Heterolytic Fragmentation. A Class of Organic Reactions

BY C. A. GROB AND P. W. SCHIESS [*]

Heterolytic fragmentation is a widespread but neglected class of organic reactions. It involves the regulated cleavage of molecules containing certain combinations of atoms such as carbon, oxygen, nitrogen, sulfur, phosphorus, silicon, boron and halogens. Fragmentation reactions are useful in degradation and structure elucidation, some are also of preparative value. A knowledge of the structural and electronic requirements makes it possible to predict and influence the course of reactions. From a theoretical viewpoint the recognition of heterolytic fragmentation has lead to the classification and correlation of a large number of apparently diverse reactions. Selected cases are reviewed in this article.

I. Definition

On the basis of mechanistic principles most reactions in organic chemistry can be reduced to a relatively small number of reaction classes. Those most extensively studied and therefore known in greatest detail are substitution, addition, elimination and rearrangement. In this manner a vast number of chemical transformations has been correlated, a development which has deeply influenced teaching and research.

About ten years ago a further reaction class was defined and termed fragmentation, since it involves the cleavage of a molecule symbolized by a–b–c–d–X into three fragments a–b, c=d and X[1]. The letters a,b,c, and d denote a sequence of atoms such as C, O, N, S, P, or B. However, fragmentation also occurs with compounds containing metal atoms[2]. In heterolytic fragmentation, which is by far the most common type in solution, X leaves with the electron pair by which it was originally attached to the rest of the molecule, *i.e.* as a nucleofuge[3]. X thereby becomes more negative by one charge unit and is converted into a nucleofugal fragment. This is usually an anion such as a halide, carboxylate and sulfonate ion. Neutral nucleofugal fragments derive from diazonium-, oxonium-, ammonium- and sulfonium-groups (Scheme 1).

Scheme 1. Heterolytic fragmentation.

Electrofugal groups and fragments		Middle and unsaturated groups and fragments		*Nucleofugal* groups and fragments	
a–b–	a⇀b or a → b	–c–d–	c=d	–X	X
HO–CR_2–	O=CR_2	–CR_2–CR_2–	R_2C=CR_2	–Cl	$Cl^{\ominus}$
RO–CR_2–	RO$^{\oplus}$=CR_2	–CR=CR–	RC≡CR	–Br	$Br^{\ominus}$
HOOC–	CO_2	–CR_2–NR–	R_2C=NR	–I	$I^{\ominus}$
R_2N–CR_2–	$R_2N^{\oplus}$=CR_2	–CR=N–	RC≡N	–SO_3R	$RSO_3^{\ominus}$
R_3C–	$R_3C^{\oplus}$	–CR_2–O–	R_2C=O	–OCOR	$RCOO^{\ominus}$
RCO–	RC$^{\oplus}$=O	–CO–O–	CO_2	–$OH_2^{\oplus}$	H_2O
$R_2C^{\ominus}$–CR_2–	R_2C=CR_2	–N=N–	N_2	–$NR_3^{\oplus}$	NR_3

HN=N–	N_2			–N$^{\oplus}$≡N	N_2

The electron deficiency on atom d resulting from the departure of X leads to heterolytic cleavage of the bond between b and c, with formation of an unsaturated fragment c=d and a fragment a–b. The latter leaves without the bonding electron pair, *i.e.* as an electro-

[1] *C. A. Grob* and *W. Baumann*, Helv. chim. Acta *38*, 594 (1955); *C. A. Grob*, Experientia *13*, 126 (1957); "Theoretical Organic Chemistry" Report on the Kekulé Symposium, Butterworth, London 1958, p. 114; *C. A. Grob* and *F. Ostermayer*, Helv. chim. Acta *45*, 1119 (1962).

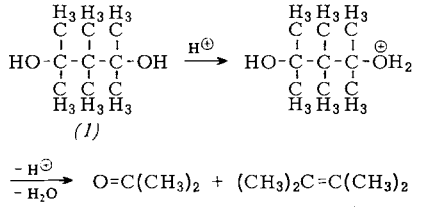
[2] The cleavage of carbonium ions into a smaller cationic fragment and an olefin in accordance with R_3C–C–C–X → $R_3C^{\oplus}$ + C=C was first recognized as a possible secondary reaction of carbonium ions by *F. C. Whitmore* and *E. E. Stahly*, J. Amer. Chem. Soc. *55*, 4153 (1933); *67*, 2158 (1945). *V. I. Maksimov*, Tetrahedron *21*, 687 (1965), has recently attempted to interpret fragmentations as cases of σ,σ-conjugation as defined by *A. N. Nesmeyanov*, Vestnik Moskovskogo Univ. Ser. II *132*, 5 (1950). This term is evidently intended to describe the electromeric participation of a σ bond β to an unsaturated center which is formed in the transition state. It would therefore correspond to hyperconjugation, which does not necessarily lead to fragmentation, *i.e.* cleavage of a σ bond.

fuge[3], becoming one unit of charge more positive in the process. Electrofugal fragments are therefore frequently cations.

Typical electrofugal fragments are carbonyl compounds (often formed as their conjugate acids), carbon dioxide, imonium-, carbonium-, and acylium-ions, olefins, diimine, and nitrogen (Scheme 1). Silicon, phosphorus, boron derivatives, and organometal ions also act as electrofugal fragments. The ease with which an electrofugal fragment a–b is formed will depend on the stabilization of the incipient positive charge on b due to the inductive or conjugative effect of a. This structural unit is frequently a hydroxyl, amino, alkyl, or aryl group. The displacement of electrons from a towards b, *i.e.*

a→b or ä–b

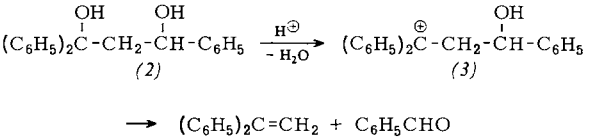
promotes the release of the unsaturated fragment c=d.



Unsaturated fragments frequently encountered are olefins, acetylenes, imines, and nitriles. Less common are carbonyl compounds, carbon dioxide, carbon monoxide and nitrogen (Scheme 1). At present more than sixty fragmentable systems are known which differ only with respect to the groups a–b and c–d. By taking into account variations of the nucleofugal group X, a far greater number of cases can be cited from the literature. Since new examples are constantly being found, a system of classification is urgently needed. The system adopted in this review is based on the nature of the three fragments in the following order: 1. middle-, 2. electrofugal- and 3. nucleofugal-fragment.

Fragmentation reactions[4] can also be classified according to mechanistic criteria, since, like elimination reactions[5], they can proceed by three basic mechanisms These differ in the order in which the fragments are released. Thus one-step and two-step processes can be distinguished depending on whether a–b and X depart simultaneously from c–d or whether a–b or X depart successively[5a]. In this review of a selected number of fragmentation reactions, questions related to mechanism will be considered only insofar as they are essential to the understanding of the particular reaction. Moreover, homolytic fragmentation and the fragmentation patterns resulting from electron impact and detected by mass spectrometry will not be discussed, since different principles are involved in these cases.

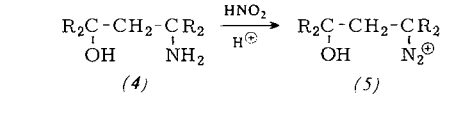
II. Olefin-Forming Fragmentations (a–b–C–C–X)



a) H–O–C–C–C–X

In many olefin-forming systems, the electron-donating part is a hydroxyl group or an alkoxide oxygen atom. In these cases the electrofugal fragment is a carbonyl compound. Probably one of the earliest examples is the acid-catalysed fragmentation of tetramethyl-2,4-pentanediol *(1)* into acetone and dimethyl-2-butene[6]:

(1)



In unsymmetrical 1,3-diols, the nucleofugal fragment is usually formed from the hydroxyl group on the more highly substituted carbon atom, as is shown by the exclusive formation of benzaldehyde and 1,1-diphenylethylene when 1,1,3-triphenyl-1,3-propanediol *(2)* is heated with acid. This suggests that the fragmentation proceeds *via* the more stable tertiary carbonium ion *(3)*[7]:

(2) *(3)*

However, fragmentation can also occur *via* the diazonium salt *(5)* as in the deamination of γ-aminoalcohols *(4)* with nitrous acid[8]. The yields vary, and depend on the substituents R and on stereochemical factors.

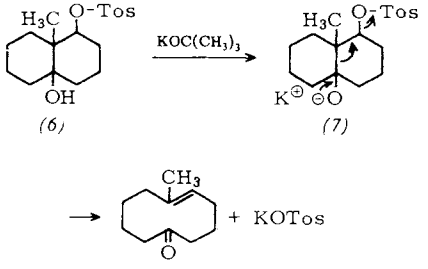
(4) *(5)*

[3] Whereas the terms nucleophile and electrophile refer to the role of reagents in bond formation the complementary terms nucleofuge and electrofuge refer to bond cleavage, specifically to the partitioning of the electrons which formed the original bond. The term leaving group is inadequate, since in fragmentation two different kinds of leaving group are involved: *J. Mathieu, A. Allais,* and *J. Valls,* Angew. Chem. *72,* 71 (1960).

[4] According to the above definition, heterolytic fragmentation is a generalization of heterolytic elimination. An elimination involves the removal of a nucleofugal group X and an electrofugal atom, usually a proton, from the β-position, whereas in fragmentation the electrofugal fragment is a group of atoms. If the chain a–b–c–d=X contains a double bond between d and X, the group X does not leave the molecule on heterolysis of the b–c bond. The molecule then breaks down into only two fragments. Reactions of this type, such as the retroaldol reaction $^{\ominus}O-C-C-C=O \rightarrow O=C + C=C-O^{\ominus}$, are 1,2-eliminations where a resonance stabilized nucleofugal group is liberated. They are therefore not considered in the present review.

[5] *C. K. Ingold*: Structure and Mechanism in Organic Chemistry. Cornell University Press, Cornell 1953, p. 419.

[5a] Mechanistic and stereochemical aspects of heterolytic fragmentation will be discussed in a later article.



[6] *A. Slawjanow*, J. Russ. Phys. Chem. Soc. *39*, 140 (1907); Chem. Abstr. *1*, 2077 (1907).

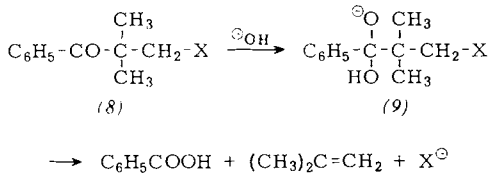
[7] *J. English* and *F. V. Brutcher*, J. Amer. chem. Soc. *74*, 4279 (1952).

[8] *J. English* and *A.D.Bliss*, J. Amer. chem. Soc. *78*, 4057 (1956); *R. R. Burford, F. R. Hewgill,* and *P. R. Jefferies*, J. chem. Soc. (London) *1957*, 2937.

In this as in many other cases, fragmentation is accompanied by substitution and elimination.

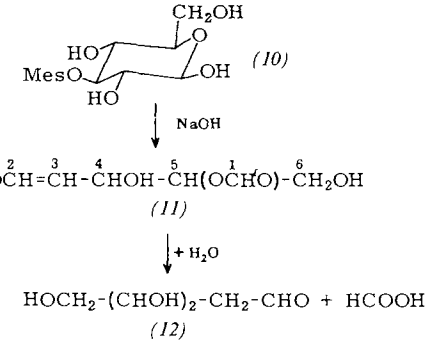
Many fragmentations, such as that of the bicyclic γ-hydroxytosylate *(6)*, are brought about by a strong base, *e.g.* potassium t-butoxide [9]; the reacting substrate is therefore the anion *(7)*.

(6) *(7)*



In such cases the fragmentation is also of preparative use, since it permits the stereospecific synthesis of medium-sized unsaturated rings that are otherwise difficult to obtain.

The reverse of this fragmentation, *i.e.* the condensation of an olefin with an aldehyde or ketone in the presence of an acid, is possible in many cases [10]. (When formaldehyde is used as the carbonyl component, this is known as the Prins reaction).

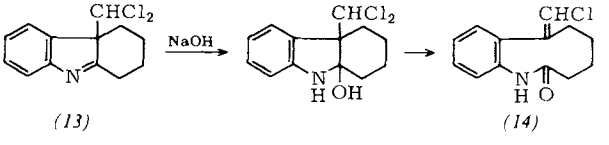


b) O=C—C—C—X

Aldehydes and ketones bearing a nucleofugal group in the β position can be cleaved into acids and olefins by treatment with alkali. This reaction is observed in particular when the usual 1,2-elimination of HX with formation of the α,β-unsaturated carbonyl compound is difficult or prevented by structural factors. Thus it has been shown that, on treatment with sodium hydroxide, 3-bromo-2,2-dimethyl-1-phenyl-1-propane[*(8a)* X = Br] (ω-bromopivalophenone) or the trimethylammonium iodide [*(8b)*, X = $N(CH_3)_3{}^{\oplus}I^{\ominus}$] breaks down *via* the adduct *(9)* into benzoic acid and isobutene [11]. This

(8) *(9)*

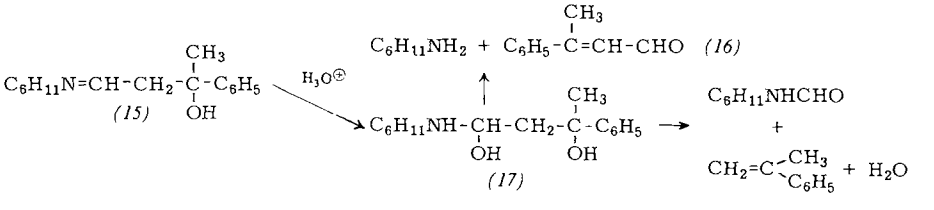
Another example is 3-mesyl-D-glucose, whose hemiacetal form *(10)* is cleaved by sodium hydroxide into the enol *(11)*, the precursor of 2-deoxy-D-ribose *(12)*, and formic acid [12].



(10)

(11)

(12)



c) —N=C—C—C—X

Imines (Schiff bases) containing a nucleofugal group in the β-position also become fragmentable after addition of a nucleophile. Thus the 3*H*-indole derivative *(13)* reacts with sodium hydroxide to form the unsaturated nine-membered lactam *(14)* [13].

(13) *(14)*

Fragmentation occurs as an undesirable side reaction in the preparation of unsaturated aldehydes by aldol condensation of an acetaldimine with ketones. For example, on treatment with acid, the β-hydroxyaldimine

(15) *(16)* *(17)*

is an example of a compound that becomes fragmentable only after an active electrofugal group has been formed by the addition of a nucleophile.

(15) not only undergoes hydrolysis and dehydration to *(16)*, but also suffers fragmentation with formation of cyclohexylformamide and α-methylstyrene [14]. The common reactive substrate is undoubtedly the product resulting from the addition of water *(17)*.

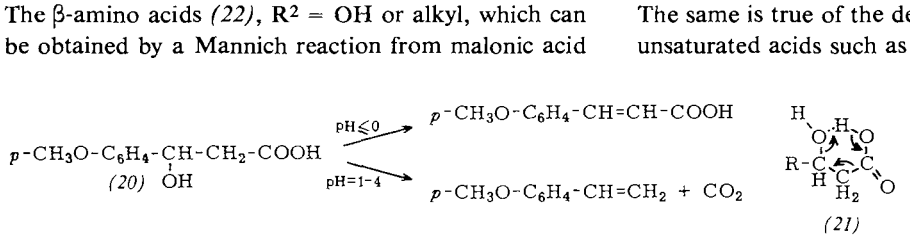
d) H—O—CO—C—C—X

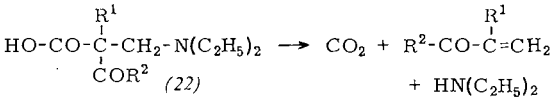
Many β-halocarboxylic acids undergo decarboxylation to an olefin when their salts are heated in solution. One of the earliest examples is the formation of styrene from 3-bromo-3-phenyl propionic acid *(18)* in aqueous soda [15].



(18)

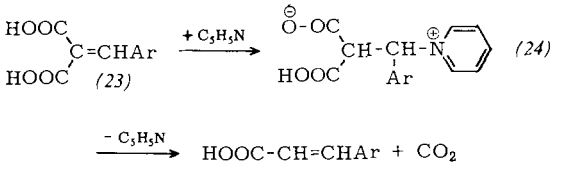
The sodium salt of the *erythro* form of dibromohydrocinnamic acid *(19)* is stereospecifically decarboxylated in a non-polar solvent such as acetone to *cis*-bromostyrene [16].

(19)



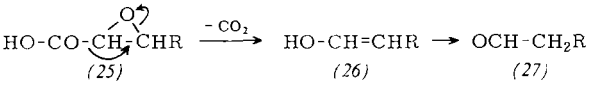
In β-hydroxycarboxylic acids decarboxylation competes successfully with the elimination of water to form the α,β-unsaturated acid. Whereas 3-hydroxy-3-(*p*-methoxyphenyl)propionic acid *(20)* is dehydrated to the cinnamic acid derivative in strongly acidic solution, the main reaction in weakly acidic solution is decarboxylation to *p*-methoxystyrene. In this case the reactive substrate is presumably *(21)*, which contains an internal hydrogen bond [17].

(20)



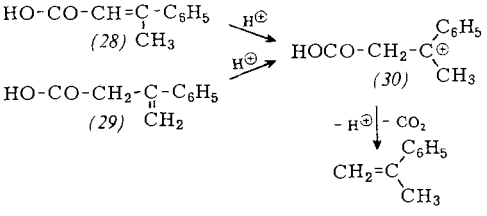
(21)

The β-amino acids *(22)*, R^2 = OH or alkyl, which can be obtained by a Mannich reaction from malonic acid and β-keto acids [18], undergo spontaneous decarboxylation to form α,β-unsaturated carbonyl compounds.



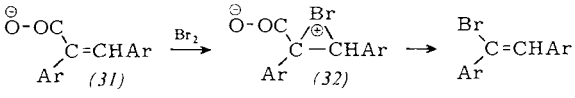
(22)

Arylethylenedicarboxylic acids *(23)* also readily undergo decarboxylation when heated with pyridine. The reactive substrate in this case is the zwitterion *(24)* which contains the nucleofugal pyridinium group β to the carboxyl group [19].



(23) *(24)*

An interesting variant of these reactions is the Darzen reaction. α,β-Epoxy acids (glycidic acids) such as *(25)* are readily decarboxylated to the aldehyde with one less carbon atom [20]. In this case the nucleofugal oxygen atom of the epoxide group remains attached to the unsaturated fragment, so that the primary product is an enol *(26)*, the precursor of the aldehyde *(27)*.



(25) *(26)* *(27)*

In principle, any carboxylic acid having a carbonium ion center in the β-position can undergo decarboxylation, as is shown by the acid-catalysed fragmentation of the α,β- and β,γ-unsaturated acids *(28)* and *(29)* [21]. In both cases the olefinic double bond is protonated to form the β-carbonium ion *(30)*.

(28) *(29)* *(30)*

The same is true of the decarboxylation of salts of α,β-unsaturated acids such as *(31)* with bromine [22] to the bromo olefin, which presumably proceeds *via* a bromonium ion *(32)*.

(31) *(32)*

e) R—O—C—C—C—X

The role of the electron-donating atom a of the electrofugal group a–b can occasionally be assumed by an ether oxygen atom. Thus when the tosylate *(33)* is heated with dimethyl sulfoxide, very little of the ex-

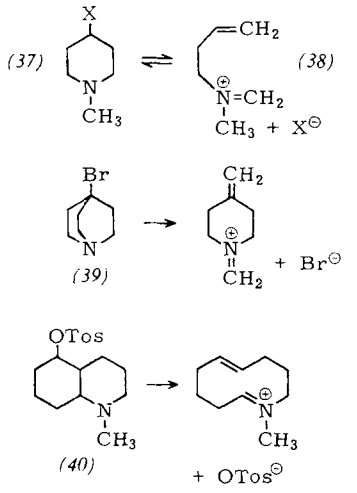
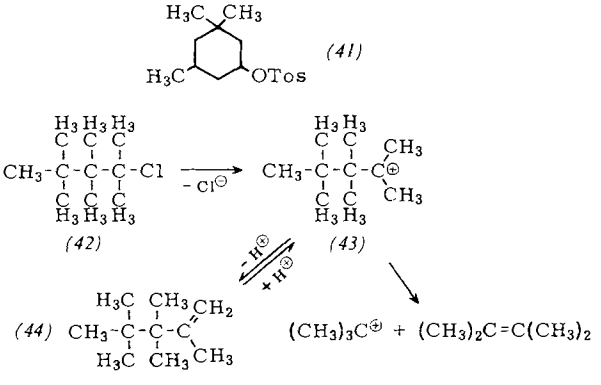
pected aldehyde is formed; instead fragmentation to the oxonium salt *(34)* yields benzophenone and 3-buten-1-ol [23].



f) R_2N—C—C—C—X

The most thoroughly studied fragmentation reactions include those of γ-amino halides and sulfonates [24]. Several cleavages of this type have been observed in alkaloids [25]. They also occur, accompanied by side reactions, with acyclic γ-amino halides. For example, the solvolysis of *N*-(3-chloro-3-methylbutyl)dimethylamine *(35)* in 80 % aqueous ethanol leads to the fragmentation product isobutylene *(36)* in about 40 % yield, together with the amino olefin, the alcohol, and the azetidinium salt [26].



Under solvolytic conditions, cyclic γ-amino halides such as 4-chloro-1-methylpiperidine [*(37)*, X = Cl] [27] and 4-bromoquinuclidine *(39)* [28], as well as *N*-methyl-5α-tosyloxy-*trans*-decahydroquinoline *(40)* [29], undergo quantitative fragmentation to imonium salts or their hydrolysis products, *i.e.* amino olefins, aldehydes, and ketones.

The reverse of this reaction, *i.e.* the Mannich olefin condensation, proceeds particularly readily when it leads to ring closure, as in the reaction *(38)* → *(37)*, X = OH.

g) R_3C—C—C—X

The fragmentation of propanol derivatives containing a tertiary γ–C atom should yield relatively stable carbonium ions $R_3C^{\oplus}$ (R = alkyl or aryl) in addition to olefins. However, experience has shown that the electrofugal activity of ordinary carbonium ions is not sufficient for cleavage. Thus no fragmentation could be observed in the solvolysis either of *cis*- and *trans*-3,3,5-trimethylcyclohexyltosylate *(41)* [30] or of 2-chloropentamethylpentane *(42)* [31]. In this last case further reaction of the intermediate carbonium ion *(43)* leads only to the olefin *(44)*. However, if the carbonium ion *(43)* is repeatedly reformed by protonation of the olefin *(44)*, the thermodynamically more favorable fragmentation to the t-butyl cation and dimethyl-2-butene takes place [31].

Fragmentation can also occur in strained compounds [30], as is shown by the formation of β-terpineol *(48)* and limonene *(49)* on treatment of α-pinene *(45)* [*] with acid [32] and on deamination of *endo*-bornylamine *(46)* with nitrous acid [33]. In both cases fragmentation leads to the formation of the carbonium ion *(47)*, the precursor of *(48)* and *(49)*.

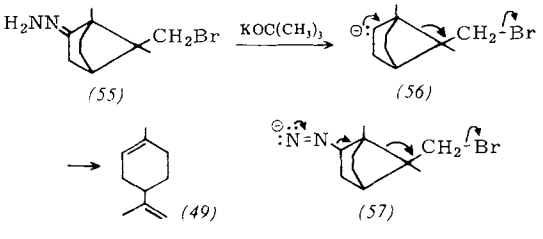
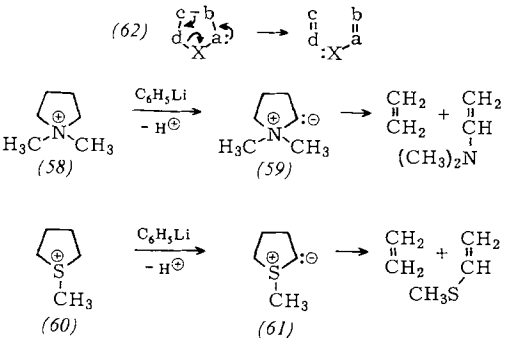
A special case is that of 2-methyl-3-tropyl-2-propanol *(50)*, which undergoes fragmentation with perchloric acid to form the very stable tropylium ion *(51)* and isobutene [34].

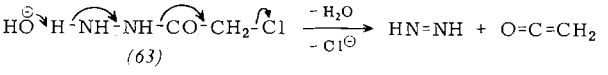


h) $-\overset{\ominus}{\ddot{C}}-C-C-C-X$

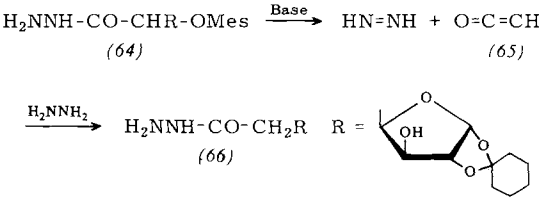


This class includes fragmentations induced by the formation of a carbanion center on the δ-carbon atom. The cleavage of 1,4-dihalides by zinc or an alkali metal possibly follows this path [35]. In the reaction of *cis*- and *trans*-1,4-dibromocyclohexane *(52)* with zinc, which yields 1,5-hexadiene exclusively, the fragmentable substrate might be the organozinc compound *(53)*. However, a reaction pathway *via* the 1,4-diradical *(54)* is not excluded since, like other 1,4-diradicals, it could undergo homolysis to form the hexadiene.

Another example is provided by the fragmentation of *trans*-8-bromocamphor hydrazone *(55)* to limonene in the Wolff-Kishner reduction [36]. If, as is generally assumed [37], the carbanion *(56)* occurs as an intermediate in this reaction, this represents a heterolytic five-center fragmentation. However a seven-center mechanism as indicated in *(57)* cannot be ruled out.



The decomposition of the five-membered cyclic ylides *(59)* [38] and *(61)* [39], which result from the action of phenyl-lithium on the ammonium *(58)* and sulfonium *(60)* ions respectively, may be regarded as fragmentations. In the first case dimethylvinylamine is formed in addition to ethylene, while methyl vinyl sulfide is formed in the second case. Since the nucleofugal group X remains attached to the atom a as in *(62)*, only two fragments are formed [40].



i) $H-N-N-C-C-X$ or $\overset{\ominus}{\ddot{N}}-N-C-C-X$

It has recently been found that diimine HN=NH can assume the role of the electrofuge in an olefin-forming fragmentation. Thus the treatment of chloroacetyl hydrazide *(63)* with aqueous sodium hydroxide leads to the formation of acetic acid besides nitrogen and hydrazine, the secondary products of ketene and diimine [41].

The recently described conversion of 1,2-*O*,*O*-cyclohexylidene-5-*O*-mesyl-D-glucofuranuronyl hydrazide *(64)* into the 5-deoxy compound *(66)* by treatment with hydrazine can be explained by a similar base-induced fragmentation to diimine and the sugar ketene *(65)*, which is the precursor of the deoxy acid hydrazide *(66)* [42].

k) $HN=N-C-C-X$ or $\overset{\ominus}{N}=\ddot{N}-C-C-X$

It has long been known that the Wolff-Kishner reduction of aldehydes and ketones containing a nucleofugal group α to the carbonyl group yields olefins instead of saturated compounds [43]. Suitable nucleofugal groups are a halogen atom, a hydroxyl, amino, even an epoxy

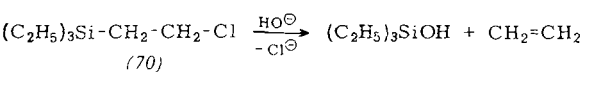
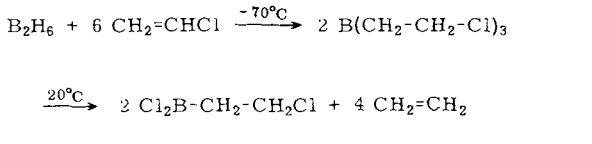
group[44] or a cyclopropane ring[45]. The base-induced formation of nitrogen and olefin can be formulated as a fragmentation of the tautomer *(68)* of the hydrazone *(67)*. The electrofugal activity of nitrogen is so high that this reaction proceeds even with notoriously poor nucleofugal groups such as OH and NR_2.



l) H—O—P—C—C—X

β-Halophosphonic acids such as *(69)* behave in the same manner as the corresponding carboxylic acids. Relatively stable in aqueous solution, they react rapidly in alkaline media with liberation of olefin and metaphosphate[46, 47].



m) R_3Si—C—C—X

β-Haloalkylsilanes such as *(70)* undergo base-induced cleavage to silanols and olefins[48].

n) B—C—C—X

β-Chloroalkylboron derivatives, which are formed by hydroboration of vinyl chlorides are also known to decompose with formation of olefins[49].

