namely, condensation of a cinnamic acid *(1)* with three acetate units, leading, on loss of a carboxyl group, to 3,5-dihydroxystilbene (pinosylvin) *(2)*. Hydroxylated cinnamic acids (*p*-coumaric, 2,4-dihydroxycinnamic, caffeic, and isoferulic acid) yield the correspondingly substituted 3,5-dihydroxystilbenes resveratrole (3,5,4′-trihydroxy-), oxyresveratrole (3,5,2′,4′-tetrahydroxy-), piceatannol (3,5,3′,4′-tetrahydroxy-), and rhapontigenin (3,5,3′-trihydroxy-4′-methoxy-stilbene).

Biosynthesis of hydrangeic acid *(3)* and hydrangenol *(4)* proceeds without loss of a carboxyl group but with intermediate reduction.

Benzoic acids, which are widely distributed in higher plants, are not formed, as previously assumed, by aromatization of dehydroshikimic acid or of shikimic acid, but by degradation of cinnamic acids[4]. In the biosynthesis of hydroxylated benzoic acids the substitution pattern can be determined at the cinnamic acid stage since conversions such as ferulic acid → vanillic acid, and *p*-coumaric acid → *p*-hydroxybenzoic acid, are known. On the other hand, for biosynthesis of gentisic acid the route cinnamic acid → benzoic acid → salicylic acid → gentisic acid has been demonstrated, *i.e.* in some cases hydroxylation occurs only at the benzoic acid stage[5].

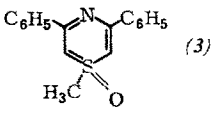
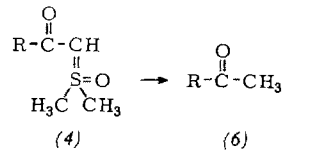
Chemistry of Sulfur Ylides



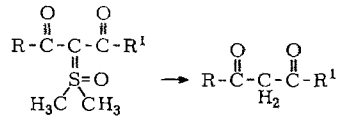
By *H. König*[*]

Whereas cinnamonitrile, like α,β-unsaturated ketones, is converted into phenylcyclopropanecarbonitrile by dimethyloxosulfonium methylide *(1)*, cinnamanilide affords only a little of the cyclopropane derivative along with much 1,3-diphenylpyrrolidone. The nature of by-products from other α,β-unsaturated amides permits conclusions to be drawn about the reaction mechanism. Reaction of a carbonyl or imine group with *(1)* occurs with methylene transfer and formation of heterocycles containing three-membered rings.

With aromatic nitriles prototropy leads to conjugated vinylsulfonium salts *(2)*. Benzonitrile gives also the novel heterocycle *(3)*.



(1) *(2)*

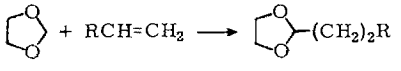


(3)

Isocyanates are not converted into the α-lactams by *(1)*, but form stable crystalline sulfur ylides of type *(4)* or *(5)*, which on desulfurization, *e.g.* by nickel, afford the carbonyl or 1,3-dicarbonyl compounds *(6)* and *(7)*. Simultaneous action of an electrophilic and a nucleophilic reagent on the ylides leads to derivatives of these carbonyl compounds with loss of dimethyl sulfoxide.

(4) *(6)*

(5) *(7)*



According to the nature of the group R, thermolysis of compounds *(4)* occurs either by reversal of the reaction by which they were formed, or – on copper catalysis – with loss of ketocarbene.

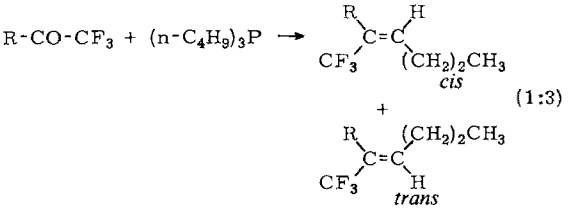
SELECTED ABSTRACTS

The light-induced addition of cyclic acetals to terminal olefins without ring cleavage has been described by *D. Elad* and *I. Rosenthal*. 1,3-Dioxolane and 1,3,5-trioxane gave mainly the

(1)

R = C_5H_{11}, C_6H_{13}, C_8H_{17}

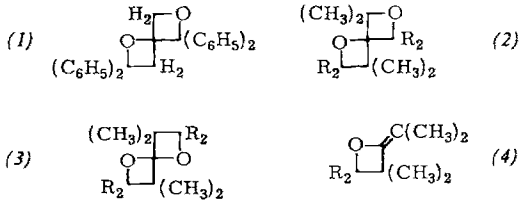


(2)

1:1 adducts *(1)* and *(2)* (yield about 20%). The reaction is carried out by exposure of a mixture of olefin and acetal to UV radiation or to sunlight in the presence of acetone./Chem. Commun. *1966*, 684 / –Ma. [Rd 611 IE]

The stoichiometry of GTP-cleavage during protein biosynthesis was measured by *F. Lipman* and co-workers. In the presence of the complex ribosome/mRNA/aminoacyl-tRNA, GTP and an enzyme system are necessary, as well as a thiol and ammonium ions, for peptide formation. The enzyme system could be purified until the GTPase-activity almost disappeared. In previous experiments the GTP-cleavage was *ca.* 500 times higher than the number of peptide bonds formed. Above a level of a GTPase activity in the region of the peptide bond forming activity it could be demonstrated that one GTP molecule is cleaved per peptide bond formed. The enzyme system could be resolved into three components: T_s (relatively stable), T_u (very heat labile) and G (including the GTPase activity). Hitherto, two components (A and B or I and II) were known. The experiments were conducted with the systems of *Escherichia coli* and *Pseudomonas fluorescens*; the poly-U dependent polyphenylalanine biosynthesis was observed. The enzymatic components of the two microorganisms proved interchangable. / Proc. Nat. Acad. Sic. U.S.A. *55*, 212 and 1562 (1966) / –Hö. [Rd 633 IE]

The reactions of aryl trifluoromethyl ketones with trialkylphosphines have been investigated by *D. J. Burton, F. E. Herkes*, and *K. J. Klabunde*. These investigators found that heating a mixture of the above substances in boiling n-hexane for 20 h resulted in replacement of the carbonyl oxygen atom by an alkylidene group, thus yielding trifluoroolefins. Octanal, benzaldehyde, and acetophenone do not react under these conditions. In the trifluoromethyl ketones, however, the electrophilic character of the carbonyl oxygen atom is increased by the electron-attracting effect of the CF_3–C group. Triphenylphosphine does not react.

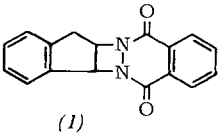


(1:3)

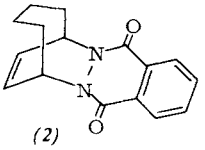
cis + *trans*

This is the first example of a ketone reacting with a trialkylphosphine to yield an olefin. R = C_6H_5, yield 43%; R = *p*-CH_3–C_6H_4, yield 64%. / J. Amer. chem. Soc. *88*, 5042 (1966) / –Ma. [Rd 639 IE]

The photoaddition of carbonyl compounds to allenes has been investigated by *D. R. Arnold* and *A. H. Glick*. The addition of radiation excited CO compounds, to allenes yields the hitherto unknown 2-alkylideneoxetanes as well as the 1,5- and 1,6-dioxaspiro[3.3]heptane ring systems. Compound *(1)* is



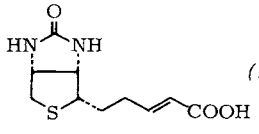
(1) *(2)* *(3)* *(4)*



a: R = C_6H_5; *b*: R = CH_3

produced on irradiation of a benzene solution of benzophenone and allene with a high-pressure Hg lamp. Compounds *(2a)*, *(3a)*, and *(4a)*, in yields of 43, 22, and 12 % respectively, result from benzophenone and tetramethyl allene under the same conditions. Acetone and tetramethylallene give *(2b)*, *(3b)*, and *(4b)* in 8, 51, and 27 % yields. All the cycloaddition products can be formed by attack of the oxygen of the carbonyl n, π^* state on the central carbon atom of the allene. / Chem. Commun. *1966*, 813 / –Ma. [Rd 640 IE]

The 1,2-cycloaddition of an azo group to an olefin has been observed by *O.L.Chapman* and *S. J. Yominianni*. Phthalizine-1,4-dione reacts with indene to form the adduct *(1)*, m.p. 256–258 °C (decomp.), yield 58 %. Phenanthrene probably gives a similar product by 9,10-addition. 1,3-Cyclooctadiene adds phthalizine-1,4-dione to give *(2)*, m.p. 314–315 °C, yield 60 %. Compound *(2)* is the first Diels-Alder adduct of



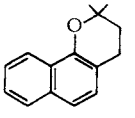
(1)

(2)

1,3-cyclooctadiene. The strong dienophilic character of phthalazine-1,4-dione is demonstrated by the fact that the reaction proceeds at *ca.* 0 °C. / J. org. Chemistry *31*, 3861 (1966) / –Ma. [Rd 641 IE]

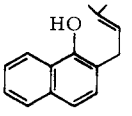
The Edman degradation of peptides which are bound to carriers is the subject of a report by *R. A. Laursen*. The peptide, the N-terminal group of which is protected by methyl isothiocyanate, is activated by *N,N'*-carbonyldiimidazole in dimethylformamide, coupled to a substituted polystyrene carrier, and cyclized to the thiazolinone with trifluoroacetic acid. The solid phase is subsequently separated and the degradation repeated. The thiazolinone, which is formed from the terminal amino acid and which is present in the

(1)



filtrate, is then analysed. The peptide residue on the carrier is treated with HCl and the aminoacids may be identified in the hydrolysate. / J. Amer. chem. Soc. *88*, 5345 (1966) / –Ma. [Rd 645 IE]

The variation of melting temperature with pressure has been expressed by *E. A. Kraut* and *G. C. Kennedy* as a simple relationship of the form



$$T_m = T_m^0(1 + C\Delta V/V_0)$$

where T_m^0 is the temperature of melting and V_0 is the volume at 1 atm. $\Delta V/V_0$, the isothermal compression, is $(V_0 - V)/V_0$ and varies from zero at 1 atm to one at infinite pressure. C is a constant for a given material. For substances which do not undergo a polymorphous change at pressures within the range used in the experiment, the melting temperature, as given by the above equation, may be extrapolated up to values of *ca.* 0.5 for the isothermal compression. Polymorphous transitions may be recognized as breaks in the curve of melting point against compression. The validity of the expression was tested for various metals, sodium chloride, and ice. / Physic. Rev. [2] *151*, 668 (1966) / –Hz. [Rd 646 IE]

A biogenetically important component of teak wood is 2,2-dimethylbenzo[*h*]chroman *(1)*, as has been found by *H. W. Sandermann* and *M. H. Simatupang*. The isolation of *(1)* (m.p. of the picrate: 135–137 °C) supports an earlier hypothesis, according to which 2-(4-methylbut-2-enyl)-1-naphthol *(2)* is a precursor of the various prenyl(= 4-methylbut-2-enyl)-

(1)

(2)

substituted naphthoquinones, of tectol, of dehydrotectol, and possibly also of the 2-methylanthraquinones. Thus the prenyl residue is probably introduced at a 2-naphthol stage, and not at a naphthoquinone stage. / Naturwissenschaften *54*, 118 (1967) / –Jg. [Rd 689 IE]

Trisodium hexahydridoaluminate was obtained in a fairly pure state (approximately 95 %) by *M. Mamula* and *T. Hanslik* by the reaction of a suspension of sodium and aluminum (atomic ratio 3:1) with hydrogen gas (approx. 5 to 150 atm; reaction rate substantially independent of pressure) at 140–200 °C in toluene or hexane in the presence of a little triethylaluminum:

$$3Na + Al + 3H_2 \longrightarrow Na_3AlH_6$$

Trisodium hexahydridoaluminate is a gray-white powder (d = 1.48), which ignites spontaneously in air or with H_2O or alcohols. The (thermal) decomposition curve indicates that the substance is uniform. Some of its reactions are:

$$Na_3AlH_6 + 2Al + 3H_2 \xrightarrow[p_{H_2} \approx 75\,atm]{140-160\,^\circ C} 3NaAlH_4$$

$$Na_3AlH_6 + 2AlH_3 + 3LiCl \longrightarrow 3LiAlH_4 + 3NaCl$$

$$Na_3AlH_6 \xrightarrow{> 200\,^\circ C} 3NaH + Al + 1.5\,H_2$$

$$Na_3AlH_6 + 6/(4-x)\ R_xSiCl_{4-x} + L \longrightarrow 6/(4-x)\ R_xSiH_{4-x} + 3NaCl + AlCl_3 \cdot L$$

(L = ether, tertiary amine)

/ Collect. czechoslov. chem. Commun. *32*, 884 (1967) / –Jg. [Rd 690 IE]

Geschiche der Chemie seit dem Wiederaufleben der Wissenschaften bis an das Ende des 18. Jahrhunderts (The history of chemistry from the scientific renaissance to the end of the 18th century) by J. F. Gmelin. 3 volumes, with viii, 777; 790, and II, 1288 pages and index (unpaginated, 96 pages). Reprographic reprint of the Göttingen edition 1797/1798/1799. Georg Olms Verlagsbuchhandlung, Hildesheim 1965; DM 398.–.

Geschichte der Chemie (History of Chemistry), by *H. Kopp*, 4 volumes, with XIX, 456; X, 428; XII, 373, and XVI, 446 pages. Repropraphic reprint of the Braunschweig edition 1843/1844/1845/1847. Georg Olms Verlagsbuchhandlung, Hildesheim 1966; DM 232.–.

The discussion of these two works together reveals, apart from the subject, an interesting relation between the authors. *Johann Friedrich Gmelin* (1748–1804), Professor of Medicine and Philosophy at Göttingen, was the father of *Leopold Gmelin* (1788–1853), the originator of the "Handbuch der theoretischen Chemie" (1817/1819), which in its 5th edition (1852/1853) was renamed "Handbuch der anorganischen Chemie". *Leopold Gmelin*, as Professor of Chemistry at Heidelberg, was the teacher of *Hermann Kopp* (1817–1892), who at the age of 26 started to publish his famous history of chemistry, which is still regarded as a standard work.

J. F. Gmelin's history forms Part 8 of a "History of the Arts, and Sciences, by a Group of Learned Authors", which was to be an encyclopedia of the development of the natural sciences up to the beginning of the 18th century. A few years earlier, *Johann Christian Wiegleb*'s three-volume "Geschichte des Wachsthums und der Erfindungen in der Chemie in der neuren Zeit" (1790/1791) and "... in der ältesten und mittlern Zeit" (1792), which contains a wealth of facts, had been published. Gmelin was aware of the complex and often contradictory material that had to be molded into a history. In the introduction to the first volume he wrote "Of all the sciences and arts that have engaged the human mind, few have undergone such frequent and rapid changes through the ages, and have had to overcome so many difficulties in their formation, elucidation, and perfection from their earliest infancy up to our own times, as chemistry". The author therefore maintains in the preface that the historian cannot achieve any useful purpose unless he is aware of the significance of the science with which he is dealing. On the other hand, he should not "allow himself to be carried away by passionate love of the subject to such an extent that the attributes to it unfounded exclusive privileges for the education of mankind and for the perfection of other sciences and arts".

In accordance with his intention "to remain true to fact in this description of the fortunes of chemistry", he unfolded before his contemporaries a comprehensive picture of chemistry as it appeared to him with the chemical knowledge of that time. His information, arranged chronologically rather than by subject, is substantiated by numerous references to the earlier and to contemporary literature. However, this work is nowadays generally regarded as having little permanent interest, and is because of the many errors that it contains often disposed of in a few words. This is most unjust in the reviewer's opinion, since the work provides a veritable mine of early views and opinions for the present-day historian.

In the development scheme of historiography given by *H. Breysig* in 1931, *Gmelin*'s work would undoubtedly belong to the purely factual phase, though the facts were subjected to a certain critical evaluation. *Johann Bartholomä Trommsdorff*'s "Versuch einer allgemeinen Geschichte der Chemie" (Erfurt 1806) and *Thomas Thomson*'s two-volume "History of Chemistry", which was published in London in 1830/1831 and is described by *J. R. Partington as* "still of value", since it also makes extensive reference to the original sources, also belong to this phase.

The second phase, classificatory historiography, began with *Alexander von Humboldt*'s five-volume work, "Kosmos, Entwurf einer physischen Weltbeschreibung" (Stuttgart 1845/1862), which also formed the highlight of this phase. In the first volume of this monumental interpretation of knowledge of natural science, the author says that the purpose of such a description is "to recognize the unit in the multiplicity; to embrace all that recent discoveries hold out to us about the particular; to examine and sift the details without being overcome by their weight". Thus this work paved the way for a turning point in the approach to history, *i.e.* the replacement of a listing of facts by their classification and the extraction from them of ideas serving as a basis for new work.

The first work of this type on the history of chemistry was probably *Ferdinand Hoefer*'s two-volume "Histoire de la chimie depuis les temps les plus reculés jusqu'à notre époque" (Paris 1842/1843). By the use of the Greek and Latin manuscripts available at the "Bibliothèque Nationale" in Paris, this author was able to present, in many respects, a better picture of the earlier period of chemistry than *Kopp*, though, as *Berthelot* was also to do later, he made many errors of interpretation. *Kopp*'s history of chemistry will therefore be generally regarded as more reliable.

Kopp gives a reason that is very common even today for the compilation of his history, which arose from notes that had become so comprehensive "that it seemed to be useful to arrange and publish them". Thus in the preface to the first volume he says, "The decision.... to publish this work was largely influenced by the fact that the history of chemistry seems to have been a much neglected field of research in recent decades". This was only natural, since these years were marked by the work in the new field of synthetic organic chemistry, and successes and progress counted for much more than retrograde understanding.

However, *Kopp* regarded this understanding and the discovery of relationships as important. "Past historians", he wrote, "attempted to report all the achievements of all chemists in one order, *i.e.* in chronological order. Owing to the volume and diversity of the material, however, a work arranged in this manner, though possibly complete in other respects, can only contain a confusion of unrelated discoveries".

Up to our own time, *Kopp*'s work remained the comprehensive work on the history of chemistry. Supplemented later by the "Entwicklung der Chemie in der neuren Zeit" (München 1873), „Beiträge zur Geschichte der Chemie" (3 parts, Braunschweig 1869/1875), and "Alchemie in älterer und neuerer Zeit" (Heidelberg 1886), it was the only comprehensive work, apart from Hoefer's, that referred to the original sources. Smaller works such as *Ernst von Meyer*'s "Geschichte der Chemie von den ältesten Zeiten bis zur Gegenwart" (Leipzig 1889 and later editions) was largely based on this history by *Kopp*.

Parallel to the development in chemistry itself, "specialization" began in chemical historiography even before the turn of the century. Though at first still leading to books covering an entire field, such as "Geschichte der organischen Chemie von ältester Zeit bis zur Gegenwart" by *Edvard Hjelt* (Braunschweig 1916) or the "Geschichte der organischen Chemie" by *Carl Graebe* (Berlin 1920), historical research moved into ever narrower sectors, the results of which were published in journals and monographs.

As a result of this specialization, it naturally became necessary to correct many of *Kopp*'s data, but there was at first no author to be found to write such a modified general history. It was only in 1961, 120 years after the publication of *Kopp*'s work, that *J. R. Partington*'s "History of Chem-

istry" began to appear (four volumes, the last of which is still to be published).

Have therefore, in view of these developments, works such as those by *Gmelin* and *Kopp* become superfluous? For the reader interested in a given event in the development of chemistry, *Partington* may be more suitable, since it presents the current state of knowledge. However, for those with a deeper interest in the problems of the history of chemistry, it will still be necessary to return to the earlier publications, since *Gmelin* and *Kopp* present the knowledge of their time in a lucid form. The publishers therefore have good reason to include these two works in their reprint program.

W. Ruske [NB 559 IE]

Grundlagen der Polarographie (Principles of Polarography) by *J. Heyrovský* and *J. Kůta*. Translated by *H. Bažantová*. Edited in German by *K. Schwabe*. Akademie-Verlag, Berlin 1965. 1st Edit., xvii, 592 pp., 256 figures. DM 73.–

The book presents a comprehensive survey of the theoretical principles of and the general information that can be obtained by classical direct-current polarography, with reference to its applications in electrochemical kinetics and the physical chemistry of solutes. Polarography in these fields has undergone a remarkable and decisive development in the past two decades.

The authors are successful in their aim of explaining the basic theoretical aspects without losing themselves in details of the mathematical derivations, which easily can be found in the original literature cited. The style is fluid and clear, so that the theoretical problems of polarography, which often are not entirely free from complications, are made accessible even to the novice. The experienced worker will also find this an indispensable and frequently consulted reference work. This applies, not only to specialists in polarography, but to electrochemists in general and all those concerned with the application of electrochemical techniques. The present volume, which reflects more than 40 years' experience of the originator of polarography and his co-worker *Kůta*, can therefore be recommended to a wide circle of readers. It is to be hoped that this book will lead to a more intensive use of the versatile possibilities of the polarographic method. The present work clearly refutes the view that polarography is unsuitable for fundamental problems. Provided that there is freedom of choice concerning the electrode material, as is usually the case in fundamental problems, the opposite is in fact true, and polarographic methods become the method of choice.

The Czech edition has been added to and brought up to date in the German translation, which takes into account the literature up to the beginning of the 1960's. The subject matter is divided into 22 chapters, which deal with the following topics: physics of the dropping-mercury and mercury-jet electrodes, influence of the resistance of the electrolyte, theory of the diffusion current and kinetically controlled limiting currents, the theory of reversible and irreversible steps including their behavior in the case of complexes and semiquinones, the evolution of hydrogen and its catalysis, adsorption and inhibition, maxima, the uses of the hitherto much neglected Kalousek switching circuit and the theory of the resulting currents, and oscillographic polarography, with special emphasis on the *Heyrovský* version. The appendix contains a useful table of half-wave potentials of inorganic and many organic depolarizers in a series of supporting electrolytes. The reviewer would have welcomed a more thorough treatment of the double-layer effect. The results for the dissociation and recombination kinetics of weak acids also require a much more critical discussion than the footnote to Table 17/3.

Finally, it should be pointed out that the numerous novel polarographic techniques, which open up formerly closed fields to electrochemical kinetics and offer a wealth of new information, are almost completely absent. Alternating-current, square-wave, and pulse polarography are mentioned only briefly, and while the increased instrumental demands are stressed no list is given of the far-reaching possibilities thus gained. No mention is made of second-order techniques (such as Faraday rectification, the use of higher harmonics, and intermodulation methods). The treatment of oscillographic pulse methods is also too short.

The German edition unfortunately contains more printing errors than such an important book should. The presentation and binding are good. *H. W. Nürnberg* [NB 556 IE]

An Introduction to Electron Paramagnetic Resonance. By *M. Bersohn* and *J. C. Baird*. From the series "Frontiers in Chemistry". W. A. Benjamin, Inc., New York-Amsterdam 1966. 1st Edit., xi, 274 pp., 110 figures, $15.00.

After a general introduction, the authors devote about 120 pages (Chapters 3 to 10) to hyperfine structure, relaxation, g factors, quantitative measurements, organic radicals, triplets, inorganic compounds, and double-resonance; a further 40 pages (Chapters 11 and 12) deal with applications in chemistry and biology. The appendix gives a more quantitative presentation of the interactions in the two-spin system, and the book ends with a list of the coupling constants of 130 selected organic radicals and radical ions.

The book is intended for chemists and biologists having no prior knowledge of the subject. The picture presented is very general, since *e.g.* the following topics are covered in a total of about 30 pages: inorganic radicals, metal complexes, nonconductors, metals, Mössbauer effect (1½ pages!), Overhauser effect, ENDOR, optical pumping, and level crossing.

A conspicuous feature of the whole book and particularly of the tables (g factors, pp. 70/71, and coupling constants, pp. 238–270), is the complete disregard of all but English-language literature. The physical chemist will sometimes be disappointed by the lack of accuracy. Thus in the discussion of the intensities of the HFS components (p. 80), the incorrect, but convenient, and hence commonly used counting rule is described in detail for the H_2^+ ion, but the reader is not told that two protons combine to give a singlet and a triplet, though this is explained in an elementary and laborious manner for the case of electrons (p. 108).

On the whole, the reviewer has gained the impression that the authors were pressed for time. However, despite the shortcomings mentioned above, the book will undoubtedly find a wide circle of readers and contribute to the growth of interest in this modern field. *K. H. Hausser* [NB 570 IE]

Investigation of Inorganic Systems at High Temperature by Mass Spectrometry

BY J. DROWART AND P. GOLDFINGER [*]

High-temperature mass spectrometry (hitherto at temperatures between 1000 and 2500 °K and at pressures between 10^{-3} and 10^{-12} atm) has already made possible the identification of many previously unknown and unpredicted diatomic and polyatomic molecular species. The present paper deals with the investigation of many oxides, of halides, and of carbon molecules and intermetallic molecules. An apparatus for the production and investigation of molecular beams is described. Knudsen cells permit the production of molecular beams under equilibrium conditions; in special cases the "double-oven" type of Knudsen cell is used. Thermodynamic and kinetic quantities such as ΔH_T^0 values, dissociation energies, and ionization cross sections of the species investigated are given.

1. Introduction

Thermodynamic investigations by mass spectrometry of high temperature systems were started by *Chupka* and *Inghram* [1] and by *Honig* [2] about fifteen years ago with the study of the vaporization of carbon. Thereafter the studies extended rapidly to other elements [3,4], to intermetallic compounds [5], to oxides [6, 7, 8], sulfides, selenides, and tellurides [5], to halides [9–13], hydroxides [14], and nitrates [15].

This method has become one of the most powerful tools for the study of gas-solid or gas-liquid equilibria at high temperatures. Hundreds of condensed systems in equilibrium with their vapor have since been studied and their mode of evaporation [a] established. Gaseous molecules, many of which had been previously studied by spectroscopic methods only or were unknown and quite unexpected, were identified and their dissociation or atomization energies obtained from their equilibrium pressures. These results have led to an appreciably modified picture of the stability of gaseous inorganic molecules and to the knowledge of many new molecular species.

During the past few years, high temperature mass-spectrometric studies have been extended to the study of the mechanism and kinetics of vaporization and condensation processes and to the investigation of

[a] The expression "mode of evaporation" is used here to describe the entirety of the overall chemical reactions observed. The detailed sequence of processes or steps of these reactions is referred to as mechanism.

chemical reactions of gases and solids [16]. In these fields, this technique is leading to the accumulation of important new data.

The method consists in: isolating a representative sample of the gaseous phase of the system investigated in the form of a molecular beam; forming ions from the neutral species present in this beam; mass analysing the ions in the spectrometer and measuring their intensity; identifying the ions and thus determining the neutral species from which they were formed; calculating the flux of neutral species in the molecular beam from the ion intensity and then deriving thermodynamic and kinetic quantities from the flux.

Comprehensive reviews [17,18] have been written which give the details of the technique, calculations, and tables of results. In the present paper, the various steps of the method outlined above are described and a brief summary is given of the contributions which the technique has made to our knowledge of gaseous inorganic molecules.

2. Experimental Details

The apparatus used for this particular application of the molecular beam technique consists of a) a molecular beam source and collimating system; b) an ionization source; c) a mass spectrometer; d) an ion-collector; e) a vacuum envelope in which the components (a–d) are placed and in which a low pressure can be maintained so that the mean free path is several times the greatest distance to be traveled by any particle (*i.e.* from the ion source to the collector).

A molecular beam is defined [19] as "a large number of molecules moving practically collision free in a highly evacuated space in straight and almost parallel trajectories". Such a beam emerges from a metal vessel (Fig. 1) with a small aperture of area s, usually called a Knudsen cell, which contains the gas or vapor to be studied. The atoms or molecules whose velocity vectors point towards the orifice effuse and continue to travel along straight lines. By placing one or more apertures in front of the orifice it is possible to select a fraction of the effusing molecules to form the beam proper. Collisions in the beam occur only on those rare occasions when a molecule overtakes a slower moving one. Monomolecular decay of complex molecules excited above their dissociation limit is also a rare occurrence and any optical transitions do not modify the chemical nature of the species. For these reasons such a beam is a truly representative sample of the system investigated.

Collisions between molecules in the effusion orifice may be avoided by maintaining the mean free path λ of the molecules in the cell large compared to the diameter d of the orifice. When $\lambda \simeq d$ transition to hydrodynamic flow ($\lambda \ll d$) takes place, which is usually avoided in the type of work described here (see, however, [20]).

When the ratio between the area of the effusion orifice s and that of the vaporizing substance S is small, the equilibrium between the gas and the condensed phase will not be perturbed by the effusion. If necessary this can be verified by measuring the rate of effusion as a function of the ratio s/S at constant temperature. When the orifice has a negligible thickness compared to its diameter, elementary kinetic theory of gases shows that the total number of molecules effusing per unit time, Z, is given [21] by

$$Z = nus/4 \qquad (1)$$

($n = p/kT$: the number density (molecules cm^{-3}) in the cell, $u = (8kT/\pi m)^{1/2}$: the average velocity; p = pressure; k = Boltzmann's constant; T = absolute temperature; m = mass).

Their intensity distribution is proportional to the cosine of the angle between the paths of the molecules and the normal to the orifice, in an analogous manner to Lambert's law for radiation emitted from a light source. When the orifice has a finite thickness x, both the rate of effusion and the angular distribution [22] are a function of x/d.

An alternate way of producing molecular beams consists in collimating the molecules freely vaporizing from the surface of the sample studied. This technique has been widely applied by Langmuir [23] and is usually referred to by his name.

To ensure the establishment of equilibrium between the condensed and the gaseous phase, Knudsen cells have been employed as molecular beam sources in a large proportion of the investigations discussed here; where the interest lay in the kinetics and reaction mechanism, the Langmuir method was used [16].

A typical apparatus is given in Fig. 1 which shows the Knudsen cell, radiation shields, and the heating element. For the study of equilibria between a condensed phase and a permanent gas, cells with a "gas-inlet" have been used [24] while for the study of the equilibria

in unsaturated vapors, measurements have been performed in "double-oven" [25] type Knudsen cells. Recently, electrochemical Knudsen cells have been employed [26].

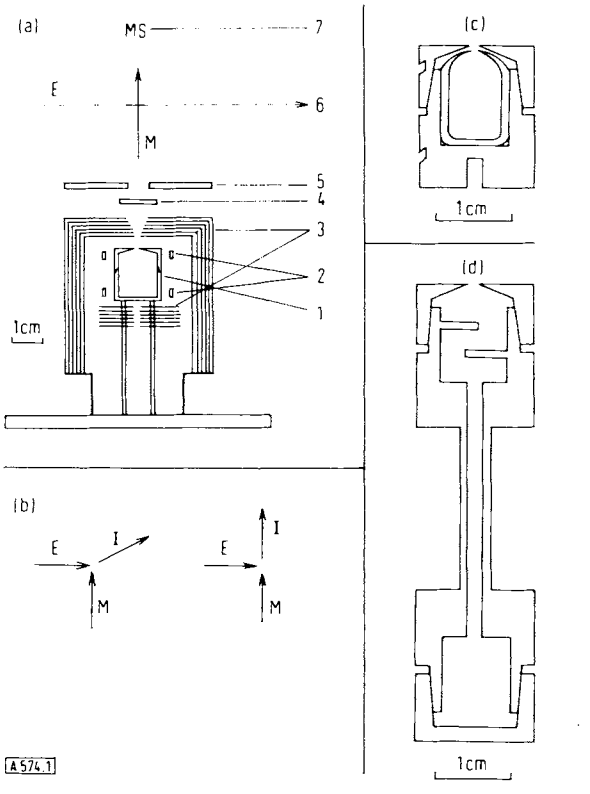

Figure 1. Knudsen Cell

(a) Assembly
(1) Knudsen cell; (2) Heating elements; (3) Radiation shields; (4) Movable shutter; (5) Entrance slit to ion source (can be water or liquid nitrogen cooled) (6) Electron beam; (7) Mass analyser.

(b) Shows mutuallv perpendicular molecular (M), electron (E), and ion (I) beams or alternatively parallel molecular (M) and ion (I) beams and vertical electron (E) beam.

(c) Detail of Knudsen cell in which a refractory ceramic or metallic crucible may be inserted and which has a number of holes for sighting with an optical pyrometer or for inserting thermocouples.

(d) Double Knudsen cell.

The cells, which are usually made from molybdenum, tantalum, or tungsten, may contain refractory metallic or ceramic liners to avoid reaction of the species with the cell material. The choice of the appropriate container materials is a serious problem at high temperatures; it can be facilitated when phase diagrams are available, but often proceeds empirically. The selection is then facilitated by the fact that gaseous reaction products or variations in activity resulting from alloy or compound formation are easily observed with the mass spectrometer.

Heating is generally performed by radiation up to temperatures of about 1000 °C and by electron bombardment at higher temperatures. Arc imaging techniques [27] and lasers [28] have also been used.

Thermocouples are used for temperature measurement in the lower range; optical pyrometers, usually monochromatic, sighting into black-body holes [b] or directly into the effusion orifice are employed at higher temperatures. Provision can be made to check temperature uniformity throughout the Knudsen cell. In the authors' opinion the reproducibility and accuracy of temperature measurements is essentially the same in the mass spectrometric system as in the classical, analogous apparatus for measuring pressures by the Knudsen, torsion, or Langmuir methods. In the temperature interval 1000–2500 °K, in which most of the measurements are performed, the temperature uncertainty is estimated to be about 1%.

The molecular beam leaving the cell is defined by an aperture in the radiation shields (see Fig. 1). A movable beam defining slit placed in front of the ion source enables one to measure the intensity distribution in the molecular beam, in order to ascertain the correct geometrical origin of the species identified in the mass spectrometer (Fig. 1 and 2) and to detect perturbing phenomena such as the creeping of liquids onto the lid of the cell or their migration through the walls *e.g.* by interboundary migration. It further permits one to distinguish the ions formed by electron impact on the vaporizing species from those produced from the background gases.

Different geometric arrangements of the molecular, electron, and ion beams have been used. In most applications, the electron beam is parallel to the entrance slit of the spectrometer and the molecular beam perpendicular to it. The ion beam can then be either coaxial with or perpendicular to the molecular beam (Fig. 1). In practice no significant differences in operation or in the results have been observed.

The ionization method is selected so as to give as faithful a picture as possible of the neutral molecules in the molecular beam and simultaneously the highest possible sensitivity. Therefore, ionization by electron impact and identification of the positive ions have been applied. Since in most cases an energy spread of a few tenths of one eV is permissible in establishing the main features of the ionization efficiency curves which are to be discussed, ion sources of conventional types [29] have been used. A retarding potential difference [30] source has been used [31] in applications where the interest lay more in the accurate study of the ionization efficiency curve of high temperature species than in the measurement of partial pressures and where, therefore, monoenergetic electrons are required, the obtention of which results in a marked loss of intensity.

Surface ionization, which is extremely sensitive, is only applicable to elements or molecules with low ionization potentials and is hence too specific. Field ionization[32] which has promising characteristics has not hitherto been applied. Recently, interesting results obtained with photoionization have been published[33].

Mass analysis has been performed in general with single focusing magnetic instruments. The characteristics of such instruments and their mode of operation have been discussed in monographs on mass spectrometry[29]. Because of better accessibility to the source and a greater ease of installing multipliers, 60° instruments have been preferred. Since 1960, time-of-flight mass spectrometers have also been applied[34]. In the sector instruments, the resolving power and detection limit have in general been better than in the time-of-flight mass spectrometers. With the assemblies described hitherto in the literature the overall pressure range accessible extends from about 10^{-3} to 10^{-12} atm in the Knudsen cell. The upper pressure limit is set by the dimension of the effusion orifice. Usually these have been 0.1 to 1 mm in diameter. The use of smaller diameters or very narrow slits as effusion orifices leads to difficulties which increase markedly with temperature. The lower limit is, generally speaking, fixed by interference with background gases and by the sensitivity of the mass spectrometer. In the former case, the pressure should be decreased below the usual value of some 10^{-6} to 10^{-7} torr; alternatively double focusing instruments can be used for which the increased resolving power enables one to separate the inorganic ions of interest here from the mostly organic ions formed from the background gases. When the limitation is set by the sensitivity of the mass spectrometer, the now available quadrupole[35] (or monopole) instruments which combine the advantage of high sensitivity and relatively high resolving power may be used. High intensity ion sources[36] and focusing lenses[27,37] present further possibilities.

3. Identification of Species

For species identification, the complete mass spectrum must be evaluated over the greatest possible temperature range. The spectrum is checked at the mass numbers corresponding to all possible combinations of the elements and their isotopes present in the system (including the container materials and possible impurities), ascertaining whether their intensity is affected by the movable beam defining slit. It is simultaneously verified that the intensity distribution of the neutral molecule in the molecular beam is normal (see Fig. 2). Ions formed from the vaporizing species are so singled out from those due to the ionization of background gases. The higher the resolving power, the greater will be the observable effect of differences in packing fraction[c] between inorganic ions and hydrocarbon ions.

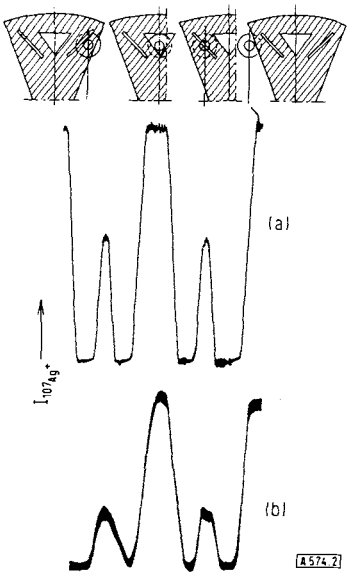

Figure 2. Measurement of the intensity distribution in the molecular beam.

Normal (a) and distorted (b) intensity profiles obtained when rotating the beam defining slit across the molecular beam. Note slopes in the profiles, width and height of peak, flat or rounded valley when narrow slits cross. The upper part of the figure represents positions of the beam defining slit corresponding to the intensity on the recording.

Since most elements have several isotopes and since there is little overlapping between mass numbers, the measurements of the isotopic distribution and beam profile will leave little ambiguity concerning the identification of the ions. The measurement of their appearance potential will often remove remaining difficulties.

In the type of application discussed here, the nature and concentration of the neutral molecules is deduced from the ions identified and an understanding of the ionization phenomena[38–42] leading to their forma-

[c] The packing fraction is defined as $(M-A)/A$ where M is the exact mass and A the corresponding whole mass number, both in atomic mass units. In the ^{12}C scale, the difference $M-A$ is *e.g.* 7825×10^{-6} for H, 0 for ^{12}C, -5085×10^{-6} for ^{16}O, -52052×10^{-6} for ^{48}Ti and $+ 50760 \times 10^{-6}$ a.m.u. for ^{238}U. Therefore the exact mass of ^{48}Ti, 47.947867, is different from that of $^{12}C_4$, 48.0 exactly, by 0.1%.

tion and not from typical mass spectra of standard samples.

All neutral gaseous species are ionized by impact with electrons. At about three to five times the ionization potential, the ionization cross section goes through a flat maximum, where its value from the lightest atoms to the heaviest molecules increases quite regularly by about a factor of fifty [d] (Table 1). In most cases, the parent ion, *i.e.* the molecular ion formed without fragmentation, will be 5 to 20 times more intense than fragment ions derived from the same molecule. Typical exceptions are molecules containing strongly electronegative atoms or groups, where the predominating ion is that formed by the loss of this atom or group. In order to identify a neutral precursor, parent and fragment ions must be distinguished; consideration of the ionization phenomena and of chemical and thermodynamic arguments enables one to make this distinction.

The basis of the ionization efficiency and appearance potential measurements is illustrated qualitatively in Fig. 3 (for a more detailed discussion, see [41]). The minimum energy at which direct ionization

$$A(g) + e \rightarrow A^+(g) + 2\,e \qquad (2)$$

takes place is the ionization potential IP of atom A. For a molecule, the minimum energy for the process

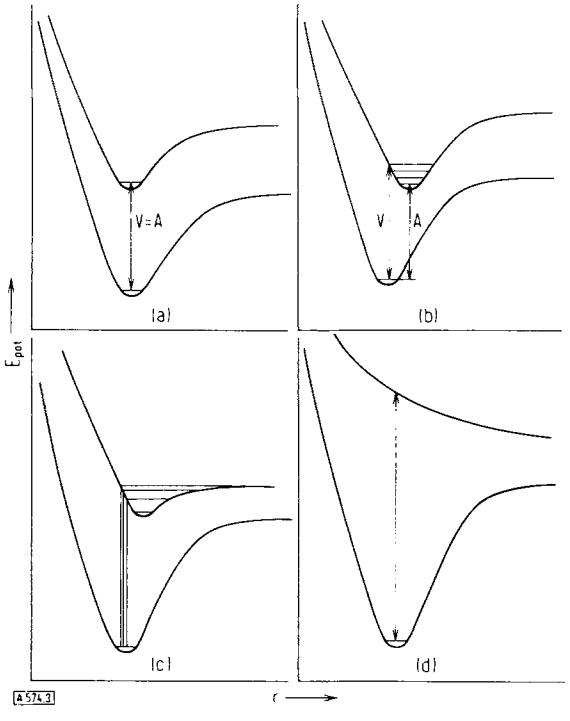

Figure 3. Potential energy curves showing: equal vertical (V) and adiabatic (A) ionization potential $V = A$ (a); $V \neq A$ (b); vertical ionization leading to, or nearly to, dissociation, with parent and fragment ions present (c); upper potential energy curve repulsive, with ionization always accompanied by fragmentation (d).

[d] Therefore ions corresponding to all species present in a gaseous mixture in widely different concentrations are observed in the mass spectrometer. This is the reason for the unique advantages of mass spectrometry in the analysis of gases. In contrast, optical absorption or emission probabilities may vary by several powers af ten from one gaseous species to another.

$$AB(g) + e \rightarrow AB^+(g) + 2\,e \qquad (3)$$

is either the adiabatic or the vertical (Fig. 3) ionization potential depending on whether or not the Franck-Condon principle, which is applicable to this process, allows the minimum of the AB^+ potential energy curve to be reached.

The minimum energy AP (appearance potential) at which fragmentation, *i.e.* the process

$$AB(g) + e \rightarrow A^+ + B(g) + 2\,e \qquad (4)$$

occurs, is given by

$$AP \geqslant IP(A^+) + D(AB) \qquad (5)$$

where the inequality results from the fact that both A^+ and B can have kinetic energy (or kinetic plus internal energy in the case where A or B represent di- or polyatomic species) [42].

Especially for process (2), theory [40], and experiment [41,43], indicate that the efficiency increases linearly with the excess energy as long as the process corresponds to a transition from one well defined lower to a similarly well defined upper state; the ionization efficiency curve will therefore have the form illustrated in Fig. 4 when the vapor contains both species A and AB so that processes (2) and (4) can occur simultaneously.

The straight line a–b corresponds to the direct ionization of A, while the difference between the line b–c and the extrapolated line a–b corresponds to the production of A^+ ions from AB molecules. In such cases it is still possible to measure the pressure for A in presence of large amounts of AB by maintaining the energy below that corresponding to point b.

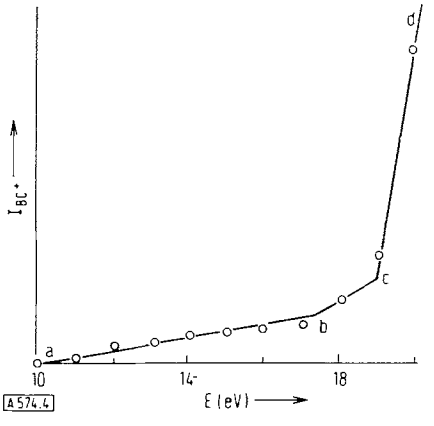

Figure 4. Ionization efficiency curve for the ion BC^+; a–b corresponds to $BC \rightarrow BC^+$; b–c and c–d correspond to $B_2C \rightarrow BC^+ + B$ and $BC_2 \rightarrow BC^+ + C$ respectively.

The difference $E_b - E_a$ should correspond approximately (relation (5)) to the dissociation energy of the bond AB. In view of difficulties in obtaining accurate dissociation energies in this manner, it has usually been preferred to obtain these data from thermodynamic calculations (Sections 5 and 6).

In the case of an atomic ion, the correctness of the identification can be easily verified by checking whether the measured ionization potential IP(A) corresponds to the spectroscopic value. Rydberg series

[43] *L. J. Kieffer* and *G. H. Dunn*, Rev. mod. Physics *38*, 1 (1966).

for molecules have been observed in few cases only. Comparison with isoelectronic molecules, for which the ionization potential is known spectroscopically or from mass spectrometry, will then be useful [39,44]. It has further been observed that the ionization potential of a molecule with no free valence electrons is about equal to the average of the ionization potentials of the constituent atoms. For molecules with free valence electrons, it tends to be closer to the ionization potential of the more metallic element.

If the potential energy curve of the molecular ion is repulsive (or only the repulsive branch is accessible in the Franck-Condon region) (Fig. 3c and 3d), the ion A^+ is formed with kinetic energy. Measurement of the latter then confirms the occurence of such processes [45].

In the case of polyatomic molecules, the excess energy can appear in internal degrees of freedom and the parent ion may be metastable. If the rate constant for dissociation of the initial ion (mass m_i, charge n_i) to fragment ions (mass m_f, charge n_f) is such that decay occurs in the region between the ion source and the analyser, it can be observed by the presence in the spectrum of peaks at an apparent mass [29] m_{app},

$$m_{app} = n_i m_f^2 / m_i n_f^2. \qquad (6)$$

Whereas there are numerous such examples for hydrocarbons, few are known presently in high temperature chemistry.

Alternative modes of ionization [38,39,46], such as

$$AB(g) + e \rightarrow A^+ + B^- + e \qquad (7)$$

have a different [41] ionization efficiency curve from that shown in Fig. 4. If this process is suspected to occur, a search for the ion B^- should be made; the cross section for this reaction is small.

For M_2 species with very low relative intensities, it is useful to verify that the peak observed is not due to second order phenomena such as charge exchange reactions [47] of the type (8)

$$M^{++} + X \rightarrow M^+ + X^+ \qquad (8)$$

which take place in the analyser, where X is a residual gas. According to (6), such reactions give rise to an apparent mass $2m_i$, which can not be distinguished from that of M_2^+ except by the isotopic distribution. Such processes are avoided by working at ionizing electron energies below the second ionization potential of M.

Other reactions which should be considered are ionization reactions caused by excited metastable A* atoms [47,48]

$$A^* + A \rightarrow A_2^+ + e \qquad (9)$$

where A* is produced by electron impact. Again, a different efficiency curve will be obtained since the process $A + e \rightarrow A^* + e$ is a resonance process.

Ion attachment reactions [49]

$$A^+ + 2\,A \rightarrow A_2^+ + A \qquad (10)$$

may also be mentioned, although the density in the source is in general too low for three body collisions. Yet another possibility is that of ion/molecule reactions [50] as in eq. (11).

$$\begin{aligned} A^+ + B_2 &\rightarrow AB^+ + B \\ A + B_2^+ &\rightarrow AB^+ + B \end{aligned} \qquad (11)$$

In this case the ionization efficiency curve for AB^+ should parallel that for A^+ or B_2^+ and may further be a function of the potentials in the ion source. If A or B_2 are permanent gases, it is useful to vary their pressure.

Independent chemical and thermodynamic arguments are sometimes necessary in the identification of the neutral precursor of an observed ion. Such arguments involve consideration of the variation of temperature, of crystalline modification, comparison of equilibrium and nonequilibrium conditions, and modification of the composition of the system. A number of examples most easily illustrate the use of such arguments. The ratio of the ion intensities for C^+ and C_3^+ varies from 2.3 to 8.0 between 1820 and 2700 °K [51]; at 2400 °K the ratio varies from 6 for vaporization from a Knudsen cell to 1.5 for vaporization from a polycrystalline filament [52,27]; this shows that C^+ and C_3^+ have different neutral precursors, namely C and C_3. The variation with temperature of the intensity of the ions LiI^+ and Li_2I^+ formed from the vapor in equilibrium with crystalline LiI is almost parallel [53], the change for Li_2I^+ is, however, double that for LiI^+ at the melting point; this demonstrates that Li_2I^+ is formed from a neutral molecule which is a dimer of the molecule from which LiI^+ is formed. Since the change forLiI^+

corresponds to the known heat of melting, LiI^+ and Li_2I^+ are formed from the neutral molecules LiI and Li_2I_2 respectively[45,54,55]. The intensities I of the ions $Ge_2O_2^+$ and $Ge_3O_3^+$ vary proportionally to $I^2(GeO^+)$ and $I^3(GeO^+)$ respectively when dismutations GeO(amorphous) → 1/2 GeO_2(glass) + 1/2 Ge(crystalline) → 1/2 GeO_2(hexagonal) + 1/2 Ge(crystalline) occur in the condensed phase. The variation in intensity, *i.e.* partial pressure of the ion GeO^+ yields thermodynamic data for GeO(amorphous) and GeO_2(glass) relative to those for GeO_2(hexagonal), which agree with the literature data. GeO^+ is therefore formed from the molecule GeO and $Ge_2O_2^+$, and $Ge_3O_3^+$ from Ge_2O_2 and Ge_3O_3 respectively[56].

The ratios of intensities for S_6^+, S_7^+, and S_8^+ are markedly different for rhombohedric, amorphous, and Engel's sulfur showing again that they are formed from different neutral precursors[57].

Mass spectrometric measurements on the polyatomic sulfur and selenium molecules have also been performed with electrochemical Knudsen cells[26b]. Such measurements are based on the use of the galvanic cell Pt, Ag/AgI/Ag_2S (or Ag_2Se), Pt, where AgI, a purely ionic conductor, is used as solid junction. When such cells are polarized the reaction

$$Ag_2S\,(\text{or } Ag_2Se)\,(\text{solid}) \rightarrow 2\,Ag\,(\text{solid}) + S_x/x\,(\text{or } Se_x)\,(\text{gas}) \quad (12)$$

occurs. Since Ag_2S and Ag_2Se have a small homogeneity range, it can be shown that the chemical potential μ of sulfur and silver in the compound are related by eq. 13, with good approximation, to the Gibbs free energy of formation of the compound and the chemical potentials μ^0 in the standard state.

$$\mu_S - \mu_S^0 = \Delta G(Ag_2S) - 2(\mu_{Ag} - \mu_{Ag}^0) \quad (13)$$

Therefore the pressure of S_x in equilibrium with a given composition is related to its pressure in equilibrium with pure sulfur by eq. (14).

$$p_{S_x} = p_{S_x}^0 \text{ exp. } x(\mu_S - \mu_S^0)/RT \quad (14)$$

If $p_{S_x}^{'}$, the decomposition pressure above Ag+Ag_2S, is chosen as reference pressure, eq. (14) becomes eq. (15).

$$p_{S_x} = p_{S_x}^{'} \text{ exp. } 2xEF/RT \quad (15)$$

(R = gas constant, E = EMF of the cell, F = Faraday constant, T = absolute temperature).

From eq. (20), the ion intensity $I^+(S_x)$ measured after mass analysis is given by eq. (16). The measurement

$$I^+(S_x)T \sim \text{exp. } 2xEF/RT \quad (16)$$

of $I^+(S_x)$ as a function of E at constant temperature thus permits the determination of x. Between 200 and 400 °C and within large limits of E, x = 2, 6, 7, and 8 respectively were measured for S_2^+, S_6^+, S_7^+, and S_8^+. These ions are therefore parent ions. At low values of E, x = 3, 4, and 5 for S_3^+, S_4^+ and S_5^+, were obtained whereas at high values of E, x tends towards higher values for these three ionic species: at low activity of sulfur they are parent ions, afterwards fragment ions.

The ratio AlO^+/Al_2O^+ changes from about 0.5 for the vapor above Al_2O_3 to less than 0.001 for that above the system Al + Al_2O_3. AlO^+ and Al_2O^+ thus result from the ionization of different molecules, actually AlO and Al_2O[58,58a].

In the system BaO/H_2O, the ion $BaOH^+$ was observed[59]. The ion intensity $I(BaOH^+)$ is proportional to $I(H_2O^+)$ at high water pressures and proportional to its square root at low pressures corresponding to the gas phase equilibria (17).

$$BaO + H_2O \rightleftharpoons Ba(OH)_2 \quad (17)$$
$$BaO + 1/2H_2O \rightleftharpoons BaOH + 1/2\,O$$

Therefore the ion $BaOH^+$ is formed from the molecules BaOH and $Ba(OH)_2$ by electron impact. The contribution of each molecular species to the common ions could be obtained quantitatively and confirmed by the study of other equilibria involving BaO, BaOH, $Ba(OH)_2$, H_2O, H_2, and O_2.

In the system $NaF{\cdot}ZrF_4$[60] (or $LiF{\cdot}BeF_2$[61]) the ternary gaseous molecules decompose under electron impact giving mainly Na^+ and ZrF_3^+ and other fragment ions. They were identified by comparing the mass spectra for the pure components and for mixtures of different activities.

4. Pressure Determination

The density (flux/velocity) in a molecular beam issuing normally from a Knudsen cell of orifice area s[e] and crossing an electron beam, at right angles at a distance L, is given by eq. (18).

$$n_s = 2\,n_c s/3\,\pi^2 L^2 \quad (18)$$

Here n_c is the number of molecules per cm^3 in the cell.

For ions formed by electron impact, the intensity I^+ measured on the collector

$$I^+ = n_s i^- l \sigma_i \eta_i \gamma_i \quad (19)$$

[e] It is assumed here that s is the area of a knife edge orifice or that correction has been applied for its thickness [22].

i^- is the intensity of the ionizing electrons, l their effective path, σ_i is the ionization cross section for the process considered for electrons of the energy used, η_i is the transmission of the mass spectrometer *i.e.* the ratio of number of ions formed to those collected after mass analysis, which may be a function of the mass of the ion. In many cases this mass discrimination [29] is not very important and may be assumed to be negligible or corrected for. γ_i is the gain for the ion i when collected on a secondary electron multiplier (when using a simple collector $\gamma_i = 1$).

Inserting the gas law $P = nkT$ in eq. (18) and (19) yields eq. (20).

$$I_i^+ T = P_i \cdot A \cdot \sigma_i \gamma_i = P_i S_i \tag{20}$$

S_i can be called the sensitivity and A combines all instrumental factors assumed independent of mass and nature of species.

The sensitivity factor S_i can be measured by combining the Hertz-Knudsen equation [21] for weight loss (G_i) by effusion of the species of molecular mass m_i (t = time)

$$P_i = G_i(2\pi kT/m_i)^{1/2}/st \tag{21}$$

with eq. (19), which yields

$$S_i = 44.33\ M_i^{1/2}\ (s/G_i)\ \Sigma I_i T^{1/2} \Delta t \tag{22}$$

M_i is now the molecular weight in a.m.u. of species i, S_i being obtained in the units (ion intensity × °K/atm).

This sensitivity determination is usually performed by vaporizing a weighed sample in the mass spectrometer and measuring ion intensities and temperatures over a period $\Sigma\ \Delta t$. The pressure determination by this method is very similar to the classical Knudsen method when only one species is present or predominates, or when the condensed phase decomposes congruently.

When several species are present in comparable amounts, eq. (20–22) can be written for all relevant species. It is, however, necessary in this case to know their relative ionization cross sections and multiplier gains. The same is true when the sensitivity of the instrument is determined by vaporizing a known amount of another substance (*e.g.* Ag), applying eqn. (22), and calculating other pressures by the relation(23).

$$P_i = P_{Ag}\ \frac{I_i T_i \sigma_{Ag} \gamma_{Ag}}{I_{Ag} T_{Ag} \sigma_i \gamma_i} \tag{23}$$

It is of course also possible to perform sensitivity calibrations using data on pressure dependent equilibria obtained from other sources; dissociation equilibria (*e.g.* $O_2 \rightleftharpoons 2\ O$) have been used for this purpose as well as decomposition pressures (*e.g.* $M_2O_3(s) \rightarrow 2\ M(g) + 3/2\ O_2$) or vapor pressure data; the use of known pressures at triple points (*e.g.* solid-liquid-gas for Ag or Au) is especially favorable. In electrochemical cells, the pressure can be readily derived from the galvanic current. In kinetic applications, the measurement of absolute fluxes may be more complex. However, it should in general be possible to apply relation (23) using the flux corresponding to the vapor pressure of the condensed element studied as a reference.

Multiplier yields are obtained by direct calibration. This is done by measuring the ratio of intensities received on the multiplier and on a simple collector which can be inserted in, and removed from, the ion path. Further experimental interpolation regularities can be used [62].

Ionization cross sections at the maximum of the ionization efficiency curve (σ_{max}) or their ratios have in general been taken from theoretical calculations of *Otvos* and *Stevenson* [63] for atoms; for molecules, the additivity of σ_{max} was postulated by the same authors. These ionization cross sections were calculated [63,63a] on the basis of a theoretical treatment by *Bethe*, which suggests that the ionization cross section of an atomic electron with quantum numbers (n,l) is approximately proportional to the mean square radius of the electron shell. With hydrogen-like wave functions the latter is given by

$$\bar{r}_{n,l}^{-2} = a_0^2\ n'^4 (Z - S_{nl})^{-2} - 1 + {}^3/_2 \left(1 - \left\{\frac{l(l+1) - {}^1/_3}{n'^2}\right\}\right) \tag{24}$$

n' is an effective quantum number and S_{nl} the screening constant.

Ionization cross sections at low energies σ_E are usually estimated by assuming that the cross section varies linearly up to the maximum with the excess energy above the appearance potential AP, *i.e.*

$$\sigma_E = \sigma_{max}(E - AP)/(E_{max} - AP) \tag{25}$$

When, E_{max} cannot be measured directly because of fragmentation of more complex molecules, the additional approximations are usually made that either $(E_{max} - AP)$ is approximately constant or that $E_{max} = n$AP. Eq. (25) then becomes eq. (25′).

$$\sigma_E = \sigma_{max}(E - AP)/(n-1)AP \tag{25'}$$

An alternate, classical theory has been developed by *Gryzinski* [64]. The cross section for ionization of a single electron of the jth electronic shell containing N_j electrons is there given by

$$\sigma_j = 6.56 \times 10^{-14} (N_j/U_j^2)\ g(x) \tag{26}$$

$$g(x) = X^{-1}[(X-1)/(X+1)]^{1/2}\{1 + {}^2/_3\ (1 - 1/2x) \ln [2.7 + (X-1)^{1/2}]\}$$

where $X = E/U_j$, E being the energy of the ionizing electron and U_j the ionization potential of the jth shell.

This theory justifies the postulated additivity of atomic cross sections since σ_j is proportional to N_j and deviations from the additivity caused by the dependence of σ_j on U_j^{-2}. It further gives an explicit dependence of the cross section on the energy. Cross sections,

---

[a] The original relative values were divided by 3 and expressed in Å² [66].

calculated by either approach [63,65], and experimental values [43,66,67] are compared in Table 1. Except for the alkali metals, the two methods of calculation lead to values in essential agreement with each other and with experimental results.

For solids AB vaporizing simultaneously to gaseous AB and $(AB)_2$, ratios of cross sections can be obtained [25,54,55] by the use of double oven type Knudsen cells in which $(AB)_2$ is thermally dissociated. One obtains the equation,

$$\sigma_{(AB)_2}/\sigma_{AB} = \frac{\sqrt{2}\,(I'_{(AB)_2}\sqrt{T'} - I_{(AB)_2}\sqrt{T})}{(I_{AB}\sqrt{T} - I'_{AB}\sqrt{T'})} \qquad (27)$$

I' and I represent intensities measured at temperatures of the upper cell T' and T respectively, the temperature in the lower cell remaining constant. The subscripts 1 and 2 refer to monomer and dimer respectively.

For stoichiometric solids AB vaporizing according to

$$AB(s) \rightarrow A(g) + \left(\frac{1-x}{2}\right) B_2 + xB(g) \qquad (28)$$

eq. (28), relative cross sections σ_A/σ_B and σ_A/σ_{B2} can be obtained [69] simultaneously from the relation (29)

$$\frac{I_A}{I_{B_2}} = \left[\frac{M_A}{M_B}\right]^{1/2} \frac{I_B}{I_{B_2}} \frac{\sigma_A}{\sigma_B} + 2\left[\frac{M_A}{M_{B_2}}\right]^{1/2} \frac{\sigma_A}{\sigma_{B_2}} \qquad (29)$$

if x varies sufficiently with temperature. If not, double oven type cells can be used to promote the thermal dissociation of B_2. Similar equations can be established

Table 2. Experimental ratios for ionization cross sections [66].

Molecules	$\sigma_i(1)/\sigma_i(2)$	Molecules	$\sigma_i(1)/\sigma_i(2)$	Ref.

than ≈ 2 as implied by the additivity rule. For simple heteronuclear molecules the latter rule leads to a fair approximation in most cases. For more complex molecules the additivity rule may overestimate the ionization cross section by up to a factor of two. However high these uncertainties may seem, it may be emphasized that, in calculating thermochemical data, they lead to inaccuracies which are not larger than those introduced by other parameters (see below).

The assumption has hitherto been made that ionization cross sections are temperature independent. In the absence of low lying excited states, this assumption is justified for atoms and probably for simple molecules with high vibrational frequencies, since the Boltzmann distribution then results in relatively little variation of the population of different vibrational levels. For polyatomic molecules with low vibrational frequencies, transition probalities and fragmentation pattern may change with temperature.

In discussing the accuracy of pressure determinations, three cases can be distinguished: that of a largely predominating component, that of a minor component and that of components of comparable importance.

1) The first case is equivalent to a conventional Knudsen experiment monitored by the spectrometer and the evaluation of the pressures becomes independent of cross sections and multiplier yields when eq. (20)–(22) are applied. Accuracy and reproducibility are then the same as in the conventional experiment and pressures can be measured with an accuracy of 5 to 20%. There are, however, a number of advantages in the mass spectrometric method: high speed, minor components can be detected, and, if necessary, corrections can be applied. Perturbations, such as creeping or interboundary migration of the condensed phase, chemical reactions with the container or residual gases, impurities, alloy formations, phase transitions, and disproportionation reactions are readily observed. The evolution of a non-stoichiometric compound to its congruently vaporizing composition and the modification of the latter with temperature can be followed.

2) The pressure of a minor component as obtained from relation (23) depends usually on an estimate of $\sigma\gamma$ ratios which can be made within a factor of 1.5 to 3, depending on the availability of data on analogous molecules with which comparisons can be made. Although this uncertainty may seem high, it must be realized that in many cases such species cannot be identified by other methods.

3) For components of comparable importance, the uncertainty in pressure data may approach one or the other of the above cases, depending on the possibility of performing $\sigma\gamma$ measurements by changing the composition of the vapor by modifications in the thermodynamic conditions.

5. Calculation of Thermochemical and Kinetic Quantities

Apart from the identification of molecular species and the measurement of their relative concentrations, great interest lies in the calculation of their free energies, enthalpies, and entropies of formation. In kinetic studies, one wishes to obtain reaction orders and activation energies from which reaction mechanisms are to be deduced.

Reaction enthalpies, ΔH_T^0, at temperature T can be obtained by the second law of thermodynamics (Clausius-Clapeyron or van't Hoff equation):

$$\Delta H_T^0 = -R \, \mathrm{d} \ln K_p / \mathrm{d}(1/T) \qquad (30)$$

$K_p = \pi P_i^{n_i}$ is the equilibrium constant of the reaction; n_i are the stoichiometric coefficients and R is the gas constant.

In kinetic studies, (30) (with k = rate constant instead of K_p) is the Arrhenius equation.

The advantage of relation (30) lies in the fact that only temperatures and variations of equilibrium constants are needed. It is assumed to a first approximation that ΔH_T^0 is constant in the temperature range in question, or that its variation with temperature has been calculated as described in standard textbooks of thermodynamics. In mass spectrometric measurements, combination of eq. (20) and eq. (30) gives the relationship (31) provided that the ionization cross sections σ_i are temperature independent.

$$\Delta H_T^0 = -R \, \mathrm{d} \ln \pi (I_i^+ T)^{n_i} / \mathrm{d}(1/T) \qquad (31)$$

An alternative method consists in the use of the third law of thermodynamics, which requires a knowledge of the absolute value of K_p

$$\begin{aligned} \Delta H_T^0 &= \Delta G_T^0 + T\Delta S_T^0 \\ \Delta H_0^0 &= \Delta G_T^0 + T\Delta S_T^0 - \Delta(H_T^0 - H_0^0) \\ &= \Delta G_T^0 - T\Delta \left(\frac{G_T^0 - H_0^0}{T} \right) \end{aligned} \qquad (32)$$

$\Delta G_T^0 = -RT \ln K_p$; the superscript ^{0} indicates that the magnitude is taken in the standard state and subscript 0 or T indicates the temperature.

In this method entropies or free energy functions $(G_T^0 - H_0^0)/T$ are calculated from specific heat data or, for gaseous molecules, from molecular parameters discussed below by the use of statistical mechanical relations [77].

If measured thermodynamic data and molecular parameters are not available, satisfactory estimates of specific heat and standard entropy can be made in many cases for condensed phases [77]. For gaseous molecules interatomic distances can be estimated from atomic radii derived from crystallographic data [78]. Vibration frequencies can be estimated by comparison with isoelectronic molecules, or from vibration frequencies of other molecules containing the same group [79].

Correlations have been made between vibration frequencies, interatomic distancies, and dissociation energies [79,80]. Probable structures for tri- and polyatomic molecules can be

found by comparison with known molecules of similar type or from rules such as those relating total number of valence electrons and structure [81]. For molecules with low numbers of valence electrons, the electronic ground state can be predicted and the approximate position of low lying excited states estimated [79]. For molecules formed from atoms with large numbers of electrons; especially transition metals, quantum mechanical calculations become necessary [82]. For polyatomic molecules, where experimental data are largely missing, simplified approximations have also been proposed [83,84].

With accurate spectroscopic or calorimetric data, the uncertainties in free energy functions are ±0.1 to 0.5 and 0.5 to 1.0 clausius^{-1} for a gaseous and a condensed phase respectively. With estimated data these uncertainties are rated to increase in simple cases to about 2–3 clausius. It may be pointed out that, in many cases, variations of the estimated free energy function with temperature will be closer to the real ones than the absolute values.

Assuming the different uncertainties independent of one another, the relative uncertainty in third law calculations can be written as follows:

$$\delta\Delta H/\Delta H = [(RT\delta \ln K_p/\Delta H)^2 + (T\delta\Delta S/\Delta H)^2 + (\delta/T/T)^2]^{1/2}$$

or (33)

$$\delta\Delta H/\Delta H = \{[\delta(\Delta S - R\ln K_p)/(\Delta S - R\ln K_p)]^2 + (\delta T/T)^2\}^{1/2}$$

where the symbol δ designates both fortuitous errors and possible systematic errors, the latter being treated as accidental.

In second law calculations the relative uncertainty is:

$$\delta\Delta H/\Delta H = [(\delta\Delta \ln K_p/\Delta \ln K_p)^2 + (\delta T_1/T_1)^2 + (\delta T_2/T_2)^2 + (\delta\Delta T/\Delta T)^2]^{1/2} \quad (34)$$

When ΔH is large, usually only a relatively small temperature interval ΔT is accessible to measurement and the dominant contribution to the uncertainty comes from the last terms in (34) which are of the order of $\sqrt{2}\delta T/\Delta T$. In the third law (eq. 33) the corresponding uncertainty $\delta T/T$ is much smaller. For low values of ΔH, the importance of the temperature uncertainty decreases and second law measurements may lead to quite accurate results, provided $\Delta \ln K_p$ is measured with sufficient accuracy. In that case ΔH^0_T can be inserted in eq. (32) to obtain entropy values. In third law calculations, the first two terms which represent an absolute, not a relative error in eq. (32) are always present; they are therefore more important in the case of low ΔH values. However, low ΔH values are usually differences between the high values of bond dissociation energies and the uncertainty should be considered relative to these large values rather than compared with the small ΔH values which are measured.

If satisfactory free energy functions are available, third law calculations will lead to a relative error of about 1% (temperature component) to which an absolute error of about 1 to 5 kcal must be added. An advantage of the third law method is that it gives for all points a ΔH value at a single reference temperature, usually 0 or 298 °K. The method thus facilitates consistency analysis of individual points of a given series as well as different series from the same or different laboratories. Further, the third law is the only method that can be applied when observations on a given species are possible only within a narrow temperature range; such restrictions apply often in mass spectrometric measurements. In the second law, the relative error will be 2 to 5% if a sufficiently large pressure and temperature range can be covered; the uncertainty can, however, increase drastically if this is not the case.

The question "should one apply the second- or third-law approach" is often raised. Undoubtedly one should use both. Naturally each case should be judged according to the discussion sketched above in order to determine what weight to give to one or the other.

6. Results [17, 18]

As mentioned in the introduction, the first result [1, 2] of the application of mass spectrometry to high temperature chemistry was the determination of the heat of vaporization of monoatomic carbon from graphite. Simultaneously these investigations led to the spectacular discovery that at the temperature studied (about 2500 °K) the main components of carbon vapor, in order of decreasing importance, are C_3, C, and C_2; C_4, and C_5 are minor components. Polyatomic species were also discovered in the vapor of other group 4 elements and their mixtures or compounds. Thus polyatomic molecules and their thermodynamic properties are now known for the elements of the 4th, 5th, and 6th group of the periodic table (Table 3) [f].

been studied. Their dissociation energies lie in the range of 30 to 60 kcal/mole; nevertheless, their concentration is always low. This can be readily understood in the light of the vaporization processes of an element [92]:

$$M_{sol.\ or\ liq.} \rightarrow M_{gas} \quad (35)$$

$$2\ M_{sol.\ or\ liq.} \rightarrow M_{2\ gas} \quad (36)$$

The corresponding free energy changes can be written as

$$\Delta G_{T,1} = -RT \ln P(M) = \Delta H_{T,1} - T\Delta S_{T,1}$$

$$\Delta G_{T,2} = -RT \ln P(M_2) = \Delta H_{T,2} - T\Delta S_{T,2} \quad (37)$$

and

$$\Delta G_{T,1-2} = \Delta G_{T,1} - \Delta G_{T,2} = -RT \ln P(M)/P(M_2) =$$
$$(\Delta H_{T,1} - \Delta H_{T,2}) - T\Delta S_{T,1-2} = D_T(M_2) - \Delta H_{T,1} - T\Delta S_{T,1-2} \quad (38)$$

The subscripts 1 and 2 refer to the process corresponding to the monoatomic and diatomic species. $D_T(M_2)$ is the dissociation energy of M_2.