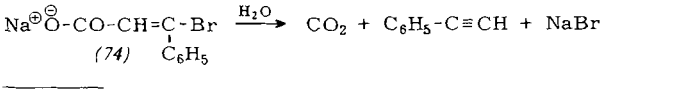
o) R—M—C—C—X

A series of organometallic compounds (M = metal) having a nucleofugal group on the β-carbon atom suffer cleavage of the metal-carbon bond. A metal cation, which may be regarded as an electrofugal fragment, and an olefin are thus formed. These reactions may therefore be regarded as fragmentations.

For example, β-hydroxyethylmercuric chloride *(71)*, which is stable in neutral media, undergoes cleavage *via* the oxonium salt *(72)* in acidic solution, with formation of $HgCl_2$ and ethylene[50].

The relatively stable (3-chloro-2-hydroxypropyl)-triphenyllead *(73)* undergoes a similar cleavage with hydrogen chloride in ether[51]:



III. Alkyne-Forming Fragmentations (a—b—C≡C—X)[52]

These fragmentations are not so numerous as the olefin-forming fragmentations discussed in Section II, probably because in these cases the nucleofugal group is attached to an unsaturated carbon atom, and therefore ionizes with difficulty. Consequently, a reaction takes place only when the nucleofugal activity of X is particularly high or when a—b is an extremely active electrofugal group.

a) HO—CO—C≡C—X

This class includes α,β-unsaturated β-haloacids the anions of which can undergo decarboxylation. For example, both *cis*- and *trans*-β-bromocinnamic acid *(74)* give phenylacetylene as the main product when their salts are heated in water. Decarboxylation occurs much less readily in the case of β-halo crotonic and acrylic acids[53].

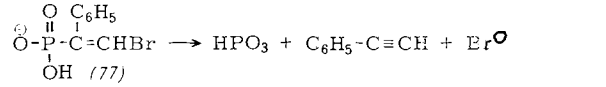
[53] *C. A. Grob*, *J. Csapilla*, and *G. Cseh*, Helv. chim. Acta *47*, 1590 (1964).

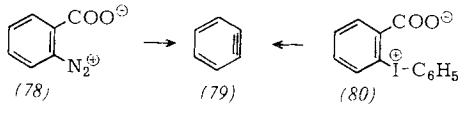
b) O=C—C=C—X



β-Halogenated α,β-unsaturated carbonyl compounds are systems that become fragmentable only upon addition of a nucleophile. Thus in the presence of aqueous sodium hydroxide, substituted β-chloroacroleins *(75)* decompose into formic acid and alkynes [54]. The reactive substrate is assumed to be the anion of the aldehyde hydrate *(76)*.

(75) *(76)*

c) HO—P—C=C—X



An example of this class of reactions is the formation of phenylacetylene from the salt of β-bromo-α-phenylvinylphosphonic acid *(77)*. The electrofugal fragment in this case is metaphosphoric acid [55].

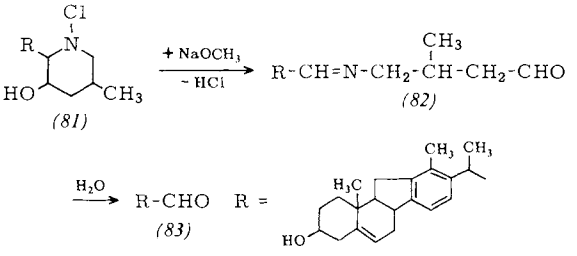
(77)

d) $^{\ominus}$OCO-*o*-C_6H_4 $X^{\oplus}$

Alkyne-forming fragmentations include, at least formally, certain reactions used in the preparation of benzyne *(79)*. Thus this unstable compound is formed by mild decarboxylation of diazotized anthranilic acid *(78)* [56] or of diphenyliodonium-*o*-carboxylate *(80)* [57].

(78) *(79)* *(80)*

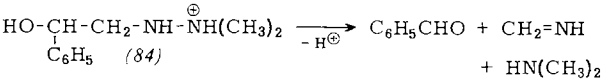
Both of these compounds contain combinations of very active electrofugal and nucleofugal groups. Whether benzyne is to be regarded as an acetylene derivative, however, is a matter of opinion.



IV. Imine-Forming Fragmentations (a–b–C–N–X and a–b–N–C–X)

In the reactions discussed so far, the nucleofugal group X was attached to a carbon atom. In the following subclasses, however, the group X is attached to a heteroatom such as nitrogen or oxygen.

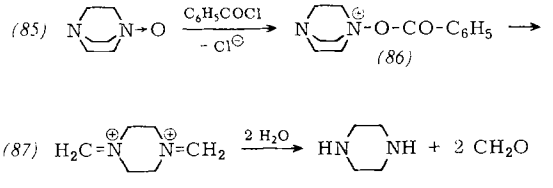
In these cases nucleophilic substitution no longer competes with fragmentation. Another difference is that cationic centers form much less readily on nitrogen or oxygen than on carbon. On the other hand, rearrangement involving a 1,2-shift of a group in the β position often competes with fragmentation in these systems.



a) HO—C—C—N—X

The β-hydroxy-*N*-chloro amine *(81)* obtainable from veratramine, undergoes fragmentation with bases to form the imine *(82)*, which is hydrolysed to the aldehyde *(83)* [58].

(81) *(82)* *(83)*



A similar acid-catalysed cleavage of *N,N'*-dimethyl-*N'*-(2-hydroxy-2-phenylethyl)hydrazinium ion *(84)* to benzaldehyde and formimine or its hydrolysis products has recently been formulated as a fragmentation [59].

(84)

b) N—C—C—N—X

Benzoylation of the *N*-oxide of 1,4-diazabicyclo[2.2.2]-octane *(85)* followed by hydrolysis yields piperazine and formaldehyde. This reaction may be regarded as a fragmentation of the ammonium salt *(86)* to the bisimonium salt *(87)* [60].

(85) *(86)* *(87)*

c) HO—CO—C—N—X

This class includes the oxidative decarboxylation of α-amino acids with halogenating agents such as hypochlorite or *N*-bromosuccinimide (NBS) [61]. *N*-halo-

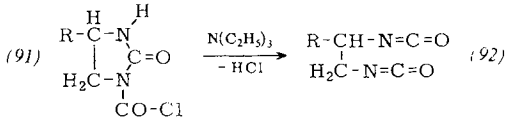
[61] Cf. *A. Schönberg* and *R. Moubacher*, Chem. Reviews *50*, 261 (1952).

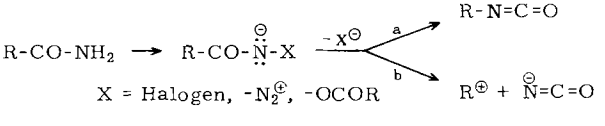
amino acids *(88)* may be assumed as intermediates, though fragmentation of the acyl hypobromite *(89)* cannot be ruled out.



N-Arenesulfonylamino acids *(90)* also undergo fragmentation when heated in pyridine [62].

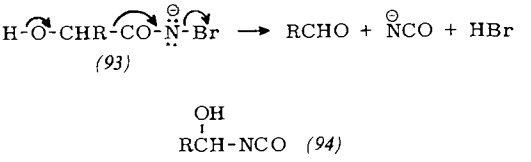
(90)

d) N—C—N—C—X



In the imine-forming fragmentations described above, the electrofugal group is attached to the carbon atom and the nucleofugal group to the nitrogen atom. However, cases are also known in which the positions of these two groups on the middle group are reversed. For example, the decomposition of the allophanyl chloride *(91)* into the diisocyanate *(92)* in the presence of triethylamine involves the formation of an N=C double bond. This reaction evidently is induced by the attack of the base on the H atom attached to nitrogen [63].

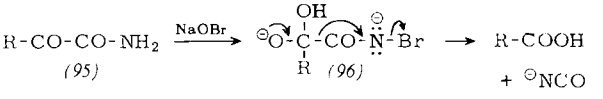
(91) *(92)*



V. Fragmentations Leading to Cyanic Acids (a—b—CO—N—X)

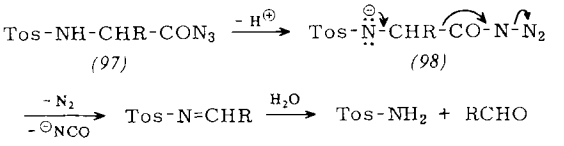
In the Hofmann, Curtius, or Lossen degradation of amides, the release of the nucleofugal group from the nitrogen atom is normally accompanied by migration of the group R to form an isocyanate (route a):

X = Halogen, $-N_2^{\oplus}$, -OCOR



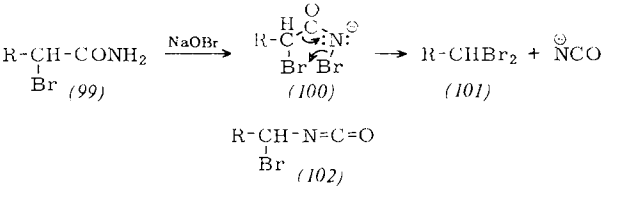
However, if R is an active electrofugal group, fragmentation can compete with the rearrangement. Such groups are present in amides of α-hydroxy, α-keto, α-amino, and α-halo acids. Thus in the Hofmann degradation of α-hydroxy carbonamides *(93)*, the expected rearrangement product α-hydroxy isocyanate *(94)* could not be detected [64], suggesting that direct fragmentation to the aldehyde and the cyanate ion has taken place in accordance with *(93)*.

(93)



(94)

The formation of carboxylic acids and cyanate ions in the Hofmann degradation of α-keto carbonamides *(95)* in aqueous alkali solution [65] can also be formulated as a fragmentation as in *(96)*.



(95) *(96)*

Azides of *N*-tosyl-α-amino acids *(97)* are relatively stable in neutral solution. When alkali is added, however, they decompose to form an aldehyde, *p*-toluenesulfonamide, cyanate ion, and nitrogen [66], indicating a fragmentation in accordance with *(98)*.

(97) *(98)*

The formation of geminal dibromides *(101)* and cyanate ion in the Hofmann degradation of α-bromo carbonamides *(99)* has been explained by an intramolecular mechanism *(100)* [67]. In any case, the hypothetical rearrangement product *(102)* is stable under the conditions of the reaction, and therefore does not occur as an intermediate.

(99) *(100)* *(101)*

(102)

VI. Nitrile-Forming Fragmentations (a—b—C=N—X and a—b—N=C—X)

If the hydroxyl group of a ketoxime [*(103)*, X = OH] is converted into a more active nucleofugal group by protonation, esterification, or etherification, a Beckmann rearrangement (route a) generally takes place [68].

[68] Cf. *L. G. Donaruma* and *W. Z. Heldt*, Org. Reactions *11*, 1 (1960).

The group R that is *trans* to X migrates to form a nitrilium ion *(104)*, which reacts further with water to form the amide[69]. However, if R is an active electrofugal group it may be wholly or partially removed, with simultaneous formation of a nitrile (route b). Processes of this type are frequently referred to as second order Beckmann reactions. A more appropriate term would be Beckmann fragmentation[70].

This reaction occurs particularly with α-amino, α-hydroxy, α-alkoxy, α-oxo, α-imino, and α-carboxy ketoxime derivatives. A number of electrofugally substituted ketoximes are listed in Scheme 2, together with products resulting from Beckmann fragmentation and subsequent hydrolysis. Classes a to h are substantiated by several examples in the literature.

Scheme 2. Examples of Beckmann fragmentations.

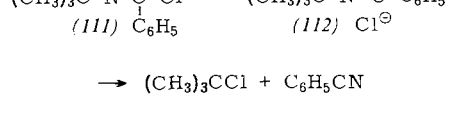
Case i, in which the electrofugal fragment contains an olefinic double bond, is new. A fragmentation of this type is observed with the compound *(105)*, which undergoes base-catalysed decomposition with formation of the unsaturated keto nitrile *(107)*[78]. The reactive substrate is undoubtedly the anion *(106)*.

The fact that a sulfur atom can induce fragmentation, as in case k, is shown by the recently described cleavage of the thioether *(108)* to the nitrile *(110)*, which presumably proceeds *via* the alkyl alkylidene sulfonium ion *(109)*[79].

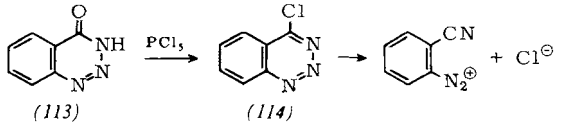


Finally, oximes with groups R of low electrofugal activity, such as α-alkylated and α-arylated ketoximes (class h in Scheme 2), frequently give fragmentation products. However, these are not formed by direct decomposition in accordance with route b, but by Beckmann rearrangement to the ion *(104)* (route a), which fragments to a greater or lesser extent (route c) depending on the reaction conditions. Amide formation is favored in a nucleophilic solvent such as water, whereas the fragmentation is favored in inert solvents and by reagents such as PCl_5 and $SOCl_2$, as well as by high temperatures[69].

In a series of nitrile-forming fragmentations, the electrofugal group is attached to the nitrogen atom and the nucleofugal group to the carbon atom of the middle group N=C.

a) $R_3C-N=C-X$

One such reaction is the fragmentation of *N*-t-butylimidoyl chloride *(111)* or of the nitrilium ion *(112)* formed from it, yielding t-butyl chloride or t-butanol, depending on the reaction conditions[80,69].



[78] *W. Eisele, C. A. Grob*, and *E. Renk*, Tetrahedron Letters *1963*, 75.

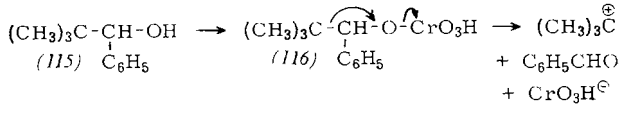
[80] *G. Schroeter*, Ber. dtsch. chem. Ges. *44*, 1201 (1911).

b) —R—N=N—N=C—X

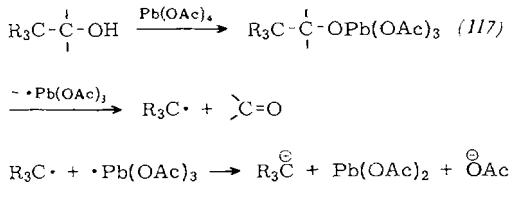
In the fragmentation of 4-chlorobenzotriazine *(114)* which is formed by the reaction of the dihydrobenzotriazinone *(113)* with PCl_5 but cannot be isolated, a diazonium ion is split off as an electrofuge, with formation of a nitrile group [81].



(113) *(114)*

VII. Carbonyl-Forming Fragmentations (a—b—C—O—X and a—b—O—C—X)

This class of fragmentations can be subdivided according to whether an aldehyde, a ketone, a carboxylic acid, or CO_2 is formed. In most cases the nucleofugal group X is attached to the oxygen atom of the middle group. Since the course of the reaction has been elucidated in very few cases and since this class of reactions is of less importance, only a few of the possible types are listed.



a) R_3C—C—O—X

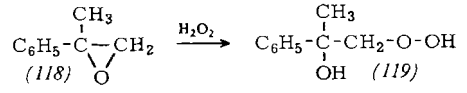
The oxidation of secondary alcohols with chromic acid can lead to varying quantities of fragmentation products besides the expected ketone if the β carbon atom is highly substituted [82]. Thus the oxidation of 2,2-dimethyl-1-phenyl-1-propanol *(115)* gives a 67 % yield of benzaldehyde, together with the t-butyl cation and its secondary products. An ester of chromic acid *(116)* is assumed to occur as an intermediate [83].

(115) *(116)*

Similar fragmentations of secondary and tertiary alcohols to carbonyl compounds are brought about by lead tetraacetate. However the decomposition of the

(117)

[81] *D. Buckley* and *M. S. Gibson*, J. chem. Soc. (London) *1956*, 3242.

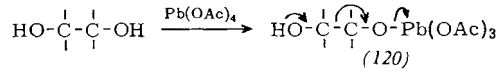


[82] *W. A. Mosher* and *H. A. Neidig*, J. Amer. chem. Soc. *72*, 4452 (1950).

[83] *P. T. Lansbury*, *V. A. Pattison*, and *J. W. Diehl*, Chem. and Ind. *1962*, 653.

initially formed alkoxylead ester *(117)* appears to be a homolytic process, the resulting radical being oxidized to the carbonium ion in a second step [84].

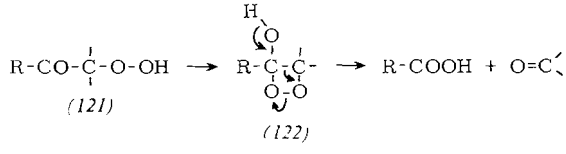
b) HO—C—C—O—X



On treatment with alkaline hydrogen peroxide, α-methylstyrene oxide *(118)* decomposes into acetophenone and formaldehyde [85]. This reaction may be regarded as a fragmentation of the initially formed β-hydroxy hydroperoxide *(119)*.

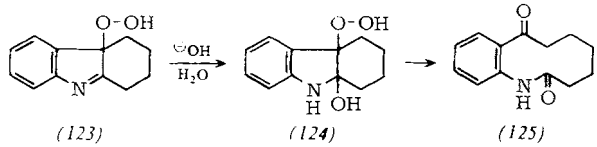
(118) *(119)*

The preferred mechanism for the cleavage of *cis*-1,2-diols [86] and of certain *trans*-1,2-diols *(120)* [87] with lead tetraacetate corresponds to a fragmentation:



(120)

c) O=C—C—O—X



α-Hydroperoxyketones *(121)* formed by the oxidation of enolizable ketones with air undergo base-induced decomposition with formation of acids and carbonyl compounds [88]. In anhydrous alcohol the electrofugal fragment is the free acid and not the ester, suggesting that a cyclic intermediate *(122)* is formed.

(121) *(122)*

d) —N=C—C—O—X or —N—C(OH)—C—O—X

The 3*H*-indole hydroperoxide *(123)*, an α-hydroperoxyketimine, undergoes fragmentation of its water adduct *(124)* to give the lactam *(125)* [89].

(123) *(124)* *(125)*

[84] *K. Heusler* and *J. Kalvoda*, Angew. Chem. *76*, 518 (1964); Angew. Chem. internat. Edit. *3*, 525 (1964).

[89] *B. Witkop*, J. Amer. chem. Soc. *72*, 1428 (1950).

e) —N—C(OH)—O—C—X

The same system as in *(124)*, but with the sequence of atoms in the middle group reversed, is present in the intermediate *(127)* formed during the ring cleavage of *N*-tosyl-5-oxazolidones *(126)* with amines. This fragmentation reaction has found use in peptide synthesis [90].

(126) *(127)*

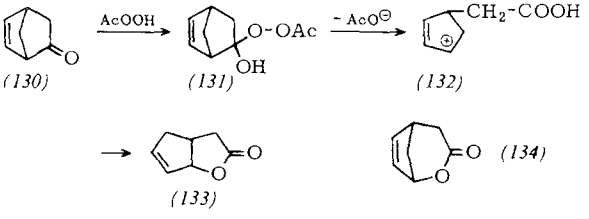
→ R NH-CO-CHR-NHTos + CH_2O

f) HO—CO—C—O—X

α-Hydroxy acids are degraded by oxidizing agents such as chromic acid [91], *N*-bromosuccinimide [92], sodium hypochlorite [93], or lead tetraacetate [94] into CO_2 and the carbonyl compound containing one carbon atom less. For example, the oxidation of lactic acid with chromic acid leads to acetaldehyde and carbon dioxide without intermediate formation of pyruvic acid [91,95]:

$$CH_3–CHOH–COOH \rightarrow CH_3CHO + CO_2$$

In this reaction it is not certain whether the oxidizing agent (Ox) attacks the carboxyl group as in *(128)*, the α-hydroxyl group as in *(129)*, or both groups *via* a cyclic intermediate.

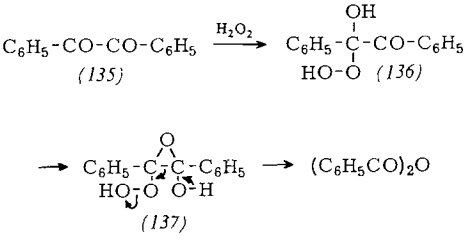


(128) *(129)*

α-Hydroxy peracids are well known to be unstable. Thus glycolic acid is decarboxylated to formaldehyde by hydrogen peroxide in acidic solution [96]. This reaction can be explained by fragmentation of the intermediate α-hydroxyperacetic acid in accordance with *(128)*, R = H, Ox = OH.

g) R_3C—C(OH)—O—X

The Bayer-Villiger oxidation of ketones to esters by peracids [97] can be superseded by fragmentation if there is an active electrofugal group α to the carbonyl group.



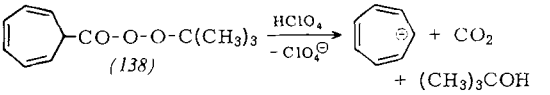
Thus the reaction of dehydronorcampher *(130)* with peracetic acid does not lead to the expected lactone *(134)*; instead, the adduct *(131)* undergoes fragmentation with formation of the carbonium ion *(132)*, the precursor of the lactone *(133)* which is isomeric with *(134)* [98].

(130) *(131)* *(132)* *(133)* *(134)*

h) O=C—C(OH)—O—X

α,β-Diketones such as *(135)* are oxidized by hydrogen peroxide or alkyl hydroperoxides to acid anhydrides [99]. This base-induced reaction probably proceeds *via* the adduct *(136)*, whose cyclic tautomer *(137)* satisfies the requirements for fragmentation to the anhydride [100].

(135) *(136)* *(137)*



i) R_3C—CO—O—X

The oxidative decarboxylation of carboxylic acids with lead tetraacetate to form acetates and olefins has recently been recognized as a homolytic reaction [101].

$$2\ R–CH_2–CH_2–COOH \xrightarrow{Pb(OAc)_4} R–CH_2–CH_2–OAc + R–CH=CH_2$$

Consequently, it does not come within the scope of this discussion.

On the other hand, the acid catalysis observed in the decarboxylation of the peroxy ester *(138)* of norcara-

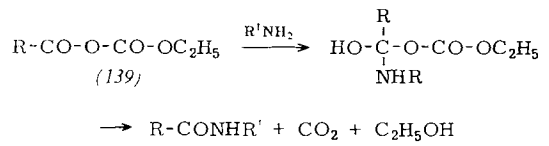
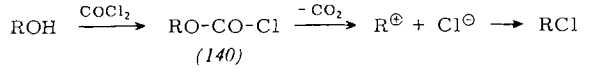
dienecarboxylic acid [which is formulated as a cycloheptatrienyl derivative to a tropylium salt points to heterolytic fragmentation [102].

k) HO—CO—CO—O—X



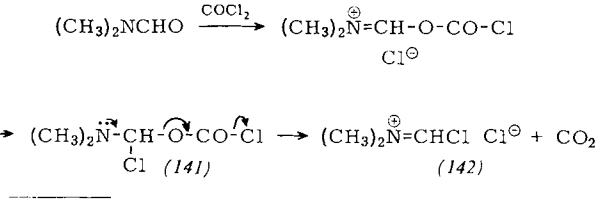
The bis-decarboxylation of oxalic acid by oxidizing agents such as permanganate can probably be formulated as fragmentation in the following manner:

In a group of CO_2-forming fragmentations, the electrofugal group is originally attached to the oxygen atom of the middle group, and the nucleofugal group to the carbon atom, as in the following examples.



l) HO—C—O—CO—X

This type includes acylations of amines and alcohols by mixed anhydrides of carbonic acid *(139)* [103].



m) R_3C—O—CO—Cl

This group of CO_2-forming fragmentations also includes the decomposition of alkyl chlorocarbonates *(140)* to alkyl chlorides [104].

n) N—C—O—CO—X

The formation of *N,N*-dimethylformimidoyl chloride derivative *(142)* from dimethylformamide and phosgene is a CO_2-forming fragmentation and proceeds *via* the adduct *(141)* [105].

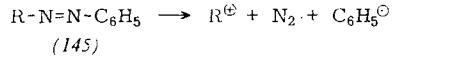
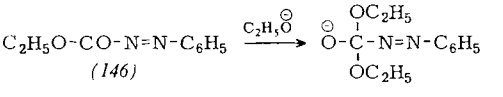
VIII. Nitrogen-Forming Fragmentations (a—b—N=N—X)

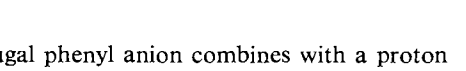
Owing to the high energy of formation of molecular nitrogen, azo compounds undergo fragmentation even when the leaving groups are as weakly electrofugal and nucleofugal as in the case of aryl and alkyl groups.

a) R—N=N—X



Aryldiazohydroxides *(143)* decompose in acidic solution into aryl cations and nitrogen. The same is true of esters of alkyldiazo hydroxides such as *(144)* [106].





b) HO—C—N=N—Ar or HN—C—N=N—Ar

A number of base-induced fragmentations have recently been described in which phenyl anions are liberated together with nitrogen from phenylazo compounds *(145)* [107]. The reactive substrate is an anion formed by loss of a proton or by addition of a base such as sodium ethoxide, as is shown by the reaction of the ester *(146)*.

R = HOOC; CH_3CO-O-$C(CH_3)_2$; C_2H_5OOC; H_2N-CO; C_6H_5-CO

The nucleofugal phenyl anion combines with a proton to form benzene. An *o*-halophenyl anion may also form benzyne by loss of a halide ion.

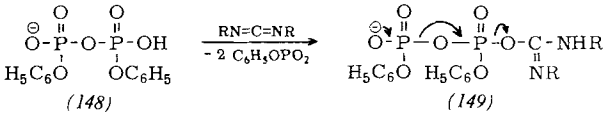
IX. Other Heteroxide-Forming Fragmentations

Of the many possible atomic combinations, two examples, one with hydrogen and one with phosphorus, will be selected.

[106] *R. Huisgen* and *Ch. Rüchardt*, Liebigs Ann. Chem. *601*, 1 (1957); *H. Maskill, R. M. Southam*, and *M. C. Whiting*, Chem. Commun. *1965*, 496.

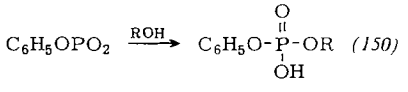
[107] *R. W. Hoffmann*, Chem. Ber. *97*, 2763 (1964); *98*, 222 (1965); *A. Angeli* and *Z. Jollés*, Ber. dtsch. chem. Ges. *62*, 2099 (1929).

a) $R_3C—O—SO—X$



The formation of alkyl chlorides from alcohols and thionyl chloride proceeds *via* alkyl chlorosulfites *(147)*, the decomposition of which into alkyl chloride and sulfur dioxide constitutes a fragmentation [108].

$$R{-}OH \xrightarrow{SOCl_2} R{-}O{-}SO{-}Cl \xrightarrow{-SO_2} R^{\oplus} + Cl^{\ominus} \rightarrow R{-}Cl$$



(147)

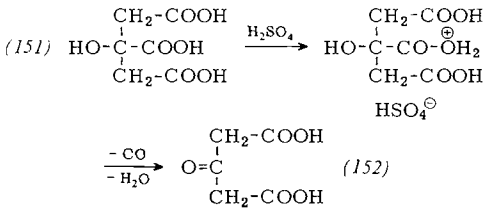
b) HO—P—O—P—X

Diaryl pyrophosphates *(148)* react with carbodiimides to form addition compounds *(149)*, which undergo fragmentation with formation of two molecules of an ester of metaphosphoric acid. The ester reacts with alcohols to give the unsymmetrical diester of phosphoric acid *(150)* [109]:

(148) *(149)*

(150)

X. α-Fragmentations



By analogy with α-eliminations, in which a proton and a nucleofugal group are removed from the same atom [110], it is possible to distinguish α-fragmentations. In this case the electrofugal and the nucleofugal groups are both removed from the same atom:

$$a{-}b{-}c{-}X \longrightarrow a{-}b + :c + :X$$

Since the valence of the atom c decreases by two in this type of fragmentation, the reaction will be observed when the lower valence state of c exhibits a certain stability. This applies *e.g.* to the carbon atom, when either carbon monoxide or an isocyanide is liberated as the unsaturated fragment. Most of the fragmentations of this type are therefore decarbonylations of carboxylic acids and their derivatives.

a) HO—C—CO—X

α-Hydroxy acids lose carbon monoxide in the presence of strong mineral acids with formation of aldehydes and ketones. For example, with concentrated sulfuric acid, citric acid *(151)* gives good yields of 3-oxopentanedicarboxylic acid *(152)* [111].