Equation (38) is the description of this system corresponding to the pressure independent reaction

$$M_{2,g} \rightarrow M_s + M_g \quad (39)$$

in which the temperature alone determines all partial pressures. This is in contrast to the more usual homogeneous system

$$M_{2,g} \rightleftarrows 2\ M_g \quad (40)$$

in which at a given temperature the partial pressures are only determined, when the total pressure is fixed.

Eq. (38) and (39) have two characteristic parameters:

a) ΔS is negative and small; for homonuclear diatomic molecules about −10 e.u. (in the range of 1000 to 2000 °K).

b) The enthalpy term may be positive or negative. In the former instance $P(M_2) > P(M_1)$; this is the case for the "classical", "low temperature" molecules of the elements of the right hand side of the periodic table. In the latter instance $P(M_2) < P(M_1)$ but $P(M_2)/P(M_1)$ increases with temperature: it is therefore appropriate to call them "high temperature molecules" in the present context [92c].

Eq. (38) can also be used to define "high temperatures" [92b]

$$T = (\Delta H_{T,1} - \Delta H_{T,2})/\{\Delta S_{T,1-2} - R \ln P(M_1)/P(M_2)\} \quad (41)$$

The definition (41) thus depends not only on the properties (ΔH and ΔS) of the system but also on the sensitivity limit of the analytical device. For the mass

		Ce 188.6 ± 3.5 [75]	Pr 180.8 [115, 116]	Nd 171.1	Pm	Sm 141.6	Eu 132.8	Gd 172.5	Tb 173.7	Dy 150.8	Ho 150.8	Er 151.9	Tm 137.8	Yb 91.0	Lu 166.3	

spectrometer this limit is about $1:10^5$; for the molecules mentioned above, with $\Delta H \geqslant 30$–60 kcal, "high temperatures" therefore lie at 1000 to 2000 °K and higher.

Eq. (35–38) can be easily generalized[93] for polyatomic homonuclear molecules and di- and polyatomic heteronuclear molecules. In such cases alternative processes to (35) and (36) take place, *e.g.*

$$1/2\ AB(s,l) \rightarrow 1/2\ A(g) + 1/2\ B(g) \quad (42)$$

$$AB(s,l) \rightarrow AB(g) \quad (43)$$

Instead of eq. (38), other pressure independent free energy equations are obtained. In each case the possibility of observing a molecule AB is favored by a high value of the dissociation energy, but the enthalpy term is descreased by the enthalpy corresponding to the atomization of condensed AB (eq. 41), possibly by that of dissociation of B_2 and/or vaporization of A. For the entropy term similar values are expected as for (37). It thus appears that, in addition to the entropy, the importance of which has been stressed in a number of recent papers[94], the value of the enthalpy difference in an equation corresponding to (38) determines the possibility of observing molecular species.

The existence and the dissociation energy of nearly all gaseous monoxides have now been established (Table 6). Of interest is the trend in the dissociation

oxides such as B_2O_3 [126], Mo_2O_5, Mo_3O_8 [127], V_2O_4, V_4O_8, V_4O_{10}, V_6O_{12}, V_6O_{14} [128], Re_2O_7 [125] have been characterized. They emphasize the frequent occurence of several valencies and differing degrees of association in gaseous compounds.

Table 8. Atomization energies of gaseous dioxides [123] (kcal/mole).

$MO_2(g) \rightarrow M(g) + 2O(g)$

Spectroscopic data [124] indicate that TaO_2 is non-linear in the ground state and hence that Walsh's rule [81] is also applicable to d electrons. According to this rule, molecules with 16 and less or 21 or more electrons are linear, the others non-linear. The atomization energies based on third law calculations given by [123] have therefore been reduced by 6 kcal/mole for the V, Cr, Mn, and Fe groups.

energies of the monoxides of the first transition series, which shows a doubly humped curve with a minimum when the d shell is half filled. An analogous curve is found for the rare earth oxides. In both cases the trend in dissociation energy of the oxide and the heat of sublimation of the metal show a striking similarity. This also applies to bonding energies in solid carbides, silicides, nitrides, and oxides and to force constants of halides [93, 117]. Besides the monoxides, suboxides (Table 7), dioxides (Table 8), trioxides (Table 9) and

Several binary oxides yield appreciable amounts of gaseous dimers and polymers. Polymerization energies (Table 10) per added monomer approach the heat of sublimation of the latter.

The equilibrium mode of evaporation of oxides is consequently strongly dependent on differences in

stability of the lattice and of the numerous possible gaseous molecules [17,93].

In general the stability of sulfides, selenides, and tellurides is lower than that of oxides; therefore the mode of vaporization is simpler. In most cases the gas phase contains a high proportion of dissociation products. The gaseous molecules which have been observed are limited to the monochalcogenides or their polymers, and a few dichalcogenides. The trends are parallel for oxides, sulfides, selenides and tellurides with a marked decrease in dissociation energy in this sequence [90,93]. However, an exception is boron sulfide which gives highly polymeric and complex gaseous molecules [136].

Carbides vaporize mainly by decomposition. In a number of cases, MC_2 and also MC_4 [137] molecules have been observed as minor components. Parallel trends in dissociation energies M–C_2 and M–O have been observed [138,139]; the analogy between C_2 and O has been pointed out [138].

Borides, silicides, nitrides, phosphides [17,86] *etc.* decompose upon vaporization [140]. Halides, hydroxides, and cyanides usually give gaseous products, which contain the same units as the lattice, or polymers [139]. In several instances dimers and trimers are the major products.

Ternary halide molecules of the type LiCl·NaCl, LiF·AlF_3, and others, behave similarly.

The study of mixtures or compounds formed from two binary compounds confirms and extends the types of gaseous ternary compounds known by classical methods; ternary halides and oxyhalides may also be mentioned in this context. Metaborates [141] and perrhenates [73] yield gaseous monomers and dimers; molybdates and tungstates [142] yield monomers; the corresponding acids [127,143] have been studied.

Systematic studies of whole groups of ternary compounds are lacking. It may, however, be pointed out that the thermochemical relations [93] for binary compounds AB (eq. 42, 43) enable one to rationalize the present observations when A and B are considered to represent binary molecules constituting the ternary compound.

In kinetic applications, rates of evaporation and vaporization and condensation coefficients have been obtained for a number of elements and compounds [16, 58a,144].

The investigation of the reaction between oxygen and molybdenum [16], tungsten [16], and tantalum [16], as well as of those of halogens with nickel [16] and yttrium [16] has made it possible to identify the gaseous species formed and the influence of time, temperature, and flux of impinging gaseous molecules on their rate of formation. Data on residence time and angular distribution of reflected molecules or reaction products have been obtained by molecular beam techniques combined with mass spectrometric detection for some of these and other reactions [16].

7. Outlook

Present gaps in the knowledge of certain types of molecules, *e.g.* the homonuclear diatomic molecules of most transition and rare earth elements can, presumably, be reduced by extending the sensitivity of the

method and its ability to cope with higher temperatures and pressures [20].

In the condensed phase, thermodynamic data have been obtained mainly for stoichiometric compounds. The present techniques readily permit one to study phase diagrams and thermodynamic properties as functions of composition of non-stoichiometric compounds [75, 145, 146]. Likewise, other aspects of heterogeneous reactions and of the mechanism and kinetics of vaporization, *e.g.* in electrochemical cells, can be studied.

Problems of electronic and molecular structure of gaseous molecules can not be solved directly by mass spectrometric techniques. The use of this technique for detecting and identifying species in magnetic and electric molecular beam experiments has, however, already given interesting results [147]. The simultaneous study of gaseous phases by mass spectrometry and by optical spectroscopy, including microwave and matrix techniques [148], are also promising developments, as is the molecular structure determination by electron diffraction [149].

Many problems and systems mentioned here are regularly covered and discussed in review articles [150].

Aromatic Fluorine as a Chemical Label for Detecting Reaction Mechanism[**]

BY H. SUSCHITZKY [*]

BASED ON WORK CARRIED OUT WITH I. K. BARBEN, M. BELLAS, P. MILES, AND R. K. SMALLEY

This article explains how nucleophilically activated fluorine can be used for the detection of ion-pair formation during the decomposition of various aryl radical generators. Thus a concurrent dual mechanism for the breakdown of certain aryl radical sources can be experimentally demonstrated by fluorine labeling. The bearing of this information on the mechanism of diazo coupling is also discussed.

In addition, labeling with aromatic fluorine is applied to the thermolysis of aryl azides, the aminolysis of 3-aryl-4-bromosydnones, and the hydrolysis of 3-arylsydnone imines. Finally some mechanistic problems are posed which may possibly be solved by this labeling technique.

I. Principle of the Method

Nucleophilic replacement of suitably activated fluorine in an aromatic structure usually occurs more readily than that of any other group or atom [1]. Foremost in this activating tendency is undoubtedly the diazonium ion $-N_2^{\oplus}$, which can render aromatic fluorine (and to a lesser extent other halogens or a nitro group) so labile that the latter can be lost inadvertently during a synthesis by being displaced in the presence of even a weak nucleophilic reagent. *Bunnett* and *Zahler* [2] have called this annoying property of a diazonium group the "nuisance effect" and the aptness of the metaphor will be appreciated by anyone who has experienced this phenomenon. An instance of such an unwanted

fluorine displacement is the loss of the fluorine atom from 4-fluoro-3-nitroaniline *(1)* which occurs during diazotization in hydrochloric acid [3] to give unexpectedly the chloro compound *(3) via* the intermediate *(2)*. Another example is the formation of the chlorodiazonium salt *(5)* when the dry 2,4-difluorobenzenediazonium fluoroborate *(4)* is heated to its melting point (which lies below its decomposition temperature) in the presence of sodium chloride [4]. Even a hydrochloric acid solution of diazotized *o*- or *p*-fluoroaniline will eventually give a positive test for fluoride ions indicating fluorine-chlorine exchange [3]. Examples of the effect of a diazonium ion on the ease of replacement of other groups, are also well known [5].

In the above reactions *(1)* → *(3)* and *(4)* → *(5)*, aromatic fluorine has in a sense acted as a chemical label since it records the presence of the diazonium ion by appearing as easily detectable ionic fluorine (HF) in the reaction mixture. This information is obviously superflous in the cases mentioned. However, a situation could be envisaged in which the intermediacy of a diazonium ion, or any other group that causes aromatic fluorine to be anionically labile, is only postulated or even unsuspected. Under these circumstances the conversion of covalent (aromatic) into ionic fluorine would clearly be of value in diagnosing the mechanism involved. Some of the results, which we obtained from experiments in which aromatic fluorine was used as a "chemical marker", are discussed in the subsequent sections. It is hoped that other workers will be stimulated to apply this simple and novel method to suitable problems.

II. Mechanism of Indazole Formation

The idea of probing into the mechanism of a reaction by fluorine labeling suggested itself to us in the course of making 5-fluoroindazole by Jacobson's method [6, 7], which entails the spontaneous decomposition of the *N*-nitrosobenz-*o*-toluide *(6)* in benzene [see Scheme 1].

Scheme 1. The preparation of 5-fluoroindazole.

The expected 5-fluoroindazole *(8)* was obtained together with an approximately equal quantity of a fluorine-free substance which proved to be 5-benzoyloxyindazole *(12)*. Fluoride ions were detected [*] in the reaction mixture [8]. Halogen replacement did not occur with the *meta* isomer (F *meta* to $N(NO)COC_6H_5$ in *(6)*) and the behavior of fluorine in the *ortho* position was not tested as the required nitroso compound could not be prepared.

Huisgen and *Nakaten* [9] have shown that the Jacobson indazole synthesis involves a rate-determining rearrangement of the nitroso compound to a diazoester (*e.g. (6)* → *(7)*) before cyclization. In this context the ready replacement of the fluorine in the *para* position is rationally explained if the covalent diazoester *(7)* dissociates into the ion pair *(9)*. Fluorine replacement by the anion $C_6H_5CO_2^{\ominus}$ is then strongly facilitated because the charged diazonium group $-N_2^{\oplus}$ activates the fluorine towards nucleophilic attack. Thereby a new ion pair *(10)* is formed in which the previously covalent fluorine has taken on the role of anionic partner. Aromatic, covalent fluorine has been changed into a fluoride ion and thus has functioned as a sensitive chemical label since it has revealed the unsuspected and transient formation of a diazonium ion pair during indazole cyclization in benzene. Moreover, fluorine is found to be specific in providing this mechanistic information since the chloro or bromo analogue of *(6)*, F = Cl or Br, yields exclusively the corresponding halogenoindazoles *(8)*, F = Cl or Br.

The existence of ion pairs raises the obvious question whether it is the covalent *trans*-diazoester, *e.g. (7)*, as previously postulated [9], or the diazonium ion pair, *e.g. (9)*, which is involved in the ring closure to give the indazole. *De Tar* [10] has investigated the cyclization

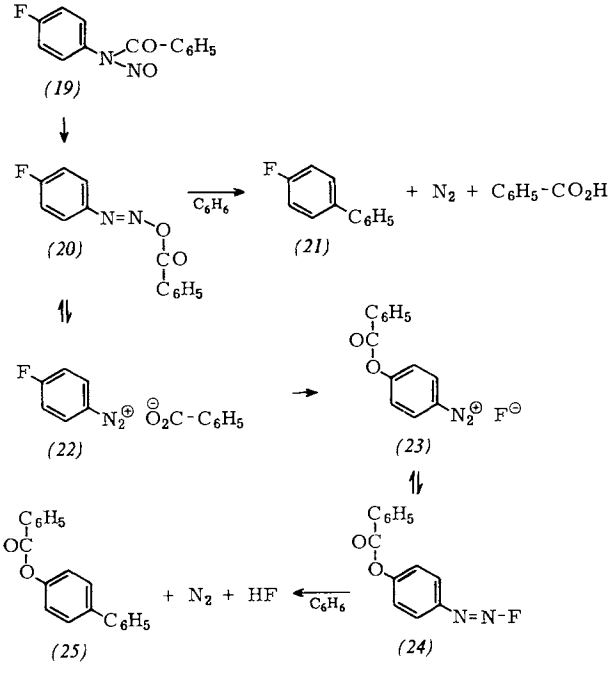
of *cis-o*-diazostilbene *(13)* and shown that indazole *(14)* is formed under conditions favoring a heterolytic process (aqueous acid) and that phenanthrene *(15)* is the main product from homolysis (copper powder). To this extent it is feasible that the cyclization step in

(13) *(14)* *(15)*

the Jacobson synthesis is also ionic in nature [see Scheme 1: *(9)* → *(8)*]. The ionic route accounts satisfactorily for the ease of internal coupling between diazo and methyl group since the diazonium ion can activate its coupling partner by a powerful +I effect. Moreover, the closeness of the carboxylate ion would promote cyclization by providing a suitable acceptor for the methyl proton which is released during ring closure.

The elegant, kinetic studies which led *Huisgen*[9] to postulate a four-center concerted mechanism within the covalent *trans*-diazoester *(16)* → *(18)* do not

(16) *(17)* *(18)*



necessarily invalidate our ionic reaction scheme for indazole formation *(17)* → *(18)*. It must be realized that association of two ions to form either the covalent *trans*-diazoester *(16)* or the intimate ion pair *(17)* is a gradual and continuous process and the two species *(16)* and *(17)* would be indistinguishable if it were not for fluorine labeling.

An obvious objection to the ionic mechanism of cyclization is the lack of indazole formation from *o*-methyl substituted diazonium compounds in aqueous mineral acid. It is, however, feasible that an activated methyl-group will undergo internal coupling only if closely associated with a proton accepting base, a situation realized in an ion pair. The fact that various nitro- and polynitro-indazoles can be made from the appropriate nitrobenzene-diazonium salts in aqueous mineral acid[11] supports the postulated mechanism: it is well known that in aqueous solutions such diazonium compounds exist to a considerable extent in their covalent form, which must be in equilibrium not only with "free" ions but also with tightly held ion pairs.

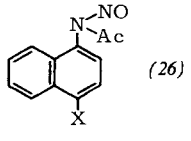
III. Decomposition of Fluorine Substituted Acylarylnitrosamines

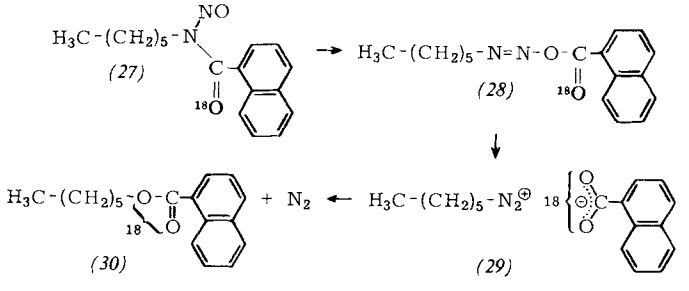


It was a logical step to extend the application of fluorine labeling to acylarylnitrosamines without an *ortho* methyl substituent[8] since these compounds are known to break down homolytically in non-polar solvents to provide aryl radicals. A benzene solution of *N*-(4-fluorophenyl)-*N*-nitrosobenzamide *(19)* kept at room temperature gave the expected 4-fluorobiphenyl *(21)* by homolytic aromatic substitution of the *p*-FC_6H_4 radical in the solvent (C_6H_6) and an equal amount of 4-benzoyloxybiphenyl *(25)*. Corresponding

(19) *(20)* *(21)* *(22)* *(23)* *(24)* *(25)*

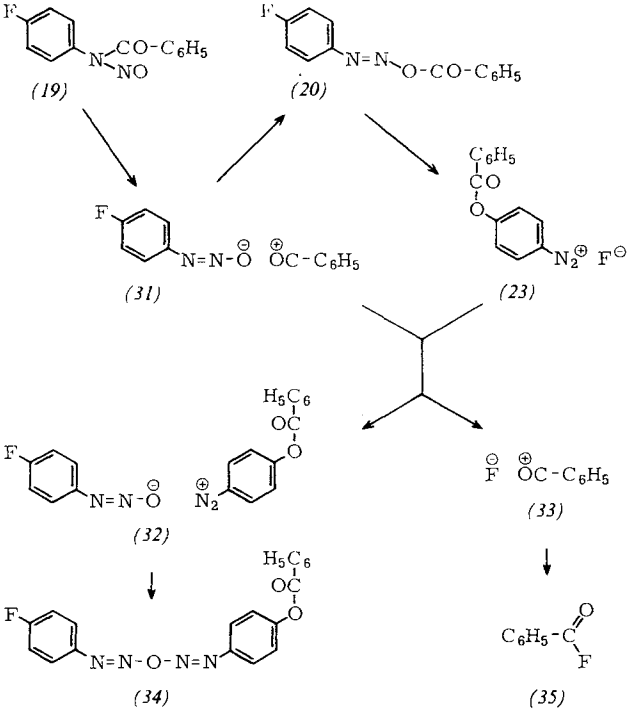
Scheme 2. Decomposition of *N*-(4-Fluorophenyl)-*N*-nitrosobenzamide.

results were observed with fluorine in the *ortho*-position and also with other acyl groups, and fluoride ions were present in each reaction mixture. Fluorine *meta* to the *N*-nitroso group, or any other halogen in *ortho* or *para* position, was not expelled. In the naphthalenes *(26)*, X = F, Cl, or Br, however, chlorine as well as bromine suffered replacement[12] in conformance with the higher reactivity of activated halogen in this ring system[13].



(26)

These results are again rationally accommodated within the accepted reaction scheme by interpreting



[12] *P. Miles* and *H. Suschitzky*, Tetrahedron *18*, 1369 (1962).
[13] *H. J. Van Opstall*, Recueil Trav. Chim. Pays-Bas *52*, 901 (1933).

the appearance of fluoride ions as evidence for the heterolysis of the covalent diazoester *(20)* into an ion pair *(22)*. At this stage the fluorine is rendered labile towards nucleophilic attack by the anionic partner [$C_6H_5CO_2^{\ominus}$ in *(22)*], and the steps leading to a mixture of biphenyls *(21)* and *(25)* are readily discernible in Scheme 2. The stages *(19)* → *(21)* represent the well-known rearrangement and homolytic substitution as revealed by the elegant work of *Hey*, *Huisgen*, and their collaborators [14,15]. This reaction scheme must, however, be augmented by the additional steps *(22)* → *(25)* to include a concomitant heterolysis, which is inferred from fluorine-labeling experiments. By contrast, heterolysis of acylarylnitrosamines in a polar medium such as acetic acid or methanol has been postulated before [15,16] but was precluded for benzene solutions [15]. It is of interest that acylalkylnitrosamines have recently been shown to decompose by a polar mechanism even in non-polar solvents as a result of ^{18}O tracer studies carried out by *White* and *Aufdermarsh* [17]. For instance, *N*-(n-hexyl)-*N*-nitroso-2-naphthamide *(27)* disintegrates *via* formation of the diazonium salt *(29)* to give the ester *(30)* with completely equilibrated oxygens. This technique is obviously not applicable to the aromatic nitroso compounds since the acyloxy moiety does not recombine with the aryl group.

When the products from the above fluorine-labeling experiments were separated by fractional distillation of the reaction mixture under anhydrous conditions, and not by extraction with aqueous solvents, the acid fluoride RCOF derived from the acyl moiety of the starting nitroso compound F–ArN(NO)COR was obtained in high yield. For instance, the benzoylarylnitrosamine *(19)* gave benzoyl fluoride, and analogous acetyl or formyl compounds in the benzene or naphthalene series yielded acetyl or formyl fluoride respectively [12]. Blank experiments excluded the possibility that these products were formed purely incidentally to the main reaction, perhaps just by combination of the organic acid RCO_2H and hydrogen fluoride, both of which are present during the reaction (see Scheme 2).

We interpret the origin of the acyl fluoride RCOF in the following way because this explanation correlates with a number of independent observations: Both the parent nitroso compound ArN(NO)–COR *(19)* and its isomeric diazoester ArN=NOCOR *(20)* can dissociate into their respective ion pairs. These relatively stable pairs can interact and exchange partners to form the new ion pairs *(32)* and *(33)*. In the case of the decomposition of the 4-fluorophenylnitroso compound *(19)* an interchange of the cationic moieties between the intimate ion pairs *(31)* and *(23)* [for the formation of the ion pair *(23)* see Scheme 2] leads to the observed benzoyl fluoride *(35)* as shown in Scheme 3.

Scheme 3. Formation of benzoylfluoride in the decomposition of *N*-(4-fluorophenyl)-*N*-nitrosobenzamide.

The simultaneously formed diazoanhydride *(38)* is a highly unstable free-radical source [18] whose breakdown products are indistinguishable from those expected from the starting nitroso compound *(19)*. Intermediacy of diazoanhydrides has indeed been postulated again recently in a modified reaction scheme for the thermolysis of acylarylnitrosamines (see Scheme 4) [19].

Edit. *4*, 964 (1965).

Moreover, the participation of an acylium ion in the isomerization of nitroso compound to diazoester [$C_6H_5-CO^{\oplus}$ in Scheme 3, *(19)* → *(20)*] is in some agreement with the kinetic results obtained by *Hey* [20] and *Huisgen* [21] although these workers prefer a non-ionic interpretation of these data. Yet it appears that the rate of this rearrangement depends on the structure of the acyl group in the nitroso compound in a way expected for an S_N1 process, *i.e.* by a mechanism involving an acylium ion. Thus the isomerization velocity of ArN(NO)CO–R increases in the order $R = H < CH_3 < C_2H_5 <$ iso-C_3H_7 but is little affected by changes in the aryl moiety; this is feasible since the aromatic ring neither participates in the migration nor has it any conjugative influence on the moving acyl or receiving nitroso group.

Since our experiments were carried out, *Rüchardt* [19] has suggested a modified decomposition mechanism of acylarylnitrosamines, which embodies several features inferred above from fluorine-labeling experiments. This new reaction scheme overcomes an intrinsic weakness of the older one [22] which assumed intermediacy not only of aryl but also of acyloxy radicals ($RCO_2\cdot$) yet could not account for the failure of the latter to liberate carbon dioxide. This anomaly was explained away by a "cage mechanism" [15,23] which, however, became incompatible with later results [24]. While we fully agree with *Rüchardt*'s reaction scheme we consider it unnecessary to postulate that the initial diazotate anion *(37)* arises from the interaction of an acetate ion and the nitrosamine.

The spontaneous dissociation of the nitroso compound *(36)*, as evidenced by acyl fluoride formation in our labeling experiments (see Scheme 3), seems to us a more feasible source for this key intermediate. Consequently the appropriate acid anhydride, *e.g. (38)*, which has been observed in several reactions [19,25] is not formed as originally suggested from the nitroso compound *(36)*, but arises later in the reaction by a process analogous to that of acyl fluoride formation in Scheme 3. This process is shown in Scheme 4, which represents essentially the reaction scheme proposed by *Rüchardt* [19] except for the modifications mentioned above with some consequential alterations. Further support of this scheme comes from recent ESR measurements [25a] which confirmed the presence of aryldiazotate radicals ($ArN_2O\cdot$).

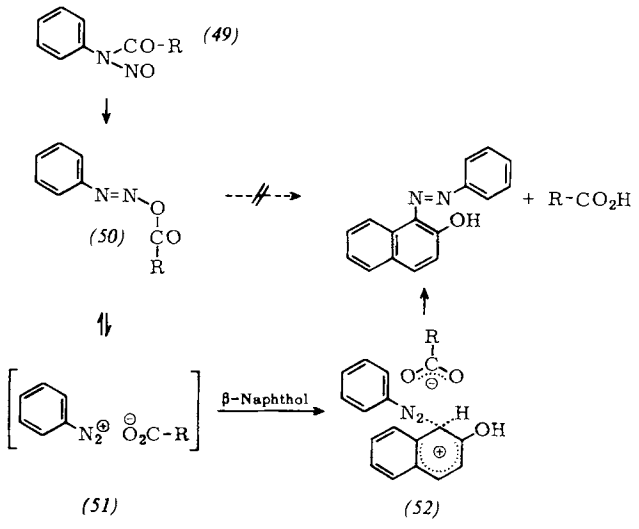
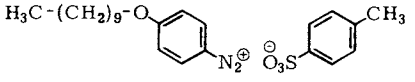
So far it has been tacitly assumed that the decomposition mechanism deduced for fluorine-substituted acylarylnitrosamines is applicable to the whole class of these compounds regardless of aromatic substituent. Fluorine is probably unique in providing mechanistic evidence in this reaction since the numerous observations of decomposition of non-fluorinated nitrosamines reported over the last twenty-five years do not contain a single observation of anionic displacement affecting another substituent. The specificity of fluorine was confirmed when chlorine replacement could not be detected by even a most careful product analysis of the reaction mixture obtained from *N*-nitroso-*p*-chlorophenylacetamide. Yet it is unlikely that only fluorine substituted nitrosamines have the prerogative of undergoing heterolysis. In order to find out whether other nitrosamines form ion pairs besides free radicals, regardless of the nature of their ring-substituent, we carried out several mixed decompositions[12]. Thus various acetylarylnitrosamines with substituents of different electronic properties [*(39)*, R = Cl, CH_3, NO_2, H in the *para* position as well as CH_3 in the *meta* position] were made to decompose (each separately) in dry benzene containing some *N*-nitroso-*p*-fluorophenylbenzamide *(40)*. If the two nitrosoamines *(39)* and *(40)* disintegrated at a similar rate and both heterolysed to give diazonium ions, two sets of ion pairs, namely *(41)* and *(42)*, would be present in the reaction mixture. As a consequence, two species of anions, namely benzoate and acetate, would be competing for displacement of aromatic fluorine in *(42)* and four different biphenyls *(45)–(48)* would be produced by subsequent events as shown in Scheme 5. Formation of the 4-acetoxybiphenyl *(47)* would be clearly indicative of the fact that the breakdown of the acetylnitrosamine *(39)* under test is not purely homolytic but has also included the ionic intermediate *(41)*. This was confirmed by product analysis using gas-liquid and column chromatography since the diagnostic 4-acetoxybiphenyl *(47)* was present (up to 17%) in each of the mixed decompositions in addition to the expected three biphenyls *(45)*, *(46)*, and *(48)*. The possibility that the crossed product *(47)* is due to substitution of the diazonium compound *(42)* by acetic acid rather than by the anion from the ion pair *(41)* was discounted by control experiments. It is thus shown conclusively that acylarylnitrosamines of all types decompose *via* a route involving homolytic and heterolytic steps.



IV. Coupling Mechanism of Acylarylnitrosamines in Non-Aqueous Media

The information gathered from fluorine labeling on the behavior of acylarylnitrosamines allows us to make some relevant observations on the mechanism of azo coupling in non-aqueous solvents. *Huisgen*[15,21,26] was able to determine the isomerization rate of acylarylnitrosamines *(49)* into diazoesters *(50)* simply by measuring colorimetrically their azo-dye production with added β-naphthol since the latter process is a much faster reaction than the former. Dye formation proceeded more rapidly in benzene than in acetic acid and as the non-polar solvent was presumed to contain only the diazoester *(50)* coupling was ascribed to this species rather than to its "dissociated" form, the diazonium ion *(51)*. This postulate is, however, at



Scheme 5. Decomposition of an acetyl and benzoylnitrosamine in admixture.

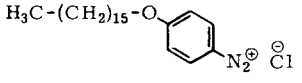


Scheme 6. Coupling of acylarylnitrosamine with β-naphthol in benzene.

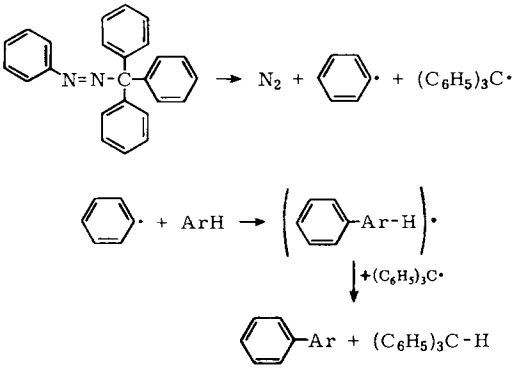
variance with *Bradley* and *Thompson*'s observation [27] on diazonium salts such as *p*-(n-decyloxy)benzenediazonium-*p*-toluenesulfonate *(52a)* or the *p*-(n-hexadecyloxy)benzene diazonium chloride *(52b)* which in

(52a)

(52b)

spite of their moderate solubility in benzene nevertheless couple readily with β-naphthol in this medium to give azo dyes. These discrepancies can, however, be resolved on the basis that diazonium ions (as borne out by fluorine-labeling experiments) exist in the non-polar media and, like carbonium ions, are prone to form intimate ion pairs as the polarity of the solvent decreases. In a solvent such as benzene it is most probably the diazo ion pair rather than the covalent ester that undergoes azo coupling (see Scheme 6). The increased azo-coupling rate in benzene is possibly due to the favorable geometrical position as well as the polarity of the anionic partner, factors which ensure a rapid proton loss from the transition state *(52)*.

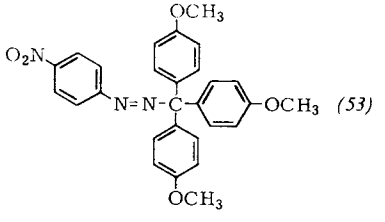
V. Fluorine Labeling of Various Aryl Radical Generators



It was thought that "fluorine tagging" of other aromatic radical sources, particularly those which operate by homolytic cleavage of an aryl-nitrogen bond, would be a simple way to discover any inherent but hidden tendency to heterolytic fission. The results of this work in relation to currently accepted mechanisms are briefly summarized in the following sections [28].

[27] *W. Bradley* and *J. D. Thompson*, Nature (London) *178*, 1069 (1956).

[28] *P. Miles* and *H. Suschitzky*, Tetrahedron *19*, 385 (1963).



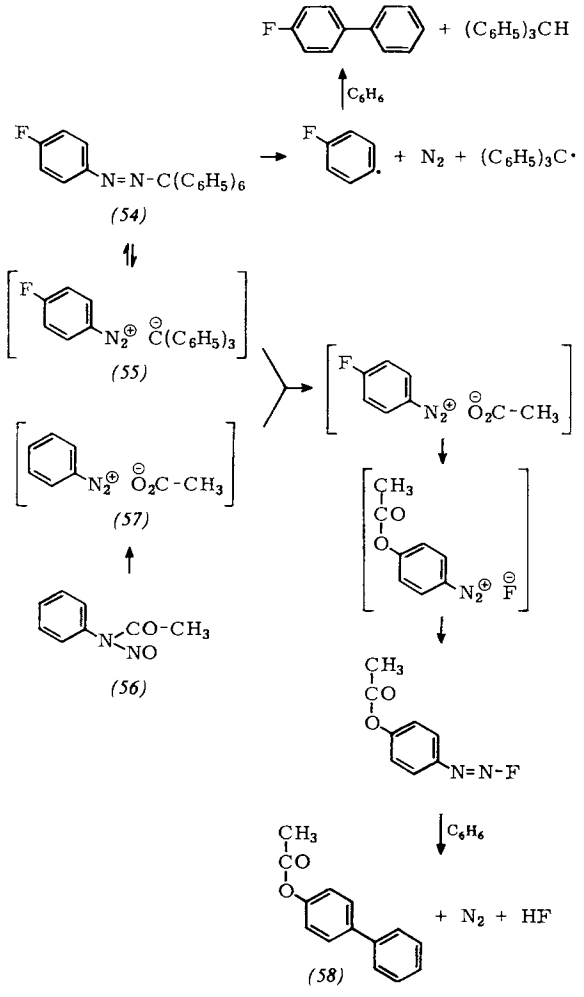
a) Phenylazotriphenylmethane

The decomposition of phenylazotriphenylmethane in hot benzene was first studied in 1934 by *Hey* [29a]. Subsequently a number of workers, *Hey*, *Wieland*, *Huisgen*, and their respective collaborators [29b–29g], have shown that the reaction involves free-radical intermediates while other workers have put forward a cage process in which free radicals are not involved [23]. The accepted mechanism for the homolytic decomposition of phenylazotriphenylmethane in an aromatic solvent ArH is outlined in Scheme 7.

Scheme 7. Homolytic decomposition of phenylazotriphenylmethane.

An unsuccessful attempt has been made to induce heterolysis by introducing electronically different substituents into the azo compound, *e.g. (53)*, and by the use of various solvents [30].

(53)



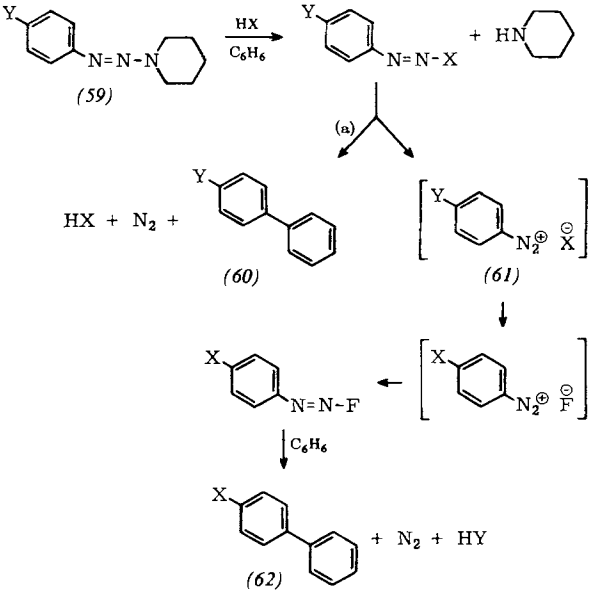
Only products indicative of a free-radical breakdown were obtained.

We studied the same problem by causing *p*-fluorophenylazotriphenylmethane *(54)* to decompose in hot benzene. Heterolysis of the former to give the diazonium ion pair *(55)* could possibly lead to fluorine replacement by the triphenylmethyl anion of *(55)*. However, no ionic fluorine was detected; this could be attributed to the unreactivity of this bulky, resonance-stabilized triphenylmethyl anion. In order to provide a more nucleophilic agent the reaction was carried out in the presence of *N*-nitrosoacetanilide *(56)*, which we know

Williams*, *ibid. 1956*, 4397. [d] *D. H. Hey*, *M. J. Perkins*, and *G. H. Williams*, Tetrahedron Letters *1963*, 445. [e] *D. H. Hey*, *M. J. Perkins*, and *G. H. Williams*, J. chem. Soc. (London) *1965*, 110. [f] *H. Wieland*, *K. Heyman*, *T. Tsatsas*, *D. Juchum*, *G. Varvoglis*, *G. Labriola*, *G. Dobbelstein*, and *H. S. Boyd-Barrett*, Liebigs Ann. Chem. *514*, 145 (1935). [g] *R. Huisgen* and *H. Nakatan*, *ibid. 586*, 70 (1954). [h] *R. Huisgen* and *R. Grashey*, *ibid. 607*, 46 (1957).

[30] *M. D. Cohen*, *J. E. Leffler*, and *L. M. Barbato*, J. Amer. chem. Soc. *76*, 4149 (1954).

from previous work (see Scheme 4) to release the reactive acetate ion under these conditions. Fluoride ions and the diagnostic 4-acetoxybiphenyl *(58)* were



Scheme 8. Mixed decomposition of *p*-fluorophenylazotriphenylmethane and *N*-nitrosoacetanilide.

in fact detected, a result which is best accounted for by interaction of the two ion pairs *(55)* and *(57)*. As is shown in Scheme 8, the ion pair *(55)* is a heterolytic product of the azo compound *(54)*.

The other reaction products were triphenylmethane, triphenylmethanol, triphenylmethylperoxide, and 4-fluorobiphenyl which are normally expected from the homolysis of *(54)*. The results of recent experiments [29e] in which two different azo compounds were made to decompose together in benzene for a limited time and in which the undecomposed azo compounds were found to have exchanged their trityl groups, albeit to a small extent, could also be explained on our ion-pair hypothesis. This evidence is, however, not fully conclusive as considerable experimental difficulties in assessing the products were reported.

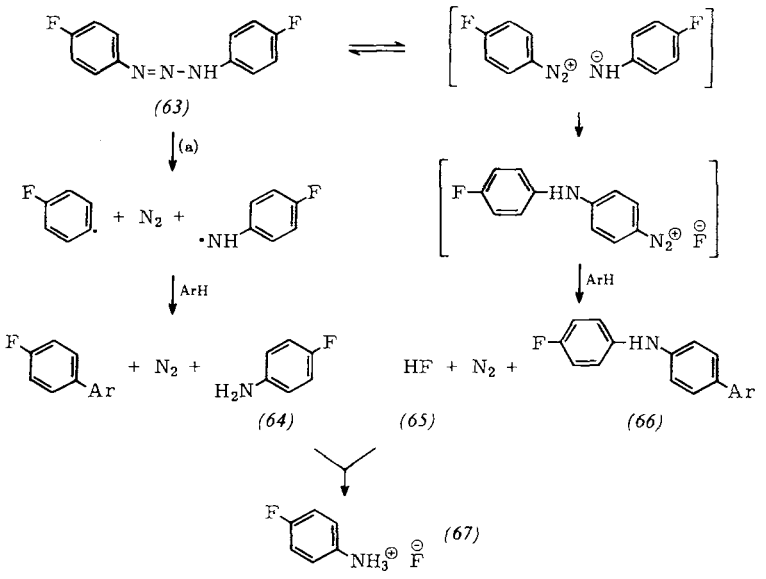
b) *N*-(*p*-Fluorophenyldiazo)piperidine

Thermolysis of triazenes [31], for instance of the piperidene derivative *(59)*, Y = H, in benzene solution (containing acids), produces, *via* the intermediate formation of free radicals, nitrogen, a biphenyl, and an amine (see Scheme 9: Route a). When the fluorine-labeled triazene *(59)*, Y = F, was made to decompose in a boiling mixture of benzene (10 parts) and acetic acid (1 part), 4-acetoxybiphenyl *(62)*, X = AcO, and fluoride ions in addition to the products expected from the homolysis *(60)*, X = AcO, were formed. An analogous result was observed when hydrochloric acid was used instead of acetic acid; the diagnostic product 4-chlorobiphenyl *(62)*, X = Cl, was formed.

Scheme 9. Thermolysis of *p*-fluorophenyldiazopiperidine.

Again the presence of the two biphenyls *(60)* and *(62)*, X = AcO or Cl, is indicative of a dual mechanism in the pyrolysis of the triazene, as set out in Scheme 9. Fluorine replacement obviously occurs at the ion-pair stage *(61)*, X = $AcO^{\ominus}$ or $Cl^{\ominus}$, while the triazene itself does not dissociate into ions for piperidinobiphenyl is not a reaction product.

c) *p,p'*-Difluorodiazoaminobenzene



Diazoaminobenzenes have recently been reported by *Hardie* and *Thomson* [32] to be sources of free radicals when heated in a high-boiling solvent. Nitrogen, and anilino and aryl radicals are produced; combination of the latter with an aromatic solvent leads to biaryl formation as set out in Scheme 10 (cf. Route a).

Decomposition of the fluorine analogue *(63)* in boiling chlorobenzene gave *p*-fluoroaniline hydrofluoride *(67)* which deposited on the walls of the reflux condenser This substance is formed undoubtedly by interaction of the homolytically produced *p*-fluoroaniline *(64)* and heterolytically formed hydrogen fluoride *(65)*. The predicted diphenylamine *(66)* was not isolated from the tarry reaction mixture which, however, gave a strong diphenylamine test [33].

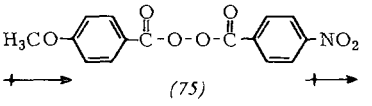
[33] Concentrated sulfuric acid and sodium nitrite produced an immediate blue color on addition of a trace of recation product *cf. F. Feigl*, Spot Tests. Elsevier, New York 1954, Vol. II, p. 126

Scheme 10. Thermolysis of *p,p'*-difluorodiazoaminobenzene in an aromatic solvent.

d) *p*-Fluorophenylhydrazine

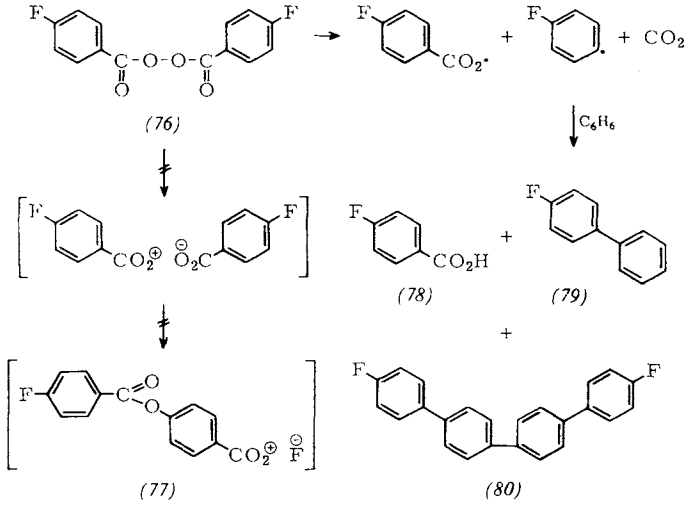


Oxidation of arylhydrazines in an aromatic solvent with silver oxide liberates aryl radicals, which attack the solvent to form biaryls [34]. This homolysis probably involves the covalent diazo compound *(69)*, which could feasibly be in equilibrium with the aryldiazonium hydride *(71)*. If so, replacement of a fluorine atom at the *para*-position by the hydride ion is possible; but this is improbable because the hydride ion will be too readily removed by the oxidizing agent. It was, therefore, not unexpected to find that treatment of *p*-fluorophenylhydrazine *(68)* with silver oxide in benzene gave *p*-fluorobiphenyl *(70)*, in accordance with Route (a) in Scheme 11, but no fluoride ions. In the presence of *N*-nitrosoacetanilide *(72)*, which provides a diazonium acetate and with it the much more effective acetate anion, the reaction products were 4-fluorobiphenyl and 4-hydroxybiphenyl [28]. Moreover, an aqueous extract of the silver residues gave a strongly positive test for ionic fluorine. The anticipated 4-acetoxybiphenyl *(73)* could not be isolated as it suffered hydrolysis *in situ* to its 4-hydroxy-derivative *(74)*. By analogy with the previous conclusions a rational scheme for phenylhydrazine oxidation can be advanced (see Scheme 11) which clearly illustrates operation of a dual mechanism.

Scheme 11. Oxidation of *p*-fluorophenylhydrazine with silver oxide in benzene.

e) *p*-Fluorobenzoyl peroxide

Thermal decomposition of diaroyl peroxides is judged to be the best method of providing aryl radicals because it usually gives the "cleanest" reaction products. Its mechanism has probably received more attention than that of any other aryl radical source [29a, 35]. Unsymmetrical peroxides such as *p*-methoxy-*p'*-nitrobenzoylperoxide *(75)* in which the substituents induce



a unidirectional electron-flow and thereby distort the molecule electronically can, according to *Leffler* [36], heterolyse in nitrobenzene in presence of acetic acid or

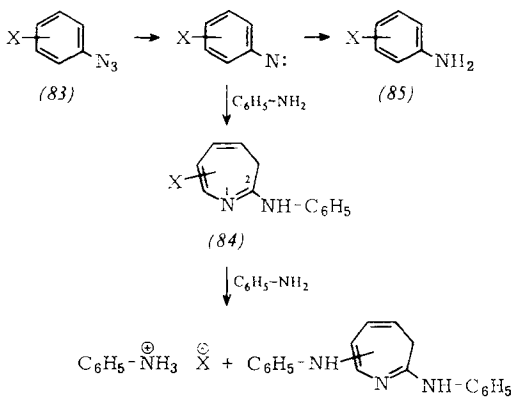
[36] *J. E. Leffler*, J. Amer. chem. Soc. *72*, 67 (1950).

thionyl chloride, as inferred from product analysis. If the fluorine labeled peroxide *(76)* can dissociate into ions (Scheme 12) then fluoride ions *(77)* should be detectable in the reaction mixture. However, only compounds expected from a free radical process, namely *p*-fluorobenzoic acid *(78)*, 4-fluorobiphenyl *(79)*, and a little *p,p'*-difluoro-*p*-quaterphenyl *(80)* were obtained in benzene [28]. Pyrolysis in the presence of *N*-nitrosoacetanilide did not lead to fluorine replacement whatever solvent was employed.



Scheme 12. Thermal decomposition of *p*-fluorobenzoyl peroxide in benzene.

VI. Thermolysis of Fluorophenyl Azides

The decomposition of aryl azides *(81)* in hot solvents leads to the loss of nitrogen and formation of a highly reactive, unstable intermediate *(82)* which, because of its isoelectronic nature with, and chemical resemblance to, carbene [38], is best called nitrene [37]. As nitrenes often behave as an electrophilic species (Ar–N:), we thought that the electron deficient nitrogen may render

$$\underset{(81)}{Ar\text{-}N_3} \xrightarrow[\text{in solution}]{\Delta} N_2 + \underset{(82)}{Ar\text{-}\ddot{N}:}$$

a *para*- or *ortho*-positioned fluorine labile towards nucleophilic attack in a manner analogous to an aromatic diazonium group $ArN_2^{\oplus}$. Indeed, thermolysis of *o*- or *p*-fluorophenyl azide in chlorobenzene [39] containing a little aniline as the nucleophile produced a sublimate in the reflux condenser which was essentially aniline hydrofluoride. When we found, however, that any halogen, even in the *meta* position, was eliminated with formation of the corresponding anilinium halide it became obvious that the loss of halogen was not due to a simple nucleophilic aromatic substitution. We are mentioning this experiment as a cautionary example. Had we been working only with compounds containing fluorine in the *o*- and *p*-positions, an erroneous conclusion could have easily been drawn. It is important to realize that mobility of a fluorine atom in the *ortho* or *para* position is diagnostic of an activating

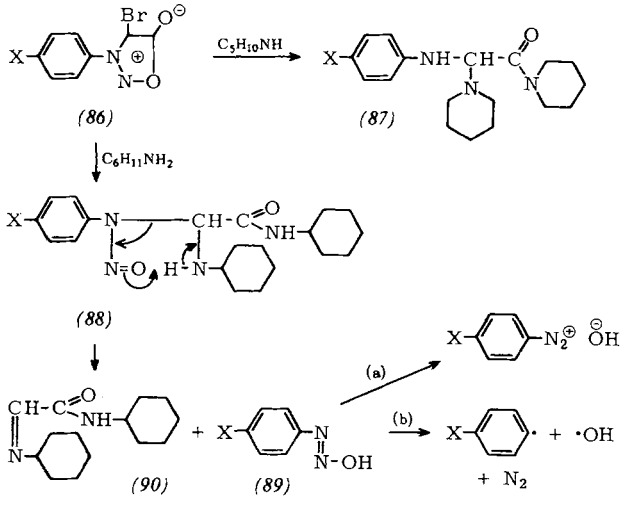
Scheme 13. Thermal decomposition of halogenophenyl azides in aniline.

aromatic intermediate only if it has been demonstrated that this halogen is not replaceable in the *meta* position.

A full discussion and presentation of the reasons for this unusual halogen replacement are outside the scope of this article but can be found elsewhere [39]. However, to complete the picture it may be briefly stated that a phenyl azide with a halogen in the *ortho*, *meta*, or *para* position *(83)* decomposes in aniline to give a small quantity of the 6-, the 3- and the 5-, or the 4-halogenoazepine *(84)*, respectively. Halogen in any position of this heterocycle was found to be prone to nucleophilic attack and is thus readily replaceable by the added aniline or by the corresponding halogenoaniline *(85)*, which is a normal by-product formed by addition of hydrogen to the halogenonitrene as shown in Scheme 13.

VII. Aminolysis of 3-Aryl-4-bromosydnones and Acid Hydrolysis of 3-Arylsydnone Imines

We found [40] that the aminolysis of 3-aryl-4-bromosydnones *(86)* with a secondary amine, for example piperidine, yielded the anticipated amino acid amide *(87)* but primary amines, for instance cyclohexylamine, gave an unexpected result. Nitrogen was slowly liberated and the main product proved to be the Schiff base *(90)* containing two cyclohexyl moieties. Tentatively we interpreted this unforeseen cleavage of the hetero-



[37] Naming of this intermediate is unfortunately not uniform at present. The terms azene and imidogen are also used in the Anglo-Saxon literature while in German the intermediate is referred to as "Imen".

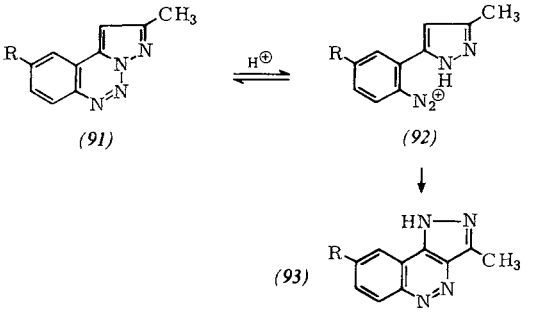
cycle as a two-step process the first stage producing the nitroso-compound *(88)*. A 1,6 interaction between the nitroso oxygen and the aminohydrogen could feasibly lead to the observed azomethine *(90)* and, of necessity, to the diazohydroxide *(89)*, a reaction scheme for which we had of course no evidence. However, this mechanism seemed capable of being tested by fluorine labeling. If the postulated diazohydroxide contained a fluorine atom in the *para* position *(89)*, X = F, then dissociation (*cf.* Route a) would render this atom sufficiently labile to promote its replacement in the nucleophilic environment. Accordingly we tested the *p*-fluorophenylsydnone *(86)*, X = *p*-F, with cyclohexylamine and found not only the expected Schiff base *(90)* but also ionic fluorine in the reaction mixture. In the case of *m*-fluorophenylsydnone *(96)*, X = *m*-F, no fluoride ions were produced thus establishing the nucleophilic nature of the replacement of the fluorine atom in the *para* position and thereby corroborating the proposed mechanism as given in Scheme 14.

Scheme 14. Aminolysis of 3-aryl-4-bromosydnones.

It is noteworthy that *p*-chlorophenylsydnone *(96)*, X = *p*-Cl, did not furnish chloride ions when treated with the amine, which again stresses the distinction of fluorine as a chemical label. One of the products from the ammonolysis of chlorosydnone was chlorobenzene, which is in keeping with the proclivity of the aryl radical $ClC_6H_4\bullet$ to abstract hydrogen. Homolysis of the intermediate diazohydroxide *(89)*, X = *p*-Cl, (Route b in Scheme 14) is responsible for the presence of this radical as well as for the observed evolution of nitrogen.

Russian workers[40a] have recently suggested that 3-phenylsydnone imine is hydrolysed on treatment with hot hydrochloric acid, a diazonium ion being formed as an intermediate. Since participation of an aryl diazonium cation can be diagnosed by using aromatic fluorine as a label we prepared the *p*-fluorophenylsydnone imine *(90a)*, and hydrolysed it with hydrochloric acid. At the postulated diazonium stage *(90b)*, the fluorine would be rendered labile towards nucleophilic attack by the chloride ions. Consequently chlorobenzene, *p*-chlorophenol, and fluoride ions should be present in the reaction mixture. On the other hand *m*-fluorophenylsydnone imine should not lose its fluorine atom. All these predictions were experimentally verified and the reaction path in (Scheme 15) for the acid hydrolysis of aryl sydnone imines is thus confirmed.

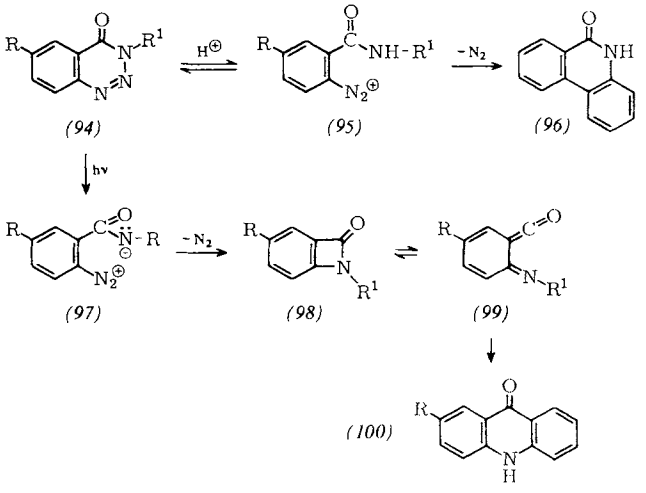


Scheme 15. Acid hydrolysis of 3-Arylsydnone imines.

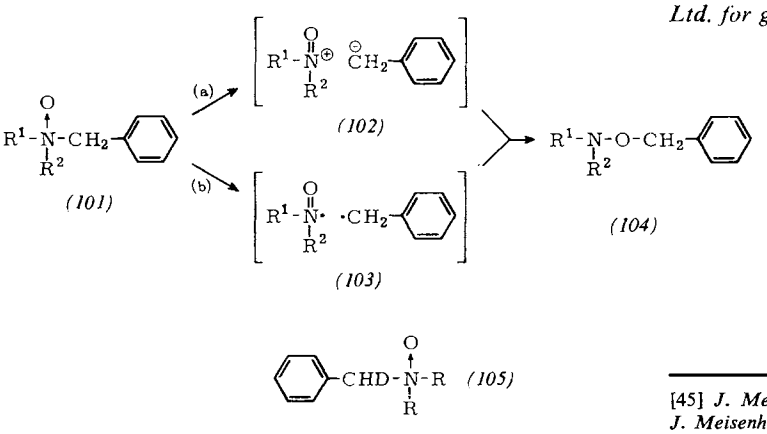
VIII. Potential Scope of Aromatic Fluorine Labeling

It seems appropriate to conclude this brief review of a novel and little explored method by drawing attention to some mechanistic problems which could well be amenable to "fluorine tagging". Even a random perusal of the literature yields a crop of reactions of uncertain mechanism where a differential diagnosis between a free radical or a heterolytic pathway could be made. Certain rearrangements of nitrogen heterocyclic compounds are a potentially fruitful field in this respect, particularly if intermediacy of a diazonium structure is suspected.

For instance, the conversion of the triazine *(91)*, R = H, into the cinnoline *(93)*, R = H, by warm hydrochloric acid has tentatively been explained[41] by a



heterolytic cleavage involving the pyrazolylphenyldiazonium ion *(92)*, R = H, as an intermediate. Its rotation through 180 ° about the central bond is followed by cyclization yielding the product *(93)*. Under similar conditions the related ring system of benzotriazin-4-one *(94)*, $R^1 = C_6H_5$, yields a small quantity of the phenanthridone *(96)*. On the other hand thermal decomposition of *(94)*, $R^1 = C_6H_5$, at 280 °C



[40a] *L. E. Kholodov* and *V. G. Yashunskii*, Ž. obšč. Chim. *33*, 3336 (1963).

[41] *M. S. Gibson*, Chem. and Ind. *1962*, 698.

was reported [42] to give a mixture of the phenanthridone *(96)* and acridone *(100)* and these results were interpreted in terms of a radical mechanism. However,

the behavior of 3-aminotriazinone *(94)*, $R^1 = NH_2$, in acid was accounted for by intervention of the diazonium ion *(95)*, $R^1 = NH_2$ [43]. Results of recent studies on the photolysis [44] of this system, *e.g. (94)*, $R' = C_6H_5$, have again led to the assumption that it dissociates first to give a diazonium ion *(97)*. Loss of nitrogen leads to the formation of the cyclic amide *(98)* or its valence tautomer *(99)* either of which is responsible for all observed products such as acridone *(100)*. Direct chemical evidence for or against participation of the postulated diazonium ions *(92)*, *(95)*, or *(97)* in these reactions could feasibly be obtained by using the "fluorine-labeled" starting materials *(91)*, R = F, and *(94)*, R = F.

The scope of fluorine labeling is by no means limited to reactions with a potential diazo intermediate. For instance, another problem which would qualify for this labeling method is the well-known but little understood Meisenheimer rearrangement [45] of amine oxides to hydroxylamines *e.g., (101)* → *(104)*, which occurs on heating. Recent evidence based on the stereochemical outcome of this isomerization, namely substantial racemization of the optically active [α-D]-benzylamine-*N*-oxide *(105)* excludes an S_Ni type of rearrangement [46]. However, no clear-cut decision between the heterolytic pathway (a) and the homolytic process (b) can really be made, although the authors of these experiments are inclined to favor the latter [46]. Since we have shown that the *N*-oxide group activates aromatic fluorine more than any other halogen towards nucleophilic substitution [47] the rearrangement of a *p*-fluorophenylamine *N*-oxide, *e.g. (101)*, $R_1 = p\text{-}F\text{-}C_6H_4$, could throw considerable light on the mode of this reaction. If the ionic mechanism (a) were operative the nucleophilically active fluorine in the starting material *(101)*, $R_1 = p\text{-}F\text{-}C_6H_4$, or possibly in the cation *(102)*, $R_1 = p\text{-}F\text{-}C_6H_4$, would suffer replacement by attack of the benzyl anion *(102)*. If on the other hand the Meisenheimer rearrangement involved, as suggested [46], a homolytic process (b), ionic fluorine would not be found in the reaction mixture.

I am much indebted to my co-workers Dr. I. K. Barben, Dr P. Miles, Dr. M. Bellas, Dr. R. K. Smalley, Dr. G. Puranik, and D. Price for their enthusiastic support and to the Research Fund of the Chemical Society (London), the Geigy Co. Ltd., Smith, Kline and French (Pa. U.S.A.), and the S. R. C. (London) for generous financial help and to Dr. P. Koch of Koch-Light Laboratories Ltd. for gifts of fluorine compounds.

Electrophilic Substitution of Heteroaromatic Compounds with Six-Membered Rings[**]

BY A. R. KATRITZKY AND C. D. JOHNSON[*]

IN COLLABORATION WITH

G. P. BEAN, P. BELLINGHAM, P. J. BRIGNELL, B. J. RIDGEWELL, N. SHAKIR, O. TARHAN, M. VINEY, AND A. M. WHITE

The limited amount of quantitative data available on the electrophilic substitution of heterocycles is surveyed. Initial objectives are first to determine the species undergoing substitution and then to find out the amount by which the heterocyclic atom or group activates or deactivates the ring by comparison with the corresponding benzenoid compound. When sufficient data are available it is hoped to correlate this by means of a Hammett-type treatment or by MO methods.

The mechanism of electrophilic substitution in benzenoid compounds is now comparatively well understood and the subject has been comprehensively reviewed [1]. On the other hand our knowledge of the mechanism of heteroaromatic electrophilic substitution is meager and it was therefore considered important to study this mechanism both to rationalize the mass of qualitative information, and to aid the prediction of the feasibility of new reactions.

For example it is a familiar fact that the nitration of pyridines proceeds only under vigorous conditions and that product yields are poor. At present it is not known whether this is due to the low reactivity of the positively charged conjugate acid of pyridine toward the electrophile $NO_2^{\oplus}$, or whether the reaction took place on the very small amount of free base present under the strongly acidic conditions.

The present review summarizes the results obtained in our studies together with results obtained by other workers, notably *J. Ridd* at University College, London, and *K. Schofield* at the University of Exeter.

There are two major questions to be answered regarding the quantitative aspects of the substitution of heterocycles: 1) What species are involved; for example as above does the heterocyclic compound react in the form of free base or as the conjugate acid? 2) In what way does the annular heteroatom affect the rate of substitution at carbon atoms in the various ring positions?

Several criteria may be used to decide which species is reacting:

1a) The most direct is to compare the kinetic rate with that for model compounds in which the possibilities of ionisation or tautomerism are eliminated.

1b) The "rate profile" may be determined, *i.e.* the manner in which the rate depends on the acidity of the medium. Then, if the manner in which the ratio of the concentration of base to conjugate acid varies over the acidity range in question is known (*i.e.* the acidity function followed by the base), the theoretical change of rate for reaction *via* each of the possible reacting forms may be calculated and compared with that found.

1c) The entropy of activation, determined by Arrhenius plots, is expected to be considerably greater for reactions between two singly charged species of the same sign (*Frost* and *Pearson* predict [2] *ca.* −20 e.u.) than for reaction between a neutral species and one with a single charge.

1d) The encounter rate criterion can be applied in those cases where the concentration of a free base in a strongly acid solution is so low that, even if every molecular collision resulted in reaction, the calculated reaction rate would be lower than that measured. This limiting rate, the encounter rate, is given by:

$$k(\text{encounter}) = \frac{kT}{3\eta} \cdot \frac{(r_A + r_B)^2}{r_A r_B} \cdot \frac{N}{100} \qquad (1)$$

(where η is the viscosity of the medium, k is Boltzmann's constant, N is Avagadro's number, and r_A and r_B are the radii of the ions).

The rate constant (k') for reaction on the free base may be calculated from

$$n \log k' = n \log k + pK_a - H_0 \qquad (2)$$

(where n is unity for a Hammett base [*], and k is the observed rate constant).

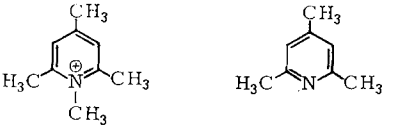
[*] Such Hammet bases are defined in [8]; reference base is *e.g.* *o*-nitroaniline.

When the nature of the reactive species in an electrophilic substitution has been elucidated, the question of the quantitative effect of the heteroatom can be considered. The rate of reaction for a heterocyclic compound is compared with that for the correspondingly substituted benzene at the same temperature (to do this, considerable extrapolation is often required). The effect of the heteroatom may be treated in two main ways:

2a) The Hammett equation approach[3] attempts to assign Hammett sigma constants σ_p and σ_m to each type of hetero group (*e.g.* $\rangle N$, $\rangle N^{\oplus}H$, $\rangle O^{\oplus}$, $\rangle N^{\oplus}-O^{\ominus}$, *etc.*) and a ρ value for each type of electrophilic substitution.

2b) The molecular orbital approach[4] assigns to each heteroatom X a Coulomb integral α_x and for bonds C–X a resonance integral β_x. These values are used to derive a variety of molecular orbital parameters with which the partial rate factors may be compared.

As yet there are insufficient data for the application of either of the above approaches. It is the aim of work being presently carried out to remedy this deficiency, and to enable a test of some of the diverse theoretical treatments which are possible.



A. Pyridines

Extensive preparative work on the electrophilic substitution of pyridines has been reviewed by *Abramovitch*[5]. The strongly deactivating and *meta*-directing influence of the heteroatom is apparent; other substituents exert influences qualitatively similar to their behavior in benzenoid systems. A complicating factor is the catalysis caused by various metal salts which is thought to result from coordination of the metal with the pyridine nitrogen atom and possible back-donation of electrons to the ring.

1. Acid-Catalysed Hydrogen Exchange

Acid catalysed hydrogen exchange of pyridines was initially studied[6,10] by use of tritium as a tracer. Although pyridine and 4-picoline were found to be unreactive under the most vigorous conditions studied, exchange proceeded smoothly with 2,6-di- and 2,4,6-tri-methylpyridine. The reactions were investigated by heating aliquots of sulfuric acid, tritiated water, and the substituted pyridine at predetermined temperatures in sealed tubes for a known time. The base was isolated as the picrate, and the water produced on combustion of the picrate was monitored. The results obtained showed that the reaction was a first order reaction and that it occurred, as is suggested by the following criteria, on the conjugate acid:

a) 1,2,4,6-Tetramethylpyridinium ion *(1)* reacted slightly faster than the 2,4,6-trimethylpyridine *(2)*; an *N*-methylpyridinium cation would be expected to react faster than the corresponding protonated pyridinium cation, just as a methyl group causes a rate enhancement in benzenes.

(1) *(2)*

b) Plots (cf. Fig. 1) show that log *k* increased linearly with $-H_o$, slopes of 0.45 to 0.77 being found. Although these slopes are smaller than those found for benzenoid derivatives[7], the evidence indicates that the magnitudes of the slopes increase as the temperature is lowered, and rough extrapolations give reasonable room-temperature slopes. Further, the slopes for the bases and the *N*-methyl derivative *(1)* are similar. If reaction had been occurring on the free base, the variation of rate with acidity would have been much less, as the increasing activity of hydrogen ions (H^+ and T^+) would be counterbalanced by a decreasing amount of free base available for reaction.

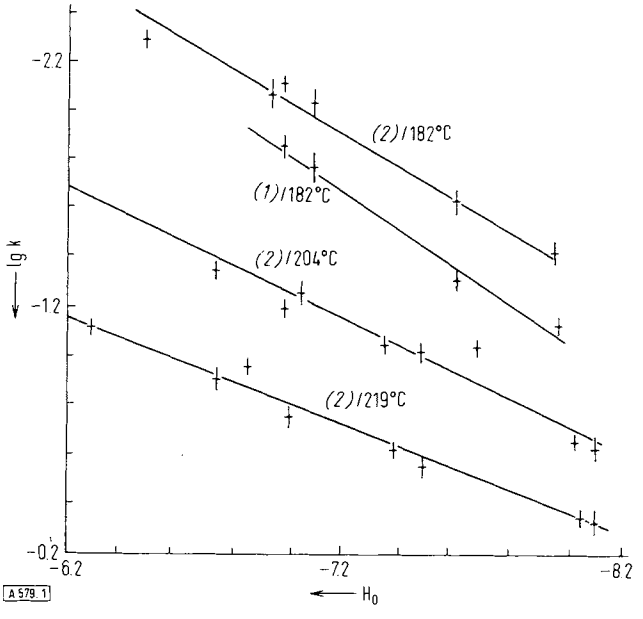


Fig. 1. Rate profiles for the acid-catalysed hydrogen exchange of 2,4,6-trimethylpyridine.

c) Calculated collision frequency factors, assuming reaction proceeds on the free base, are quite unreasonable, and exclude reaction *via* the free base (for details, examples, and discussion cf. [6]).

Rate comparisons with benzenoid compounds to obtain values for the deactivating effect of the $=\overset{\oplus}{N}H-$ group, as compared with $=CH-$, are as yet approximate because of lack of data, but indicate a deactivating factor of *ca.* 10^{-18} at the *meta* position.

[5] *R. A. Abramovitch* and *J. G. Saha* in *A. R. Katritzky*: Advances in Heterocyclic Chemistry. Academic Press, New York-London 1966, Vol. 6.

[6] *A. R. Katritzky* and *B. J. Ridgewell*, J. chem. Soc. (London) *1963*, 3743.

[7] *V. Gold et al.*, J. chem. Soc. (London) *1965*, 3609.

The acid-catalysed hydrogen exchange of aminopyridines is potentially more complicated. Here reaction could occur *via* free base, first conjugate acid, or second conjugate acid. For ideal behavior, where equilibrium and kinetic protonation both follow H_0, we should expect a rate profile as in Figure 2.

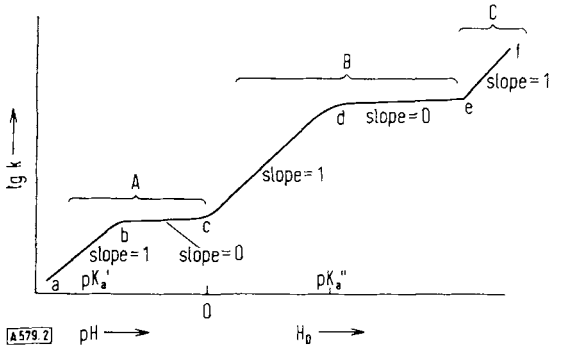

Fig. 2. Idealized rate profile for acid-catalysed hydrogen exchange of various highly protonated aromatic bases.
A: free base; B: first conjugate acid; C: second conjugate acid.