(151) *(152)*

b) O=C—CO—X

Similarly, α-keto acids are degraded by mineral acids to the next lower carboxylic acid. The decarbonylation of phenylglyoxylic acid *(153)* for example, can proceed stepwise [112].

$$C_6H_5{-}CO{-}COOH \xrightarrow{H^{\oplus}} C_6H_5{-}CO{-}CO{-}\overset{\oplus}{O}H_2 \xrightarrow{-H_2O}$$

(153)

$$C_6H_5{-}CO{-}\overset{\oplus}{C}O \xrightarrow{-CO} C_6H_5{-}\overset{\oplus}{C}O \xrightarrow{H_2O} C_6H_5COOH$$

The thermal decarbonylation of esters of oxalic acid may proceed in a similar manner [113].

c) HO—CO—CO—X

The acid-catalysed decomposition of the protonated form *(154)* of oxalic acid into CO and CO_2 is also an α-fragmentation.

$$HOCO{-}COOH \xrightarrow{H^{\oplus}} HOCO{-}CO{-}\overset{\oplus}{O}H_2 \xrightarrow[-H^{\oplus}]{}$$

(154)

$$CO_2 + CO + H_2O$$

Owing to the high electrofugal activity of the carboxyl group, the monochloride and the monoanhydride of oxalic acid [*(155)*, X = Cl or O–CO–COOH] are unstable [114].

HOCO–CO–X

(155)

d) N—C—CO—X

The acyl chlorides *(157)* of free α-(dialkylamino)acids *(156)* readily undergo decarbonylation during preparation, with formation of iminium salts [115].

[108] *E. S. Lewis* and *C. E. Boozer*, J. Amer. chem. Soc. *76*, 794 (1954); *D. J. Cram, ibid. 75*, 332 (1953).

[109] *F. Cramer, K. H. Scheit*, and *H. J. Baldauf*, Chem. Ber. *95*, 1657 (1962); *J. A. Shofield* and *A. Todd*, J. chem. Soc. (London) *1961*, 2316.

[113] *M. Calvin* and *R. M. Lemmon*, J. Amer. chem. Soc. *69*, 1232 (1947).

[114] *I. Ugi* and *F. Beck*, Chem. Ber. *94*, 1839 (1961); *C. K. Rosenbaum* and *J. H. Walton*, J. Amer. chem. Soc. *52*, 3366 (1930).

[115] *N. A. Poddubnaya* and *V. I. Maksimov*, Ž. obšč. Chim. *29*, 3483 (1959); *V. I. Maksimov*, Tetrahedron *21*, 687 (1965).

$$R_2N-CHR'-COOH \xrightarrow{PCl_5} R_2N-CHR'-CO-Cl \xrightarrow{-CO}$$
(156) *(157)*

$$R_2\overset{\oplus}{N}=CHR'\ Cl^{\ominus}$$

A base-induced variant of this reaction is observed with chlorides of α-(*N*-arenesulfonyl)amino acids. Thus *N*-tosylphenylalanyl chloride *(158)* decomposes *via* the anion *(159)* to the *N*-tosylimine *(160)* [116].

$$\underset{(158)}{Tos-NH-\underset{\displaystyle CH_2-C_6H_5}{\underset{|}{CH}}-CO-Cl} \xrightarrow[-H_2O]{HO^{\ominus}} \underset{(159)}{Tos-\overset{\ominus}{N}-\underset{\displaystyle CH_2-C_6H_5}{\underset{|}{CH}}-CO-Cl}$$

$$\xrightarrow[-Cl^{\ominus}]{-CO} \underset{(160)}{Tos-N=CH-CH_2-C_6H_5}$$

e) $R_3C-CO-X$

Chlorides of tertiary carboxylic acids are decarbonylated in the presence of Friedel-Crafts catalysts such as $AlCl_3$. The intermediate acylium ion *(162)* formed from pivaloyl chloride *(161)* can be intercepted by anisole with formation of 1-(p-methoxyphenyl)-2,2-dimethyl-1-propanone. The less reactive solvent benzene is only alkylated by the t-butyl cations *(163)* formed by decarbonylation of *(162)* [117].

$$\underset{(161)}{(CH_3)_3C-CO-Cl} \xrightarrow[-Cl^{\ominus}]{AlCl_3} \underset{(162)}{(CH_3)_3C-C\overset{\oplus}{\equiv}O} \xrightarrow{-CO} \underset{(163)}{(CH_3)_3C^{\oplus}}$$

[116] *R. H. Wiley* and *R. P. Davis*, J. Amer. chem. Soc. *76*, 3496 (1954); *A. F. Beecham*, J. Amer. chem. Soc. *79*, 3257 (1957); Austral. J. Chem. *16*, 889 (1963).

[117] *E. Rothstein* and *R. W. Saville*, J. chem. Soc. (London) *1949*, 1946, 1950, 1954.

The reverse of this reaction, *i.e.* the formation of carboxylic acids by carbonylation of carbonium ions, is also known [118].

f) $O=C-CNR-X$

Mention finally should be made of an example of an α-fragmentation in which an isocyanide is formed as the unsaturated fragment. Thus acylformimidoyl chlorides such as *(164)* decompose when heated to form an acyl chloride and an isocyanide. At lower temperatures the reaction proceeds in the reverse direction, *i.e.* as a 1,1-addition [119].

$$\underset{(164)}{C_6H_5-CO-\underset{\displaystyle N-C_6H_5}{\underset{\|}{C}}-Cl} \rightleftharpoons C_6H_5-\overset{\oplus}{C}O + \overset{\ominus}{C}l + C_6H_5-N\equiv C$$

XI. Outlook

These examples do not exhaust the list of fragmentable systems. Other combinations of electrofugal and middle groups lead to further cases. New fragmentations are constantly being reported in the literature. As was mentioned in the introduction, detailed studies of the mechanism and stereochemistry of fragmentation reactions have been carried out in only a few cases. In view of their great variety, fragmentation reactions present a wide field for future investigations.

F. Conclusion

A. Cycloadditions: Possible Mechanisms

Cycloadditions (this term is defined in [1]) can be used to gain access to compounds of various ring sizes, as illustrated in the following examples for the formation of three-membered to six-membered rings.

In every case, two new σ bonds are formed between the reactants at the expense of π bonds. The reaction may follow one of several courses, which will be briefly outlined for the diene synthesis.

The new σ bonds between the reactants may be formed simultaneously in a multicenter mechanism, as indicated by route A. We are dealing, therefore, with a one-step reaction, whose energy profile contains only one activation barrier (Fig. 1a).

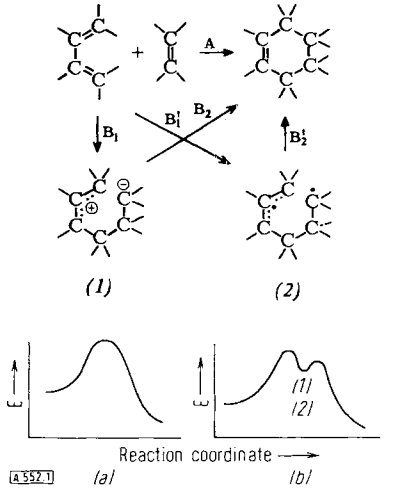

Fig. 1. Energy profile for (a) a one-step and (b) a two-step reaction.

Another possibility is that the two σ bonds are formed in two successive reaction steps. The energy profile of the two-step reaction (Fig. 1b), which contains two transition states, then includes a zwitterion *(1)* or biradical *(2)* intermediate. For *(2)*, we must in principle consider a singlet state (paired electrons) as well as a triplet species.

The following discussion of stereochemical and kinetic results, orientation phenomena in the combination of

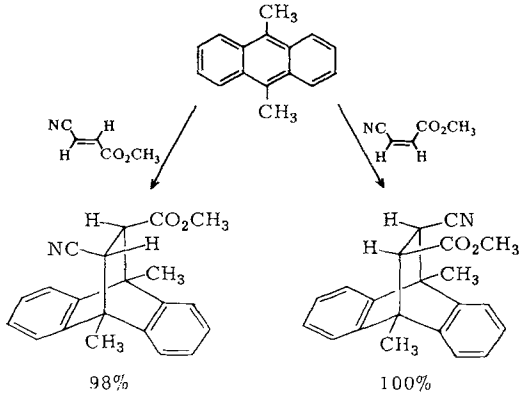
[**] Part I see [2].

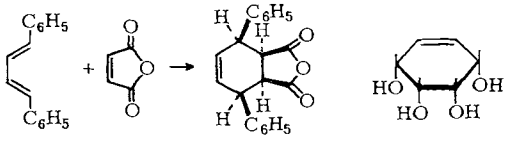
[1] *R. Huisgen, R. Grashey,* and *J. Sauer* in *S. Patai*: The Chemistry of Alkenes. Interscience, London 1964, p. 739.



unsymmetrical reactants, catalyst effects, rearrangements, and isotope effects should provide some idea of what criteria may be used to distinguish between one-step and two-step reactions. As in Part I of this series [2], no attempt is made to survey all the existing data.

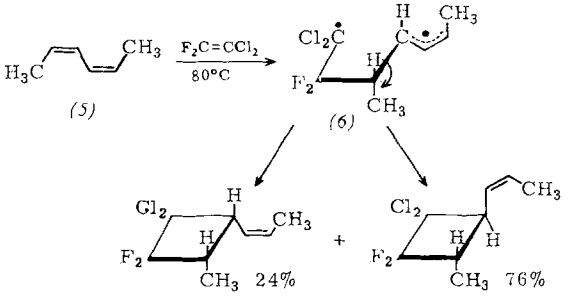
B. Stereochemical Course of Diels-Alder Additions

The stereochemical study of a reaction often presents an insight into its mechanism. *Alder* and his school made valuable contributions in this respect, which have been critically discussed, together with results obtained by other authors, by *Martin* and *Hill* [3]. The study of the stereochemical course of diene additions is sometimes difficult, owing to the ability of the adducts to redissociate [2] (examples occur with furans, fulvenes, and 9,10-disubstituted anthracenes as diene components). In many cases the 1:1 adducts resulting from a kinetically controlled and a thermodynamically controlled reaction are formed simultaneously, giving the impression that the Diels-Alder reaction yields a mixture of structural or stereoisomers. However, information about the stereochemical course of the reaction can be obtained only from the 1:1 adduct resulting from a kinetically controlled reaction.



1. The "*cis*" Principle

It was recognized very early that the steric arrangement of substituents in the dienophile and in the diene is preserved in the 1:1 adduct, *i.e.* that diene additions are pure "*cis*" additions, and this observation was formulated by *Alder* and *Stein* as the "*cis*" principle [4]. *cis*- or *trans*-Dienophiles react with dienes to give 1:1 adducts in which the *cis* or *trans* arrangement of the substituents in the dienophile is retained; this is illustrated for the reactions of the isomeric methyl β-cyanoacrylates [5] (in boiling dioxane).



According to *Hendrickson*, the addition of *cis*- and *trans*-β-sulfoacrylic acid ($HO_3S-CH=CH-CO_2H$) to cyclopentadiene leads to the same adduct, in which the substituents of the dienophile are *trans* to each other [6]. This result, which is the only known exception to the "*cis*" principle, is remarkable from the mechanistic standpoint, but according to the author it requires further corroboration.

The *cis* principle applies also to substituents in the diene components, as is shown by many examples [3, 7]. In the 1:1 adduct *(3)*, which can be obtained almost quantitatively from *trans,trans*-1,4-diphenylbutadiene and maleic anhydride (in boiling benzene), the phenyl groups are *cis* to each other [8]. The synthesis of all-*cis*-3,4,5,6-cyclohexenetetrol *(4)* (Kondurit D) [9], the first step of which is the Diels-Alder reaction of vinylene carbonate with *trans,trans*-1,4-diacetoxybutadiene, is also stereoselective. Heterodienophiles also obey the "*cis*" principle in the addition to dienes [9a].

The almost universal strict *cis* addition can be readily explained by synchronous formation of the bonds between the two components in a one-step reaction (Section A, route A), but does not, in principle, rule out the possibility of a two-step reaction *via (1)* or *(2)*. If the step B_2 or B'_2 is much faster than rotation about C–C single bonds, the two-step mechanism should also lead to stereoselectivity.

Bartlett et al. [10] recently found a two-step mechanism with a biradical intermediate in cycloadditions leading to cyclobutane derivatives. In the reaction of the *cis-trans*-isomeric 1,4-dimethylbutadienes with 1,1-dichloro-2,2-difluoroethylene, the step leading to the formation of the four-membered ring is not stereoselective, as is illustrated for *cis,cis*-2,4-hexadiene *(5)*. The rate of rotation about a C–C single bond (indicated by a curved arrow) in the intermediate *(6)* is comparable with the rate of the second step in the two-step reaction, *i.e.* the ring closure, so that the stereoselectivity is partially lost.

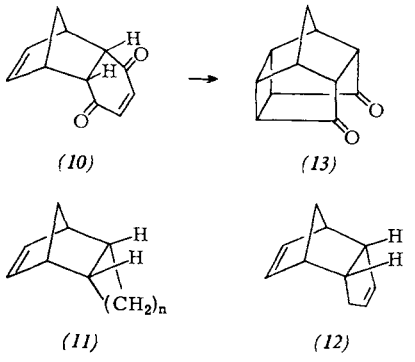
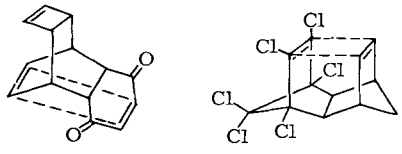
It is significant in this connection that the Diels-Alder reactions of *cis*- and *trans*-1,2-dichloroethylene with pentadiene, which could involve biradical intermediates *(7a)* and *(7b)*, respectively, of comparable stability, give strict *cis*-addition [11], *i.e.* there is no interconversion *(7a)* $\rightleftharpoons$ *(7b)*. The addition of hexachlorocyclopentadiene to α-methyl-β-deuterostyrene is also stereospecific.

(7a) *(7b)*



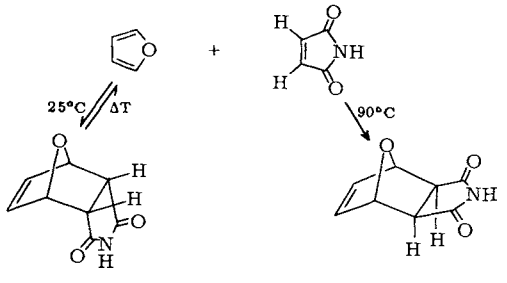
2. The Alder *"endo"* Rule: Validity and Exceptions

The combination of cyclic dienes with cyclic dienophiles could in principle follow two courses; in general, however, only one of these is actually realized. After a "sandwich-like" preorientation of the reactants, the dienophile is added in such a way as to give a "maximum concentration" of double bonds [4] in the transition state; according to *Alder* and *Stein* [4] this includes not only the π systems directly involved in the reaction, but also those of the "activating ligands" (see Section D). The addition of maleic anhydride to cyclopentadiene leads almost exclusively to the *endo* adduct *(8)*. The thermodynamically more stable *exo* compound *(9)* is formed in yields of less than 1.5 % [12].



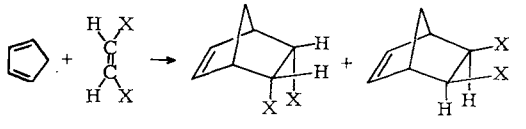
(9) *(8)*

Preferential or exclusive formation of the *endo* adduct is also found in the reactions of cyclopentadiene with *p*-benzoquinone, cyclopentene [13], and cyclopropene [14] to give *(10)*, *(11)*, n = 3, and *(11)*, n = 1, and in the dimerization of cyclopentadiene to form *(12)* [4]. The configurations of *(10)* and *(12)* were determined by photochemically induced cycloaddition to form a four-membered ring, as is illustrated for the conversion of *(10)* into *(13)* [15]. Cage compounds of the type *(13)* can be formed only by *endo* adducts. The *endo*



(10) *(13)* *(11)* *(12)*

configuration of the adducts *(14)* and *(15)* can be proved in the same way [15]; the π bonds that react are indicated by broken lines. The reaction of cyclohexadiene with cyclic dienophiles, like that of cyclopentadiene, also leads almost exclusively to the *endo* adducts.



(14) *(15)*

The *endo* rule is only apparently violated by the reaction of the cyclic diene furan with the cyclic dienophiles maleic anhydride and maleimide [16] and by the diene additions of the fulvenes [17]. In these cases the adduct redissociates at temperatures only slightly above room temperature (more rapidly at 90 °C), permitting the conversion of the *endo* adduct resulting from the kinetically controlled reaction into the thermodynamically more stable *exo* isomer.

The reaction of cyclic dienes with *cis*-1,2-disubstituted olefins *(16)* obeys *Alder*'s *endo* rule only in part. For example, when X = C_6H_5–SO_2 or C_6H_5–CO the *endo*

(16) *(17)* *(18)*

adducts *(17)* are obtained with no spectroscopically detectable amounts of the *exo* isomers *(18)*, whereas in the reaction with the dimethyl ester or dinitrile of maleic

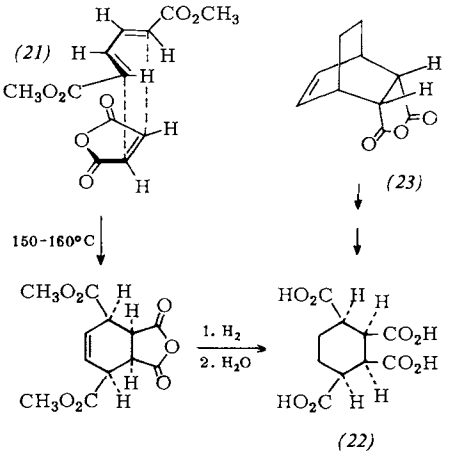
[17] *D. Craig*, *J. J. Shipman*, *J. Kiehl*, *F. Widmer*, *R. Fowler*, and *A. Hawthorne*, J. Amer. chem. Soc. *76*, 4573 (1954); *R. B. Woodward* and *H. Baer*, *ibid. 66*, 645 (1944).

acid *(16)*, X = CO_2CH_3 or CN, the adducts *(17)* and *(18)* are formed in the approximate ratio 75:25 [5]. Similar results were obtained with cyclohexadiene [18].

Cyclic dienes generally react with monosubstituted olefins to yield mixtures of isomers. Cyclopentadiene and methyl acrylate give *(19)* and *(20)* in the approxi-

(19) *(20)*

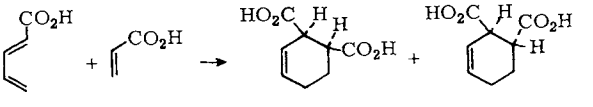


mate ratio 76:24 [19]; with acrylonitrile, the product ratio *endo*:*exo* = 60:40 approaches the statistical value [20], which is attained in the reaction of cyclohexadiene with acrylonitrile [20]. In these cases *Alder*'s rule is not valid. The stereochemical course of these Diels-Alder reactions is strongly influenced by the introduction of a methyl, phenyl, or chloro substituent into the α or β position of the acrylate [7, 21, 22].

Interesting solvent and catalyst effects on the stereochemistry of the addition of acrylates to cyclopentadiene have recently been recognized. *Berson* [22] showed that the proportion of the *endo* isomer *(19)* in the mixture increases with the polarity of the solvent. Since the activated complex leading to *(19)* has a higher dipole moment than that leading to *(20)*, the former is more strongly favored by an increase in solvating power of the solvent. *Berson* also derived a new empirical scale of solvent polarity [22] based on the *endo*:*exo* ratio, which can be determined accurately by gas chromatography; this scale parallels other solvent functions [23].

As will be explained in Section D 5, the rate of diene additions is considerably increased by addition of Lewis acids. It was only recently recognized that the ratio of the structurally isomeric or stereoisomeric 1:1 adducts also changes on addition of a catalyst [24, 25]. At 0 °C in dichloromethane, *(19)* and *(20)* are formed in the approximate ratio 80:20, whereas when catalysed by Lewis acids (10-mole-% of $AlCl_3 \cdot O(C_2H_5)_2$, $BF_3 \cdot O(C_2H_5)_2$, $SnCl_4$, or $TiCl_4$), the reaction gives a 95:5 mixture; at −70 °C in the presence of $AlCl_3 \cdot O(C_2H_5)_2$ or $BF_3 \cdot O(C_2H_5)_2$, practically pure *(19)* is formed [25].

Similar results are obtained in the addition reactions of methyl methacrylate, methyl crotonate, and maleic esters to cyclopentadiene [25a].



The *endo* rule is frequently satisfied also in the reaction of acyclic dienes with cyclic dienophiles, as has already been seen from the synthesis of Kondurit D *(4)* and the reaction of *trans,trans*-1,4-diphenylbutadiene with maleic anhydride (Section B.1). The addition of dimethyl *trans*-muconate *(21)* to maleic anhydride also proceeds in high yield and strictly in accordance with the *endo* rule, as shown by the all-*cis* arrangement of the carboxyl groups in the cyclohexanetetracarboxylic acid *(22)*

(22)

derived from the adduct. The configuration of *(22)* is confirmed by the oxidative degradation of the cyclohexadiene-maleic anhydride adduct *(23)*, the configuration of which is known [26].

Open-chain dienes and open-chain dienophiles obey the *endo* rule only at low temperatures, as shown in Table 1 for the reaction of *trans*-butadiene-1-carboxylic acid and acrylic acid [3, 7].

(24) *(25)*

Table 1. Effect of temperature on the stereochemistry of the reaction of *trans*-butadiene-1-carboxylic acid with acrylic acid.

Temperature (°C)	75	90	100	110	130
Ratio *(24)*:*(25)*	*(24)* only	7:1	4.5:1	2:1	1:1

No quantitative theoretical approach to *Alder*'s *endo* rule has yet been found. The exclusive *endo* addition of *p*-benzoquinone to cyclopentadiene has been attributed to dipole-induced dipole forces between the polar groups in the dienophile and the readily polarizable diene [27]; this phenomenon is now described, probably more accurately, as a "charge-transfer" interaction (see Section E 3). The fact that dienophiles *without* polar substituents, such as cyclopropene [14], cyclopentene [13], and even allyl bromide and

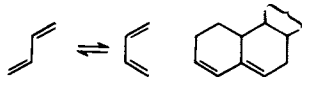
propene[28], react with cyclopentadiene to give exclusively or predominantly the *endo* adduct somewhat weakens the above working hypothesis[22].

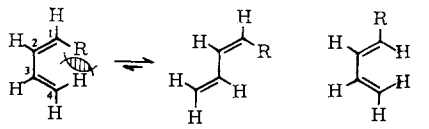


As pointed out earlier, the *endo*:*exo* ratio in the cyclopentadiene/methyl acrylate system depends on the solvent. The transition state with the higher overall dipole moment is passed preferentially in this kinetically controlled reaction. The fact that this energetically less favorable transition state occurs at all is evidence of a second orienting force, possibly the charge-transfer interaction. The combination of strongly polar reactants on the other hand, should proceed *via* a transition state with a very low overall dipole moment, as was shown by *Horner* and *Dürckheimer*[29] in the dimerization of various *o*-benzoquinones to the *endo* adduct.

It should be stressed at this point that the forces that dictate the steric course of the reaction are relatively weak. Even the preference of one isomer in the ratio 99:1, *i.e.* a practically stereospecific reaction, corresponds to a difference in activation energies of less than 3 kcal/mole for the two competing reaction mechanisms. In view of the many factors that can influence the formation of possible stereoisomers, an accurate prediction for new systems is not yet possible. The examples described above should be regarded rather as a guide.

Woodward and *Hoffmann*[29a] have recently attempted a quantitative MO treatment of the *endo* rule. They showed that *endo* addition is energetically more favorable in the reaction of dienes with dienophiles containing conjugated π systems. This treatment has not yet been applied to the *endo* addition of cyclopropene, cyclopentene, allyl bromide, or propene mentioned above.

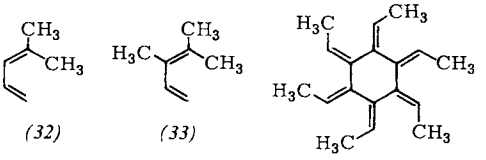
3. Influence of Conformation on Diene Reactivity: *cisoid* and *transoid* Dienes



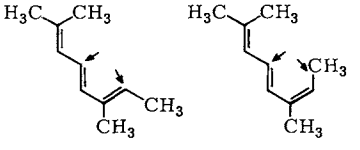
Open-chain 1,3-dienes exist in the conformational equilibrium *(26)* ⇌ *(27)*; only the *cisoid* conformer *(27)* can undergo diene addition[1,2,7]. Cycloaddition to form a six-membered ring is prevented if the conformation *(26)* is fixed, *e.g.* by incorporation into the polycyclic ring system of the steroids *(28)*. On the other hand, addition of the dienophile is

(26) *(27)* *(28)*

facilitated if the *cisoid* conformer is fixed (*e.g.* by incorporation of the diene system into a ring or by fusion of a ring on positions 2 and 3 of the diene, see Section D 2). Substituents in acyclic dienes can cause a considerable change in the rates of diene additions, not only as a result of their electronic effects, but also by displacement of the above equilibrium as a result of purely steric influences.



In preparative studies *cis*-1-substituted butadienes *(29)* are found to be much less reactive diene components than their *trans* isomers *(31)*. As R becomes more bulky the equilibrium *(29)* ⇌ *(30)* is displaced in favor of the *transoid* conformer *(30)*.



(29) *(30)* *(31)*

The reaction of *(29)*, R = CH_3, with maleic anhydride gives only a 4 % yield of the 1:1 adduct[30]; the reaction of the corresponding *trans* compound *(31)*, on the other hand, is quantitative and exothermic. The reactivities towards tetracyanoethylene differ by a factor of almost 10^5 (at 20 °C in CH_2Cl_2)[39,69]. The diene reactivity decreases further through *cis*-1-ethyl- and *cis*-1-isopropylbutadiene, and disappears completely with 1-t-butyl- and 1-phenylbutadiene[7,31]. The inability or reluctance of these *cis*-substituted dienes to add to dienophiles is explained in the literature by overlap of the spheres of influence of the substituent R on C-1 and of the hydrogen atom on C-4 of the diene chain. Coplanar arrangement, and hence Diels-Alder addition, becomes difficult or impossible, and the diene exists preferentially or completely in the *transoid* conformation *(30)*. The difference in the ease of addition of *(29)* and *(31)* can be utilized for the preparation of the pure, less reactive *cis* isomers *(29)*, R = C_6H_5[32], R = $CH{=}CH_2$[33], R = halogen[7,34].

However, the situation is not quite so clear as would appear from the above examples, as is shown by the systems *(32)* to *(36)* which, with the exception of *(35)*, contain reaction-inhibiting *cis*-1-substituents on the diene system. Compound *(32)* reacts with tetracyanoethylene at room temperature to

(32) *(33)* *(34)*

(35) *(36)*

give a mixture of the Diels-Alder adduct and the four-membered cycloaddition product[35]. Compound *(33)* reacts with maleic anhydride in boiling benzene to give a high yield of the expected 1:1 adduct[36]; the reaction of *(34)*, *e.g.* with TCNE, maleic anhydride, or *p*-benzoquinone, immediately

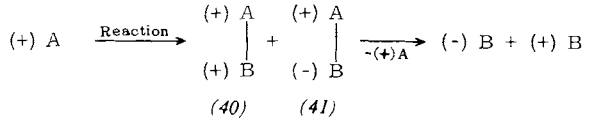
yields the diadduct [37]. The two isomeric alloocimenes *(35)* and *(36)* add on maleic anhydride in good yields in the positions indicated [38]. Kinetic measurements will probably provide more definite information on this behavior than preparative experiments, which are often difficult to compare [39].

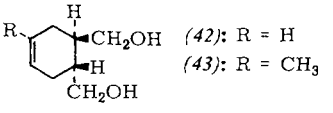
In 2-substituted butadienes, on the other hand, bulky substituents promote the diene addition [40]. The k_2 value [*] for the addition of maleic anhydride (at 25 °C in benzene) is 50 times as great for 2-neopentylbutadiene than for butadiene.