For other cases it can be shown[7a] that for exchange on a species, the concentration of which is not changing rapidly with acidity, $\delta \log k/\delta H_0 = \delta H_x/\delta H_0$ where H_x is the acidity function for kinetic C-protonation. For exchange of a species mainly present as its conjugate acid:

$$\delta \log k/\delta H_0 = \delta H_x/\delta H_0 - \delta H_y/\delta H_0$$

where H_y is the acidity function followed for equilibrium protonation of the species in question. The study of the hydrogen exchange of 4-amino-, 4-amino-2,6-dichloro-, and 2-amino-5-methyl-pyridine has shown rate profiles corresponding to the portions b-c, c-d, and d-e of Figure 2[7a].

The above treatment requires assumptions about the acidity functions followed by pyridines, and the variation of acidity functions with temperatures. Polyhalogeno-pyridines have been shown to be Hammett bases[8]. Available data on the effect of temperature on acidity functions is sparse and does not include observations for temperatures above 80 °C. There is an indication, however, that such effects are neither large nor discontinuous[9].

2. Nitration

1,2,4,6-Tetramethylpyridinium ion can be nitrated under the same reaction conditions as 2,4,6-trimethylpyridine, indicating that the latter compound reacts as the conjugate acid[11]. This is confirmed by the kinetic results; a rate profile for 2,4,6-trimethylpyridine at 101.3 °C is shown in Fig. 3. The general shape of the plot indicates conjugate acid nitration. This shape is characteristic[12] for a nitration in which the substrate concentration does not change significantly

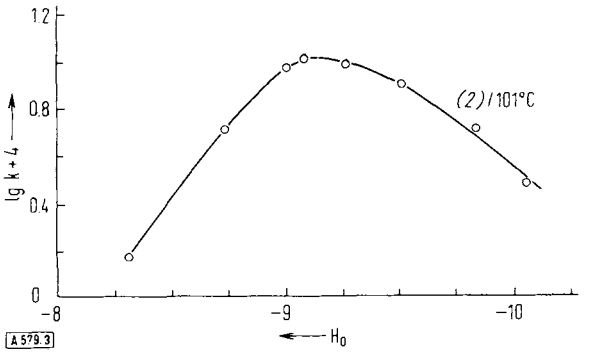

Fig. 3. Rate profile for the nitration of 2,4,6-trimethylpyridine at 101 °C.

with acidity. For nitration as free base a different shape is expected; the curve should be tilted in a clockwise direction because of the decreasing concentration of the substrate available for nitration as the acidity increases (cf. Fig. 4). In addition, calculated encounter rates show that there is insufficient free base present for its nitration to explain the results obtained. Again, rate comparisons with benzenoid compounds are complicated by lack of data, but a rough estimate gives a deactivating factor of *ca.* 10^{-12} for $=NH^{\oplus}$ at the *meta* position; however, derivation of this value necessitates assumptions regarding the constancy of the effect of methyl groups.

Nitration of a pyridine derivative *via* the free base might be expected (if the basicity of the pyridine nitrogen were low).

2,6-Dichloropyridine ($pK_a = -2.8$[8]) was found to undergo nitration in the 3-position smoothly at 100 °C, and a partial rate profile for nitration at this position,

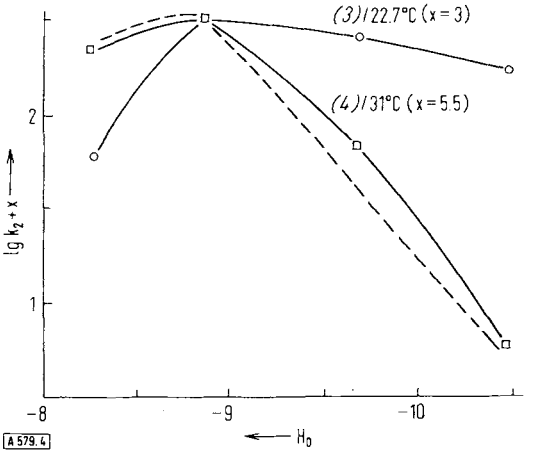

Fig. 4. Rate profiles for the first and second nitrations of 2,6-dimethoxypyridine (the broken curve was calculated for the free base).

together with a low entropy of activation (−10 e.u. in 98.3 % H_2SO_4), indicated reaction as the free base. 2,6-Dimethoxypyridine *(3)* could be nitrated to yield successively the 3-mono- *(4)* and 3,5-di-nitro derivative *(5)*[13]. The rate profiles (Fig. 4) show that the first of these nitrations occurs on the conjugate acid of 2,6-dimethoxypyridine, and that the introduction of the first nitro-group lowers the basicity such that

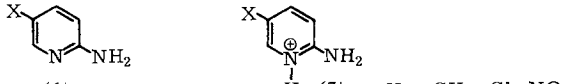
(3) (4) (5)

sufficient of the free base of *(4)* is present for it to compete successfully with the corresponding conjugate acid in the second nitration stage.

Fig. 4 also shows a "corrected" line which has been obtained from the conjugate acid curve by incorporating the concentration of free base, assuming that it is still a Hammett base at these acidities. This closely parallels the curve obtained for 3-nitro-2,6-dimethoxypyridine, indicating that the latter undergoes further nitration *via* the free base, or conversely, we may consider it as an indication that pyridine compounds follow the Hammett acidity function in very strong sulfuric acid medium.

By measuring the rates of nitration of 1,3-dichloro- and 1,3-dimethoxy-benzene, the deactivation relative to benzene of the $\rangle N$ "substituent" may be calculated. These rates have been measured, giving values of



$$\log \frac{k_2\,(\text{dichlorobenzene})}{k_2\,(\text{dichloropyridine})} = 1.5 \text{ and } \log \frac{k_2\,(\text{dimethoxybenzene})}{k_2\,(\text{dimethoxypyridine})} = 2.3;$$

where k_2 is the bimolecular rate constant.

These values are far smaller than is expected, and suggest that the same substituent may exert a different mesomeric effect in the pyridine than in the benzene system.

3. Bromination [14]

5-Substituted 2-aminopyridines *(6)* are brominated smoothly at the 3-position in aqueous sulfuric acid and the rates may be conveniently measured by the decrease in the bromine/bromide potential. At acidities in the range +0.5 (pH) to −3.5 (H_0) straight line rate profiles with approximately unit slopes are found, indicating that bromination is occuring on the free base species *(6)*, and not on the conjugate acids *(7)*.

(6) (7) X = CH_3, Cl, NO_2

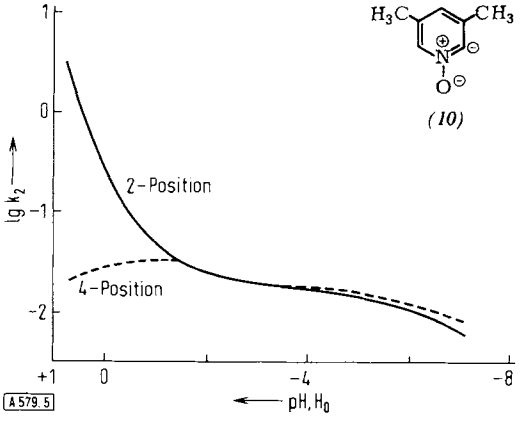
By comparison with corresponding *para*-substituted anilines, it is found that the $\rangle N$ "substituent" deactivates by a factor of *ca.* 0.54 for this particular reaction [15].

Numerous examples of other electrophilic substitution reactions are known to occur in pyridines, but no kinetic work has been carried out on them. The qualitative work reported has been well reviewed by *Abramovitch* [5] and includes sulfonation, mercuration, nitration and diazo coupling.

B. Pyridine *N*-Oxides

The discovery by *Ochiai* [16] that pyridine *N*-oxide is easily nitrated in the 4-position was one of the most important discoveries in pyridine chemistry, and led to further work on the electrophilic substitution reactions of pyridine *N*-oxides [5, 17].

The electrophilic substitutions [16] of pyridine *N*-oxide to yield the 4-nitro derivative on nitration, but the 3-sulfonic acid on sulfonation, has given rise to some speculation. Kinetic evidence is now available which



(8) (9)

proves that 4 substitution is a reaction of the free base *(8)*, and that 3 substitution occurs on the conjugate acid *(9)*. This evidence is detailed below.

1. Acid-Catalysed Hydrogen Exchange [19, 20]

Hydrogen exchange in 2,4,6 trimethylpyridine *N*-oxide was found to proceed smoothly in the 3- and 5-positions at 200 °C without decomposition. Plotting log k against H_0 gave a slope of 0.35 which, although less than the slopes for the pyridine series, nevertheless suggests that exchange proceeds through the conjugate acid. Entropies of activation are consistent with this conclusion. Attempts to measure the exchange on 1-methoxy-2,4,6-trimethylpyridinium ion failed due to decomposition of this substrate. 2,6-Dimethylpyridine *N*-oxide proved difficult to study because of concurrent decomposition; however, exchange was shown to occur in the 3-position at an H_0 of −8.15. There is some indication from the NMR spectrum that at sufficiently low acidities there is a change in mechanism leading to exchange in the 4-position.

3,5-Dimethylpyridine *N*-oxide was found to undergo ready exchange of the 2- and 4-position protons.

(10)

[19] *C. D. Johnson, A. R. Katritzky,* and *A. White,* J. chem. Soc. (London), in press.

[20] *A. R. Katritzky, B. J. Ridgewell,* and *A. M. White,* Chem. and Ind. *1964,* 1576.

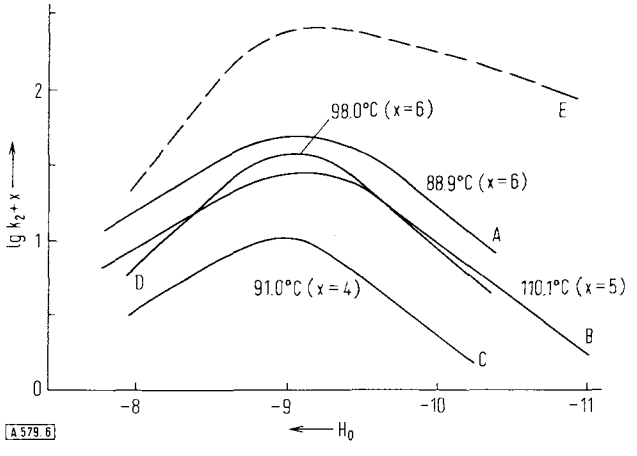
Exchange rates for these positions vary little with acidity (Fig. 5); the rate profiles rescemble that for 4-pyridone (Fig. 7), which is known to exchange as the free base (see section C 1). At low acidities the exchange rate at the 2-position increases rapidly, probably due to the formation of increasing amounts of zwitterions of type X; similar zwitterions are formed by deprotonation of pyridine *N*-oxide itself [18].

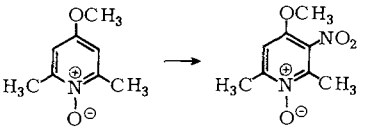
Comparison of rates of exchange of 2,4,6-trimethylpyridine and 2,4,6-trimethylpyridine *N*-oxide indicates that $\diagdown N^{\oplus}-OH$ is slightly more deactivating than $\diagdown N^{+}H$; this is probably due to the electron-attracting effect of the hydroxyl group [20].

Preliminary studies have also been made on 3-hydroxypyridine, for which the rate profile shows that reaction proceeds *via* the free base. It is not yet certain, however, whether the 2- or 6-hydrogen is exchanging [19]. 3,5-Dimethoxypyridine *N*-oxide exchanges in the 2-position; below about H_0 −3.5, the reaction proceeds *via* the free base, and at higher acidities on the conjugate acid [19].

2. Nitration

Schofield has shown that the *N*-methoxypyridinium cation does not undergo nitration under the conditions which allow easy reaction of pyridine *N*-oxide and concluded that the latter is nitrated as the free base [21].





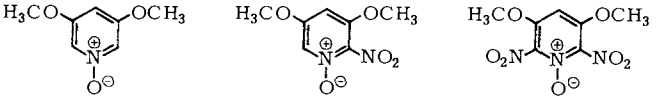


Fig. 6. Rate profile for the nitration of pyridine *N*-oxides [A: 2,6-dichloropyridine *N*-oxide; B: pyridine *N*-oxide; C: 3,5-dimethylpyridine *N*-oxide; D: 3,5-dichloropyridine *N*-oxide]. The broken curve represents the corrected rate profile (H_A function) for 2,6-dichloropyridine *N*-oxide.

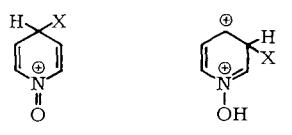
The rate profiles have been measured (Fig. 5) [22] for the nitration of 2,6-dichloro-, 3,5-dichloro-, and 3,5-dimethylpyridine *N*-oxide together with that for the parent compound. A recent paper [8] indicates that pyridine *N*-oxides are Hammett bases; a reappraisal of this work involving pyridine *N*-oxides of much lower basicity than those originally reported modified this conclusion and showed that the pyridine *N*-oxides follow approximately the H_A function [25]. Adjustment of the rate profiles (Fig. 6), using this information to correct for the variation in concentration of free base, gives a curve which is similar in shape to that obtained for the concentration of nitronium ion, confirming reaction *via* the free base.

(11) *(12)*



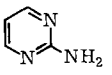
Nitration of a pyridine *N*-oxide in the 3-position was achieved in the case of the 2,6-dimethyl-4-methoxy derivative *(11)* → *(12)*; here the rate profiles indicate [13] nitration on the conjugate acid. The partial rate factor for nitration at the 4-position in pyridine-*N*-oxide is estimated as 10^{-4} [21]. Nitration in the 2-position has also been achieved [21a,22] in the case of 3,5-dimethoxypyridine *N*-oxide *(13)*. The 3,5-dimethoxy-2-nitropyridine *N*-oxide *(14)* then undergoes 6- rather than 4-nitration to yield the 2,6-dinitro compound *(15)*. Rate profile data indicate that reaction in both cases is *via* the conjugate acid.

(13) *(14)* *(15)*

3. Substitution Orientation

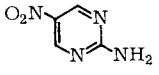
The nitration of pyridine *N*-oxides occurs preferentially in the 4-position while the slower, and therefore usually more selective, reaction of electrophilic hydrogen exchange attacks the more abundant but less reactive conjugate acid molecule in the 3-position. A possible explanation for this difference in substitution orientation is that the electron withdrawing effect of the nitro group in the Wheland intermediate *(16)* for 4-substitution is acceptable, whereas this inductive effect causes a large decrease in stability for the doubly-charged Wheland intermediate *(17)* for 3 substitution.

(16) *(17)*



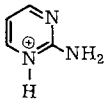
In these reactions, the transition state is probably close to the Wheland intermediate, and it could be that the inductive effects mentioned cause nitration to proceed *via (16)* whereas acid-catalysed hydrogen exchange can occur *via (17)*.

[21] *R. B. Moodie, K. Schofield,* and *M. J. Williamson,* Chem. and Ind., *1964,* 1577.



[21a] *H. J. den Hertog, M. van Ammers,* and *S. Schukking,* Recueil Trav. chim. Pays Bas *74,* 1171 (1955).

[22] *C. D. Johnson, A. R. Katritzky,* and *N. Shakir,* J. chem. Soc. (London), in press.



As a test of this hypothesis we[23] measured the first and second pK_a values of the pyrimidines *(18)* and *(19)*. The structure of the mono- and di-cations are of types *(20)* and *(21)*[23a]; a larger effect of the nitro group on the second pK_a than on the first pK_a would be expected if the above hypothesis were valid. The effect on the second pK_a due to the nitro group is 1.0 pK unit greater than its effect on the first pK_a, which is in the right direction, but smaller than expected.

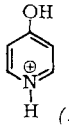
(20)

(21)

C. Pyridones and Pyrones[24,26]

The mechanism of substitution of the pyridones is of particular interest both because of the ease with which such compounds are attacked by electrophiles and because of the large number of forms which could undergo reaction. For 4-pyridone these include the anion *(22)*, the oxo form *(23)*, the hydroxy form *(24)* and the cation *(25)*.



(22)

(23)

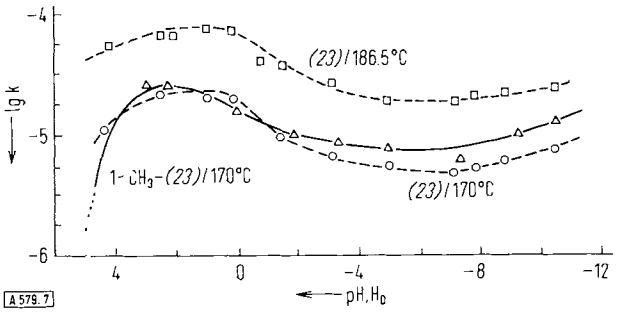
(24)

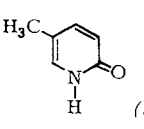
(25)

1. Acid-Catalysed Hydrogen Exchange

Rate profiles for the deuteration of 4-pyridone at two temperatures (Fig. 7) show that the rate varies by less than a factor of 4 over 14 logarithm units of acidity (pH=4 to H_0 =−10). This indicates that the reaction proceeds *via* a neutral form of pyridone; a conclusion which is supported by the low entropy of activation (*ca.* −8. e.u.).

The rate profile of 1-methyl-4-pyridone (Fig. 7) is similar to that of 4-pyridone, whereas 4-methoxypyridine does not react under these conditions: these





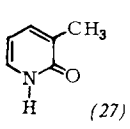


Fig. 7. Rate profile for the acid-catalysed hydrogen exchange of 4-pyridone *(23)* and for 1-methyl-4-pyridone (continuous line).

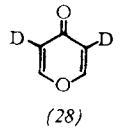
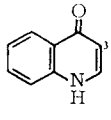
facts show that 4-pyridone undergoes reaction on the oxo form *(22)*. The hydroxy form is further excluded by encounter rate calculations, which were made assuming that *N*-protonation of the hydroxy form *(24)* would follow the Hammett acidity function and that *O*-protonation of the oxo form *(19)* would follow the amide acidity function (H_A)[25].

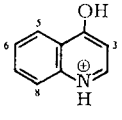


Consideration of the rate of exchange of the phenoxide anion shows that the introduction of $NH^{\oplus}$ for CH in this ion *meta* to the reacting site lowers the rate by a factor of about 10^7.

(26)



(27)



(28)

Preliminary studies of deuterium exchange in the 3-position of 5-methyl-2-pyridone *(26)* and in the 5-position of 3-methyl-2-pyridone *(27)* indicate that in both these cases also the reaction proceeds *via* the neutral oxo form shown.

It has also been shown that 4-quinolone at low acidities (H_0 <−7) exchanges as the neutral species *(29)* at the 3-position. On increasing the acidity, reaction *via* the conjugate acid occurs successively in the 3-, 6-, 8-, and 5-positions *(30)*.

(29)

(30)

For 2,6-dimethyl-4-pyridone there is a changeover from conjugate acid to free base reaction on lowering the acidity to H_0 = −3 which indicates a deactivation of *ca.* 10^7 on protonation.

Investigation of the hydrogen-exchange reactions of pyrones and thiopyrones is also being carried out[26].

4-Pyrone is converted to the 3,5-dideuterio-derivative *(28)* in neutral or weakly acidic solution; however, this reaction is not a simple electrophilic substitution[27], but proceeds *via* a base-catalysed mechanism.

Preliminary results indicate that compounds *(31a)* and *(31b)* exchange as the conjugate acids.

(31a), Z = O
(31b), Z = S

2. Nitration [23]

4-Pyridone can be nitrated in mixed acids to yield successively 3-nitro- *(32)* and then 3,5-dinitro-4-pyridone. A spectrophotometric study of the first nitration gave a rate profile (Fig. 8) indicating reaction

(32) *(33)*

on a species whose concentration was not altering significantly in the range $H_0 = -8.2$ to -10.5. This can only be the conjugate acid *(25)*; a conclusion supported by the large negative entropy of activation (−20.3 e.u.) found from an Arrhenius plot at $H_0 = -9.33$. The nitration rate was found to be comparable with that for the nitration of 4-methoxypyridine, and that for 1-methyl-4-pyridone.

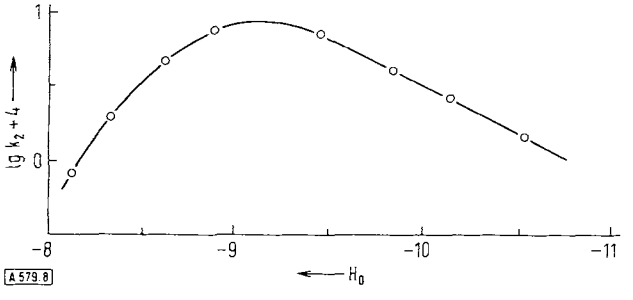

Fig. 8. Rate profile for the nitration of 4-pyridone *(23)* at 86 °C.

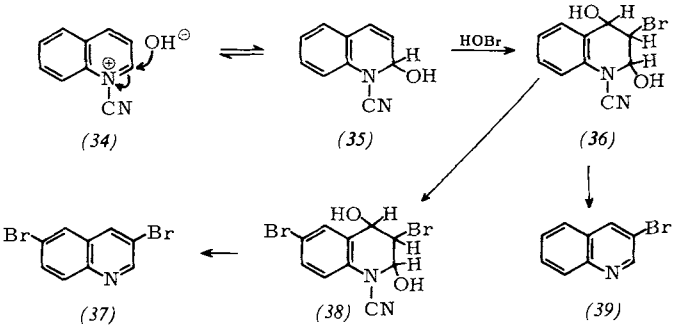
It is of interest that 4-pyridone is nitrated as the conjugate acid within an acidity range in which it undergoes acid-catalysed hydrogen exchange as the free base. This must be due to the greater selectivity of the hydrogen-exchange reaction compared to the nitration which involves the more reactive $NO_2^{\oplus}$ ion. This behavior serves to emphasize the abnormality of the reverse sequence already described for the pyridine *N*-oxides.

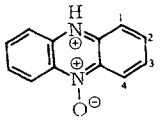
D. Polycyclic Heteroaromatic Compounds with Six-Membered Rings



Much work has been done in determining the position of substitution in polycyclic heteroaromatics, and in some cases accurate ratios of the various isomers formed have been determined. The positions of substitution within individual compounds have been correlated with considerable success by *Dewar* and *Maitlis* [28] using MO methods, but this work is outside the scope of the present review. Data enabling the determination of the nature of the species reacting, and absolute partial rate factors are very much more sparse. In addition, as discussed in detail by *Ridd* [4], only very limited success has attended attempts to correlate available rate data with MO parameters.

Austin and *Ridd* [29] have examined the kinetics of nitration of quinoline, which yields 5- and 8-nitroquinoline in approximately equal amounts. The slope of the rate profile, encounter-rate calculations, and the entropy of activation (−19.3 e.u.) in reactions with 85–98% sulfuric acid, all indicate that the reaction proceeds *via* the conjugate acid. Stepwise comparisons led to partial rate factors of *ca.* 10^{-7}. Independent work by *Schofield et al.* confirmed these conclusions by investigations in the lower acidity region (71–84% sulfuric acid); they also reported results for *N*-methyl quinolinium ions [21]. Similar work [21,30] with isoquinoline and the *N*-methylisoquinolinium cation again indicated reaction *via* the conjugate acid.

Schofield has also examined the nitration in the 5- and 8-positions of isoquinoline *N*-oxide in the acidity range 76.4–83.1% sulfuric acid. This compound has a rate profile which indicates reaction *via* the *N*-hydroxyisoquinolinium cation; this is borne out by the similar kinetics found for *N*-methoxyisoquinolinium perchlorate [21].



Johnson and *Ridd* [31] have clarified the mechanism whereby *N*-cyanoquinolinium ion *(34)* with aqueous solutions of bromine gives 3-bromoquinoline *(39)*. The reaction involves intermediate formation of the pseudo-base 1-cyano-1,2-dihydro-2-hydroxyquinoline *(35)*, which then undergoes bromination *via* an addition elimination (*(35)* → *(36)*) rather than a substitution mechanism, although straightforward electrophilic substitution may occur with excess bromine in the benzene ring, finally yielding 3,6-dibromoquinoline *(37)*.

J. Ridd et al. have demonstrated a 100-fold enhancement of the rate of nitration of *o*-phenanthroline [32] at

the 5-position over that of the parent compound by coordination with cobalt(III) cations. Studies are in progress to determine whether the difference in reactivity derives from reduction of the effective charge on the nitrogen or whether there is also an important degree of π-electron donation to the ring from the filled Co d_e orbitals.

(40)

Phenazine 5-oxide undergoes nitration at the 3-(and to a minor extent the 1-) position; kinetic criteria show that the monocation *(40)* is the reactive species [33].

[33] *A. R. Katritzky* and *B. Swedlund*, unpublished.

E. Conclusion

Very much remains to be accomplished. On the experimental side it is necessary to gain quantitative data as to the effect on rate of substitution (by a wide variety of electrophiles) of the replacement of a CH-group by an uncharged nitrogen atom, by various types of group incorporating a partially charged nitrogen ($N^{\oplus}H$, $N^{\oplus}-O^{\ominus}$, $N^{\oplus}-R$, $N^{\oplus}-OH$, *etc.*), and by charged $=S^{\oplus}-$ or $=O^{\oplus}-$. Only when more is known of the effects of these replacements towards the *ortho*, *meta*, and *para* positions, as well as effects relayed from one ring to another, will it be possible to develop and test the theoretical treatments, and, hopefully, to gain a real understanding of the field.

Acetylcholinesterase[**]

BY N. ENGELHARD, K. PRCHAL, AND M. NENNER [*]

Acetylcholinesterase plays a vital part in the functioning of nerves, and serious physiological damage arises from its blockage by esters of phosphonic and phosphoric acid used e.g. in pesticides. The properties and the mechanism of action of acetylcholinesterase, which show many similarities to those of other hydrolases, are described. Therapeutic agents (reactivators) for the toxic phosphorus compounds specified are also discussed.

A. Introduction

The mechanism by which impulses are conducted along nerves and transferred from one nerve to another or to an end organ entails a complex interplay of electrical and chemical processes [1–3].

A nerve cell or neuron ordinarily consists of a nucleated cytoplast, short and extensively branched fibers (dendrites) projecting from it together with a filament (axon or neurite), up to 1 m long and generally branched at its end, and finally a membrane enveloping all these. During the conduction of an exciting impulse, an electric potential (action potential) travels along the neuron. This potential is produced by selective diffusion of Na^+ and K^+ through the membrane, as a result of which the concentration of these ions is changed on either side of the membrane. The transfer of an impulse to other excitable elements (neurons, muscles, or glands) occurs at meeting places (synapses) between the axons of one nerve

cell and appropriate receptors (*e.g.* dendrites) of another. The presynaptic membrane of the ramified axon accommodates minute vesicles, and it is probable that these vesicles, actuated by the action potential, release a chemical into the 100–200 Å wide synaptic gap between the presynaptic and the postsynaptic membrane (this chemical has been variously named action substance, transmitter substance, neurohumoral transmitter, *etc*). This substance thus reaches the receptor organ of the other excitable element and causes – *via* still unknown specific receptors – a very fast change in the ion-permeability of the membrane, which in turn produces an electric potential.

The first action substance was found by *Loewi* in 1921 during experiments on the *Nervus vagosympathicus* of excised frog's heart [4]. It was named 'vagus substance' and later identified [6, 7] as *O*-acetylcholine *(1)*, whose action on blood

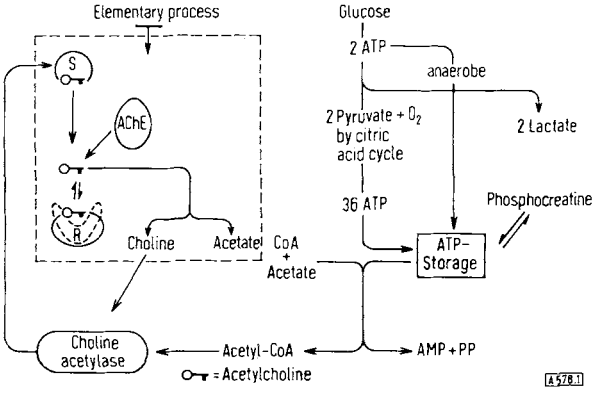
$$(CH_3)_3\overset{\oplus}{N}-CH_2-CH_2-O-CO-CH_3\overset{\ominus}{O}H \qquad (1)$$

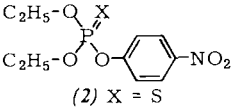
pressure, heart, and nerves had been known since 1914 [5]. Acetylcholine was subsequently shown to be the essential action substance of the parasympathetic and motor nerves, as well as of the sympathetic nerve fibers from the brain and spinal cord to the nerve ganglia. This group of nerves is therefore described as cholinergic. The other (postganglionic) nerves of the sympathetic nervous system are described as adrenergic, because their action substances are adrenalin and noradrenalin (sympathin I and E).

Not much is yet known of the manner in which acetylcholine affects the permeability of the membrane. According to *Nachmansohn*'s theory [2, 8], acetylcholine is responsible both for the transfer of impulses across the synaptic junction, and for their conduction along the neuron membrane. However, this second function has been questioned, and the theory of *Dale et al.* [11], according to which acetylcholine is involved only in the transfer of impulses across the synaptic junction, is now preferred.

According to an interesting theory proposed by *Koelle* [9], the action potential actuates the release of only a small amount of acetylcholine on the presynaptic membranes of nerves, probably including non-cholinergic ones, and this small amount then triggers off the liberation of a larger amount of acetylcholine in cholinergic nerves, or the liberation of some other action substance in non-cholinergic ones, the excitation being only then transferred to the postsynaptic membrane *via* the synaptic gap.

Before a second impulse can be transmitted the original state of the membranes must be re-established, and for this purpose the acetylcholine must be rapidly eliminated in a refractory phase. This is achieved by a highly active enzyme acetylcholinesterase (acetylcholine acetylhydrolase [3.1.1.7]) which hydrolyses acetylcholine within a few microseconds to acetic acid and choline having hardly any physiological action. In the presence of ATP and CoA, acetylcholine is resynthesized by the enzyme acetyl-CoA:choline-*O*-acetyltransferase [2.3.1.6], also called choline acetylase, discovered in 1943 by *Nachmansohn* and *Machado* [10]. Acetylcholine is finally stored in an inactive form and made ready for being triggered off a second time by a new action potential [2, 8, 10, 11] (see Fig. 1).





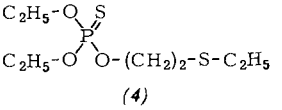


Fig. 1. Action of acetylcholine and its esterase in correlation with the metabolism (after *Nachmansohn* [2b]; cf. also [1a], p. 207). AChE = acetylcholinesterase; R = receptor protein; S = storage protein; The dotted boomerang in R indicates how this protein changes its shape, as a result of which the ion-permeability of the membrane is altered.

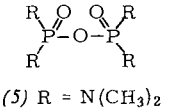

When the action of acetylcholinesterase is blocked, acetylcholine accumulates, and the original state of the membrane cannot be re-established. This leads to severe and often fatal endogenous poisoning involving *e.g.* irritation and paralysis. Death is generally caused by respiratory paralysis [3, 12, 13].

The most dangerous inhibitors of acetylcholinesterase are "alkyl phosphates", which are mixed anhydrides of phosphonic (or phosphoric) acid esters formed with organic or inorganic acids[12,14]. These compounds include pesticides such as Parathion (E 605®) *(2)*, Systox® *(4)*, OMPA (Schradan) *(5)*, TEPP *(6)*, as well as the highly active chemical warfare agents (nerve gases) DFP *(7)*, Tabun *(8)*, Sarin *(9)*, and Soman *(10)*. Some alkyl phosphates have been introduced in therapy; thus, Paraoxon (E 600, Mintacol®) *(3)* is used as a miotic (pupillary contractant) in ophthalmology.

Acetylcholinesterase has been the subject of intensive research, promoted partly by the investigation of its physiological importance and partly by the need for an efficient therapeutic method against cases of poisoning by alkyl phosphates[13]. The main results of this work will be summarized below.

B. General Properties of Acetylcholinesterase [2,3,15–17]

I. Discovery and Characterization

Loewi[7] suggested as early as 1926 that acetylcholine is rapidly hydrolysed by an esterase in the blood, thus making its identification difficult. This was subsequently confirmed, and the enzymes responsible for this hydrolysis were detected in blood and in practically all animal tissues and organs[18]. In 1932, *Stedman, Stedman*, and *Easson*[19] succeeded in concentrating by a factor of about seven an esterase present in horse serum, which rapidly hydrolysed choline esters and was regarded as the enzyme responsible for the hydrolysis of acetylcholine. However, *Alles* and *Hawes*[20] later (1940/1941) found that the real enzyme, specific for acetylcholine, is another esterase present also in erythrocytes, one that is identical with neural acetylcholinesterase but different from the acetylcholinesterase in the serum.

As a result of much subsequent investigation, we now describe as cholinesterase in the broader sense all hydrolases that cleave choline esters and are inhibited by physostigmine (eserine) in a concentration of 10^{-5} M. Cholinesterases are subdivided into the following two types[15b,15d,21]:

a) Acetylcholine acetylhydrolase [3.1.1.7][22], acetylcholinesterase which is the acetylcholine-cleaving enzyme, and has variously been called in earlier literature erythrocyte-cholinesterase (e-type cholinesterase), cholinesterase I, and true or specific cholinesterase; this enzyme will be denoted by AChE.

b) Acetylcholine acylhydrolase [3.1.1.8][22], which has also been called cholinesterase (ChE), pseudocholinesterase, serumcholinesterase (s-type cholinesterase), non-specific cholinesterase, cholinesterase II, X-cholinesterase, and by names such as propionylcholinesterase and butyrylcholinesterase; this enzyme will be denoted by ChE.

It is often difficult to decide which type of cholinesterase one is dealing with, because the enzyme preparations are frequently mixtures of both types.

The above two types differ in the following respects[15d,21,24–26]:

1. The activity of AChE on homologous *O*-acylcholines decreases in the series acetyl $\geqslant$ propionyl $>$ butyryl, whilst the activity of ChE increases along the same series.

2. Acetylcholine concentrations exceeding about 3×10^{-3} M inhibit AChE, whereas ChE is not inhibited even by much higher concentrations (10^{-1} M).

3. AChE and ChE differ in their susceptibility to inhibition by selective inhibitors – a particularly important distinction.

Only AChE seems to be responsible for the hydrolysis of acetylcholine in the body, and the physiological function of ChE is still unknown. Nor is it yet certain whether the same acetylcholinesterase is present in various organs and organisms, and the origin of extracts must always be known for accurate characterization.

1. Occurrence of Acetylcholinesterase[2,15,27]

Acetylcholinesterase is one of the most widely distributed enzymes in the animal kingdom, but it has not been found in plants, and its occurrence in unicellular organisms is questionable.

Acetylcholinesterase occurs in tissues particularly at those sites which need it for their biological function, though it has also been found in other places, where its physiological function and identity with neural acetylcholinesterase are uncertain. In man and most other mammals, such acetylcholinesterase is localized almost entirely in the erythrocytes, whilst the serum (except bovine serum) is rich in cholinesterase. In fishes and birds, on the other hand, the erythrocytes are generally poor whilst the serum is rich in acetylcholinesterase. Hydrolases of the AChE type are also found in the blood of

the edible snail [27a] and in the venom of some snakes such as the cobra.

Particularly significant is the AChE content of the electric organ of the electric eel *(Electrophorus electricus)* [28,29] (this organ is therefore the preferred starting material in the preparation of concentrates) and of varieties of torpedo fish *(Torpedo marmorata, T. oscellata,* and *T. occidentalis)*. This enzyme has also been detected in the cranial ganglia of cuttlefish *(Loligo pealii* and *Sepia officinalis)*.

2. Analytical Determination [21,26]

Kinetic studies and the determination of the acetylcholinesterase activity in biological fluids, homogenates, extracts, and enzyme preparations are based on determining the amount of the substrate that remains unchanged after incubation with the enzyme for a specified time, or else on determining the amount of the products formed by the enzymatic reaction (*e.g.* the amount of acetic acid formed when the substrate is acetylcholine which is preferred in this capacity, though other substrates can also be used). Owing to their inaccuracy, the biological methods often used earlier for the determination of unchanged acetylcholine have been abandoned.

Hestrin's [30] chemical microanalytical method is generally used, in which the unchanged acetylcholine reacts with an alkaline solution of hydroxylamine to give acetylhydroxamic acid, whose ferric iron complex is then determined photometrically. Amongst the many modifications of this method, those devised by *Pilz* [31] and by *Bockendahl* and *Ammon* [32] seem to be suitable for routine clinical tests.

Hestrin's method enables one to vary the conditions of incubation – which of course is essential for kinetic studies – but it is said to give values 15–20% low for the initial rate of the enzymatic reaction [33], and is therefore better reserved for rapid routine tests.

In a sensitive micro-scale method for the direct photometric determination of the reaction product [34,35], *S*-acetylthiocholine is used as a substrate and the resulting thiocholine is determined with the aid of 5,5′-dithiodi-(2-nitrobenzoic acid). This method is particularly suitable for continuous monitoring of the hydrolysis with acetylcholinesterase [35].

Ammon's much-used determination of acetylcholinesterase depends on manometric measurements, in a Warburg apparatus, of the carbon dioxide liberated from $NaHCO_3$ by acetic acid formed in the enzymatic reaction [32,36,37]. This method enables one to follow the course of the reaction on a single charge, and it can therefore be used for kinetic studies. For routine work, however, this technique is too time-consuming. In kinetic investigations, furthermore, it suffers from the disadvantage that the pH of the reaction mixture can hardly be varied.

Further methods are based on the colorimetric [38] or the electrometric [39] determination of the slight pH change caused by the liberated acetic acid in a buffered medium. The activity of the enzyme is then calculated from the pH change in unit time. Alternatively, the pH is kept constant by continuously neutralizing the acetic acid with NaOH solution from a burette [40], the titer being directly proportional to the amount of acetylcholine that is hydrolysed by the enzyme. An accurate and fast method based on the use of an automatic titrating and recording device (pH-stat) [41,42] enables a number of parameters, such as the pH, the temperature, and the type and the concentration of salts, substrates, and inhibitors, to be varied within wide limits in kinetic work. Methods suitable for cytological investigations have been summarized by *Koelle* [27].

3. Preparation of Acetylcholinesterase Concentrates [15a,15b,16,21,43]

Mammalian erythrocytes and the electric organs of certain fishes are generally used as the source for this purpose.

A difficulty encountered in the isolation from erythrocytes is that the enzyme probably adheres to the cell membrane [15a, 44]. To effect the necessary separation, *Augustinsson* [15a] used lysolecithin, *Cohen* and *Warringa* [45] a pancreas extract, and *Zittle et al.* [46] a surfactant, polyoxyethylene-sorbitan laurate (Tween 20). However, the best concentrates so far prepared from erythrocytes showed a specific activity [47] of only 42 [45], and the yields were low.

Much more highly concentrated samples have been prepared from the electric organ of the electric eel, in

[47] Definitions by [23]: Specific activity = number of enzyme units per mg of protein; Enzyme unit = amount of enzyme that converts in 1 min 1 μmole of substrate (here acetylcholine) under specified conditions (here generally at pH 7–7.5 and 37–38 °C).

which the specific activity is initially much higher. Thus, *Rothenberg* and *Nachmansohn* [43,48] obtained concentrates with specific activities of up to 7700. The value of 11000 (pH 7.0, 25 °C) subsequently reached by *Kremzner* and *Wilson* [33] corresponds to almost maximum purity. This was achieved by eluting the prepurified extracts [48] on the following columns in succession: benzyl-DEAE-cellulose, Sephadex G-200, Cellex P, and DEAE-cellulose (twice).

4. Physical and Kinetic Characteristics of Acetylcholinesterase

The values reported for the molecular weight of acetylcholinesterase vary between 70000 and 31 million. Even the extreme values appeared plausible, since they were obtained for samples which had been proved uniform by electrophoretic, chromatographic, and centrifugal analysis. However, the wide variations in the molecular weight cannot be explained even if one assumes that the samples were not pure and that there were variations according to the source of the enzyme. It might be proposed that the enzyme forms variously large associated or polymeric molecules, depending on the experimental conditions [46,48–51].

It has been shown [52] that samples with specific activities between 5000 and 11000 behave alike on sedimentation, although the less active ones of these can be separated chromatographically into several components. One may regard as the most reliable the values obtained by *Kremzner* and *Wilson* with a sample extracted from electric eels [33] and having a specific activity of 11000 (25 °C, pH 7) [52] (see Table 1).

The equivalent weight per site points to four sedimenting subunits. However, it is not yet clear whether these can dissociate and exhibit independent activity.

Table 1. Physical and kinetic characteristics of acetylcholinesterase.

Sedimentation constant $s_{20\,°C,\,w}$	10.8 S	[52]
Diffusion coefficient $D_{4\,°C}$	2.6×10^{-7} cm²sec⁻¹	[52]
Friction ratio f/f_0	≈ 1.25	[52]
Molecular weight		
by sedimentation and diffusion	≈ 230000	[52]
by gel filtration	≈ 250000	[52]
by activity per site [50]	> 240000	[52]
Equivalent weight per site	≈ 54000	[52]
UV Absorption spectrum	λ_{max} = 280 mμ (2.29) λ_{min} = 250 mμ (1.37) shoulders at 290, 278, and 258 mμ	[53]
Optimum pH	8.25 (8.0–8.5)	[54]
Michaelis constant K_m (automatic titrator, 15–35 °C)	1×10^{-4}	[55]
Activity per site [56]	6.1×10^5 mole/min [also 52, 57, 50]

[54] *J. A. Cohen* and *R. A. Oosterbaan* in [3], p. 299.

The kinetic characteristics of this enzyme have been the subject of many investigations under widely varying conditions [2b,3,15,54] (see also Table 1). The number of active sites has been determined *e.g.* from the inhibitory action of diethoxyphosphorylthiocholine or tetraethyl pyrophosphate [TEPP, *(6)*] labeled with ^{32}P [50]. *Wilson* and *Harrison* [57] carried out the determination by titration with *N,N*-dimethylcarbamoyl fluoride, whilst *Bender* and *Stoops* [61] have described a method in which *o*-nitrophenyl *N,N*-dimethylcarbamate is used. It has been deduced from the activity per site in 1 mole that the local concentration of acetylcholinesterase *in vivo* must be about 5×10^{-6} to 5×10^{-5} N in order to decompose acetylcholine at a sufficiently high rate [57].

The activity of the enzyme is affected by inorganic ions [54]. Thus, it is increased or decreased in the presence of NaCl according to whether the acetylcholine concentration is above or below about 10^{-3} M. *Myers* [58] has attributed this to an effect of the ionic strength on the equilibrium constants of the Michaelis complex ES and a substrate-inhibited complex ES_2. Divalent ions (*e.g.* Mg^{2+}) enhance the enzymatic activity much more than monovalent ions. The reason for this is not clear, but acetylcholinesterase is probably not a "metal-enzyme" [59]. To eliminate fortuitous ionic effects, it is advisable [54] to use *ca.* 0.15 M NaCl and 0.01–0.04 M $MgCl_2$ solutions, which has in fact been done in all the kinetic investigations discussed below. A protein such as gelatine is also often added to stabilize the enzyme solution [60].

C. Active Center and Reaction Mechanism [2b,15,17,54,62–64]

Most of the following discussion applies not only to acetylcholinesterase but also to related hydrolases, and conversely, many results obtained with the latter (*e.g.*

[55] *I. B. Wilson* and *E. Cabib*, J. Amer. chem. Soc. *78*, 202 (1956).

[56] The term "turnover number" should no longer be used [23].

[64] Various lectures on this topic are to be found in: a) Discuss. Faraday Soc. *20* (1955); b) *P. A. E. Desnuelle*: Molecular basis of enzyme action and inhibition (Proc. 5th International Congress of Biochemistry, Moscow 1961, Vol. 4), Internat. Union Biochemistry, Symposium Series. Pergamon Press, Oxford 1963, Vol. 24.

cholinesterase [65] and especially α-chymotrypsin [66]) are valid for acetylcholinesterase.

The catalytic action of acetylcholinesterase is due not to a coenzyme but to the structure of the enzyme protein itself. As the protein molecule folds, certain amino acid residues at distant sites of the chain are brought close to one another, forming an active center. The latter comprises two active sites: one fixes the substrate and is chiefly responsible for the specificity (anionic site), and the other effects the cleavage of the substrate (esteratic site).

I. Fixation of the Substrate, and Specificity (Anionic Site)

Acetylcholinesterase cleaves preferentially esters containing a cationic group (alkylammonium group). The best substrate is acetylcholine, whilst esters in which the cationic group is separated from the alcoholic oxygen by more than or fewer than two CH_2 groups are less suitable. Nevertheless, such esters are often efficiently hydrolysed by other cholinesterases. Chain branching and steric factors also play a part. Neutral esters such as ethyl acetate are cleaved much more slowly.

The preference for substrates containing a cationic group suggests the presence of an anionic site in the active center [67–71], *i.e.* a site which holds the substrate by electrostatic forces and which is accompanied by an adjacent esteratic site to catalyse the hydrolysis. The assumption that the enzyme contains two anionic sites [63, 72, 73] is probably incorrect [15c, 74].

Further evidence for an anionic site has emerged from experiments with reversibly cleavable inhibitors. The most active of the latter also possess a positively charged nitrogen atom; their inhibitory action is reduced when the cationic group is converted into a neutral one [68]. Finally, the salt effect of inorganic ions exerted on the inhibitory process also indicates an interaction of charged groups during fixation [70].

Other forces participating in the fixation of the substrate besides Coulombic ones are van der Waals forces involving the methyl groups of choline and uncharged substrates [71, 74, 75], and weak covalent bonding forces between the carbonyl carbon of the ester and the esteratic site [76–78]. Concerning the participation of hydrogen bonds see [71, 80b].

II. Cleavage of the Substrate (Esteratic Site)

According to *Wallenfels* and *Streffer*, enzymatic catalysis often relies on acid-base catalysis (cf. [86]). This necessitates the presence, in the esteratic site, of an "acidic" and a "basic" active group, whose function in the enzymatic reaction depends on the degree of protonation and thus on the pH of the medium. The existence of such active groups in acetylcholinesterase has been inferred by *Wilson* and *Bergmann* [68, 76] from the bell-shaped activity/pH curves (Fig. 2) which indicate a diminished activity above and below the optimum pH.

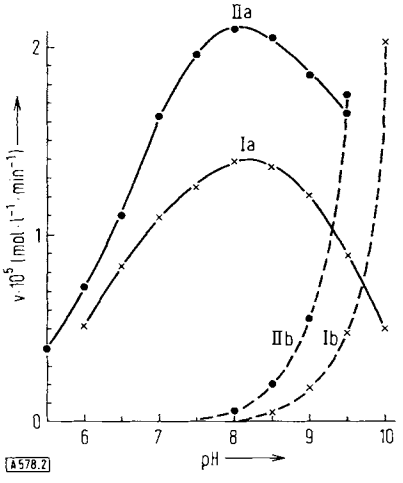

Fig. 2. Variation of the acetylcholinesterase activity with pH.
Curves Ia and IIa — rate of enzymatic cleavage of acetylcholine.
Curves Ib and IIb — rate of autohydrolysis of acetylcholine.
Acetylcholine concentration: × 2.06×10^{-4} mole/l, • 8.24×10^{-4} mole/l.
Enzyme concentration: 10 mg/l, bovine erythrocyte-AChE preparations (ex Mann Research Laboratories, New York; cf. [60]) in 0.1 M NaCl + 0.01 M $MgCl_2$ solution.
Titration with 0.02 N NaOH at 35 °C under nitrogen, with the aid of a pH-stat (Titrigraph, ex Radiometer Copenhagen).

The decrease in activity in acidic medium is due to inactivation of the basic active group by protonation. *Krupka* investigated the pH-dependence of the maximum cleavage rate of charged and uncharged substrates, and concluded that the basic group is composed of a first (B_1) and a second (B_2) group (pK 6.3 and 5.5, respectively) [80]. The activity drop in alkaline medium, on the other hand, is attributable to the inactivating deprotonation of the acidic group AH (pK

9.2)[78,79]. Equations for the pH-dependence of the activity can be found in[76,79,81,82].

According to the simplest scheme for enzymatic reactions, an enzyme E and a substrate S combine to form a complex ES, which then decomposes into the reaction products. With acetylcholinesterase, these products are choline and an acetylated enzyme EAc[84,85]. The latter is finally hydrolysed to give the free enzyme and acetate (see Fig. 4).

In non-enzymatic ester hydrolysis, which generally proceeds *via* a $B_{Ac}2$ mechanism, the electrophilic carbonyl carbon of the ester suffers an attack by the OH ion, the basic group. Similarly, in the enzyme-catalysed hydrolysis of acetylcholine, the carbonyl carbon is probably attacked nucleophilically by the basic group B_2, and the acetylated enzyme EAc is formed. The acidic group AH first forms a hydrogen bond with the alcoholic oxygen atom and the choline residue is then cleaved off in the next step. A configurational change finally brings the acetylated group close to the basic group B_1, which catalyses the deacetylation by water or other nucleophilic substances[78,83]. The rate-determining step is deacetylation in the case of acetylcholine, acetylthiocholine, and phenyl acetate, but acetylation in the case of relatively poor substrates such as methylaminoethyl acetate[80]. Evidence for this mechanism includes the ^{18}O-exchange between the acetate and labeled water in the presence of acetylcholinesterase[87,88], and the fact that kinetic equations based on this postulated mechanism account best for the experimental values. Furthermore, the formation of an acetylated enzyme explains the observation that acetylcholinesterase can act as a transacetylating agent[83], and it is clearly analogous to the formation of a phosphorylated enzyme in the reaction with alkyl phosphates.

1. Chemical Nature of the Active Sites and Groups

a) *Anionic Site*

ω-Carboxyl groups of aminodicarboxylic acids seem the most likely carriers of negative charge on the anionic sites. Degradation studies have shown that the active center involves glutamic acid in AChE, but aspartic acid in other esterases[89,90].

b) *Esteratic Site*

A great number of findings indicates that serine, which contains an OH group and is present in all hydrolases[89,90], plays an important part in the esteratic site[91]. It has been shown, for example, that hydrolases can be inhibited stoichiometrically with diisopropyl fluorophosphate (DFP) *(7)* labeled with ^{32}P[92,93] (see also[50,57]), and that subsequent hydrolysis of the protein gives *O*-diisopropoxyphosphorylserine[94] (cf. also[95]). Though phosphorylation and acetylation with *p*-nitrophenyl acetate[96] seem to involve the serine residue, the site of acetylation in ordinary substrate cleavage is not yet certain[97].

The amino acid sequence, so far elucidated only for tripeptide units, is –Glu–Ser–Ala– in acetylcholinesterase[98] and butyrylcholinesterase, but –Asp–Ser–Gly– in several other esterases[89,90].

Under physiological conditions, free serine does not catalyse the hydrolysis of esters[99], nor does it react with alkyl phosphates[100,101]. It must therefore be activated by other amino acid groups in the enzymes. The imidazole group of histidine probably represents such an activating group[102]; this group is known to possess numerous biochemical and catalytic functions[103]. By analogy with chymotrypsin and trypsin, one may assume that each of the two basic groups B_1 and B_2 consists of an imidazole residue, and that they are brought close to each other in the protein by a conformational change[80b]. Various mechanisms have been proposed for the cooperative action of the active groups[2b,54,62,63,104,106–109]. According to the most probable mechanism, the doubly bonded nitrogen of the imidazole ring abstracts a proton from the OH group of serine, presumably in a concerted mechanism (cf.[86]). The resulting serine alkoxide anion then attacks the substrate or the alkyl phosphate nucleophilically (see below), and the acetylated serine thus formed is brought into the vicinity of the second imidazole group by a configurational change. This imidazole group abstracts a proton from water (this has already been found in the catalysis of activated esters by imidazole[91,100,105,

[110, 111]) and thus effects hydrolysis, *i.e.* deacetylation of the serine. A simple scheme of this mechanism has been given by *Krupka* [80b] (see Fig. 3).

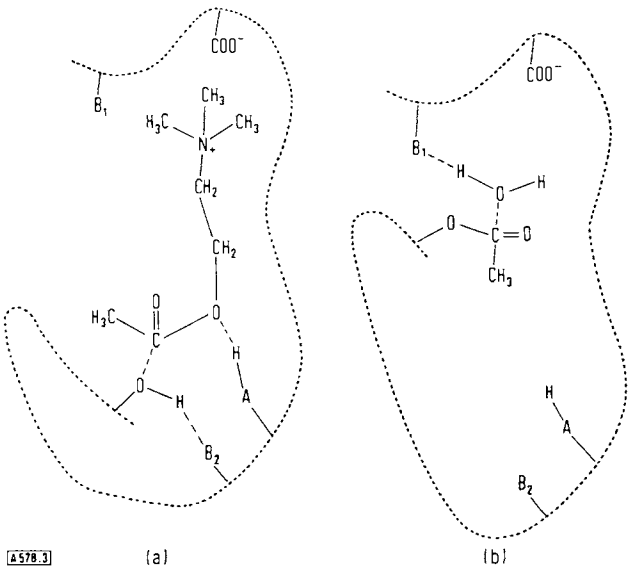

Fig. 3. Schematic representation of the active site in acetylcholinesterase. B_1 and B_2 are the basic groups (pK 6.3 and 5.5, respectively), AH is the acidic group (pK 9.2), OH and COO^- are the serine hydroxide group and the anionic active site.

(a) Enzyme-substrate (ES) complex in the case of acetylcholinesterase;

(b) Acetylated enzyme (EAc) (after *Krupka* [80b]).

Only hypotheses exist as yet about the nature of the acidic group, but various indications suggest that it is the OH group of tyrosine [63, 105]. According to *Koshland*, on the other hand, tyrosine seems to play no part in the catalysis, at least not in the case of chymotrypsin [91].

c) *Steric Configuration of the Active Center*

The protein must be present in a suitable steric configuration (*e.g.* having a "substrate cavity" [86]) in order to permit the joint attack of the active groups, which – like serine and histidine in the amino acid chain – are not adjacent. In hydrolases such as α-chymotrypsin, ribonuclease, and carboxypeptidase A, serine and histidine are brought together by a folding of the protein molecule fixed by disulfide bridges [112, 113]. According to the theory of induced fit [113, 114], the substrate, too, brings about a catalytically active configuration of the active center of the protein. The ability of the protein to fit itself to the substrate may affect the substrate specificity.

Information about the steric configuration of the active center in acetylcholinesterase has been obtained from experiments with substrates and reversibly cleavable inhibitors. In these experiments the inhibition or the rate of cleavage was ascertained in order to establish which are the ones that fit best [17, 115–119]. The protonated basic group B_1 can impede the access of a reversible inhibitor to the adjacent anionic site. The lowering of the inhibition constant for tetramethylammonium chloride, accompanying a change in the pH in the region of the dissociation constant of the first basic group B_1, indicates that the distance from the anionic site cannot exceed 5.5 Å. Since such an effect has not been found with the second basic group B_2 and the acidic group AH, these groups do not interact with the anionic site, and are situated from it at distances of 8–10 and 9 Å, respectively [80].

D. Inhibition

I. Inhibition by the Substrate and Reversible Inhibitors

When the rate of hydrolysis of acetylcholine by acetylcholinesterase is plotted against the substrate concentration, the resulting bell-shaped curve shows a strong decrease in the enzymatic activity at substrate concentrations exceeding $2.5\text{-}3 \times 10^{-3}$ M (examples are given in [2b, 54]), except with certain substrates, such as glyceryl triacetate, which lack such inhibiting action even at higher concentrations. This action of the substrate is characteristic for hydrolysis by AChE, and may be used to differentiate between the latter and other hydrolases. The above inhibition was earlier ascribed to the formation of an inactive (or weakly active [58]) ES_2 complex whose anionic and esteratic sites are occupied by two molecules of acetylcholine, so that the steric configuration impedes the activation of the ester bond [20a, 67]. However, the experimental data are not explained in a satisfactory manner by the kinetic equations based on this assumption (*e.g.* [58, 120, 121]; cf. also [54]). More feasible is the theory [119] according to which the intermediate acetylated enzyme EAc in which the anionic site is unoccupied (as in the free enzyme), combines with excess substrate to form a much less active complex EAcS. This is supported by kinetic equations proposed by *Krupka* and *Laidler* [119].

Reversible inhibitors are those which form enzyme-inhibitor complexes that can dissociate, *i.e.* inhibitors which can therefore be separated from the enzyme *e.g.* by dialysis. In the broadest sense, this group of inhibitors comprises all substances that show a more or less strong affinity for the active center of the enzyme, comprising therefore also substances such as substrates, reactivators, and cleavage products. Essentially, these substances are substituted derivatives of the ammonium ion, which, because of their structure, become attached mainly to the anionic site, similarly to

"proper" substrates, and can thus block the formation of the ES complex and the deacetylation of EAc [124]. *Long* has listed all the compounds whose reversible inhibitory action has been investigated [122]. The substrate cleavage and the inhibition by the substrate S and reversible inhibitors I are best described by the following scheme, proposed by *Krupka* and *Laidler* [17, 119] (Fig. 4).

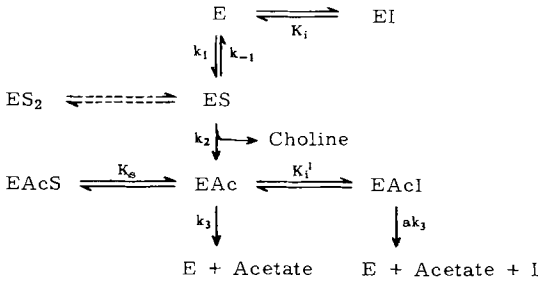

Fig. 4. Scheme for the cleaving off of the substrate and the inhibition by excess substrate [17,119].

According to the steady-state theory, the rate of the cleaving off of the substrate in the presence of inhibitors and an excess of substrate is given by the general equation:

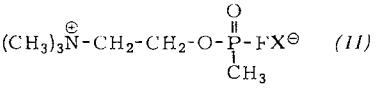
$$v = \frac{k_2[E]_0\overline{K}[S]}{1 + K_i[I] + \overline{K}[S]\left\{1 + \frac{k_2}{k_3}\left(\frac{1 + \overline{K}'_i[I] + K_s[S]}{1 + a\overline{K}'_i[I]}\right)\right\}}$$

where $[E]_0$ is the total enzyme concentration and

$$\overline{K} = \frac{k_1}{k_{-1} + k_2}$$

The equation for inhibition by the substrate alone can be derived from this by putting [I] = O. For very small [S], the equation is simplified to the usual form:

$$v = \frac{V_{max}\,[S]}{K_m + [S]},$$



In the case of acetylcholinesterase, v_{max} and K_m can be expressed in the following way [17, 119, 123]; (cf. also [124, 125]):

$$V_{max} = \frac{k_2[E]_0}{1 + \frac{k_2}{k_3}} \text{ and } K_m = \frac{k_{-1} + k_2}{k_1\left(1 + \frac{k_2}{k_3}\right)}$$

II. Inhibition by Irreversible Inhibitors (Alkyl Phosphates) [2b,12a,12b,12d,13,126,194]

Unlike the inhibition by substrates and reversible inhibitors discussed above, the irreversible inhibition of acetylcholinesterase by the alkyl phosphates *(2)–(10)* listed in Section A is based on a phosphorylation that basically corresponds to acetylation of the enzyme in the normal enzymatic reaction. However, unlike the acetylated enzyme, the phosphorylated enzyme is hydrolysed by water very slowly, if at all [127], and only stronger nucleophilic reagents can remove the phosphoric acid residue from the enzyme and thus reactivate it [127].

Normal alkyl phosphate hydrolysis may serve as a model reaction for the phosphorylation of the enzyme. In place of the OH^- ion in the S_N2 reaction [128], we have in the enzyme a center with a relatively high electron density. This analogy is further manifested in the similarity between the activation energies: phosphorylation of the enzyme (paraoxon *(3)* [diethyl-*p*-nitrophenyl phosphate] + AChE) E = 10.6 kcal/mole [129]; hydrolysis of the alkyl phosphate (paraoxon + OH^-) E = 12.4 kcal/mole [130]. However, the alkyl phosphate reacts much faster (by several powers of ten) with the enzyme than with the OH^- ion [129, 131, 130b], and one can therefore assume that it is fixed on active sites of the enzyme in a way that favors the subsequent reaction [132]. The affinity of the inhibitor for the enzyme (and thus the inhibitory action) is increased – as with the other substrates – by the introduction of a cationic group in the alkyl phosphate, bearing in mind the distance from the anionic and the esteratic site (two CH_2 groups) (*Tammelin*'s esters, *e.g.* choline methylphosphonofluoridate *(11)* [133]):

(11)

Furthermore, the facts that the inhibition depends on pH in the same way as the acetylcholine cleavage [68], and that acetylcholine itself can compete with the inhibitor [134] justify the concept that alkyl phosphates can be regarded as particularly poor substrates, and indicate that the reaction of *e.g.* diisopropyl fluorophosphate with the esteratic site can be described analogously to ordinary substrate cleavage [15c].

The phosphorylated enzyme is converted into an unreactive form in a relatively slow secondary reaction (aging), which hampers the investigation *in vitro* and especially *in vivo* [135 to 138]. This aging is probably due to the cleaving off of an alkyl

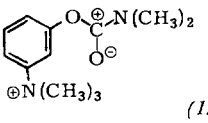
group from the dialkylphosphorylated enzyme, the remaining monoalkylphosphorylated enzyme anion being no longer susceptible to attack by the anion of a reactivator [139]. Isopropanol formed from the eliminated alkyl group was in fact detected [140] in a medium in which acetylcholinesterase had been inhibited by sarin *(9)* and then allowed to age (cf. [141]).

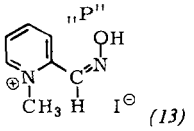
Literature data on the inhibitory action refer to the molar concentration of the inhibitor that gives a 50% inhibition of AChE, or to the negative logarithm pI_{50} of this concentration [142]. The pI_{50} values generally lie between 6 and 9 [143]. Less often, ordinary rate constants are given.

It is difficult to correlate the chemical structure with the inhibitory action, since the latter involves many factors. On the other hand, a good correlation has been found between the inhibition and Hammett's σ-constants for 17 aromatic dialkyl phosphates [144].



E. Reactivation [2b,12b,12d,13,145,194]

I. Development of Reactivators



The reactivation of acetylcholinesterase by displacing the phosphate residue with nucleophilic reagents is not merely of theoretical interest, but is also the basis of an effective therapy of alkyl phosphate poisoning, which is difficult to combat with atropine alone (atropine is the pharmacodynamic antagonist of acetyl choline [146]).

The acetylated enzyme can transfer its acetyl group to hydroxylamine to form acetylhydroxamic acid [147], and it was therefore logical to assume that the phosphorylated enzyme would react analogously. Thus, *Wilson* [127] found that treatment with 0.7 M hydroxylamine solution led to a 50% reactivation of acetylcholinesterase inhibited with TEPP *(6)*, and numerous nucleophilic reagents were subsequently tested as potential reactivators [148]. However, the relatively high concentration at which hydroxylamine and reactivators without a positive charge are active does not permit their therapeutic use.

Notwithstanding its weak nucleophilic character, choline is quite a good reactivator [148]. This fact indicates that, like a substrate or an inhibitor, a reactivator must contain a cationic center in order to become attached to the anionic site of the enzyme [149]. The idea of combining with a cationic center the nucleophilic group for the displacement of the phosphate group made *Wilson* use the reversible inhibitor neostigmine *(12)* as a model reactivator. The carbamate carbon in neostigmine corresponds to the position of phosphorus ("P") in the active center of the phosphorylated enzyme, whose steric features are best satisfied by 2-(hydroxyiminomethyl)-1-methylpyridinium iodide (2-PAM), *(13)* [150] (cf. [151, 152]).

(12)

(13)

2-PAM has since been established in combination with atropine as a clinical antidote for alkyl phosphate poisoning [153, 154]. However, the large 2-PAM cation does not penetrate the blood-cerebral barrier, and cannot therefore react with inhibited AChE in the central nervous system [155].

According to *Wilson*'s hypothesis concerning the position of phosphorus in the phosphorylated enzyme, the *anti*-form of 4-(hydroxyiminoethyl)-1-methylpyridinium iodide (4-PAM) should be more active than the *syn*-form [152]. However, *Poziomek* [156] has found the opposite to be the case, and *Wilson*'s suggestions are therefore best viewed merely as working hypotheses.

The idea of tailor-made reactivators has been found very fruitful [157] and led to a new group of reactivators consisting of two hydroxyiminomethylpyridinium groups linked together by a chain [158–160] and corresponding therefore to reversible inhibitors with two positive centers. In these, the hydroxyiminomethyl group must be in the 4-position, and not in the 2-position. Thus, 1,1'-trimethylenedi-(4-hydroxyiminomethylpyridinium) dibromide (TMB-4) considerably surpasses the corresponding 2-isomer [160, 161]. However, the relatively high toxicity of TMB-4 restricts its therapeutic application [162, 165]. Oxybis-(4-hydroxyiminomethylpyri-

dinium-1-methyl) dichloride (LüH6, Toxogonin®, *(14)* [163, 164] is less toxic than TMB-4 [165], therapeutically more active than 2-PAM [166–168] and can reactivate inhibited acetylcholinesterase in the central nervous system as well [169, 168b]. The reactivity of Toxogonin®, which surpasses that of TMB-4 [170], indicates that the chain connecting the two substituted pyridinium residues plays an important part in the reactivation [171]. Systematic variation of this chain has led to an antidote equalling Toxogonin® in its activity: 2,3-dihydroxybutylene[1,1'-bis-(4-hydroxyiminomethylpyridinium)] dibromide, R-21 *(15)* [172].

II. Mechanism of the Action of Reactivators

The ability of a reactivator to reactivate AChE inhibited by an alkyl phosphate depends on factors that influence the formation of a reaction complex between the reactivator and the inhibited enzyme, and the elimination of the phosphoryl group from the enzyme.

1. The Reaction Complex

The first step of reactivation resembles the enzymatic hydrolysis of acetylcholine insofar as it involves the formation of a reaction complex EIR (EI is the inhibited enzyme and R is the reactivator), which then decomposes into free enzyme E and the phosphorylated reactivator RI [149, 137, cf. 173b]:

$$EI + R \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} EIR \xrightarrow{k_2} E + RI$$

$$\text{where } K_r = \frac{[EI]\cdot[R]}{[EIR]} = \frac{k_{-1}+k_2}{k_1}$$

If we regard the constants K_r of the reactivators in Table 2 as Michaelis constants K_m for various substrates, a comparison shows that K_r is considerably higher for uncharged reactivators, such as hydroxyiminoacetone, than for reactivators having a cationic center (*e.g.* 2-PAM). Thus, 2-PAM itself is a weak reversible inhibitor, and it can compete with cations for the anionic site [175]. A similar effect is exerted by a bulky group extending between the esteratic site and the anionic site (a group such as isopropyl in the case of AChE inhibited by diisopropyl fluorophosphate), which impedes the access of the cationic center of 2-PAM to the anionic site [136, 137, cf. 176]. A further important variable is the rate constant k_2 for the decomposition of the reaction complex EIR into the reactivated enzyme E and the phosphorylated reactivator RI. A method for the determination of k_2 has been given by *Green* and *Smith* [174].

Table 2. Equilibrium constants K_r and decomposition rate constants k_2 of the reaction complex EIR.

Reactivator	Blocking group	K_r (mole/l)	k_2 (min^{-1})
Hydroxyimino-acetone [173]	i-C_3H_7O–P(CH_3)O	1×10^{-2}	2.4×10^{-1}
Hydroxyimino-acetone [173]	$(C_2H_5O)_2PO$	2×10^{-2}	1.6×10^{-1}
2-PAM *(13)* [174]	$(C_2H_5O)_2PO$	1.4×10^{-4}	8.1×10^{-2}
2-PAM *(13)* [174]	$(i\text{-}C_3H_7O)_2PO$	8×10^{-4}	1.5×10^{-2}
3-Pyridincarbo-hydroxamic acid [149]	$(C_2H_5O)_2PO$	3.4×10^{-2}	

Compounds with two hydroxyiminomethylpyridinium groups, and particularly those with a three-membered chain (*e.g.* TMB-4 [177] and Toxogonin® [170]), are even faster reactivators than 2-PAM, possibly because of an additional bond formed with an assumed second anionic site [157], or else because of an enhanced reactivity with the phosphorylated enzyme [178]. It seems probable that the enzyme becomes attached to different groups depending on the configuration of the reactivators [172, 179]. Thus, in the case of 2-pyridinecarbohydroxamic acid, a hydrogen bond is formed with the ring nitrogen [173].

2. Elimination of Phosphoryl Group from the Enzyme

After the complex EIR has been formed, the nucleophilic group of the reactivator reacts with the electrophilic phosphorus atom, and the free enzyme is liberated [180]. The rate of reactivation is therefore determined by the electrophilicity of phosphorus [181]

and the nucleophilicity of the attacking agent [145]. A measure of the latter is the ability of the reactivator to accelerate the hydrolysis of the alkyl phosphate in question [128a, 182–187].

With a substance whose anion delivers a nucleophilic attack, the pK_a value plays an important role. For an efficient therapy, the dissociation should be virtually complete in the physiological medium at pH 7–8. Since a low pH, which favors dissociation, reduces the nucleophilicity of the molecule, the optimum reaction rate is a function of both the pK_a and the pH. In the case of substituted hydroxamic acids, $pK_a = pH + 0.6$ [188], cf. [172].

The attack by a nucleophilic particle can be promoted by the pull exerted by the electrophilic group, and this push-pull mechanism has been accepted for the reactions of alkyl phosphates with copper(II) hydroxide [189], hydrogen peroxide [190–192], and the mono-anion of pyrocatechol [193]. In the case of Toxogonin®, *Lüttringhaus et al.* [164] have isolated the corresponding mono-anion. According to these authors the two pyridinium rings are presumably arranged in a sandwich fashion. The hypothesis of concerted action is further supported by the fact that the mono-anion of pyrocatechol is superior to those of resorcinol and hydroquinone [195], c.f. [178].

3. Rephosphorylation of the Enzyme

Acetylcholinesterase can be rephosphorylated in an undesirable reverse reaction by the phosphorylated reactivator RI formed in the reactivation of the enzyme [196], cf. [197]:

$$RI + E \rightleftharpoons EI + R$$

The most important phosphorylated reactivators fit in with the P–XYZ system of phosphorylating agents [198]. Both the α-hydroxyimino ketones and the hydroxyiminomethylpyridinium salts possess an electron acceptor Z (C=O or ring nitrogen, respectively) required for taking up the electrons from the P–X bond in the phosphorylation. The ring nitrogen is linked to the hydroxyiminomethyl group by a conjugated system Y whose UV-spectrum indicates a negative solvatochromic effect in the case of 2-PAM and 4-PAM, but not with the inactive 3-PAM, where the system is not properly conjugated [199]. Whilst the phosphorylated α-hydroxyimino ketones [200] and hydroxamic acids [201] cannot be intercepted because they decompose rapidly, hydroxyiminomethylpyridinium salts phosphorylated by sarin *(9)* – which show a structural resemblance to the highly toxic *Tammelin*'s esters *(11)* – are sufficiently stable [202] to phosphorylate and thus inhibit acetylcholinesterase [203]. This is the reason why the inhibition of cholinesterases in the plasma by Rogor® [204] might even be further aggravated by large doses of Toxogonin®. One should therefore never administer overdoses of specific antidotes [205].

Mention should be made in this connection of the important investigations concerning the conditions under which the phosphorylated oxime, or a model compound, decomposes irreversibly into non-toxic substances. Thus, with warm acetic anhydride, 2-PAM forms the nitrile [206]. The nitrile is formed similarly in boiling ethanol by 4-PAM esterified with *p*-nitrobenzoyl chloride on the hydroxyiminomethyl group [207], cf. [208]. Furthermore, pyridinium chlorides that – like Toxogonin® – contain an ethereal oxygen atom α to the ring nitrogen, lose their side chain in boiling ethanol, and form pyridine hydrochloride. Solvolysis of the corresponding benzoyloxyiminomethylpyridinium compounds leads to 4-cyanopyridinium chloride or a mixture of this and pyridine-4-aldoxime hydrochloride, depending on the solvent and the temperature [207].

The authors wish to acknowledge the financial assistance they have received from the Fraunhofer-Gesellschaft and the Bundesamt für zivilen Bevölkerungsschutz, Bad Godesberg.

Preparation of Dichlorohexafluoropropane by Fluorination of 1,2-Dichloropropane [1]

By *M. Schmeisser, K. P. Ehlers,* and *P. Sartori* [*]

Dedicated to Prof. F. Asinger on the occasion of his 60th birthday

Hitherto little has been known of the action of elementary fluorine on chlorohydrocarbons [2]. As in electrochemical fluorination, the presence of chlorine atoms in the molecule inhibits the reaction of elementary fluorine in the substitution of hydrogen by fluorine.

We have investigated the suitability of 1,2-dichloropropane *(1)* for the preparation of 1,2-dichlorohexafluoropropane *(2)* b.p. 34.7 °C. The latter compound, which is a possible starting material for the preparation of hexafluoropropane [3], has hitherto only been prepared by complicated procedures [4].

The fluorination of *(1)* was carried out in the vapor phase at a temperature between 100–200 °C in a copper reaction furnace (diameter 80 mm, length 1150 mm) filled with copper wool, which in principle corresponds to the apparatus described by *Bigelow, Calfee,* and *Miller* [5]. Fluorine diluted with nitrogen, and a nitrogen stream loaded with *(1)* in the vapor state were fed together through the reaction furnace and the products of reaction passed over NaF to remove HF, and then finally collected in cold traps. A small excess of fluorine was used. Large amounts of CF_4, C_2F_6, and C_3F_8 were produced as well as chlorine-containing fluorination products.

The chlorine-containing fluorination products could be quantitatively frozen out at −78 °C. They were separated by fractional distillation in a Podbielniak column or by preparative gas chromatography, and identified by chemical analysis and IR spectroscopy. Isomers containing equal numbers of chlorine atoms could not be separated. The proportions of *(2)* and 1,3-dichloroperfluoropropane in the reaction mixture were determined by treatment of the mixture with zinc in ethanol, hexafluoropropene being formed from *(2)* and chlorohexafluoropropane from 1,3-dichloroperfluoropropane. As the table shows, the yield of *(2)* is dependent on temperature and is a minimum at 150–175 °C.

Therefore, *(2)* can be isolated in one step from relatively simple starting materials and in yields comparable with those obtained by the usual methods [4].

Free chlorine could not be detected in the reaction mixture. However, extensive isomerization and the formation of chlorine-free, as well as chlorine-containing, products suggest intermediary chlorine fission. Under the reaction conditions chlorine can react rapidly with fluorine to form ClF, which then reacts with CH compounds to bring about chlorine substitution and HF formation.

The analogous fluorination of propane and of butane leads to the formation of the corresponding perfluorination products C_3F_8 and C_4F_{10}, respectively, in yields of 75 to 80% [6].

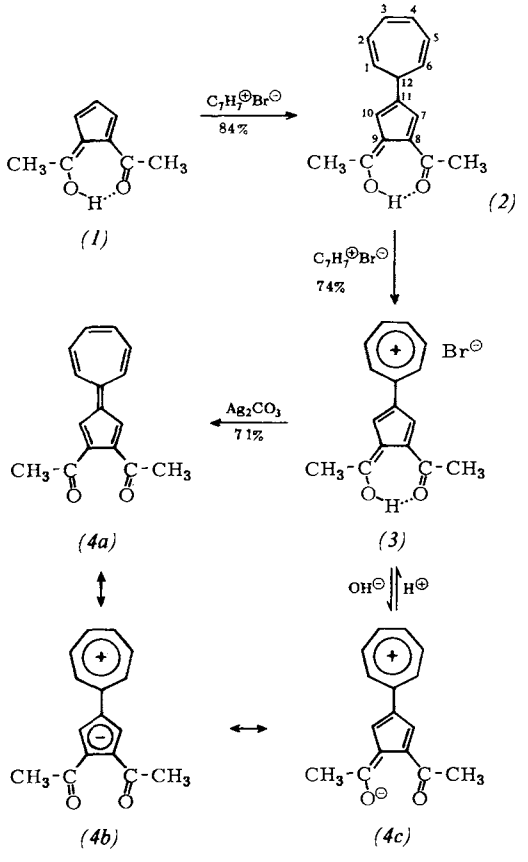
8,9-Diacetylsesquifulvalene



By *E. Koerner von Gustorf, M. C. Henry,* and *P. V. Kennedy* [*]

Dedicated to Professor G. Wittig on his 70th Birthday

8,9-Disubstituted sesquifulvalenes have not hitherto been prepared. We have found that 8,9-diacetylsesquifulvalene is accessible in good yield by the reaction sequence *(1)* → *(4)*.

When tropylium bromide in CH_3OH is added dropwise to 1,5-diacetylcyclopentadiene [1] (whose existence in the tautomeric fulvene form *(1)* is confirmed by ^1H-NMR studies [2]), the product *(2)* is precipitated as yellow needles (m.p. 135.5 – 136.5 °C). Small amounts of admixed *(3)* can be readily removed since *(3)* is insoluble in ether. Compound *(3)* is formed by hydride transfer on addition of *(2)* in ether to tropylium bromide in CH_3OH and separates as carmine-red platelets (decomp. 230 °C). Shaking *(3)* with an excess of Ag_2CO_3 in CH_3OH affords analytically pure, dark red 8,9-diacetylsesquifulvalene *(4)* [m.p. 127–128 °C (decomp.)], which is stable in air.

The increased or decreased shielding of the protons of the five- and seven-membered rings shown by the NMR data indicates participation of dipolar resonance structures such as *(4b)* and *(4c)* in the ground state of *(4)*. Protonation of *(4)* occurs mainly on the carbonyl-oxygen; the ^1H-NMR spectra of *(3)* and *(4)* are thus identical in CF_3COOH.

^{1}H—NMR data (δ values; tetramethylsilane as internal standard) [6].

	(2) in CCl_4	(4) in $CDCl_3$	(3), (4) in CF_3COOH
2 CH_3	2.51 (s) [a]	2.40 (s)	2.80 (s)
—OH···O=C	17.8 (s)	—	below CF_3COOH
H(7), H(10)	7.18 (s)	6.92 (s)	8.25 (s)
H(1), H(6)	5.3 (m)	6.7 (m)	8.5 (m)
H(2), H(5)	6.2 (m)		
H(3), H(4)	6.65 (m)	7.4 (m)	9.0 (m)
H(12)	2.6 (m)	—	—

[a] s = singlet, m = multiplet.

The shapes and chemical shifts of the signals for the protons in the seven-membered ring of *(3)* correspond to those of 7,8,9,10-tetraphenylsesquifulvalene in CF_3COOH [3]. Compounds *(3)* and *(4)* are water-soluble (after wetting with CH_3OH). The basicity of water suffices to convert *(3)* into *(4)*. Protonation of *(4)* (λ_{max} = 498 mμ; log ε = 4.596) [4] to *(3)* (λ_{max} = 467 mμ; log ε = 4.568) [4] (*e.g.* with HCl) in an aqueous system is accompanied by a color change from reddish-orange to yellow. Since alternate deprotonation (*e.g.*, by dilute NH_3) and protonation can be repeated indefinitely, this system can be used as a pH indicator. Concentrated NaOH solution decolorizes *(4)*, probably by attack of the double bond between C-11 and C-12; this process is also reversible.

1,5-Dibenzoylcyclopentadiene reacts with tropylium bromide [5] in the same way as *(1)*.

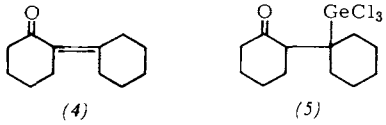
Reactions of Trichlorogermane with Ketones and Alcohols

By *O. M. Nefedov, S. P. Kolesnikov*, and *B. L. Perlmutter* [*]

Dedicated to Professor G. Wittig on his 70th Birthday



Under the influence of $HGeCl_3$, ketones of type *(1)* condense to give β-unsaturated ketones *(2)*, which readily add trichlorogermane with formation of trichlorogermyl ketones *(3)*.

R = Alkyl or Aryl; R^1 = H, Alkyl, or Aryl.

For instance, heating 0.22 mole of $C_6H_5COCH_3$ with 0.1 mole of $HGeCl_3$ (160 °C, 30 min) gives a 96 % yield of 1,3-diphenyl-3-(trichlorogermyl)-1-butanone *(3)*, R = C_6H_5, R^1 = H; m.p. 172–174 °C (from C_6H_6), IR spectrum $\nu_{C=O}$ = 1670 cm^{-1}, NMR spectrum δ = 1.45 (singlet, CH_3 group), 3.05 (quartet, CH_2 group), and 7.3 to 8.5 (C_6H_5 groups) in the ratio 3:2:10.

Similarly, 0.51 mole of cyclohexanone and 0.085 mole of $HGeCl_3$ afford a 97 % yield of 2-(1′-trichlorogermylcyclohexyl)cyclohexanone *(5)*, m.p. 174–176 °C (from C_6H_6), IR spectrum $\nu_{C=O}$ = 1710 cm^{-1}, together with 2-cyclohexylidenecyclohexanone *(4)* (4.5 g).

The trichlorogermyl ketone *(5)* is also formed on treatment of $HGeCl_3$ with 1-methoxycyclohexene (yield 35 %), with *(4)* (yield 85 %), or with 2-(1′-chlorocyclohexyl)cyclohexanone (yield 65 %), or by treatment of the last-mentioned ketone with the dioxane-germanium dichloride complex $C_4H_8O_2 \cdot GeCl_2$ (yield 60 %).

Reaction of 0.22 mole of cycloheptanone with 0.1 mole of $HGeCl_3$ gives a 98 % yield of 2-(1′-trichlorogermylcycloheptyl)cycloheptanone, m.p. 112–115 °C (from C_6H_6), IR spectrum $\nu_{C=O}$ = 1680 cm^{-1}.

Ketones that cannot condense in this way react differently with $HGeCl_3$. For example, use of $(C_6H_5)_2CO$ leads to $(C_6H_5)_2CHGeCl_3$ *(6)* [1] [yield 14 %, m.p. 78–79 °C (from CCl_4 and C_6H_6), b.p. 147–152 °C/0.5 mm] and polymeric products. NMR spectrum of *(6)*: δ = 4.6 (singlet, CH group) and 7.2 ppm (singlet, C_6H_5 groups) in the ratio 1:10. Forma-

tion of *(6)* is explained by the strong reducing action of $HGeCl_3$ [2]. The alcohol *(7)* is probably formed first and then condenses to give the ether *(8)*. Under the influence of $HGeCl_3$ ethers can decompose to alkyl- or arylalkyl-trichlorogermanes and alcohols [3]. In fact, the reaction of the alcohol *(7)* with $HGeCl_3$ also gives the compound *(6)* (yield 89%).

$$2\ (C_6H_5)_2CO \xrightarrow{(HGeCl_3)} 2\ (C_6H_5)_2CHOH \xrightarrow[-H_2O]{(HGeCl_3)}$$
(7)

$$(C_6H_5)_2CH\text{-}O\text{-}CH(C_6H_5)_2 \xrightarrow{HGeCl_3} (C_6H_5)_2CHGeCl_3 + (7)$$
(8) *(6)*

Other alcohols react similarly with trichlorogermane. Thus t-C_4H_9OH gives t-$C_4H_9GeCl_3$ (70 % yield), s-C_4H_9OH gives s-$C_4H_9GeCl_3$ (42 % yield), n-C_4H_9OH gives n-$C_4H_9GeCl_3$ (46.5 % yield), and CH_3OH gives CH_3GeCl_3 (47 % yield).

Preparation of Fluorocyclopropanes by Reductive Dechlorination of Chlorofluorocyclopropanes

By *M. Schlosser* and *G. Heinz* [*]

Dedicated to Professor G. Wittig on his 70th birthday

Recently, Japanese authors [1] reported the first preparation of fluoronorcarane from chlorofluoronorcarane and tri-n-butyltin hydride. We have found that chlorofluorocyclopropanes may be advantageously reduced by alkali metals in protonic solvents (see Table).

Chlorofluorocyclopropanes are formed when dichlorodifluoromethane is treated with a base in the presence of an olefin. In order to obtain the products in a higher state of purity we used organolithium compounds (methyl-lithium, n-butyl-lithium) as base instead of potassium t-butoxide [2].

The chlorofluorocyclopropanes were distilled in a spinning band column and then taken up in tetrahydrofuran. The resulting solution was added dropwise to a solution of a stoichiometric amount of sodium in liquid ammonia; the latter turned colorless immediately. The ammonia was removed by evaporation and the reaction product isolated by distillation or by preparative gas chromatography. Evidence of the structure of the product was provided by elemental analysis and by IR, NMR, and mass spectrometry.

Metallic lithium in t-butanol/tetrahydrofuran (1:3) [3], or sodium in methanol, will also reduce chlorofluorocyclopropanes. However, with these systems the metals must be present in excess and halogen-free cyclopropanes are formed as by-products (see Table).

The fluorine, and not the chlorine, is first partly replaced by hydrogen in what is clearly a radical side-reaction.

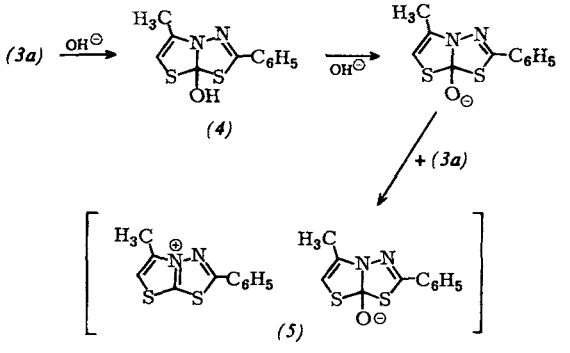
7-Methyl-4-phenyl-8*H*-1,3,5,6-dithiadiazocin-2-one, an Eight-Membered Heterocycle with Chiral Conformation

By *G. Ege* [*]

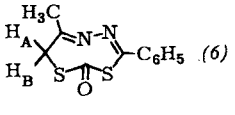
Dedicated to Prof. G. Wittig on the occasion of his 70th birthday



The compounds described as dihydrothiadiazinethiones *(1)* [1] have in reality the structure *(2)* [2]. These 3-benzoylaminothiazole-2-thiones *(2)* cyclize in concentrated sulfuric acid [3] at 20 °C to form the water-soluble thiazolo[2,3-*b*]-1,3,4-thiadiazolium salts *(3)*, $X^{\ominus} = HSO_4^{\ominus}$, from which the difficultly soluble perchlorates and iodides can be obtained.

(1)

(2) *(3)*



On treatment with 2N NaOH the compound *(3a)* adds hydroxide anion at the immonium double bond. The resulting hydroxy compound is, however, immediately deprotonated and reacts with the cation of *(3a)* to form the difficultly soluble salt *(5)* (m.p. 167 °C, yield 80 %).

	R^1	R^2	R^3	(3), $X^\ominus = HSO_4^\ominus$ M.p. (°C)	Yield (%)	(3), $X^\ominus = ClO_4^\ominus$ M.p. (°C)	(3), $X^\ominus = I^\ominus$ M.p. (°C)
(a)	H	CH_3	H	243	70	241	300 (decomp.)
(b)	H	C_6H_5	H	242	86		
(c)	H	CH_3	NO_2	270 (decomp.)	82		300
(d)	CH_3	CH_3	H	245	30	180	
(e)	CH_3	CH_3	NO_2	230 (decomp.)	70		

The fact that *(5)* is actually present as a salt and not as an ether follows from the NMR spectrum. The spectrum shows that the methyl group protons and olefinic protons from the cation and anion are not equivalent (two doublets at $\tau = 7.3$ and $\tau = 8.1$ for each of the three protons, a quartet at $\tau = 4.2$ for one proton, and one multiplet for eleven protons between $\tau = 1.9$ and 2.9).

When *(5)* is boiled in aqueous methanolic hydrochloric acid, the compound 7-methyl-4-phenyl-8*H*-1,3,5,6-dithiadiazocin-2-one *(6)* [colorless crystals, m.p. 120 °C, yield 90% with respect to the anion of *(5)*] is formed by transannular ring opening of the anion. The cation of *(5)* can be precipitated unchanged as the perchlorate.

The structure of *(6)* follows from the IR spectrum: a CO band at 1695 cm^{-1} and absence of absorption in the NH region.

One would expect the methylene protons, H_A and H_B, in *(6)* to be equivalent if they were to rapidly oscillate about the plane of the ring. The NMR spectrum of *(6)*, at *ca.* 20 °C, shows (see Fig. 1), however, an AB system ($\tau_A = 5.9$ and $\tau_B = 6.5$, with $J_{AB} = 11$ Hz) for the two methylene protons. The AB system is also conserved on heating the compound *(6)* to 150 °C.

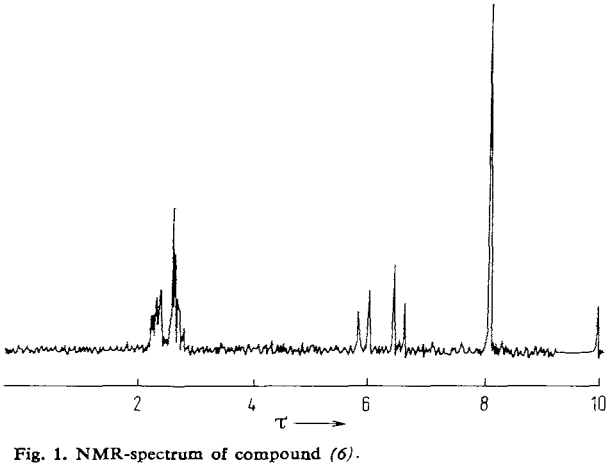


Fig. 1. NMR-spectrum of compound *(6)*.

A fixed, non-planar, and therefore chiral, conformation of the eight-membered heterocycle can thus be assumed, at least for temperatures up 150 °C. The compound *(6)* should therefore be resolvable into optical antipodes – experimental work with this aim in view is in progress.

ortho-Semidine Rearrangement of 1,2-Diphenyl-1,2-diazetidinone [1]

By *W. Fischer* and *E. Fahr* [*]

According to work by *Wittig et al.* [2], 1,2-diazacycloalkanes of type *(1)* undergo the *ortho*-semidine rearrangement only when *n* is at least 4. We have, however, found that the rearrangement occurs also with 1,2-diazetidinones of type *(2)*.

If the 1,2-diazetidinone *(2a)* (3 mmoles) is boiled under reflux (2 h) in methanolic solution (300 ml) with sulfuric acid (3 ml) [3], a mixture is obtained from which compound *(3a)* (m.p. 192 °C, 34% yield) separates, having been formed by an *ortho*-semidine rearrangement [4]. The structure of *(3a)* was proved by synthesis (86% yield) from *o*-aminodiphenylamine hydrochloride and phenylglyoxylic acid (equimolar amounts in a little water at room temperature). Use of preparative thin-layer chromatography (silica gel, $CHCl_3$) led to isolation, from the rearrangement mixture, of the hydrazide *(5a)* [m.p. 145 °C; yield 23%; IR (KBr), 3280 (NH), 1660 (conj. C=O) cm^{-1}; NMR ($CDCl_3$), aromatic CH and NH signals between $\tau = 2.43$ and $\tau = 3.37$, $\tau = 4.82$ (t-CH), $\tau = 6.67$ (OCH_3)], which is formed from *(4)* by rupture of the C–N bond.

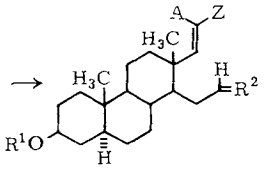
A New Fragmentation Reaction of 20-Chloro-16β-hydroxy Steroids



By *G. Adam*[*]

When heated with 5 % methanolic potassium hydroxide (3 h; 80 °C), 20-chloropregnan-16β-ols[1] fragment with loss of HCl and opening of ring D to form 17(20)-unsaturated 16,17-seco-16-aldehydes in 80–90 % yield. The reaction is stereospecific, its course being determined by the configuration at C-20. In this way (20*R*)-20-chloro-5α-pregnane-3β,16β-diol *(1)* affords *trans*-3β-hydroxy-16,17-seco-5α-pregn-17(20)-ene-16-aldehyde *(4)* (m.p. 121–122 °C; $[\alpha]_D^{20} = -22.3°$ ($CHCl_3$)), and the (20*S*)-stereoisomer *(2)* affords the *cis*-aldehyde *(8)* (double m.p. 82–85 and 113–116 °C; $[\alpha]_D^{18} = -9.2°$).

(1): (20*R*)
(2): (20*S*)

(3), A = H; Z = CH_3
(7), A = CH_3; Z = H

A = H, Z = CH_3:
(4), R^1 = H, R^2 = O
(5), R^1 = Ac, R^2 = O
(6), R^1 = H, R^2 = NOH

A = CH_3, Z = H:
(8), R^1 = H, R^2 = O
(9), R^1 = Ac, R^2 = O
(10), R^1 = H, R^2 = NOH

The structure of the steroid aldehydes *(4)* and *(8)* was proved as follows: In the mass spectra (negative ionization)[2] main peaks occur at *m/e* = 317 = M – 1, corresponding to a molecular formula $C_{21}H_{34}O_2$. The 100 MHz NMR spectra[2] for the *trans*- and *cis*-isomers, respectively, contain quadruplets at δ = 9.5 and 9.6 ppm (aldehyde-proton), multiplets at 5.25 and 5.15 ppm (vinyl-proton), 3.55 ppm (H on C-3), doublets centered at 1.62 and 1.71 ppm (21-methyl), and two singlets each at 0.78 and 0.87, and 0.77 and 1.08 ppm (19- and 18-methyl). The IR spectrum of *(4)* shows bands at 975 (*trans*-CH=CH–), 1678 (C=C), 1731, 2710, 2815 (aldehyde), 3025 (–CH=CH–), and 3629 cm^{-1} (OH). In the IR spectrum of *(7)* the absorption at 975 cm^{-1} is replaced by a band at 700 cm^{-1} (*cis*-CH=CH–). The two seco-steroids were also characterized as their *O*-acetyl derivatives *(5)* and *(9)* with, respectively, m.p. 84–86 °C, $[\alpha]_D^{19} = -34.2°$, and double m.p. 85–90 ° and 98–100 °C, $[\alpha]_D^{19} = -19.1°$, and as the oximes *(6)* and *(10)* with, respectively, m.p. 196–198 °C, $[\alpha]_D^{20} = -31.0°$, and m.p. 194–198 °C, $[\alpha]_D^{19} = -17.6°$.

The fragmentations observed can be regarded as special cases of olefin-forming Grob fragmentation[3]. When regard is paid to the *trans*-elimination principle and the known configurations of *(1)* and *(2)* at C-20 a synchronous reaction mechanism such as *(3)* and *(7)* can be formulated, whereby the stereospecific formation of the *trans*-aldehyde *(4)* from *(1)* and of the *cis*-aldehyde *(8)* from *(2)* is explained.

A Continuous Process for the Preparation of Diphenylketene

By *W. Ried* and *P. Junker*[*]

Up to the present, diphenylketene has been prepared either by heating a benzene solution of azibenzil to 70 °C[1] or by allowing this solution to drip, in a N_2 stream, into a flask heated to 105–110 °C[2].

R = C_6H_5, CH_3

Both methods suffer from the disadvantage that the diphenylketene already formed must be heated until all the azibenzil has decomposed and rearranged. With large batches (>0.5 mole) this leads to considerable losses since diphenylketene readily polymerizes when heated and, further, can also react with both azibenzil and the intermediate carbene. Good yields of diphenylketene are obtained, however, by use of the apparatus shown in Figure 1, by means of which the ketene formed is at once removed from the hot reaction zone.

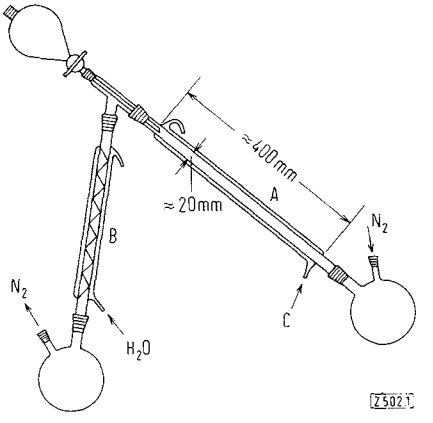

Fig. 1. Apparatus for continuous preparation of diphenylketene.

A heating fluid (*e.g.* paraffin oil), heated to 130 °C, is passed through the jacket C of the inclined condenser A, and a slow stream of N_2 is passed through the apparatus from the lower end of the heated tube. As soon as the air is removed, a benzene solution of azibenzil is added slowly from the dropping funnel. The solvent evaporates at once, while the azibenzil decomposes and rearranges; the benzene vapors are condensed in the condenser B. The rate of drip of the solution is determined so that evolution of nitrogen terminates about 5 cm above the lower end of the heated zone. The diphenylketene formed is washed out of the heated tube into the cold receiver by the reaction solution. After vacuum distillation the yield amounts to about 80 %.

The apparatus can be used also for the preparation of dimethylketene from azibutanone[3] if the reaction tube is heated at 170–180 °C. Since dimethylketene boils at 34 °C a high-boiling solvent such as tetralin or 1-methylnaphthalene must be used. This flows through the hot reaction tube while the ketene distils off and is condensed in a cold trap mounted in place of the condenser B or is used directly for further work in the gas phase. The yields of dimethylketene obtained in this way have not yet been as high as those obtained by decomposition of dimethylketene dimethylmalonyl acylal[4].

Diphenylketene:

Benzil monohydrazone (224 g, 1 mole) is mixed with yellow mercuric oxide (320 g) and anhydrous sodium sulfate (100 g) in anhydrous benzene (800 ml), methanolic KOH (1 to 2 ml) is added, and the whole is stirred for one hour with ice-cooling and then filtered. The filtrate is allowed to drip into the apparatus described (temp. of heating fluid: 130–135 °C) and the crude product that collects in the receiver is finally distilled as quickly as possible. Yield 149 g (77 %); yellow liquid, b.p. 109 °C/1 mm ([2]: 125 °C/4 mm).

Pentahendecafulvalene

By *H. Prinzbach* and *L. Knothe*[*]

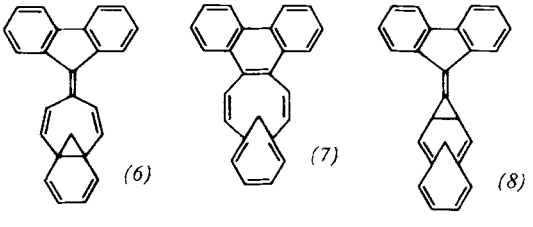
Pentahendecafulvalene *(3)* is the next higher homologue in the series calicene *(1)*[1] – sesquifulvalene *(2)*[2].

We have accomplished the first synthesis of a derivative of *(3)*, namely, 11,12;13,14-dibenzo-3,8-methanopentahendecafulvalene *(4)* in which the eleven-membered ring is bridged and the five-membered ring doubly annelated, as well as two isomers thereof to which we provisionally assign structures *(5)* and *(11)*.

When 8 mmoles of fluorenyl-lithium are treated in ether/tetrahydrofuran (1:1 v/v) at −30 °C with 6.9 mmoles of bicyclo[5.4.1]dodecapentaenylium fluoroborate[3] and the resulting mixture of hydrocarbons is oxidized with 8.1 mmoles of chloranil in carbon tetrachloride, a mixture is isolated consisting of a yellow component *(4)* and two red conponents *(5)* and *(11)*[4]. A satisfactory chromatographic separation of these components has not yet been achieved. The yellow

component can be separated from the two red ones by utilizing their differing basicities. Compounds *(5)* and *(11)* give insoluble salts with HBF_4 in ether/cyclohexane (1:10 v/v), whereas *(4)* remains in solution. *(4)* precipitates from benzene as yellow crystals, m.p. 223.5–224.5 °C, in 14 % yield. Treating the salt mixture with triethylamine in $CHCl_3$, or with $NaHCO_3$ in H_2O, regenerates *(5)* and *(11)* as dark red needles having a green sheen, m.p. 179–182 °C [from benzene/petroleum ether, 1:9 v/v; yield 16 %, content of *(5)* > 95 %]. The relative yields of the isomers can to some extent be controlled by varying the reaction temperature.

The structure of *(4)* follows from the NMR[5] and the mass spectrum[6] as well as from the result of ozonolysis which affords fluorenone in good yield.



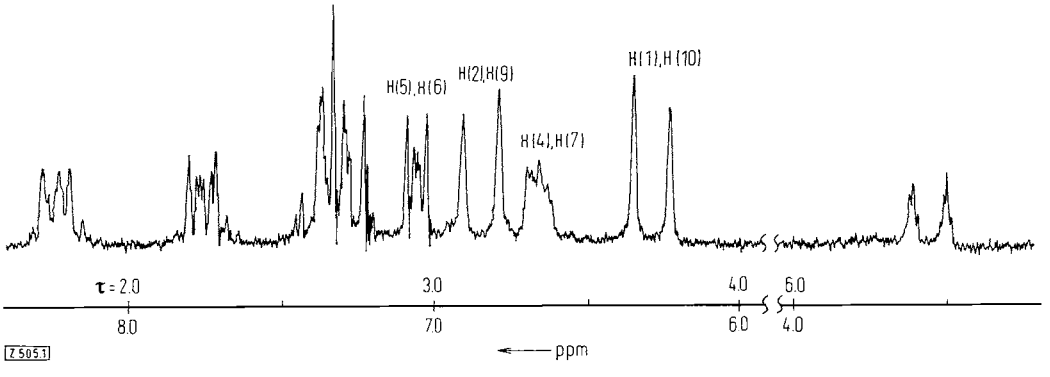
The following conclusions can be drawn from the NMR spectrum:

a) The molecule has a plane of symmetry (10 types of proton in the ratio 2:2:2:2:2:2:2:2:1:1).

b) The molecule does not exist in the norcaradiene form *(6)* (J_{gem} of the CH_2 bridge = 11.0 Hz)[7].

c) Conversion into *(7)* has not occurred; the positions of the signals of the eight "aromatic" protons is typical of the fluorene skeleton, but much too "high" for a phenanthrene ring[1] (cf. the ozonolysis).

d) The steric hindrance between protons H(1)–H(10) and H(3′)–H(6′) to be expected for the completely conjugated perimeter of *(4)* does not cause conversion into the unhindered structure *(8)*.



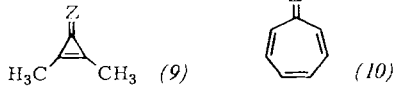


Fig. 1. NMR spectrum of *(4)* in $CDCl_3$. Tetramethylsilane as internal standard. 100 MHz, 27 °C. A further doublet with J = 11.0 Hz lies at τ = 9.80.

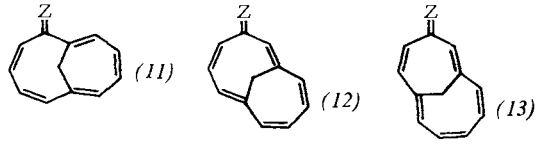
The mass spectrum of *(4)* includes the following strong signals: M^+ = 318 (100 %), 319 (45 %), 317 (35 %), 315 (15 %), 313 (12 %), 303 (26 %), 302 (40 %), 289 (25 %), 276 (11 %), 189 (36 %), 165 (21 %), 153 (16 %), 129 (14 %), 128 (12 %). The fact that the molecular ion gives the strongest signal indicates a stable, fully conjugated molecule. The low intensity of the fragment with *m/e* = 165 indicates further that the fluorenyl group is attached by a double bond.

IR (KI): $\tilde{\nu}$ = 1621 cm^{-1}, 1600, 1575, 1541, 1475, 1447, 1351, 1348.

UV: λ_{max} (cyclohexane) = 399 nm (ε = 20200), 342 (26800), 304 (16400, s), 294 (15840, s), 263 (40500, s), 260 (41800, s), 255 (42200), 239.6 (61500).



The basicity of *(4)* is surprisingly low; it is not protonated by 70 % $HClO_4$, CF_3CO_2H, or HBF_4 in ether. In the same media dibenzocalicene *(9)* [1], dibenzosesquifulvalene *(10)* [2], as well as the unsymmetrical isomers *(5)* and *(11)*, exist almost wholly as the conjugate acids.

(9) *(10)*

Z = 9-Fluorenylidene

(5) and *(11)* to *(13)* represent possible structures for the red pentahendecafulvalenes isomeric with *(4)*. Because of the

(11) *(12)* *(13)*

Z = 9-Fluorenylidene

considerable differences in chemical shift of the signals for H(6') and H(3'') and the low position of one of these signals, we consider structures *(5)* and *(11)* as the most probable. Quantum-mechanical results [8] favor structure *(5)* for the major red component.

The pentahendecafulvalenes *(4)*, *(5)*, and *(11)* are thermally very stable; they can be sublimed unchanged at 150–160 °C/0.001 mm). N–V' excitation of *(4)* causes a red shift of 26 nm compared with the system of *(10)* that is smaller by two C=C double bonds [λ_{max} (cyclohexane) = 373 nm, ε = 24000]; this and the relatively weak solvatochromic effect are of the expected order of magnitude. The basicities of *(5)* and *(11)*, which are greater than that of *(4)*, and the N–V' transitions [*(5)*, 488 nm, ε = 23000] which are at much longer wavelengths indicate a lower stability of the unsymmetrical isomers. According to our results so far, compound *(4)*, like *(10)*, but unlike *(9)*, does not react with dimethyl acetylenedicarboxylate.

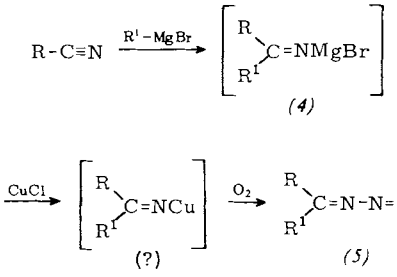
"Dimerization" of Organic Nitrogen Compounds *via* Copper-Containing Intermediates [1]

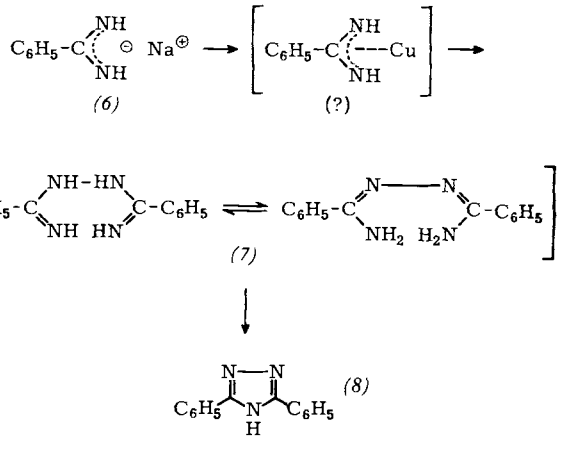
By *Th. Kauffmann, J. Albrecht, D. Berger*, and *J. Legler* [*]



Acetylenes can be dimerized by oxidizing their copper(I) compounds with oxygen in the presence of NH_3 or amines (Glaser reaction) [2]. We have found that cyclic secondary amines, and also imines and amidines, can be dimerized analogously.

Dimerization of Amines: The secondary amines were converted by phenyl-lithium into the lithium amides, which on reaction at 20 °C with one molar equivalent of anhydrous CuCl in a mixture (1 : 1 v/v) of diethyl ether and free amine gave colorless suspensions that probably contained copper(I) amides of the type *(1)* [3]. These suspensions become dark brown when oxygen is passed into them (1 h) and a strongly exothermic reaction leads in each case to a hydrazine derivative of type *(2)* and an azomethine *(3)*. Yields, calculated on the lithium amide are: *(2)*, X = O 80 %, X = CH_2 109 %; *(3)*, X = O <5 %, X = CH_2 60 %. The yields in excess of 100 % for *(2)* + *(3)* when X = CH_2 show that the free amine enters into reaction in this case. – Under the above conditions pyrrolidine and diethylamine give almost exclusively the azomethines.

(1) *(2)* *(3)*



Dimerization of Imines: The colorless iminomagnesium halides *(4)* obtained by reaction of benzonitrile with a molar equivalent of Grignard reagent were treated with anhydrous CuCl in ether/tetrahydrofuran (2 : 1 v/v) at 20 °C; a yellow (R^1 = C_6H_5) or pale grey (R^1 = C_2H_5) suspension was formed. After oxygen had been passed in at 20 °C (1 h), an azine of type *(5)* could be isolated from the mixed products in each case. The best yields (94 % when R^1 = C_6H_5, 75 % when R^1 = C_2H_5; based on nitrile) were obtained when 0.05 to 0.2 mole of CuCl was used per mole of nitrile.

(4) (?) *(5)*

Dimerization of Amidines: The sodium amidines *(6)* obtained by treatment of benzonitrile with sodium amide were treated with a molar equivalent of anhydrous CuCl in 1,2-

dimethoxyethane at 20 °C. Oxygen was then passed into the yellowish-green mixture at 85 °C (15 h). The triazole *(8)* could be isolated in 40 % yield [based on *(6)*] from the black mixture. The diazabutadiene-1,4-diamine *(7)* may be a precursor of *(8)*, but attempts to isolate this compound, which rapidly loses NH_3 to form *(8)* [4], were unsuccessful. When $CuCl_2$ was used in place of CuCl the yield of *(8)* amounted to 74 %.

Tetracarbonyl(hexamethylbicyclo[2.2.0]hexadiene)-chromium(0)

By *E. O. Fischer*, *C. G. Kreiter*, and *W. Berngruber* [*]

Reaction of $(CH_3CN)_3Cr(CO)_3$ [1] with hexamethyl(Dewar benzene) [2] in dioxane (1.5 h at 40 °C) followed by filtration, evaporation of the filtrate to dryness, and chromatography of the residue on Al_2O_3 (Grade III) using n-hexane as eluant gave the first π-complex of the Dewar-benzene system, namely, the yellow, well crystalline compound $C_{12}H_{18}Cr(CO)_4$ *(1)* (yield *ca.* 5 %). The complex *(1)* is monomeric in organic media such as benzene, chloroform, and n-hexane in which it is also readily soluble. The composition of *(1)* has been established by means of elemental analysis of the crystalline material which sublimes unchanged at 60 °C in a high vacuum and decomposes above 115 °C as indicated by a darkening in color.

The ^1H–NMR spectrum of *(1)* indicates that hexamethylbicyclo[2.2.0]hexadiene, functions as a bidentate ligand in the complex. In $CDCl_3$ solution, the spectrum shows only two sharp signals at $\tau = 8.26$ and 9.1 (tetramethylsilane as internal standard) having the relative intensities 2:1 respectively. The chemical shifts are thus only slightly different from those of free hexamethyl(Dewar benzene) ($\tau = 8.45$ and 8.94). On warming, hexamethyl(Dewar benzene) is readily converted into hexamethylbenzene, whose $Cr(CO)_3$ complex displays only one ^1H–NMR signal at $\tau = 7.67$.

Four sharp bands at 2025, 1940, 1920, and 1900 cm^{-1} in the ν_{CO} region of the IR spectrum of *(1)* are in accord with the $Cr(CO)_4$ group and, when compared with the similarly constituted complex norbornadiene-$Cr(CO)_4$ [3] (4 ν_{CO} at 2032, 1960, 1946, and 1915 cm^{-1} in n-hexane), demonstrate a somewhat weaker binding of hexamethyl(Dewar benzene). ν_{CO} bands of hexamethylbenzene-$Cr(CO)_3$ [4], which lie at 1960 and 1890 cm^{-1}, were not found in the IR spectrum of *(1)*.

The shift of the ν(C=C) vibration at 1694 cm^{-1} (film) of free hexamethyl(Dewar benzene) to 1543 cm^{-1} (KBr disc) in the spectrum of *(1)* confirms that both the C=C double bonds are coordinated to the metal.

The mass spectrum [5] of *(1)* shows, in addition to the molecular ion $C_6(CH_3)_6Cr(CO)_4^+$ (*m/e* = 326), the characteristic fragment ions $C_6(CH_3)_6Cr(CO)_3^+$ (298), $C_6(CH_3)_6Cr(CO)_2^+$ (270), $C_6(CH_3)_6Cr(CO)^+$ (242), $C_6(CH_3)_6Cr^+$ (214), Cr^+ (52), CO^+ (28), and $C_6(CH_3)_6^+$ (162).

Further confirmation [6] of the structure is provided by the liberation of hexamethyl(Dewar benzene) when *(1)* is treated with pyridine.

Photofragmentation of Oxaziranes

By *Ernst Meyer* and *G. W. Griffin* [*][**]

The spirooxazirane *(2)* is obtained [1] by addition of the anil *(1)* (8.6 g; 0.05 mole) in anhydrous ether (25 ml) to an anhydrous solution of peracetic acid [2] in benzene (0.05 mole) diluted with ether (25 ml) at 0 °C. After standing at room temperature for one hour, the reaction mixture is washed in turn with 10 % sulfuric acid and 10 % sodium carbonate and finally dried over potassium carbonate. The solvents are then removed by distillation under reduced pressure and the residue is dissolved in petroleum ether (b.p. 40–60 °C). On filtration of this solution through Celite and activated charcoal and subsequent concentration and cooling, compound *(2)* crystallizes out [m.p. 73–74 °C (lit. [1]: 75 °C); yield 3.0–3.5 g (36 %)].

Irradiation (24 hours) of *(2)* (3.0 g; 0.16 mole) in freshly distilled diethylamine (70 ml) [3] affords the 2-diethylamino-3*H*-azepine *(3)* (0.26 g; 10 %) which can be isolated by gas chromatography [4] after a preliminary distillation (70 to 120 °C/0.5 mm). The NMR and IR spectra are identical with those of an authentic sample prepared independently in 34 %

yield by irradiation of phenylazide (0.24 g, 0.002 mole) in diethylamine[5, 6].

Aniline is also produced upon photolysis of *(2)* but no accurate determination has been made of the yield (approximately 9 %). It is reasonable to assume that phenyl nitrene is formed as intermediate in the photolysis of *(2)* and *(4)*[7]. The photolabile compound *(5)* is formed if irradiation is carried out in cyclohexylamine.

Reaction of Carbon Monosulfide and Monoselenide with Chalcogens and Halogens

By *R. Steudel*[*]

CS is formed by dissociation of CS_2 in a high-frequency discharge (0.1 mm) and can be isolated in a flow system at −190 °C and detected by low-temperature IR spectrometry[1]. By using the same experimental technique[2] it has now been found that CS undergoes a heterogeneous reaction (even at room temperature) to form SCSe and SCTe, if the walls of the discharge tube are covered with Se or Te, respectively.

In the high-frequency discharge, CSe_2 clearly gives CSe which, although it cannot be isolated, can be trapped as SeCS or SeCTe by reaction with solid sulfur or tellurium. High concentrations of mixed carbon dichalcogenides are, however, formed only on reaction of CS or CSe with gaseous chalcogens. For this purpose the discharge tube was heated until the chalcogen began to sublime. SeCTe, previously unknown, could thus be obtained in about 8 % yield (calculated on CSe_2).

For the reaction of CS with Cl_2, Br_2, or I_2 the gaseous halogen (in the proportion 0.2:1 to 0.5:1 calculated on CS_2; temperature 25 °C) was added continously behind the glowing zone of the high-frequency discharge in CS_2. Condensation was effected after a reaction time of about 0.1 sec; the thiocarbonyl halides $SCCl_2$, $SCBr_2$, and the new compound SCI_2 could thus be isolated.

SeCTe and SCI_2 are very sensitive thermally and cannot be sublimed in a high vacuum. They were identified from the following IR absorptions (at −190 °C, in a CS_2 or CSe_2 matrix), as also was $SCBr_2$ which was previously incompletely characterized (wave numbers in cm^{-1})[3]:

SeCTe: $\nu_3 = 1179$ vs, $\nu_3(Se^{13}CTe) = 1136$ w, $\nu_1 + \nu_3 = 1473$ m
$SCBr_2$: $\nu(C{=}S) = 1097$ s, $\nu(C{-}Br) = 685$ s
SCI_2: $(C{=}S) = 1062$ s, $(C{-}I) = 602$ s

The wave number of the C=S stretching vibration is particularly low for $SCCl_2$ (compared with the other thiocarbonyl halides), which can be interpreted as due to participation of a resonance structure with C−S and C=Cl bonds in the ground state of thiophosgene.

Tris-(7*H*-dibenzo[*c*,*g*]fluorenylidenemethyl)methane a New Highly Acidic Hydrocarbon [1]

By *R. Kuhn* and *D. Rewicki*[*]

7*H*-Dibenzo[*c*,*g*]fluorene *(1)* is about 4 powers of ten more acidic than fluorene[2]. Tris(biphenylylenevinyl)methane[3,4] has the highest acidity of the fluorene-substituted hydrocarbons described hitherto. It seemed to us, therefore, of interest to prepare tris-(7*H*-dibenzo[*c*,*g*]fluorenylidenemethyl)methane *(4a)*.

The hydrocarbon *(4a)* was obtained in admixture with its tautomer *(4b)* by a method given by *Jutz* and *Amschler*[4]. A concentrated solution of dibenzo[*c*,*g*]fluorene *(1)* (2 mol. equiv.) and the diperchlorate *(2)* (1 mol. equiv.) in pyridine was treated with 3 N $NaOCH_3$ solution (2.3 mol. equiv.). After warming the reaction mixture for a short time the dimethylamino compound *(3a)* was precipitated as dark red crystals, m.p. 265–270 °C, $\lambda_{max} = 506$ nm, $\log \varepsilon = 4.70$ (in tetrahydrofuran), in 80 % yield. Analyses, molecular-weight determinations, and the NMR spectrum of the chromatographically homogeneous substance agreed with formula *(3a)*. The dibenzofluorene *(1)* (1.7 mol. equiv.) was converted in tetrahydrofuran and under nitrogen into its lithium salt by means of 1 N ethereal phenyl-lithium solution. The dimethylamino compound *(3a)* (1 mol. equiv.) was added to this solution and the whole was boiled for 1 h under reflux. The resulting dark green solution was decolorized with O_2-free 2 N HCl and then extracted with benzene. On removal of the benzene and recrystallization of the residue from benzene/petroleum ether (8:2 v/v) a 65 % yield of the orange-brown hydrocarbon $C_{67}H_{40}$ was obtained that decomposed at 210 to 215 °C. Analyses and molecular-weight determinations agreed with this molecular formula. A thin-layer chromato-

gram [SiO_2; solvent, benzene/cyclohexane (1:9)] showed a double spot, which is attributed to presence of the mixture of tautomers *(4a)/(4b)*.

The NMR spectrum of the mixture (in $CDCl_3$) includes two doublets (τ = 3.64 and 4.64 ppm, J = 10 Hz), corresponding to the >C=CH–CH< group of *(4b)*, as well as a multiplet (τ = 1.2–3.0 ppm).

In dimethyl sulfoxide (DMSO) the hydrocarbons *(4)* give a deep green carbanion when treated with bases (*e.g.* NaOH, tri-n-propylamine). This anion (λ_{max} = 697 nm, log ε = 5.15) is fairly stable to oxygen but on oxidation with $K_3Fe(CN)_6$ it affords the radical tris-(7*H*-dibenzo[*c*,*g*]fluorenylidenemethyl)methyl (λ_{max} = *ca.* 860, 545 nm in benzene) which is carmine-red in solution but brownish-red in the crystalline state. This radical is sensitive to oxygen. Its ESR spectrum[5] in benzene shows four lines with relative intensities 1:3:3:1 (a_H = *ca.* 7 gauss), corresponding to coupling of the radical electron with the three equivalent vinyl protons. In the solid state the radical is partly monomeric.

As expected, the hydrocarbons *(4)* have high acidity. A 10^{-5} M solution in carefully purified DMSO is almost completely dissociated even without addition of base. A 10^3-fold molar excess of HCl in DMSO/water (85:15 mol.-%) depresses the dissociation but does not suffice to decolorize the green solution. We have determined the relative acidities of some highly acidic hydrocarbons by spectrophotometric measurements in various solvents (DMSO/water/HCl, DMSO/glacial acetic acid/sodium acetate, DMSO/tri-n-propylamine, DMSO/ethanol/sodium methoxide) and by means of 9-cyanofluorene (pK = 11.4)[6] have derived the following pK values (referred to water)[2].

Hydrocarbon [a]	pK value
BiphCH–C_6H_5	19.6 (18.6 [6])
BiphC=CH–HCBiph	14.2
[BiphC=CH]$_2$$CH_2$	12.3 [b]
BiphCH–CN	11.4 [6]
[BiphC=CH]$_3$CH	10.4 [b]
(3b)	8.2 [b]
(4a) + *(4b)*	5.9 [b]

[a] Biph = [b] Gross pK value.

Preparation of Isocyanates from Carbamates by Reaction with Phosgene

By *H. Ulrich*, *B. Tucker*, and *A. A. R. Saytgh*[*]

The synthesis of isocyanates from carbamates by means of phosphorus pentachloride[1] or pyrocatechol-phosphorus trichloride[2] has been recorded. However, it often involves difficulties in separating the isocyanates from the phosphorus oxide chlorides that are also formed[1]. In the case of alkylcarbamates, use of phosgene in place of phosphorus chlorides would result in formation of gaseous or low-boiling inert by-products. However, on reaction of ethylurethane with phosgene, carbonyldiurethane is the main product and carbamoyl chloride is formed only in small amount[1].

We have now found that reaction of carbamates in an inert solvent containing *N*,*N*-dimethylformamide (DMF) as catalyst gives isocyanates and alkyl chlorides. Reaction occurs even at low temperatures, and thus there is no reason to assume dissociation of the carbamates. The formimidoyl chloride *(1)* formed from phosgene and DMF apparently reacts with the enolic form of the carbamates, with formation of chloroformimidates *(2)* and regeneration of DMF. Thermolysis of the chloroformimidates to yield isocyanates and alkyl chlorides is known[3].

R	Solvent	Isocyanate B.p. (°C/mm)	Isocyanate Yield (%)
$CCl_3CH(OH)$	Chlorobenzene	41–54/7.5 [a]	13.2
CCl_3CHCl	Toluene	68–72/20 [a]	48.2
CH_2=CH–CH_2	*o*-Dichlorobenzene	85	57.2
C_6H_5–CH_2	Toluene	80/7	65.4
m-Cl–C_6H_4	Chlorobenzene	58–62/2.2	40.0

[a] The same isocyanate with R = CCl_3CHCl is obtained in these two cases.

Experimental:

Phosgene (1 g/min) is passed for 225 min into a boiling solution of 8.9 g (0.05 mole) of ethyl *N*-benzylcarbamate and

0.44 g of *N,N*-dimethylformamide in 90 ml of toluene. After removal of the excess of phosgene in a stream of nitrogen and rectification, 4.35 g (65.4 %) of benzyl isocyanate, b.p. 80 °C/7 mm, is obtained. No isocyanate is formed in the absence of catalyst under otherwise similar conditions.

Preparation of Hexaazidophosphates

By *H. W. Roesky*[*]

We recently reported the preparation of the tetrachlorodicyanophosphate ion $[PCl_4(CN)_2]^{\ominus}$[1]. We have now accomplished complete substitution at the phosphorus atom by the more electronegative azide group and been able to prepare the hexaazidophosphate ion $[P(N_3)_6]^{\ominus}$ for the first time.

For the synthesis, sodium azide is added slowly, with vigorous stirring, to phosphorus pentachloride in anhydrous acetonitrile (molar ratio $PCl_5:NaN_3 = 1:10$). The reaction is slightly exothermic. Stirring is continued for 10 minutes at room temperature and an excess of 5 % aqueous tetraphenylphosphonium chloride solution is then added dropwise. A yellow viscous oil separates which can be reprecipitated from acetone/water. 1 g of PCl_5 gives 0.2 g of $(C_6H_5)_4P^{\oplus}[P(N_3)_6]^{\ominus}$. Tetraphenylarsonium chloride gives $(C_6H_5)_4As^{\oplus}[P(N_3)_6]^{\ominus}$ under the same conditions. All operations are carried out under a rapid current of dry nitrogen. The substances explode violently on slight warming.

The purest samples are obtained by separating the oil immediately after its preparation and drying it over P_4O_{10} in a vacuum desiccator. When moist, the compounds slowly evolve N_3H. The IR spectrum of $(C_6H_5)_4P[P(N_3)_6]$ in the NaCl region shows strong bands at 2150, 1250 with a shoulder, and 755 cm^{-1}, which are ascribed to $\nu_{as}(N_3)$, $\nu_s(N_3)$, and $\nu(P-N)$ vibrations. Further strong bands at 560 and 585 cm^{-1} are ascribed to deformation vibrations.

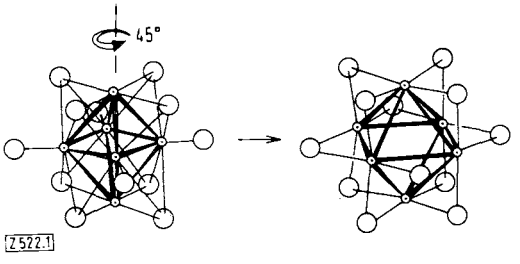
Tungsten Trichloride $[W_6Cl_{12}]Cl_6$

By *R. Siepmann, H.-G. v. Schnering*, and *H. Schäfer*[*]



Compounds with the groups $[M_6X_8]$ and $[M_6X_{12}]$, where X = halogen, are known for the heavy transition metals[1]. When M = Mo or W the first type is regularly formed, and when M = Nb, Ta, Pd, or Pt the second.

Two exceptions to this rule are now known: (i) the recently discovered[2] iodide $[Nb_6I_8]I_{6/2}$ and (ii) the chloride $[W_6Cl_{12}]Cl_6$, which is described below.

Tungsten dichloride $[W_6Cl_8]Cl_{2}Cl_{4/2}$[1,3] reacts with liquid chlorine at *ca.* 100 °C, forming a black substance that contains 3 chlorine atoms per tungsten atom and gives sharp X-ray diagrams. The WCl_6 formed simultaneously is extracted with liquid chlorine at *ca.* 40 °C. Structural elements of the starting material apparently withstand this vigorous reaction with Cl_2. WCl_4 is converted completely into WCl_6 under similar conditions. The trichloride obtained is soluble in a small amount of warm $(CH_3)_2SO$, giving a dark brown solution. If this solution is treated with dilute aqueous H_2SO_4 and Na_2SO_4, only about 2.5/18 of the Cl becomes titratable with Ag_2SO_4. More AgCl is precipitated only on warming, and the W complex is thereby destroyed with precipitation of elemental Ag. The firm binding of the halogen is characteristic of the groups $[M_6X_8]$ and $[M_6X_{12}]$.

The structure of the trichloride was determined from Guinier measurements (by comparison with the Pt_6Cl_{12} structure). The material crystallizes in the hexagonal rhombohedral form with $a = 14.91$ Å, $c = 8.45$ Å, $c/a = 0.568$, $a_{rh} = 9.05$ Å, $\alpha_{rh} = 110.8°$, in the space group $R\bar{3}$-C_{3i}^2. The unit cell contains three formula units W_6Cl_{18} (X-ray density 5.33 g/cm^3). According to detailed calculation of intensities (trial-and-error procedure) the atoms have the following positions [position 18(f)]: 18 W with $x = 0.120$; $y = 0.016$; $z = 0.140$; 18 Cl_I with $x = 0.134$; $y = 0.018$; $z = -0.310$; 18 Cl_{II} with $x = 0.249$; $y = 0.151$; $z = 0$; and 18 Cl_{III} with $x = 0.268$; $y = 0.035$; $z = 0.310$. The W parameters were determined by comparison of intensities, the Cl parameters by consideration of bond distances. The structure contains discrete molecules $[W_6Cl_{12}^i]Cl_6^a$, which are arranged in a (distorted) body-centered cube. Interatomic distances are: $W-W = 2.9_2$, $W-Cl^i = 2.3_0$, $W-Cl^a = 2.5_2$, all $Cl-Cl > 3.6$ Å.

Conversion of the grouping $[M_6X_8]$ into $[M_6X_{12}]$ can occur in single steps by changing positions of X. However, the conversion $[M_6X_8]X_4 \rightarrow [M_6X_{12}]$ is also possible if the halogen sphere and the M_6 octahedron rotate in one step by 45 ° relative to each other (see Figure).

It is interesting that analogous "conversion" of the cationic group does not occur when Br_2 reacts with "tungsten dibromide" $[W_6Br_8]Br_2Br_{4/2}$; in this case the system changes with formation of polybromide.

Detection of the Molecules W_2Cl_6 and W_3Cl_9 in the Gaseous State

By *K. Rinke* and *H. Schäfer*[*]

The solid lower tungsten halides are of particular interest because of the formation of W–W bonds[1,2]. These bonds are probably essential also for the stability of the molecules

W_2Cl_6 and W_3Cl_9 that have now been observed in the mass spectrometer.

The Table shows the compounds studied and the relative ion intensities observed (a dash denotes not observed). Isotopic distribution was taken into account. The smaller fragments are not given for electron energies of 50 eV; for 12 and 15.5 eV the Table contains, however, all the $W_xCl_y^+$ ions observed.

No.	Substance	Approx. sample temp. (°C)	Electron energy (eV) uncorr.	Relative ion intensities

[a] $WCl_{3.4}$ is a material, amorphous to X-rays, containing 60.4% of W and 39.8% of Cl, obtained by *R. Siepmann* [2].

The products of hydrolysis WO_2Cl_2 and $WOCl_3$ occurred in the mass spectrum as well as the chlorides, but the results are not invalidated thereby.

The substances were placed in graphite crucibles (WCl_5 in a glass capillary) and heated in the ion source of the mass spectrometer (CH 4 from Fried. Krupp, MAT, Bremen). The measuring range of the apparatus was up to mass number 1350. The ions recorded were identified by their mass numbers and isotopic distribution. Even the W_3Cl^+ ion group with its low intensity could be resolved (Fig. 1).

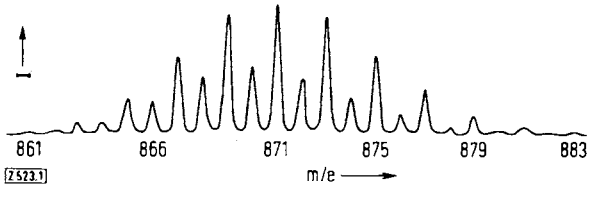

Fig. 1. $W_3Cl_9^+$ ion group. Ordinate: Ion current.

Only the ions WCl_5^+, WCl_4^+, $W_2Cl_6^+$, and $W_3Cl_9^+$ observed at low electron energies (*ca.* 12 eV) are to be considered as primary ionized gas molecules. All the other ions are fragments of the evaporated parent molecules. This follows from a study of the measured appearance potentials when WCl_4 was heated (reference value: ionization energy of argon 15.8 eV): WCl_5^+ 9.1 eV, WCl_4^+ 8.0 eV, WCl_3^+ 11.8 eV, $W_2Cl_6^+$ 9.5 eV, $W_2Cl_5^+$ 11.9 eV, $W_3Cl_9^+$ 9.3 eV.

Conclusions:

WCl_5 sublimes without decomposition (Experiment 2). W_2Cl_{10} was not observed although dimers were assumed from measurements of equilibria [3] (disputable; cf. reaction entropy).

WCl_4 decomposes to some extent on volatilization (Experiments 3 and 4). Disproportionation leads to the molecules WCl_5, W_2Cl_6, and some W_3Cl_9.

The other compounds (Experiments 5—11) give the same gaseous products as does WCl_4.

It is important that the monomeric WCl_3 does not occur alongside the considerable concentrations of W_2Cl_6. The dimer is obviously considerably more stable against thermal decomposition to monomers than is, *e.g.*, Al_2Cl_6 or Fe_2Cl_6. Further, all the chlorine-deficient fragment ions, such as W_2Cl^+ to $W_2Cl_5^+$ and $W_3Cl_3^+$ to $W_3Cl_8^+$, observed to be formed from W_2Cl_6 and $W_3Cl_9^+$ at 50 eV gave considerably lower intensities than did the corresponding parent ions $W_2Cl_6^+$ and $W_3Cl_9^+$. In this respect W_2Cl_6 and W_3Cl_9 are comparable with the halides Re_3Cl_9 [4,5], Re_3Br_9 [5,6], Tc_3Cl_9 [6], and Cu_3Cl_3 [7]. Experiments with $MoCl_5$, $MoCl_4$, $MoCl_3$, and Mo_6Cl_{12} gave no indication of the occurrence of polymeric molecules in the gas phase [8].

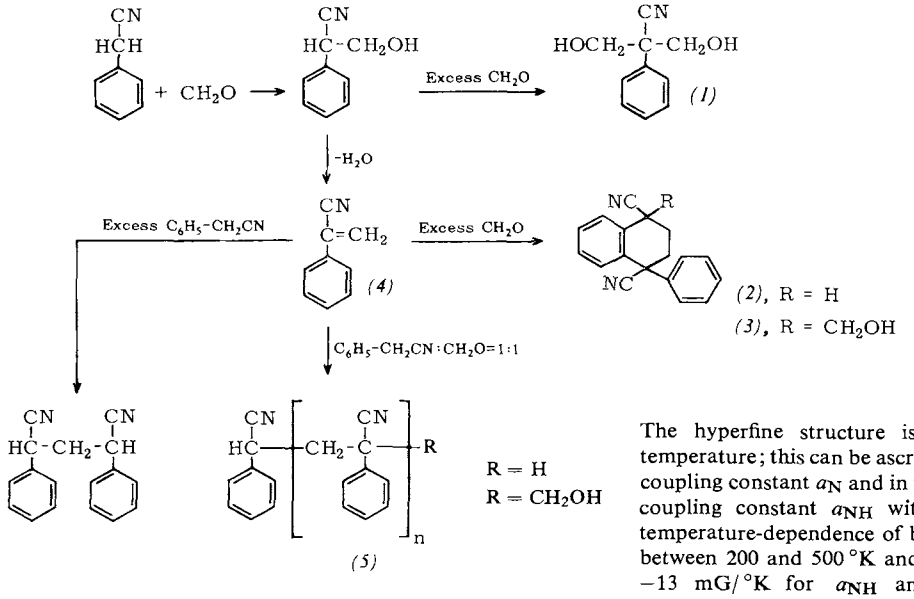
Erratum

In the communication "Synthesis and Template Properties of Deoxyoligonucleotides with Repeating Triplet Sequences" by *F. Cramer*, *W. Frölke*, and *H. Matzura*, Volume 6, June 1967, the following correction should be made.

On page 562, right-hand column, line 30, "0.05 Mole of each trinucleotide" should read "0.50 mmole of each trinucleotide".



Cross-Linked Polymers from α,α'-*p*-Phenylenediacrylonitrile

By *W. Funke*[*]

p-Phenylenediacetonitrile reacts with formaldehyde (molar ratio 1:2) in a homogeneous medium (nitrile 0.128 mmole per ml of CH_3OH; CH_3ONa 0.57 mole per mole of nitrile; *ca.* 65 °C; 1 h) as well as in heterogeneous medium (nitrile 0.04 mmole per ml of H_2O; NaOH 0.22 mole per mole of nitrile; 60–100 °C; 1 h), yielding α,α'-*p*-phenylenediacrylonitrile which, however, like the α-cyanostyrene that arises from phenylacetonitrile and formaldehyde, cannot be isolated because it immediately polymerises anionically[1].

Unlike the products formed in a homogeneous medium, the cross-linked polymers of α,α'-*p*-phenylenediacrylonitrile that are obtained from a heterogeneous medium contain only ≥CH and $-CH_2OH$ as end-groups, so that quantitative determination of the end-groups and study of the initiation and termination steps would appear to be simpler. Nevertheless, quantitative analysis of the end-groups is not completely satisfactory for the cross-linked polymers, so that the end-groups were investigated for the linear polymers *(5)* prepared from phenylacetonitrile and formaldehyde *via* α-cyanostyrene. It has been shown earlier that, for reactions in a homogeneous medium, these linear polymers are good models for the cross-linked polymers.

The hydroxymethyl end-groups were determined by titration with phenyl isocyanate and by nuclear resonance spectroscopy. The ratio of hydroxymethyl to phenyl groups was calculated from the oxygen and nitrogen contents. The ratio of ≥CH to phenyl groups was evaluated by nuclear resonance spectroscopy. In this way the ≥CH/CH_2OH ratio was found to be 2.7 to 3.0, whence it is concluded that the phenylacetonitrile anion is the preferred initiator for anionic polymerization of the intermediate monomer, even in the presence of water, and that addition of a proton to the anionic end of the chain in a termination reaction is not the only way in which the ≥CH end-groups are formed.

When a large excess of formaldehyde (molar ratio 10:1) was used in a heterogeneous medium at 64 °C, α,α-bis(hydroxymethyl)phenylacetonitrile *(1)* was isolated, and dimeric α-cyanostyrene *(2)* and its formaldehyde adduct *(3)* were identified. When a shorter reaction time (10 min) was used, larger amounts of α-cyanostyrene *(4)* were identified by hydrogenation, IR spectra, and formation of the dimer.

Detection of Mesomeric Limiting Structures by Electron Spin Resonance

By *H. B. Stegmann* and *K. Scheffler*[*]

4-Amino-2,6-di-t-butylphenols can be converted into stable paramagnetic compounds by oxidation with alkaline ferricyanide solution or by heavy-metal oxides in solvents such as alcohols, ether, benzene, or pyridine.

(1)

R = H, CH_3, $CH(CH_3)_2$, C_6H_5

In the ESR spectra of these radicals, a hyperfine structure is recognizable that is to be attributed to interaction of the unpaired electron with the nitrogen, as well as with the protons of the amino group and of the substituent R. This indicates that in descriptions of such systems, in addition to the usual mesomeric limiting structures of aroxyls, structures must be considered in which there is an appreciable spin density at the nitrogen atom.

The hyperfine structure is very strongly dependent on temperature; this can be ascribed to a decrease in the nitrogen coupling constant a_N and in the splitting of the amino-proton coupling constant a_{NH} with increasing temperature. The temperature-dependence of both coupling constants is linear between 200 and 500 °K and when R = H the gradients are −13 mG/°K for a_{NH} and −1.3 mG/°K for a_N. The relationships can be best described, qualitatively, by a model in which the amino group carries out hindered rotation around the $C_{arom.}$-N bond. The hindering potential is derived, not from the steric situation, but from the gain in delocalization energy connected with the orientation of the molecule at low temperatures.

In experimental study of 4-amino-2,5-di-t-butylphenoxyl, qualitatively and quantitatively the same temperature-dependence for nitrogen and amino-protons was observed even though the steric environment had been considerably altered. Further, an increase in spin density in the aroxyl ring can be assumed from the increase, with temperature, of the coupling parameters of the proton in position 6. Thus aminoaroxyls can be described as mesomeric radicals in which limiting structures that account for free electron density on the nitrogen contribute a considerable part, although with rising temperature these limiting forms decrease significantly in favor of "aroxyl structures".

Active Transport of Ions through Biogenic Membranes

By *E. Broda*[*]

Active transport is the movement of a solute against the gradient of the electrochemical potential; it is observed only at biogenic membranes. For instance, NaCl is enriched on the inner side of surviving frog skin; thus separation occurs if an NaCl solution is divided by a frog skin. Experiments with other salts, and in particular experiments by *Ussing* and *Zerahn*'s "short circuit" method [1], have shown that, in the frog skin, active transport is specific for sodium – the counterion follows the resulting potential difference. According to *Ussing* the electrical potential between the two sides of frog skin first observed by *DuBois-Reymond* in 1848 is to be ascribed to active transport.