(37) *(38)* *(39)*

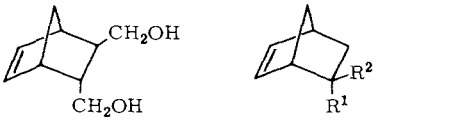
In contrast to the *cis*-1-substituted butadienes, a bulky group R displaces the conformational equilibrium *(37)* ⇌ *(38)* in favor of the strainless *cisoid* conformation *(38)* required for the reaction.

As expected, large substituents R in 2,3-disubstituted butadienes *(39)* prevent the molecule from assuming the planar *cisoid* conformation. 2,3-Dimethylbutadiene reacts rapidly with maleic anhydride (see Section D), whereas 2,3-dichloro- and 2,3-di-t-butylbutadiene [7,41] cannot be forced to undergo Diels-Alder additions with maleic anhydride. Surprisingly, 2,3-diiodobutadiene enters into diene additions under relatively mild conditions [42]. This is another case where a thorough kinetic investigation would be desirable in order to find an explanation for this behavior. Many apparent failures of the Diels-Alder reaction can possibly be explained by competition between the cycloaddition and a faster polymerization of the diene or by copolymerization of the diene and the dienophile.



4. Partial Asymmetric Syntheses with Diels-Alder Reactions

The synthesis of asymmetric molecules, *e.g.* optically active compounds, from inactive material always leads to the racemate. If, on the other hand, the asymmetric center B is formed under the influence of an auxiliary asymmetric center [(+)A in the formula scheme] already present in the molecule, the possible diastereoisomers *(40)* and *(41)* are no longer formed in equal quantities, since the transition states leading to *(40)* and *(41)* are already diastereoisomeric in character (different energy contents), *i.e.* the rates of formation of *(40)* and *(41)* are different. If the auxiliary asymmetric center (+)A is now split off, one obtains a mixture (+)B/(−)B in which one of the two enantiomers predominates. This scheme of partial asymmetric syntheses [43] can be applied to many types of reactions; it sometimes gives an insight into the detailed reaction mechanism, and if the optical yield is sufficiently high, it may be of preparative interest, since it is then possible to avoid resolution of the racemate.



(40) *(41)*

Diels-Alder reactions were only recently studied for their suitability for partial asymmetric syntheses [44–46a,25]. The reaction of optically active menthyl fumarate with butadiene, isoprene, or cyclopentadiene followed by reduction of the 1:1 adduct with $LiAlH_4$ and removal of the auxiliary asymmetric center (−)-menthol (which corresponds to (+)A in the above scheme) gives optically active samples of the compounds *(42)–(44)* in optical yields of only 1–9 %. Under the same conditions, menthyl acrylate and cyclopentadiene give the compounds *(45)* and *(46)*, again in optical yields of 1–9 %.

(42): R = H
(43): R = CH_3

(44)

(45): R^1 = CH_2OH, R^2 = H
(46): R^1 = H, R^2 = CH_2OH

However, the optical yields can be increased to a maximum of 88 % by the addition of Lewis acids to the reaction mixture. The absolute configuration of the predominant enantiomer can be predicted from the known absolute configuration of the auxiliary asymmetric center in the cases studied [46,46a].

This offers a promising field for further investigations. The establishment of rules for the prediction of the predominant absolute configuration would seem to be a worthwhile objective; it would then be possible to produce a large number of optically active compounds of known absolute configuration, in high optical yields, by partial asymmetric syntheses using the versatile diene synthesis.

C. Orientation Phenomena in Reactions of Unsymmetrical Components

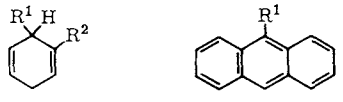
The relative amounts of structurally isomeric adducts formed in many reactions of unsymmetrical components cannot yet be explained on the basis of mechanism. Since comprehensive reviews exist on this subject [7,47], the present discussion can be confined to a few facts characteristic of orientation problems. The earlier view[31] that one of the possible structural isomers is often formed to the exclusion of all others had to be revised in most cases as a result of improvements in analytical methods. Since often the composition of the reaction product was not deduced from the primary Diels-Alder adducts, but from degradation products (numerous reaction steps), the accuracy of the numerical data in Tables 2 and 3 should not be overestimated. More recent investigations on the mixtures of primary adducts by analytical gas chromatography[48] cast some doubt on earlier results. However, the general trends evident in Tables 2 and 3 are probably real.

1. 1-Substituted Dienes

The discussion of *trans*-1-substituted butadienes[49] will be restricted to a reaction with acrylic acid derivatives. The electronic effect of the substituent R^1 in the diene *(47)* is reflected in the rate of diene additions (see Section D 2), but not in the orientation. The predominant product in every case is the 1,2-disubstituted cyclohexene derivative *(49)*, the 1,3-isomer *(50)* being formed only in small amounts.

(47) *(48)* *(49)* *(50)*

Table 2. Orientation in the reaction of *trans*-1-substituted dienes *(47)* with unsymmetrical dienophiles *(48)* [7,47].

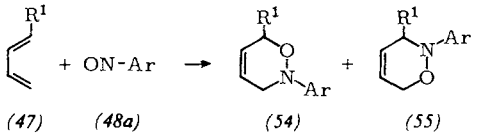


R^1	R^2	R^3	Temp. (°C)	Ratio *(49)*:*(50)*	Yield (%) of *(49)* + *(50)*
Electronic substituent effects					
$N(C_2H_5)_2$	H	$CO_2C_2H_5$	20	*cis-(49)* only	94
CH_3	H	CO_2CH_3	20	18:1	64
C_6H_5	H	CO_2CH_3	150	39:1	61
CO_2H	H	CO_2H	150	8.8:1	87
CO_2H	H	CO_2H	70–75	*cis-(49)* only	67
CO_2Na	H	CO_2Na	220	1:1	50–60
Steric effect of substituents in the diene					
CH_3	H	CO_2CH_3	200	6.8:1	85
$CH(CH_3)_2$	H	CO_2CH_3	200	5:1	60
$C(CH_3)_3$	H	CO_2CH_3	200	4.1:1	76
Steric effect of α-substituents in the dienophile					
$C(CH_3)_3$	H	CO_2CH_3	200	4.1:1	76
$C(CH_3)_3$	CH_3	CO_2CH_3	200	2.6:1	75
$C(CH_3)_3$	$CH(CH_3)_2$	CO_2CH_3	200	0.9:1	19

Since the combined yield of *(49)* and *(50)* is sometimes not much greater than 60%, these data seem rather uncertain.

The orientating forces are relatively weak, as is clearly shown by the influence of steric factors and of Coulomb repulsion. The anions of *trans*-butadiene-1-carboxylic acid and acrylic acid give equal amounts of *(49)* and *(50)*, whereas the free carboxylic acids give only *(49)*. The extent to which the difference in reaction temperature is responsible for the change in the isomer ratio was not studied in detail for the carboxylates. Branching in the substituents R^1 or R^3 also favors formation of the 1,3-disubstituted cyclohexene *(50)*.

As mentioned above the numerical values in Table 2 should be viewed with caution; the yields relate to the primary mixture of the 1:1 adducts, while the isomer ratios *(49)*:*(50)* in the examples of Sections 2 and 3 often were determined *via* degradations involving several steps. It was not rigorously established in every case whether the reactions in question were kinetically or thermodynamically controlled.



The reactions of 1-substituted dienes with dienophiles containing a carbon-carbon triple bond follow the same orientation rules as those with the double-bond analogues. Methyl propiolate and free propiolic acid react with 1-methyl- and 1-phenylbutadiene, respectively, to give the 1:1 adducts *(51)* and *(52)*, which correspond to *(49)* with one extra double bond.

(51): $R^1 = CH_3$, $R^2 = CO_2CH_3$ (85%) *(53)*
(52): $R^1 = C_6H_5$, $R^2 = CO_2H$ (30%)

9-Substituted anthracenes *(53)* may be regarded formally as 1-substituted butadienes; however, the rules evident from Table 2 are not applicable to the diene reactions of *(53)* with unsymmetrical dienophiles. Depending on the nature of the substituent R^1 in *(53)* or in the dienophile, the reaction sometimes leads exclusively to the Diels-Alder adduct corresponding to *(49)* or to that corresponding to *(50)*, while in other cases mixtures are obtained[51,52]. It is not yet possible to give a clear mechanistic interpretation of the results.

In recent years, the orientation problems with nitroso compounds as heterodienophiles have been studied extensively by NMR methods[53,54,55]. In every case

the reaction was found to be kinetically controlled. Compounds *(47)* and *(48a)* with $R^1 = CH_3$, $Ar = C_6H_5$ give a mixture of *(54)* and *(55)* in the ratio 58:42; on the other hand, with $R^1 = CH_3CO_2$, $(CH_3)_2N$, CH_3O_2C, $(CH_3)_3C$, or *p*-Z–C_6H_4 (Z = CH_3O, CH_3, Cl, NO_2), only the structural isomer *(54)* can be isolated. Studies are being carried out at present on the reactions with *N*-sulfinylamines *(56)* [55].

2. 2-Substituted Butadienes

Some of the results obtained with 2-substituted butadienes *(57)* are shown in Table 3. The numerical values must be regarded with the same caution as those of Table 2.

The electronic nature of the substituents in the diene *(57)* again has little effect on the isomer ratio *(59)*:*(60)*; the 1,4-disubstituted cyclohexene *(59)* always predominates. The dependence of the ratio *(59)*:*(60)* on steric factors probably is of little significance in view of the simultaneous decrease in the overall yields *(59)* + *(60)*.

(57) *(58)* *(59)* *(60)*

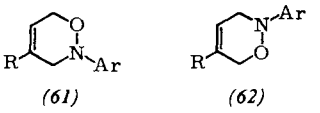

Table 3. Orientation in the reaction of 2-substituted dienes *(57)* with unsymmetrical dienophiles *(58)* [7, 47].

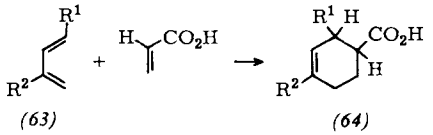
R^1	R^2	Temp. (°C)	Ratio *(59)*:*(60)*	Yield (%) of *(59)* + *(60)*
Electronic substituent effects				
OC_2H_5	CO_2CH_3	160	*(59)* only	50
CH_3	CO_2CH_3	20	5.4:1	54
C_6H_5	CO_2CH_3	150	4.5:1	73
Cl	CO_2CH_3	160	*(59)* only	60
CN	$COCH_3$	95	*(59)* only	86
Steric effect of substituents in the diene				
n-C_3H_7	CO_2CH_3	200	2.4:1	81
$CH(CH_3)_2$	CO_2CH_3	200	3.0:1	65
$C(CH_3)_3$	CO_2CH_3	200	3.5:1	47
Effect of temperature				
CH_3	CO_2CH_3	20	5,4:1	54
CH_3	CO_2CH_3	120	4.0:1	74
CH_3	CO_2CH_3	200	2.0:1	84
CH_3	CO_2CH_3	400	1.4:1	18
CH_3	CO_2CH_3	25–350	2.33:1 [48]	39–82

A distinct temperature effect was reported [56] for the system isoprene/methylacrylate (and also with acrylic acid and methyl methacrylate as dienophiles), the proportion of *(59)* in the mixture decreasing with rising temperature. The isomer ratio *(59)*:*(60)* was found in some cases by a series of degradation steps, and in others by gas chromatography. However, according to *Hennis* [48], who analysed the mixture of Diels-Alder adducts by capillary gas chromatography, the isomer ratio does not change in the temperature range studied (25–350 °C). This critical study casts doubt on the earlier results.

As with 1-substituted dienes, dienophiles containing triple bonds exhibit the same orientation behavior as their double-bond analogues [57].

The reaction of nitrosoaromatic compounds with 2-substituted butadienes generally leads to the adduct *(61)*, whereas the reaction of 2-arylbutadienes or 2-chlorobutadienes with α-chloronitrosocyclohexane yields a mixture of *(61)* and *(62)* or only *(62)* (with Ar = 1-Cl–C_6H_{10}) [55].

(61) *(62)*



R = C_6H_5, *p*-Z–C_6H_4 (Z = CH_3O, CH_3, Cl); Ar = C_6H_5

R = C_6H_5; Ar = *p*-Z–C_6H_4 (Z = Cl, OCH_3)

R = CH_3, Cl, CF_3, CN; Ar = C_6H_5

3. Disubstituted Dienes

The problems arising in the Diels-Alder reactions of polysubstituted dienes will be illustrated with only two disubstituted dienes; for comprehensive reviews see [7, 47]. In 1,3-disubstituted dienes *(63)*, the directing effects of R^1 and R^2 are additive; the adduct contains the substituent of the dienophile in the preferred 1,2- and 1,4-arrangement in relation to R^1 and R^2, respectively [58]. It is reported that at 200 °C 1,3-dimethylbutadiene and

(63) *(64)*

$R^1 = CH_3$, $R^2 = C_6H_5$

$R^1 = C_6H_5$, $R^2 = CH_3$

methyl acrylate also give small quantities of the second possible isomer (methyl 3,5-dimethyl-3-cyclohexencarboxylate) [59].

In the case of 1,4-disubstituted butadienes *(65)*, it is possible in principle to obtain information about the relative orienting forces of various substituents from the relative yields of the isomers *(66)* and *(67)*. According to earlier work of *Alder*'s school [60], to which

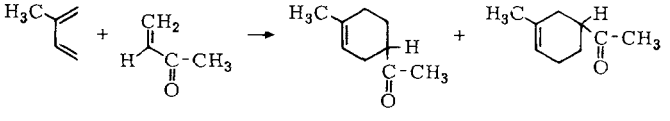
(65) (66) (67)



the previously mentioned reservations regarding analytical procedure apply, the orienting forces decrease in the order:

$C_6H_5 \gg CH_3 \geqslant CO_2H$.

More comprehensive and more reliable investigations with nitroso compounds as dienophiles [55] show that the direction of addition is influenced by the ability of the substituents R^1 and R^2 to attract electrons by an inductive effect.

4. Influence of Catalysts on Orientation Phenomena

As pointed out in Section B 2, Lewis acids can effect the relative yields of the stereoisomers formed in diene additions. Recently *Lutz* and *Bailey* [61] showed that they also change the relative amounts of structurally isomeric products.

Toluene, 120 °C, no catalyst	71	:	29
Toluene, 25 °C, $SnCl_4 \cdot 5\ H_2O$	93	:	7

Acrolein may also be used as the dienophile. The reaction rate increases and the product becomes more uniform, a fact that is important for preparative work. A systematic extension of these experiments would appear worthwhile; reactions at low temperatures in the presence of Lewis acids under mild conditions should lead to almost perfectly uniform Diels-Alder products.

As was shown by *Inukai* and *Kojima* [61a], the change in isomer ratio in the presence of a catalyst cannot be explained by steric factors (the catalyst is coordinately bonded to the carbonyl function in vinyl methyl ketone, and so increases the bulk of the acetyl group). Thus the overall reaction rate increases rapidly from butadiene *via* 2-methylbutadiene to the 2,3-dimethyl derivative.

D. Kinetic Studies of Diels-Alder Reactions

In addition to stereochemical aspects, rate measurements often give an insight into the mechanistic details of a reaction. The diene additions, many of which proceed quantitatively, are excellent subjects for a kinetic study. The characteristic chromophores in the diene and dienophile components disappear during the reactions, which can therefore be readily followed by spectrophotometry. Since diene additions are accompanied by a decrease in volume, dilatometry can also be used. Pioneering work on the kinetics of Diels-Alder reactions was carried out by *Wassermann* [27] and *Kistiakowsky* [62].

1. The "Alder Rule": Influence of Activating Substituents in the Dienophile

In preparative experiments *Alder* found that the reaction rate is often increased by electron-donating substituents [*e.g.* $N(CH_3)_2$, OCH_3, CH_3] in the diene and by electron-attracting substituents (*e.g.* CN, CO_2CH_3, CHO, NO) in the dienophile. This result was extended without question to all dienes and dienophiles, and appeared in the literature as the "Alder rule" [63]. That this generalization does not include every case is shown by the phenomenon of diene additions with "inverse" electron demand (see Section D 3).

Kinetic studies on the electron-rich dienes cyclopentadiene and 9,10-dimethylanthracene (Tables 4 and 5) prove the validity of the Alder rule for dienes of this type [5,64]. The difference in rates is particularly marked for the cyanoethylenes (Table 4). Table 5 contains quantitative data for a comparison of the reactivities with other activating substituents on the double bond of the dienophile.

Such dienophile activity series are of interest in the investigation of the reaction mechanism; they are also a guide to the rates of other Diels-Alder reactions. However, these activity series must not be applied indiscriminately to dienes that have not yet been investigated, since the purely electronic substituent effect is sometimes masked or even reversed by steric factors.

Important for preparative work are the higher reactivity of dienophiles containing double bonds relative to similarly substituted acetylene derivatives, the difference in the effects of methyl groups in the α or β position of acrylonitrile or methyl acrylate, and the much higher reactivity of some *trans* dienophiles relative to the *cis* isomers (Table 6) [65]. It is interesting that diethyl *cis*-azodicarboxylate reacts much more rapidly with cyclopentadiene than the *trans* form [65a]. Since all these

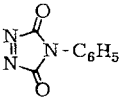
$NC-CH=CH-CO_2CH_3$	—	—	2 00
$NC-CH=CH-CN$	1.03	1.15	1.04

phenomena can be explained substantially as for 1,3-dipolar additions (cycloadditions leading to five-membered heterocycles [1,5,66]), they will not be discussed here.

The high dienophile activity of tetracyanoethylene (TCNE) compared to other dienophiles can be seen from Table 4. However, TCNE is not the strongest dienophile.

A comparison of the k_2 values (towards cyclopentadiene at 20 °C in dioxane) in the series *(68)–(71)* shows that the double bond indicated is more strongly activated by the cyclic structural elements in the compounds *(68)* to *(70)* than by a *cis*-dinitrile arrangement in the dinitrile of maleic acid *(71)*. The replacement of one *cis*-dinitrile

(68) *(69)* *(70)* *(71)*



$k_2$rel. 61 43 (R=CH_3) 10 ≡1.00
77 (R=C_6H_5)

grouping in TCNE by the stronger activating groups in *(68)–(70)* should lead to very active dienophiles. This expectation is fulfilled by *p*-benzoquinone-2,3-dicarboxylic anhydride and by dicyanomaleimide, which sometimes add much more rapidly than TCNE to the dienes of Table 7 [67].

Table 7. Kinetics of the reaction of dienophiles with
(a) 2,3-dimethylbutadiene;
(b) anthracene;
(c) isoprene
at 20 °C in dichloromethane [67] (values of 10^2 k_2, in l mole^{-1}sec^{-1}).

Dienophile	(a)	(b)	(c)
p-Benzoquinonedicarboxylic anhydride	14900	8300	900
2,3-Dicyanomaleic anhydride	830	680	85
Tetracyanoethylene	240	390	7.7
2,3-Dicyano-*p*-benzoquinone	15	—	1.26

The strongest dienophile known, according to recent kinetic measurements [67], is the cyclic azo compound *(72)*, which was recently studied by *Cookson et al.* [68]. Dienophiles containing N=N double bonds, such as esters of azodicarboxylic acid, generally are more reactive than the C=C analogues [69].

(72)

2. Reactivity of Dienes towards Maleic Anhydride and Tetracyanoethylene

The "Alder rule" can be used also to estimate the rate of addition of electron-poor dienophiles with various dienes. This is illustrated in Table 8 for reactions with maleic anhydride and with TCNE. Cycloaddition is promoted by the electron-donating methyl or alkoxy group in the diene, and inhibited by the electron-attracting chlorine [1,40,69,70]. The reactions of phenylated butadienes (*trans*-1-,2-, or *trans,trans*-1,4-isomers) show different reactivity series, depending on the dienophile used (maleic anhydride, dicyanomaleimide, TCNE) [1,69] a phenomenon which cannot yet be explained.

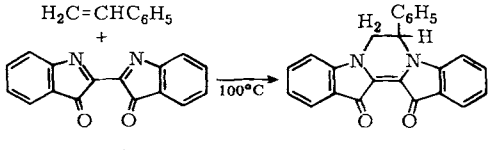
Table 8. Kinetics of the reaction of (a) maleic anhydride and (b) tetracyanoethylene in dioxane with dienes.



Diene	(a) $10^8\ k_2$ (at 30 °C) (l mole^{-1} sec^{-1})	(b) $10^5\ k_2$ (at 20 °C) (l mole^{-1} sec^{-1})
Cyclopentadiene	9210000	*ca.* 43000000
9,10-Dimethylanthracene	1600000	*ca.* 1300000000
1,3-Cyclohexadiene	13200	7290
Hexachlorocyclopentadiene	1.14	—
1,2-Dimethylenecyclohexane	755000	1230000
1,1'-Bicyclopentenyl	118000	1900000
1-Methoxybutadiene	84100	598000
2,3-Dimethylbutadiene	33600	24300
trans-1-Methylbutadiene	22700	2060
2-Methylbutadiene	15400	1130
Butadiene	6830	519
2-Chlorobutadiene	690	1.0

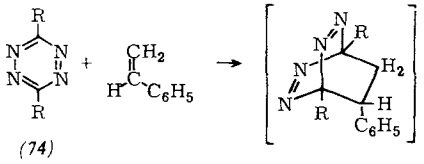
The reactivity of hexachlorocyclopentadiene is surprisingly low compared to that of cyclopentadiene itself; no Diels-Alder adduct could be obtained with TCNE even under forcing conditions[71]. However, hexachlorocyclopentadiene is often found to be a reactive diene component[1]; in fact, *Alder* classified perchlorocyclopentadiene as the "diene with the highest possible addition ability"[63]. This apparent contradiction of the rate data in Table 8 can be readily explained by the phenomenon of Diels-Alder reactions with "inverse" electron demand.

3. Diels-Alder Reactions with Inverse Electron Demand

The data in Tables 4 to 8 demonstrate the validity of the Alder rule in the reactions of electron-rich dienes and of electron-poor dienophiles: the reaction is accelerated by electron-donating substituents in the diene and by electron-attracting substituents in the dienophile. Cycloadditions with formation of six-membered rings are particularly fast when the components are very different in their electronic character, *e.g.* in the reaction of cyclopentadiene or 9,10-dimethylanthracene with TCNE.

Many reactions that can be described formally as Diels-Alder additions do not obey the Alder rule. α,β-Unsaturated carbonyl compounds and *o*-quinones combine preferentially with electron-rich dienophiles[2]; similar deviations are observed in the reactions of some substituted tetracyclones (tetraphenylcyclopentadienones)[72], thiophene 1,1-dioxides[73], hexafluorocyclopentadiene[73a], and of dehydroindigo *(73)*, which gives

(73)



a 1:1 adduct with styrene, but not with the reactive dienophile maleic anhydride[74].

Bachmann and *Deno*[75] first proposed that the converse of the Alder rule should also hold, *i.e.* that electron *poor* dienes should react preferentially with electron-*rich* dienophiles; they termed this type of cycloaddition *Diels-Alder reactions with "inverse" electron demand*, but were unable to find a suitable model system. However, this postulated inversion of the diene activity scale was in fact observed in a kinetic study with the electron-poor hexachlorocyclopentadiene[71,76]. The data in Table 9 show this inversion in a comparison of hexachlorocyclopentadiene and the electron-rich compound 9,10-dimethylanthracene. This phenomenon becomes particularly striking in the reactions of the dienophiles cyclopentene and maleic anhydride or the *p*-substituted styrenes.

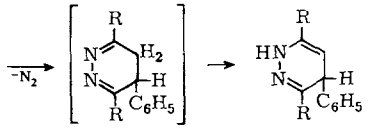


Table 9. Kinetics of the reaction of (a) hexachlorocyclopentadiene and (b) 9,10-dimethylanthracene with dienophiles in dioxane at 130 °C[71,76].

Dienophile	$10^6\ k_2$ (l mole^{-1} sec^{-1}) (a)	(b)

2,3-Dihydrofuran	333	—
Norbornene	72	36
Cyclopentene	59	7.8
Maleic anhydride	29	1410000

The reactions of 1,2,4,5-tetrazines with olefins to form 1,4-dihydropyridazines *(76)*[77] are also diene additions with inverse electron demand, as has been established by kinetic measurements[78]. The addition of dienophile (formulated for styrene) to the diene system in *(74)*, R = aryl, CO_2CH_3, $CHF{-}CF_3$, *etc.*, is rate-determining; this is followed by rapid liberation of N_2 from the 1:1 adduct *(75)*, which cannot be isolated. Electron-attracting substituents R in the tetrazine *(74)* promote the reaction. The inversion of the dienophile scale in

this system was particularly clear with dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate *(74)*, R = CO_2CH_3 [79] (Table 10). Special mention should be made of the similar [76,80] activity of *p*-substituted styrenes in the reactions with hexachlorocyclopentadiene and dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate, as well as of the strong reaction-promoting effect of enamine groupings in the dienophile. The Diels-Alder reactions of these

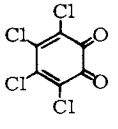

Table 10. Kinetics of the reaction of dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate with dienophiles in dioxane at 30 °C [78, 80].

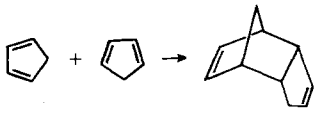
tetrazines with electron-rich dienophiles (enamines, enol ethers, enol esters) permit a one-step pyridazine synthesis and the preparation of diaza analogues of tropylidene and norcaradiene [81,82].

It is to be expected that other electron-poor diene systems will obey the principle of Diels-Alder reactions with inverse electron demand. For example, tetramethyl furantetracarboxylate or 6-*p*-nitrophenyl-1',2',3',4'-tetrachlorofulvene do not react with electron-poor dienophiles (*e.g.* maleic anhydride, esters of acetylenedicarboxylic acid) [83,84]; on the other hand, it cannot yet be decided from preparative studies whether tetrachlorofuran [85] and perchloro-α-pyrone [86] obey the Alder rule.

Kinetic studies by *Horner* and *Geyer* showed inversion of the dienophile activity for the carbocyclic diene system in perchloro-*o*-benzoquinone *(76a)*. The *p*-substituted styrenes approximately obey a Hammett relationship with a negative



(76a)

ρ value ($k_{p\text{-}CH_3O\text{-styrene}}$: $k_{p\text{-}NO_2\text{-styrene}} \approx 40{:}1$ at 20 °C) [86a]. In the reaction of styrene with substituted *o*-benzoquinones, there is a linear relationship between the redox potentials of the latter and the logarithms of the rate constants for the Diels-Alder addition.

Kinetic data, solvent effects, and activation parameters show that the additions of hexachloropentadiene and of the 1,2,4,5-tetrazines are mechanistically of the same reaction type as the reactions in Tables 4 to 6.

4. Solvent Effects and Activation Parameters

The rate of diene additions is only slightly affected by a change of solvent. The dimerization of cyclopentadiene to dicyclopentadiene is only about three times as fast in nitrobenzene or ethanol as in benzene; this Diels-Alder reaction has a comparable rate in the gas phase [87].

(77)

This low solvent dependence is a general kinetic characteristic of cycloadditions leading to six-membered rings [88]; k_2 rarely increases by a factor of more than 10 on change to a solvent of higher solvating power, as can also be seen from Table 11 [64]. The solvent effect is of the same order of magnitude even for a combination

Table 11. Influence of the solvent on the rate of addition of fumaronitrile to 9,10-dimethylanthracene [64].

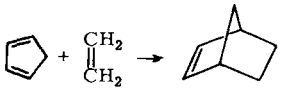
The effect of the solvent on the reaction of tetracyanoethylene with anthracene and bicyclo[2.2.1]hepta-2,5-diene was studied by *P. Brown* and *R. C. Cookson,* Tetrahedron *21,* 1977 (1965).

The small solvent effect on the rate of addition in Diels-Alder reactions and the fact that a number of cycloadditions leading to six-membered rings proceed at comparable rates in the gas phase and in solution may be taken as an indication that the rate-determining transition state is only slightly more polar than the ground state, or that in many cases it requires no stabilization by the solvent.

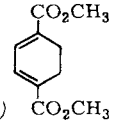
Important evidence for the establishment of a reaction mechanism is often provided by the activation parameters, *i.e.* the activation enthalpy $\Delta H^{\neq}$ and the activation entropy $\Delta S^{\neq}$; these values can be readily determined from experimental data by means of the Eyring equation. In practically every case examined it was found that, like the mechanistically related 1,3-dipolar additions[66], the Diels-Alder reactions require only a relatively small enthalpy of activation ($\Delta H^{\neq} < 25$ kcal/mole). The strongly negative entropies of activation, $\Delta S^{\neq}$, are remarkably constant; an average value of about −35 e.u. points to a highly ordered rate-determining transition state[1,5,27,64,88a]. There is no difference in the activation parameters of Diels-Alder reactions that obey the Alder rule and those with inverse electron demand. It should already be mentioned here that the strongly negative values of $\Delta S^{\neq}$ must be regarded as important evidence of synchronous bond formation.