Active transport increases the total free energy of the solutions separated by the membrane, and decreases their entropy. Clearly a compensating decrease in free energy and increase in entropy results from metabolic processes in the membrane. Presumably it is adenosine triphosphate formed in metabolism that drives the "ion pump", and its efficiency is found to be considerable (*ca.* one half). The unknown endogenous substrate can be replaced experimentally by a defined exogenous substrate (radioglucose). The CO_2 formed can be measured with a gas counter and a consumption of 10^{-12} mole cm^{-2} h^{-1} can be determined. The share of the glucose in transport work, as found experimentally, can be represented over five powers of ten in glucose concentration by a mechanism according to which glucose-6-phosphate resulting from hexokinase reaction competes with endogenous (non-radioactive) glucose-6-phosphate.

Apparently all biogenic membranes are capable of specific active transport of some substance or other (even neutral molecules), and by participation of "passive" diffusion in the opposite direction this leads finally to a stationary state.

Radiochemical experiments with *Chlorella* algae show that the energy for transport of potassium (uptake from the nutrient solution) is made available either by respiration or by illumination (photophosphorylation). The mechanism for transport of potassium is largely specific for that element (and for rubidium). Bromide is also subject to active transport by the algae; the bromide transport system can also bring chloride into the interior of the cells, but not other anions. It is at present not clear why glucose inhibits active transport of bromide; this is not due to an osmotic effect since galactose and mannitol are ineffective. Trace elements also, *e.g.* zinc, can be enriched actively by algae. However, proof is more difficult with polyvalent cations as these are also taken up strongly by ion exchange, *i.e.* a passive process.

The stationary states brought about by active transport are a special case of the dynamic states characteristic of life. There is a further special case when organic compounds occur in organisms in stationary concentrations that surpass those given by equilibria; an example is the coexistence of serum albumin with the amino acids of which it is composed. Supply of free energy (for albumin by way of adenosine triphosphate) is necessary also for preservation of these dynamic conditions.

Since work is required for the maintainance of stationary states, even in conditions of strongly depressed life activity, we have measured the respiration of spores of *Bacillus cereus*. It corresponded (in water at 30 °C) to a half-life for "self consumption" of several hundred years, and was smaller by powers of ten than the respiration of the vegitative forms. At 19 °C or in the dry condition, the respiration of the spores was immeasurably small, but it was much increased by exogenous glucose or dinitrophenol. It is possible that on further improvement of the sensitivity of the radiochemical methods an energy metabolism can be demonstrated in all cryptobiotic systems.

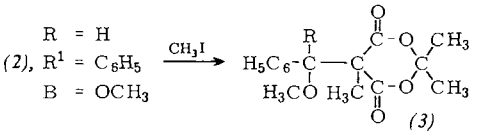
A New Class of Lewis Acids

By *F. Wessely*[*]

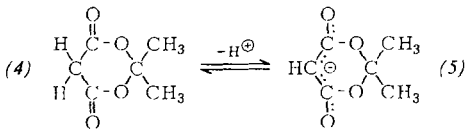
Condensation products from cyclic malonyl acylals *(1)* and aldehydes or open-chain or cyclic ketones can be titrated as monoprotic acids. Chemical and physicochemical measurements as well as quantum mechanical calculation (after *Polansky et al.*) show that an $HO^{\ominus}$ or alkoxide ion $B^{\ominus}$ is attached to the β-carbon atom with formation of the anion *(2)*, which is stabilized by delocalization of the negative charge.



(1) *(2)*

The evidence is:

1a) In most cases, *e.g.* R = H, R^1 = alkyl or aryl, compound *(1)* yields no CH_4 with the Zerewitinoff reagent.

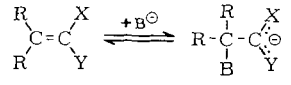


1b) Formation of compound *(3)* is proved by degradation reactions.

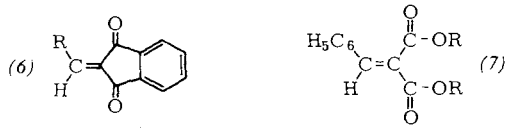
(3)

1c) Alkaline solutions of compounds *(1)* cannot be catalytically hydrogenated.

2a) Compounds *(1)* in neutral solution give a UV spectrum that changes characteristically when the anion is formed in alkaline solution. A band is formed that is peculiar to the anion *(5)* of Meldrum's acid *(4)*. This anion is also stabilized by delocalization of the negative charge.



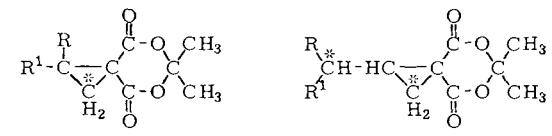
2b) Addition of $CD_3O^{\ominus}$ in CD_3OD shifts the signal of the olefinic proton in the ^1H–NMR spectra of *(1)*, R = H, $R^1 = C_6H_5$ or $(CH_3)_3C$, to higher field, to the region where the signals of aliphatic ethers appear.



3a) The calculated π-electron densities (molecular diagrams) show maxima of positive charge on the β-carbon atom or on the two carbonyl-carbon atoms of *(1)*. The positive charge on the carbonyl-carbon atoms is the greater, but the activation energies are appreciably less favorable than for addition to the β-carbon atom.

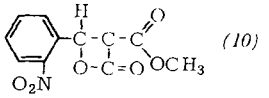
3b) Calculations of the π-electron activation energy by the Pariser-Parr method give excellent agreement with the values found experimentally.

Thus in compounds *(1)* a partial positive charge is preformed on the β-carbon atom by the electron-acceptor groups. One may therefore regard these compounds as pseudo-Lewis acids:



Delocalization of the π-electrons in the acceptor system is of decisive importance. In this way one can understand why, for instance, compound *(6)* also acts as an electrically neutral

Lewis acid, whereas the benzylidenemalonic ester *(7)* has no Lewis acid character; in the latter case the two C=O groups must be brought into a coplanar position to achieve maximal delocalization, and thus the entropy factor has an appreciable negative value.



In 99 % methanol the pK_L values for the compounds studied lie between 6 and 11 according to the nature of the substituents.

A further interesting reaction has been found in the effect of ethereal diazomethane on methanolic solutions of compounds of type *(1)*. Whereas compound *(4)* reacts violently with formation of dimethyl malonate and acetone, compounds of type *(1)* give cyclopropane derivatives (immediate reaction at −70 °C; no formation of polymethylenes) with inclusion of one [*(8)*] or two [*(9)*] CH_2 groups. In the latter case, which occurs particularly with aromatic substituents (R^1 = aryl), an anionotropic migration is a prerequisite. The C atoms marked with an asterisk in formulae *(8)* and *(9)* originate in the diazomethane. A reaction can also be achieved with other diazo compounds, *e.g.* diazoacetic ester.

(8) *(9)*, R = H, R^1 = Aryl

In attempts to establish the migratory aptitude of the group R^1 of *(1)* an unusual and hitherto unexplained solvent effect was observed: If *(1)*, R = H, $R^1 = p\text{-}NO_2\text{–}C_6H_4$, is treated with diazomethane solution in methanol, *(8)* is formed in 80 % yield; in chloroform, however, *(9)* is obtained in 80 % yield. Steric reasons account for the formation of the lactone *(10)* when the 2-nitrobenzylidene compound *(1)*, R = H, $R^1 = o\text{-}NO_2\text{–}C_6H_4$, in methanol is treated with ethereal diazomethane solution; *(10)* is formed in 65 % yield.

Relations between Structure and Thermodynamic and Chemical Properties of Molten Halides

By *H. Kühnl* [*]

The type of chloro complex formed on dissolution of chlorides of multivalent metals in alkali chloride melts can be predicted qualitatively from a consideration of the liquidus curves of the phase diagrams. A suitable method for this purpose was developed by *Flood et al.* from a simple quasi-lattice model and leads to the assumption that metal dichlorides dissolve as $(MCl_4)^{2-}$ complexes in chloride melts whose cations are equal in size to, or larger than, K^+, whereas metal trichlorides dissolve as $(MCl_6)^{3-}$ ions. This assumption accords with results of spectroscopic measurements by *D. M. Green et al.* Exceptions are $TiCl_2$ and VCl_2, from which polynuclear complexes are formed, and $AlCl_3$ and $FeCl_3$, which must occur as dimers of the type $(M_2Cl_8)^{2-}$. Smaller cations, *e.g.* Na^+, in the chloride melt lead to lower mean coordination numbers for the complexes.

The influence of the carrier melt on the stability of the complexes was measured for solutions of $FeCl_2$ and $FeBr_2$ in molten alkali and alkaline-earth chloride or bromide mixtures. For this purpose EMF measurements were used to determine activity coefficients and partial solution enthalpies for the iron(II) halide at 800–950 °C at concentrations up to 10 mole-%. The influence of the cations and anions of the solvent on the thermodynamic values can always be represented as a continuous function of the mean ion potential if the latter is defined as the sum of the mole-fractional contributions of the quotient ionic charge/ionic radius. The lower the cation potential of the melt and the higher the anion potential, the more strongly will the Fe(II) halides be bound in the complex. Changes in the anion potential are ten to fifteen times more effective than changes in the cation potential, since the anions exert their effect on the iron(II) from the first coordination sphere and the cations only from the second.

The effect of composition and compound formation on the chemical behavior is shown by reactions of alkali chloride/aluminum chloride melts with oxides or oxo salts. For instance, CrO_2Cl_2 is formed when $K_2Cr_2O_7$ is added to $LiAlCl_4$ at 120 °C. Anhydrous $CrCl_3$ is precipitated from $NaAlCl_4$ at 160–180 °C, with evolution of chlorine, and at higher temperatures some Cr_2O_3 is obtained. WO_3 and Na_2WO_4 react with an equimolar $NaCl/AlCl_3$ melt to afford WO_2Cl_2 which can be readily isolated by sublimation; an excess of $AlCl_3$ leads to pure $WOCl_4$. Under the same conditions MoO_3 yields either MoO_2Cl_2 or a complex mixture of volatile Mo(VI) and Mo(V) oxide chlorides containing some $AlCl_3$.

Determination of the Secondary and Tertiary Structure of Nucleic Acids by Chemical Methods

By *F. Cramer* [*]

The number of adenosine residues that are not base-paired [1] can be determined for transfer ribonucleic acid (t-RNA) by

(1)

N-oxidation of the adenine groups. From the degree of oxidation at 20 and 40 °C (difference: 4.5 base pairs) and from the changes in physical properties it can be concluded that the tertiary structure of t-RNA is destroyed by warming from 20 to 40 °C. The model *(1)* is proposed for the tertiary structure common to all t-RNA's. This structure arises by folding together of three base-paired regions, namely, the dihydro-U region, the TΨ region, and the CCA end region. Only the anticodon region is not drawn into the tertiary structure. In this way the molecule achieves a rigid structure which in particular holds the CCA end in a fixed position and enables the specific recognition of the t-RNA by the aminoacyl transferase.

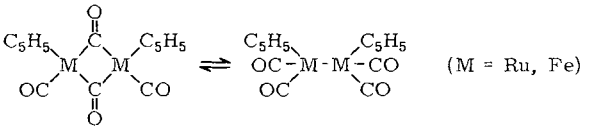
SELECTED ABSTRACTS

Maya blue, a pigment which was used by the Mayas in Yucatan during the final pre-Spanish era of their civilization, has been investigated by *H. Van Olphen.* The pigment is strikingly stable and is decomposed neither by treatment with hot concentrated mineral acids nor by heating to *ca.* 520 °C. The main constituent is the colorless mineral attapulgite and the pigment is probably an adsorption complex of this mineral and natural indigo (< 0.5 %). A synthetic equivalent can be prepared by mixing attapulgite with indoxyl ester or indigo, or by vat dying with reduced indigo and subsequent heating to 75–150 °C. The dye is adsorbed on the outermost surface of the mineral particles. A similar pigment can be produced from sepiolite and indigo. / Science (Washington) *154*, 645 (1966) / –Ma. [Rd 642 IE]

A new synthesis of esters of halogenoacids from esters of hydroxy acids under mild, almost neutral, conditions has been described by *J. B. Lee* and *I. M. Downie.* A hydroxy acid ester is heated rapidly to *ca.* 80 °C with a tertiary phosphine (triphenylphosphine) in CCl_4 or CBr_4. A rapid reaction ensues in which triphenylphosphine oxide, chloro- (or bromo-)esters, and $CHCl_3$ (or $CHBr_3$) are formed. If moisture is excluded, the reaction proceeds in a neutral medium. Inversion occurs at the reaction center. The reaction probably proceeds *via* an ion *(2)* which reacts with the

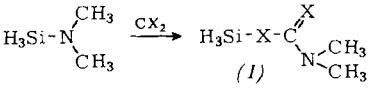


$$\underset{(3)}{R{-}CHOH{-}COOR'} + \underset{(2)}{[(C_6H_5)_3P^{\oplus}CHal_3]\,Hal^{\ominus}} \rightarrow$$

$$\underset{(4)}{[(C_6H_5)_3P^{\oplus}OCHR{-}COOR']\,Hal^{\ominus}} \xrightarrow{-HCHal_3} R{-}\underset{Hal}{CH}{-}COOR' + (C_6H_5)_3PO$$

(1)

hydroxy compound *(3)* to form anionic intermediate *(4)* that decomposes to give the haloester *(1)*. / Tetrahedron *23*, 359 (1967) / –Ma. [Rd 643 IE]



Isomerism in metal complexes has been studied by *R. D. Fischer, A. Vogler,* and *K. Noack.* Analysis of the C–O vibrations of $[C_5H_5Ru(CO)_2]_2$ and $[C_5H_5Fe(CO)_2]_2$ between –100 °C and 100 °C showed that solutions of both complexes contain equilibrium mixtures of two isomers. At low temperatures form *(a)*, which was formerly thought to be the only form, is more stable, while form *(b)* is more stable at high temperatures.

(a) *(b)*

In the Fe complex, form *(a)* still predominates strongly at room temperature, whereas in the Ru complex the two isomers are present in approximately equal quantities. The homologous Os compound, on the other hand, exists only in form *(b)*, both in solution and in the solid phase. Forms *(a)* and *(b)* appear to exist in solution entirely in the *cis* configuration; in any case, they have lost the center of symmetry of the *trans* configuration that apparently exists in the crystalline form. The tendency of the practically free molecules to adopt the *cis* configuration could be due to π or δ components in the metal-metal bond. / J. organometallic Chem. *7*, 135 (1967) / –Sch. [Rd 660 IE]

The reactions of some silylamines with CO_2, COS, and CS_2 were studied by *E. A. V. Ebsworth, G. Rocktäschel,* and *J. C. Thompson. N,N*-Dimethylsilylamine reacts to form unstable silyl *N,N*-dimethyl-carbamates, -thiocarbamates, and -dithiocarbamates.

(1)

The solid white compounds, whose IR, UV, and NMR spectra (SiH resonance and ^{29}SiH coupling) indicate the structure *(1)*, lose SiH_4 on standing. In the thiocarbamate, the silyl group is presumably attached exclusively to the oxygen. Trisilylamine and methyldisilylamine do not react with CO_2, COS, or CS_2, even at 30 atm. / J. chem. Soc. (London) A 1967, 362 / –Bu. [Rd 673 IE]

Halogenated 1,3-dicyano- and 1,3,5-tricyanobenzenes have been synthesized by *K. Wallenfels, F. Witzler,* and *K. Friedrich.* These compounds are particularly interesting in that they have a reactivity similar to that of the corresponding polynitro compounds, but do not exert the troublesome oxidizing action of the latter. The synthesis can be illustrated by the preparation of 2,4,6-tricyanofluorobenzene (m.p. 98–99 °C). The treatment of bromomesitylene with $KMnO_4$ yields bromotrimesic acid, the amide of which (prepared *via* the acyl chloride) is dehydrated with $POCl_3$ (yield 55–60%). The bromo compound is converted into 2,4,6-tricyanofluorobenzene by sublimation through a hot layer of active fluorides (KF; CsF, pure, or mixed with BaF_2 or MgF_2). This method of fluorination can also be used with *e.g.* 1,2-dichloro-1,2-dicyanoethylene. 2,4-Dicyanofluorobenzene (m.p. 82–84 °C), 1,3,5-trifluoro-2,4,6-tricyanobenzene (m.p. 148–150 °C), and their chlorinated precursors were also synthesized. All the fluorinated compounds very readily undergo nucleophilic substitution, though more slowly than the corresponding nitro compounds. / Tetrahedron 23, 1353, 1359, 1845 (1967) / –Bu. [Rd 674 IE]

The bonding of ^{32}P-labeled trinucleotides to t-RNA was detected by *G. Högenauer.* The bonding of ^{14}C-aminoacyl-t-RNA to ribosomes in the presence of trinucleotides had already been used by various research groups for the assignment of the amino acid trinucleotide codon. t-RNA-trinucleotide interactions have now also been observed in the absence of ribosomes. During the chromatography of ^{32}P–AAG (also AUG, ACG, CAG, and UUG) together with a t-RNA mixture from yeast on Sephadex G 50, a part of the radioactivity that was proportional to the quantity of ^{32}P–AAG used was always found with the high molecular weight t-RNA; this was not the case when mono- and dinucleotides were used. Fixed ^{32}P–AAG could not be displaced from the t-RNA even by a 2×10^6-fold excess of AAG-free trinucleotides. The trinucleotide-t-RNA complex is so stable that no decomposition occurs during chromatography on 30 to 40 cm Sephadex columns at pH = 7 and +2 °C. / Hoppe-Seylers Z. physiol. Chem. *348*, 227 (1967) / –Hö. [Rd 680 IE]

Two new u-amino acids having a bacteriostatic action have been isolated by *A. D. Argoudelis et al.* from the culture media of *Streptomyces* strains; they are 2-amino-3-dimethylaminopropionic acid *(1)* and 2-amino-4,4-dichlorobutyric acid *(2)*. 2.5 g of crystalline *(1)* could be obtained from 240 l of culture medium with the aid of ion-exchange chromatography, while 400 mg of *(2)* were obtained from 290 l by a Craig distribution (n-butanol/water). The bacteriostatic activity was used as a purity check. The structure was determined with the aid of IR spectra and NMR data. *(1)* was found to be identical (thin-layer and paper-chromatography; NMR-spectrum; biological action) with synthetic DL material; *(2)* was reduced with sodium borohydride, and the reduction product was identical with homoserine on paper and thin layer chromatography, in Craig distribution, and in the amino-acid analyser. Since the specific rotation of the protonated form is more positive than that of the neutral form [*(1)*: $[\alpha]_D^{25} = +48.3°$; *(2)*: $[\alpha]_D^{25} = +33.6°$] it was concluded that both substances are in the L form. *(1)* and *(2)* are moderately toxic to mice; the effects were observed on subcutaneous injection of more than 80 and 25 mg/kg respectively. The bacteriostatic and toxic effect is probably due to leucine antagonism. / Biochemistry *6*, 165 (1967) / –Hö. [Rd 681 IE]

Enzyme-bound coenzyme A has been detected by *L. B. Hersh* and *W. A. Jencks* in succinyl-CoA: 3-oxoacid CoA-transferase (E.C. 2.8.3.5). The enzyme (E) catalyses the reversible transfer of CoA from succinyl-CoA to acetoacetate. The reaction takes place in two steps I and II.

$$E + \text{succinyl-CoA} \rightleftharpoons E\cdots\text{succinyl-CoA} \rightleftharpoons E\text{–CoA} + \text{succinate} \quad \text{I}$$

$$E\text{–CoA} + \text{acetoacetate} \rightleftharpoons E\cdots\text{acetoacetyl-CoA} \rightleftharpoons E + \text{acetoacetyl-CoA} \quad \text{II}$$

When the enzyme and [1,3-^{14}C]-acetoacetyl-CoA are chromatographed on Sephadex G 50, CoA is found together with the enzyme activity, while the radioactivity is found in the low molecular weight fraction. If the same experiment is carried out with succinate, no CoA bound to high molecular weight substances can be detected. When the E–CoA isolated on Sephadex was incubated with succinate, the CoA was quantitatively transferred to the succinate. The half-lives of the decomposition of the E–CoA at pH = 6.5, 7.4, and 8.0 are 42, 30, and 14 min respectively; the complex is stable for more than an hour in 0.1 M HCl. / J. biol. Chem. *242*, 339 (1967) / –Hö. [Rd 682 IE]

Effective hydrogenation catalysts obtained by reduction of Pt^{IV} salts with solvents are reported by *G. Henrici-Olivé* and *S. Olivé.* Such catalysts were obtained *e.g.* from solutions of $PtCl_4$ in solvents having electron-donor properties (alcohols such as methanol and isopropanol, esters such as ethyl acetate, and ethers such as propylene oxide and tetrahydrofuran). Support materials such as silica gel or alumina are soaked with a solution of the type described, the excess solvent is distilled off (about 25 °C in vacuum), and the dried material is heated (reduction of the Pt_{IV} solvate) for about 1 hour at 150 to 200 °C to obtain optimum catalyst activity (best concentration of Pt_{IV} on the support: 0.1 to 0.3 wt.-%). Hydrogenation rates of up to 250 moles of H_2 per g-atom of Pt per min were obtained with 1-octene. Solutions of $PtCl_4$ in propylene oxide become black-brown on prolonged standing at 20 °C or when heated for a short time at 90 °C; the stable, highly viscous solution obtained on concentration can be used, even in toluene or cyclohexane, for hydrogenations under very mild conditions. Aldehydes cannot be used for the production of these catalysts; the deposition of Pt is hindered by even small quantities of water in the solvent. / Chimia *21*, 87 (1967) / –Jg. [Rd 688/IE]

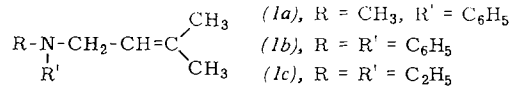
Dialkyltin dithiolates have been prepared from dialkyltin dialkoxides and oxides by *D. Sukhani, V. D. Gupta,* and *R. C. Mehrotra.* Unlike the alkoxides of Al, Ti, and Zr, dialkyltin dialkoxides react readily with thiols (molar ratio 1:2) when refluxed in anhydrous benzene (yield 90 to 99%) *e.g.*:

$$(C_4H_9)_2Sn(OC_2H_5)_2 + 2\ RSH \rightarrow (C_4H_9)_2Sn(SR)_2 + 2\ C_6H_5OH$$

Dialkyltin oxides react in a similar manner if the water formed is removed by azeotropic distillation

$$(C_4H_9)_2SnO + 2\ RSH \rightarrow (C_4H_9)_2Sn(SR)_2 + H_2O$$

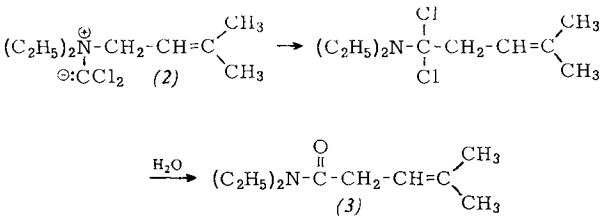
R = C_2H_5, C_3H_7, C_4H_9, i-C_4H_9, t-C_4H_9, $C_{12}H_{25}$, C_6H_5, $C_6H_5CH_2$



Apart from the dodecyl derivative (decomp.), the thiolates can be distilled at 0.1 to 1 mm Hg. Ebullioscopic measurements indicate that they are monomeric in benzene. Unlike the Si–S bond, the Sn–S bond is highly resistant to hydrolysis. Attempts to isolate $(C_4H_9)_2Sn(OC_2H_5)SR$ led to dismutation. Cleavage into the starting components takes place only on heating for about 200 hours with a large excess of alcohol in the presence of *p*-toluenesulfonic acid as catalyst. With this catalyst, higher thiols (molar ratio 2:1) can be introduced on removal of the lower thiol by azeotropic distillation (in cyclohexane), *e.g.*:

$$(C_4H_9)_2Sn(SC_3H_7)_2 + 2\ RSH \rightarrow (C_4H_9)_2Sn(SR)_2 + 2\ C_3H_7SH$$

R = dodecyl, 2-tolyl.



/ J. organometallic Chem. *7*, 85 (1967) / –Jg. [Rd 691 IE]

The reaction of allylamines with dichlorocarbene has been studied by *W. E. Parham* and *J. R. Potoski*. Dichlorocarbene is produced from potassium t-butoxide/chloroform method (I), n-butyl-lithium/carbon tetrachloride method (II), and ethyl trichloroacetate/sodium methoxide method (III). The

(1a), R = CH_3, R' = C_6H_5
(1b), R = R' = C_6H_5
(1c), R = R' = C_2H_5

allylamines, *e.g. (1a)*, unlike the analogous allyl sulfides, give the dichlorocyclopropane derivatives, the yield of which increases with decreasing basicity of the amine. For *(1a)* the yields obtained by methods I, II, and III are 28 %, 26 %, and 18 %, while for *(1b)*, methods I and II give yields of 45 % and 73 %. When *(1c)* is used as the starting material, the reaction leads to the dichlorocyclopropane derivative (5 %) together with an amide *(5)* (yield 7 %; n_D^{25} = 1.4680), the formation of which can be explained by Stevens rearrangement of the ylide *(2)*. This rearrangement is more important

(2) *(3)*

in the reactions of the allyl sulfides, since the sulfur ylide is resonance-stabilized owing to the participation of the d orbitals of sulfur: $R_2\overset{\oplus}{S}-\overset{\ominus}{C}\!\!\swarrow \leftrightarrow R_2S{=}C\!\!\swarrow$. / J. org. Chemistry *32*, 275 (1967) / –WG. [Rd 703a IE]

BOOK REVIEWS

Klinik und Therapie der Vergiftungen. (Clinical treatment and therapy of poisoning) by *S. Moeschlin*. Georg Thieme Verlag, Stuttgart 1964. 4th revised and enlarged Edit., 750 pp., 99 figures. Reprinted unchanged 1965; cloth, DM 66.–.

In 1951, *Moeschlin* wrote the first German-language reference book on poisoning for clinicians. According to the preface, the reason for writing the book was the "occurrence of a very large number of new poisons in industry and in the pharmacopoeia". In the second and third additions, the author "included many drugs in response to numerous requests by colleagues", and the fourth edition, published in 1964, included a "Section on plastic substances".

According to the preface, "the arrangement into groups of poisons follows practical rather than strictly chemical principles": After general discussions on poisoning, the fundamentals of the therapy of poisoning,*etc.*,some 200 pages are devoted to "Poisoning by inorganic substances", and the next 305 pages to "Poisoning by organic compounds", including analgesics and antipyretics, as well as "Plastics and resins", soporifics, insecticides, the "principal chemical warfare agents", and vitamins and hormones. This is followed by 60 pages on "Plant poisons and their derivatives", 35 pages on "Analeptics", "Antihistamines", and "Antibiotics", and finally about 50 pages on toadstool poisons and animal venoms. The book closes with a list of "Guiding symptoms in cases of poisoning" (40 pages) and a 34-page subject index.

For each substance the use, the acute and chronic poisoning symptoms (with many of the author's own cases), and the methods of identifying the substance in poisoning cases are described briefly, and in most cases numerous suggested treatments are added.

In the past 15 years, "Moeschlin" has become a "Bible' to many clinicians dealing with cases of poisoning, although this faith is not always justified.

It is of less concern to the reader of this journal that too little space is given to general treatments and too much to antidotes. The chemist is more interested in whether the book will provide him with information about substances that are injurious to health and about the prevention of poisoning by potentially dangerous chemicals. Unfortunately, the first edition contained incorrect information which had been taken directly from compilations by uncritical authors (particularly in connection with occupational diseases), and this information has been included unchanged in subsequent editions. It is impossible in a short review to mention the numerous errors, incorrect chemical data, and doubtful treatments contained in the book, and only a few examples will be given here:

It is generally known nowadays that benzene is a dangerous hemotoxin and that toluene and xylene are not, since alkylbenzenes are rapidly detoxicated by side-chain oxidation. However, *Moeschlin* states on p. 351: "It was *formerly* thought, mainly on the basis of animal experiments, that toluene and xylene are relatively safe for humans.... However, from various observations on similar chronic poisoning phenomena in persons working with pure toluene or xylene and from positive animal experiments, *today* it must be concluded that toluene and xylene are substantially equivalent to benzene in their toxic action". The "recent" literature data included were published in 1929, 1933, 1939, and 1942. Moreover, the author cannot quote a single case of blood damage in humans as a result of working with pure toluene and xylene. It is only too well known that toluene and xylene were formerly often contaminated with benzene. However, according to *Moeschlin*, "only the quantity of these methylated benzenes absorbed is generally rather smaller, owing to their higher boiling point". Chemists will have their own ideas about the hypothesis presented on p. 352, with a structural formula, according to which benzene acts by direct addition to cysteine (*via* an –S– bond), so leading to a marked cysteine deficiency and a secondary cytochrome deficiency

Under Benzene derivatives" (p. 371), the book surprisingly includes naphthalene, naphthol, thymol, and phenolphthalein, which are reported to cause hemolysis and methemoglobin formation, "like aniline and nitrobenzene". Under nitrobenzene (p. 387) and aniline (p. 399), it is not pointed out that methemoglobin formation is promoted by alcohol. In a case of acute dinitrobenzene poisoning (p. 392), on the other hand, one glass of beer six weeks later is reported to cause a relapse. The author's explanation is that the dinitrobenzene "was stored in adipose tissue, and can be remobilized by fat-soluble agents (alcohol)". (The alcohol concentration in the blood after a glass of beer cannot be much more than 0.03 %).

According to *Moeschlin*, the narcotic Halothan® (= fluothane) which can allegedly cause acute yellow dystrophy of the liver, can no longer be used as an anesthetic (p. 338). Substances such as α,β-dichlorodiethyl ether and even ethylene chlorohydrin (p. 344), "should no longer be used in industry in any circumstances". Such statements are somewhat too strong. *Moeschlin* should have protested against the use of benzene and carbon tetrachloride as solvents in the home. Substances such as carbon tetrachloride and methyl bromide are prohibited from use in fire extinguishers (in Germany at least), though *Moeschlin* repeatedly states that they (and even methyl chloride) are used in fire extinguishers, and does not object; he should have demanded a ban in this case.

In the bizarre treatment of "Smog" (pp. 374–277), "18 very toxic nitroolefins" in Los Angeles are confused with the carcinogenic hydrocarbons. Here the author (p. 355) claims that "about 300 to 500 new chemical substances are released for general use every year; in the production of these many by-products are formed, the major part of which passes into the atmosphere".

The new short section on "Plastics and resins" (p. 455) is full of errors. ε-Caprolactam is reported to have a sensitizing action, and the "danger of sensitization is greatest during the manufacture of plastics, and less during use of the finished commercial products".

According to the book, in one place "toluene diisocyanate is not a highly toxic substance", whereas, *e.g.*, it is correctly stated on p. 458 that "isocyanates, *e.g.* Desmodur®, are highly toxic substances, the inhalation of which leads to necrosis of the mucous membranes and possibly to fatal bronchiolitis".

A most surprising section is that on p. 457 dealing with the "Toxic effects of inhalation of liquid particles of plastic into the lungs". With reference to the alleged cases of thesaurosis (= storing-up) due to hair sprays containing polyvinylpyrrolidone (*Bergmann* 1958), *Moeschlin* states: "The inhaled particles solidify in the alveoli of the lungs to form solid particles of plastic, which can only be partly eliminated in the sputum" (polyvinylpyrrolidone is water-soluble). *Moeschlin* is evidently unaware of the fact that most of these "cases" were incorrectly diagnosed (Boeck's morbus). On the contrary, he concludes that "hair sprays containing liquid plastics should be prohibited". (In fact, some of the so-called "cases of thesaurosis" were due to allergic reactions to shellac, *i.e.* a *natural* resin in the hair spray!).

Methyl violet in indelible pencils is claimed to have "a strong toxic action on tissue, owing to its alkaline reaction". The "immediate excision of the injured part" (*e.g.* of the hand) suggested by *Moeschlin* has long been recognised as foolish. On p. 403 the author refers to the "frequent production of keratitis and conjunctivitis by numerous aniline dyes" (references from 1905 and 1906!).

Though any number of such errors could be quoted, the positive points should also be mentioned. An excellent reference list is given at the end of each chapter and, since the various authors are named in the text, the physician can at least check the often doubtful statements about cases of poisoning. Thus the book could be useful if read very critically. In a future edition, the entire contents should be critically sifted and brought up to date by the inclusion of the latest literature, particularly on industrial toxicology.

The author should preferably enlist the aid of a toxicologist who is familiar with chemistry, in order that the deserving work put into the book over the past 15 years may finally enable the clinician, with the aid of this bible, to diagnose, assess, and treat poisoning. *H. Oettel* [NB 564 IE]

Advances in High Pressure Research, Vol. 1. Edited by *R. S. Bradley*, Academic Press, London-New York 1966. 1st Edit., x, 396 pp., numerous figures and tables, 100 s.

Up to 1952, *Bridgman*'s classic "The Physics of High Pressure" was practically the only monograph on basic high pressure research. Since 1960, however, at least twenty specialized works on high pressure have been published, and a series entitled "Advances in High Pressure Research" has now been started. The editor has already been very successful with a two-volume monograph on "High Pressure Physics and Chemistry" published in 1963 by the same publishers. Since high pressure research is mainly defined by the application of certain experimental techniques, contributions from very diverse fields will be expected in such a progress report. This is found even in the first volume, which contains six chapters of some seventy pages each. The authors of these chapters have become well known through their own work in the fields that they describe.

In the first section ("Construction and operation of ultrahigh pressure equipment"), *J. Lees* describes the construction and operation of the "tetrahedral arrangements"; the production and calibration of high pressures is critically discussed.

In the second article, *S. D. Hamann* describes the effects of intense shock waves. A particularly interesting part of this article is the section on the possibility of achieving pressures of millions of atmospheres with the aid of reflected and converging shock waves. In connection with the article by *E. Whalley* on the refractive and the dielectric properties of solids and liquids under pressure, special mention should be made of the discussion of the modifications of ice. *R. C. Newton* describes the state and future of geophysical research with high static pressures. Even the outsider will find the detailed description of the present knowledge of the earth's crust, mantle, and core interesting. "The stability of solids under pressure" is discussed by *M. Tosi* and *A. Arai*. Special mention should be made of the section on the transition from the nonmetallic to the metallic state. The last article, by *L. S. Whatley* and *A. van Valkenburg*, is on high pressure optics. It is mainly confined to the description of the elegant and versatile diamond piston arrangement jointly developed by the authors in the Bureau of Standards for high pressure experiments on a microscopic scale.

The volume can be recommended both to those who are experimenting with high pressures and to those who are interested in recent information on highly compacted matter.

E. U. Franck [NB 591 IE]

The Peptides. Vol. I. By *E. Schröder* and *K. Lübke*. Translated from the German by *E. Gross*. Academic Press, Inc., New York-London. Methods of Peptide Synthesis. 1st Edit. 1965, xvii, 481 pages, several figures, $ 20.00.

All chemists interested in the synthesis of peptides will certainly welcome the publication of this book. The authors, who are known to all experts in this field by virtue of their numerous publications, work in the main laboratory of *Schering AG.*, Berlin. It is therefore only natural that the present volume is intended for the preparative chemist. The references, which are 2719 in number and cover the literature from 1950 to the end of 1964, permit a rapid and almost complete assessment of the methods available to date for the synthesis of peptides.

After a comprehensive discussion of the various protective groups and the methods of coupling peptide bonds, a detailed treatment is given of the behavior of individual amino acids – including some of the rarer ones – in preparative chemistry. The tabular presentation of the most important derivatives of amino acids containing side-chain functional groups deserves special mention.

Shorter sections are devoted to the synthesis of cyclic peptides, depsipeptides, and peptoids. The plastein reaction, solid-phase peptide synthesis, and the problem of racemization are also discussed. A most significant part of the book, 155 pages, contains a bibliography and an index. The occasional misprint in these sections is something that can hardly be avoided. On the other hand, the failure of the authors to adopt the nomenclature recommended by the European Peptide Symposium in 1962 is rather surprising.

Up-to-date tables of synthesized peptides, such as those that *Greenstein* and *Winitz* were able to include in their "Chemistry of the Amino Acids" in 1961, can no longer be expected; such an inclusion would render the book unwieldy. In accord with the subtitle of this first volume, no problems – such as desalting, purification, and analysis – are touched upon which are not directly concerned with the synthesis of peptides.

Printing and presentation of the book are excellent. The volume will, without doubt, soon be found in every peptide and protein laboratory, where it will fill a long-standing gap.

However, the practice of the publishers is regrettable – the book was not available in Germany until the spring of 1966 although it appeared in America on September 30th, 1965.

H. Zahn [Nb 596a]

The Peptides. Vol. II. By *E. Schröder* and *K. Lübke*. Translated from the German by *E. Gross*. Academic Press, Inc., New York-London. Synthesis, Occurrence, and Action of Biologically Active Polypeptides. 1st Edit., 1966, xxvii, 632 pages, several figures, $ 30.00.

A 90-page bibliography with about 2800 entries and a 60-page index mark this volume at first sight as an encyclopedia of biologically active peptides and polypeptides. The literature is almost completely covered up to mid-1965.

The subdivision of the material into linear, heterode cyclic and homode cyclic peptides corresponds to the point of view of the chemist working in synthetic chemistry, for whom this book is primarily intended. The inclusion of biochemical and pharmacological facts is useful, since the biological properties of the peptides discussed are generally the reason for their synthesis in the laboratory.

In the biological parts of the book, the authors can only sum up the relevant literature. However, in the description of syntheses, they offer a critical evaluation based on wide experience. This is particularly useful in the discussion of hormones of which numerous analogues have been synthesized. A number of characteristic synthetic routes are shown in each case, usually with reaction schemes; similar syntheses can then be described simply by reference to changes in the details of the method. Biological activities are generally compared in tables.

While the first volume of the work lacked an introduction to the isolation and purification of peptides, the description of the syntheses in the present volume also include the processes for the purification of many intermediate and final products. This is useful, since these operations are strongly dependent on the nature of the peptide, and cannot be generalized.

The ten chapters of the book cover a wide area of the polypeptide field. From glutathione to insulin and from antibiotics to enzyme sequences, nearly every polypeptide that has a characteristic biological action and whose synthesis could be of some interest is discussed. The reviewer would like to have seen a chapter on polyamino acids and "sequential polypeptides", though the biological actions of these substances lie mainly in the field of immunochemistry. It is naturally difficult to fit in substances whose structures are not yet known. However, these are not ignored, as is so often the case in the literature, but included according to source and pharmacological properties of known substances.

The various chapters of the book are more or less self-contained, and are well written throughout. A book suitable for reading from start to finish cannot be expected, in view of the heterogeneous nature of the subject matter. The second volume of "Peptides" is intended for a specialist readership, to whom it will prove an indispensable aid. The print and presentation are of the same high quality as in the first volume. Each volume is provided with an index and notes on nomenclature, so that the two can be used independently.

H. Zahn [NB 596b IE]

Theory of Elementary Gas Reaction Rates. By *D. L. Bunker*. The International Encyclopedia of Physical Chemistry and Chemical Physics, Topic 19, Vol. 1. Edited by *E. A. Guggenheim, J. E. Mayer*, and *F. C. Tompkins*. Pergamon Press, Oxford-London-Edinburgh-New York-Toronto-Paris-Braunschweig 1966. 1st Edit., xii, 115 pages, 18 figures, 9 tables, 35s.

After a short introduction, the book deals with three simple types of gas reactions: bimolecular exchanges, monomolecular reactions, and dissociation and recombination reactions. An effort is made to interpret the rates of these reactions with the aid of classical mechanics, quantum mechanics, and statistical mechanics. The mathematical treatment has been kept simple, but a study of the book will not be possible without a certain knowledge of theoretical physics. The discussion shows that we are still far from a general understanding of even the simplest reactions. However, it also shows that the introduction of new experimental methods (*e.g.* shock waves, molecular beams) has led to new information that brings us closer to an understanding of the reactions.

In looking through the references, the reviewer experiences a certain sadness, since only four of the 300 references, nearly all of which are very recent, are in German. Has the German language and German science really become so unimportant?

U. Schindewolf [NB 597 IE]

The Proteins: Composition, Structure, and Function. Edited by *H. Neurath*. Vol. IV. Academic Press, New York-London 1966. 2nd Edit., xviii, 508 pages, numerous figures, 35 tables, $ 20.00.

The fourth volume of "The Proteins"[*] contains three chapters. The first chapter, "Genetic Control of Protein Structure" by *Helinski* and *Yanofsky*, deals not only with the genetic control of the primary structure and the influence of mutations on the structure and activity of proteins, but also with the formation of the native conformation and the association of polypeptide chains to form the multimeric enzyme molecule. In the second chapter ("The Basic Structure of Glycoproteins"), *Gottschalk* and *Graham* discuss mainly orosomucoid, ovalbumin, and the submaxillary gland glycoprotein. Two thirds of the volume (303 Pages) are devoted to a description of "The Structure Proteins" by *Seifter* and *Gallop*. This field has recently become rather involved, partly because of the numerous widely scattered and difficultly obtainable publications. The authors have divided the material very clearly, and by examination of more than 1100 publications, they have collected all the important facts. This survey will be welcomed by anyone who wishes to learn more about structure proteins.

The literature is largely covered up to 1965, so that the volume represents the latest situation. The authors, who are well known for their experimental work have maintained the high standard set by the previous volumes.

H. Sund [NB 600 IE]

[*] Cf. Angew. Chem. *78*, 343 (1966); Angew. Chem. internat. Edit. *5*, 327 (1966).

Comprehensive Biochemistry. Vol. 14: Biological Oxidations. Edited by *M. Florkin* and *E. H. Stotz*. Elsevier Publishing Company, Amsterdam-London-New York 1966. 1st Edit., xvi, 512 pp., numerous figures and tables, Dfl. 70.–. / 140s., subsc. Dfl. 56.–. / 112s.

This volume of "Comprehensive Biochemistry"[1] is really gigantic. Ten chapters covering more than 500 pages (this time on thicker and coarser paper than before) deal with electron-transfer processes. The sections were systematically chosen from the vast field of biochemical reaction mechanisms and placed in the hands of specialists who had already proved themselves several times in the writing of such reviews. One consequence of this is that the reviews that have now appeared in numerous handbooks are very similar.

It is the more surprising, therefore, that this volume has taken so long to appear. On closer examination, it is found that a few of the ten chapters were late in being submitted, with the result that the more conscientious contributors are now likely to be blamed for submitting outdated and inadequately checked articles (e.g. photophosphorylation, mitochondrial electron transport system). Other authors had evidently planned the work differently from the outset, and so produced articles that could hardly become outdated in any case (oxy-

genases, catalases). However, as a result of careful selection and concise presentation of the material, these articles are also interesting and informative. The literature is generally fully covered up to 1964, and a few references from 1965 are also included.

The content of the volume ranges from the substrate to oxygen, and even a list of the author's names is enough to show the authority behind the discussions and to assure one that the quality of even the shortest contribution is very high. *S. P. Colowick*, *J. van Eys*, and *J. H. Park* deal at length with the dehydrogenases, with special emphasis on the chemistry, bonding, and mode of reaction of the prosthetic group. This is followed by a discussion of the lipoic acid enzymes (*L. J. Reed*) and their chemistry, function, and structure in the multienzyme complex of the α-ketoacid oxidases. In dealing with the flavoprotein dehydrogenases of the respiratory chain, *T. P. Singer* discusses the diphosphopyridine nucleotide and succinate dehydrogenases, and compares the modes of action of enzymes from different sources. The functional complexes of mitochondrial electron transport (*Y. Hatefi*) include oxidoreductions involving coenzyme Q. *K. Okunuki* describes in detail the isolation and crystallization of cytochromes and cytochrome oxidases from various sources. The functional complex of the mitochondrial electron transport system is described by *D. E. Green*, who concentrates on the function of the mitochondrial membrane, the subunits obtained from it, and their recombination.

The chapter by *E. C. Slater* on oxidative phosphorylation contains less personal color, but is more informative. On the basis of the phenomenon of different P/O ratios, the author discusses the possibility of formation of high-energy bonds, for which neither high-energy carriers nor phosphate intermediates have so far been isolated. Special emphasis is therefore placed on the chemiosmotic theory, which does not depend on such intermediates, and the formation of the pyrophosphate linkage as a result of a pH gradient transverse to the membrane is discussed.

Photosynthetic phosphorylation (*A. W. Frenkel* and *K. Cost*) is to some extent a reversal of oxidative phosphorylation, but the two processes are by no means identical. This electron transfer involves the conversion of light energy into thermochemical pyrophosphate energy. Though the process has been substantially broken down indirectly into unit steps, the intermediates have not yet been identified as chemical species. In all these reactions oxygen is only an indirect substrate; on the other hand, it is directly utilized in the enzymatic activation of oxygen, which is discussed by *L. L. Ingraham*. However this concise article takes into account very little of the work that has been published since 1960. The recent literature is also practically ignored in the article by *A. S. Brill* on the peroxidases and catalases.

Apart from these faults, the book is again a useful broad introduction to an extremely topical sector of biochemistry, and rounds off excellently Section III of the work. The presentation, as usual, is good. However, art paper has been used for the half-tone illustrations, and even the very small diagrams would have been much clearer and easier to follow on smooth paper. It is to be hoped that the later volumes will be of equal quality, but will not take so long to appear.

L. Jaenicke [NB 588 IE]

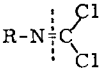
New Methods of Preparative Organic Chemistry IV

Syntheses of Isocyanide Dihalides[**]

BY E. KÜHLE, B. ANDERS, AND G. ZUMACH[*]



The methods for the preparation of isocyanide dihalides, and particularly of isocyanide dichlorides, are described. The scopes and courses of the various processes are critically discussed.

I. Introduction

In contrast to phosgene, thiophosgene, and the isocyanates and isothiocyanates derived from them, only a few of the structurally related isocyanide dihalides and their derivatives have been described in the literature until very recently. Even a recent standard work on organic chemistry [1] contains only a short discussion (without experimental details) of the syntheses of isocyanide dichlorides by the addition of chlorine to isocyanides and by chlorination of isothiocyanates. In recent years, various research groups have published numerous reports, which deal in particular with the chemistry of the isocyanide dichlorides and difluorides. The present article is intended as a review of the known methods for the preparation of isocyanide dihalides.

II. Nomenclature and Classification

The isocyanide dichlorides, which are sometimes also referred to as isonitrile dichlorides, carbylamine dichlorides, dichloromethyleneamines, carbonyl dichloride imide, or iminophosgene, are derivatives of carbonic acid. These special names become understandable on close examination of the isocyanide dichloride molecule.

The right-hand part of the formula shows the relationship with phosgene and thiophosgene, and so explains the name "iminophosgene". The analogy with phosgene and thiophosgene is further accentuated by the fact that the two geminal chlorine atoms can react selectively in succession.

The left-hand part of the above formula expresses the relationship of the isocyanide dichlorides with the isocyanates, isothiocyanates, and carbodiimides, and with certain limitations to the isonitriles. This is particularly emphasized by the fact that isonitriles can be prepared from isocyanide dichlorides; conversely, isocyanide dichlorides can be obtained from isocyanates, isothiocyanates, carbodiimides, and isonitriles.

III. Preparation of Aliphatic and Aromatic Isocyanide Dihalides

None of the many methods for the synthesis of isocyanide dihalides, and particularly of isocyanide dichlorides, is capable of general and unrestricted application. However, the methods are more or less mutually complementary.

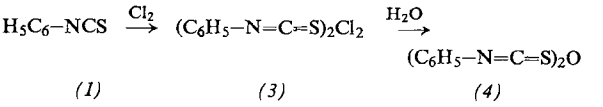
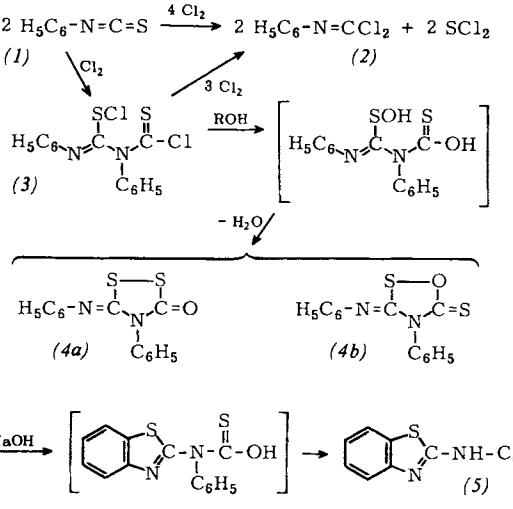
1. Chlorination of Isothiocyanates[2]



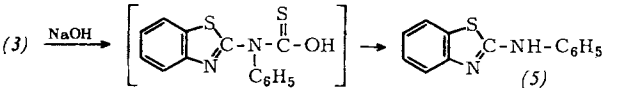
The oldest method for the production of isocyanide dichlorides is the chlorination of isothiocyanates[3], which was discovered almost 100 years ago. Chlorination of phenyl isothiocyanate *(1)* at low temperature in chloroform led to the elimination of sulfur dichloride and formation of phenyl isocyanide dichloride *(2)*.

This reaction, which was subsequently carried out on the industrial scale[4], generally gives yields of more than 90%[5] when the solvent is chloroform, carbon tetrachloride, or carbon disulfide. It can also be carried out in the absence of solvent, but the sulfur dichloride formed must then be removed under mild conditions, *e.g.* by distillation under reduced pressure.

Nef[6] was able to show that the phenyl isocyanide dichloride obtained by *Sell* and *Zierold*[3] also contained a nuclear chlorination product. More recently, *Murphy*[7] obtained 4-chlorophenyl isocyanide dichloride in 61% yield by introduction of an excess of chlorine into a solution of phenyl isothiocyanate. No nuclear chlorination takes place when carbon tetrachloride is used as the solvent.

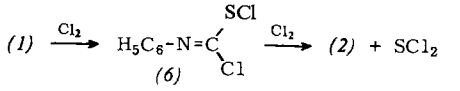


A few years ago, the chlorination of isothiocyanates was extended to the aliphatic and cycloaliphatic series[8], while individual alkyl isocyanide dichlorides had already been synthesized[9]. Yields of 70 to 95% are obtained when the reaction solutions are treated with sodium sulfite/sodium carbonate solution after chlorination, in order to remove interfering by-products containing chlorine and sulfur.

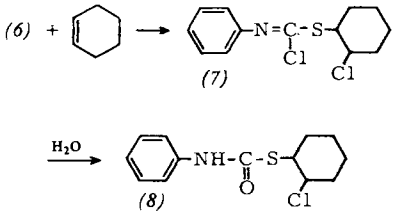


The structure of the intermediates occurring in the chlorination of isothiocyanates was investigated even by early workers. Thus *Sell*[10] isolated from the chlorination products of ethyl isothiocyanate in ether an unstable substance ("chloroethyl isothiocyanate"), which is converted by alkaline hydrolysis into an ethyl isothiocyanate oxide $(C_2H_5NCS)_2O$ having m.p. 42 °C. *Helmers*[11] later investigated the products obtained on partial chlorination of phenyl isothiocyanate *(1)*, and isolated a difficultly soluble, unstable substance *(3)* ("phenyl isothiocyanate monochloride") having m.p. 150–160 °C (decomp.). Treatment of *(3)* with alcohol or warm water gave a compound containing no chlorine and having a m.p. 118 °C, which was mentioned in the literature as "phenyl isothiocyanate oxide" *(4)*[12].

(1) *(3)* *(4)*



Dyson and *Harrington*[13] re-examined problems associated with the chlorination of phenyl isothiocyanate and proposed the following reaction scheme:



We repeated these chlorination experiments, since the constitution given for compound *(3)* seemed very unlikely in view of its poor solubility; furthermore, contrary to the report by *Dyson* and *Harrington*[13], the compound *(3)* could not be further chlorinated to form phenyl isocyanide dichloride *(2)*.

We found that the chlorination of phenyl isothiocyanate *(1)* yields first the primary chlorine adduct *(6)*[14] in a strongly exothermic reaction; further chlorination of *(6)* then leads to the elimination of sulfur dichloride and formation of phenyl isocyanide dichloride *(2)* with no appreciable evolution of heat.

N-(Chloro-chlorothiomethylene)phenylamine *(6)* can be isolated from the products of chlorination below 0 °C, can be destilled under vacuum (b.p. 84–86 °C/0.15 mm Hg), and can be stored for about 8 days under nitrogen. Addition to cyclohexene and hydrolysis of the adduct *(7)* gave *S*-(2-chlorocyclohexyl)-*N*-phenylmonothiocarbamate *(8)*, m.p. 105–106 °C, thus showing that *(6)* is a sulfenyl chloride.

(7) *(8)*

[2] The bromination of phenyl isothiocyanate leads only to bromine adducts, cf. *M. Freund*, Liebigs Ann. Chem. *285*, 154 (1895).

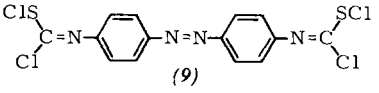
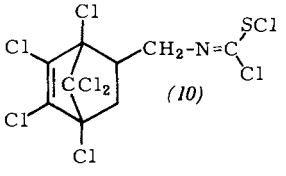
[13] *G. M. Dyson* and *T. Harrington*, J. chem. Soc. (London) *1942*, 150

[14] The formation of a chlorine adduct on chlorination of 2,2-difluoroethyl isothiocyanate was first reported by *N. N. Yarovenko et al.* [9c].

The same conclusion was reached by *Ottmann* and *Hooks jr.*[15], who also isolated *(6)* (yellow oil; $n_D^{24} = 1.6291$) as an intermediate in the chlorination of *(1)*; these authors also characterized the compounds *(6a)* and *(6b)*, m.p. 82–83 °C and 75–75.5 °C, respectively.

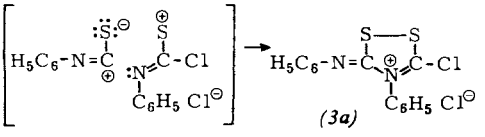


(6a)



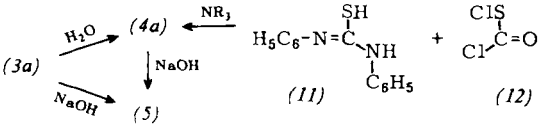
(6b)

Depending on the isothiocyanate used, chlorination under normal conditions does not proceed beyond the chlorine adduct stage. For example, chlorination of 4,4'-bis(isothiocyanato)azobenzene or of hexachlorinated bicyclo[2.2.1]-hept-2-enylmethyl isothiocyanate leads to good yields of the chlorine adducts *(9)* (m.p. 158–160 °C) and *(10)* (undistillable oil), respectively[16].



(9)

(10)

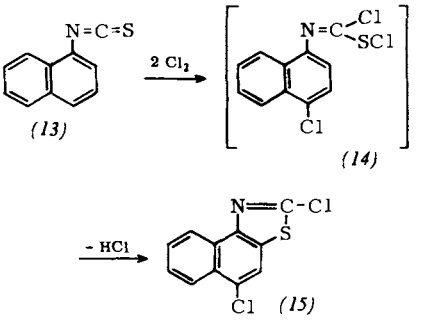


When phenyl isothiocyanate *(1)* in chloroform is added to an equimolar quantity of *N*-(chloro-chlorothiomethylene)phenylamine *(6)*, a difficulty soluble precipitate separates out after a short time. This precipitate is identical in its physical and chemical properties with "phenyl isothiocyanate monochloride" *(3)*, and cannot be further chlorinated. This shows that the difficultly soluble substance is not an intermediate, but a by-product of the chlorination of isothiocyanates; the extent to which it is formed is determined by the reaction conditions. On the basis of its unusual properties (*e.g.* poor solubility in organic solvents) and the results of an independent synthesis carried out by us, we suggest the polar structure *(3a)*[16a].

(1) + *(6)* ⟷

(3a)

The formation of 3-oxo-4-phenyl-5-phenylimino-1,2,4-dithiazolidine *(4a)* on hydrolysis of *(3a)* and the formation of 2-anilinobenzothiazole *(5)*, probably *via (4a)*, on alkaline saponification are now readily explained. The structure *(4a)*[17] has also been confirmed by synthesis from *N,N'*-diphenylthiourea and chlorocarbonylsulfenyl chloride *(12)*[18] in the presence of a tertiary amine.



(3a) *(4a)* *(5)* *(11)* *(12)*

Similar results were obtained in the chlorination of methyl isothiocyanate.

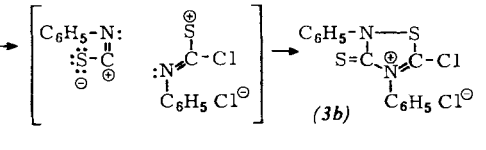
The chlorination of isothiocyanates is not generally applicable for the synthesis of isocyanide dichlorides. Thus 2-nitrophenyl isocyanide dichloride cannot be prepared from 2-nitrophenyl isothiocyanate, since the reaction product decomposes explosively after removal of the solvent (water bath!)[19]. Products containing sulfur are sometimes obtained in the case of ring-chlorinated phenyl isothiocyanates[20].

In the chlorination of 1-naphthyl isothiocyanate *(13)*[21], the chloroadduct *(14)* loses hydrogen chloride with cyclization to form 2,5-dichloronaphtho-[1,2-*d*]thiazole *(15)*. Even "overchlorination" leads, not to the isocyanide dichloride, but to a more highly chlorinated naphthothiazole $C_{11}H_2Cl_5NS$, m.p. 235 °C.

(13) *(14)* *(15)*

On the other hand, isothiocyanates having an ether linkage at the α-position with respect to the nitrogen atom can be chlorinated smoothly and without chlorination in the side chain, *e.g.*

$$CH_3O{-}CH_2{-}NCS \xrightarrow{2\,Cl_2} CH_3O{-}CH_2{-}NCCl_2 + SCl_2\ [8,22].$$



A special case of the chlorination of isothiocyanates was described by *Holtschmidt et al.*[23], who found that the chlorination of benzyl isothiocyanate leads *via* benzyl isocyanide dichloride *(17)*, by side-chain

[15] *G. Ottmann* and *H. Hooks jr.*, Angew. Chem. *77*, 427 (1965); Angew. Chem. internat. Edit. *4*, 432 (1965).

[16] *B. Anders*, unpublished.

[16a] A compound *(3b)* isomeric with *(3a)* would also be possible as follows:

(1) + *(6)* →

(3b)

[17] *(4a)* undergoes ring cleavage with aniline to form *N,N',N''*-triphenylmonothiobiuret.

[18] Chlorocarbonyl sulfenylchloride is formed on hydrolysis of trichloromethylsulfenyl chloride with sulfuric acid. Belg. Pat. 672167 (Nov. 11, 1964), Farbenfabriken Bayer AG, Inv.: *W. Weiss.*

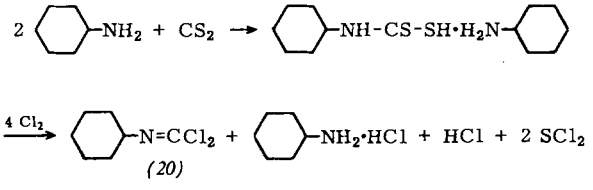
chlorination at 150 to 180 °C in the presence of UV radiation, to 1,1,3,3-tetrachloro-3-phenyl-2-azapropene *(18)* [24].

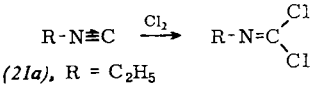
$$H_5C_6{-}CH_2{-}N{=}CS \xrightarrow[-SCl_2]{2\,Cl_2} H_5C_6{-}CH_2{-}N{=}CCl_2 \xrightarrow[-2\,HCl]{2\,Cl_2} H_5C_6{-}CCl_2{-}N{=}CCl_2$$



(16) *(17)* *(18)*

The fact that isothiocyanates are very readily obtainable by oxidation of *N*-monosubstituted dithiocarbamates with phosgene, iodine, or sodium hypochlorite, enabled us to obtain isocyanide dichlorides by single-step oxidation with chlorine and chlorination of dithiocarbamates, *e.g. (19)* [25]:

(19) *(20)*



In a further simplification of this process, isocyanide dichlorides are prepared directly in a single vessel from 2 moles of a primary amine, 1 mole of carbon disulfide, and 4 moles of chlorine. In the case of cyclohexyl isocyanide dichloride *(20)*, the yield was 79% based on the amine used.

(20)

2. Addition of Halogen to Isocyanides

The addition of chlorine to isocyanides was first described in 1892 by *Nef* [26]; the starting compounds he used were ethyl isocyanide *(21a)* and phenyl isocyanide *(21b)*. The addition of bromine had already been reported by *Tscherniak* [27].

(21a), R = C_2H_5
(21b), R = C_6H_5

This straightforward process, which generally proceeds smoothly and almost quantitatively, subsequently attracted very little interest – possibly because of the limited availability of isocyanides. It was only as a result of the work of *Ugi et al.* [28] and other research groups that isocyanides became easily and economically obtainable by "dehydration" of *N*-monosubstituted formamides, *e.g.* with phosgene in the presence of a tertiary base.

The addition of chlorine or bromine to isocyanides takes place even in the cold or at room temperature. The isocyanide is dissolved in an inert organic solvent, one equivalent or a small excess of chlorine or bromine is added, and the reaction is allowed to proceed until the generally characteristic isocyanide odor has disappeared. The addition of chlorine to isocyanides is not a generally applicable process. Thus dodecyl isocyanide and its higher alkyl homologues [29] do not give isocyanide dichlorides on reaction with chlorine, since the principal reaction in these cases is side-chain chlorination.

In the preparation of isocyanates from isocyanides, the addition of halogen is to some extent a catalytic intermediate stage. Thus on addition of 5 mole-% of bromine to an equimolar mixture of isopropyl isocyanide *(23)* and dimethyl sulfoxide *(24)* in boiling chloroform, *Johnson jr.* and *Daughhetee jr.* [30] obtained isopropyl isocyanate *(25)* and dimethyl sulfide *(26)*; in this reaction, bromine is eliminated from the intermediate isocyanide dibromide and added on to free isonitrile. The reaction also proceeds in the presence of chlorine or iodine.

$$(CH_3)_2CH{-}N{\equiv}C + Br_2 + (CH_3)_2SO$$

(23)

$$\rightarrow [(CH_3)_2CH{-}N{=}CBr_2 + (CH_3)_2SO]$$

(24)

$$\rightarrow (CH_3)_2CH{-}N{=}CO + (CH_3)_2S + Br_2$$

(25) *(26)*

Isonitriles containing a tertiary amino group have also been converted into isocyanide dichlorides by the addition of chlorine [31]:

$(CH_3)_2N{-}CH_2{-}CH_2{-}CH_2{-}N{=}CCl_2$
m.p. 130.5–132 °C (hygroscopic), yield 62%

$(C_2H_5)_2N{-}CH_2{-}CH_2{-}CH_2{-}N{=}CCl_2$
m.p. 120–122 °C (hygroscopic), yield 64%

3. Chlorination of Monosubstituted Formanilides in the Presence of Thionyl Chloride

Bly, Perkins, and *Lewis* [5] observed that the chlorination of formanilide in chloroform in the presence of thionyl chloride leads to a mixture of phenyl, 4-chlorophenyl, and 2,4-dichlorophenyl isocyanide dichlorides as well as 2,4-dichloroformanilide. This observation formed the basis of our investigations of the preparation of aromatic isocyanide dichlorides. The results have already been reported in full [32], and we need only give the general reaction scheme here:

[24] This compound was recently also obtained by *R. Neidlein* and *W. Haussmann*, Chem. Ber. *99*, 239 (1966), by reaction of benzoyl isocyanide dichloride with phosphorus pentachloride in boiling chlorobenzene.

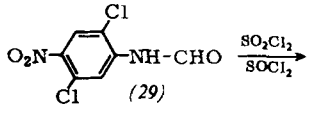
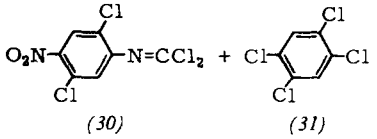
[32] *E. Kühle*, Angew. Chem. *74*, 861 (1962); Angew. Chem. internat. Edit. *1*, 647 (1962).



Contrary to the information given in the literature [5], we use thionyl chloride as the reaction solvent. Not only does this give better yields, but the separation of thionyl chloride from chloroform by distillation, which is particularly troublesome on the industrial scale, becomes unnecessary.

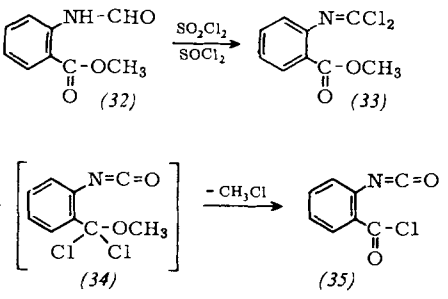
We had already pointed out that very good yields of isocyanide dichloride are always obtained when the aromatic ring can no longer be readily chlorinated, because of substituents (halogen, nitro, carboxyl, aryl residues, *etc.*) already present. Many substituents react with thionyl chloride; thus 4-formylaminobenzoic acid *(27)* gives 4-chlorocarbonylphenyl isocyanide dichloride *(28)*.



(27) *(28)*

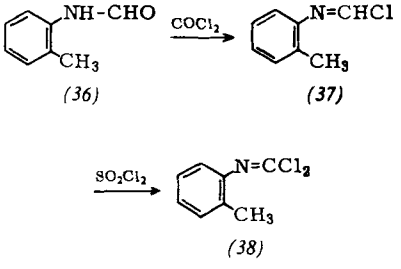
If the aromatic nucleus carries substituents that facilitate aromatic substitution, cyanogen chloride is readily eliminated from the isocyanide dichloride grouping. For example, the reaction of 2,5-dichloro-4-nitroformanilide *(29)* with thionyl chloride/sulfuryl chloride yields not only the desired isocyanide dichloride *(30)*, but also considerable quantities of 1,2,4,5-tetrachlorobenzene *(31)*.

(29)



(30) *(31)*

In one case, we observed intramolecular chlorine/oxygen exchange [33]. Thus when methyl 2-formylaminobenzoate *(32)* reacts with sulfuryl chloride in thionyl chloride, the corresponding isocyanide dichloride *(33)* is obtained as a crude product when the excess thionyl chloride is evaporated off. During the distillation of the crude product, secondary reaction leads to elimination of methyl chloride and chlorine/oxygen exchange, probably *via* the intermediate *(34)*, with formation of 2-chlorocarbonylphenyl isocyanate *(35)* [34].



[33] *E. Kühle* and *E. Klauke*, German Pat. Appl. F 48971 IVb/12 o (April 20, 1966), Farbenfabriken Bayer AG.

[34] This isocyanate cannot be obtained by phosgenation of anthranilic acid, since isatoic anhydride is formed.

(32) *(33)* *(34)* *(35)*

The chlorination of monosubstituted aromatic formamides can, in principle, also be carried out in phosphorus oxide trichloride, phosgene, or oxalyl chloride instead of in thionyl chloride, but the yields of isocyanide dichloride are then much lower. Thus *Sayigh* and *Ulrich* [35] have described the chlorination of 2-tolylformamide *(36)* with phosgene and sulfuryl chloride in dichloroethane, which leads to 2-tolyl isocyanide dichloride *(38)* probably *via* the intermediate *(37)*.

(36) *(37)* *(38)*

We had observed earlier [32] that the use of this process with aliphatic and cycloaliphatic formamides generally leads to isocyanates [36]. However, when *N*-cyclohexylformamide in an excess of thionyl chloride is heated at 40 °C until the evolution of sulfur dioxide stops, the subsequent addition of sulfuryl chloride yields cyclohexyl isocyanide dichloride as the main product in yields of up to about 50%.

In attempts to prepare aromatic isocyanide dibromides from the corresponding formanilides with bromine in thionyl chloride, hydrogen bromide is split off and only the isocyanide dichlorides are obtained. Similar experiments with bromine in thionyl bromide led only to resinification products.

4. Chlorination of Isocyanates with Phosphorus Pentachloride [37]

In contrast to the chlorination of isothiocyanates, isocyanide dichlorides were only recently obtained from isocyanates.

Gumpert [38] had already treated boiling phenyl isocyanate with phosphorus pentachloride but, apart from phosphorus oxide trichloride, only resinous products were isolated from the reaction mixture.

[35] *A. A. R. Sayigh* and *H. Ulrich*, J. chem. Soc. (London) *1963*, 3146.

[36] German Pat. 1090197 (Aug. 19, 1959), Farbenfabriken Bayer AG, Inv.: *E. Kühle*.

[37] The chlorination of phenyl isothiocyanate with phosphorus pentachloride, which leads to phenyl isocyanide dichloride, was carried out by *A. W. Hofmann*, Ber. dtsch. chem. Ges. *12*, 1126 (1879).

[38] *F. Gumpert*, J. prakt. Chem. *31*, 119 (1885).

When an isocyanate is allowed to react with an equimolar quantity of phosphorus pentachloride at 20 to 50 °C in a chlorine-resistant solvent such as chlorobenzene, or in the phosphorus oxide trichloride formed in the reaction, an isocyanide dichloride is obtained in accordance with the following equation:

$$R{-}N{=}C{=}O + PCl_5 \rightarrow RN{=}CCl_2 + POCl_3.$$

This reaction gives moderate to good yields in the lower aliphatic and cycloaliphatic series [39,40], but side-chain chlorination must be expected with long-chain aliphatic isocyanates.