5. Acceleration of Diels-Alder Reactions by Catalysts and by Pressure

Many diene additions are reasonably fast at room temperature or on gentle heating. With less reactive systems, however, it would be interesting to accelerate the reaction with catalysts. Until recently it was thought that diene additions could be influenced only slightly by catalysts[89,90]. The dimerization of cyclopentadiene and the additions of *p*-benzoquinone[89] and fumarodinitrile[71] to dienes are only slightly accelerated by α-halogenated acetic acids.

Yates and *Eaton*[91] were the first to recognize that diene additions proceed much more rapidly in the presence of $AlCl_3$. It was subsequently found that these reactions are also catalysed by other Lewis acids (BF_3, $SnCl_4$, $TiCl_4$)[92]. As pointed out in Section B 2, the acceleration is considerable, and often the reaction temperature can be lowered by more than 100 °C with no decrease in rate.



The catalytic action probably is due to complex formation between the Lewis acid and the polar groups of the activating substituents in the dienophile (*e.g.* in maleic anhydride, ethyl maleate and fumarate, and esters of acrylic acid) or in the diene (reaction of tetraphenylcyclopentadienone with ethylene). The complex formation has been confirmed by IR spectra[25,64]. In all the cases studied, *cis-trans* isomeric dienophiles give diastereoisomeric adducts in the presence of Lewis acids just as in the uncatalysed reaction, *i.e.* the catalysed reactions also are pure *cis* additions[65,91]. There is therefore no reason to believe that the catalysis by Lewis acids involves any change in mechanism of the Diels-Alder reaction; an ionic two-step mechanism is occasionally discussed[61a].

Schrauzer and *Glockner*[93] found that homo-Diels-Alder additions[2] are catalysed by Ni(0) complexes. It is not yet known whether the acceleration of the reaction of ethylene with cyclopentadiene (at 144 °C; catalyst: $CuCl/NH_4Cl$/activated charcoal) is due to formation of

a metal complex[94]. Rhodium on activated charcoal converts norbornadiene (bicyclo[2.2.1]hepta-2,5-diene) into a mixture of dimers and trimers, whose structures correspond to a cycloaddition with formation of a four-membered ring and to a homo-Diels-Alder reaction, respectively[94a]. No catalysis by Lewis acids has been observed in systems with no polar groups, *i.e.* with purely olefinic components. It may be possible in such cases to accelerate the diene additions by the addition of metal complexes[95].

The yield of Diels-Alder reactions is increased by an increase in pressure (*e.g.*[96–98]). This effect is particularly important for gaseous reactants; for example, ethylene adds smoothly to *(78)* at 165 °C/1000 atm[98]

(78)

The reaction of naphthalene with maleic anhydride at 10000 atm gives the 1:1 adduct in 78 % yield, whereas at 1 atm and under otherwise identical conditions the yield is only 1 %[97].

[88a] An exception in the system diphenylisobenzofuran + acrylonitrile has been reported by *M. Gillois* and *P. Rumpf*, Bull. Soc. chim. France *1959*, 1823. The values of log *A* in the Arrhenius equation vary with the solvent between 2.2 and 14.5; no product analysis was carried out.

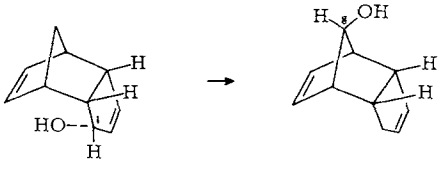
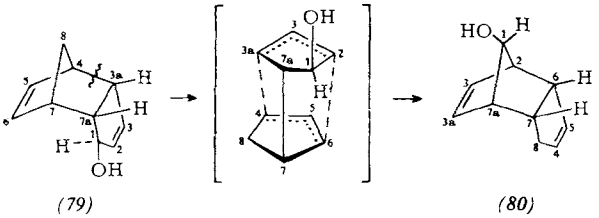
E. On the Mechanism of Diels-Alder Reactions



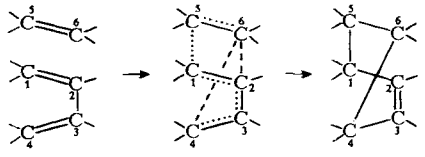
The possible mechanisms for diene additions were described in Section A. Numerous recent publications testify to the interest shown in a final elucidation of the course of this cycloaddition [99].

1. Rearrangements of Diels-Alder Adducts

A stereoselective intramolecular rearrangement takes place when α-(1-hydroxy)dicyclopentadiene *(79)* is heated; at 140 °C, *(79)* exists in equilibrium with about 50 % of the 8-*syn* isomer *(80)* [100]. Similarly, the epimeric β-alcohol *(81)* is converted into the 8-*trans* form *(82)*. Using optically active compounds, *Woodward* and *Katz* [100] showed that this reaction does not

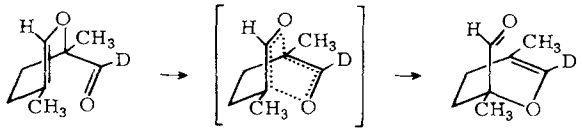


(79) *(80)*



(81) *(82)*

involve dissociation into the fragments cyclopentadiene and cyclopentadienol, but is intramolecular. The results could be explained by the assumption that only the bond between C-3a and C-4 is broken. Decomposition into cyclopentadiene and its 1-hydroxy derivative, *i.e.* breakage of the second bond, (C-7)–(C-7a), in the Diels-Alder adduct, occurs only above 140 °C.



(79) *(80)*

On the basis of the principle of microscopic reversibility, the authors assumed that Diels-Alder reactions in general must proceed by a two-stage mechanism, in which the bonds between the components are formed in succession. The diene and the dienophile are first oriented in parallel planes; in the rate-determining step, only one bond, *i.e.* that between C-1 and C-5, is formed; "secondary attractive forces (attractive electrostatic, electrodynamic, and even to some extent exchange forces)" between the centers C-6, C-4, and C-2, which are not directly involved in the primary bond formation, are assumed to be responsible for the observed stereospecific *cis* addition by preventing rotation about C-C single bonds.

(83)

Several authors have questioned this mechanistic generalization [101,102]. There is as yet no conclusive experimental evidence that the Woodward-Katz rearrangement is not a special case of the Cope rearrangement, in which no intermediate has so far been detected [103]. The Woodward-Katz rearrangement appears to be confined to adducts in which both components possess diene character, and so is not of general validity [104]. The stereospecific rearrangement of the deuterated methacrolein dimer *(84)* fits into this scheme [105].

(84)

On the other hand, the rearrangements *(85)* ⇌ *(86)* [102], *(87)*→*(88)* [106], *(89)* ⇌ *(90)* [107], and *(77)* ⇌ *(77a)* [107a] definitely proceed by a retro-Diels-Alder reaction, *i.e.* the two bonds between the components are broken in the course of the rearrangement (see also [108]).

The Woodward-Katz scheme (two-stage mechanism) has another consequence, which is amenable to experimental test. In *(83)*, "secondary attractive forces" operate from C-6 to C-2 and C-4; it might be expected that cycloadditions leading to four-membered rings and

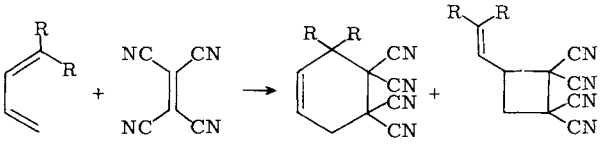
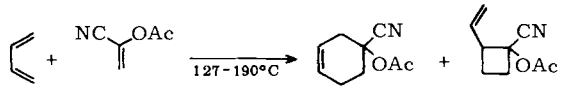
(85) (86)

(87) (88)



(89) (90)

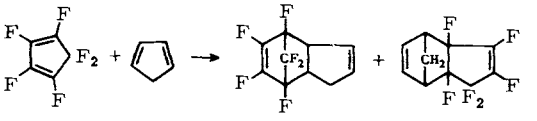


(77) (77a)

those leading to six-membered rings would involve the same intermediate. According to *Stewart*[35], 1,1-dimethylbutadiene reacts with TCNE to give both the cyclohexene derivative *(91a)* and the cyclobutane derivative *(92a)*. The use of a different solvent leads to

(91) a: R = CH_3 (92)
b: R = C_6H_5

a marked change in rate only for the cycloaddition leading to *(92)*. Thus *(91a)* and *(92a)* cannot be formed *via* the same intermediate[35]. 1,1-Diphenylbutadiene gives mainly *(92b)* together with a little *(91b)*; when heated in solution, however, *(92b)* rearranges to the thermodynamically more stable *(91b)*[108a]. On the other hand, the product ratio *(93)*:*(94)* obtained from butadiene and 1-cyanovinyl acetate (α-acetoxyacrylonitrile) is relatively insensitive to changes of solvent (cyclohexane, toluene, acetonitrile, nitromethane) and temperature[109]; *Little* prefers to interpret his results



(93) (94)

[108a] *J. J. Eisch* and *G. R. Husk*, J. org. Chemistry *31*, 589 (1966).

[109] *J. C. Little*, J. Amer. chem. Soc. *87*, 4020 (1965).

by a two-step mechanism and rejects the alternative explanation that the competing cycloadditions leading to the fourmembered ring and to the six-membered ring have comparable activation enthalpies and similar polar transition states.

The reaction of equimolar amounts of hexafluorocyclopentadiene with cyclopentadiene always yields a mixture of the adducts *(94a)* and *(94b)* in the constant yield ratio of 16:84, irrespective of the temperature (20–120 °C) or of the solvent (n-hexane, nitrobenzene)[109a]. Neither *(94a)* nor *(94b)* rearranges to the other under these conditions. The best interpretation in

(94a) (94b)

this case appears to be formation of *(94a)* and *(94b)* *via* a common intermediate, *i.e.* that the reaction proceeds by a two-step mechanism, probably by way of a biradical intermediate.

2. Kinetic Isotope Effects

Primary and secondary kinetic isotope effects have been used as mechanistic criteria in many reactions[110,110a]. A number of recent investigations using this method provide information about the hybridization of the transition states of Diels-Alder additions and of the redissociation of diene adducts[111–114] (Table 13). Since the addition step involves the conversion of sp^2

Table 13. Secondary isotope effects in Diels-Alder additions (at 25 °C).

System	k_D/k_H per D atom	Ref.
With deuterated dienes		
[9,10-D_2]Anthracene + maleic anhydride	1.06	[111]
[9,10-D_2]Anthracene + tetracyanoethylene	1.06	[114]
[1,1,4,4-D_4]Butadiene + maleic anhydride	1.07	[111]
With deuterated dienophiles		
[D_2]Maleic anhydride + butadiene	1.01	[111]
[D_2]Maleic anhydride + cyclopentadiene	1.03	[111]
[D_2]Maleic anhydride + anthracene	1.05	[111]

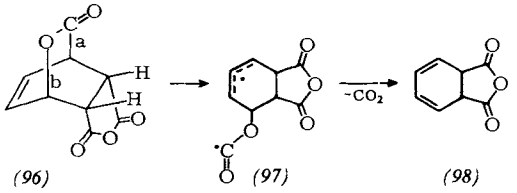
into sp^3 centers, it is found, in agreement with theoretical considerations[115,110a], that $k_D:k_H > 1$, *i.e.* that there is an inverse secondary isotope effect.

The low magnitudes of the inverse secondary isotope effects are taken as evidence that the hybridization of the reaction centers in the transition state has changed only very slightly. Thus the rate-determining energy threshold occurs very early on the reaction coordinate, so that the transition state is structurally similar to the original diene and dienophile. According to the authors, the magnitude of the secondary isotope effect agrees with a multicenter mechanism, *i.e.* with synchronous bond formation. Results on the systems [9-D]anthracene + acrylonitrile, 1,1-dicyanoethylene, tricyanoethylene, and chlorotricyanoethylene[114] can be explained by the assumption that, with highly unsymmetrical dienophiles, bond formation at the four centers probably begins simultaneously, but has proceeded to different extents in the transition state (see the similar discussion for 1,3-dipolar additions[11]); with acrylonitrile and 1,1-dicyanoethylene, it should be most advanced at the electrophilic end of the double bond in the dienophile.

It should be mentioned that unlike the primary isotope effect the small magnitude of the secondary isotope effect makes high experimental accuracy essential. The numerical values cannot yet be fully explained. Thus it is difficult to understand why the hybridization changes in the diene (larger isotope effect) should be more marked in the transition state than those in the dienophile. It is also surprising that the secondary isotope effect is independent of the reactivity of the dienophile used. The dienophile activities differ by many orders of magnitude between TCNE and maleic anhydride and between acrylonitrile and 1,1-dicyanoethylene; the inverse secondary isotope effects observed are equal within the limits of error.



Many Diels-Alder additions can be reversed even under mild conditions. The cleavage of a number of adducts has been studied with the aid of labeled compounds[112,113]. The 2-methylfuran/maleic anhydride adduct *(95a)* in the form of its partially deuterated derivatives is particularly suitable for such investigations. According to *Seltzer*[112], the secondary isotope effects observed indicate synchronous breakage of the bonds in the cleavage step; on the basis of the principle of microscopic reversibility, the author postulates a one-step multicenter mechanism for the addition.

(95a): X = Y = Z = H
(95b): X = Y = D; Z = H
(95c): X = Y = H; Z = D
(95d): X = D; Y = Z = H
(95e): X = Z = H; Y = D

$k_{(95a)}: k_{(95b)} = 1.16$
$k_{(95a)}: k_{(95c)} = 1.08$
$k_{(95d)}: k_{(95e)} = 1.00$

In contrast, *Goldstein* and *Thayer*[113] conclude from the primary carbon and oxygen isotope effects ($k_{12C}/k_{13C} = 1.030$; $k_{16O}/k_{18C} = 1.014$) that the elimination of CO_2 from the α-pyrone/maleic anhydride adduct *(96)* proceeds in two steps, the first involving the breakage of the bond *a* to the carbonyl carbon, while the C–O bond *b* is still practically unaffected. These

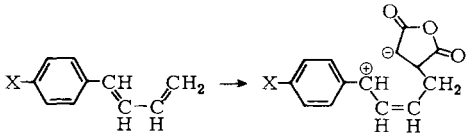
(96) *(97)* *(98)*

authors assume that the addition of CO_2 as a dienophile to *(98)* (which has not yet been achieved experimentally) would proceed by a two-step mechanism involving the intermediate *(97)*. It would seem premature, however, to assume from this one result that *all* Diels-Alder additions are two-step reactions.

3. One-Step or Two-Step Reaction?

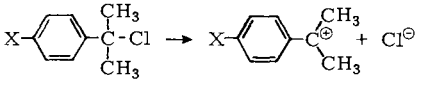
The data discussed in Sections B to E can at present be most easily explained by a multicenter mechanism, the two new σ bonds (Section A) between the diene and the dienophile being formed simultaneously. However, the formation of these σ bonds will not have reached exactly the same extent at the peak of the activation barrier, except in the extreme case. In general, though the bonds begin to form at the same time, they will not both be equally pronounced in the transition state. If the bond formation is rather faster at one center than at the other, the dienophile will necessarily assume a partial positive or negative charge (or a partial free-radical character). These partial charges will be small, and will depend on the nature of the reacting components.

The practically universal stereospecific *cis* addition is a necessary result of synchronous bond formation between the reactants; the experimental results would agree with a two-step mechanism only on the basis of the additional hypothesis, mentioned in Section A, that rotation about C–C single bonds in the intermediate is impossible, *i.e.* that ring closure to form the adduct is very fast. No biradical intermediates[10], such as occur in cycloadditions leading to four-membered rings, have been detected[11].



No satisfactory explanation can be given for the orientation phenomena (Section C)[116]. The relative yields of the structural isomers are largely independent of the electronic nature of the substituents in the dienes; this rules out the possibility of a zwitterion intermediate, but could be compatible with a biradical intermediate.

The kinetic results discussed in Section D also indicate a synchronous mechanism. The effects of substituents in the diene and in the dienophile on the rate of the reaction are very large in absolute terms, but are much too small for a rate-determining transition state that corresponds closely to a zwitterion intermediate. Thus



[115] *A. Streitwieser, R. H. Jagow, R. C. Fahey,* and *S. Suzuki,* J. Amer. chem. Soc. *80*, 2326 (1958).

[116] Cf. also *A. Streitwieser*: Molecular Orbital Theory for Organic Chemists. Wiley, New York 1961, p. 432.

when CH_3O is replaced by NO_2 in the reaction of *p*-substituted 1-phenylbutadienes *(99)* with maleic anhydride, the k_2 value decreases by only a factor of 10[117]; on the other hand, the rate of solvolysis of *p*-substituted α,α-dimethylbenzyl chlorides *(101)* to give the ion pair decreases to 7×10^{-9} of the original value when the *p*-NO_2 compound is used instead of the *p*-CH_3O compound[118]. Thus it is unlikely that the

(99) *(100)*

(101) *(102)*

reaction proceeds *via* a zwitterion intermediate *(100)* similar in structure to the carbonium ion in *(102)*. The partial charges are small in other diene additions also, as shown by the fact that the ρ values are always low[119]. The k_2 values for diene additions of arylated dienes or dienophiles can be better interpreted by a σ^+ relationship as described by *H. C. Brown*[118]. In reactions of tetraphenylcyclopentadienone with esters of substituted phenylpropiolic acid the effect of substituents in the nucleus can be better described by σ^- values ($\rho \approx 0.3$)[119a].

The small positive solvent effect on the reaction rate and the fact that diene additions also proceed at comparable rates in the gas phase show that the transition states in all the cases studied are only slightly more polar than the ground states, and often (in gas reactions) do not require solvation, and are therefore essentially nonpolar. These facts also oppose a zwitterionic two-step mechanism.

The synchronous mechanism imposes high steric demands on the rate-determining step, since four centers must come together in a favorable arrangement in order that a collision may be successful. The highly negative activation entropies characteristic for such multicenter mechanisms are found in nearly all the systems studied. The fact that the values of $\Delta S^{\neq}$ are relatively constant, irrespective of the absolute rate of the Diels-Alder reaction, points to a common mechanism, *i.e.* synchronous bond formation, in all the systems studied. Diene additions with inverse electron demand are no exception.

Recent attempts to obtain more detailed insight into the mechanism of cycloadditions and mechanistically related valence isomerizations with the aid of MO calculations and symmetry considerations appear promising [120–122]. A multicenter mechanism is possible for the thermal 4 + 2 cycloadditions, but impossible for the photochemical reactions; photochemical Diels-Alder reactions probably proceed by a two-step mechanism. As pointed out in Section B 2, a quantitative description of *Alder*'s *endo* rule could be possible on the basis of MO considerations. Earlier calculations[123], which were based on the assumption of synchronous bond formation between the diene and the dienophile, had already led to correct predictions of the reactive positions in polycycles and of the relative reactivities of various dienes; however, steric factors, which play a considerable part in Diels-Alder reactions in general, were not taken into account.

The pressure-dependence of the rate of a reaction permits the determination of the activation volume $\Delta V^{\neq}$, *i.e.* the volume difference between the reactants and the transition state. The fact that $\Delta V^{\neq}$ for the dimerization of isoprene is equal to half of the total volume decrease led *Walling* and *Peisach*[124] to assume a two-step mechanism for this reaction involving a biradical intermediate. A similar relationship was found for the reaction of butyl acrylate with 2,3-dimethylbutadiene, but not for the dimerization of cyclopentadiene[125]. It was concluded from the $\Delta V^{\neq}$ values that the Woodward-Katz rearrangement and retro-Diels-Alder reactions have the same energy profile, and have a different mechanism from Cope rearrangements[126]. Experimental difficulties and the theoretical interpretation of these experiments[127,128] are still under discussion.

A biradical triplet intermediate has been fairly definitely ruled out. Compounds that catalyse singlet-triplet transitions have no effect on Diels-Alder reactions[102]. The entropies of activation for the cleavage of the adducts are "normal", so that a change in multiplicity can be excluded; consequently, from the principle of microscopic reversibility, such a change can also be ruled out for the addition step. The fact that photochemically induced (photosensitized) diene additions that definitely pass through a triplet state give more

[128] *C. Walling* and *D. D. Tanner,* J. Amer. chem. Soc. *85,* 612 (1963).

products than thermal diene additions is a further argument against a triplet intermediate[129]. In the photosensitized dimerization of cyclopentadiene, for instance, the products *(103)* to *(105)* of cycloadditions

leading to six-membered rings and those leading to four-membered rings are formed in equal amounts. Similar results were obtained with cyclohexadiene and isoprene the diene components[129]. The reaction of cyclopentadiene with its hexafluoro derivative (see Section E 1), on the other hand, shows that a biradical singlet intermediate must be seriously considered.

In conclusion, a still unsolved problem may be mentioned. In 1942, *Woodward*[130] suggested that the actual Diels-Alder reaction is preceded by formation of an intermediate charge-transfer complex. *Andrews* and *Keefer*[131] showed that it is impossible to distinguish between the alternative mechanisms A and B by kinetic measurements alone:

$$\text{A: diene} + \text{dienophile} \underset{}{\overset{\text{fast}}{\rightleftharpoons}} \text{complex} \xrightarrow{\text{slow}} \text{adduct}$$

$$\text{B: complex} \overset{\text{fast}}{\rightleftharpoons} \text{diene} + \text{dienophile} \xrightarrow{\text{slow}} \text{adduct}$$

The mathematical development leads to the same formal kinetics for both possibilities. Abundant experimental data show qualitatively that both the formation of the charge-transfer complexes and the Diels-Alder reactions are favored by increasing donor stength of the diene and by increasing acceptor strength of the dienophile.

However, no definite quantitative relationship could be found for a number of model systems in which steric factors were practically eliminated[67]. Whereas the reactivities of the dienophiles in Table 7 change in the same order for various dienes, no such clear relationship is found for the formation of charge-transfer complexes with the same dienophiles (acceptors); dicyano-*p*-benzoquinone, although having the lowest dienophile activity, is relatively "too strong" as an acceptor, while the relative acceptor strength of TCNE is a function of the donor used (hexamethylbenzene, durene, pyrene, naphthalene, anisole). In view of the fact that the same sandwich structure is proposed for the transition state of the diene additions and the charge-transfer complexes, the above possibility A appears more probable.

F. Conclusion

Almost four decades have passed since *Diels* and *Alder* recognized the general applicability of these cycloadditions with formation of six-membered rings. As in many other fields the mechanistic interpretation of these reactions has also lagged behind the accumulation of experimental data. However, it is to be hoped that all the details of the mechanism of Diels-Alder reactions will be fully elucidated in the near future, thereby stimulating new investigations that will bring new preparative possibilities.

I am grateful to the Deutsche Forschungsgemeinschaft, the Max-Buchner-Forschungsstiftung, and the Fonds der Chemischen Industrie for their support, which has made possible the work of my co-workers H. Wiest, D. Lang, Barbara Schröder, J. Kredel, G. Heinrichs, Christa Rücker, and *A. Mielert.*

Spin Density Distribution in 2,4,6-Triphenylphenoxyl

BY K. DIMROTH, A. BERNDT, F. BÄR, A. SCHWEIG, AND R. VOLLAND[*]

The distribution of the unpaired electron over the oxygen and the 24 carbon atoms in the free 2,4,6-triphenylphenoxy radical was determined by electron spin resonance spectroscopy and quantum-mechanical approximation methods. The hyperfine splitting was evaluated with the aid of the spectra of triphenylphenoxyls deuterated in some or all of the substituent phenyl groups. The results of the quantum-mechanical approximations were checked by recording the ESR spectra of triphenylphenoxyls labeled with ^{13}C in positions 1, 2, 3, or 4 of the central ring. The spin density distribution permits a first discussion of the ^{17}O-coupling constants of correspondingly labeled triphenylphenoxyl and other organic free radicals.

The dehydrogenation of 2,4,6-triphenylphenol[1] and many other 2,4,6-triarylphenols[2] in an alkaline or a neutral medium leads to phenoxy radicals, which are unusually stable: they do not react with oxygen and, despite their high oxidation potentials[3], they can be kept in organic solvents for a long time without any change. As in the case of 2,4,6-tri-t-butylphenoxyl[4], blocking of the reactive 2, 4, and 6 positions with aryl groups suppresses the susceptibility of the ring to further addition and substitution. Since the steric hindrance with phenyl groups is less than with t-butyl groups another factor must be present in 2,4,6-triphenylphenoxyl to compensate for the decrease in steric hindrance. This effect is due to the participation of the phenyl groups in the π-electron system thus enabling the unpaired electron to occupy 25 positions, as compared to only seven in phenoxyl or trialkylphenoxyls.

The distribution of the unpaired electrons over the various atoms can be determined from the ESR spectra[5], and in particular from the resulting coupling constants and empirical relations between the latter and the spin densities. The development of special syntheses of triphenylphenoxyl isotopically labeled in distinct positions[6] was also an essential requirement for the determination of the spin density distribution.

ESR spectra with proton hyperfine structure can be used to determine the spin densities only on carbon atoms carrying hydrogens, and, for the other ("blind"[7]) atoms, one can use quantum-mechanical approximations in such a way that the calculated results agree with the experimental values for the hydrogen-carrying carbons. However, it has been shown on *p*-benzosemiquinone[7], that this technique may lead to incorrect values for the blind atoms. We have therefore checked the calculated spin densities of the blind atoms with triphenylphenoxyl labeled in known positions with ^{13}C. From the experimental spin density distribution and the ^{17}O-coupling constant[8], we could make an inference concerning the connection between the ^{17}O-coupling constant and the spin density on oxygen.

1. The Proton Hyperfine Structure of the ESR Spectrum of 2,4,6-Triphenylphenoxyl

The ESR spectrum of 2,4,6-triphenylphenoxyl *(1)* consists of about 100 proton hyperfine structure lines having approximately equal separation (Fig. 1)[a].

No grouping of the proton hyperfine structure lines exists that would permit analysis of the spectrum on the basis of the characteristic intensity ratios[9].

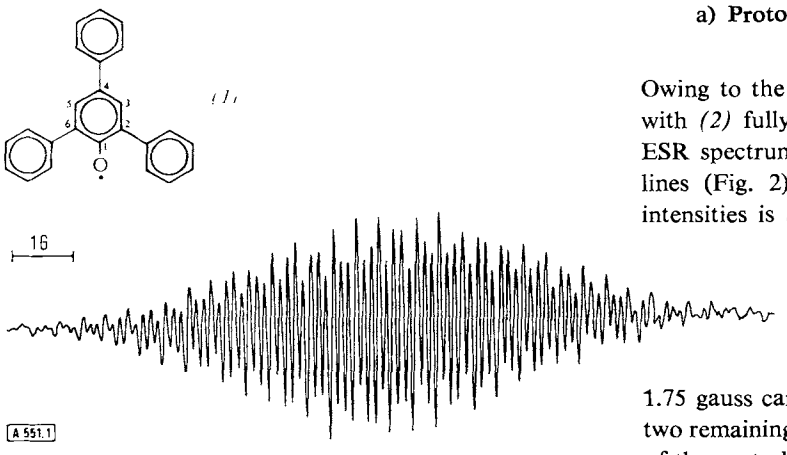

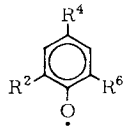

Fig. 1. The ESR spectrum of 2,4,6-triphenylphenoxyl in benzene at 50 °C.

Furthermore, the coupling constants cannot be assigned from the ESR spectrum of 2,4,6-triphenylphenoxyl alone, since there are several groups present with the same number of equivalent protons. Examination of a spectrum with an expanded abscissa has given the value of 0.37 gauss for the smallest coupling constant.

The deuterated compounds *(2)* to *(5)* were prepared to find the other coupling constants and to assign them to the hydrogens of *(1)* [b].