Aromatic isocyanates react with phosphorus pentachloride only above about 100 °C, with elimination of phosgene. Isocyanide dichlorides are formed only in small quantities. According to *Ulrich* and *Sayigh* [41], the main products are carbodiimides, which cannot be detected in the aliphatic and cycloaliphatic series. Thus the reaction of aromatic isocyanates with phosphorus pentachloride probably proceeds in accordance with the following reaction scheme:

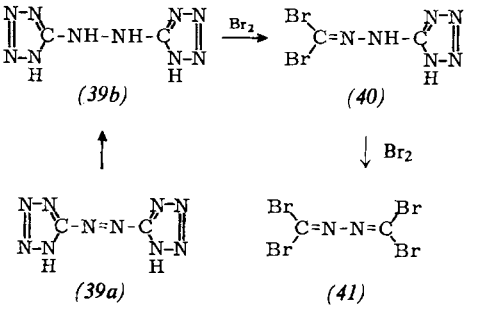
$$Ar{-}N{=}C{=}O + PCl_5 \longrightarrow Ar{-}N{=}CCl_2 + POCl_3$$

$$Ar{-}N{=}CCl_2 + POCl_3 \longrightarrow Ar{-}N{=}PCl_3 + COCl_2$$

$$Ar{-}N{=}C{=}O + Ar{-}N{=}PCl_3 \longrightarrow Ar{-}N{=}C(-O{-}Ar){-}N{-}PCl_3$$

$$\longrightarrow Ar{-}N{=}C{=}N{-}Ar + POCl_3$$

5. High-temperature Chlorination of Tertiary Amines and Acyl Derivatives of Secondary Amines

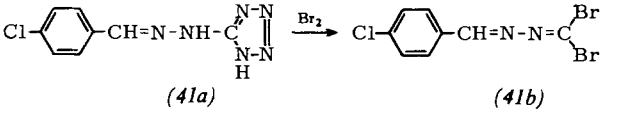


The high-temperature chlorination of tertiary amines, which is accompanied by dealkylation, and the high-temperature chlorination of acyl derivatives of secondary amines, which is accompanied by deacylation, have been described by *Holtschmidt* [42].

6. Special Methods for the Preparation of Individual Isocyanide Dihalides [42a]

The literature contains occasional references to compounds having the isocyanide dihalide structure, but which cannot be prepared by any of the methods described above. Moreover, special methods have recently been reported for the preparation of isocyanide dichlorides. These will be discussed below in chronological order.

a) Diisocyanogen Tetrabromide (Tetrabromoformalazine)



On bromination of hydrazotetrazole *(39b)*, which can be obtained by the reduction of the sodium salt of azotetrazole *(39a)*, *Thiele* [43] obtained diisocyanogen tetrabromide *(41)* [43b] (m.p. 42 °C), which is formed *via* the isolable *N'*-tetrazol-5-yldibromoformaldehyde hydrazone *(40)* (m.p. 177 °C), but which decomposes on storage.

(39b) *(40)* *(39a)* *(41)*

Similarly, the arylidene derivatives of 5-tetrazolylhydrazine react with bromine in aqueous acetic acid to form dibromomethylene compounds [43a].

Thus the 4-chlorobenzylidene derivative *(41a)* gives the dibromomethylene derivative *(41b)* in 80% yield.

(41a) *(41b)*

b) Trichloromethyl Isocyanide Dichloride

Trichloromethyl isocyanide dichloride *(43)* was first prepared by *Prandtl* and *Sennewald* [44] from trichloronitrosomethane *(42)* [45]. Trichloronitrosomethane decomposes on storage, or more rapidly when heated, to form trichloromethyl isocyanide dichloride *(43)*, chloropicrin *(44)*, and nitrosyl chloride in accordance with the following equation:

$$\underset{(42}{3\ Cl_3C{-}NO} \rightarrow \underset{(43)}{Cl_3C{-}N{=}CCl_2} + \underset{(44)}{Cl_3C{-}NO_2} + NOCl$$

[39] The yields are strongly dependent on the quality of the phosphorus pentachloride.

[42a] The "unsubstituted isocyanide dichloride" (*N*-dichloromethyleneamine) which is formed by the addition of hydrogen chloride to cyanogen chloride, was obtained in the form of a salt by *E. Allenstein* and *A. Schmidt*, Chem. Ber. *97*, 1286 (1964).

[43] *J. Thiele*, Ber. dtsch. chem. Ges. *26*, 2645 (1893); Liebigs Ann. Chem. *303*, 57 (1898).

[43a] *F. L. Scott* and *D. A. Cronin*, Chem. and Ind. *1964*, 1757.

[43b] The analogous diisocyanogen tetrafluoride has recently been obtained by *R. A. Mitsch*, J. Heterocyclic Chem. *1*, 59 (1964), together with other products by pyrolysis of difluorodiazirine above 165 °C.

[44] *W. Prandtl* and *K. Sennewald*, Ber. dtsch. chem. Ges. *62*, 1754 (1929).

[45] According to *Holtschmidt* [42], this compound is formed in good yield in the high-temperature chlorination of *N,N*-dimethylcarbamyl chloride.

c) Dichloroformaldoxime (Phosgene Oxime)

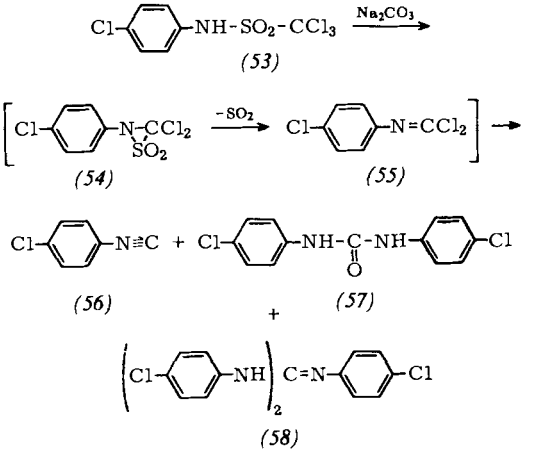
Prandtl and *Sennewald*[44] obtained dichloroformaldoxime *(45)* in 44 to 50% yield by reduction of trichloronitrosomethane *(42)* with hydrogen sulfide or aluminum amalgam; the yield could be increased to 70% by the use of a different reducing agent[46]. Dichloroformaldoxime (m.p. 39–40 °C; b.p. 47 °C/18 mm Hg) cannot be stored for long periods; it has a pungent odor and attacks mucous membranes[47].

$$\underset{(42)}{Cl_3C{-}NO} + H_2S \rightarrow \underset{(45)}{Cl_2C{=}NOH} + HCl + S$$

Dichloroformaldoxime and its bromine and iodine analogues, *(46a)* and *(46b)*, can be obtained in yields of 65 to 85% from mercuric or sodium fulminate[48].

(46a) M.p. 68–69 °C; B.p. 73–75 °C/14 mm

(46b) m.p. 69 °C

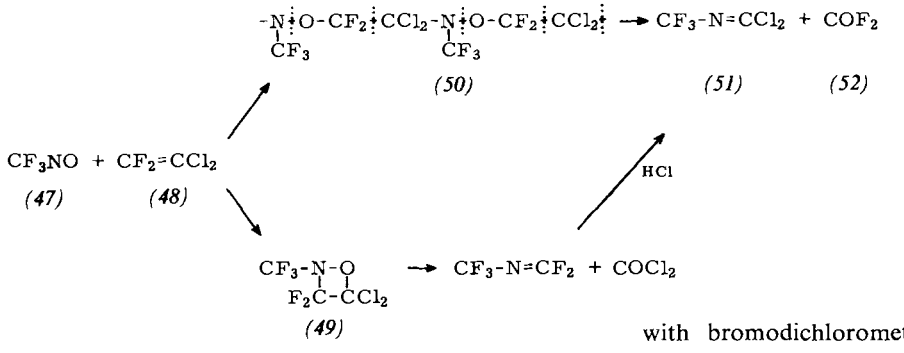


Dichloroformaldoxime can also be prepared by electrolytic reduction of trichloronitromethane in acidic media[49], chlorination of 1-chloro-1-hydroxyiminoacetone (from acetone, nitric acid, and hydrochloric acid)[50], and treatment of chloronitroacetyl chloride with hydrochloric acid[51].

d) Trifluoromethyl Isocyanide Dichloride

Barr, Haszeldine, and *Willis*[52] obtained a mixture of a 1,2-oxazetidine *(49)* and a 1:1 copolymer *(50)* from trifluoronitrosomethane *(47)* and 1,1-dichloro-2,2-difluoroethylene *(48)*; the copolymer decomposes at 550 °C into trifluoromethyl isocyanide dichloride *(51)*[53] and carbonyl difluoride *(52)*, while pyrolysis of the 1,2-oxazetidine (≈ 550 °C) yields trifluoromethyl isocyanide difluoride *(74)* (cf. Section III.7).

e) Alkaline Decomposition of *N*-Trichloromethanesulfonyl-4-chloroaniline



The alkaline hydrolysis (Na_2CO_3 solution) of *N*-trichloromethanesulfonyl-4-chloroaniline *(53)* probably proceeds *via* the three-membered heterocyclic compound *(54)* and 4-chlorophenyl isocyanide dichloride *(55)*, since the isocyanide *(56)*, the urea *(57)*, and the guanidine *(58)*, as well as 4-chloroaniline, could be isolated as reaction products[54].

(53) *(54)* *(55)* *(56)* *(57)* *(58)*

f) Cleavage of Carbodiimides by Dichlorocarbene

A recent publication describes the cleavage of carbodiimides with bromodichloromethylphenylmercury[55]. Thus the reaction of diisopropylcarbodiimide *(59)* with bromodichloromethylphenylmercury *(60)* in a molar ratio of 1:2 in chlorobenzene at 80 °C leads to isopropyl isocyanide dichloride *(61)* in 92% yield.

(47) *(48)* *(49)* *(50)* *(51)* *(52)*

$$\underset{(59)}{(CH_3)_2CH{-}N{=}C{=}N{-}CH(CH_3)_2} + \underset{(60)}{C_6H_5{-}Hg{-}CCl_2Br} \rightarrow \underset{(61)}{(CH_3)_2CH{-}N{=}CCl_2} + C_6H_5HgBr + (CH_3)_2CH{-}N{\equiv}C$$

[46] *W. Prandtl* and *W. Dollfus*, Ber. dtsch. chem. Ges. *65*, 754 (1932).

[47] Gas masks and rubber gloves must be worn when handling this compound.

[48] *L. Birckenbach* and *K. Sennewald*, Liebigs Ann. Chem. *489*, 7 (1931); *G. Endres*, Ber. dtsch. chem. Ges. *65*, 65 (1932).

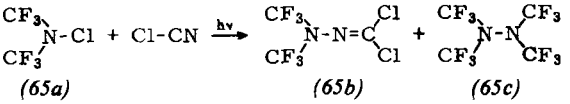
g) Isocyanide Dichlorides by Friedel-Crafts Reaction

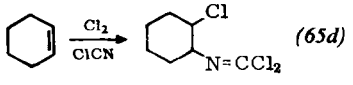
In special cases, isocyanide dichlorides can be obtained from chlorinated isocyanide dichlorides by Friedel-Crafts reactions in the presence of aluminum chloride. Thus the reaction of chloromethyl isocyanide dichloride *(62)* in boiling benzene in the presence of aluminum chloride yields benzyl isocyanide dichloride *(63)* [56].



$$\underset{(62)}{ClCH_2-N{=}CCl_2} \xrightarrow[AlCl_3]{C_6H_6} \underset{(63)}{H_5C_6-CH_2-N{=}CCl_2}$$

Trichloromethyl isocyanide dichloride *(43)* reacts with benzene in the presence of aluminum chloride to form triphenylchloromethane *(65)*, probably by elimination of cyanogen chloride from the intermediate triphenylmethyl isocyanide dichloride *(64)*, which cannot be isolated [57].

$$(43) \xrightarrow[AlCl_3]{C_6H_6} \underset{(64)}{[(C_6H_5)_3C-N{=}CCl_2]} \xrightarrow{-ClCN} \underset{(65)}{(C_6H_5)_3CCl}$$



h) Reactions with Cyanogen Chloride

When a mixture of *N*-chlorobis(trifluoromethyl)amine *(65a)* and cyanogen chloride is irradiated, bis(trifluoromethyl)aminocarbylamine dichloride *(65b)* is formed in a yield of more than 40%, together with tetrakis(trifluoromethyl)hydrazine *(65c)* [57a].

(65a) *(65b)* *(65c)*

Arlt [57b] recently obtained α-chlorinated aliphatic and cycloaliphatic isocyanide dichlorides by the addition of chlorine to olefins in the presence of cyanogen chloride. For example, the chlorination of a solution of cyanogen chloride in cyclohexene at 0–10 °C gives 2-chlorocyclohexyl isocyanide dichloride *(65d)* in a yield of about 50% (b.p. 85 °C/0.8 mm Hg).

i) Hexachlorohexyl Isocyanide Dichloride

The radiation-induced addition of chlorine to phenyl isocyanide dichloride *(2)* leads to hexachlorocyclohexyl isocyanide dichloride *(65e)* [57c].

(65e)

7. Isocyanide Difluorides

Isocyanide difluorides cannot be prepared by the methods described so far. A special isothiocyanate fluorination process [61] has recently been developed but, apart from a few highly fluorinated aliphatic isocyanide difluorides, this class of compounds can generally be obtained only *via* the corresponding isocyanide dichlorides.

a) According to *Petrov* and *Neimyseva* [58], isocyanide dichlorides react with anhydrous hydrogen fluoride in an alternating addition-elimination reaction to form *N*-trifluoromethylamines *(66)*, which yield the isocyanide difluorides *(67)* on treatment with potassium fluoride at 140 to 150 °C in the absence of solvent.

$$\underset{}{R-N{=}CCl_2} \xrightarrow{HF} \underset{(66)}{RNH-CF_3} \xrightarrow{KF} \underset{(67)}{R-N{=}CF_2}$$

b) Aromatic isocyanide dichlorides react with an excess of an alkali-metal fluoride at 150 to 350 °C in a high-boiling inert solvent such as tetramethylene sulfone to form the corresponding isocyanide difluoride, sometimes in very good yields [60,61], *e.g.*

$$H_5C_6-N{=}CCl_2 \xrightarrow[\text{tetramethylene sulfone}]{NaF/200-240\,^\circ C} H_5C_6-N{=}CF_2$$

c) Whereas hydrogen fluoride is not eliminated from *N*-trifluoromethylaniline on reaction with quinoline [59],

$$\underset{(66)}{RNH-CF_3} + ClCO-R' \xrightarrow{N(C_2H_5)_3} \begin{cases} \not\rightarrow\ CF_3-RN-CO-R' & (68) \\ \rightarrow\ (67) + FCO-R' + (C_2H_5)_3N\cdot HCl \end{cases}$$

other *N*-trifluoromethylamines react, even at room temperature, with acyl chlorides in the presence of a strongly basic tertiary amine such as triethylamine.

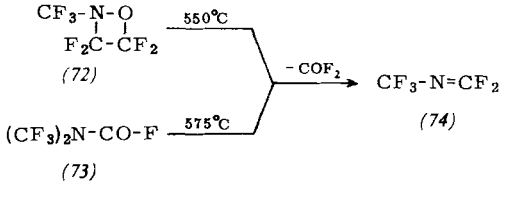
[57c] US-Pat. 3254105 (Feb. 26, 1963), Diamond Alkali Comp., Inv.: *I. Rosen*.

[58] *K. A. Petrov* and *A. A. Neimyseva*, Ž. obšč. Chim. *29*, 2169 (1959); *D. A. Barr* and *R. N. Haszeldine*, J. chem. Soc. (London) 1955, 2532.

[59] *K. A. Petrov* and *A. A. Neimyseva*, Ž. obšč. Chim. *29*, 2695 (1959).

[60] *E. Klauke* and *E. Kühle*, DAS 1235291 (July 29, 1965), Farbenfabriken Bayer AG.

[61] According to *W. A. Sheppard*, J. Amer. chem. Soc. *87*, 4338 (1965), this reaction proceeds best with silver fluoride.



Instead of the expected acylation product *(68)* [62], the reaction yields the corresponding isocyanide difluoride together with the acyl fluoride [63]. Thus, under these conditions, the trifluoromethylamines act as fluorinating agents. As a by-product, this reaction sometimes gives a dimeric isocyanide difluoride, which can also be obtained from pure isocyanide difluoride with a trace of triethylamine, and which is assigned the structure *(69)* on the basis of its reactions [64].

$$2\ (67) \longrightarrow \underset{\underset{F}{|}}{\overset{\overset{|}{}}{R\text{-}N{=}C\text{-}N\text{-}R}}\ \underset{CF_3}{|} \quad (69)$$

d) According to *Sheppard* [61], the reaction of mercuric fluoride with aliphatic and aromatic isothiocyanates is a general method for the preparation of isocyanide difluorides. Whereas the reaction of aryl isothiocyanates leads not only to the desired isocyanide difluoride (yield in the case of phenyl isothiocyanate: 17%) but also to *N*-trifluoromethylaniline and the dimeric isocyanide difluoride, these by-products are not formed in the reaction of alkyl isothiocyanates. Thus ethyl isocyanide difluoride *(71)* is obtained in 37% yield from ethyl isothiocyanate *(70)*.

$$\underset{(70)}{C_2H_5\text{-}N{=}C{=}S} + HgF_2 \rightarrow \underset{(71)}{C_2H_5\text{-}N{=}CF_2} + HgS$$

e) Highly fluorinated lower aliphatic isocyanide difluorides have been obtained by various methods in recent years, generally by pyrolysis reactions. The simplest compound in this series, trifluoromethyl isocyanide difluoride (perfluoro-2-azapropene) *(74)* (b.p. −33.7 °C), is formed quantitatively on pyrolysis of 2-trifluoromethylperfluoro-1,2-oxazetidine *(72)* [65] or of bis(*N*-trifluoromethyl)carbamyl fluoride *(73)* [66] at 550 to 575 °C by elimination of carbonyl difluoride. According to the results of other pyrolysis experiments, *(74)* is obtained only in moderate yields or as a by-product [67].

Compound *(74)* can also be obtained under very mild conditions from bis(*N*-trifluoromethyl)halogenoamines *(75)* (Hal = Cl, Br) and pentacarbonyliron [68].

$$\underset{(75)}{(CF_3)_2NHal} \xrightarrow{Fe(CO)_5} (74)$$

The higher perfluoroalkyl isocyanide difluorides are obtained by pyrolysis of suitable perfluorinated tertiary amines [69], *e.g.*:

$$(C_2F_5)_3N \rightarrow CF_3\text{-}CF_2\text{-}N{=}CF_2;\ \text{b.p. } -18 \text{ to } -13\ ^\circ C$$

IV. Preparation of Acyl Isocyanide Dichlorides

Acyl isocyanide dichlorides are most easily and most smoothly obtained by chlorination of acyl isothiocyanates or their percursors (*e.g.* acylated dithiocarbamates).

The isothiocyanates of carboxylic acids [70] and of phosphorus acids [71] can be readily obtained by treatment of the acid chlorides with lead or alkali metal thiocyanates. An elegant process that proceeds in the homogeneous phase and gives consistently higher yields was described by *Anders* and *Malz* [72]. This process involves the reaction of silyl isothiocyanates [73] with acyl and carbamyl chlorides, esters of chlorocarbonic acid, or any compound of chlorine and phosphorus. In the simplest case, trimethylsilyl isothiocyanate *(77)*, which is readily obtainable from trimethylchlorosilane *(76)* and alkali metal thiocyanate, reacts with an acyl chloride to form the acyl isothiocyanate *(78)*, with regeneration of *(76)*.

$$\underset{(76)}{(CH_3)_3SiCl} \xrightarrow{KSCN} \underset{(77)}{(CH_3)_3Si\text{-}N{=}CS} \xrightarrow{RCOCl} R\text{-}CO\text{-}N{=}CS + \underset{(78)}{(76)}$$

Sulfonyl isothiocyanides cannot be prepared from sulfonyl chlorides, but are readily obtainable from the salts of *N*-sulfonyliminodithiocarbonic acid [74].

The sulfenyl isothiocyanates are as yet unknown, since sulfenyl chlorides react with metal thiocyanates to form sulfenyl thiocyanates [75].

1. Chlorination of Isothiocyanates of Carboxylic Acids

Acyl isothiocyanates *(79)* can generally be readily chlorinated, either in the absence of a solvent or in chloroform or carbon tetrachloride at 0 to 50 °C, in

[62] *N*-Trifluoromethylamides of carboxylic acids can be obtained from *N*-trifluoromethylamines *via* the thiobis-*N*-trifluoromethylamines. *T. E. Stevens*, J. org. Chemistry *26*, 3451 (1961).

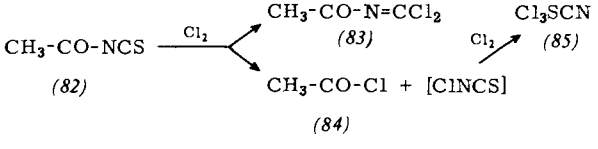
[74] *K. Dickore* and *E. Kühle*, Angew. Chem. *77*, 429 (1965); Angew. Chem. internat. Edit. *4*, 430 (1965); *K. Hartke*, Arch. Pharmaz. *299*, 174 (1966).

[75] Houben-Weyl: Methoden der organischen Chemie. 4th Edit. Georg Thieme Verlag, Stuttgart 1955, Vol. IX, p. 280.

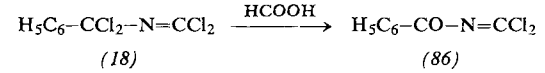


the same way as the aliphatic or aromatic isothiocyanates. $AlCl_3$ or $TiCl_4$ may be used as catalysts [76c].

As with normal isothiocyanates, the reaction proceeds in two steps. An *N*-(chloro-chlorothiomethylene)-carbonamide *(80)* is first formed by addition of chlorine [77]; further chlorination and elimination of sulfur dichloride then yields the acyl isocyanide dichloride

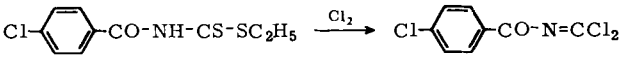
(79) *(80)* *(81)*

(81). In most cases the chlorination proceeds very smoothly; the yield of acyl isocyanide dichloride is about 50 to 95%. Even bisacyl isothiocyanates such as terephthaloyl diisothiocyanate can be converted directly into the bisacyl isocyanide dichlorides. Only the lower aliphatic acyl isothiocyanates give unwanted by-products on chlorination. Thus the chlorination of acetyl isothiocyanate *(82)* gives only a low yield of the desired acetyl isocyanide dichloride *(83)*, the principal products being acetyl chloride *(84)* and thiocyanogen trichloride *(85)*.



(82) *(83)* *(85)* *(84)*

The lower aliphatic acyl isocyanide dichlorides decompose into acyl chlorides and cyanogen chloride on prolonged standing, *e.g.*



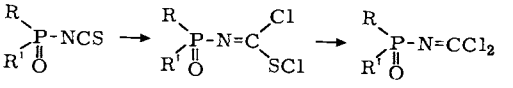
However, acyl isocyanide dichlorides containing longer chains (more than 6 C atoms) or a negative residue (*e.g.* chlorine or chlorophenoxy) are readily obtainable.

Structural evidence of the acyl isocyanide dichloride grouping was obtained by partial hydrolysis of the 1,1,3,3-tetrachloro-3-phenyl-2-azapropene *(18)*, which is formed on further chlorination of benzyl isothiocyanate. Benzoyl isocyanide dichloride *(86)* can be obtained by partial hydrolysis of *(18)* with formic acid [78].

(18) *(86)*

The chlorination of *N*-acylated dithiocarbamates [79] [*e.g. (87)*] was re-examined in a recent study [76e]. In methylene chloride at room temperature, this reaction gives acyl isocyanide dichlorides [*e.g. (88)*] in yields of more than 80%. The same article contains a report on the chlorination of diethyl benzoyliminodithio-

(87) *(88)*



carbonate *(89)* in carbon tetrachloride at 60 °C, which leads to benzoyl isocyanide dichloride *(90)* in 69% yield.

(89) *(90)*

2. Chlorination of Phosphoryl Isothiocyanates

The chlorination of diorganylphosphoryl isothiocyanates *(91)* leads *via* the chlorine adduct [80] *(92)* to the phosphoryl isocyanide dichloride *(93)* [81].

(91) *(92)* *(93)*

This process is very versatile, since the residues R and R′ can be varied, and since phosphoryl compounds containing several chlorine atoms can be converted *via* the phosphoryl di- and tri-isothiocyanates into the corresponding phosphoryl di- and tri-isocyanide dichlorides. Thus phosphoryl tris(isocyanide dichloride) *(95)* (b.p. 83–85 °C/0.08–0.07 mm Hg) is obtained from phosphorus oxide trichloride *via* phosphoryl triisothiocyanate *(94)*.

(94) *(95)*

Alimov and *Levkova* [81b] described dichlorophosphoryl isocyanide dichloride *(97)* (b.p. 83–86 °C/25 mm Hg), which is formed by the reaction of diethoxyphosphoryl isocyanide dichloride *(96)* with phosphorus pentachloride.

(96) *(97)*

3. Sulfonyl Isocyanide Dichlorides by Chlorination of:

a) Sulfonyl Isothiocyanates

The chlorination of sulfonyl isothiocyanates does not proceed as smoothly as that of the isothiocyanates discussed so far. The reaction does not take place at temperatures below 40 to 60 °C; the elimination of sulfur dichloride is also very slow [82]. The intermediate

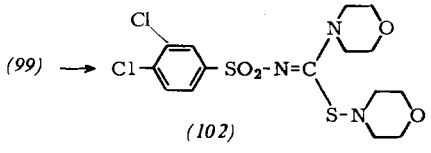
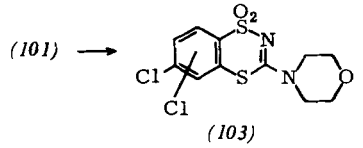
Kirsanov*, *G. I. Derkač*, and *N. J. Liptuga*, Ž. obšč. Chim. *34*, 2812 (1964); d) cf. also *E. S. Kozlov* and *B. S. Drač*, *ibid. 36*, 760 (1966).



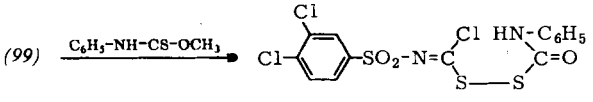
[82] Belg. Pat. 656843 (Dec. 11, 1963), Farbenfabriken Bayer AG, Inv.: *B. Anders*, *E. Kühle*, and *K. Dickoré*.

chlorine adduct sometimes escapes further chlorination in the aromatic ring by cyclization. Thus in the chlorination of 3,4-dichlorobenzenesulfonyl isothiocyanate *(98)*, the compounds *(99)* and *(101)* are formed as intermediates, but only *(99)* can be further chlorinated to form the desired 3,4-dichlorobenzenesulfonyl isocyanide dichloride *(100)*.

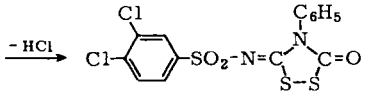


(98) *(99)* *(101)* *(100)*

The constitutions of *(99)* and *(101)* were established by reaction with morpholine; *(99)* reacts with 2 moles and *(101)* with only one mole of the amine to give *N*-(morpholinomorpholinothiomethylene)-3,4-dichlorobenzenesulfonamide *(102)*, m.p. 139 °C, and 3-morpholino-6,?-dichlorobenzo[1,4,2]-dithiazine 1,1-dioxide *(103)*, m.p. 165–167 °C (decomp.), respectively.

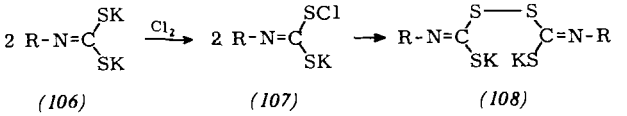


(102)

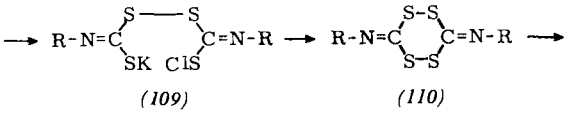


(103)

The compound *(99)* also reacts as a sulfenyl chloride with methyl *N*-phenylthiocarbamate, *via* the disulfide *(104)*, to give 3-(3,4-dichlorobenzenesulfonylimino)-5-oxo-4-phenyl-1,2,4-dithiazolidine *(105)* (m.p. 268 to 269 °C).

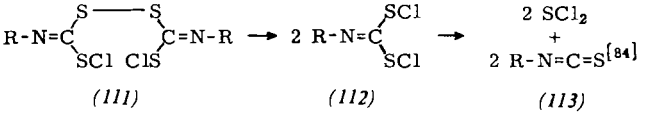


(104)

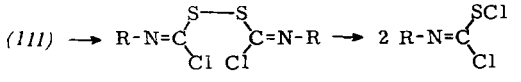


(105)

b) Salts and Esters of Sulfonyliminodithiocarbonic Acids

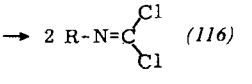


The chlorination of alkali metal salts of sulfonyliminodithiocarbonates *e.g.* in suspension in CCl_4 proceeds much more readily and at lower temperatures than that of the compounds mentioned in Section IV.3.a, with formation of sulfonyl isocyanide dichlorides [82]; furthermore, the number of steps required is one less [83]. Despite the good yields, the reaction appears to be much more complex than the chlorination of isothiocyanates. Thus in the chlorination of potassium dimethylaminosulfonyliminodithiocarbonate *(106)*, we were able to isolate a series of intermediates that suggest the following reaction course.



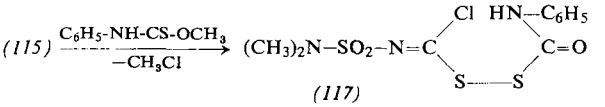
(106) *(107)* *(108)*

(109) *(110)*

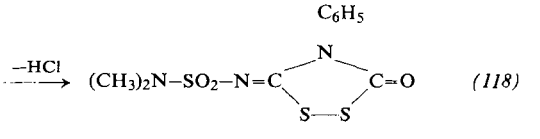


(111) *(112)* *(113)*

(114) *(115)*



M.p. 127–130 °C B.p. 104–105 °C/0.075 mm
R = $(CH_3)_2N-SO_2-$



(116)

M.p. 64 °C

Compound *(115)* reacts as a sulfenyl chloride with methyl *N*-phenylthiocarbamate; elimination of methyl chloride takes place resulting in formation of the disulfide *(117)*, which cyclizes with loss of HCl to give 3-(dimethylaminosulfonylimino)-5-oxo-4-phenyl-1,2,4-dithiazolidine *(118)* (m.p. 189 °C).

(117)

(118)

The dimethyl esters *(119)* obtained by methylation of the sulfonyliminodithiocarbonates give good yields of the sulfonyl isocyanide dichlorides *(120)* on chlorination in boiling carbon tetrachloride [85].

[83] Isothiocyanates can be obtained from the *N*-sulfonyliminodithiocarbonates.

[84] B.p. 47–55 °C/0.09–0.06 mm; cf. *K. Hartke* [74]: B.p. 55–56 °C/0.01 mm.

[85] *R. Neidlein* and *W. Haussmann*, Tetrahedron Letters *1965*, 1753.

$$R-SO_2-N=C(SCH_3)_2 \xrightarrow[-CH_3SCl]{Cl_2} R-SO_2-N=CCl_2$$
(119) *(120)*

Reaction with sulfuryl chloride under the same conditions yields the *N*-sulfonyliminothiocarbonate chloride *(121)* [86].

$$(119) \xrightarrow{SO_2Cl_2} R-SO_2-N=C(SCH_3)(Cl) \quad (121)$$

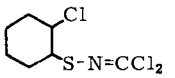
4. Special Acyl Isocyanide Dichlorides

a) Thiocyanogen Trichloride

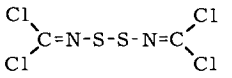
Thiocyanogen trichloride was synthesized by *Kaufmann* and *Liepe* [87] (in 1924) by chlorination of dithiocyanogen in ethyl bromide. This compound was subsequently examined by several groups of workers, who attempted to establish its constitution.

$$(SCN)_2 \xrightarrow{Cl_2} Cl_3SCN$$

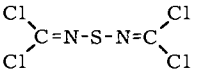
(122a): $ClS-C(Cl)=N-Cl$



(122b): $ClS-N=C(Cl)_2$



According to *Fehér* and *Weber* [88], thiocyanogen trichloride is a 1,2,3-trichlorothiocyanogen *(122a)*. This conclusion was based on the Raman spectrum and on chemical reactions, which, however, involved the sulfur chloride grouping only.



Bacon et al. [89,90] proposed the same structure *(122a)* on the basis of IR measurements and chemical reactions, but pointed out in a footnote (in [90]) that the isomeric *N*-chlorosulfenyl isocyanide dichloride form *(122b)* could not be ruled out. Chemical proof of the structure of thiocyanogen trichloride is difficult to obtain, since the thermally stable compound (b.p. 154–155 °C) splits off cyanogen chloride in most reactions and reacts as sulfur dichloride.

We have also studied thiocyanogen trichloride and, on the basis of its IR spectrum, we favor the structure *(122b)*, since such a structure would account for the characteristic isocyanide dichloride bands at about 900 and 1600 cm^{-1} (cf. also Section V.).

We also investigated the IR spectra of the compounds *(123)* and *(124)*, which are described in the literature and which are obtained from thiocyanogen trichloride [89], as well as the compound *(125)*, which is obtained from thiocyanogen trichloride and cyanogen chloride in the presence of dimethylformamide [91].

(123): 

(124): 

(125): 

The characteristic isocyanide dichloride bands were present in every case [92].

Finally, mention should be made of an elegant process for the production of thiocyanogen trichloride. On chlorination of trimethylsilyl isothiocyanate *(77)*, the weak silicon-nitrogen bond is immediately broken with formation of trimethylchlorosilane *(76)* and chloroisothiocyanate, which cannot be isolated, but which immediately adds on chlorine and rearranges to give chlorosulfenyl isocyanide dichloride *(122b)* [93].

$$(CH_3)_3Si-N=CS \xrightarrow{Cl_2} (CH_3)_3SiCl + [ClN=CS]$$
(77) *(76)*

$$[ClN=CS] \xrightarrow{Cl_2} ClS-CCl=NCl \longrightarrow ClS-N=CCl_2$$
(122a) *(122b)*

b) Addition of Cyanogen Chloride to Acyl Chlorides

Bacon et al. [89] were able to synthesize thiocyanogen trichloride in moderate yields by the addition of cyanogen chloride to sulfur dichloride. A recent Ameri-

$$ClSCl \xrightarrow{ClCN} ClS-N=CCl_2$$
(122b)

can patent [94] describes the addition of cyanogen chloride to sulfur chloride pentafluoride *(126)* on UV irradiation of a mixture of these compounds. Sulfur pentafluoride isocyanide dichloride *(127)* (b.p. 86 to 88 °C) is formed in 38% yield.

$$SF_5Cl \xrightarrow{ClCN} SF_5-N=CCl_2$$
(126) *(127)*

Pawellek [95] recently converted various acyl chlorides into the corresponding acyl isocyanide dichlorides by treatment with cyanogen chloride. Thus the reaction of chloroacetyl chloride *(128)* with cyanogen chloride in a molar ratio of 1:3 at 50 °C gives chloroacetyl isocyanide dichloride *(129)* in a yield of more than 60%.

$$ClCH_2-CO-Cl \xrightarrow{ClCN} ClCH_2-CO-N=CCl_2$$

c) Tetrameric Cyanogen Chloride

Tetrameric cyanogen chloride may be regarded as a special case of the addition of cyanogen chloride. The residue left on distillation of cyanuryl chloride, which is formed by trimerization of cyanogen chloride, contains a compound having the same empirical formula, ClCN; this product is the tetramer. The compound was identified a few years ago as 4,6-dichloro-2-triazinyl isocyanide dichloride *(134)* [96,97]. The tetramerization of cyanogen chloride is best carried out in the presence of hydrogen chloride and dimethylformamide [98].

Japanese workers [99] were able to show that tetrameric cyanogen chloride is not formed from cyanuryl chloride. They therefore proposed a reaction mechanism, in which the first step is the addition of hydrogen chloride to cyanogen chloride to form *(130)*, which dimerizes to give dichloroaminomethyl isocyanide dichloride *(131)*. In the principal reaction, *(131)* reacts with *(130)*, with elimination of HCl, to form cyanuryl chloride *(132)*. Compound *(131)* can also enter into a side reaction in which HCl is split off *via (133)* to yield tetrameric cyanogen chloride *(134)*:

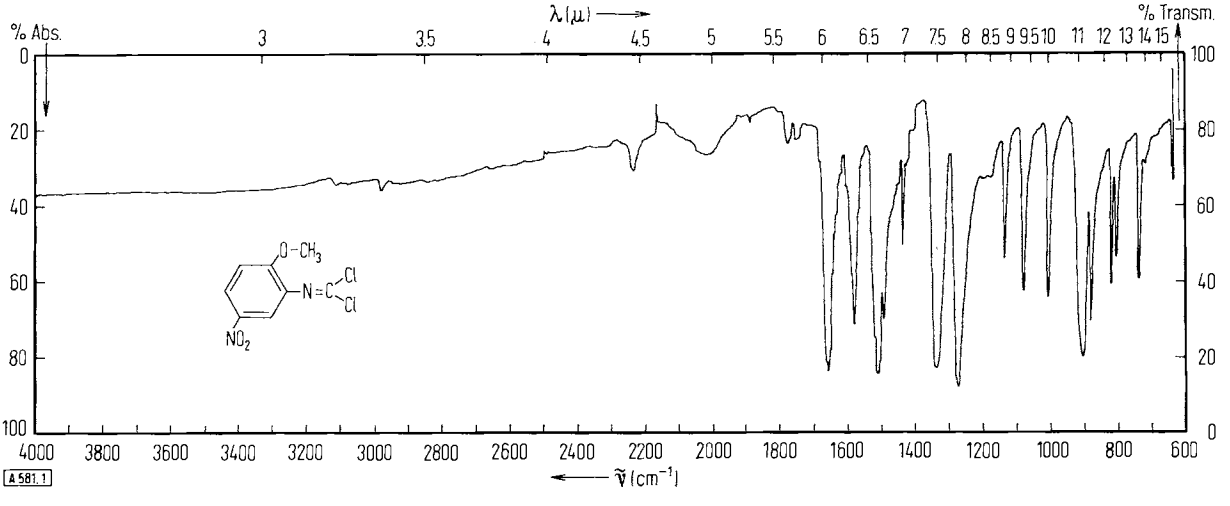
(130) *(131)* *(132)*

(133) *(134)*

d) Chlorocarbonyl Isocyanide Dichloride

According to *Holtschmidt* [42] α-chlorinated isocyanates react as acid chlorides. An interesting special case is that of trichloromethyl isocyanate *(135)*, which is obtained by chlorination of methyl isocyanate, and whose chemical behavior [99a] and IR spectrum (CO band at 1770 cm^{-1}; $N{=}CCl_2$: at 1650 and 925 cm^{-1}) correspond to the structure of *N*-chlorocarbonyl isocyanide dichloride *(136)*.

$$CH_3N{=}CO \xrightarrow{Cl_2} (Cl_3C{-}N{=}CO) \longrightarrow Cl_2C{=}N{-}COCl$$



(135) *(136)*

V. Spectroscopy [100]

In IR spectra of the aliphatic, cycloaliphatic, and aromatic isocyanide dichlorides, the band corresponding to the NC double bond appears at 1645 to 1660 cm^{-1}, while the stretching vibrations of the CCl bonds occur at 850 to 910 cm^{-1}. The NC band for the isocyanide dibromides is situated at 1650 to 1680 cm^{-1}.

Owing to the strong electronegativity of fluorine, the bands for the isocyanide difluorides are displaced to much shorter wavelengths, the NC bands appearing at 1789 to 1790 cm^{-1} and the FC stretching bands at 1260 to 1275 cm^{-1} and 1220 to 1237 cm^{-1}; all the bands are very strong.

The bands for the NC double bond vary considerably between different acyl isocyanide dichlorides, and in the case of the phosphoryl isocyanide dichlorides these bands are actually split.

[96] This compound was identified independently by chemists at J. R. Geigy AG and at Farbenfabriken Bayer AG.

[97] According to *H. Holtschmidt*, tetrameric cyanogen chloride is also very readily obtainable by high-temperature chlorination of 2,4-dichloro-6-dimethylaminotriazine.

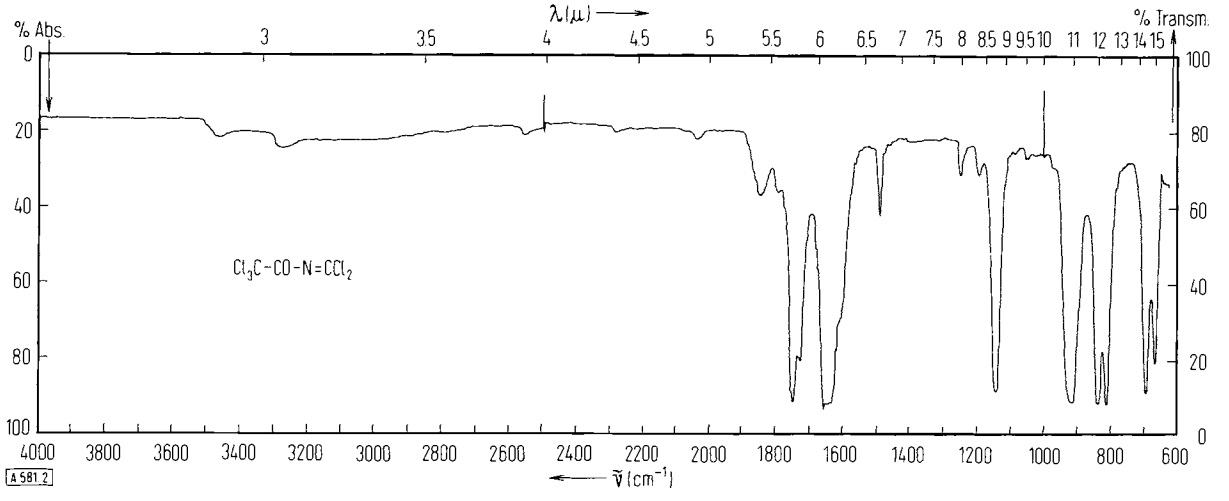
1) Acyl isocyanide dichlorides of

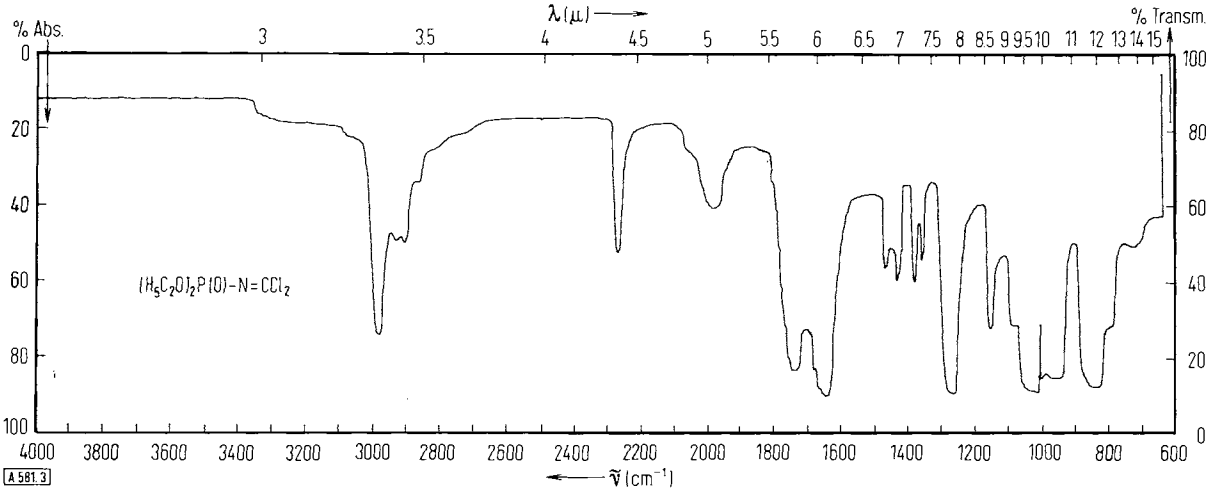
a) aliphatic carboxylic acids:

C=O double bond: 1735 to 1750 cm^{-1}
N=C double bond: 1635 to 1650 cm^{-1}
Cl–C bond: 890 to 930 cm^{-1}

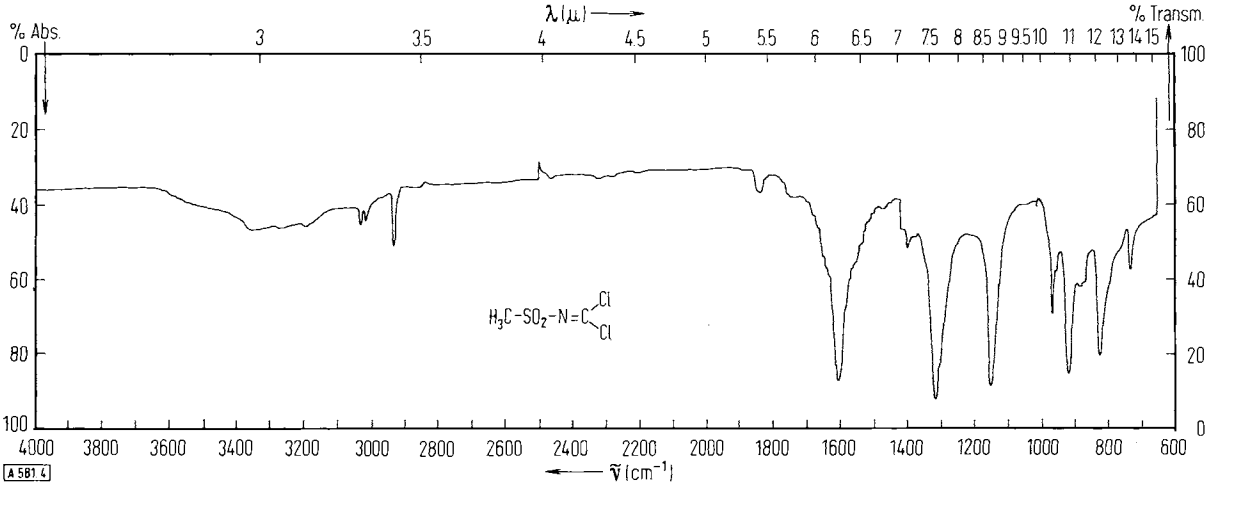
b) aromatic carboxylic acids:



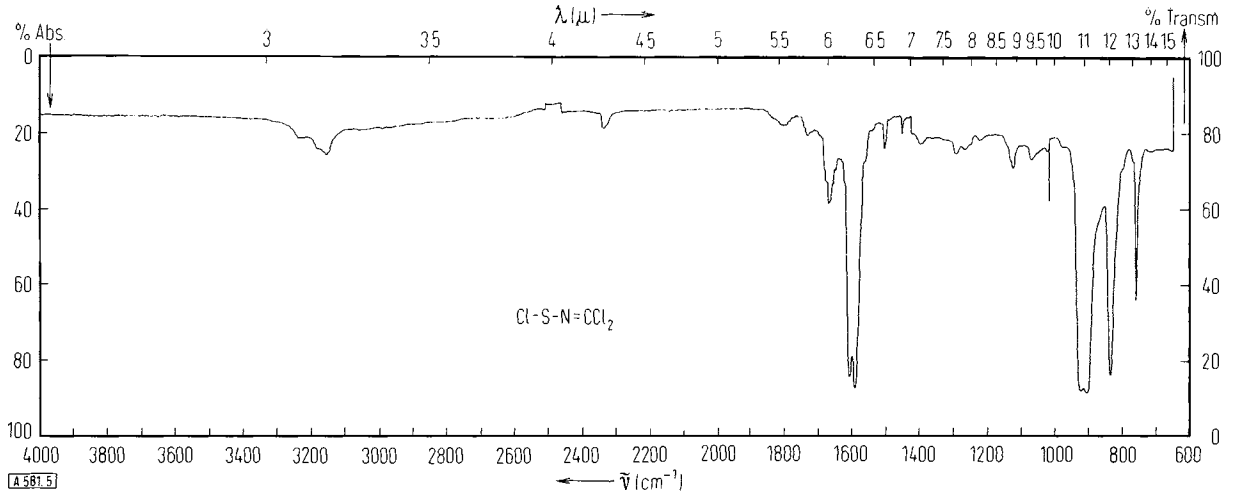
C=O double bond: 1705 to 1722 cm^{-1}
N=C double bond: 1630 to 1640 cm^{-1}
Cl–C bond: 890 to 915 cm^{-1}



2) Phosphoryl isocyanide dichlorides



N=C double bond: 1735 to 1770 cm^{-1} (m);
1640 to 1645 cm^{-1} (s)
Cl–C bond: 840 to 885 cm^{-1}



3) Sulfonyl isocyanide dichlorides

N=C double bond: 1580 to 1610 cm^{-1}
SO_2 group: 1317 to 1360 cm^{-1}
and 1145 to 1175 cm^{-1}
Cl–C bond: 860 to 915 cm^{-1}

4) Sulfenyl isocyanide dichlorides having the structure $-SN=CCl_2$

N=C double bond: 1578–1592 cm^{-1}

Cl–C bond: 895– 915 cm^{-1}

VI. Procedures

1. *Phenyl Isocyanide Dichloride by Chlorination of Phenyl Isothiocyanate*

A solution of 2905 g of phenyl isothiocyanate in 5 l of carbon tetrachloride is introduced into a 10 l three-neck flask fitted with a stirrer, a reflux condenser, a thermometer, and inlet and outlet tubes. The solution is cooled with ice, and 3075 g of chlorine are passed in at 5 to 15 °C. Stirring is continued for one hour; most of the solvent and the sulfur dichloride formed in the reaction are distilled off on a water bath at constant pressure, and the remainder of the solvent is removed under vacuum. The residue is then distilled on an oil bath (bath temperature 120–130 °C) under vacuum. 3622 g (96%) of phenyl isocyanide dichloride, b. p. 83–85 °C/11 mm Hg, is obtained.

2. *Cyclohexyl Isocyanide Dichloride by Chlorination of Cyclohexylamine N-Cyclohexyldithiocarbamate*

198 g of cyclohexylamine is dissolved in 450 ml of carbon tetrachloride, and 90 g of carbon disulfide is added dropwise at 5 to 40 °C, with cooling. The mixture is stirred for 1 h. Stirring is then continued while the excess carbon disulfide is distilled off up to a distillation temperature of 75 °C (about 75 ml of distillate). The reaction mixture is cooled, and a total of 284 g of chlorine is passed in at 10 to 30 °C over a period of 4 hours. Heat is liberated strongly at first, but much less rapidly when evolution of HCl begins. The mixture is stirred for several hours, the precipitated cyclohexylamine hydrochloride is filtered off, and the carbon tetrachloride and sulfur dichloride are evaporated off from the filtrate. The cyclohexyl isocyanide dichloride is distilled under vacuum. Yield: 142 g (79% based on the amine used), b.p. 79–82 °C/13 mm Hg.

3. *t-Butyl Isocyanide Dichloride by Addition of Chlorine to t-Butyl Isocyanide*

15 g of chlorine (a 5% excess) is passed into a solution of 17 g of t-butyl isocyanide in 200 ml of chloroform at 0 to 5 °C, with cooling. When the strongly exothermic reaction is complete, the mixture is stirred for 10 minutes at room temperature, and the solvent is then distilled off. 16 g (52%) of t-butyl isocyanide dichloride, b.p. 129–131 °C, $n_D^{20} = 1.4520$, is obtained.

Table 2. Isocyanide dichlorides (R–N=CCl_2 and $Cl_2C=N-R'-N=CCl_2$) by addition of chlorine to isocyanides.

4. *Phenyl Isocyanide Dibromide by Addition of Bromine to Phenyl Isocyanide*

32 g of bromine is added dropwise to an ice-cooled solution of 21 g of phenyl isocyanide in 150 ml of chloroform at 0 to 5 °C. The mixture is stirred for 10 minutes, the solvent is evaporated off under vacuum, and the residue is distilled. Yield: 40 g (76%) of phenyl isocyanide dibromide, b.p. 76.5—77.5 °C/0.15 mm Hg.

A similar method can be used for the preparation of cyclohexyl isocyanide dibromide, $n_D^{20} = 1.5494$, which decomposes on distillation or on prolonged standing.

5. *4-Chlorophenyl Isocyanide Dichloride by Chlorination of 4-Chloroformanilide in Thionyl Chloride*

67.5 g of sulfuryl chloride is dissolved in 150 ml of thionyl chloride in a 500 ml three-neck flask fitted with a stirrer, thermometer, reflux condenser, and gas outlet tube. 77.5 g of 4-chloroformanilide is added in portions at 15 to 20 °C. The solution is stirred for several hours at room temperature and heated slowly to an internal temperature of 80 °C, HCl and SO_2 escaping continuously. The excess of thionyl chloride, which can be used in further preparations, is distilled off, and the residue is fractionated under vacuum. 89 g (86%) of 4-chlorophenyl isocyanide dichloride is obtained as a pale yellow oil, b.p. 110—113 °C/10 mm Hg.

6. *n-Butyl Isocyanide Dichloride by Chlorination of n-Butyl Isocyanate with Phosphorus Pentachloride*

49 g of n-butyl isocyanate is added dropwise to a suspension of 104 g of phosphorus pentachloride in 80 ml of phosphorus oxide chloride at 55 °C. The mixture is stirred until it becomes clear, the phosphorus oxide chloride is distilled off under vacuum; further distillation yields 38 g (50%) of n-butyl isocyanide dichloride, b.p. 45—45.5 °C/14 mm Hg.

7. *Phenyl Isocyanide Difluoride by Reaction of N-Trifluoromethylaniline with Potassium Fluoride*

8 g of freshly distilled *N*-trifluoromethylaniline and 4.5 g of powdered potassium fluoride (150% excess) are stirred for 5 hours at 140 °C. The reaction product is separated at room temperature from the solid (4.9 g), which is then washed with ether. The washings are combined with the filtrate and distilled under vacuum after removal of the solvent. Redistillation yields phenyl isocyanide difluoride, b.p. 49 °C/12 mm Hg, $n_D^{21.5} = 1.4805$.

8. *Pentachlorophenyl Isocyanide Difluoride by Reaction of Pentachlorophenyl Isocyanide Dichloride with Potassium Fluoride*

A mixture of 143 g of pentachlorophenyl isocyanide dichloride and 174 g of well dried potassium fluoride is heated to 225 °C within 2 hours in a V2A steel vessel fitted with a stirrer and a small column with a descending condenser; in the course of a further hour, the mixture is heated to 320 °C while being stirred vigorously. Pentachlorophenyl isocyanide difluoride ($n_D^{20} = 1.5744$) distils over continuously and crystallizes in the receiver. Yield: 88 g, m.p. 54—58 °C.

Table 4. Isocyanide difluorides (R—N=CF_2) by reaction of aryl isocyanide dichlorides with potassium fluoride.

R	B.p. (°C/mm)	n_D^{20}
Phenyl-	74—78/50	1.4762
4-Tolyl-	72—74/14	1.4771
4-Chlorophenyl-	82—83/15	1.5035
2,5-Dichlorophenyl-	92—95/15	1.5071
2,4,6-Trichlorophenyl-	130—137/23	1.5205

9. *4-Chlorophenyl Isocyanide Difluoride by Reaction of N-Trifluoromethyl-4-chloroaniline with Acetyl Chloride in the Presence of Triethylamine*

195.5 g of *N*-trifluoromethyl-4-chloroaniline and 78 g of acetyl chloride are dissolved in 400 ml of benzene, and 102 g of triethylamine in 100 ml of benzene is added to the solution at 20 to 40 °C with cooling. The mixture is stirred for a time, the triethylamine hydrochloride is filtered off, and the filtrate is evaporated to dryness under vacuum. Double distillation yields 66 g of 4-chlorophenyl isocyanide difluoride, b.p. 62–68 °C/12 mm Hg.

10. *Ethyl Isocyanide Difluoride by Reaction of Ethyl Isothiocyanate with Mercuric Fluoride*

15 g of ethyl isothiocyanate is added dropwise to 96 g of mercuric fluoride that has been heated to 100 °C. The volatile distillate is condensed in a cold trap (dry ice). Distillation yields 4.3 g of ethyl isocyanide difluoride, b.p. 17–18 °C.

11. *Dichloroacetyl Isocyanide Dichloride by Chlorination of Dichloroacetyl Isothiocyanate*

2 ml of titanium tetrachloride is added to 724 g of dichloroacetyl isothiocyanate, and 800 g of chlorine is passed in below 20 °C, with cooling. Subsequent distillation gives, after the sulfur dichloride has been removed, 771 g of dichloroacetyl isocyanide dichloride, b.p. 80–82 °C/15 mm Hg.

Table 5. Acyl isocyanide dichlorides (Ac–N=CCl_2, Cl_2C=N–Ac'–N=CCl_2) by chlorination of acyl isothiocyanates.

12. *Diisopropoxyphosphoryl Isocyanide Dichloride by Chlorination of Diisopropoxyphosphoryl Isothiocyanate*

310 g of chlorine is passed into 283 g of diisopropoxyphosphoryl isothiocyanate over 6 hours at 10–20 °C, with cooling. The low-boiling components are removed in a water-jet vacuum. The residue is then distilled under vacuum. 273.5 g of diisopropoxyphosphoryl isocyanide dichloride, b.p. 81–83 °C/1 mm Hg, is obtained.

Table 6. Phosphoryl isocyanide dichlorides ($(RO)_2PO$–N=CCl_2) by chlorination of phosphoryl isothiocyanates.

Neighboring-Group Effects and Rearrangements in Reactions of Cyclopropylmethyl, Cyclobutyl, and Homoallyl Systems

BY M. HANACK AND H.-J. SCHNEIDER [*]

The neighboring-group effect produced by a double bond in the homoallyl position or by a cyclopropane or cyclobutane ring leads to interesting rearrangements, which are discussed in this paper mainly from the point of view of mechanism, but also from that of preparative work. The question of the postulated non-classical carbonium ions acquires a special significance in this connection.

Introduction

The unusual reactions of cyclopropylmethyl, cyclobutyl, and homoallyl compounds, which are frequently accompanied by rearrangement of one of these systems into another (homoallyl rearrangement), have attracted considerable attention in recent years. While the earlier literature contains only a few observations on these rearrangements [1a], the recent growth of interest in the mechanisms of the reactions of carbonium ions and in the bonding in small rings has led to numerous investigations in this field [1].

The cyclopropylmethyl, cyclobutyl, and homoallyl esters, which can form carbonium ions, are solvolysed 10 to 10^{14} times as rapidly as the open-chain or saturated compounds used for comparison. Moreover, the solvolysis is often accompanied by complete rearrangement. These reactions are therefore particularly good examples of neighboring-group effects. For example, the three-membered ring not only lowers the energy required, so increasing the reaction rate, but also causes modification of the structure by the formation of new bonds. The decrease in energy due to charge delocalization in ionic intermediates that are incapable of resonance led to the assumption that non-classical ions occur [1l,2]. Finally, these rearrangements are also becoming increasingly important in preparative work.

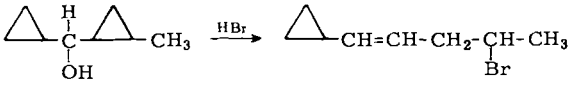
Direction of Rearrangement and Reaction Conditions

The strong influence of the reaction conditions on the direction of the homoallyl rearrangement is due to the difference in the energies of the compounds concerned, which are appreciable in most cases.

In kinetically controlled reactions the ratio of the products depends on their rates of formation, and hence also on the stability and structure of the intermediates. Thus the solvolysis of homoallyl esters *(1)*, X = OSO_2R or Hal, generally leads to the isomeric cyclic systems *(2)* and *(3)*, X = OR', which are about 10 kcal/mole more strained in the ground state, but which are more stable than the open-chain systems as ionic intermediates.



A necessary condition for the rearrangement is the production of a carbonium ion by an S_N1 reaction. For example, homoallyl *p*-toluenesulfonate *(1)*, X = OTs, which tends to undergo S_N2 reactions, gives the rearrangement products *(2)* and *(3)*, X = –O–CH=O, only in the weakly nucleophilic but strongly ionizing (ionizing power Y = 2.1 [1k]) formic acid [3]; for the same reason, less rearrangement is observed on alcoholysis than on acetolysis or hydrolysis [4].

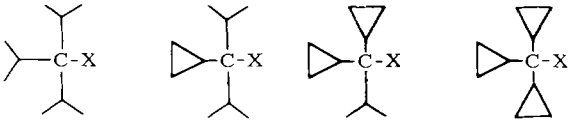
The formation of a carbonium ion by an S_N1 reaction is also possible on deamination of homoallylamines *(1)*, X = NH_2. Nevertheless, the quantity of cyclization products obtained is generally very small; hydride shifts [4,5] take place in addition to retention of structure. As will be shown later, the double bond assists the release of the acid residue during solvolysis, so that the resulting carbonium ion already has the optimum conformation for the subsequent ring closure. On the other hand, the carbonium ion formed by the removal of nitrogen from a diazonium ion probably adopts the thermodynamically more stable extended conformation, which is unfavorable for the rearrangement, and as a "hot" carbonium ion, it can

readily provide the energy required for a hydride shift [6,7].

In thermodynamically controlled rearrangements, the initial products can react again until a reversible equilibrium has been established, as in the reaction if cyclic alcohols *(2)* and *(3)*, X = OH, with strong acids, zinc chloride, thionyl chloride, or phosphorus halides [8–10]. The conversion into the stable, predominantly *trans* homoallyl system is more or less complete, depending on the reaction conditions [11].

When the dicyclopropylcarbinol *(4)* is treated with HBr, the substituted ring is opened [12] to give the homoallyl system *(5)*, whose carbonium ion is particularly strongly stabilized by substituents [13].

(4) *(5)*



The acid-catalysed ring cleavage of cyclopropylcarbinols has been investigated by numerous Russian authors [1a, 14], and has been used in particular by *Julia et al.* in an elegant preparation of open-chain isoprenoids [15].

Kinetic Neighboring-Group Effects

The earliest and most important indication of the formation of non-classical cations from cyclopropylmethyl, cyclobutyl, and homoallyl compounds was given during the determination of the kinetic neighboring-group effect, which is defined as the ratio of the rate of solvolysis of a compound containing a neighboring group to that of a structurally similar compound with no neighboring group [16]. The magnitude of this ratio depends, not only on the substitution and stereochemistry of the system, but also on the solvents used. The neighboring-group effect of a homoallyl sulfonate can be less than 1 in ethanol [4], but about 10^2 in formic acid [7]. This is because the primary effect of the neighboring-group is frequently to displace the reaction mechanism from S_N2 toward S_N1 [17]. This effect can be determined *e.g.* by kinetic measurements in different solvents [18].

The ratio of rate constants $k_{unsaturated}/k_{saturated}$ for unsubstituted homoallyl *p*-toluenesulfonate *(1)*, X = OTs, in formic acid is only 3.7 [7], and so corresponds to an unusually small neighboring-group effect for a homoallyl compound. On the other hand, if there were no neighboring-group effect, the inductive effect of the double bond should slow the reaction by a factor of 10^2 to 10^3 [19].

For the same reason, the cyclopropyl group should have a retarding (not accelerating [20]) effect; however, cyclopropylmethyl *p*-toluenesulfonate is acetolysed $\sim 10^6$ times as rapidly as the comparable isobutyl *p*-toluenesulfonate [21]. The rate of hydrolysis of cyclopropylmethyl chloride *(2)*, X = Cl, is even 40 times as high as that of methylallyl chloride [8]. Even in the presence of sodium alkoxide, the alcoholysis of cyclopropylmethyl benzenesulfonate *(2)*, X = $OSO_2C_6H_5$, is first order, and proceeds without any additional increase in rate [22]. A second and third three-membered ring each make an additional contribution of the same magnitude to the stabilization of the carbonium ion, as was concluded by *Hart et al.* from the increase in the hydrolysis constants of the *p*-nitrobenzoates *(6)* to *(9)* [23].

(6) *(7)* *(8)* *(9)*

$k_{rel.}$ = 1 250 $23{,}5 \times 10^3$ ca. 25×10^6

The ratio of the rate constants for the acetolysis of cyclobutyl and cyclohexyl *p*-toluenesulfonates is 11 [24], and the ratio for the hydrolysis of the chlorides is 40 [25]. On the other hand, from the total strain energy (I strain), one would expect the formation of an sp^2 state with a C–C angle of 120° to be much more difficult for the four-membered than for the six-membered ring [26]. The particularly clear conflict between the reactivity of the cyclobutyl compound and the classical theory also led *H. C. Brown* to postulate a different structure for the carbonium ion in this case [24].

Non-Classical Carbonium Ions

According to classical views, ionic intermediates may be stabilized in two fundamentally different ways. Steric factors can increase the reaction rate, parti-

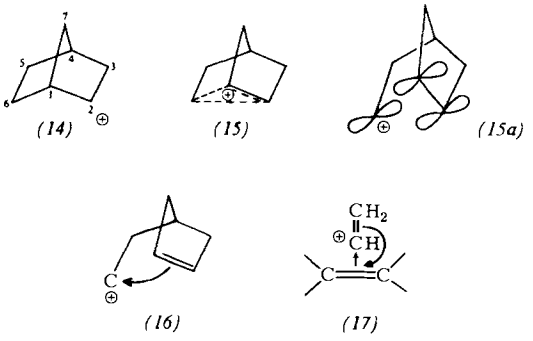
cularly of cyclic compounds, by allowing the total strain energy (I strain)[27] to become large in the ground state and small in the ionic state. The obvious idea of a gain in energy by relief of the high strain in the three-membered ring during the solvolysis of cyclopropylmethyl compounds is refuted, *inter alia*, by the fact that the three-membered ring is generally found to have remained intact in the reaction products[23]. The second classical means of stabilization of carbonium ions is distribution of the charge concentrated on the C atom with the aid of π electrons in the conjugation position. This resonance *(10)* which is characterized by a pure π overlap, is ideally achieved in allyl and benzyl cations and related systems.



Non-classical ions, on the other hand, are relatively stable intermediates, which exhibit charge delocalization involving electron pairs having a high σ character[11] or more distant double bonds that cannot enter into resonance[2,28]. The bonds concerned are partially broken, so that the C atoms can accept part of the charge. This is indicated in the formulae by dotted bonds.

Non-classical carbonium ions have been postulated on the basis of various ideas. Electron acceptors such as protons or metal cations can form stable complexes, not only with lone pairs of electrons on suitable donors (*e.g.* NH_3), but also with the pairs of π electrons in olefins. The covalent bond in such π-complexes, which is distributed over three centers, was represented by *Dewar* as shown in formula *(11)*; the interaction of a carbonium ion with a double bond gives a typical electron-deficient compound, and is represented in a similar manner[29]. The bonding results from the overlap of the bonding π orbitals with the vacant acceptor orbital[30] [*(12)* and *(15a)*][31].

(10) *(11)* *(12)* *(13)*

Winstein and other authors[32] formulated bridged ions *(13)* without invoking double bonds *(13)*, an example being the norbornyl cation[11,21], *(14)* = *(15)*. Ions such as *(14)* can also be formulated as π complexes by formal cleavage at their weakest point to form a double bond suitable for complex formation [*e.g.* C(1)–C(6) in *(14)* → *(16)*]. According to this view, the cyclopropylmethyl, cyclobutyl, and homoallyl cations would contain a vinyl group *(17)* capable of accepting and simultaneously back-donating π electrons[29].

(14) *(15)* *(15a)* *(16)* *(17)*

Walsh has proposed an explanation of the three-center bond that does not involve extensive cleavage of the molecule. According to this explanation, an acceptor can be coordinately bound, not only by free pairs of electrons, but also by pairs of bonding electrons, though only on condition that the bond formed by these electrons is weak[33]. For example, the weak B–H bond interacts with the p orbital of a second boron atom to give a filled molecular orbital linking the three atoms B,H,B, in the boron hydrides[33]. Apart from the system involving π electrons, the non-classical ions described so far all have one or more weakened C–C bond close to the carbonium ion (cyclopropylmethyl, cyclobutyl, 2-norbornyl, and cyclobutylmethyl cations). These bonds can make their electrons available to the carbonium ion for the formation of a coordinate multicenter bond *(13)*. The non-classical ions would thus provide the connection observed in many systems between an increase in reaction rate and a tendency toward isomerization.

On the basis of the high rates of reaction and rearrangement in a number of Wagner-Meerwein rearrangements, *Ingold* and *Hughes* postulated the formation of a type of non-classical ion, which is described as a "synartetic" ion *(13)*[34]. This is a carbonium ion (which is isoelectronic with a boron atom) that is not stabilized in any other way than by entering into an energy-reducing interaction with the σ electrons of a C–C bond. This interaction removes the energy barrier between the classical ions and permits "resonance"[34,36] between them, as was also suggested by *Winstein*[35]. The concept of non-classical carbonium ions has been definitely rejected by some authors. The concepts developed by *H. C. Brown et al.*[28] are, in essence, opposed to the participation of σ bonds in the ionization. The rearrangements of systems having the structure *(14)* are explained by means of rapid equilibria between classical cations in which kinetics, and composition of product, are controlled by steric effects.

Homoallyl Resonance and Bicyclobutonium Ions

The i-steroid rearrangement[1d], which has been known for some time, is stereospecific in that only the 3β-cholesteryl derivatives *(18)* cyclize to give 6β-cyclocholestanyl derivatives *(19)*, while no 3α compounds[1d] are formed on solvolysis. *Winstein et al.* found that the cyclopropylmethyl system *(19)*, X = Cl, is solvolysed $10^{7.4}$ times as rapidly as the homoallyl system *(18)*, X = Cl; the hydrolysis of *(19)* is only about 10 times as fast as that of the stereoisomeric 6α product, despite the less favorable position of the

three-membered ring with respect to the leaving substituent in the latter case [37]. *Winstein* interprets the rearrangements and its kinetics on the basis of a common non-classical intermediate *(22)*, in which the charge is delocalized by "homoallyl resonance" *(20)* ↔ *(21)* [38].