		R^2	R^4	R^6
[c]	*(2)*	C_6D_5	C_6D_5	C_6D_5
	(3)	C_6D_5	C_6H_5	C_6D_5
	(4)	C_6D_5	C_6H_5	C_6H_5
	(5)	C_6H_5	C_6D_5	C_6H_5

The coupling constant a_k of a nucleus k is proportional to μ_k/I_k, eq. (I)[12] (μ_k = magnetic moment, I_k = nuclear spin

$$a_k = (8\pi\mu_k/3\,I_k)\,\rho_k(o) \qquad (I)$$

and $\rho_k(0)$ = net spin density of all the electrons on nucleus k). Furthermore, since deuterium has a smaller magnetic moment and larger nuclear spin ($\mu_{k.D}$ = 0.85738 $\mu_{k.B}$, $I_{k.D}$ = 1; $\mu_{k.B}$ is the nuclear Bohr magneton), the coupling constant of deuterium is smaller than that of hydrogen ($\mu_{k.H}$ = 2.79267 $\mu_{k.B}$, $I_{k.H}$ = 1/2) by a factor of 6.514. The spectrum may therefore be simplified by the substitution of D for H on carbons with a small spin density, since the hyperfine lines of the remaining hydrogens may then appear in groups.

a) Proton Coupling Constant of the Central Ring

Owing to the absence of deuterium hyperfine splitting with *(2)* fully deuterated in the substituent rings, the ESR spectrum of this radical shows only three broad lines (Fig. 2). Since the ratio of the corresponding intensities is about 1:2:1, the coupling constant a = 1.75 gauss can be assigned unambiguously to the only two remaining hydrogens, *i.e.* those in positions 3 and 5 of the central ring.

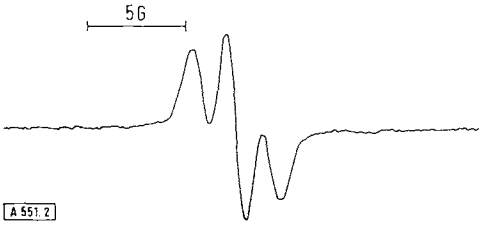

Fig. 2. The ESR spectrum of 2,4 6-tris(pentadeuteriophenyl)phenoxyl in benzene at 50 °C.

The coupling constant is seen to differ only slightly from that of the unsubstituted phenoxy radical (1.8 gauss[13]; 1.9 gauss[14]), in agreement with the more general observation that phenyl substituents affect only slightly the spin densities on carbons adjacent to the substituted positions[4b,4d,15,16].

b) Coupling Constants of Hydrogens in the 4-Phenyl Group

Fig. 3 shows that the ESR spectrum of 2,6-bis(pentadeuterophenyl)-4-phenylphenoxyl *(3)* consists of a sextet with the approximate intensity ratio of 1:5:10:10:5:1, and is assignable to five protons with $|a|$ = 1.75 gauss [d].

Fig. 3. The ESR spectrum of 2,6-bis(pentadeuterophenyl)-4-phenylphenoxyl in benzene at 60 °C.

[b] Some of these results were included in a lecture at the EUCHEM Conference on ESR Spectroscopy in Cirencester (England), March 28th to April 2nd, 1965.

[c] *I. S. Hyde* (Varian Ass., Palo Alto, California) has found from the ENDOR spectrum [10] that the 2-phenyl and the 6-phenyl groups in *(2)* are not fully deuterated. Deuterium analysis has also given a decrease in deuterium content of about 22%. Thus, some D must have been replaced by H during the synthesis [11] from 2,4,6-triiodophenol and hexadeuteriobenzene (>99 atom-% D).

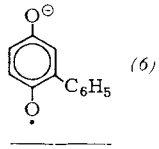
[16b] *E. A. C. Lucken*, J. chem. Soc. (London) *1963*, 5123.

[d] The range of deviation can here be up to a fourth of the bandwidth of 0.88 gauss [9]. *J. S. Hyde* (cf. note [c]) has made a more accurate determination of the coupling constants of *(1)* by the ENDOR method [10] with the aid of these and other deuterated 2,4,6-triphenylphenoxyls (personal communication).

Two of these have appeared before as 3- and 5-hydrogens, and the other three must belong to the 4-substituent. They are assigned to the *p*- and the two *o*-positions, since with all known phenyl-substituted radicals [15, 16a, 17], the coupling constants of the *o*- and the *p*-protons in substituent rings are 2–3 times as great as those of the *m*-protons.

The spectrum of *(3)* contains no hyperfine lines corresponding to coupling with the *m*-protons of the 4-phenyl group. It follows from the band-width of 0.88 gauss that the splitting constant must be smaller than 0.7 gauss.

Using the SESRS computer program [18], one can compute theoretical spectra from the coupling constants and the experimental band-widths. In the present case, we assumed 1.75 gauss for five coupling constants and varied the coupling constant a_m of the two *m*-protons in the 4-phenyl group between 0.50 and 0.80 gauss in steps of 0.05 gauss and then between 0.62 and 0.68 gauss in steps of 0.02 gauss. The best agreement between the theoretical and the observed spectra was obtained at $a_m = 0.64$ gauss.



c) Coupling Constants of Protons in the 2- and the 6-Phenyl Groups

Only these are now required for a full elucidation of the ESR spectrum of *(1)*, and they can be estimated from a comparison between the following approximate ranges of the various spectra: 13, 8, 12, 12, and 8 gauss for *(1)–(5)*, respectively [no resolved hyperfine lines appeared for *(4)* and *(5)*]. The decrease in the coupling constants caused by deuteration is correlated as follows with the decrease ΔA in the spectral range:

$$\Delta A = \sum_{i=1}^{n} (1-1/6.514)\,|\,a^{H}{}_i\,| \qquad \text{(II)}$$

where n is the number of hydrogens replaced by deuterium. From the experimental coupling constants given in Fig. 4, the value of ΔA is estimated at 5.5 gauss for the 4-phenyl group, *i.e.* the spectral ranges of *(2)* and and *(5)* should be shorter by 5.5 gauss than those of *(3)* and *(1)* respectively. This is in a fairly good agreement with the observed values (4–5 gauss).

Since the spectral range of *(1)* differs from that of *(3)* and *(4)* only by 1 gauss, the coupling constants of the 2- and the 6-phenyl groups must be considerably smaller than that of the 4-phenyl group. This indeed is to be expected on account of the fact that the steric effect of the oxygen atom must twist these adjacent phenyl groups well out of the central plane.

(6)

[17] See, *e.g.*, *D. C. Reitz*, J. chem. Physics *30*, 1364 (1959); *34*, 701 (1961); *H. Ueda*, J. physic. Chem. *68*, 1304 (1964).

[18] *E. W. Stone* and *A. H. Maki*, J. chem. Physics *38*, 1999 (1963).

Analogously to all known phenyl-substituted radicals [15, 16a, 17], the smallest coupling constant of *(1)* (0.37 gauss) can be assigned to the *m*-protons of the 2- and the 6-phenyl groups. Furthermore, since generally $a_o \approx a_p \approx 2a_m$, we can estimate a value of 0.7–0.8 gauss for the coupling constants of the *o*- and the *p*-protons.

Of all radicals containing a phenyl substituent, phenyl-*p*-benzosemiquinone [15] is best comparable with *(1)*, because the phenyl group is *ortho* to the oxygen. The coupling constants of protons in the phenyl substituent of this radical are as follows: $a_o = a_p = 0.29$ gauss and $a_m = 0.16$ gauss. On account of the similarity between this radical and *(1)* as regards the twisting of the phenyl substituents, one may assume that the *o,p*:*m* ratio of the coupling constants is the same for *(1)* as for this radical. This leads to $a_o = a_p = 0.7$ gauss for the 2- and the 6-phenyl groups in *(1)* (cf. note [d]). The coupling constants thus obtained are mapped in Fig. 4.

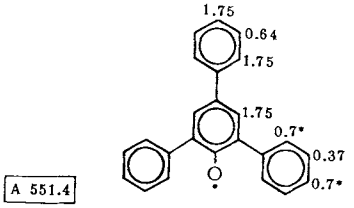


Fig. 4. Proton coupling constants in 2,4,6-triphenylphenoxyl *(1)* Asterisks denote estimated values.

2. Spin Density Distribution on Carbons Carrying Hydrogen Atoms

According to *McConnell* [19], the proton coupling constant a^H is proportional to the spin density ρ_C on the carbon atom to which it is bonded:

$$a^H = Q_{C\text{-}H}{}^H \rho_C \qquad \text{(III)}$$

The value of −27 gauss was adopted for the proportionality constant $Q_{C\text{-}H}{}^H$, because recent investigations had shown it to be better than the previous values of −23 to −24 [7, 20] [e]. As the sign of a^H is difficult to determine, one must generally be content with the magnitude of the spin densities. These are mapped below for the 17 hydrogen-bearing carbons in *(1)*.

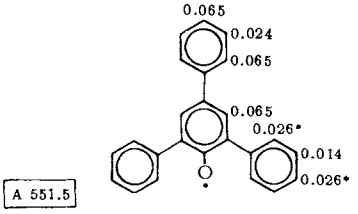

Fig. 5. Spin densities on the hydrogen-bearing carbon atoms in 2,4,6-triphenylphenoxyl *(1)*. Asterisks denote estimated values.

[19] *H. M. McConnell*, J. chem. Physics *24*, 764 (1956).

[20] *L. C. Snyder* and *T. Amos*, J. chem. Physics *42*, 3670 (1965); *K. Möbius*, Z. Naturforsch. *20a*, 1102 (1965).

[e] Furthermore the σ-π parameters of *Das* and *Fraenkel* [7] also involve $Q_{C\text{-}H}{}^H = -27$ gauss. These parameters are used in the calculation of the ^{13}C-coupling constants from the spin densities (see Section 4).

3. Calculation of the Spin Density Distribution by McLachlan's Method

In order to obtain the spin densities on carbon atoms carrying no hydrogens calculations were carried out using *McLachlan*'s SCF–MO method [21]. By taking into account electronic interactions, *McLachlan*'s method leads to spin density distributions that are in better agreement with experiments than are the results of the Hückel MO method [22]. It also gives negative spin densities, which have been clearly observed in experiments [23].

The common value of $\lambda = 1.2$ for *McLachlan*'s parameter was used and the values for the Coulomb integral of the oxygen atom ($\alpha_O = \alpha_C + h\beta_{CC}$), the resonance integral for the C–O bond ($\beta_{CO} = k\beta_{CC}$), and the angle of twist of the 4-phenyl group (φ_4) and the 2- and 6-phenyl groups ($\varphi_{2,6}$) were chosen so as to ensure the best possible agreement between the resulting spin densities on the hydrogen-bearing carbon atoms and the experimental values in Fig. 5. As usual, the effect of twisting was taken into account by using the expression $\beta_{C-C}(\varphi) = \beta_{C-C} \cos\varphi$ to calculate the resonance integrals of bonds between the central ring and the phenyl substituents [22]. In order to avoid arbitrary variation of the parameters and to minimize the computational work (quite considerable if all the parameters are varied simultaneously), the parameters h and k as well as φ_4 were first determined on simpler systems, namely on phenoxyl [13,14] and on 2,6-di-t-butyl-4-phenylphenoxyl [4b,4d].

a) Spin Density Distribution in Phenoxyl

The parameters k and h were varied in steps of 0.1 within the range generally considered [7,24] with radicals containing C–O bonds, *i.e.* $k = 0.8$ to 1.6 and $h = 1.0$ to 2.0. The best agreement with the spin densities obtained from the coupling constants of phenoxyl [13,14] and with $Q_{C\text{-}H}{}^{H} = -27$ gauss was found at $k = 1.6$ and $h = 1.9$ [f]. The spin densities in phenoxyl calculated by various authors are listed in Table 1.

b) Spin Density Distribution in 4-Phenyl-2,6-di-t-butylphenoxyl

In this calculation, the value of k was kept constant at 1.6 and the influence of the t-butyl groups was neglected. The angle of twist φ_4 of the 4-phenyl group was varied between 0 and 50° in steps of 5°, and between 0 and 20° in steps of 2°, whilst the value of h was varied between 1.0 and 1.9.

The use of different h values for phenoxyl and the radical in question is justifiable, since the coupling constants were determined in water for phenoxyl and in benzene for the other radical. The effect of the solvent on the spin distribution of the radicals [30] can be taken into account in the calculations by changing the Coulomb integral of the heteroatom, which reflects the change in the electronegativity caused by the solvation [7,31]. The solvation of 2,4,6-triphenylphenoxyl and 4-phenyl-2,6-di-t-butylphenoxyl may be influenced by the steric effect of the 2- and the 6-substituents.

[g] The spin density distribution obtained with 2,4,6-tris(diphenylmethyl)phenoxyl, which is supposed to be essentially unaffected by substitution of the aroxyl and therefore to hold also for the phenoxy radical, must be viewed with reserve as regards the spin densities on C-1, C-2, and O. The assumption that the bulky diphenylmethyl groups next to the oxygen rotate freely seems as untenable as the assumption that the electron distribution is essentially left unchanged by the replacement of the oxyl oxygen by the azyl group, –N–H. In fact, as we go from benzyl to phenoxyl [14], the change in the electronegativity χ (from 2.5 for C to 3.5 for O) causes an appreciable change in the spin densities on the benzene ring, as a result of which the spin densities on the methylene group and the oxygen will also differ considerably. The spin distribution in the phenylamino radical, $C_6H_5HN\cdot$ ($\chi_N = 3.0$), is expected to lie between that of benzyl and that of phenoxyl. If we assume as a first approximation a linear relationship between electronegativity and spin density on the exocyclic atom, we then find by extrapolation $\rho_O = 0.27$ for the spin density on the oxygen in phenoxyl by the use of $\rho_{CH_2} = 0.61$ and $\rho_N = 0.44$ (with $Q_{N\text{-}H}{}^{H} = 27$gauss).

[30] See, *e.g., J. Gendell, J. H. Freed*, and *G. K. Fraenkel*, J. chem. Physics *37*, 2832 (1962); *E. W. Stone* and *A. H. Maki*, J. Amer. chem. Soc. *87*, 454 (1965).

[31] For example *P. H. Rieger* and *G. K. Fraenkel*, J. chem. Physics *30*, 609 (1963).

The best agreement with the experimental spin densities obtained from the coupling constants [4b,4d] and $Q_{C\text{-}H}{}^{H}$ = −27 gauss (Table 2) was obtained at $\varphi_4 = 0°$ and $h = 1.2$.

c) Spin Density Distribution of 2,4,6-Triphenylphenoxyl

In this calculation, we kept constant $k = 1.6$, $h = 1.2$, and $\varphi_4 = 0$ and varied $\varphi_{2,6}$ between 40 and 70 ° in steps of 10 °, and then between 42 and 48 ° in steps of 2 °. The best agreement with the experimental spin density distribution of the hydrogen-bearing carbon atoms shown in Fig. 5 was obtained at $\varphi_{2,6} = 46°$ (Table 3). The calculations show therefore that, in accordance with expectations, the 2- and the 6-phenyl groups are twisted by the oxygen out of the plane of the central ring much more than is the 4-phenyl group.

4. Use of ^{13}C-Labeled 2,4,6-Triphenylphenoxyl to Check the Calculated Spin Densities

To test the calculated spin densities at the blind atoms (Table 3), we prepared the labeled radicals *(7)* to *(10)* with an enrichment of 55 atom-% of ^{13}C.

The corresponding ESR spectra are shown in Fig. 6.

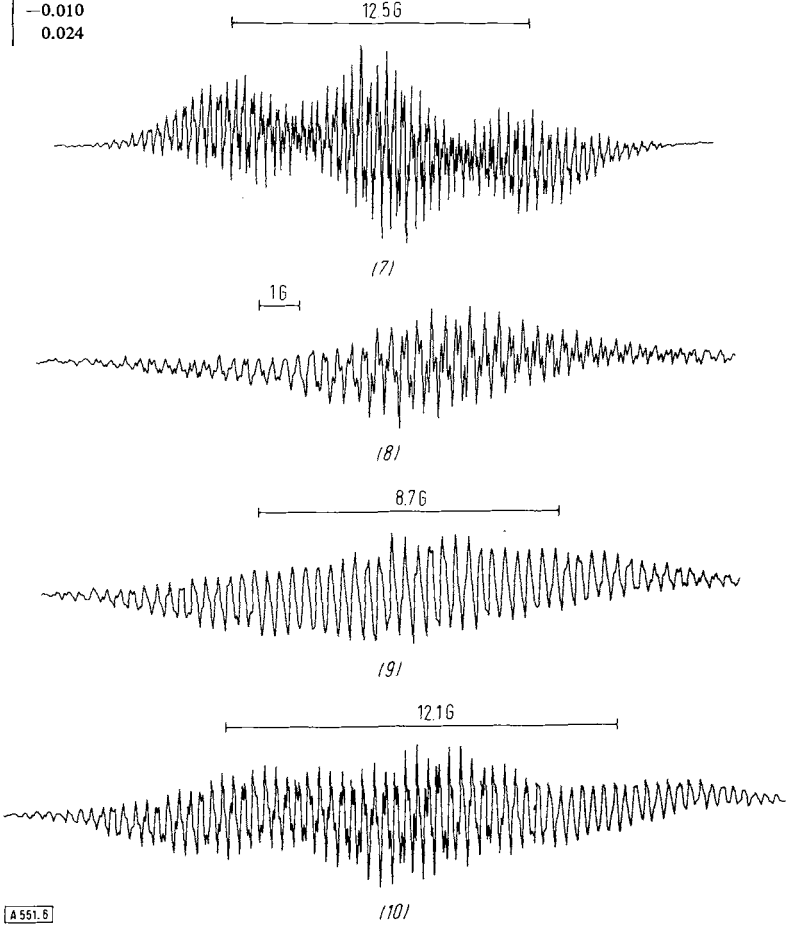

Fig. 6.
The ESR spectra of 2,4,6-triphenylphenoxyls labeled with ^{13}C.

The ^{13}C-coupling constant $a_{^{13}C}$ depends both on the spin density ρ_i of the labeled atom, i, and on the spin densities of all the adjacent atoms ρ_j[32]:

$$a_{^{13}C} = (-12.7 + \sum_{j=1}^{3} Q_{ij})\rho_i + \sum_{j=1}^{3} Q_{ji}\rho_j \qquad \text{(IV)}$$

The following values were used for the $\sigma-\pi$ parameters Q_{ij} and Q_{ji} belonging to the adjacent hydrogen, carbon, and oxygen atoms[7, 32]:

Q_{ij}: $Q_{^{13}C\text{-}H}C = 19.5$; $Q_{^{13}C\text{-}C}C = 14.4$ [h]; $Q_{^{13}C\text{-}O}C = 17.7$

Q_{ji}: $Q_{H\text{-}^{13}C}C = 0$; $Q_{C\text{-}^{13}C}C = -13.9$ [h]; $Q_{O\text{-}^{13}C}C = -27.1$

Using eq. (IV) and the calculated spin densities in Table 3, one can calculate the ^{13}C-coupling constants for the radicals *(7)* to *(10)*. The results are compared in Table 4 with the experimental values.

Table 4. ^{13}C-coupling constants of *(7)* to *(10)*, $a_{^{13}C}$ (in gauss)

Radical	calc. *McLachlan*	($\varphi_4 = 0°$) ρ_3 (exp.) considered	exp	calc. ($\varphi_4 = 30°$) ρ_3 (exp.) considered
(7)	−11.8	—	±12.5	−12.4
(8)	+ 7.0	+7.1	± 4.7 [*]	+ 7.4
(9)	− 7.9	−8.3	± 8.7	− 8.6
(10) [**]	+ 8.5	±8.8	±12.1	+ 9.1

[*] This coupling constant could not be obtained unambigously from the spectra, since the ^{13}C content was not sufficiently high. Therefore, we calculated the theoretical spectrum of *(8)* for various values of the ^{13}C-coupling constant, on the basis of the experimental spectrum of unlabeled 2,4,6-triphenylphenoxyl and a ^{13}C enrichment of 55 atom-%. The best agreement with the experimental spectrum was obtained with the values given here.

[**] *Note added in proof* (Nov. 1st, 1966): By synthesis of 2,6-diphenyl-4-[1−^{13}C]phenylphenoxyl the ^{13}C-coupling constant for the junction of the phenylsubstituted in the 4-position of 2,4,6-triphenylphenoxyl has been determined. It is 6 gauss, to be compared with the value of 5.4 gauss calculated according to *McLachlan*.

In comparison with the results for other ^{13}C-labeled radicals[33–35], there is a good agreement between the experimental and the theoretical ^{13}C-coupling constants of *(7)* and *(9)*, and the agreement is still better when we use $\varphi_4 \neq 0°$. The last column in Table 4 gives ^{13}C-coupling constants derived from spin densities obtained with $\varphi_4 = 30°$. In the case of radical *(8)*, on the other hand, the agreement with the experiment is less good. Such deviations with the radicals *(8)* and *(10)* carrying phenyl substituents on labeled carbon atoms may be due to the unjustifiability of using the specified $\sigma-\pi$ parameters $Q_{^{13}C\text{-}C}C$ and $Q_{C\text{-}^{13}C}C$ for the bond between the central ring and the substituent, caused by the fact that the length of this bond differs from that of aromatic sp^2 C–C bonds[32]. This is supported by the poor agreement between the calculated and the experimental ^{13}C-coupling constants of triphenylmethyl[32] [i] [j] [37a].

The improvement in the agreement in the ^{13}C-coupling constants of *(7)* and *(9)* by increasing φ_4 is accompanied by a deterioration in the agreement between calculated and experimental spin densities at hydrogen-bearing carbon atoms in the 4-phenyl substituent.

5. Spin Density on the Oxygen Atom

On the basis of the general theory of *Karplus* and *Fraenkel*[32], which has been applied to the coupling constants of ^{13}C[7, 33–35], ^{14}N[31, 36], ^{19}F[37b], and ^{17}O[38], we can use eq. (V) to express the correlation between the ^{17}O-coupling constants and the spin density ρ_O on the oxygen in radicals whose oxygen is linked only to one atom:

$$a_{^{17}O} = Q_1\rho_O + Q_2\rho_n \qquad \text{(V)}$$

where ρ_n is the spin density on the atom adjacent to the oxygen.

The parameters Q_1 and Q_2, which may depend on the nature of the neighboring atom, are not known, and the available experimental results are insufficient for their exact determination. However, it seems permissible for the interpretation of the results to assume a direct proportionality between the ^{17}O-coupling constant and the spin density on the oxygen[k]:

$$a_{^{17}O} = Q^O\rho_O \qquad \text{(VI)}$$

On the basis of the following arguments, we propose the value of $Q^O = 40 \pm 4$ gauss:

a) We obtain $\rho_O = 0.26$ from the value of calculated spin density distribution of *(1)* which agrees the best with the experimental H- and ^{13}C-coupling constants. On the basis of this and $a_{^{17}O} = 9.7$ gauss [8], eq. (VI) gives $Q^O = 37$ gauss.

[i] Although the ^{13}C-coupling constant calculated by the VB method agrees well with the experimental value, the corresponding spin densities on hydrogen-bearing carbons differ considerably from observed data.

[j] Neglect of the deviation in the bond length from that in aromatic sp^2 C–C bonds may perhaps also account for the discrepancy between experimental and theoretical coupling constants in the 7,7,8,8-tetracyanoquinodimethane radical anion [35].

[k] A direct proportionality between the ^{14}N-coupling constants and the spin density at the nitrogen has been assumed for some nitrogen radicals [36].

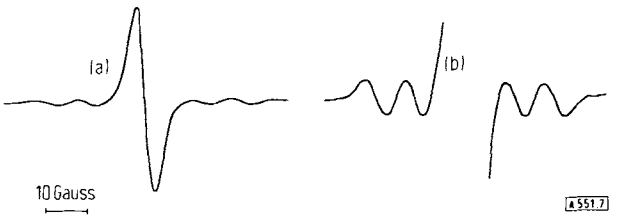

Fig. 7. ESR-Spectrum of ^{17}O-labeled 2,4,6-triphenylphenoxyls. (b) corresponds to (a) enlarged 10 ×.

b) *McLachlan*-type SCF calculations for 2,4,6-tri-t-butylphenoxyl[1] ($a_{^{17}O}$ = 10.23 gauss[39]) have led to ρ_O = 0.261. Substitution in eq. (VI) gives Q^O = 39.2 gauss[39a].

c) The^{14}N- and the^{13}C-spectra of di-t-butylnitroxyl(t-Bu_2NO) recorded in various solvents show that the ^{14}N-coupling constant does not depend on the spin density on the oxygen atom[42]. On the basis of an LCAO calculation[43] and in agreement with results for other radicals[36a–36c], the proportionality constant can be taken as Q_N = 26 gauss. This has given ρ_N = 0.515 for di-s-butylnitroxyl (s-Bu_2NO), the first ^{17}O-labeled organic radical to be described[44]. Therefore, the spin density on the oxygen is ρ_O = 0.485. With an ^{17}O-coupling constant of 19.71 gauss, we obtain Q^O = 40.7 gauss.

Rieger and *Fraenkel*[31] have obtained ρ_O = 0.199 for the oxygen atoms in the nitrobenzene radical anion by adjusting the parameters to the experimental spin densities of the phenyl-ring carbon atoms. The ^{17}O-coupling constants of 8.86 gauss for acetonitrile and 8.84 gauss for dimethylformamide[38] lead to Q^O = 44.5 gauss. However, since these authors used $Q_{C\text{-}H}{}^H$ = −23.7 gauss instead of the more recent value of −27 to −28 gauss, their spin density on the benzene ring is probably too high and that on the nitro group and hence on the oxygen probably too low, in which case the value of Q^O should be less than 44.5 gauss.

The authors thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Adolf-Haeuser-Stiftung for financial support of the present work. Acknowledgment is also due to the Deutsches Rechenzentrum, Darmstadt, for the numerical calculations with an IBM 7090 computer.

[1] The calculations were carried out with k = 1.6 and the usual auxiliary parameter accounting for the inductive effect of the alkyl groups ($\Delta\alpha = -0.3\ \beta_{C-C}$ [40]). To account for the effect of solvation of phenoxyl in water and 2,4,6-tri-t-butylphenoxyl in benzene, the value of h was varied between 1.1 and 1.9 and then between 1.59 and 1.55. The best agreement with the experimental spin concentration in the 3- and 5-positions (0.067) and with the experimental ^{13}C-coupling constant for C-1 (9.6 gauss [41] was obtained at h = 1.56. The spin densities are then as follows: ρ_0 = 0.261, ρ_1 = 0.127, $\rho_{2,6}$ = 0.247, $\rho_{3,5}$ = 0.067, and ρ_4 = 0.253. These values lead to 9.6 gauss for the ^{13}C-coupling constant of C-1.

[39a] *Note added in proof* (Nov. 1st, 1966): Since submission of this paper the σ–π-parameters for C adjacent to the oxygen atom have been determined by *W. M. Gulick* and *D. H. Geske* with [^{17}O]benzosemiquinone [J. Amer. chem. Soc. *88*, 4119 (1966)]. Their values are $Q_1 \equiv Q_{C-O}{}^O$ = −40.41 gauss, $Q_2 \equiv Q_{C-O}{}^O$ = −16.69 gauss. With the spin densities in Table 3 one obtains from equation (1) $a_{^{17}O}$ = −10.8 gauss (exp. ± 9.7 gauss). For 2,4,6-tri-t-butylphenoxyl $a_{^{17}O}$ = −12.7 gauss (exp. = ± 10.23 gauss) is obtained from the calculated spin densities [39].

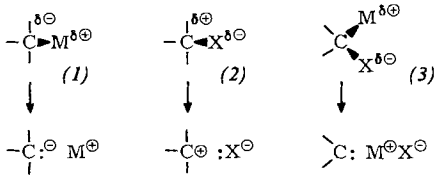
Chemistry of Stable α-Halogenoorganolithium Compounds and the Mechanism of Carbenoid Reactions[1]



BY G. KÖBRICH [*]

IN COLLABORATION WITH A. AKHTAR, F. ANSARI, W. E. BRECKOFF, H. BÜTTNER, W. DRISCHEL, R. H. FISCHER, K. FLORY, H. FRÖHLICH, W. GOYERT, H. HEINEMANN, I. HORNKE, H. R. MERKLE, H. TRAPP, AND W. ZÜNDORF

Some years ago we found that α-halogenoorganolithium compounds (carbenoids) previously postulated as transient intermediates in organolithium-initiated α-eliminations can be obtained in a stable form. The present paper is a review of the methods for their preparation and of their reactivity. They possess both nucleophilic and electrophilic properties, which can be utilized singly or combined for the synthesis of substances of very different types. Their thermolability, which is considerably reduced (with only one known exception) by the solvent tetrahydrofuran, is due to electrophilic secondary reactions, in which carbenes evidently do not occur as intermediates. A mechanism is proposed which fits the experimental data for various carbenoid reactions.