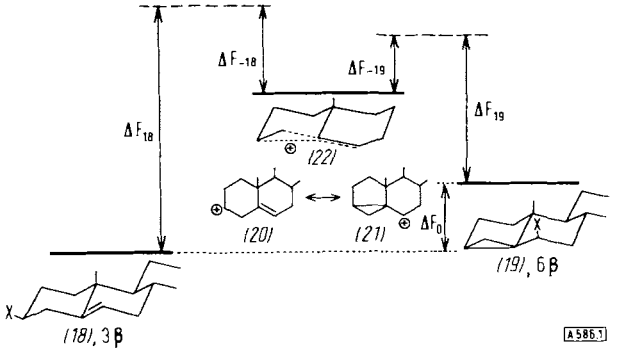

Fig. 1. Homoallyl resonance in the i-steroid rearrangement.

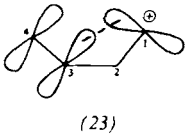
It can be deduced from Figure 1 that

$$\Delta F_0 = RT \ln K = (\Delta F_{18} - \Delta F_{19}) - (\Delta F_{-18} - \Delta F_{-19})$$



or

$$K = [(18), X = Cl]/[(19), X = Cl] = R \times P$$

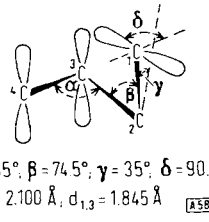
where R is the ratio of the rate constants $k_{(18),\ X=Cl}/k_{(19),\ X=Cl}$ and P is the ratio of the products [*(19)*, X = OH]/[*(18)*, X = OH] after hydrolysis. (However, a similar relationship can be deduced if several ionic intermediates are postulated (see p. 670).) The calculated difference between the strain energies of *(19)* and of *(18)*, $\Delta F_0 = 9$ kcal/mole, shows the importance of the energy of the ground state in the kinetics and direction of homoallyl rearrangements [37].

According to *Winstein* and *Simonetta*, the mixed π, σ overlap [31] of the vacant p orbital with the first double-bond orbital in the homoallyl cation *(23)* should result in an energy gain of 6 kcal/mole [38a]. The principle of such calculations involves the estimation of the delocalization energies (DE) and strain energies (SE) for several positions of the atoms by an LCAO–MO procedure. The arrangement in which the difference (DE–SE) is greatest is the most probable arrangement; the greatest difference (DE–SE) is thus the most probable energy gain.

However, *Dewar* and *Coulson* [29] have pointed out that since the different repulsive forces between electrons and between nuclei are disregarded, a single MO calculation of geometrically different systems is practically impossible.

(23)

Nevertheless, mention should be made of the recalculation of the homoallyl cation *(23)* by the same method by *Roberts* and *Howden*. This calculation gave a (DE–SE) value of only 2.8 kcal/mole for simple 1,3 overlap, but 11.4 kcal/mole when a 1,4 interaction was also taken into account. The optimum geometry of the cation is shown in Fig. 2 [38b].



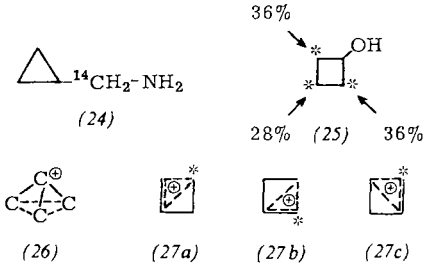


Fig. 2. Geometry of the bicyclobutonium ion [38b].

A structure in which both a 1,3 and a 1,4 interaction are assumed is the bicyclobutonium ion postulated by *Roberts*. On solvolysis and deamination of simple homoallyl, cyclopropylmethyl, and cyclobutyl derivatives, the reaction products were repeatedly found to occur in the same ratio [8]. This observation together with the fact that the reaction of labeled compounds resulted in substantial migration of the isotope [39], led to the assumption that all the isomers give the same ionic intermediate. The reaction of [α-^{14}C]-cyclopropylmethylamine *(24)* gave a non-uniform distribution of the ^{14}C, see *(25)* [40]; this rules out the possibility of the fully symmetrical intermediate *(26)* (tricyclobutonium ion) [39]. On the other hand, this ^{14}C distribution and many substituent effects would be compatible with the existence of three pyramidal bicyclobutonium ions *(27a)* to *(27c)*, which are converted rapidly, but at different rates, into one another [40]. Each bicyclobutonium ion yields cyclopropylmethyl, cyclobutyl, and homoallyl products, which differ only in the position of the ^{14}C atom.

Bisected Cyclopropylmethyl Ions and Isomeric Carbonium Ions

While the kinetic behavior of the compounds discussed gives a clear indication of the formation of non-classical ions, the structure and number of these intermediates can be deduced only from a series of further observations, some of which contradict the bicyclobutonium ion model.

In non-classical structures such as *(13)* and *(27)*, substitution can take place only from the unbridged side, and will therefore be stereospecific. However, the rearrangement of cyclic homoallyl compounds does not yield sterically uniform products [17,41]. The racemization that accompanies the

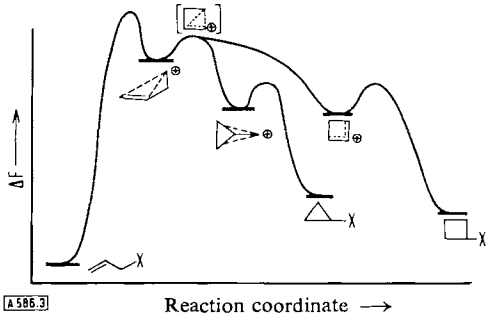
solvolysis of optically active cyclopropylmethyl derivatives [42] and the fact that the rates of racemization and of solvolysis are the same [43] show that the solvent can attack from both sides of the cyclopropylmethyl cation.

A product expected on the basis of a common bridged intermediate may not be formed if a carbonium ion corresponding to the product is particularly unstable [17].

Methyl groups on cyclopropylmethyl *p*-nitrobenzoates increase the rate of hydrolysis, even when they are attached to the C atom that is uncharged in the bicyclobutonium ions *(27a)* to *(27c)*. This means that the charge must in fact be delocalized over all the C atoms [44].

According to the models discussed so far, the dissociation products of the homoallyl, cyclopropylmethyl, and cyclobutyl compounds are identical; the common intermediate means, not only ease of isomerization, but also a decrease in the ionization energies of all the compounds involved, owing to the delocalization of the charge. However, many homoallyl compounds exhibit little or no kinetic neighboring-group effect, though they undergo substantial cyclization. Conversely, it is often found that the very systems that do not rearrange have very high rates of solvolysis.

Hanack and *Schneider* explained these observations by assuming separate but rapidly isomerizing carbonium ions [17]. Accordingly, for example, a homoallyl ester dissociates relatively slowly to give the homoallyl cation, in which there is generally little delocalization. Owing to its high energy content, this cation quickly isomerizes into the cyclopropylmethyl and cyclobutyl cations, which experience greater non-classical stabilization.



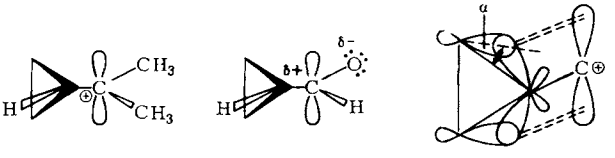


Fig. 3. Energy relationships in the solvolysis of homoallyl esters.

Thus in the solvolysis of homoallyl esters, the composition of the product depends on the relative stabilities of the isomeric ions; however, it also depends on the rates of substitution of the ions by the solvent and on the ratio of the isomerization energy to the substitution energy (Fig. 3). The rearrangement of an ion, the rate of which depends on the energy of the non-classically stabilized transition state (bicyclobutonium ion), competes with substitution by the solvent. The various activation energies can also be deduced mathematically. The relationship obtained is similar to that presented on p. 669 [17, 45].

The elucidation of the structure of cyclopropylmethyl carbonium ions was aided in particular by the direct investigation of the ionic intermediates obtained, according to *Olah* [46,47] and *Deno* [48], by reaction of the alcohols with strong acids in solution at low temperatures. The tricyclopropylcarbinyl cation corresponding to *(9)* is even formed in weaker acid than is required for the triphenylcarbinyl cation [49], which has been known for some time. The UV spectra of the tricyclopropylcarbinyl and cyclopropyldimethylcarbinyl cations show conjugation with the three-membered ring (λ_{max} = 270 mμ, ε = 22000 [49] or λ_{max} = 289 mμ, ε = 10800 [47]), whereas the t-butyl cation shows practically no absorption above 200 mμ [50].

The NMR spectra of cyclopropylmethyl cations impressively demonstrate the delocalization of the positive charge over all the C atoms: the 2 to 3 ppm shift of the α-proton signal of the three-membered ring toward lower fields could, in certain circumstances, be due to the inductive effect of the positive charge, but this could not explain the larger shift of the β-proton signals [46,47,51]. The position of the $C^{\oplus}$–H signal is displaced by the positive charge to τ = −3.5 in the isopropyl cation, to τ = 0.2 in the diphenylmethyl cation, but only to τ = 1.9 in the dicyclopropyl cation, since the charge in the last case is distributed over other atoms [47]. The signal due to the methyl protons in the cyclopropyldimethylcarbinyl cation *(28)* differ by 0.54 ppm, indicating [47] that the methyl groups occupy different positions in a fixed bisected form *(28)* [48].

(28) *(29)* *(30)*

The fact that a bisected form is a necessary condition for conjugation is also clear, *inter alia*, from the NMR [47] and UV spectra [1f,52,53] of cyclopropyl ketones *(29)*, olefins, and nitriles, as well as from the kinetics of the solvolysis of *p*-cyclopropylbenzyl systems [54].

The homoallyl carbonium salts obtained by reaction of 1-butenyl or 2-pentenyl bromides with $AgBF_4$ in nitromethane or methylene chloride rearrange immediately, even at low temperatures, to give the three-

and four-membered ring systems. The more stable cyclopropylmethyl and cyclobutyl cations, on the other hand, isomerize much more slowly, as can be seen by hydrolysis of the carbonium salts after various times [55].

The non-classical interaction in cyclopropylmethyl carbonium ions depends on the fact that the vacant $C^{\oplus}$ orbital is parallel to the plane of the three-membered ring [1f]. The published theoretical studies on cyclopropane, in which a wide range of methods was used, all agree that the C–C bonds have a considerable p component in the plane of the ring. *Walsh* formulated cyclopropane as a combination of three trigonal sp^2-hybridized C atoms in which the 2p orbitals are situated parallel to one another in one plane [56]. *Coulson* carried out complicated VB calculations [57] and simpler calculations using the principle of maximum overlap [58], according to which cyclopropane is most stable when the atomic orbitals that form the C–C bonds are $\alpha = 22$ to 24° outside the C–C axis, cf. *(30)*. The hybridization parameters show a particularly small amount of s character. Calculation of the C–C bonds in cyclopropane by the MO method gave an angle of $\alpha = 21$ to 25°, and a higher p component for the atomic orbitals of the carbon [59].

The charge delocalization in the cyclobutyl cation is probably also due to the ring strain. Both VB [57] and MO calculations [59] indicate that the C–C orbitals are situated 5 to 10° outside the ring, and that they have a p character intermediate between that of the three-membered ring and that of the strain-free bonds.

Simple Substituted Homoallyl, Cyclopropylmethyl, and Cyclobutyl Compounds

The composition of the solvolysis products and the kinetic neighboring-group effect of the double bond have been particularly intensively studied for aliphatic homoallyl compounds. It can be seen from Table 1 that the neighboring-group effect $k_{unsaturated}/k_{saturated}$ (see p. 667) is influenced not only by the solvent used, but also by the substituent on the double bond. Whereas the ratio $k_{unsaturated}/k_{saturated}$ for ethanolysis is smaller than, or only slightly greater than 1, considerably higher rates of solvolysis are found for the homoallyl compounds in less nucleophilic solvents (acetic acid, formic acid) [4,7]. The neighboring-group effect increases with the number of substituents on the double bond (Table 1).

Table 1. Kinetic neighboring-group effects in the solvolysis of homoallyl sulfonates.

The UV spectra of alkyl-substituted olefins show that the strength of the electrostatic bonding of the π electrons decreases with the number of alkyl groups [60] (red shift). As can be seen from Fig. 4, an approximately linear relationship exists between the ionization energies of olefins [61], found spectroscopically and by electron or photon impact methods, and the logarithm of the solvolysis constants (which are proportional to the activation energy) of corresponding homoallyl compounds in S_N1 reactions [62].

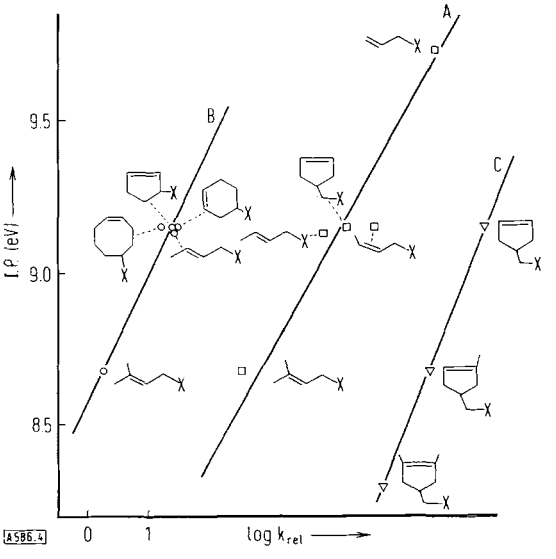

Fig. 4. Relationship between rate of solvolysis (k_{rel}) and the spectroscopically determined ionization potential (IP).

A: formolyses, X = OTs (after [7]); B: acetolyses, X = OTs (after [1a]); C: acetolyses, X = *p*-$NO_2C_6H_4SO_3$ – [k_{rel} calculated from data given by *P. D. Bartlett* and *G. D. Sargent*, J. Amer. chem. Soc. *87*, 1297 (1965)].

A similar relationship is found for cyclic homoallyl compounds and other compounds which solvolyse with participation of a double bond (B and C in Fig. 4.).

Under the conditions of a kinetically controlled S_N1 reaction, the substituted homoallyl systems listed in Table 1 are solvolysed exclusively to cyclopropyl derivatives formed from more stable carbonium ions [4]. Special mention should again be made of the difference in the compositions of the solvolysis products and of the products formed on deamination of appropriate homoallylamines (see p. 666) [4,6].

If the alkyl group is situated in position 3 on the double bond *(31)*, the reaction leads exclusively

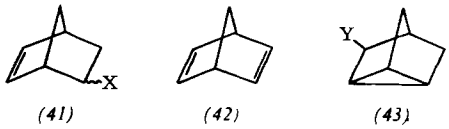
(31) (32) (33) (34) (35) (36) (37)

to rearrangement into the cyclobutane compound *(35)* [7,63].

In the solvolysis and in the deamination of simple substituted cyclopropylmethyl and cyclobutyl compounds, one isomer again predominates in the product. Compounds *(32)* and *(34)* [21] give *(33)*, whereas *(35)* and *(37)* give *(36)* [63,64]. An explanation for this [6,63] is that the positive charge in the bicyclobutonium ions [cf. *(27a)* to *(27c)*] is concentrated on the substituted C atom.

Cyclopropylmethyl compounds having the structure *(38)*, R = CH_3, X = NH_2, rearrange during deamination, mainly with formation of *(36)*, R = CH_3, Y = OH [6]. On the other hand, hydrolysis of 2-vinylcyclopropylmethyl *p*-toluenesulfonate *(38)*, R = $-CH=CH_2$, X = OTs is accompanied by a cleavage of the three-membered ring and formation of *(39)* and *(40)*. This ring cleavage, which has not been observed in any other kinetically controlled reactions, is explained by the high stability of the allyl cation corresponding to *(39)* and *(40)* [65].



(38) (39) (40)

Cyclopropylmethyl derivatives having the structure *(37)*, R = CH_3 or C_6H_5, X = p-CO_2-C_6H_4-NO_2, as esters of secondary alcohols, are solvolysed particularly rapidly [66], whereas tertiary cyclobutyl esters *(32)* react at roughly the same rate as the corresponding t-butyl esters [63]. This indicates that the ionization of *(37)* proceeds *via* a non-classical intermediate, and that of *(32)* *via* a classical intermediate. The presence of the strongly electronegative CF_3 group in *(35)*, R = CF_3, X = OTs, and *(37)*, R = CF_3, X = OTs, directs the hydrolysis both toward *(35)*, R = CF_3, X = OH, and *(38)*, R = CF_3, X = OH, and toward the corresponding homoallyl alcohol (4-trifluoromethyl-3-buten-1-ol) [67].

The rearrangements of cyclic homoallyl compounds and of bicyclic cyclopropylmethyl and cyclobutyl compounds are particularly interesting, since they provide a further insight into the mechanism of the rearrangements. As can be deduced from considerations of models and from the rules of conformational analysis, the geometry of the compounds taking part in the rearrangements is partly fixed in such a way that the ability of the orbitals involved to overlap is considerably altered (see p. 669), with the result that both the direction of the rearrangement and the kinetics are affected. The same arguments apply to the carbonium ion formed during the rearrangement, whose tendency to be formed depends both on the possibility of delocalization of the positive charge and on the strain in the system formed (see p. 669). As was mentioned earlier, a stereochemically, uniform reaction course is of the utmost importance to the assumption that non-classical bridged ions are involved [1,2] (see p. 669). The stereochemistry of the homoallyl rearrangement has become known only by the study of cyclic compounds.

Rearrangements of Bicyclic Homoallyl Compounds

The influence of strain on the direction of rearrangement can be illustrated by the example of a bicyclic homoallyl compound. The solvolysis of 2-norbornenyl derivatives *(41)* leads to nortricyclyl derivatives *(43)* [11,68–70] not only under the conditions of a kinetically controlled reaction, but also (in contrast to the examples discussed so far) in thermodynamically controlled reactions. Thus the reaction of bicycloheptadienes [71–73] *(42)* or norborneols *(41)*, X = OH, with acids (HCl, $HCl/ZnCl_2$, HF) leads to rearrangement and formation of *(43)*, X = Cl or F [70,74]. *Schleyer* showed by the position of the equilibrium between norbornene and nortricyclene, that the cyclo-

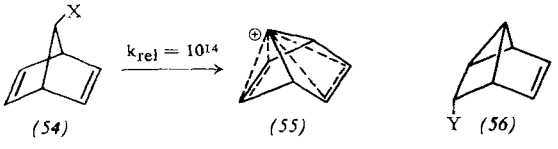
propane systems *(43)* are more stable than their homoallyl isomers *(41)*, both as the carbonium ions and as the final products, owing to their tricyclic structure [75].

Though both *exo*- *(44)* and *endo*-norbornyl derivatives *(47)* rearrange during solvolysis to give the nortricyclyl system *(43)* for the reasons given above [68, 69], a characteristic difference is found in the rates of solvolysis, owing to the different positions of the substituents in relation to the double bond. 2-*exo*-Norbornenyl *p*-toluenesulfonate *(44)*, X = OTs, acetolyses at almost the same rate as the saturated 2-*exo*-norbornyl *p*-toluenesulfonate [69, 76], since the arrangement of the orbitals of *(45)* favors overlap. On the other hand, the *endo*-compound *(47)*, X = OTs, reacts more slowly than the saturated comparison system, owing to the less favorable arrangement *(48)*.



The higher rate of solvolysis of *(44)* and the distribution of ^{14}C between positions 2 and 3 in the products obtained on acetolysis of [2-^{14}C]- or [3-^{14}C]-2-norbornenyl sulfonates point to the formation of the non-classical cation *(46a)* [68]. Since the ^{14}C is also found in positions 1 and 7 after solvolysis with the weakly nucleophilic formic acid, secondary formation of the symmetrical ion *(46b)* from *(46a)* is assumed to take place [69, 76a]. On the other hand, the acetolysis of 3-*cis*-deuterio-2-*exo*-norbornenyl brosylate also yields 7-deuterated acetate, pointing to primary formation of *(46b)* or to the establishment of an equilibrium *(46a)* ⇌ *(46c)* [77].

The 7-*anti*-norbornenyl system satisfies the steric requirements for a substantial σ overlap (see p. 669). Consequently, 7-*anti*-norbornenyl derivatives *(49)*, X = OTs or Cl, are solvolysed 10^{11} times as rapidly as the corresponding 7-norbornyl compounds in acetic acid [78, 79]. NMR-spectroscopic investigation of the ion *(50)* showed that the charge is located mainly on C-5 and C-6, and less on C-7 [80, 81].

7-*syn*-Norbornenyl *p*-toluenesulfonate *(52)* is also solvolysed 10^4 times as rapidly as the saturated system. Since the position of the vacant orbital in relation to the double bond is unfavorable for overlap, the high rate of solvolysis is assumed to be due to the energetically favorable formation of the allyl cation *(53)* [82]. The introduction of a second double bond *(54)*, X = Cl, leads to a further increase in the rate of solvolysis [83, 84]. Ionization leads to *(55)*, which is assigned an asymmetric form on the basis of the NMR spectrum of a solution of 7-norbornadienyl tetrafluoroborate in liquid SO_2 [81, 85].

The systems *(49)* and *(54)*, which are particularly favorable for charge delocalization, do not rearrange into the tricyclic derivatives *(51)* and *(56)* on solvolysis under the conditions indicated. However, *(51)* and *(56)*, Y = H, can be obtained by reaction of *(49)*, X = OTs [86], or *(54)*, X = OTs or Cl [86, 87], with $NaBH_4$ or $LiAlH_4$. Methanolysis of *(49)*, X = OTs or Cl, and *(54)*, X = Cl, yields the tricyclic *endo*-methyl ethers *(51)*, Y = OCH_3, and *(56)*, Y = OCH_3, if the strongly nucleophilic sodium methoxide is used in excess [80, 88, 89].

Kinetic studies and analysis of the products have also revealed neighboring-group effects in other bicycloheptyl systems having a double bond in the homoallyl position with respect to the C atom carrying the functional group [1a]. The 7-isopropylidene-2-*endo*-norbornyl system *(57)* satisfies the stereoelectronic requirements for the formation of a non-classical ion *(58)*; the acetolysis rate constant is therefore much higher than that of *endo*-2-norbornyl *p*-toluenesulfonate, and the reaction proceeds with retention of configuration. The same is true of the 2-*exo* system *(59)*, since delocalization involving the second double bond is possible in this case with formation of *(60)*. In *(61)*, on the other hand, overlap with π-electron orbitals is geometrically impossible, so that the solvolysis of this compound is practically no faster than that of *exo*-2-

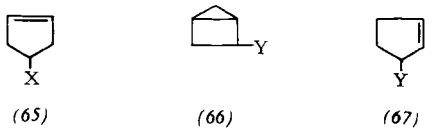
norbornyl *p*-toluenesulfonate, and leads to the product *(62)* of a Wagner-Meerwein rearrangement, such as would be expected from a 2-norbornyl system; *(63)* reacts similarly to give *(64)* [90].

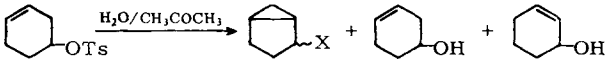
(57) *(58)* *(59)* *(60)* *(61)* *(62)* *(63)* *(64)*



Kinetic neighboring-group effects and homoallyl rearrangements have also been observed with bicyclo[2.2.2]octenyl and bicyclo[3.2.1]octenyl compounds [1a]. The resulting tricyclic cyclopropane derivatives have a low thermodynamic stability. Reports on the other related systems have also been published [1a].

Rearrangements of Monocyclic Homoallyl Compounds

The dependence of the neighboring-group effect on stereochemistry and on the strain in the systems can be seen even in simple cyclic homoallyl compounds and in the cyclopropylmethyl and cyclobutyl derivatives obtained from them.



The lowest homologue of the 3-cycloalkene series, *i.e.* the 3-cyclopentene system *(65)*, does not undergo a homoallyl rearrangement to form the bicyclo[2.1.0]-pentyl system *(66)*. The absence of a neighboring-group effect of the double bond, which is due to the planar conformation of the cyclopentene ring, is also indicated by the low rate of solvolysis of *(65)*, X = Br or β-naphthylsulfonate (ONs), in comparison with corresponding cyclopentyl derivatives [62,91]. The investigation of various 3-cyclopentenyl derivatives *(65)*, X = Br, OTs, or ONs, showed that solvolysis leads mainly to 2-cyclopentenyl compounds *(67)* [62,92].

Since the position of the double bond in relation to the positive charge is unfavorable for overlap of the orbitals, the ion is stabilized by hydride shift. However, on solvolysis with complex anions, *e.g.* in the reaction of 3-cyclopentenyl *p*-toluenesulfonate *(65)*, X = OTs, with $LiAlH_4$ or $NaBH_4$, a small quantity of an unstable intermediate can also be intercepted in the form of bicyclopentane *(66)*, Y = H [92].

(65) *(66)* *(67)*

The 3-cyclohexenyl carbonium ion can assume a conformation close to the homoallyl resonance model (see p. 669), so that the rearrangement should be facilitated. *Hanack et al.* not only found that the rate of acetolysis of 3-cyclohexenyl *p*-toluenesulfonate *(68)* was higher than that of cyclohexyl *p*-toluenesulfonate, but also isolated the expected bicyclo[3.1.0]hexyl compounds *(69)* on acetolysis and hydrolysis [41,93].

(68) 7% cis + 8% trans *(69)* 70% *(70)* 15% *(71)*

The dependence of the three-membered ring-carbonium ion interaction on the spatial position of the three-membered ring is not very pronounced in the bicyclo[3.1.0]hexyl derivatives *(69)*. *cis*-Bicyclo[3.1.0]hex-2-yl *p*-nitrobenzoate *(69)*, X = *p*-NO_2–$C_6H_4CO_2$, is hydrolysed only 1.5 times as rapidly as the *trans* isomer [94], and both of these compounds also hydrolysed only slightly more slowly than methylcyclopropylcarbinyl *p*-nitrobenzoate *(37)*, R = CH_3, X = *p*-$NO_2C_6H_4CO_2$, which can assume the optimum conformation for a neighboring-group effect of the three-membered ring [66]. The hydrolysis of *(69)* is not stereospecific, but yields a mixture of *cis*- and *trans*-bicyclo[3.1.0]hexan-2-ol [94].

Because of their greater conformational mobility, 3-cycloheptenyl *(75)*, *n* = 3, and 3-cyclooctenyl derivatives *(75)*, *n* = 4, can attain almost completely the geometry required for homoallyl resonance (see p. 669). As was shown by *Cope et al.* [95], derivatives of these systems are solvolysed much more rapidly than corresponding cyclohexyl compounds, and the solvolysis is accompanied by extensive rearrangement into the *cis-trans*-isomeric bicyclic derivatives *(74)*.

2-Cycloalkenylmethyl compounds with small rings do not undergo the homoallyl rearrangement. Thus neither 2,3-diphenyl-2-cyclopropenylmethyl *(72)* [96] nor 2-cyclobutenylmethyl *p*-toluenesulfonate [97] *(73)*, *n* = 1, X = OTS, rearranges to give the corresponding bicyclic compound; the main products are those formed by ring expansion, as is shown *e.g.* by the formation of the isomeric cyclopentenols *(75)*, *n* = 1, Y = OH, and

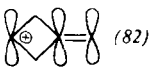
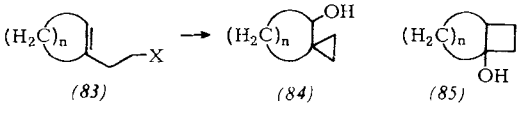
(76), $n = 1$, Y = OH, on hydrolysis of *(73)*, $n = 1$, X = OTs. The rate of acetolysis of cyclobutenylmethyl *p*-toluenesulfonate, which is lower by a factor of 3 than that of cyclobutylmethyl *p*-toluenesulfonate [97], can again be explained by the unfavorable position of the C atom carrying the functional group in relation to the double bond.

(72) *(73)* *(74)* *(75)* *(76)*



A further increase in ring size in the 2-cycloalkenylmethyl system *(73)* allows the homoallyl rearrangement to predominate over ring expansion. 2-Cyclopentenylmethyl derivatives *(73)*, $n = 2$, X = OTs or NH_2, rearrange on solvolysis or deamination into the stereoisomeric bicyclo[3.1.0]hexyl compounds *(74)*, $n = 2$. The 3-cyclohexenyl derivatives are obtained – particularly in weakly nucleophilic solvents [17]. The neighboring-group effect of the double bond in the more mobile systems *(73)*, with $n = 2$, is also reflected in the kinetics; *(73)*, $n = 2$, X = ONs, is acetolysed 10 times as rapidly as the saturated cyclopentylmethyl naphthylsulfonate [17].

In methylenecyclohexylcarbinyl *p*-toluenesulfonate *(77)*, the C atom carrying the functional group can assume the axial position, so that the steric requirements for a homoallyl rearrangement are satisfied. The hydrolysis of *(77)* leads not only to *(78)* but also to *(79)*, which is formed from the bicyclo[4.2.0]octyl cation corresponding to *(78)* by isomerization into the spirooctyl cation corresponding to *(79)* [18]. Another product is assigned the structure *(80)*. To explain the formation of this product, it is assumed that the homoallyl rearrangement is accompanied by ring expansion to form the ion *(81)*, which then rearranges into the bicyclo[4.1.1.] system *(80)*.



(77) *(78)* *(79)* *(80)* *(81)*

3-Methylenecycloalkyl derivatives, which lead directly to the carbonium ion *(81)*, have not so far been studied very extensively. It can be seen particularly clearly in the case of the 3-methylenecyclobutyl cation *(82)* that the reactivity of a homoallyl compound is determined by the positions of the p orbitals of the double bond and of the vacant orbital of the carbonium ion. Since these are parallel in *(82)*, σ overlap is impossible. Accordingly, the solvolysis of 3-methylenecyclobutyl bromide is slower by a factor of 160 than that of 3-butenyl bromide, and the deamination of 3-methylenecyclobutylamine proceeds without rearrangement [98].

(82)

The 1-cycloalkenylethyl derivatives *(83)*, which are influenced only slightly by steric effects, are examples of the few cases in which cyclopropane and cyclobutane compounds are formed simultaneously. As was shown by *Hanack* and *Schneider* [99], it is possible in this way to obtain both spirocyclopropane derivatives *(84)* and condensed cyclobutane derivatives *(85)* in good yields. The rearrangement of homoallyl compounds, which has so far been studied mainly from the point of view of mechanism, is also of preparative importance in this case. The hydrolysis of 1-cyclohexenylethyl *p*-toluenesulfonate *(83)*, $n = 4$, X = OTs, gives spiro[2.4]octan-1-ol *(84)*, $n = 4$, in 50 % yield, and deamination of *(83)*, $n = 4$, X = NH_2, leads by acid-catalysed secondary rearrangement of *(84)*, $n = 4$, to a 50 % yield of bicyclo[4.2.0]octan-1-ol *(85)*, $n = 4$.

(83) *(84)* *(85)*

In addition to 1-cyclopentenylethyl derivatives [99, 100], corresponding medium-sized rings were also subjected to this rearrangement; spiro compounds and bicyclic compounds containing four-membered rings, some of which had previously been known only as hydrocarbons, were obtained [101].

Condensed Cyclopropylmethyl and Cyclobutyl Compounds

These systems, which have been studied mainly by *Wiberg* and his co-workers, show particularly clearly that the formation of a non-classical cation is dependent on certain structural and steric conditions. Acetolysis of *exo*-bicyclo[2.2.0]hex-2-yl *p*-toluenesulfonate *(86)*, $n = 2$, does not lead to rearrangement into the cyclopropylmethyl system, as is expected of a cyclobutyl compound; on the contrary, the main products isolated are *exo*-bicyclo[2.1.1]hexyl derivatives *(87)*, X = OTs or OAc [102, 103]. The rigid planar

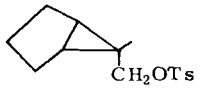
fusion of the two four-membered rings prevents the formation of a bicyclobutonium ion. Similarly, the isomeric compound *(88)*, $n = 2$, which is acetolysed to *(89)* without rearrangement, cannot react *via* this ion. The slightly higher rate of solvolysis of *(88)* in comparison with cyclopropylmethyl *p*-toluenesulfonate leads to the conclusion that stabilization of the carbonium ion by the cyclopropane ring is also possible in this system.

(86)



(87)

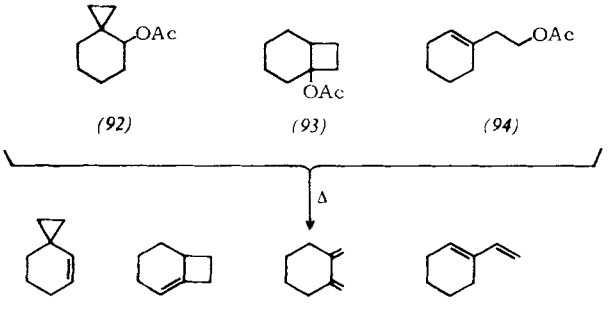
(89)

(90)



(91)

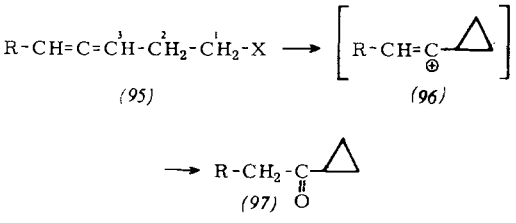
exo- and *endo*-Bicyclo[3.1.0]hex-6-ylmethyl *p*-toluenesulfonate *(88)*, $n = 3$, and *(90)* are acetolysed at approximately the same rate, but give different products [103]. While the *exo-p*-toluenesulfonate *(88)*, $n = 3$, gives the same products as the *exo-p*-toluenesulfonate *(86)*, $n = 3$ [104], the *endo* isomer *(90)* cannot form the same bicyclobutonium ion as *(91)*. Consequently, acetolysis of *(90)* and of *(91)* leads to different products.

Rearrangements during Pyrolysis

The rearrangements of cyclopropylmethyl, cyclobutyl, and homoallyl systems into one another have so far been considered only in connection with typical carbonium ion reactions such as solvolysis or deamination. However, they have recently also been observed

(92) *(93)* *(94)*

in the pyrolysis of esters having the structures *(92)*, *(93)*, and *(94)* [105], which give not only the olefins of the same structure, but also isomeric hydrocarbons.



These products, as well as the pyrolysis kinetics [105], show that the pyrolysis of esters can also proceed *via* an ionic mechanism if the formation of a carbonium ion is facilitated by neighboring-group effect or by steric effects *(e.g.* in tertiary esters). The strong temperature-dependence of the composition of the products indicates that several parallel reactions are involved [105].

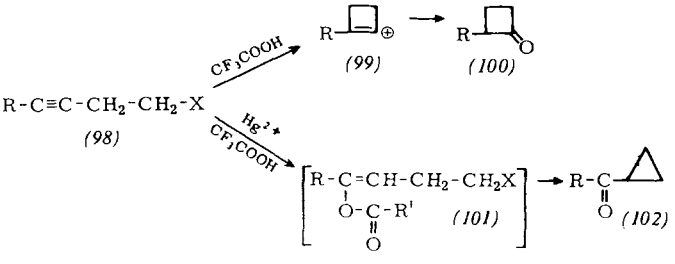
Allene Derivatives

The allene derivatives *(95)*, which are similar to the homoallyl compounds, can also cyclize to give cyclopropane derivatives, though a vinyl cation *(96)* is involved as an intermediate in this case [106]. Solvolysis of *(95)*, R = H or alkyl, X = ONs, leads mainly to the cyclopropyl ketones *(97)*; cyclobutyl compounds have also been obtained from 1- or 3-substituted allenes [107].



(95) *(96)* *(97)*

The direct participation of an allene double bond in the carbonium ion reaction has been detected by kinetic studies [106, 108].

Acetylene Derivatives

An interesting and useful cyclization reaction is exhibited by acetylene derivatives having the structure *(98)*, R = CH_3, C_2H_5, i-C_3H_7, X = *m*-SO_3–$C_6H_4NO_2$. Solvolysis with a solvent having a low nucleophilic strength and a high ionizing power leads to practically quantitative rearrangement into α-alkylcyclobutanones *(100)* [109, 110].

(99) *(100)* *(98)* *(101)* *(102)*

The solvolysis of phenyl-3-butynyl sulfonates *(98)*, R=C_6H_5, X = OSO_2R, leads mainly to phenyl cyclopropyl ketone, though other products are also formed. Ethoxy-3-butynyl *p*-toluenesulfonate *(98)*, R=C_2H_5O, X = OTs, partly rearranges on hydrolysis to give ethyl cyclopropanecarboxylate [111]. The cyclization of *(98)*

[111] *M. Hanack* and *W. Kaiser*, unpublished.

(R = alkyl) presumably involves the direct participation of the triple bond, and, as with the allene derivatives, proceeds *via* a vinyl cation *(99)*. This is supported by the fact that, despite the strong inductive effect of the triple bond, the rates of solvolysis of the acetylene derivatives *(98)*, R = alkyl, are only slightly lower than those of the corresponding saturated compounds. The formation of the cyclobutanones *(100)* could also be explained by addition of the solvent to the triple bond and subsequent homoallyl rearrangement. In the presence of Hg^{2+} salts, which are known to catalyse the addition to the triple bond, solvolysis of *(98)*, R = alkyl, leads mainly *via (101)*, R = alkyl, to cyclopropyl ketones *(102)*, R = alkyl. This indicates that the uncatalysed solvolysis of *(98)*, R = alkyl, proceeds *via* a direct participation of the triple bond [112].

Conclusion

The present survey of the reactions of cyclopropylmethyl, cyclobutyl, and homoallyl compounds has had to be confined to selected typical examples. The large number of articles published even very recently shows that this field is not yet closed. The present article has been concerned only with cationic reactions. No mention has been made of numerous publications *e.g.* from the steroid field, or of the interesting rearrangements of carbanions, free radicals, and carbenes [1a]. Finally, it should be pointed out that cyclizations involving a double bond have been observed, not only with homoallyl compounds, but also with other unsaturated systems [8c, 113].

Formation and Properties of Carbosilanes [1]

BY G. FRITZ [*]

The present paper describes the formation of silicon-carbon compounds (carbosilanes), the molecular skeletons of which consist of alternate Si and C atoms, and which can be obtained by thermal decomposition of $Si(CH_3)_4$, CH_3SiCl_3, $(CH_3)_2SiCl_2$, and $(CH_3)_3SiCl$. The description of the formation of carbosilanes is followed by a discussion of the reactions of polychlorinated carbosilanes with organometallic compounds.

1. Synthesis of Carbosilanes by Pyrolysis

Carbosilanes are compounds with alternate Si and C atoms in their molecular skeleton [2]. They may be open-chain or cyclic compounds, *e.g.* $(Cl_3Si\text{-}CH_2)_2SiCl_2$ (1,1,1,3,3,5,5,5 - octachloro - 1,3,5 - trisilapentane) or $(SiCl_2\text{–}CH_2)_3$ (1,1,3,3,5,5-hexachloro-1,3,5-trisilacyclohexane). The work described in this article arose from experiments in which compounds containing SiH were pyrolysed and made to react with hydrogen compounds of other elements [3]. Such reactions can in fact be carried out once H atoms and silyl radicals have been produced, as is shown by the formation of numerous organosilicon compounds on reaction of SiH_4 with ethylene [4] and with vinyl chloride [5] above 400 °C, as well as by the reaction of SiH_4 with PH_3 to form $H_3Si\text{–}PH_2$ and other silylphosphines [6]. Since these and other observations on silicon chemistry pointed to the possibility of obtaining complicated silicon compounds from simple compounds by free-radical reactions, we tried to utilize the thermal cleavage of Si–CH_3 and C–H groups for the synthesis of silicon-carbon compounds.

The Si–C bond in simple alkylsilanes is much more stable to heat than the Si–H bond [7]. The thermal

decomposition of $Si(CH_3)_4$ or $Si(C_2H_5)_4$ can be readily followed only above 650 °C [8], whereas H_2 is split off from the Si–H groups at 400 °C. When the alkylsilanes are heated for several hours in the gaseous phase at about 700 °C, they are almost completely decomposed, with deposition of silicon, carbon, silicon carbide and similar products, while hydrogen and lower hydrocarbons (mainly methane) escape. However, if the pyrolysis mixture is removed from the reaction zone after a short time and cooled, the primary radicals produced in the gaseous phase can form a series of silicon compounds [9]. The products are mainly compounds having an Si–C–Si skeleton. The proportion of high molecular weight compounds in the reaction mixture increases with rising pyrolysis temperature and with increasing residence time in the reaction vessel.

To prepare these products in reasonable quantities we used a system consisting of a storage vessel containing tetramethylsilane or methylchlorosilanes, a rotary pump (to transport the evaporating starting material through the reaction vessel, which is heated in a furnace), and traps situated under the reaction vessel to collect the reaction products [9, 10]. Since the pressure in the reaction vessel very quickly reaches atmospheric pressure, owing to the relatively high vapor pressures of tetramethylsilane and of the methylchlorosilanes, the conditions remain constant so long as the storage vessel still contains liquid starting material.

2. Treatment of the Pyrolysis Mixture

The pyrolysis mixture was worked up by distillation followed by gas chromatography [10]. Approximately half of the pyrolysis mixture can be distilled off and resolved into more than 50 compounds, each of which accounts for between 0.01 and 10 % of the total pyrolysis product. The undistillable residue consists of higher silicon compounds. The liquid fraction also contains very small quantities of lower hydrocarbons (up to hexane). All the higher fractions contain silicon compounds having large molecules and with several Si atoms. The principal gaseous products are hydrogen and methane. The products containing more than two Si atoms per molecule are listed in Table 1.

The higher products (> 5 Si atoms per molecule) in the undistillable residue, which account for about 50 % of the reaction mixture in the pyrolysis of $Si(CH_3)_4$, are particularly interesting. Before being further investigated, the residue must be resolved into pure compounds. However, this cannot be achieved by distillation or by gas chromatography, particularly since further reactions take place when the pyrolysis mixture is heated above 280 °C. In order to isolate and investigate further the various compounds, and to study, firstly, the influence of the reaction conditions on the composition of the pyrolysis mixture and, secondly, the secondary changes of the pyrolysis products, it was necessary to develop new chromatographic methods for their separation. A considerable proportion of our work was devoted to the solution of these problems.

Table 1. Compounds formed on pyrolysis of $Si(CH_3)_4$ (700 °C, residence time in reaction vessel ~ 1 min).

	Compound	B.p. (°C/mm) (m.p. (°C))	Proportion of total pyrolysis product (vol.-%)
(1)	$(CH_3)_3Si-CH_2-SiH(CH_3)_2$	120/768	2.4

(4)	1,1,3,3-Tetramethyl-1,3-disila-4-cyclopentene [12]	138.5/745	0.7
(5)	$C_6H_5Si(CH_3)_3$	172/745	5.6
(6)	1,1,3,3,5,5-Hexamethyl-1,3,5-trisilacyclohexane	205/745	7.5
(7)	1,1,3,3,5-Pentamethyl-1,3,5-trisilacyclohexane	201/767	7.5
(8)	$[(CH_3)_3Si-CH_2]_2Si(CH_3)_2$	206/760	7.5
(9)	1,3,5,7-Tetramethyl-1,3,5,7-tetrasilaadamantane	103/1 (m.p. 122)	10.1
(10)	$Si_5C_{13}H_{34}$	126–132/1	
(11)	$Si_6C_{14}H_{36}$	150–153/1	
(12)	$Si_7C_{18}H_{46}$ [13]	170–195/1	
(13)	$Si_8C_{20}H_{50}$	200–230/1	
(14)	$Si_8C_{24}H_{66}$	230–240/1	
(15)	$Si_9C_{27}H_{74}$	245–300/1	
(16)	$Si_7C_{16}H_{36}$		
(17)	$Si_9C_{19}H_{46}$		

Compound *(12)* consists of three six-membered rings with alternating Si and C atoms. The Si valences that are not involved in the skeleton are occupied by CH_3 groups or by an H atom, while the carbon valences are satisfied by hydrogen atoms. *(16)* and *(17)* consist of six-membered rings in a three-dimensional arrangement and joined by Si–C groups. The entire skeleton consists of alternate Si and C atoms. The Si valences that are not involved in the skeleton are occupied by CH_3 groups and the carbon valences by H atoms [14a].

2.1. Chromatographic Separation of the Pyrolysis Products

Preliminary experiments showed that after the distillable fractions have been removed, the higher-boiling products of the pyrolysis of $Si(CH_3)_4$ can be separated into three groups on alumina columns. The first group (A) is not adsorbed on the column from a solution of the reaction mixture in benzene. The second group (B) can be eluted with benzene, and the third group (C), which remains in the column on elution with benzene, can be washed out with benzene-methanol mixtures. Group C can be further resolved on the column by successive elution with benzene-methanol mixtures having increasing methanol contents [14] (cf. Fig. 1).

Group A can be further resolved on an alumina column with pentane. This group includes two crys-

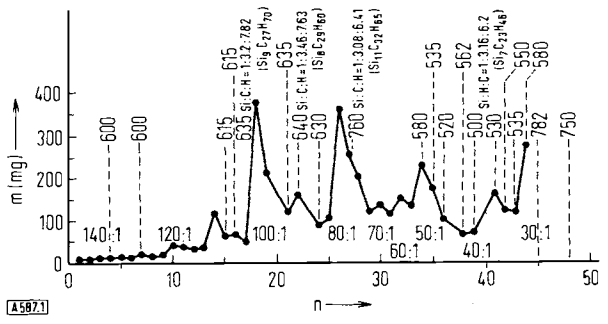

Fig. 1. Resolution of group C of the products from the pyrolysis of $Si(CH_3)_4$ (Al_2O_3 column neutral activity grade I, length 66 cm, diameter 3.5 cm) with benzene-methanol mixtures (140:1, 120:1, 100:1, 80:1, 70:1, 60:1, 50:1, 40:1, 30:1); volume of solvent per fraction: 5 l.
Ordinate: quantity m of substance eluted (mg);
Abscissa: number of fractions n.
The quantities of the various fractions were determined after the solvents had been distilled off. The molecular weights are given against the broken lines and the atomic ratios found by elemental analysis are given in many cases together with the empirical formulae. These empirical formulae are "averages" since it is not yet known whether the fractions were pure [14].

talline substances ($Si_7C_{16}H_{36}$ and $Si_9C_{19}H_{40}$, *(16)* and *(17)* in Table 1). The solid products formed on pyrolysis of $Si(CH_3)_4$ are deep brown, and fluoresce in organic solvents. The fluorescence of individual compounds and mixtures becomes more clearly visible on separation and further resolution of the groups, and can be used as a means of following the separation processes [14], particularly in the case of the compounds of group B.

2.2. Changes in the Pyrolysis Products on Distillative Separation

The development of the chromatographic separation method makes it possible to study the secondary changes that take place on distillation of the pyrolysis mixture. These changes can be represented as follows (see Table 2) [14, 15]:

The products formed when $Si(CH_3)_4$ was heated were distilled in a high vacuum to remove as much as possible of the more volatile products, the temperature of the pyrolysis mixture not being allowed to exceed 20 °C (Column 1). A second portion of the original pyrolysis mixture was then freed from all the components that distilled off up to 110 °C/1–2 mm Hg; to achieve this, it was necessary to heat the pyrolysis mixture to 200–260 °C (Column 2). Part of the residue was distilled further to remove all the components that distilled off up to 260 °C/1 mm Hg; this involved heating the pyrolysis mixture to 340–400 °C (Column 3). Part of this last residue was heated for 4 hours at 430 to 450 °C (Column 4), and part for 5 min at 600 °C (Column 5).

The composition of the pyrolysis mixture clearly becomes more complex with rising temperature on separation by distillation, since the quantities of high molecular-weight components increase rapidly. This is particularly true of the substances of groups D and E, which are initially almost entirely absent. The quantity of substances of group C also increases (but without formation of insoluble products) when the temperature in the distillation vessel is raised from 260 to 400 °C. Group B forms only a very small part of the mixture; this group appears to be formed only on heat treatment, and is destroyed again when heated further.

The investigation showed that the mixtures of higher molecular-weight compounds formed on pyrolysis of tetramethylsilane are simpler than was originally thought, and that complex chemical changes take place on distillation of the reaction mixtures.

To obtain an insight into the secondary changes that take place on distillation of the pyrolysis mixture, the thermal stabilities of a number of substances and groups of substances were studied. The temperature ranges in which changes begin were determined, and the changes were followed by means of molecular-weight determinations. The gases formed during the heat treatment were collected with a view to obtaining

information about the processes which bring about the increase in molecular size. The substances used in the investigation were an untreated reaction mixture from the pyrolysis of $Si(CH_3)_4$, the substances of group A obtained by column chromatography of the pyrolysis mixture, and the compounds $Si_4C_{10}H_{24}$ [Table 1, *(9)*], $Si_9C_{16}H_{36}$, and $((CH_3)_3Si)_2CH_2$ [Table 1, *(3)*].

The experiments showed that the untreated pyrolysis mixture changed appreciably even when heated to about 400 °C (increase in the average molecular weight, formation of benzene-insoluble components; group E), while only small quantities of gas are formed. When a sample of the pyrolysis mixture was heated at 430 to 490 °C for 46 hours, 72 % of the product was converted into benzene-insoluble residues, with formation of only very small quantities of methane and hydrogen. The separated group A exhibits similar behavior only at about 230 °C, though no benzene-insoluble material is formed [15].

On the other hand, $Si_4C_{10}H_{24}$, which has a tetrasilaadamantane skeleton *(9)*, was found to have an extremely high thermal stability, and showed practically no change when heated for 37 hours at 520 to 540 °C. No extensive decomposition occurred, even when the substance was heated at 550 to 560 °C (70 hours). Marked decomposition is observed only at 580 °C, and after 24 hours at this temperature a benzene-insoluble residue can be isolated (about 33 %). By far the greatest part of the benzene-soluble fraction consists of unchanged $Si_7C_{10}H_{24}$.

The crystalline compound $Si_7C_{16}H_{36}$, the structure of which has not yet been fully elucidated, resembles $Si_4C_{10}H_{24}$ in its thermal stability. It shows practically no change after 54 hours at temperatures up to 490 °C, and forms an insoluble residue (42 % of the original substance) only when heated at 560 °C (55 hours); the benzene-soluble fraction still contains the unchanged compound. The decomposition temperature of $[(CH_3)_3Si]_2CH_2$ is about 500 °C, *i.e.* somewhat lower than that of the more symmetrical, crystalline compounds $Si_4C_{10}H_{24}$ and $Si_7C_{16}H_{36}$.

These investigations [15] show that the observed molecular-weight changes in the pyrolysis mixtures are due to changes in carbosilanes of a few structural types.

3. Synthesis of Chlorinated Carbosilanes by Pyrolysis

Many carbosilanes of various molecular weights are obtainable by the pyrolysis of tetramethylsilane. Most of these compounds are unreactive, since they contain no functional groups. However, compounds with the same basic skeleton, but with reactive groups attached to the Si atoms, are required in many investigations. Compounds of this nature can be obtained by the pyrolysis of the three methylchlorosilanes [16]. The thermal decomposition of the methylchlorosilanes is reasonably fast at about 700 °C. The pyrolysis products are obtained in useful amounts by the principle used in the pyrolysis of tetramethylsilane. Of the products formed on pyrolysis of $(CH_3)_3SiCl$, some 60 vol-% consist of fractions that boil at temperatures between 163 and 200 °C at normal pressure, while 40 vol-% are oily and solid fractions that dissolve in non-polar solvents. About 85 % of the pyrolysis products of CH_3SiCl are colorless liquids, while 15 % are oils or solids that are fusible and colored. All the compounds that were formed on pyrolysis of the three methylchlorosilanes and that have boiling points below 250 °C have been detected by gas chromatography, and their relative proportions have been determined [17, 18].

The carbosilanes obtained from the methylchlorosilanes are listed in Table 3. All the possible chlorinated and methylated compounds having the basic structure $Si-CH_2-Si$ have been isolated from the pyrolysis products of $(CH_3)_3SiCl$. The distribution of the 1,3-disilapropanes *(17)* to *(26)* in the pyrolysis products of the three methylchlorosilanes are compared in Table 3. The 1,3-disilapropanes accounted for 32 % of the total pyrolysis product from $(CH_3)_3SiCl$, 43 % of that from $(CH_3)_2SiCl_2$, and 60 % of that from CH_3SiCl_3.

4. Reduction of the Chlorinated Carbosilanes

In order to investigate the high molecular weight products from the pyrolysis of the methylchlorosilanes, it was necessary to separate the various compounds from the mixture. However, even for substances containing three Si atoms per molecule, the distillative separation of Si-chlorinated carbosilanes is difficult, owing to the high boiling points of the compounds. The chromatographic methods are also unsuitable for the same reason. Attempts were therefore made to replace the chlorine by hydrogen in Si-chlorinated carbosilanes by treatment with $LiAlH_4$. The corresponding compounds with SiH groups boil at lower temperatures, and can be separated by distillation and gas chromatography. The hydrogenation takes place with no change in the Si–C–Si skeleton, as was shown by the investigation of Si-chlorinated 1,3-disilapropanes having known structure, and of 1,1,3,3,5,5-hexachloro-1,3,5-trisilacyclohexane, *(30)*, which crystallizes well [19].

The fractions of the pyrolysis products containing the compounds *(27)* to *(40)* were hydrogenated. Comparison of the proportions of the various compounds in the hydrogenated pyrolysis mixtures shows that the tendency toward the formation of six-membered rings with alternating Si and C atoms increases with the number of $SiCH_3$ groups in the starting compound.

In the high molecular weight compounds formed on pyrolysis of the methylchlorosilanes, the SiCl groups can again be converted into SiH groups without modification of the skeleton,

(44)	$Si_8C_8H_{16}Cl_{16}$ [27] [b]					

[a] The distribution of the CH_3 groups on the Si atoms of the molecule has not yet been established unambiguously.

[b] *(44)* consists of four condensed six-membered rings with alternating Si and C atoms. The Si valences that are not involved in the skeleton are occupied by Cl, and the carbon valences by H atoms. *(43)* has a similar structure.

[c] This compound has been obtained by the reaction of $SiCl_4$ and $(CH_3)_3SiCl$ in the presence of $AlCl_3$ at high pressures. — *A. Lee Smith* and *H. A. Clark*, J. Amer. chem. Soc. *83*, 3345 (1961).

so that these compounds containing SiH groups, which are less sensitive to hydrolysis, can also be separated. The mixture is again resolved into three groups of substances by chromatography on Al_2O_3 columns. Group C can be further resolved by elution with benzene-methanol mixtures having increasing methanol contents. The fractions obtained by chromatographic separation (molecular weights between 400 and 800) all contain compounds having relatively small differences in their molecular weights (*e.g.* 544 to 571; 817 to 834)[21].

5. Conclusions Concerning the Formation of Pyrolysis Products

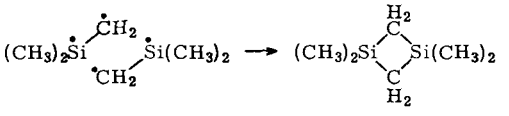
The formation of compounds in the gaseous phase at about 700 °C is assumed to be a free-radical process[2,3,10]. The initial step of the decomposition is thought to be reaction (1). This is followed by reaction (2).

$$Si(CH_3)_4 \rightarrow (CH_3)_3\dot{S}i + \dot{C}H_3 \quad (1)$$

$$(CH_3)_3Si-CH_3 + \dot{C}H_3 \rightarrow (CH_3)_3Si-\dot{C}H_2 + CH_4 \quad (2)$$

These processes yield the free radicals required for the formation of the Si–C–Si skeleton. The parent compound is probably formed in accordance with (3).

$$(CH_3)_3Si-\dot{C}H_2 + \dot{S}i(CH_3)_3 \rightarrow (CH_3)_3Si-CH_2-Si(CH_3)_3 \quad (3)$$



[20] *G. Fritz*, *E. Krahe*, and *H. G. v. Schnering*, unpublished.

[20a] *G. Fritz* and *R. Haase*, unpublished.

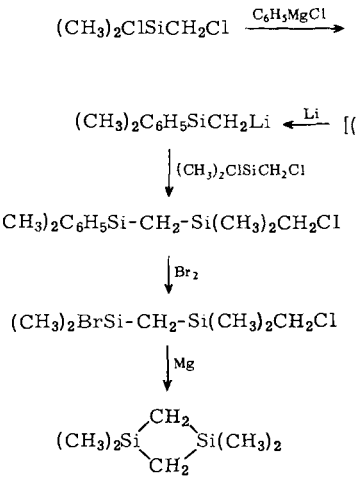
[21] *G. Fritz* and *W. König*, unpublished.

This does not explain the preferential formation of cyclic carbosilanes. The isolation of 1,3-disilacyclobutane from the pyrolysis products [11] seems particularly significant; this product could be formed by reactions (4) and (5).

$$(CH_3)_3Si-\dot{C}H_2 \rightarrow (CH_3)_2\dot{S}i-\dot{C}H_2 + \dot{C}H_3 \qquad (4)$$

(5)

The formation of the six-membered ring can also be explained as proceeding *via* the radical $(CH_3)_2\dot{S}i-\dot{C}H_2$.



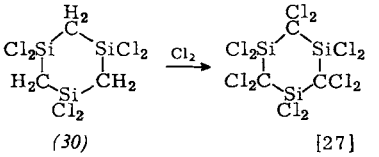
The Si-chlorinated carbosilanes could be formed in a similar manner from the three methylchlorosilanes in the gaseous phase [2,3]. As in the pyrolysis of $Si(CH_3)_4$, the SiC and CH bonds may be expected to be cleaved. However, the products isolated show that the SiCl bond must also be broken, since the pyrolysis products of $(CH_3)_3SiCl$ and $(CH_3)_2SiCl_2$ include compounds in which the Si atom carries more Cl atoms than in the starting material. Moreover, the 1,3-disilapropanes formed in the greatest quantities are those whose formation involves large transpositions, *e.g.* $Cl_3Si-CH_2-SiCl_3$ and $(CH_3)_3Si-CH_2-SiCl_3$ from $(CH_3)_3SiCl$ or $(CH_3)_2SiCl_2$. Further assumptions are necessary in order to explain the formation of these compounds. If it is assumed that SiCl bonds are broken, the formation of the compounds could be explained by the recombination of suitable radicals; however, this assumption is open to certain objections.

It should be stressed that we have never found pyrolysis products containing Si–Si bonds, which could possibly have arisen by the recombination of radicals such as $(CH_3)_3Si\bullet$ (see eq. (1)). Since the bond energy of the Si–C bond (76 kcal) is higher than that of the Si–Si bond (53 kcal), the arrangement Si–C–Si is energetically favored in relation to Si–Si–C. This is confirmed by a series of catalytic and even thermal rearrangements [22].

6. Synthesis of Carbosilanes Containing Functional Groups

The stepwise organometallic synthesis of carbosilanes with functional groups on the Si atom [2,3,23] is made difficult by the fact that functional groups on Si readily undergo undesirable side reactions with organolithium or organomagnesium compounds.

The obvious remedy was to carry out the synthesis of the organometallic compounds, and as far as possible their further reaction, with derivatives having protective groups on the Si atom. These groups must prevent undesirable condensations, and it must be possible to remove them at a later stage to give an Si atom carrying a functional group. A suitable group for this purpose is the $Si-C_6H_5$ group, which can be split by reaction with halogens or hydrogen halides, depending on the other substituents on the Si atom [24]. This principle was used for the preparation of a number of carbosilanes containing functional groups [25], *e.g.*:



The four-membered ring has now also been synthesized from $(CH_3)_2ClSiCH_2Cl$ and Mg [25a].

The chemical properties of the carbosilanes are determined largely by the groups attached to the Si atoms and to the skeletal C atoms. The compounds in which the Si atoms are fully methylated are (generally) inert. Reactions are observed only under extreme conditions or where strained ring systems are involved. Thus 1,1,3,3-tetramethyl-1,3-disilacyclobutane undergoes ring cleavage with HBr. The corresponding six-membered ring compound does not exhibit this reaction.

Photochlorination leads to chlorination of the CH groups of the carbosilane skeleton, the reaction proceeding as far as steric factors allow [26,27] (cf. eqs. (6)–(8)). Intermediates can be isolated in only a very few cases [28], one such substance being $Cl_3Si-CHCl-SiCl_3$ [27a].

$$Cl_3Si-CH_2-SiCl_3 \xrightarrow{Cl_2} Cl_3Si-CCl_2-SiCl_3 \qquad (6)$$
(17)

$$(Cl_3Si-CH_2)_2SiCl_2 \xrightarrow{Cl_2} (Cl_3Si-CCl_2)_2SiCl_2 \qquad (7)$$
(27)

These *C*-chlorinated carbosilanes are particularly interesting in their reaction with organometallic compounds. While methylation of *C*-chlorinated methylchlorosilanes with CH_3MgCl or CH_3Li leads mainly to the Si-methyl compound, *e.g.* the reaction of $(CH_3)_2ClSi-CHCl_2$ with CH_3MgCl yields $(CH_3)_3Si-CHCl_2$, a similar reaction is hardly ever observed with chlorosilanes in which the skeletal C atom is chlorinated. After the methylation of $(Cl_3Si)_2CCl_2$ with CH_3MgCl or CH_3Li, not even small quantities of the Si-methylated compound $[(CH_3)_3Si]_2CCl_2$ can be isolated. Reaction under a wide range of conditions leads instead to $[(CH_3)_3Si]_2CH_2$, $[(CH_3)_3Si]_2CHCH_3$, $[(CH_3)_3Si]_2C=CH_2$, and $[(CH_3)_3Si]_2C(CH_3)_2$, as well as other compounds that have not yet been fully characterized [29]. Although these transformations cannot be satisfactorily interpreted at present they have opened up new avenues in carbosilane chemistry.

The above investigations were carried out with the support of the Fonds der Chemie, the Deutsche Forschungsgemeinschaft, and Farbenfabriken Bayer, Leverkusen. I am particularly grateful to my co-workers.

Siloxane Compounds of the Transition Metals

BY F. SCHINDLER AND H. SCHMIDBAUR [*]

Heterosiloxanes of transition metals contain the characteristic grouping Si–O–X; in the compounds known so far, X may be Au, Zn, Cd, Hg, Ti, Zr, Hf, V, Nb, Ta, Cr, U, Re, Fe, Co, Ni, or Pt. Most of these compounds are obtained from silanols, metal silanolates, acyloxysilanes, disiloxanes, or alkoxysilanes, i.e. from compounds that already contain an Si–O bond. The transition metal may be introduced e.g. as a halide, as an organometallic compound, as an alkoxy compound, or as an oxide. Heterosiloxanes are also formed on reaction of many silicon compounds that do not contain oxygen with transition metal compounds containing oxygen. Some of these compounds, e.g. some titanosiloxanes, are very stable, whereas others decompose explosively. Oligomeric and polymeric heterosiloxanes exist in addition to the monomeric compounds.

The heterosiloxane grouping Si–O–X (X = hetero atom) is one of the most important structural units of inanimate nature. The various metal silicates are built up from such units, and profit from their high chemical and thermal stability. Numerous attempts have been made to prepare organometallic polymers from metal-substituted silicones, in order to make use of the advantageous properties of the heterosiloxane group. Heterosiloxanes of elements of the main groups were discussed in an earlier article [1]. The present article deals with the corresponding compounds of the transition elements, which were almost unknown until a few years ago. Efforts to synthesize new inorganic polymers [2, 3] have also led to fundamental investigations in this field.

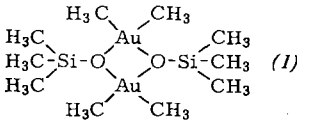
I. Siloxanes of Copper, Silver, and Gold

Preliminary experiments with copper and silver were not very promising. Thus the reaction of disodium diphenylsilanediolate with copper(II) chloride gives an intermediate product presumed to have the composition $[Si(C_6H_5)_2-O]_x[-Cu-O]_y$, but this immediately decomposes into copper(II) oxide and octaphenylcyclotetrasiloxane [4].

Attempts to prepare siloxanes of silver by reaction of silver perchlorate or nitrate with sodium trimethylsilanolate in many different solvents did not yield a definite silver trimethylsilanolate, but only silver oxide and hexamethyldisiloxane [5].

$$2\,AgClO_4 + 2\,NaOSi(CH_3)_3 \rightarrow 2\,NaClO_4 + Ag_2O + [(CH_3)_3Si]_2O$$



It is not certain whether $AgOSi(CH_3)_3$ occurs as an unstable intermediate in this reaction.

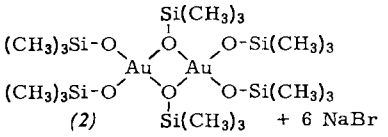
[5] *H. Schmidbaur* and *M. Bergfeld*, unpublished; *M. Bergfeld*, Dissertation, Universität Würzburg 1967.

Attempts to prepare an aurosiloxane, on the other hand, were successful [6]. The reaction of dimethylgold bromide with sodium trimethylsilanolate in diethyl ether gives pentamethyl-aurosiloxane *(1)* in good yield.

$$2\ (CH_3)_2AuBr + 2\ NaOSi(CH_3)_3 \rightarrow 2\ NaBr +$$



(1)

The colorless compound *(1)* (m.p. 37–39 °C, sublimation at 40 °C/0.001 mm Hg) is one of the few organogold compounds that evaporate without decomposition. It decomposes at 135 °C with deposition of a gold mirror, and molecular-weight determinations in benzene show it to be a dimer with a gold-oxygen four-membered ring system. Compound *(1)* was characterized by its IR and NMR spectra, some details of which are given in Table 1 [6]. The compound is diamagnetic, and the arrangement of the four ligands of the gold atoms is therefore assumed to be planar.

Anhydrous $AuBr_3$ reacts with sodium trimethylsilanolate to form the much less stable tris(trimethylsiloxy)gold *(2)*. This product forms yellow crystals, which decompose even at room temperature into

$$Au_2Br_6 + 6\ NaOSi(CH_3)_3 \rightarrow$$

(2)

$$+ 6\ NaBr$$

lower gold oxides, oxygen, and hexamethyldisiloxane [6]. IR and NMR data indicate a constitution having bridge-type and terminal siloxy groups.

Compound *(2)* is converted by an excess of $NaOSi(CH_3)_3$ into the complex sodium tetrakis(trimethylsiloxy)aurate(III), which can be isolated as the colorless salt, and which is insoluble in nonpolar organic solvents [6].

$$\{Au[OSi(CH_3)_3]_3\}_2 + 2\ NaOSi(CH_3)_3 \rightarrow 2\ Na\{Au[OSi(CH_3)_3]_4\} \quad (3)$$

Heterosiloxanes of monovalent gold, like those of monovalent silver, are unknown.

II. Siloxanes of Zinc, Cadmium, and Mercury

Siloxy compounds of elements of the Group II triad have not been extensively studied so far. Two articles deal with the incorporation of Zn, Cd, and Hg into polyorganometallosiloxanes [4,7], and two others describe low molecular weight mercurosiloxanes [8,9].

Recent investigations by the present authors [5,10,11] have shown that dimethylzinc and dimethylcadmium (but not dimethylmercury) react with trimethylsilanol at room temperature, with evolution of methane and formation of compounds containing Zn–O–Si and Cd–O–Si structural units:

$$4(CH_3)_2Zn + 4HOSi(CH_3)_3 \rightarrow 4CH_4 + [CH_3ZnOSi(CH_3)_3]_4 \quad (4)$$

$$4(CH_3)_2Cd + 4HOSi(CH_3)_3 \rightarrow 4CH_4 + [CH_3CdOSi(CH_3)_3]_4 \quad (5)$$

Molecular-weight determinations show that the resulting heterosiloxanes of zinc and cadmium are tetrameric. The proposed cubane structure of the com-

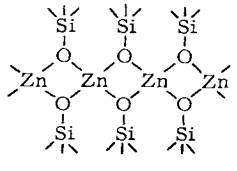
pounds is confirmed by spectroscopic investigations and by (an almost completed) X-ray analysis. The corners of the distorted cube are occupied alternately by zinc or cadmium and oxygen atoms.



(4), M = Zn
(5), M = Cd

A similar structure has been suggested [12] and confirmed by X-ray analysis [13] for the recently prepared methylzinc methoxide ($CH_3Zn-OCH_3$). According to the crystallographic data, *(4)* forms monoclinic crystals of the space group P 2/n ($Z = 4$, $a = 17.625$ Å; $b = 19.839$ Å; $c = 9.85$ Å; $\beta = 97.49°$). The zinc-oxygen distances correspond to those in methylzinc methoxide (2.09 Å), while the silicon-oxygen distances are somewhat increased as a result of the coordination of the oxygen with three zinc atoms.

(4) and *(5)* are colorless crystalline substances; owing to the small size of their molecules they are readily soluble in organic solvents, and sublime under vacuum without decomposition. NMR and IR data and the physical constants of the compounds are listed in Table 1. Both compounds react with water to form methane, metal hydroxide, and trimethylsilanol.

Bis(trimethylsiloxy)zinc *(6)* and -cadmium *(7)* are formed in high yields as colorless, evidently polymeric compounds [5] by the metathetic reaction of $ZnCl_2$ and $CdBr_2$ with alkali metal trimethylsilanolates in diethyl ether. They are sparingly soluble in organic solvents, and do not sublime without decomposition. This behavior (which corresponds to that of zinc and cadmium alkoxides [12, 14]) and the spectroscopic data are compatible with a chain structure *(6)* or with a layer structure similar to that of lithium methoxide [14a].

(6)

The zinc atoms in both forms would have the coordination number 4. Attempts to sublime bis(trimethylsiloxy)zinc led to a surprising result. Above 110 °C, a colorless sublimate was formed that was positively identified as the tetramer *(4)*. The heating had evidently led to transmethylation, in which a methyl group was transferred from a silicon to a zinc atom [5]. The dimethylpolysiloxane required to balance the equation could also be detected in the reaction products.

$$\underset{(6)}{\{Zn[OSi(CH_3)_3]_2\}_n} \rightarrow \frac{n}{4}\ \underset{(4)}{[CH_3ZnOSi(CH_3)_3]_4} + [(CH_3)_2SiO]_n$$

This is one of the very few reactions in which organosilicon residues act as alkylating agents for other metals [15, 16]. The cadmium compound *(7)* does not exhibit this reaction under comparable conditions.

The first of the two articles that have so far dealt with the preparation of mercurosiloxanes [8] describes the reaction of $HgCl_2$ with sodium trimethylsilanolate in dioxane, which leads to the formation of impure, unstable bis(trimethylsiloxy)mercury *(8)*.

$$HgCl_2 + 2\ NaOSi(CH_3)_3 \rightarrow \underset{(8)}{Hg[OSi(CH_3)_3]_2} + 2\ NaCl$$

The compound has so far been characterized by IR spectroscopy only.

The other article [9], which was published soon afterwards, describes the preparation of tetraphenylmercurosiloxane *(9)* *via* the intermediate bis(triphenylsiloxy)mercury.

$$2(C_6H_5)_3SiONa + HgCl_2 \rightarrow [(C_6H_5)_3SiO]_2Hg + 2\ NaCl$$

$$x[(C_6H_5)_3SiO]_2Hg \rightarrow (x\text{-}1)\ \underset{(9)}{(C_6H_5)_3SiOHgC_6H_5} + (C_6H_5)_3SiO-[(C_6H_5)_2SiO]_x-HgC_6H_5$$

The same authors also synthesized *(9)* from phenylmercury chloride, potassium, and triphenylsilanol in diethyl ether.

$$(C_6H_5)_3SiOH + K + C_6H_5HgCl - 1/2\ H_2 \rightarrow \underset{(9)}{(C_6H_5)_3SiOHgC_6H_5} + KCl$$

Compound *(9)* forms colorless crystals having m.p. 140–141 °C. It reacts with HCl in diethyl ether to form C_6H_5HgCl and $(C_6H_5)_3SiOH$. When *(9)* is heated to 145 °C under nitrogen, diphenylmercury and a phenylpolysiloxane that contains mercury, $(C_6H_5)_3SiO[(C_6H_5)_2SiO]_x \cdot HgC_6H_5$, are formed.

The simplest mercurosiloxane $CH_3Hg-O-Si(CH_3)_3$ *(10)*, which cannot be prepared from dimethylmercury and trimethylsilanol, has become readily obtainable by the reaction of methylmercury halides with alkali metal trimethylsilanolates [11].

$$CH_3HgCl + NaOSi(CH_3)_3 \rightarrow NaCl + \underset{(10)}{CH_3Hg-O-Si(CH_3)_3}$$

Compound *(10)* is formed in excellent yields as a colorless sublimable compound, which is readily soluble in organic solvents, and which is even more sensitive to moisture than *(4)* and *(5)*. The results of molecular-weight determinations on solutions of *(10)* in benzene indicate a concentration-dependent equilibrium between monomer and oligomer. The measured molecular weight approaches the value for the monomer only at high dilution. On the other hand, X-ray analysis [17] shows that the compound is entirely tetrameric

in the solid state. The distorted cubane structure of these molecules, in which the monomeric units are still clearly recognizable, is not retained in solution, in contrast to the behavior of the corresponding zinc and cadmium compounds. The tetramer undergoes degradation by the solvent into dimer and monomer. This clearly shows that mercury is a much weaker acceptor than zinc or cadmium.

The unit cell of the tetragonal crystals of *(10)* (space group P 4_2/nmc) has the following dimensions: a = 13.18 Å; c = 9.85 Å; d_{exp} = 2.2; d_{calc} = 2.37; Z = 8. The physical constants of the compound and its IR and NMR data are listed in Table 1.

According to recent investigations [5], the bis(trimethylsiloxy)mercury *(8)* obtained by the *Tatlock* and *Rochow* method [8], like the zinc and cadmium derivatives, is polymeric and has no definite melting point or decomposition point. However, attempted sublimation again resulted in intramolecular alkylation, which above 90 °C led to volatile tetramethylmercurosiloxane *(10)*.

$$\underset{(8)}{\{[(CH_3)_3SiO]_2Hg\}_n} \rightarrow n\ \underset{(10)}{CH_3HgOSi(CH_3)_3} + [(CH_3)_2SiO]_n$$

The methylmercury grouping in the sublimate could be detected by IR and NMR spectroscopy. A substance identical with that obtained from methylmercury chloride and sodium trimethylsilanolate was isolated.

No investigations on siloxy derivatives of monovalent mercury have so far been reported.

III. Siloxanes of Scandium, Yttrium, and Lanthanum

No heterosiloxanes of the elements of Group IIIb or of the lanthanide and actinide series are known as yet. The only exception is uranium, siloxy compounds of which were prepared and studied by *D. C. Bradley et al.* [18, 19]. This work will be discussed in Section VI.

IV. Siloxanes of Titanium, Zirconium, and Hafnium

The titanosiloxanes are the most extensively studied group of heterosiloxanes of transition elements. Polymeric titanosiloxanes with a wide range of organic substituents both on the silicon and on the titanium have been prepared and studied by *K. A. Andrianov et al.*, as well as by other research groups. The incorporation of titanium into the inorganic skeleton of silicones can have a very favorable effect on the thermal stability of the compounds [20–23]. The stability of such compounds toward hydrolysis is fairly satisfactory, and is much better *e.g.* than that of the corresponding aluminosiloxanes [23–25].

A large number of polymeric and telomeric titanosiloxanes with alkyl and aryl substituents on the Si and Ti atoms [20–56]

and with chelated Ti atoms[57–76] have been prepared and studied. However, a description of all the titanosiloxanes would be beyond the scope of the present article, and the reader is referred to monographs on the subject[2,3,77–85].

Low molecular weight titanosiloxanes can be prepared by the following methods:

a) By silylation of titanium alkoxides with acyloxysilanes[84,86–88]:

$$(RO)_4Ti + 4R'_3SiOCOR'' \rightarrow Ti(OSiR'_3)_4 + 4R''COOR$$

b) By silylation of titanium alkoxides with silanols[84,86,89–92]:

$$(RO)_4Ti + 4R'_3SiOH \rightarrow Ti(OSiR'_3)_4 + 4\ ROH$$

c) By heterolysis of siloxanes with titanium tetrahalides[84,93,94]:

$$TiX_4 + R_3SiOSiR_3 \rightarrow R_3SiOTiX_3 + R_3SiX$$

d) By silylation of titanium tetrahalides with silanols in the presence of tertiary amines[84]:

$$TiX_4 + 4R_3SiOH + 4R_3N \rightarrow Ti(OSiR_3)_4 + 4\ R_3HN^{\oplus}X^{\ominus}$$

e) By degradation of dialkyl metatitanates with alkoxysilanes [84,95]:

$$(RO)_2Ti{=}O + (R'O)_4Si \rightarrow (R'O)(RO)_2TiOSi(OR')_3$$

f) By metathetic reaction of alkali metal [84,96,97] or heavy metal silanolates [84,98] with titanium halides:

$$TiX_4 + 4\ R_3SiOM^I \rightarrow Ti(OSiR_3)_4 + 4\ M^IX$$

The titanosiloxanes obtained in this way are listed in Table 2, together with their principal physical constants. The simple titanosiloxanes are colorless, distillable liquids or low-melting crystalline solids, most of which are readily soluble in organic solvents. The compounds are all monomeric, and with only a few exceptions, the titanium atom has the coordination number 4. A coordination number of 5 can be reached only in the presence of polydentate ligands such as $N(CH_2{-}CH_2OH)_3$ [89].

Table 2. Heterosiloxanes of titanium.

[a] Abbreviations: Me = CH_3, Et = C_2H_5, Ph = C_6H_5, Pr = n-C_3H_7, Bu = n-C_4H_9, Cp = cyclopentadienyl, iPr = i-C_3H_7 iBu = i-C_4H_9.

According to investigations by *Andrianov* and *Zhdanov* [103], the Ti—O—Si linkage has a high resistance to hydrolysis. In compounds of the type $[(C_2H_5)_3SiO]_{3\text{ or }4}\ M^{III\text{ or }IV}$ (M = Ti, Al, Sn), the stability of the MOSi linkage to hydrolysis decreases in the order Ti > Al > Sn (ratio 2220:27.2:1). However, the stability of compounds of this type, as expected, also depends strongly on the nature of the organic substituent on the silicon. Bulky groups considerably increase the stability of a compound to hydrolysis.

Bradley et al. [86,104], in their work on titanosiloxanes, also studied analogous compounds of zirconium. Compounds containing Zr—O—Si linkages were prepared by two methods, which had also been successfully used for the preparation of titanosiloxanes. Zirconium tetraalkoxides react with trialkylsilanols in boiling benzene to form tetrakis(trialkylsiloxy)zirconium.

$$(RO)_4Zr + 4\ R'_3SiOH \rightarrow (R'_3SiO)_4Zr + 4\ ROH$$

If the alcohol is removed continuously by azeotropic distillation with benzene, the yields are greater than 70 %. Compounds of the same type can also be obtained from zirconium alkoxides and trialkylsilyl acetates. The yields in this case are higher than 50 %.

$$(RO)_4Zr + 4R'_3SiOCOCH_3 \rightarrow (R'_3SiO)_4Zr + 4CH_3COOR$$

Zirconosiloxanes can also be obtained readily and in high yields by elimination of alkali metal halide. Tetrakis(triphenylsiloxy)zirconium *(48)* has been prepared by this method [97].

$$ZrCl_4 + 4(C_6H_5)_3SiONa \rightarrow [(C_6H_5)_3SiO]_4Zr + 4NaCl \qquad (48)$$

The zirconosiloxanes are colorless, distillable substances and, like the titanosiloxanes, they are only slightly hydrolysed. Controlled partial hydrolysis in dioxane leads to polymeric organosiloxyzirconium oxides of varying composition [105], whereas total hydrolysis yields silanols and zirconium hydroxide. The zirconosiloxanes known so far, unlike the titanosiloxanes, are characterized by a tendency to associate that is strongly dependent on the bulk of the ligands R attached to the silicon. Molecular-weight determinations showed various degrees of oligomerization [86], the perethylated compound *(47)* being monomeric while the permethylated compound *(46)* is dimeric. This dimer is assumed to have a bridged structure in which the zirconium atom has a coordination number of 5.

(46)

However, the NMR spectrum of solutions of this substance in CCl_4 shows only one proton signal at room temperature, indicating a rapid transposition of the ligands on the zirconium atoms or else a very mobile oligomerization equilibrium (cf. *e.g.* [106]).

The reaction of diphenyldichlorosilane with propyl orthozirconates leads to polymers of the type $[(Si(C_6H_5)_2-O)_m-Zr(OC_3H_7)_2-O]_n$ [107].

[118] *H. Schmidbaur*, Dissertation, Universität München 1960.

Two groups of workers have so far reported on heterosiloxanes of hafnium. *Bradley et al.* [104] give the IR spectrum of $Hf[OSi(C_2H_5)(CH_3)_2]_4$ *(53)*, but do not describe either the preparation or the properties of this compound; *Gutmann et al.* [97] obtained tetrakis(triphenylsiloxy)hafnium *(54)* by reaction of sodium triphenylsilanolate with hafnium tetrachloride in boiling xylene.

$$4(C_6H_5)_3SiONa + HfCl_4 \rightarrow Hf[OSi(C_6H_5)_3]_4 + 4NaCl \qquad (54)$$

Tetrakis(triphenylsiloxy)hafnium forms white crystals having m.p. 383 °C, which can be recrystallized from benzene or toluene. The compound decomposes on melting, with deposition of carbon. There is no evidence that the siloxanes of hafnium tend to associate. The physical constants of some heterosiloxanes of zirconium and hafnium are listed in Table 3.

V. Siloxanes of Vanadium, Niobium, and Tantalum

Heterosiloxanes of pentavalent vanadium of the type $(R_3SiO)_3VO$, which may also be regarded as triorganosilyl vanadates, can be synthesized by eight different routes and isolated in the pure state. *M. G. Voronkov et al.* [91,108,109] used the reaction of triorganosilanols with vanadium pentoxide, which gives the desired products in yields of 50–80 % when the water is continuously removed from the equilibrium mixture.

$$6\ R_3SiOH + V_2O_5 \rightarrow 2\ (R_3SiO)_3VO + 3\ H_2O$$

The same silyl vanadates are also formed by the reaction of triorganosilanols with alkyl orthovanadates (yield approximately 90 %).

$$3\ R_3SiOH + R'_3VO_4 \rightarrow (R_3SiO)_3VO + 3\ R'OH$$

$VOCl_3$ may also be used as the vanadium component instead of V_2O_5 or R_3VO_4. The replacement of halogen by the triorganosiloxy residues of alkali metal silanolates leads almost quantitatively to the desired compounds.

$$VOCl_3 + 3\ R_3SiONa \rightarrow (R_3SiO)_3VO + 3\ NaCl$$

Even silanols react with $VOCl_3$ in the presence of hydrogen halide acceptors such as pyridine (yield 60–80 %).

$$VOCl_3 + 3\ R_3SiOH + 3\ C_5H_5N \rightarrow 3\ C_5H_5N^{\oplus}HCl^{\ominus} + (R_3SiO)_3VO$$

Schmidt and *Schmidbaur* independently obtained the compounds at the same time and by other routes [110].

Silver orthovanadate undergoes a heterogeneous but practically complete reaction with trimethylchlorosilane in benzene or methylene chloride:

$$Ag_3VO_4 + 3\ (CH_3)_3SiCl \xrightarrow{12\,^{\circ}C} [(CH_3)_3SiO]_3VO + 3\ AgCl \qquad (55)$$

Small quantities of silyl vanadate could also be obtained from V_2O_5 and hexamethyldisiloxane.

$$V_2O_5 + 3\ (CH_3)_3SiOSi(CH_3)_3 \rightleftarrows 2\ [(CH_3)_3SiO]_3VO \quad (55)$$

However, the yields in this reaction are unsatisfactory ($< 10\,\%$).

Other methods for the formation of V–O–Si linkages are the reaction of vanadium oxide chloride with lead silanolates [111] and the "alkoxy-acyloxy reaction" [112].

$$3\ Pb[OSi(C_2H_5)_3]_2 + 2\ VOCl_3 \rightarrow 2[(C_2H_5)_3SiO]_3VO + 3\ PbCl_2 \quad (56)$$

$$V(O\text{-}i\text{-}C_3H_7)_3 + (CH_3)_3SiOCOCH_3 \rightarrow (CH_3)_3SiOV(O\text{-}i\text{-}C_3H_7)_2 + CH_3COO\text{-}i\text{-}C_3H_7 \quad (66)$$

Thus nearly all the methods that have been used for the preparation of titanosiloxanes are also suitable for the preparation of heterosiloxanes of vanadium [113–116].

The physical constants of the compounds prepared by the above methods are listed in Table 3. The compounds with aliphatic substituents are colorless; they are very sensitive to moisture, and immediately become intensely red in presence of traces of water. The compounds are thermally relatively stable, and decompose only at high temperatures with elimination of hexaalkyldisiloxane and formation of polymeric trialkylsilyl metavanadates. The latter are brown compounds, are sparingly soluble in organic solvents, and

$$n(R_3SiO)_3VO \rightarrow n\ R_3SiOSiR_3 + (R_3SiOVO_2)_n$$

are hydrolysed only slowly [118]. Tris(trimethylsilyl)-vanadate *(55)* can be distilled without decomposition at 230 °C. The phenylated compounds are not only stable to heat, but also exhibit considerable stability to water and can therefore be purified in many cases by washing with water [114]. This stability is thought to be mainly due to steric effects.

Heterosiloxanes of tetravalent vanadium, such as *(64)*, are obtained by reaction of VCl_4 with alkali metal silanolates.

$$VCl_4 + 4\ (C_6H_5)_3SiONa \rightarrow 4\ NaCl + V[OSi(C_6H_5)_3]_4 \quad (64)$$

Tetrakis(triphenylsiloxy)vanadium *(64)* is the only member of this series that has been positively characterized. The compound is interesting because of the four oxygen atoms coordinated to the central vanadium atom, which is in the oxidation state +4 (cf. [119]). In the presence of atmospheric oxygen, *(64)* is slowly converted into tris(triphenylsilyl)orthovanadate *(57)* [114].

$$2V[OSi(C_6H_5)_3]_4 + 1/2\ O_2 \rightarrow 2[(C_6H_5)_3SiO]_3VO + [(C_6H_5)_3Si]_2O$$
(64) *(57)*

[119] *G. F. Kokoszka, H. C. Allen jr.*, and *G. Gordon*, Inorg. Chem. 5, 91 (1966).

Reaction with sulfur yields the corresponding thiovanadate *(63)* [114], which, like its oxygen analogues, is stable to cold water and is thermally very stable even above 200 °C.

$$2V[OSi(C_6H_5)_3]_4 + 1/8\ S_8 \rightarrow [(C_6H_5)_3SiO]_3VS \quad (63)$$
$$+ [(C_6H_5)_3SiO]_3VO + (C_6H_5)_3SiOSi(C_6H_5)_3 \quad (57)$$

Reactions of $VOCl_3$ with hexamethyldisiloxane led to the first trimethylsiloxy derivatives of monochloro- and dichlorovanadic acids [110, 118].

$$(CH_3)_3SiOSi(CH_3)_3 + VOCl_3 \rightarrow (CH_3)_3SiCl + (CH_3)_3SiOVOCl_2 \quad (62)$$

$$2(CH_3)_3SiOSi(CH_3)_3 + VOCl_3 \rightarrow 2(CH_3)_3SiCl + [(CH_3)_3SiO]_2VOCl \quad (61)$$

The cleavage of the siloxane takes place in stages, and if the trimethylchlorosilane is not removed from the equilibrium, the reaction stops at the dichlorovanadate stage *(62)*. If the equilibrium is displaced, the monochlorovanadate *(61)* is formed. The two silylchlorovanadates can also be obtained by the reaction of trimethylchlorosilane with trimethylsilyl orthovanadate or -chlorovanadate.

Finally, orthovanadate and dichlorovanadate coproportionate readily:

$$[(CH_3)_3SiO]_3VO + (CH_3)_3SiOVOCl_2 \rightarrow 2[(CH_3)_3SiO]_2VOCl \quad (61)$$

(61) and *(62)* are pale yellow and yellow liquids, respectively, which become brilliant red on contact with traces of moisture. They are hydrolysed in water, with formation of hydrogen chloride, trimethylsilanol, and vanadic acid. They can be distilled under vacuum without decomposition, but they decompose at high temperatures with elimination of trimethylchlorosilane.

Heterosiloxanes of vanadium have been suggested and patented for use as catalysts for the cracking of petroleum, as corrosion inhibitors, and as fuel and dye additives [40, 113, 116]. However, their effectiveness has not yet been confirmed.

Polymers containing the structural unit V–O–Si [120] are formed *e.g.* in the reaction of VCl_4 with diphenylsilanediol [115].

Whereas vanadium forms siloxanes of the types $(R_3SiO)_4V$ and $(R_3SiO)_3VO$, niobium and tantalum form only heterosiloxanes having the general formulae $(R_3SiO)_5Nb$ and $(R_3SiO)_5Ta$ [86, 104]. These compounds can be synthesized by the same methods as are used for Ti, Zr, and V compounds, *e.g.*:

$$(RO)_5Nb + 5R'_3SiOCOCH_3 \rightarrow (R'_3SiO)_5Nb + 5CH_3COOR$$
$$(RO)_5Ta + 5R'_3SiOH \rightarrow (R'_3SiO)_5Ta + 5ROH$$

The compounds of this class that are listed in Table 3 are colorless liquids or crystalline solids, which can be volatilized under vacuum without decomposition. They are all monomeric, and the metal atoms have a coordination number of 5. It is not known whether

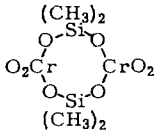
the arrangement of the ligands is trigonal-bipyramidal or tetragonal-monopyramidal. No spectroscopic studies have so far been carried out. Heterosiloxanes of niobium and tantalum are all sensitive to hydrolysis and alcoholysis. Their properties are very similar to those of the corresponding alkoxides.

It was recently reported by *Bradley et al.*[121] that careful hydrolysis of pentakis(trimethylsiloxy)tantalum, unlike that of compounds of the type $El(OR)_5$ (where El = element of Group Va of the periodic system), but like that of $Ti[OSi(CH_3)_3]_4$ and of $Zr[OSi(CH_3)_3]_4$, yields soluble polymers of the type $\{TaO_x[OSi(CH_3)_3]_{(5-2x)}\}_n$. Other polymeric siloxanes of Nb and Ta are described in a report mentioned earlier[120].

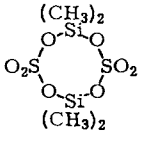
VI. Siloxanes of Chromium, Molybdenum, Tungsten, and Uranium

In most of the heterosiloxanes of chromium that have been described so far, the element is present in the hexavalent state. Working with chromosiloxanes (silyl chromates) has proved to be extremely dangerous, and very often leads to serious explosions[122–124]. Consequently, these compounds must not be handled carelessly.

Bis(trimethylsilyl)chromate $[(CH_3)_3SiO]_2CrO_2$ *(73)* is a brilliant orange-red liquid, which can be prepared in good yields from anhydrous chromium trioxide and hexamethyldisiloxane.



$$(CH_3)_3SiOSi(CH_3)_3 + CrO_3 \rightarrow [(CH_3)_3SiO]_2CrO_2 \qquad (73)$$



This heterolysis of the disiloxane bridge by chromium trioxide proceeds in a manner similar to the cleavage with sulfur trioxide or selenium trioxide[125–127]. Complete reaction of the chromium trioxide is observed in an excess of siloxane, even under mild conditions[124]. The product can be purified by careful vacuum distillation, but this can lead to explosion for no apparent reason. Even when no explosion occurred, the compound was found to decompose slowly with deposition of dark, lower chromium oxides. Bis(trimethylsilyl)chromate (b.p. 60 °C/0.2 mm Hg and $n_D^{20} = 1.4937$) is immediately hydrolysed by water to chromic acid and trimethylsilanol.

$$[(CH_3)_3SiO]_2CrO_2 + 2\,H_2O \rightarrow 2\,(CH_3)_3SiOH + H_2CrO_4$$

The quantitative determination of the chromic acid may be used for the analysis of the compound.

Experiments with dimethylpolysiloxane and octamethylcyclotetrasiloxane instead of hexamethyldisiloxane[118] have shown that CrO_3 can also be incorporated into these compounds to give products that are deep yellow silicone oils, in which some of the Si–O–Si groups have not been converted into Si–O–CrO_2–O–Si bridges. Before the reaction is complete, decomposition with deposition of lower chromium oxides again takes place. Owing to the danger of explosion, no attempt was made to separate by distillation the pure dimethylsilyl chromate, which, like the corresponding sulfate, should be dimeric with an eight-membered ring structure.

The product obtained is probably best described by the general formula:

$$[-O-Si(CH_3)_2]-[CrO_4-Si(CH_3)_2]_a-[O-Si(CH_3)_2-]_b \qquad (a, b = 1, 2, 3 \ldots)$$

F. C. Saunders[122] reported a violent explosion when a mixture of methylpolysiloxanes was heated with CrO_3.

Solutions of chromosiloxanes in an excess of hexamethyldisiloxane can be used as oxidizing agents for organic compounds[118]. CrO_3 is a milder oxidizing agent in this form than in *e.g.* glacial acetic acid. The fact that the oxidation can be carried out in homogeneous nonaqueous or aprotic solvents is often an advantage. The dangerous silyl chromates need not be isolated for this purpose, the substance in question simply being allowed to react with CrO_3 in hexamethyldisiloxane.

Compounds containing the Cr–O–Si grouping have also been obtained by other routes. Thus the reaction of chromyl chloride with sodium triphenylsilanolate yields bis(triphenylsilyl) chromate having m.p. 138 to 140 °C[115].

$$CrO_2Cl_2 + 2NaOSi(C_6H_5)_3 \rightarrow [(C_6H_5)_3SiO]_2CrO_2 + 2NaCl \qquad (74)$$

Siloxy compounds of tetravalent chromium can be prepared from Cr^{IV} alkoxides and silanols[128].

$$Cr(OC_4H_9)_4 + 4(C_2H_5)_3SiOH \rightarrow [(C_2H_5)_3SiO]_4Cr + 4C_4H_9OH \qquad (75)$$

The silyl chromates prepared are listed, together with their physical constants, in Table 4.

Silyl chromates of the type $R_3Si-O-CrO_2-O-SiR_3$ have been used as catalysts for the polymerization

of olefins [129, 130]. (For polymeric chromosiloxanes see [120].)

Attempts to prepare halogenochromic acid derivatives of the silanols have been unsuccessful [118]. The reaction of the acid anhydrides sulfur trioxide and selenium trioxide with halogenosilanes [131, 132] could not be observed in the case of CrO_3 and trimethylchlorosilane.

$$SO_3 + (CH_3)_3SiCl \rightarrow (CH_3)_3SiO{-}SO_2{-}Cl$$

$$CrO_3 + (CH_3)_3SiCl \rightarrow (CH_3)_3SiO{-}CrO_2{-}Cl$$

Whereas no reaction could be detected below 50 °C, a redox reaction with evolution of chlorine took place above 50 °C.

Descriptions of the preparation of chromosiloxanes from siloxanes and CrO_2Cl_2 in the patent literature are particularly interesting in this connection [133]. Such a reaction would have to proceed *via* silyl chlorochromates. However, it would be necessary to establish that these reactions can be carried out in the desired manner.

Thus of the analogous series of compounds

$Cl_3TiOSi(CH_3)_3$ $Cl_2OVOSi(CH_3)_3$

$ClO_2CrOSi(CH_3)_3$ $O_3MnOSi(CH_3)_3$

only the first two can be prepared, whereas the last two (see below) autoxidize spontaneously.

Attempts to prepare heterosiloxanes of molybdenum and of tungsten by conventional methods were unsuccessful for a long time. Neither the reaction of siloxanes with molybdenum trioxide nor the reaction of alkylchlorosilanes with silver molybdate led to the desired compounds [118].

Molybdenum dioxide dichloride reacted with hexamethyldisiloxane, but isolation of the desired product was prevented by a subsequent redox reaction with separation of molybdenum blue. However, compounds containing the system Mo–O–Si are reported to be formed by the reaction of sodium triphenylsilanolate with the dimethylformamide complex of $MoO(OH)_2Cl_2$ [115] but the compounds formed have not yet been fully characterized.

Polyheterosiloxanes of tungsten have been prepared by *M. M. Chamberlain* [120]. However, no definite low molecular weight siloxy compounds of tungsten have been reported as yet.

Heterosiloxanes of the actinide element uranium have been studied by *D. C. Bradley et al.* [18, 19]. The compounds were prepared by methods that have already been mentioned several times:

$$U(OC_2H_5)_5 + 5R_3SiOH \rightarrow U(OSiR_3)_5 + 5C_2H_5OH$$

$$U(OC_2H_5)_6 + 6R_3SiOH \rightarrow U(OSiR_3)_6 + 6C_2H_5OH$$

$$UCl_4 + 2(C_2H_5)_2CH_3SiOLi \rightarrow Cl_2U[OSi(C_2H_5)_2CH_3]_2 + 2LiCl \quad (76)$$

The resulting compounds of pentavalent uranium are yellow-brown to yellow-green, whereas those of the hexavalent metal are orange-red to red sublimable solids; the only known derivative of tetravalent uranium is a green distillable solid. Molecular-weight determinations in boiling benzene showed that the permethylated silanolate of pentavalent uranium is associated; it is almost dimeric on average (n = 1.77). Pentakis(triethylsilyl)uranate(v), on the other hand, is strictly monomeric. A similar dependence of association on the substituent has already been mentioned in connection with the heterosiloxanes of zirconium. The silanolates of hexavalent uranium are all monomeric, irrespective of the nature of the organic substituent. This observation seems quite plausible in view of the steric conditions.

VII. Siloxanes of Manganese, Technetium, and Rhenium

No heterosiloxanes of manganese are known as yet. Several attempts have been made to prepare the fundamentally feasible compounds $R_3SiOMnO_3$ of heptavalent manganese from trimethylchlorosilane and silver permanganate and from hexamethyldisiloxane and dimanganese heptoxide [118]. However these reactions always resulted in reduction of the heptavalent manganese and deposition of manganese dioxide. As in the case of chromium(VI) compounds, explosions occur when these compounds are handled carelessly.

Reactions of this type were not carried out with technetium compounds. Owing to the much weaker oxidizing power of Tc^{VII} compared with that of manganese, however, it should be possible to prepare silyl pertechnates, and these should be reasonably stable.

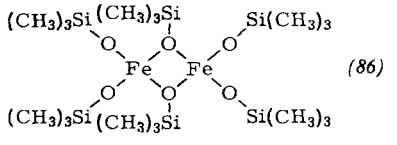
[133] *F. E. Granchelli* and *G. B. Walkers*, US.-Pat. 2863891 (1958); French Pat. 1179740 (1959).

The remarkably stable rhenium siloxane *(85)* was prepared in very good yields several years ago [134].

$$(CH_3)_3SiCl + AgReO_4 \xrightarrow{-AgCl} (CH_3)_3SiReO_4 \quad (85)$$



$$1/2\ [(CH_3)_3Si]_2O + 1/2\ Re_2O_7 \rightarrow$$

Trimethylsilyl perrhenate forms colorless crystals having m.p. 79.5–80.5 °C, which are very soluble in organic solvents. Hydrolysis leads to trimethylsilanol and to quantitative formation of perrhenic acid, which can be titrated alkalimetrically.

VIII. Siloxanes of Iron, Cobalt, Nickel, and Platinum

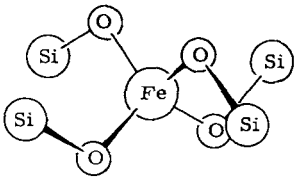
A number of low molecular weight heterosiloxanes of trivalent iron have become known in recent years [135–140]. Dimeric tris(trimethylsiloxy)iron *(86)* is formed in good yields [125,139] in accordance with the following equation:

$$2\ FeCl_3 + 6\ NaOSi(CH_3)_3 \longrightarrow 6\ NaCl +$$

(86)

The compound forms yellow-green, wax-like crystals having m.p. 179–181 °C, which are very readily soluble in aprotic organic solvents.

Like the corresponding aluminum and gallium derivatives [141,142], the compound has a structure with a four-membered iron-oxygen ring system. The 3-coordinate oxygen atoms in this dimer give the compound a distinctly unsaturated character, which becomes particularly noticeable on addition of alkali metal or pseudoalkali silanolates. The four-membered ring system is opened and each of the iron atoms acquires an additional silanolate ligand. In this way the metal retains a coordination number of four without the need for unstable bridge bonds.



The alkali metal or pseudoalkali tetrakis(trimethylsiloxy)ferrates [135,137,139,140], *(87)–(90)*, are formed in accordance with the equation:

$$\underset{(86)}{\{Fe[OSi(CH_3)_3]_3\}_2} + 2\ MOSi(CH_3)_3 \rightarrow 2\ M\{Fe[OSi(CH_3)_3]_4\}$$

(87), M = Li *(89)*, M = K
(88), M = Na *(90)*, M = $(CH_3)_4Sb$

The ionic compounds *(87)–(89)* are pale yellow, and are very sparingly soluble in organic solvents. They do not melt or sublime below about 200 °C, at which temperature they decompose slowly with deposition of Fe_2O_3. The well-formed crystals of the ionic tetramethylstibonium tetrakis(trimethylsiloxy)ferrate *(90)* [137,140] are readily soluble in polar organic solvents, but only slightly soluble in nonpolar solvents. They melt at 193 °C and sublime at 190 ° C/1 mm Hg.

Crystallographic investigations on *(90)* [143] indicated an orthorhombic structure having the space group P_{mmn} with $a = 13.50_8$ Å; $b = 11.95_8$ Å; $c = 9.81$ Å; $U = 1584.9$ Å^3; $d_{exp.} = 1.25$; $d_{calc.} = 1.246$.

The compound *(90)* is therefore isostructural with the corresponding tetrakis(trimethylsiloxy)aluminates and gallates [143]. The four oxygen atoms are arranged tetrahedrally around the iron atom.

The recently prepared complex of this iron siloxane with trimethylamine oxide has a similar structure. This coordination compound is formed almost quantitatively in accordance with

$$(86) + 2\ (CH_3)_3NO \rightarrow [(CH_3)_3Si{-}O]_3Fe{-}O{-}N(CH_3)_3.$$

The pale yellow crystals, which are very sensitive to hydrolysis and to autoxidation, have m.p. 86–90 °C and can be distilled at 145–148 °C/1 mm Hg. The donor strength of trimethylamine oxide is evidently sufficiently great to displace the bridge siloxy oxygen atoms from the coordination with the iron atom and to open the four-membered ring [143a].

Only two articles have been published on polymeric siloxanes of iron [144,145]. *K. A. Andrianov et al.* [144] obtained polyheterosiloxanes containing Fe–O–Si structural units from anhydrous $FeCl_3$ and $C_6H_5Si(OH)_2ONa$ and by the action of aqueous NaOH and iron(III) ammonium sulfate on a polyphenylsiloxane prepared from $H_2O/C_4H_9OH/(C_6H_5)SiCl_3$. The preparation of polyferrosiloxanes by treatment of the monoalkali metal salt of an organosilandiol or -triol with FeX_3 is described in a patent [145]. The resulting compounds which contain the structural unit $-Fe(OSiR_3)-OSiR_2-OSiR_2-O-$ were not characterized further.

Little is known as yet about heterosiloxanes of cobalt and nickel. $CoCl_2$ and sodium trimethylsilanolate give the deep blue, wax-like crystalline bis(trimethylsiloxy)-

[145] Distillers Co. Ltd., Brit. Pat. 978666 (1962); Chem. Abstr. *62*, 6650 (1965).

cobalt *(91)* [146], in accordance with the following equation:

$$CoCl_2 + 2\ NaOSi(CH_3)_3 \rightarrow Co[OSi(CH_3)_3]_2 + 2\ NaCl$$
(91)

Compound *(91)* sublimes at 160–180 °C/1 mm Hg, is paramagnetic, and is extremely sensitive to oxygen and moisture; its structure has not yet been elucidated.

In addition to this compound, a number of polymers having Co–O–Si and Ni–O–Si structural units have been described; these are reported to have extremely high thermal stabilities and to be slowly hydrolysed only in hot water. These polymers are obtained from dialkyldialkoxysilanes and cobalt or nickel acetate. The reaction of diorganosilanediolates with cobalt chloride leads to compounds of this type [147, 148].

An article by *Andrianov* and *Zhdanov* [149] is particularly interesting in this connection. According to these authors, compounds containing Co–O–Si and Ni–O–Si structural units could not be obtained by the reaction of $RSi(OH_2)ONa$ with $CoCl_2$ or $NiCl_2$ in butanol. The addition of $AlCl_3$ in the case of $CoCl_2$ yields a violet polymer, while with $NiCl_2$ a green polymer is obtained; however, in addition to the desired structural units, these compounds also contain Al–O–Si bonds. The thermochemical properties of polycobaltsiloxanes have recently been studied [7].

Heterosiloxanes of the light and heavy platinum metals have so far been almost completely ignored. The first success was reported only very recently in the case of the heterosiloxanes of platinum [5]. Trimethylplatinum chloride reacts with lithium tetramethylsilanolate in tetrahydrofuran with deposition of LiCl and formation of a hexamethylplatinosiloxane *(92)*, which can be isolated with some difficulty:

$$(CH_3)_3PtCl + LiOSi(CH_3)_3 \rightarrow (CH_3)_3Pt{-}O{-}Si(CH_3)_3 + LiCl$$
(92)

The compound *(92)*, which forms colorless crystals having m.p. 98 °C, does not sublime without decomposition but can be recrystallized from petroleum ether. Above 100 °C *(92)* decomposes with deposition of metallic platinum. The NMR spectrum ($\delta_{CH_3(Pt)} = -69$ Hz; $\delta_{CH_3(Si)} = -6.5$ Hz; J (^1H–C–^{195}Pt) = 78.5) confirms the proposed composition, as does the IR spectrum (νSiO = 904; νSiC = 671, 615; νPtC = 584, 558; νPtO = 440).

Compound *(93)* represents an important addition to the homologous series of the heterosiloxanes of the heavy metals: $Me_3PtOSiMe_3$; $Me_2AuOSiMe_3$; $MeHgOSiMe_3$; $TlOSiMe_3$; $Me_2TlOSiMe_3$; $Me_3PbOSiMe_3$; $Me_2BiOSiMe_3$ (Me = CH_3) [5].

Note: A monograph on "Organoelement Compounds of Silicon" by *S. N. Borisov, M. G. Voronkov,* and *E. Ya. Lukevits* has now been published (Izd. Khimiya, Leningrad 1966), in which the subject of the present article is dealt with at length.

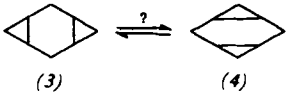
COMMUNICATIONS

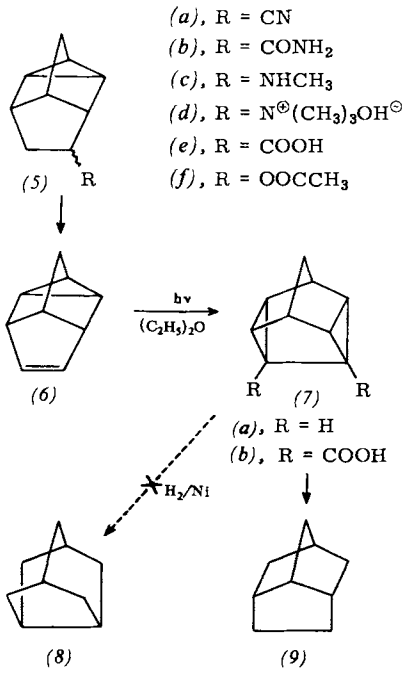


Valence Isomerizations of Hydrocarbons Containing Three-Membered Rings

By *E. Wiskott* and *P. v. R. Schleyer* [*]

Several examples of light induced valence isomerizations of the general type *(1)* → *(2)* have been reported recently [1a]. It is known that reverse reactions *(2)* → *(1)* can sometimes take place thermally [1b]. Thermal automerizations (degenerate isomerizations) [1c] of type *(3)* ⇌ *(4)* are of particular

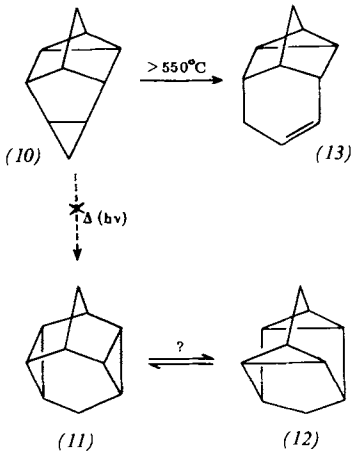
(1) *(2)*



(3) *(4)*

interest, but transformations of this type are formally forbidden by the Woodward-Hoffmann rules [2], and attempts to detect such rearrangements have failed [3]. Only one exception is known to us, and this involves a compound activated by carboxyl substituents [4]. Stimulated by recent literature reports [5, 6] we herewith present our own observations on molecules representative of these two classes.

Tetracyclo[4.3.0.$0^{2,4}$.$0^{3,7}$]non-8-ene *(6)* [6–8], the starting material for our investigations, was prepared by two different methods from the readily available nitrile *(5a)* [9]. The first route involved the following steps: Partial hydrolysis of *(5a)* to the amide *(5b)*; Hofmann rearrangement of the latter in methanol to a methyl urethane followed by $LiAlH_4$ reduction to methylamine *(5c)*; and quaternization of *(5c)* to *(5d)*. Hofmann elimination of *(5d)* gave the desired olefin in 22 % overall yield, calculated from *(5a)*. The second route (based on the method of *LeGoff* and *Slee* [8]) was somewhat simpler: Hydrolysis of the nitrile *(5a)* gave an acid *(5e)* which could be converted to the acetate *(5f)* by the action of lead tetraacetate. Pyrolysis of *(5f)* at 500 °C gave *(6)* in 70 % yield. The overall yield of *(6)* calculated from *(5a)* was 32 %.



When *(6)*, a compound of type *(1)*, was irradiated in ether (450 W Hanovia lamp, no filter), pentacyclo[4.3.0.-$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]nonane *(7a)*, m.p. 85–87 °C, was produced. A yield of 30 % was realized using gas chromatographic isolation.

Very recently, failure of a similar attempt to convert *(6)* into *(7a)* has been reported [6]. This failure was due, evidently, to the use of acetone as the solvent, *i.e.* the experiment was

conducted under conditions which favor dimerization rather than isomerization. A description of a different preparation of *(7a)*, by bisdecarboxylation of *(7b)*, has just appeared[5]. The physical and spectroscopic properties of *(7a)* produced by the two routes are in agreement.

We had hoped to be able to prepare noradamantane *(8)* by hydrogenation of *(7a)*. However, with Raney-nickel catalyst under high pressure conditions, brendane *(9)*[10] was the main product and only a trace, at most, of noradamantane *(8)* was formed[11]. Both cyclopropane rings were reduced from the same side of the molecule, a reduction course also observed with triasterane *(14)*[12].

Cyclopropanation[13] of *(6)* gave pentacyclo[4.4.0.0^{2,4}.0^{3,7}.0^{8,10}]decane *(10)*, b.p. 170–172 °C, in 65 % yield. NMR in CCl_4 at 60 MHz: τ = 7.94 (2H); 8.61 (2H); 8.76 (1H); 8.80–9.05 (5H); 9.45–10.20 (2H). The mass spectrum of *(10)* gave a parent peak at *m/e* = 132, a base peak at *m/e* = 118, and additional prominent peaks at *m/e* = 39, 54, 78, 91, 104, and 116.

All our attempts to isomerize *(10)*, a compound of type *(3)*, to "tetradehydroadamantane" *(11)* failed. Thermally *(10)* was stable below 550 °C. Above that temperature only rearrangement to an olefin, probably *(13)*, occurred. After irradiation of *(10)* for 200 hours under the conditions used for *(6)*, only starting material was recovered. We are now attempting to isomerize derivatives of *(10)*, activated by suitable substituents.

In view of the failure of *(10)* to isomerize to *(11)*, and of *(14)* and *(15)* to interconvert[3], the ready transformation of *(11)* into *(12)* also seems unlikely. As mentioned, all of these valence isomerizations are of the type *(3)* $\rightleftharpoons$ *(4)* which the Woodward-Hoffmann rules[2] indicate to be forbidden processes.

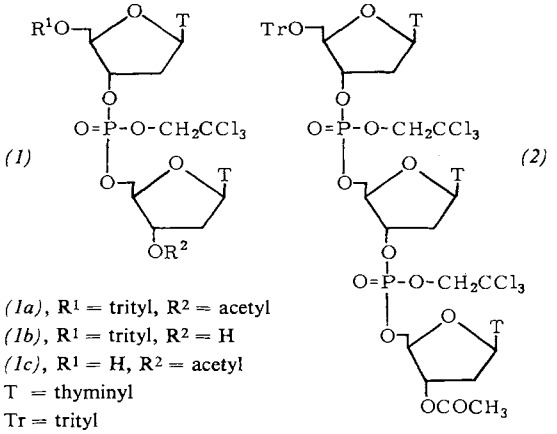
Synthesis of Oligonucleotides by Use of Phosphoric Triesters [1]

By *F. Eckstein* and *I. Rizk* [*]



In the synthesis of higher oligonucleotides by-products arise that can be traced to activation of the internucleotide bond by the condensing agent[2]. Esterification of the free OH groups on the phosphate bridges should repress these side reactions and, further, make it possible to separate the products on silica gel.

We therefore activated the pyridinium salt of 2,2,2-trichloroethyl 5′-trityl-3′-thymidylic acid ($NH_4^{\oplus}$ salt: m.p. 226 °C)[3,4] (0.5 mmole) with 2,4,6-triisopropylbenzenesulfonyl chloride (1 mmole) in pyridine (3 ml) (12 h at room temperature)

and then condensed the product with 3′-*O*-acetylthymidine (0.5 mmole) (further 12 h at room temperature)[5]. We were then able to isolate the triester *(1a)*[4] in 55% yield by preparative thin-layer chromatography of the reaction mixture (Merck-Kieselgel PF 254, chloroform/methanol = 93:7 v/v).

Reduction of *(1a)* with Zn dust in 80% acetic acid (20 min at room temperature) and subsequent removal of the trityl and acetyl groups gave TpT[6] (90% yield).

Hydrolysis of *(1a)* with concentrated ammonia (2 h) gave tritylthymidine, thymidine, and *(1b)* in the relative yields 25:20:55, together with phosphoric acid diesters. Acid hydrolysis (80% acetic acid, 100 °C, 10 min) afforded exclusively *(1c)*.

(1) *(2)*

(1a), R^1 = trityl, R^2 = acetyl
(1b), R^1 = trityl, R^2 = H
(1c), R^1 = H, R^2 = acetyl
T = thyminyl
Tr = trityl

Replacing the acetylthymidine in the condensation by *(1c)* yields 55% of the oligonucleotide ester *(2)*[4] (amorphous, m.p. 143 °C). Fission of the trichloroethyl group by reduction with Zn dust and 80% acetic acid and removal of the trityl and acetyl groups gives TpTpT[6] (85% yield).

RF values on Merck DC-prepared silica gel plates F_{254}, chloroform/methanol = 93:7 v/v

5′-Tritylthymidine	0.63	*(1a)*	0.86
3′-Acetylthymidine	0.52	*(1b)*	0.38
(2)	0.57	*(1c)*	0.42

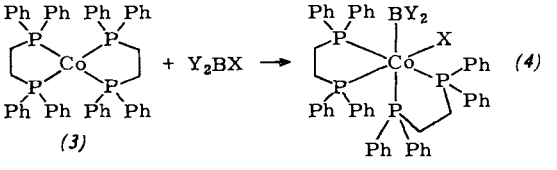
Synthesis of Metal-Boron Coordination Compounds by Oxidative Addition

By *G. Schmid, W. Petz, W. Arloth*, and *H. Nöth*[*]

Complex metal hydrides or metal alkyls are formed by oxidative addition of H_2, HX, or RX, respectively, (X = halogen) to d^8- and d^{10}-metal compounds in low oxidation states[1,2].



For instance, (i) the planar complex $[(C_6H_5)_3P]_2Ir(CO)Cl$ is converted by HCl into the octahedral iridium(III) complex $[(C_6H_5)_3P]_2IrH(CO)Cl_2$[1], and (ii) reaction of RX with the tetrakis(triphenylphosphine)platinum(0)[3] results in loss of 2 mol. equiv. of $(C_6H_5)_3P$ to give halogenoalkylbis(triphenylphosphine)platinum(II)[4].

We have found that the method of oxidative addition is eminently suited for the synthesis of covalent metal-boron compounds. Titanocene *(1)*[5] reacts with boron halides Y_2BX in ether at room temperature; the deep green of the solution of *(1)* changing to the purple color of the compound *(2)*.

$$[(\pi\text{-}C_6H_5)_2Ti]_2 + 2\ Y_2BX \longrightarrow 2\ (\pi\text{-}C_5H_5)_2Ti\begin{matrix}X\\BY_2\end{matrix}$$

(1) *(2)*

Bis(tetraphenyldiphosphinoethane)cobalt(0) behaves similarly; for example, in benzene it is oxidized by diphenylboron chloride to *cis*-diphenylborochlorobis(tetraphenyldiphosphinoethane)cobalt(II) *(4a)*. The boron halides BCl_3, BBr_3, and BI_3 may be used in place of diphenylboron chloride.

(3) *(4)*

Tetrakis(triphenylphosphine)platinum(0) *(5)* in boiling cyclohexane[7] reacts with diphenylboron chloride to yield triphenylphosphine and crystalline diphenylborochlorobis(triphenylphosphine)platinum(II) *(6a)*.

$$[(C_6H_5)_3P]_4Pt + Y_2BX$$

(5)

$$\longrightarrow 2\ (C_6H_5)_3P + [(C_6H_5)_3P]_2Pt\begin{matrix}X\\BY_2\end{matrix}$$

(6)

Sufficient Lewis-acidity on the part of the boron halide is of decisive importance for the success of the above synthesis. The weakly acidic compounds $(C_4H_9)_2BCl$, $[(CH_3)_2N]_2BCl$, $B[N(CH_3)_2]_3$, and $(C_6H_5)_2B{-}N(C_2H_5)$ do not react.

Surprisingly, bis(tetraphenyldiphosphinoethane)platinum(0)[8] reacts with diphenylboron chloride or bromide in boiling cyclohexane according to:

$$(TPE)_2Pt + 2(C_6H_5)_2BX \rightarrow (TPE)Pt{\cdot}2(C_6H_5)_2BX + TPE.$$

(7a), X = Cl
(7b), X = Br

The structures of the pale yellow products *(7a)*, m.p. 214 °C, and *(7b)*, m.p. 210 °C (decomp.), are not yet known. Reaction with pyridine results in loss of one mol. equiv. of $(C_6H_5)_2BX$ and formation of *cis*-diphenylborotetraphenyldiphosphinoethaneplatinum(II) halides. Therefore, we classify *(7a)* and *(7b)* as diphenylboron halide adducts of the compound *(8)*.

$$[(H_5C_6)_2P{-}CH_2{-}CH_2{-}P(C_6H_5)_2]PtX[B(C_6H_5)_2]$$

(8)

Evidence for the structure of the newly prepared compounds is provided by their chemical behavior and by elemental analysis, molecular-weight determinations, magnetic measurements, and spectrochemical data.

	X	Y	M.p. (°C)	Color	Yield (%)
(2a)	Cl	C_6H_5	300 (decomp.)	black-violet	80
(2b)	Br	Br	300 (decomp.)	black-violet	75
(2c)	Cl	Cl	300 (decomp.)	black-violet	80
(4a)	Cl	C_6H_5	115 [a]	red-brown	92
(4b)	Br	Br	120	red-brown	95
(4c)	Cl	Cl	115 (decomp.)	red-brown	97
(6a)	Cl	C_6H_5	244 (decomp.)	beige	87
(6b)	Br	C_6H_5	198–200	pale yellow	88
(6c)	Br	Br	306	white	85
(8a)	Cl	–	208 (decomp.)	white	65
(8b)	Br	–	150	white	70

[a] Magnetic moment: 4.8 BM.

Since tetrakis(triphenylphosphine)platinum(0) reacts with Si_2Cl_6 to give the compound $[(C_6H_5)P]_2Pt(SiCl_3)_2$, m.p. 180 °C (decomp.), and also reacts with metal-halide complexes of the type L_nMX_m (L = phosphine, X = halogen) to give $[(C_6H_5)_3P]Pt(X)-MX_{m-1}L_n$ [9], it may be predicted that not only boron halides, but also other non-metal halides, as well as metal halide complexes, may react with the systems that we have investigated and thus provide a simple route to numerous new metal-element compounds.

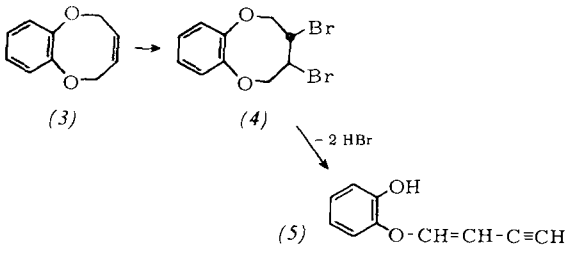
1,6-Benzodioxocin: Synthesis and Properties

By *W. Schroth* and *B. Werner* [*]

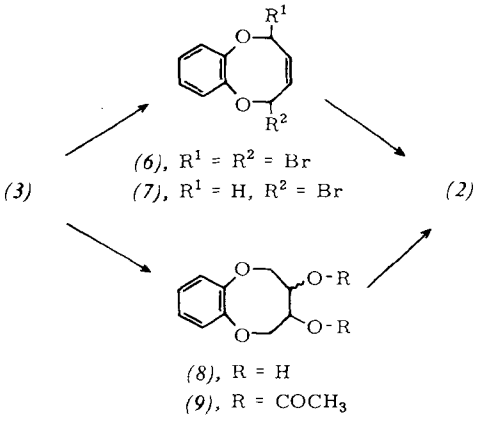


Heterocyclic compounds of the type *(1)*, X = O, N–R, S (1,4-diheterocins) may be formally regarded as 10 π-electron systems. We have prepared and investigated a member of this series [1], namely, 1,6-benzodioxocin *(2)*.

(1) *(2)*

The substance used as starting material was 2,5-dihydro-1,6-benzodioxocin *(3)* [2], which was formed (along with 2-vinyl-2,3-dihydro-1,4-benzodioxin and 2,3:10,11-dibenzo-1,4,9,12-tetraoxacyclohexadeca-all-*cis*-2,6,10,14-tetraene) on reaction of pyrocatechol with *cis*-1,4-dichloro-2-butene.

Double dehydrobromination of *(4)* [2,3], the *trans* dibromo-adduct obtained from *(3)*, with potassium t-butoxide does not yield *(2)*, but gives 1-(*o*-hydroxyphenoxy)but-1-en-2-yne *(5)* (b.p. 124 °C/10 mm). The elimination involves 3-bromo-2,5-dihydro-1,6-benzodioxocin (m.p. 30 °C) as an intermediate, which is formed by reaction of *(4)* with 1,5-diazobicyclo[4.3.0]non-5-ene [4].

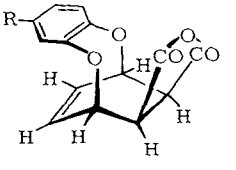


(3) *(4)* *(5)*

Compound *(2)* may be prepared by the following methods:

a) By bromination of *(3)* with two mol. equiv. of *N*-bromosuccinimide to form *(6)*, which is not isolated but is reduced with zinc dust in dimethylformamide. Yield approximately 10 % (with respect to *(3)*).

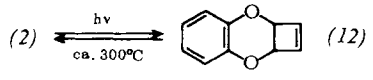
b) By monobromination of *(3)* with *N*-bromosuccinimide to form 2-bromo-2,5-dihydro-1,6-benzodioxocin *(7)*, which subsequently is treated with triethylamine.



c) By oxidation of *(3)* to *cis*- and *trans*-3,4-dihydroxy-2,3,4,5-tetrahydro-1,6-benzodioxocin *(8)* [1] (*cis* compound: m.p. 112 °C; *trans* compound: m.p. 111 °C), acetylation to the diacetoxy derivatives *(9)* (*cis* compound: m.p. 62 °C; *trans* compound: m.p. 88 °C), and pyrolysis (450 °C). Yield up to 3 % (with respect to *(3)*).

(8), R = H
(9), R = $COCH_3$

Compound *(2)* is a colorless oil (b.p. 109 °C/13 mm) which crystallizes on cooling (m.p. 5 °C). The ^1H–NMR signals [5] of the heterocyclic ring protons in *(2)* lie in the "olefinic range" (τ = 3.05 and 4.65, both signals being split into double doublets with J = 5 and 2 Hz, respectively); the resonance of the benzene-ring protons lies at τ = 2.40. The fact that the UV absorption of *(2)* (λ_{max} = 277, 272 nm; log ε_{max} = 3.47, 3.49 in cyclohexane) is at shorter wavelengths than that of *(3)* (λ_{max} = 282, 275; log ε_{max} = 3.30, 3.33 in cyclohexane) indicates reduced coplanarity, *i.e.* hindered conjugation of the hetero ring with the benzene ring, in compound *(2)*. Thus, in spite of satisfying the $4n+2$ rule (n = 2), π-electron delocalization in the heterocyclic ring of *(2)* takes place to a limited extent only, if at all [6].



At 190 °C (bath temperature), *(2)* reacts with maleic anhydride to give the Diels-Alder adduct *(10)*, m.p. 220 °C; ^1H–NMR: τ = 3.20 (aromatic-ring protons), 3.82 (olefinic protons), 4.86 (CH-O), and 6.07 (CH-CO-O), relative areas = 2:1:1:1. Proof of structure is provided by hydrolysis (HBr/acetic acid) to phthalic acid. The formulated *exo* configuration of *(10)* is in agreement with the fact that no bromo-

(10), R = H
(11), R = Br

lactonic acid is formed on treatment with hypobromous acid; instead, bromination of the benzene ring occurs. Dehydration under vacuum at 150 °C yields *(11)*, m.p. 263; ^{1}H–NMR τ = 3.10, 3.19 (aromatic-ring protons), 3.56 (olefinic protons), 4.83 (CH–O), and 5.72 (CH–CO–O), relative areas = 3:2:2:2.

On being irradiated with UV light (50 h, 20 °C) compound *(2)* undergoes disrotatory valence isomerization to 3,4-benzo-2,5-dioxabicyclo[4.2.0]octa-3,7-diene *(12)*, m.p. 63 °C; ^{1}H–NMR: τ = 3.21 (aromatic-ring protons), 3.80 (olefinic protons), 4.81 (CH–O), relative areas = 2:1:1. Thermally

induced isomerization of *(12)* back to *(2)* requires temperatures of about 300 °C. At these temperatures decomposition starts to take place and small amounts of *(12)* are cleaved to 1,4-benzodioxin[7] and acetylene.

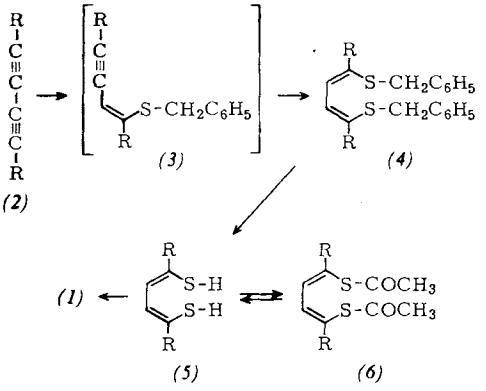
1,2-Dithiins, a New Type of Heterocycle [1]

By *W. Schroth, F. Billig*, and *G. Reinhold*[*]

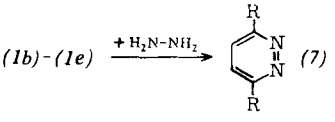
The, as yet, unknown 1,2-dithiins *(1)* have a disulfide structure in cyclic conjugation and thus formally represent an 8-π electron system. To account for the great lability of the recently synthesized[2] parent compound *(1a)* (a red oil that is easily polymerized and splits off sulfur with the formation of thiophene) it was necessary to investigate the 3,6-disubstituted derivatives.



(1)

	R	M.p. (°C) [B.p. (°C/mm)]	λ_{max} [a] (nm)	log ε
(1a)	H	[45/4]	451	2.88
(1b)	C_6H_5	143	468	3.12
(1c)	*p*-CH_3–C_6H_4	162	470	3.46
(1d)	*p*-CH_3O–C_6H_4	179	467	4.43
(1e)	2-Thienyl	123	481	3.76

[a] In the visible spectral region; in cyclohexane.



The synthesis of such derivatives was accomplished by nucleophilic addition of phenylmethane thiol to butadiynes *(2)* to give *cis,cis*-1,4-bis(benzylthio)butadienes *(4)*. Reductive debenzylation of *(4)* with sodium in liquid ammonia (–70 °C) gives the *cis,cis*-1,4-dimercaptobutadienes *(5)*, which on oxidation (with air) in alkaline solution give the desired products. In a few cases (R = *p*-CH_3–C_6H_4, *p*-CH_3O–C_6H_4, CH_3) the mono-addition products *(3)* were obtained.

	R	*(3)* M.p. (°C)	*(4)* M.p. (°C)	*(5)* M.p. (°C) [B.p. (°C/mm)]	*(6)* M.p. (°C)
(a)	H	–	129	[38/0.3]	148
(b)	C_6H_5	–	118	99	159
(c)	*p*-CH_3–C_6H_4	91	136	138	193
(d)	*p*-CH_3O–C_6H_4	73	157	148	167
(e)	2-Thienyl	–	116	–	156
(f)	CH_3	55	98	–	–

The relatively unstable dithiols *(5)* are stored as the diacetyl compounds *(6)* from which they can be regenerated by the action of dilute alkalis.

The 3,6-disubstituted 1,2-dithiins *(1b)–(1e)* are obtained as deep red crystals. They may be reduced with sodium tetrahydridoborate or with sodium in liquid ammonia to give the dithiols *(5)*. They readily split off sulfur (especially rapidly on heating or on UV irradiation) to form the 2,5-disubstituted thiophenes. This reaction predominates in all attempts to prepare Diels-Alder adducts of the compounds *(1b)–(1e)* with maleic anhydride or tetracyanoethylene. Oxidation of *(1b)* with hydrogen peroxide in glacial acetic acid leads to the 1,4-diphenylbutadiene-1,4-disulfonic acid (m.p. 108 °C; IR: strong absorption at 1170–1200 and 3400–3450 cm^{-1}). When the compounds *(1b)–(1e)* react with hydrazine in pyridine, or in dimethylformamide, H_2S is evolved and 3,6-disubstituted pyridazines *(7)* are formed.

Compounds of type *(1)* (R = acetylene/olefin side chains) have recently been detected in plants, presumably as precursors of natural thiophene derivatives[3]. The spontaneous elimination of sulfur and their light absorption in the visible region suggested the formulation of the valence isomer *(8)*[3a,4].

We consider that the following facts bear out the cyclic disulfide structure *(1)*: (i) If the compound *(1a)* had the structure *(8)*, then an NMR signal of the thioaldehyde hydrogen atoms would lie at very low field strengths[5] – this was not the case (the chemical shifts are τ = 3.87 and 4.03;

1,4-dithiin: $\tau = 4.05$); (ii) If the compounds *(1b)–(1e)* were to have the structure *(8)*, they would be aromatic thioketones, which absorb at considerably greater wavelengths (at 600 nm)[6].

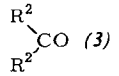
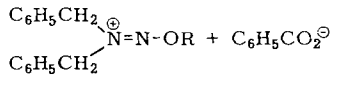
The Synthesis of Carbonylazo Compounds by the Reaction of Alkoxydiazenium Salts with Carboxylates [1]



By *Th. Eicher, S. Hünig,* and *H. Hansen*[*]

Alkoxydiazenium salts are easily accessible by the alkylation of nitrosamines with trialkyloxonium salts, or $AgClO_4$/alkyl halide[2]. The reaction of carboxylates with alkoxydiazenium cations *(1)*, in which R^1 is an aromatic or tertiary aliphatic residue[3], generally leads to the formation of carbonylazo compounds *(2)* in high yield. Equivalent amounts of the carbonyl compound *(3)* are also formed[4].



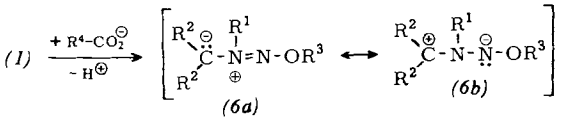
(1) *(2)*

R^1 = Aryl, tert.-Butyl
R^2 = H, CH_3, C_6H_5
R^3 = CH_3, C_2H_5
R^4 = Aryl, Alkyl

(3)

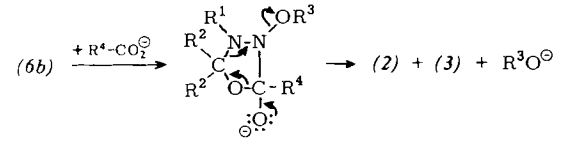
The carbonylazo compounds are not obtained from cations *(1)* when R^1 is a substituent with an α-hydrogen atom, *e.g.* CH_3, $CH_2C_6H_5$; in this case the isomers of the acylhydrazones *(4)* are formed by proton migration[5].

(4)



The carbonylazo compounds *(2)* are isolated as red substances after the usual techniques of product recovery by chromatography or crystallization. When difficulties are encountered in purification of the crude compounds *(2)* they are reduced with sodium dithionite to the stable hydrazides *(5)* which are easier to obtain pure.

R^1–NH–NH–CO–R^4



R^1	R^4	*(2)* Yield (%)	*(2)* M.p. (°C)	*(5)* Yield (%)	*(5)* M.p. (°C)
C_6H_5	C_6H_5			93	163–165 [a]
p-CH_3O–C_6H_4	C_6H_5	90	68–69	84	138–139 [b]
p-Cl–C_6H_4	C_6H_5	98	73–74	96	156–157
p-CH_3O–C_6H_4	p-O_2N–C_6H_4	84	148–150		
p-CH_3O–C_6H_4	CH_3			50	133–134 [c]
$(CH_3)_3C$	C_6H_5			75	94–96

[b] *S. Goldschmidt* and *J. Bader,* Liebigs Ann. Chem. *473*, 125 (1929).
[c] *J. Altschul,* Ber. dtsch. chem. Ges. *25*, 1842 (1892).

Although the investigations of the mechanism of the reaction have not yet been completed, the following scheme is a plausible representation of the formation of compounds *(2)* and *(3)* from *(1)*:

(6a) *(6b)*

(7)

Deprotonation of *(1)* leads to the dipolar entity *(6)*, which, in the ground state, might have the structure *(6b)* on account of the differences between the electronegativities of the participating centers. The carboxylate anion is alkylated by *(6)* and undergoes simultaneous N–C ring closure to form the intermediate *(7)* which yields *(2)* and *(3)* *via* a seven-center cyclic fragmentation.

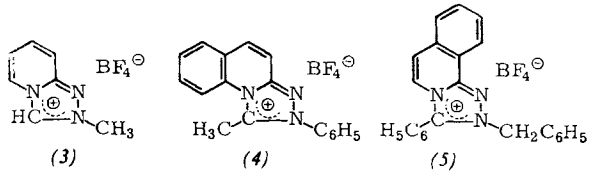
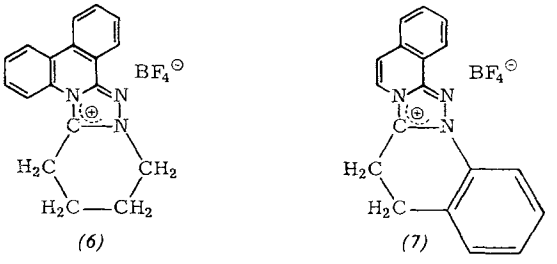
Synthesis of *s*-Triazolium Cations by Reaction of Alkoxydiazenium Salts with Nitrogen Heterocycles [1]



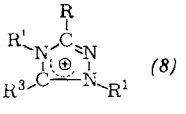
By *Th. Eicher, S. Hünig,* and *P. Nikolaus*[*]

Alkoxydiazenium cations[2] of the type *(1)*, in an organic or an aqueous medium, add smoothly to nitrogen heterocycles such as pyridine, quinoline, isoquinoline, phenanthridine, or benzthiazole to form heterocyclo[2,1-*c*]-*s*-triazolium salts *(2)*. The reaction proceeds *via* formal loss of alcohol and two hydrogen atoms.



(1) R^2H_2C $BF_4^\ominus$ (2)

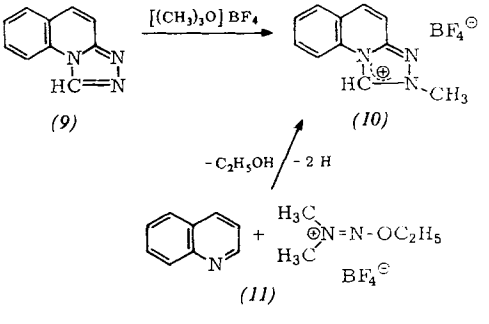
R^1 = Aryl, Alkyl
R^2 = Aryl, Alkyl
R^3 = CH_3, C_2H_5



(3) (4) (5)

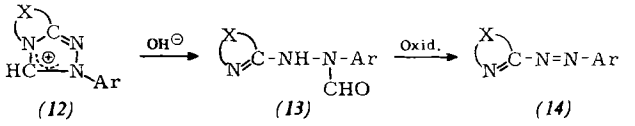
(6) (7)

	M.p. (°C)	Yield (%)
(3)	157–158	67
(4)	275–277	30
(5)	241–242	76
(6)	289–291	32
(7)	319–320	46



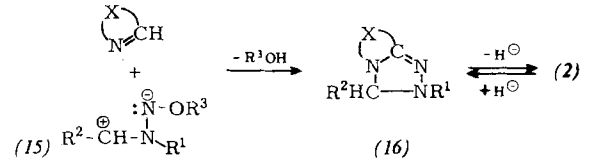
The compound *(1)* also adds on Schiff bases resulting in formation of the non-anellated *s*-triazolium cations *e.g. (8)* [*(8)*, R = R^1 = R′ = R^3 = C_6H_5: m.p. *ca.* 340 °C (decomp.), yield 58%].

(8)



The assignment of the structure *(2)* is based on the NMR spectra, the assumption being made that an alkyl- or aryl-migration is improbable. The following chemical findings provide additional evidence:

a) The alkylation of 5,6-benzpyrido[2,1-*c*]-*s*-triazole *(9)* with trimethyloxonium tetrafluoroborate forms the same triazolium cation *(10)* as is formed in the reaction of 2-ethoxy-1,1-dimethyldiazenium tetrafluoroborate *(11)* with quinoline.



(9) *(10)* *(11)*

b) Alkaline fission of triazolium cations of the type *(12)* and subsequent oxidation leads, *via* the formylhydrazine *(13)*, to the 2-arylazoheterocycle *(14)* [3], thus confirming the presence of the heterocycle-*N*–*N*-aryl grouping in the cation *(12)*. The reaction sequence, heterocycle + *(1)* → *(12)* → *(14)* is simultaneously a new route for the direct introduction of azoaryl residues into heterocycles.

(12) *(13)* *(14)*

The formation of *(2)* probably proceeds also *via* the dipole *(15)* [4].

(15) *(16)*

The expected adduct *(16)* is not obtained as it is immediately dehydrogenated to *(2)* by *(1)*. This step can be proved in a separate experiment, since *(16)* can be prepared by the action $NaBH_4$ on *(2)* [3].