1. Introduction

Carbon is often connected with ligands of lower (*e.g.* the alkali metals M) or higher electronegativity (*e.g.* the halogens X). The result in both cases is a polarization of the bond (though in opposite directions), *i.e.* the bond has ionic character. In one case [formula *(1)*] the carbon assumes a negative charge, which explains its nucleophilic reactivity; in the other [formula *(2)*] it carries a positive charge, and therefore undergoes electrophilic reactions. The extreme is the ionization of the polar bonds with liberation of carbanions or carbonium ions, respectively.

When M and X are attached to the same carbon atom, the polarization of the bonds may be represented as in formula *(3)*; owing to the mutual interaction of M and X, this polarization should be even more pronounced than in *(1)* or *(2)*. Compounds of this type are extremely unstable. When $M^{\oplus}$ and $X^{\ominus}$ are released from the common carbon atom to form MX, this leaves a molecular "residue" with an electron sextet on carbon. This carbene contains both the lone pair that characterizes carbanions and the unoccupied p orbital typical of carbonium ions; it can therefore, in particular, undergo electrophilic reactions.

One need not emphasize the value of this carbene concept[3], developed by *Hine* for the alkali hydrolysis of haloforms, as a heuristic principle in organic chemistry. On the other hand, it can be seen that the formation of a carbene, like that of carbonium ions or carbanions, evidently depends on favorable conditions (*e.g.* solvent and substituent effects). One may therefore ask whether many of the typical electrophilic carbene or "carbenoid"[4] reactions, particularly in the organometallic reactions discussed here, which are always carried out in solvents of low polarity, might not be due to the organometallic species *(3)* instead of to carbenes.

"Amphophilic" or "ambiphilic" (both nucleophilic and electrophilic) behavior would be plausible for the compounds *(3)*, in view of their relationship with the substrates *(1)* and *(2)*. In fact, there is evidence that the free-carbene stage may be by-passed in α-eliminations in ethereal media[4]. In reactions that proceed *via* the same (carbene) intermediate, one would expect the same products to be formed in the same ratios from different substrates and by different reaction paths. However, this is not the case in two typical carbene reactions, *i.e.* addition to olefins[4] and intramolecular insertion in C–H bonds in the γ position[5], both of which give cyclopropanes. Moreover, a number of stable α-halogenoorganyls of zinc[6,7] and aluminum[8]

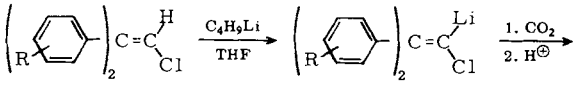
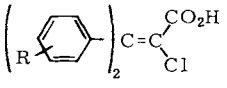
(3) (M = Zn/2 or Al/3) can react with olefins to form cyclopropanes evidently without first undergoing α-elimination. For this reason carbene mechanisms for α-eliminations from organometallic compounds of alkali metals are nowadays generally advanced only with reservations.



The study of the postulated intermediates *(3)*[9] in these reactions, which have been detected indirectly in many cases, should provide more accurate information. Until recently, however, such studies were impossible because of the instability of these compounds.

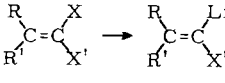
The present paper is a review of our preparative work and of the associated investigations on the reaction behavior of α-halogenoorganolithium compounds *(3)* (M = Li). In anticipation of the subsequent discussion these compounds are termed carbenoids.



2. Preparation

In α-eliminations in ethereal media, use is made of *Wittig*'s observation[10] that the α-hydrogen of many chlorinated hydrocarbons is acidified by the halogen to such an extent that it can be replaced readily by lithium on reaction with organolithium reagents. However, this metalation is generally followed by fast secondary reactions characterized by the elimination of lithium chloride. To avoid these, it would *a priori* be desirable to carry out the metalation at low temperatures and to use substrates whose α-carbon is relatively stable in the anionized state and whose α-halogen is relatively firmly bound. The most favorable conditions are offered by olefinic carbon atoms, which are more electronegative than saturated carbon atoms.

Our experiments based on these considerations, and starting from 1-chloro-2,2-diarylethylenes, led in 1963 to the first, and so far the simplest, method for the preparation of carbenoids[11]. The action of n-butyl-lithium on the substrates *(4)* in tetrahydrofuran at a low temperature gives the stable lithium derivatives *(5)*, as is shown by the formation of the carboxylic acids *(6)*, generally in excellent yields, on subsequent carboxylation.

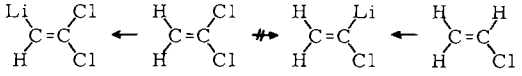


(4) *(5)*

(6)

The reaction can be carried out with numerous olefins having, instead of aryl groups[12], H or Cl, alkyl, or vinyl ligands in one or in both β positions[13–17] (see Table 1). The lower limit of the optimum reaction temperature depends on the rate of metalation and its upper limit on the thermal stability of the resulting carbenoids.

When metalation is slow the lithium may be introduced by halogen-metal interconversion on a geminal dihalide, which, for bromine derivatives, is faster than an H/Li



X, X' = Cl, Br

(7) *(8)*

exchange[10]. In this way one obtains the bromine or chlorine derivative *(8)* from the dibromide *(7)*, X = X' = Br, and chlorobromo derivatives (X = Br, X' = Cl) respectively. A less obvious reaction is the smooth Cl/Li exchange often observed with geminal dichlorides *(7)*, X = X' = Cl, which can be used for the preparation of carbenoids *(5)*[18,19]. The reaction with geminal dichloroolefins is slower than the metalation of the corresponding monochloroolefins.

Thus trichlorovinyl-lithium is formed only at a moderate rate from tetrachloroethylene at –110 °C, whereas the metalation of trichloroethylene proceeds violently under the same conditions. Further, the reaction of 1,1-dichloroethylene with butyl-lithium does not lead to α-chlorovinyl-lithium *(10)*, which can be obtained by metalation of vinyl chloride at –110 °C as a stable compound, but instead of a Cl/Li interconversion, metalation of the β position occurs to give the unstable product *(9)*[20].

(9) *(10)*

On the other hand, the Cl/Li exchange with dichlorides of saturated hydrocarbons can be faster than the metalation. Thus 7,7-dichloronorcarane can be used to prepare the carbenoids *(11)* and *(13)*, which cannot be obtained by metalation of the stereoisomeric 7-chloronorcaranes. This reaction leads to a mixture of stereoisomers, but the ratio of the components, which are characterized as the carboxylic acids *(12)*, m.p. 92 to 92.5 °C, and *(14)*, m.p. 108–108.5 °C, can be controlled by variation of the conditions. The principal product

at −110 °C is *(11)*, since the *exo* chlorine atom is exchanged 3 to 4 times as rapidly, probably on steric grounds. The reaction at −80 °C leads mainly to the isomer *(13)*, because of decomposition and partial isomerization of the less stable *(11)* [21].

[21] *W. Goyert*, Diploma Thesis, Universität Heidelberg, 1966.

As can be seen from Table 1, the methods described can also be used for the preparation of carbenoids with a saturated carbon atom. Thus dichloromethane is completely converted into the stable dichloromethyllithium by the action of butyl-lithium in tetrahydrofuran at −70 °C [22], the less thermostable trichloromethyllithium can be prepared quantitatively in a similar manner from chloroform at temperatures below −100 °C [22]. The same compound can be obtained by halogen-metal interconversion from bromotrichloromethane in ether [23] or from carbon tetrachloride [24, 25].

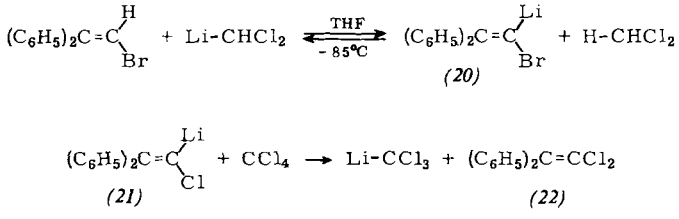
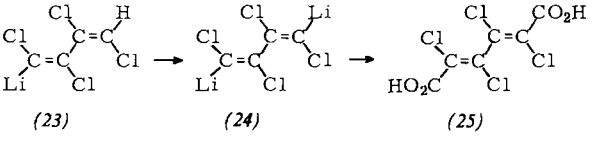
[25] *H. Büttner*, unpublished.



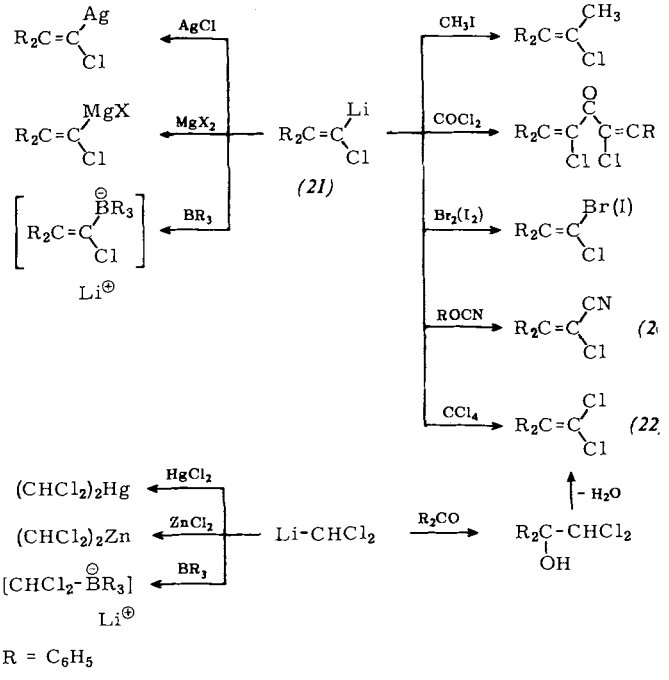
Since the Br/Li exchange is much faster than metalation, the action of organolithium reagents on substrates of the type *(15)* always leads predominantly to the halogen-free compound *(16)* at the expense of the carbenoid *(17)*. However, the observation that the action of *(5)* (R = H) on dibromomethane leads almost exclusively to H/Li exchange [26] forms the basis of a method favoring the metalation *(15)* → *(17)*. This is achieved by the use of carbenoids that are more basic than the

desired compound *(17)* [27]. Thus tribromomethyl-lithium *(18)* can be obtained not only by the reaction of tetrabromomethane with butyl-lithium, but also by transmetalation of bromoform with dichloromethyl-lithium (together with a little dibromomethyl-lithium). Similarly, the reaction of dibromomethane with dichloromethyl-lithium leads to dibromomethyl-lithium *(19)*, which was formerly also unknown, while the Br/Li interconversion between bromoform and butyl-lithium, which might be considered as an alternative route, is preparatively unproductive owing to side reactions [27].



For carbenoids of similar basicities the metalation can be shown to be reversible, and equilibrium mixtures are conceivable. Thus the reaction of dichloromethyl-lithium with 1,1-diphenylbromoethylene in tetrahydrofuran at −85 °C gives about 30 % of the carbenoid *(20)*, which is identified as the carboxylic acid. On the other hand, when *(20)*, prepared by another route, is added to dichloromethane under the same conditions, dichloromethyl-lithium is formed [27].

In principle, carbenoids can also undergo halogen-metal exchange. Thus the action of tetrachloromethane on *(21)* at −85 °C gives the dichloro compound *(22)*, which is isolated in 91 % yield, together with trichloro-methyl-lithium [25]. This smooth reaction reflects the unusual readiness with which the anionized haloform is formed.



The "active" role in the anionization of other substrates is in contrast to the remarkable case in which a carbenoid is itself metalated. The compound *(23)*, which can be prepared from 1,2,3,4-tetrachlorobutadiene and butyl-lithium at −110 °C, reacts with a second mole of butyl-lithium to form *(24)*, which is isolated in high yield as the dicarboxylic acid *(25)*, m.p. 207–208 °C [25].

3. Nucleophilic Reactions

The stable carbenoids prepared by the methods discussed can undergo the nucleophilic reactions of "normal" organolithium compounds.

The formation of carboxylic acids is generally the best method of characterization, since the carboxylation proceeds to completion. A number of other reactions, all of which are probably generally applicable, are indicated in Scheme 1. These include alkylations, acylations, and halogenations [26]. Corresponding to the reaction of phenylmagnesium bromide with esters of cyanic acid [29], *(21)* reacts with naphthyl cyanate to give the nitrile *(26)* [30]. The reaction of dichloromethyl-lithium with diaryl ketones yields alcohols, which can be readily dehydrated to form diaryldichloroethylenes

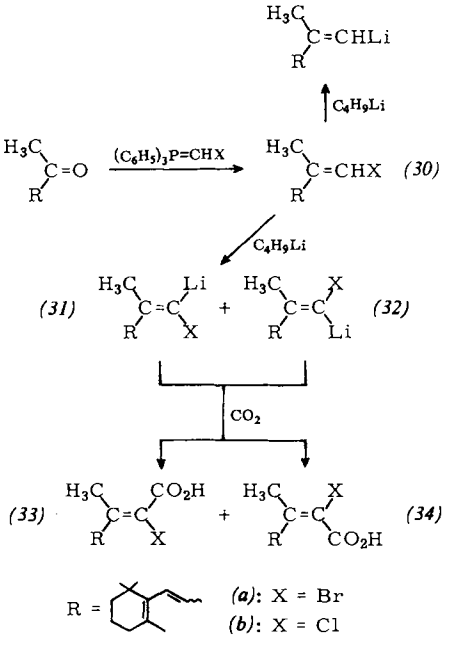
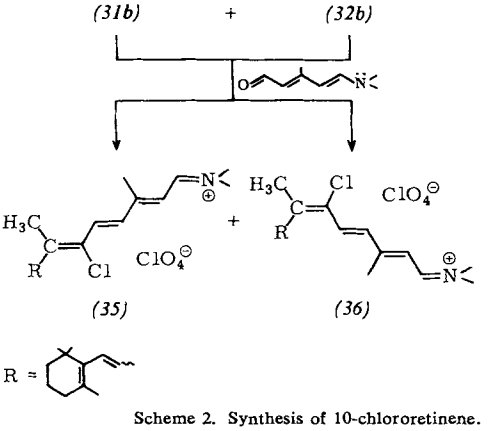
(22) [18,19] providing a convenient route to these compounds.

Special mention should be made of the reaction with derivatives of other metals which yields new α-halogeno-organometallic compounds [18,22,26,31–33]. Because of the well-known metathesis of the alkali metal compounds with salts of less electropositive metals [34], this reaction offers a route to a wide range of compounds having potential carbenoid character, starting from the lithium compounds.

The metal compounds of Scheme 1 are thermally more stable than the corresponding lithium derivatives. Others decompose immediately on formation. For example, *trans*-dichlorovinyl-lithium and iron(III) chloride react stereospecifically, presumably *via* an organo-iron intermediate that decomposes by a radical mechanism, to give the hitherto unknown isomer *(27)* of 1,2,3,4-tetrachlorobutadiene in good yield. This compound, which exhibits strong steric hindrance, dimerizes to 1,2,3,4,5,6,7,8-octachloro-1,3,5,7-octatetraene *(28)*, m.p. 54.5–55.5 °C, on reaction first with butyl-lithium and then with iron(III) chloride.



Longer-chain chloropolyenes of the general structure *(29)* can be synthesized by the same method [25].



The nucleophilic reactions indicated in Scheme 1 are, in principle, typical organometallic reactions. The higher rate of these reactions in tetrahydrofuran (compared to diethyl ether), largely compensate for the very low reaction temperature.

If α-elimination is prevented by the use of sufficiently low temperatures, the stabilizing effect of the α-halogen on the C–Li bond becomes evident, as shown by the following example.

Ionylidenebromomethane *(30a)* and -chloromethane *(30b)* are readily obtainable [16,18] by Wittig halogeno-olefination [35]. When *(30a)* is treated with butyl-lithium in tetrahydrofuran at –95 °C, the principal product should be ionylidenemethyl-lithium, resulting from a Br/Li exchange. Owing to its tendency to polymerize, however, this product cannot be isolated, whereas the α-bromo compounds *(31a)* and *(32a)* formed by metalation can be detected by carboxylation to form *(33a)* and *(34a)* [15]. In the same way, the stereoisomeric α-chloroionylideneacetic acids *(33b)*, m.p. 124 °C, and *(34b)*, m.p. 99–100 °C, can be obtained from the chloro compound *(30b)* in a total yield of 82 % [16].

The stability of these carbenoids provides a basis for a new, simple synthesis of compounds of the vitamin A series [16,36]. The reaction of *(31b)* and *(32b)* with 3-methyl-5-dimethylaminopentadienal [37] followed by the action of perchloric acid gives a 68 % yield of the dimethylimonium perchlorates of all-*trans*- and 9-*cis*-10-chlororetinene *(35)* and *(36)* (Scheme 2), which can be readily converted into other derivatives whose structures have been verified by spectroscopic methods.

Scheme 2. Synthesis of 10-chlororetinene.

4. Solvent Effect and Thermal Stability

Some carbenoids, *e.g.* trichlorovinyl-lithium, α-chlorovinyl-lithium, and the norcarane derivative *(11)*, decompose more or less rapidly in tetrahydrofuran even

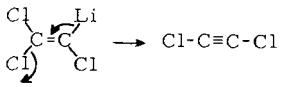
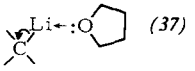
at temperatures below −100 °C. Others, such as dichloromethyl-lithium and 1,2-*trans*-dichlorovinyl-lithium, decompose only at a moderate rate at −30 °C. The most stable carbenoid is fluorenylidenebromomethyl-lithium, which can be detected as the carboxylic acid even at room temperature.

The stability is determined by the nature of the α-halogen, the nature of the α- and possibly β-substituents, and the solvent. No accurate comparative measurements on the influence of the α-halogen have been made. However, chloro derivatives are generally more stable than the corresponding bromo compounds.

Statements about substituent effects are naturally possible and meaningful only if the compounds in question decompose by the same mechanism. This is the case for carbenoids of the type *(5)*; these compounds are increasingly destabilized by electron-donating substituents in the β-aryl groups. On the other hand, the order of stability of the compounds as determined in tetrahydrofuran, *i.e.*:





suggests that in spite of their structural similarity, they decompose by different routes [20] (see below).

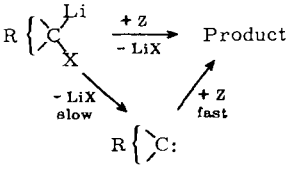
A decisive factor with regard to the easy accessibility of the carbenoids is the use of tetrahydrofuran as the solvent. This substance fulfils two functions. Comparison with diethyl ether shows that tetrahydrofuran enables or accelerates the formation of the carbenoids, and particularly the metalation at low temperature. A more important point, however, is the fact that the carbenoids formed are much more stable in tetrahydrofuran than in ether, as has been shown by direct comparison in numerous cases [15,26,33,38].

The stabilizing influence persists even in admixture with other solvents. Thus dichloromethyl-lithium is stable at −74 °C in pure tetrahydrofuran and in tetrahydrofuran/ether mixtures containing up to 80 vol-% of ether, but cannot be detected in pure ether [33,38]. Consequently, in reactions carried out at temperatures below −100 °C, it is advantageous to use, instead of pure tetrahydrofuran, the "Trapp mixture" of tetrahydrofuran, ether, and light petroleum ether or hexane (4:4:1), which has a low viscosity and still exhibits the favorable influence of tetrahydrofuran.

There is no causal relation between the greater ease of formation of the carbenoids and their greater stability in tetrahydrofuran, so that one does not follow from the other. This is shown by the fact that trichlorovinyl-lithium, which is formed more rapidly in tetrahydrofuran than in ether, also decomposes more rapidly (contrary to the rule) in this solvent [20]. The decomposition mechanism is obviously different from that of the other compounds. The chlorine atoms in the β position and the greater stability of *trans*-dichlorovinyl-lithium point to a *trans*-β-elimination of LiCl [20]

(37)

As in the formation of the carbenoids, the activating influence of tetrahydrofuran on the C–metal bond in organolithium compounds (*e.g.* butyl-lithium) is noticeable [39]. This activation can be explained by the more effective complexing of the lithium atom with the relatively polar tetrahydrofuran, which leads to stronger polarization of the C–Li bond and so strengthens the carbanion character and thereby the nucleophilicity of the molecule [formula *(37)*].



(3)

The nucleophilic character of the carbenoids is, in principle, weaker than that of the other organolithium compounds, owing to the interaction of the C–Li bond with the halogen in the α-position; however, it is also strengthened by tetrahydrofuran, so that if this were the factor determining the stability, the carbenoids should decompose more rapidly. However, the thermal decomposition is due to electrophilic reactions of the carbenoid carbon, as shown in the next section, and the retardation of these reactions by tetrahydrofuran is the reason for the thermal stability of the substrates in this solvent.

5. Electrophilic Reactions

Most of the reactions in which the carbenoid carbon behaves electrophilically are known as secondary reactions of organometallic α-eliminations [9,40], so that the question of primary interest is whether this behavior is due to the carbenoids themselves or perhaps to carbenes formed from them by elimination of lithium halide.

A carbene formed in a preliminary step would react rapidly with a nucleophile Z. The rate of formation of the end product would thus be determined by the slow carbene-formation step, and unlike the rate of a direct reaction of the carbenoid with Z, it should be affected neither by the nature nor by the concentration of the nucleophile Z [eq. (1)].

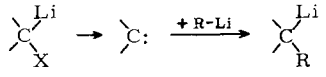
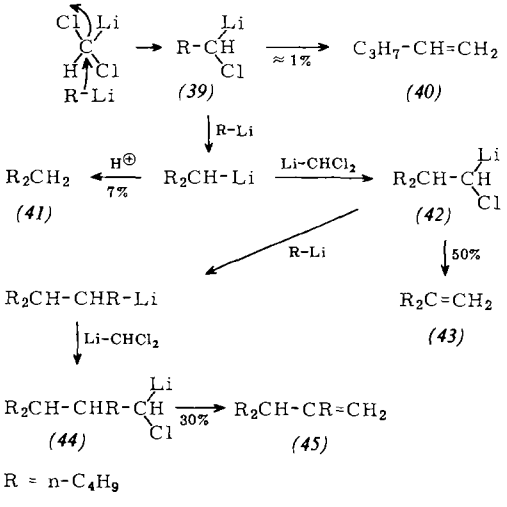
A carbene (and also an intermediate in which the C-halogen bond is merely ionized) has an unoccupied p-orbital, and so has a higher symmetry than the substrate. Consequently, the stereochemistry of suitable carbenoid reactions provides a second criterion of the mechanism.

a) Formation of Dichlorocyclopropanes from Trichloromethyl-lithium and Olefins



This reaction, which has also been studied by two American research groups [23,24], is more complex than was originally thought. The trichloromethyl-lithium produced from bromotrichloromethane in diethyl ether undergoes several secondary reactions even at temperatures below −100 °C. It is therefore difficult to decide whether the formation of 7,7-dichloronorcarane observed under these conditions with cyclohexene [23] is due to a reaction of trichloromethyl-lithium itself or of an initially formed cleavage product [41]. Trichloromethyl-lithium is stable in tetrahydrofuran at −100 °C, but it is also inert towards cyclohexene under these conditions. However, its slow decomposition in this solvent at −72 °C is accelerated by cyclohexene and other olefins. Moreover, the difference between the amount of decomposition with and without cyclohexene roughly corresponds to the yield of 7,7-dichloronorcarane. In view of these results it is probable that trichloromethyl-lithium can react with olefins without first decomposing to dichlorocarbene, and that this cyclopropane formation competes successfully with other reactions of the carbenoid [41].

From the fact that dimethyl-2-butene reacts more rapidly than *cis*- or *trans*-2-butene, each giving only one cyclopropane, it may be concluded that the reaction with the olefin is electrophilic and stereospecific. A cyclic transition state *(38)* offers a plausible interpretation of these observations. It differs from that formulated for the cyclopropane formation from dichlorocarbene in that lithium halide is also present.

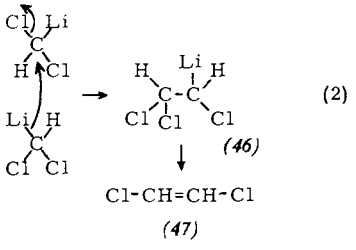


b) Reaction of Dichloromethyl-lithium with n-Butyl-lithium

The α-elimination from halohydrocarbons with organolithium compounds frequently leads to products in which the organic residue of the organolithium is attached to the carbenoid carbon [9]. This type of reaction leads *e.g.* to the formation of trityl-lithium from chloroform and excess of phenyl-lithium [10] or to 1-pentene from dichloromethane and butyl-lithium [42]. It was originally formulated as a direct substitution of halogen in the metalated halogenohydrocarbon [10], but after development of the carbene concept it was regarded as an insertion of the initially formed carbene in the C–Li bond of the organometallic compound.

We found [33] that dichloromethyl-lithium enters into a smooth multistep reaction with n-butyl-lithium in tetrahydrofuran at −74 °C to give the hydrocarbons *(40)*, *(41)*, *(43)*, and *(45)*. According to Scheme 3, the first step is the replacement of a halogen by butyl to form α-chloropentyl-lithium *(39)*. This reaction takes place under conditions in which dichloromethyl-lithium is thermally stable, and so does not proceed *via* chlorocarbene. The second halogen in the intermediate *(39)* is also preferentially replaced by butyl in a fast reaction; elimination of LiCl and hydrogen shift with formation of 1-pentene *(40)*, which is the principal reaction path in ether [42], is almost completely suppressed in tetrahydrofuran. This can be explained by the lower electrophilicity of *(39)* and the greater nucleophilicity of butyllithium in tetrahydrofuran. It is only in the higher condensation products *(42)* and *(44)* that the hydrogen, owing to its position on a tertiary carbon atom, is sufficiently mobile to be able to compete successfully with the intermolecular chloride substitution.

Scheme 3. Course of the reaction of dichloromethyllithium with n-butyl-lithium.



c) Dimerizing α-Elimination

The formation of carbene dimers is well known from a variety of carbene or carbenoid reactions, and is also observed during the thermal decomposition of several carbenoids in tetrahydrofuran. For example, dichloromethyl-lithium gives 1,2-dichloroethylene (which then

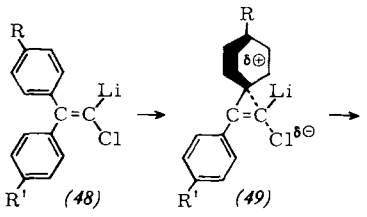
[41] *G. Köbrich, K. Flory*, and *R. H. Fischer*, Chem. Ber. *99*, 1793 (1966); *G. Köbrich, K. Flory*, and *H. R. Merkle*, Tetrahedron Letters *1965*, 973.

[42] *G. L. Closs* and *L. E. Closs*, J. Amer. chem. Soc. *81*, 4996 (1959); *84*, 809 (1962).

reacts further)[33]. Possibly chlorocarbene is formed and inserted in the C–Li bond of a second molecule of dichloromethyl-lithium (the dimerization of two carbenes need not be considered). According to eq. (1), this reaction should be of the first order. However, dichloromethyl-lithium decomposes with a shorter half-life at higher concentrations than in dilute solution. Thus the dimerizing α-elimination is better considered as a kind of Wurtz-Fittig reaction in which one carbenoid molecule acts as nucleophile, the other as electrophile, followed by a rapid β-elimination of lithium halide[33].

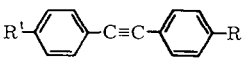
(2)

(46)



(47)

As expected, the replacement of α-halogen in the carbenoid by the more reactive butyl-lithium takes place at lower temperatures than the dimerizing α-elimination, in which the less nucleophilic carbenoid assumes the role of the nucleophile.

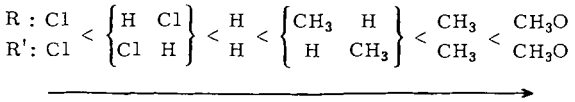


d) Fritsch-Buttenberg-Wiechell Rearrangement

The Fritsch-Buttenberg-Wiechell rearrangement is generally observed during the action of bases on diarylhalogenoethylenes, and involves α-elimination of hydrogen halide and migration of an aryl group to give diarylacetylenes[40]. It was recognized by its discoverer as a sextet rearrangement. However, experiments with labeled *cis-trans*-isomeric starting compounds (as shown in Scheme 4 for another case) have shown that both in alcohols and in ether, migration of the aryl group *trans* to the vinyl halogen to the neighboring carbon atom always predominates[43,44]. This rules out the carbene as a common intermediate, and indicates that the migration of the aryl group and the elimination of halogen takes place simultaneously. On the basis of the analogy to the isoelectronic Beckmann rearrangement, *Bothner-By*[43] postulated that the aryl group undergoes electrophilic attack by the α-carbon atom, so that a transition state *(49)* should occur [eq. (3)]. Thus the rearrangement was the first case in which a distinction was made between a carbene and (in current terminology) a carbenoid mechanism and the latter accepted as correct.

This view has been confirmed by the study of the stable carbenoids *(48)* (R = R')[45]. On thermolysis, these compounds are quantitatively converted into diarylacetylenes *(50)*, the ease of this conversion increasing in

(48) *(49)*



(3)

(50)

the order Cl < H < CH_3 < CH_3O; this corresponds to the order of stabilization of the partial positive charge on the migrating aryl group in the transition state by these groups. The importance of steric factors can be seen from the acceleration of the rearrangement when the *p*-substituent is (formally) moved to the *o*-position.

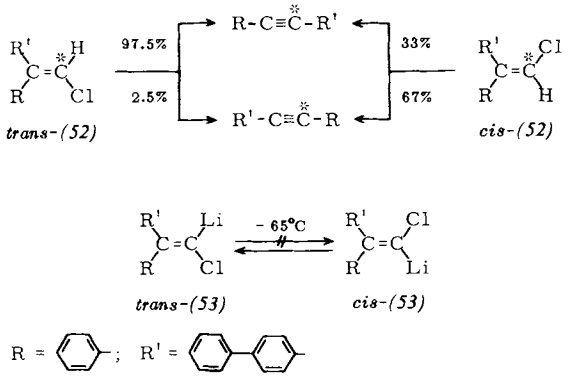
Surprisingly, the substituent in the stationary aryl group in eq. (3) has approximately the same effect, from the point of view of both direction and magnitude, as that in the migrating group. Thus the ease of rearrangement of a compound in which only one aryl group carries a substituent is intermediate between that of the unsubstituted compound and that of the compound with two substituents of the type in question, and differs only slightly for the two possible pairs of isomers[19]; schematically:

Increasing tendency of *(48)* to rearrange

Thus the greater ease of removal of the α-halogen [formula *(51)*] expected when the stationary aryl Ar' group contains electron-donating substituents is also of

(51)

decisive importance to the rate of rearrangement. Control experiments show that this substituent effect is not due to a rapid *cis-trans* isomerization of the carbenoids.

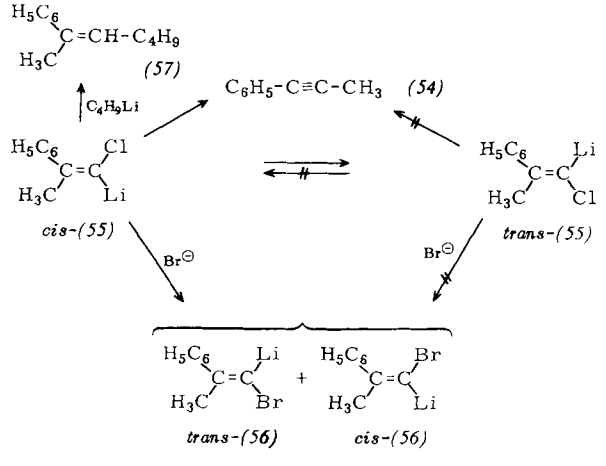


In other cases isomerization of carbenoids is observed, particularly with longer reaction times. This is surprising, since vinyl-lithium compounds without α-halogen are configuratively stable. For example, on slow thermolysis of the carbenoids *(53)* obtained from the two isomeric α-^{14}C-labeled chloroolefins *(52)*, the distribution of radioactivity between the two carbon atoms of the resulting acetylene shows that in the case of *trans-(52)*, the migrating group is almost exclusively the biphenylyl group; in *cis-(52)*, both aryl residues migrate in the statistical ratio of 2:1, the *trans* group (phenyl) again having the advantage. It has been shown that under the experimental conditions, *cis-(53)* is irreversibly converted into *trans-(53)*. The ratio of the rates of the Fritsch-Buttenberg-Wiechell rearrangement and the

[43] *A. A. Bothner-By*, J. Amer. chem. Soc. *77*, 3293 (1955).

[44] *D.Y.Curtin, E.W. Flynn*, and *R. F. Nystrom*, J. Amer. chem. Soc. *80*, 4599 (1958).

[45] *G. Köbrich* and *H.Trapp*, Chem. Ber. *99*, 680 (1966).

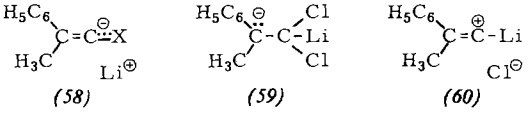


isomerization is approximately 2:1. It must therefore be concluded that the rearrangement step for both carbenoids *(53)* is highly stereoselective or even stereospecific, and that the apparent non-stereospecificity is due to a previous *cis-trans* rearrangement [19].

Scheme 4. Stereochemistry of the rearrangement of labeled chloroolefins.

e) Isomerization and Halogen/Halogen Exchange

Additional information on the stereochemistry of the Fritsch-Buttenberg-Wiechell rearrangement and its relationship with other carbenoid reactions is provided by a study of the two isomeric carbenoids *(55)*, which are obtained quantitatively [17] by metalation of the chloroolefins at −110 °C [46]. At −85 °C, the less stable *cis* compound decomposes slowly with formation of phenylmethylacetylene *(54)*; rearrangement to *trans-(55)* occurs simultaneously. The presence of lithium bromide during this reaction leads by halogen exchange to the formation of both isomers of the bromine compound *(56)*; the coupling product *(57)* is also obtained with butyl-lithium (after hydrolysis).



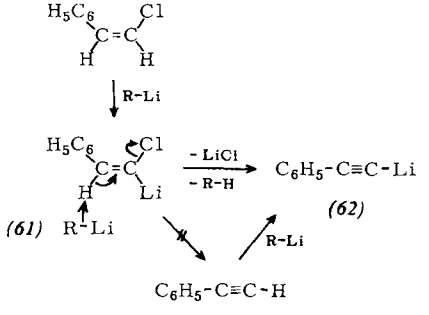
Scheme 5. Carbenoid reactions of *(55)* at −85 °C.

Since migration of a methyl group does not occur under these conditions (see below), and since *trans-(55)* is practically inert at −85 °C, *(54)* must have been formed from *cis-(55)* by *cis*-phenyl migration.

[46] The steric assignment of the substrates is confirmed by UV and NMR spectra.

The activation energy of the "*trans*-migration" that predominates in the β,β-diaryl compounds *(53)* evidently differs only slightly from that of the "*cis*-migration", which was first observed with *cis-(55)*; obviously, even small additional factors can lead to another mechanism. The greater ease of decomposition of *cis-(55)* may be due to a steric effect. It is conceivable that the interaction of the bulkier phenyl group with the chlorine atom facilitates the release of the halogen.

In the isomerization *cis-(55)* → *trans-(55)*, possible intermediates such as *(58)* and *(59)* are shown to be unlikely by solvent and substituent effects. On the other hand, a common intermediate with an ionized C–halogen bond could be responsible both for the isomerization

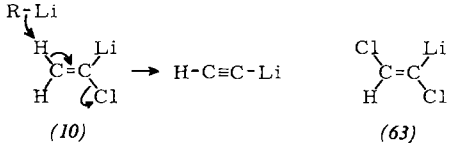


and for the other reactions in Scheme 5. However, this suggestion conflicts with the fact that no products resulting from interception by olefins or tetrahydrofuran can be detected (see below). Moreover, we have seen that isomerization is possible also in the carbenoid *cis-(53)*, in which an intermediate with an unoccupied p orbital, corresponding to *(60)*, is impossible on grounds of symmetry, owing to the stereospecificity of the Fritsch-Buttenberg-Wiechell rearrangement.

f) E2cb Mechanism

Schlosser's investigation of the organolithium-induced elimination of hydrogen chloride from *cis-* and *trans-*styryl chloride provided evidence for a previously unknown type of elimination, which would be described in *Ingold*'s system as an E2cb mechanism [47,48].

Fast metalation of styryl chloride at the chlorinated vinyl carbon atom occurs at the expense of a "classical" β-elimination, as can be shown by kinetic experiments at 0 °C in ether and by the synthesis of the metalated compounds [*e.g. (61)*] in tetrahydrofuran at lower temperatures. However, the decomposition of *(61)* to lithium acetylide *(62)* does not proceed *via* phenylacetylene (with elimination of lithium chloride and hydride shift), as might be assumed by analogy with the



[47] *M. Schlosser* and *V. Ladenberger*, Tetrahedron Letters *1964*, 1945.

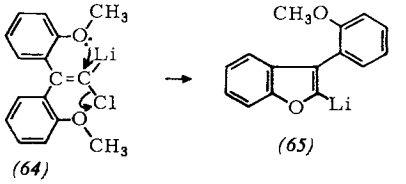
[48] *M. Schlosser*, Habilitation Thesis, Universität Heidelberg 1966.

Fritsch-Buttenberg-Wiechell rearrangement or with the H shift that can take place in aliphatic compounds [*e.g.* as in *(42)* → *(43)*]. Instead, the attack of the organolithium base on *(61)* initiates a β-elimination of HCl, which leads directly to the final product.

In the thermal decomposition of *(61)* at −110 °C, a second molecule of *(61)* assumes the function of the base R−Li. Added butyl-lithium or phenyl-lithium accelerate the formation of *(62)*, since these stronger bases can attack the hydrogen of *(61)* more readily. The slower elimination of DCl from the deuterated substrate *(61)* (with D instead of H) also indicates that the rate-determining step is the rupture of the C−H bond.

The fact that *trans*-β-elimination from *trans-(61)* occurs more readily than the *cis*-elimination from the *cis* isomer also explains the greater ease of decomposition of α-chlorovinyl-lithium *(10)* (which is further increased by the presence of butyl-lithium) in comparison with *trans*-dichlorovinyllithium *(63)* (cf. Section 4)[13,20]. Thus, though *(63)* contains a more acidic hydrogen, it does not offer the possibility of *trans*-elimination of HCl.

(10) *(63)*



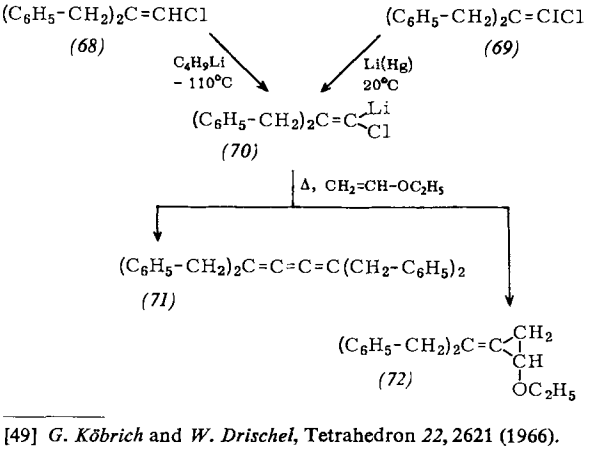
As in the other reactions discussed here, a pair of electrons is supplied to the carbenoid carbon in the step *(61)* → *(62)*, with formation of a new C−C bond and elimination of halogen.

g) Competition Phenomena

Some of the carbenoid reactions described are extremely selective, and in particular those in which the formally underlying carbene is only slightly stabilized by electron-donating substituents, *i.e.* in which the selectivity should be particularly low if the carbene actually occurred as an intermediate. Thus, in the decomposition of *(10)* to lithium acetylide in the presence of an excess of methyl-lithium, no replacement of the α-chlorine atom by methyl [corresponding *e.g.* to the formation of *(57)* from *cis-(55)*] is observed[20]. The thermal decomposition of dichloromethyl-lithium in tetrahydrofuran to 1,2-dichloroethylene (see Section 5c) is so strongly favored that no cyclopropane is formed with added olefins (which are only weakly basic in comparison to organolithium compounds). The reaction of dichloromethyl-lithium with the more nucleophilic butyl-lithium, on the other hand, takes place at −74 °C, and no dimerizing α-elimination occurs. The α-chloropentyl-lithium formed in this reaction (Scheme 3) also reacts selectively with further butyl-lithium; neither the possible reaction with dichloromethyl-lithium nor the intramolecular hydride shift takes place to any appreciable extent[33].

Conversely, reactions in which a relatively "stable" carbene might be expected are surprisingly unselective. Thus in the thermal decomposition of trichloromethyl-lithium or of the norcarane derivatives *(11)* and *(13)*, one observes the dimerizing α-elimination, reaction with olefins and with butyl-lithium, and insertion in the α-C−H bond of the solvent tetrahydrofuran[21,41].

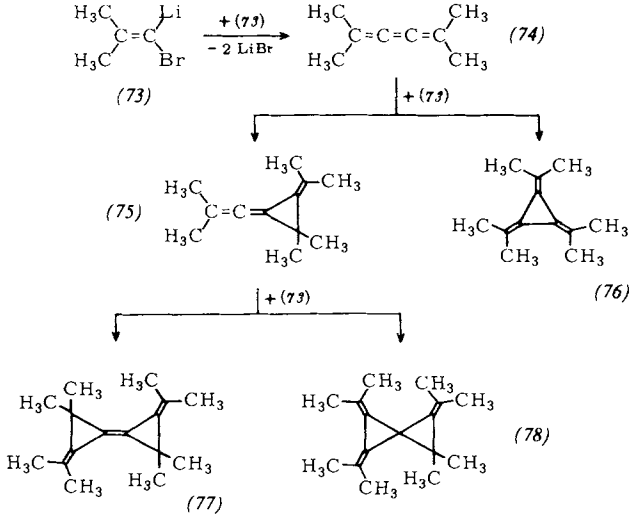
The thermolysis of the carbenoids *(48)* to diarylacetylenes is accompanied by a side reaction only in the case of the methoxy derivative *(64)*; the steric position of the ether oxygen is such that it can replace the α-halogen at −70 °C, as can be deduced from the lithium compound *(65)*, characterized as the corresponding



(64) *(65)*

carboxylic acid[45]. Competing intermolecular reactions, such as the dimerizing α-elimination or the reaction with added olefins, do not occur.

On the other hand, the thermal decomposition of the α-chloro silver compounds leads not only to diarylacetylenes, but also to tetraarylbutatrienes [about 30 % of *(67)* from *(66)*][32]. Dimerization actually becomes the main reaction with carbenoids in which the β-positions are occupied by alkyl groups, which cannot rearrange under these conditions. This fact can be utilized for the preparation of tetraalkylcumulenes, which were formerly difficult to obtain.

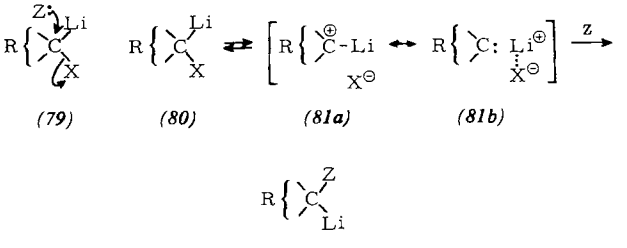


$$(C_6H_5)_2C{=}CAgCl \quad (66)$$
$$\longrightarrow C_6H_5{-}C{\equiv}C{-}C_6H_5 + (C_6H_5)_2C{=}C{=}C{=}C(C_6H_5)_2$$
$$(67)$$

Thus the thermolysis of the carbenoid *(70)*, obtained from *(68)* at −110 °C, leads to tetrabenzylbutatriene *(71)* in good yield. The cyclopropane derivative *(72)* is formed to only a small extent (about 15 %) even in the presence of a 30-fold excess of ethyl vinyl ether. If the carbenoid is produced from the dihalide *(69)* with lithium amalgam at room temperature, the reaction in ether again yields *(71)*, but the reaction in ethyl vinyl ether leads predominantly to *(72)*. Thus in this case the reaction can be made to proceed in one direction or the other by a suitable choice of conditions[22,49].

[49] *G. Köbrich* and *W. Drischel*, Tetrahedron *22*, 2621 (1966).

In the decomposition of the more reactive carbenoid *(73)*, even the initially formed cumulene *(74)* can act as an olefin with *(73)* if the latter is produced under conditions such that it is sufficiently reactive. Of the resulting oligomers *(75)–(78)* of "isopropylidenecarbene", triisopropylidenecyclopropane *(76)* is particularly interesting as the first and very stable [3]-radialene [50].



h) Mechanism

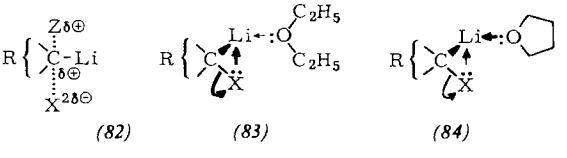
All the results indicate that no carbene intermediates are formed in the reactions discussed. Two extreme cases are conceivable for the substitution of the α-halogen in a carbenoid by a nucleophile Z:

1. The reaction proceeds by a synchronous mechanism as in "normal" S_N2 reactions [formula *(79)*].

2. Compound *(80)* first undergoes a fast, reversible reaction to give an intermediate [*(81a)*, *(81b)*], which then reacts with the nucleophile Z. This two-step process would be formally comparable with "normal" S_N1 reactions *via* carbonium ions.

Formulae *(81a)* and *(81b)* differ only in the bonding between the lithium and the carbon. They are best regarded as canonical structures of a single species. The intermediate *(81)* differs from the substrate *(80)* in that the C–halogen bond is ionized, and from a carbene in the inclusion of lithium halide in the same solvent cage. Structure *(81)* seems to be a logical formulation for the "carbene complex" sometimes discussed in the literature [51].

(79) *(80)* *(81a)* *(81b)*



However, neither of the two extremes [*(79)* and *(81)*] can explain all the experimental results. The contradiction is that in substrates in which a build-up of negative charge occurs on the carbenoid reaction center owing to electron-donating substituents, the approach of the nucleophile Z should be difficult and reactions of the S_N2 type should therefore be hindered. On the other hand, the stability of the intermediate *(81)* in a carbenoid reaction of S_N1 type, and hence also its selectivity in secondary reactions, should increase with increasing compensation of the positive charge by electron-donating substituents. Neither of these expectations is confirmed by experiment. Further, in the Fritsch-Buttenberg-Wiechell rearrangement, in which the substituent effects point to the S_N1 type, the intermediate *(81)* can be ruled out on stereochemical grounds.

This leads us to assume that the carbenoid reactions discussed take place somewhere between the extremes indicated by the formulae *(79)* and *(81)*; this assumption is readily compatible with the experimental results:

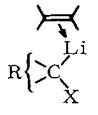
In the reaction of a carbenoid with a nucleophile Z, the rupture of the C–halogen bond is faster than the formation of the bond between C and Z. Thus in the transition state *(82)*, the carbon carries a partial positive charge (if we assume for the moment that partial negative charge due to the lithium atom is constant). The later the energy-supplying bond between C and Z is formed, *i.e.* the weaker the nucleophilic character of Z, the greater will be the positive charge, and hence the energy of the transition state.

If there are no electron-donating substituents available to stabilize the partial charge on the carbon, the nucleophilicity of Z becomes the dominant factor. Thus the reaction with a strong nucleophile Z (*e.g.* butyllithium), which approaches the S_N2 extreme, is possible under conditions such that the reaction with a weaker nucleophile, which involves a higher positive charge on the carbenoid carbon (*e.g.* the insertion in the α-C–H bond of tetrahydrofuran or the formation of cyclopropanes with olefins), does not yet take place. These reactions are therefore very selective.

With increasing stabilization of the positive charge on the carbenoid carbon by (inductively or mesomerically) electron-donating substituents R (and possibly also by their steric interaction with the α-halogen), the release of the halogen becomes easier and the energy requirement of the transition state *(82)* is reduced. Carbenoid reactions, even with weaker nucleophiles, are then possible under relatively mild conditions. The reaction then approaches the S_N1 extreme, for which the selectivity should be lower, since the nucleophilic strength of Z is

(82) *(83)* *(84)*

[50] *G. Köbrich* and *H. Heinemann*, Angew.Chem.77, 590 (1965); Angew. Chem. internat. Edit. *4*, 594 (1965); *G. Köbrich, H. Heinemann*, and *W. Zündorf*, Tetrahedron, in press.



[51] The dissociation of one of the two ligands, lithium or halogen, can probably be ruled out in view of the low polarity of the solvent.

less important in this case. This type probably includes in particular the reactions of those carbenoids which can insert in the α-C–H bond of tetrahydrofuran, such as trichloromethyl-lithium and the norcarane derivatives *(11)* and *(13)*.

So far we have ascribed only a minor role (which is certainly inadmissible) to the C–Li bond. It was assumed as early as 26 years ago that the high polarity of this bond (*i.e.* the carbanion character of the carbenoid carbon) is responsible for the easy release of the α-halogen [10]. An increase in the s character of the metal-bonding electron pair evidently leads to an increase in the p character of the halogen-bonding orbital.

It may be assumed that the metal-bonding electron pair already interacts with the subsequent bond partner in the transition state of the cyclopropane formation from olefins (and possibly also in the Fritsch-Buttenberg-Wiechell rearrangement). A more important and more general role is evidently assumed by the lithium atom itself. Owing to its (potential) cationic and hence Lewis-acid character, it interacts with the lone pairs of the α-halogen and so withdraws the halogen from the carbenoid carbon. Thus the push provided by Z is supplemented by the pull of the lithium. The pull effect decreases when the Lewis-acid character of the lithium atom is reduced by solvation with a more polar medium [formulae *(83)* and *(84)*]. This explains why the thermal stability of carbenoids is greater in tetrahydrofuran than in the less polar ether [38,41]. The smooth formation of cyclopropanes from olefins in non-polar solvents [9] also agrees with this view. The strong pull of the lithium atom on the α-halogen provides the high positive charge on the carbenoid carbon required for the attack of the weakly nucleophilic olefin.

Presumably, nucleophilic substances such as olefins [c.f. (85)] are first attached to the lithium atom before

(85)

reacting with the carbon atom of the carbenoid. The displacement of a solvent molecule thus entailed is no doubt more difficult in the case of tetrahydrofuran than for less powerful solvating media. This is a further possible reason for the apparent reluctance of carbenoid reactions to take place in tetrahydrofuran. It is by no means the sole reason, as can be seen from the fact that the intramolecular Fritsch-Buttenberg-Wiechell rearrangement is subject to the same solvent effects.

6. Future Prospects

It appears that the synthesis of stable carbenoids offers attractive possibilities for preparative organic chemistry and makes available new methods for the study of reaction mechanisms. However, it would be wrong to consider the class of compounds described here in isolation. It is to be expected, and has been proved in several cases, that analogous chemical behavior will be found with substrates *(3)* containing metals other than lithium and leaving groups other than halogen. For example, the α-halogenoorganozinc compounds [*(3)*, M = Zn/2], which have been extensively studied, can enter into typical carbenoid reactions such as cyclopropane formation with olefins (Simmons-Smith reaction), dimerizing α-elimination, and intramolecular C–H insertion [6,7]. However, in view of the differences in valence and bonding, the relative importance of the various factors discussed can scarcely be expected to be the same as for the lithium compounds.

Many other metal derivatives are obtainable directly [52] and now also indirectly. Thus paths are indicated for the further development of this field.

Our investigations were supported generously by the Deutsche Forschungsgemeinschaft, the Wirtschaftsministerium des Landes Baden-Württemberg, the Fonds der Chemischen Industrie, and the Bundesministerium für Wissenschaftliche Forschung.

Trifluorophosphine Complexes of Transition Metals[**]

BY TH. KRUCK[*]

The present paper deals with a new class of inorganic coordination compounds, the first member of which, tetrakis(trifluorophosphine)nickel(0), was discovered in 1951. Not only have the neutral metal(0) trifluorophosphines been prepared, but also a number of their derivatives (trifluorophosphinemetal hydrides and trifluorophosphinemetallates, as well as nitrosyl, carbonyl, halogeno, and aromatic trifluorophosphine complexes). These compounds have been characterized by their chemical behavior and by spectroscopic and magnetochemical studies. Trifluorophosphine has the strongest π-acceptor properties of all neutral ligands, and is therefore particularly suitable for the stabilization of unusually low oxidation states (zero and negative) of transition metals.

I. Introduction and Statement of Problem

Until about 1951, the metal carbonyls occupied a special place in coordination chemistry by virtue of their stoichiometric composition and their physical and chemical properties. The discovery of ferrocene, however, then led to a rapid development of organometallic chemistry, in which other unsaturated carbon compounds displaced carbon monoxide from its special position. It is well known that aromatic compounds and olefins, as well as isonitriles and acetylenide and cyanide ions, can stabilize the oxidation state zero in transition metal compounds.

It was recognized that an important condition for the stability of complexes M^0L_n is the possibility of formation of double bonds between the central transition metal atom M and the ligand L. However, it appeared unlikely that this ability should be confined to unsaturated carbon compounds, as was shown *inter alia* by the existence of nitrosyl[1] and bipyridyl complexes[3] and of carbonyl derivatives containing organo-substituted or chloro-substituted ligands of trivalent phosphorus and its homologues[2]. No purely inorganic ligand had been found that, like carbon monoxide, forms a system of homogeneous inner-orbital complexes with a large number of transition metals in the oxidation state zero.

The insight gained, mainly in the last two decades, into bonding, *e.g.* in metal carbonyls, indicated that a neutral inorganic molecule would have to satisfy the following further requirements if it were to be capable of stabilizing the lowest oxidation states of transition metals:

a) The molecule L must possess a lone pair in order to form a coordinate L→M σ bond (donor function);

b) the molecule must also have available unoccupied π orbitals of suitable energy and symmetry to accept the electronic back-donation (M→L), which relieves the metal of the negative charge placed on it by the σ bond (acceptor function); and

c) its steric structure must favor the establishment of a coordination number *n* that satisfies the "inert gas rule".

The question immediately arises of the extent to which the simultaneous donor and acceptor properties of a ligand affect its ability to form complexes. One extreme, that of pure donor ligands (*e.g.* amines NR_3), has been extensively studied. Tertiary amines are particularly suitable for complex formation with transition metals in medium positive oxidation states. Carbon monoxide, the donor and acceptor properties of which are almost equal, forms homogeneous coordination compounds with metals in the (formal) oxidation states +1, 0, −1, and −2, but the complexes with the oxidation states −1 and −2 in particular, *i.e.* the carbonylmetallates, are extremely sensitive to oxidation. Even of the metal carbonyls and the metal carbonyl cations, only a few are stable to about 150 °C. On the other hand, ligands whose bonding to the transition metal depends mainly on their acceptor properties have not so far been considered.

In view of the requirements a) to c), the most electronegative carrier of a lone pair of electrons is trivalent phosphorus. Not only are the donor properties of this atom most effectively weakened by fluorine, but the acceptor properties of its 3d orbitals are also most strongly enhanced. Thus trifluorophosphine, as a typical π acceptor, should stabilize the lowest oxidation states (zero and negative) of transition elements to a greater extent than any of the usual ligands; on the other hand, the preparation of homogeneous cationic trifluorophosphine complexes seems problematical.

These arguments were supported by the existence of tetrakis(trifluorophosphine)nickel, $Ni(PF_3)_4$, which is more stable than the analogous tetracarbonylnickel[4]. For the past three years, therefore, we have been studying the ability of trifluorophosphine to form complexes with numerous transition metals. These investigations, which have led to the discovery of a new class of coordi-

nation compounds, have already shown that this molecule fulfils our highest expectations. The metal compounds of trifluorophosphine that are known at present are therefore reviewed in this article.

II. General Remarks

Trifluorophosphine has a trigonal-pyramidal structure (P–F distance = 1.535 Å), and the F–P–F angle is 104 ° [5], *i.e.* almost tetrahedral, owing to a high component of sp^3 hybridization. PF_3 is a poisonous gas, which burns in air in the presence of nitric oxide as a catalyst [7]. Like carbon monoxide, PF_3 forms a complex with the hemoglobin of human blood [6], but this complex is destroyed by hydrolysis within a few minutes. Some of the most important properties of trifluorophosphine are compared with those of carbon monoxide in Table 1.

Table 1. Properties of trifluorophosphine and carbon monoxide.

	PF_3	CO
Color	colorless	colorless
Odor	odorless	odorless
Melting point (°C)	−151.5	−199
Boiling point (°C)	−101.8	−191.5
Critical temperature (°C)	− 2.1	−140.2
Critical pressure (atm)	42.7	34.5
ΔH (kcal/mole)	− 71 (OPF_3)	− 67.6 (CO_2)
Dipole moment (D)	1.025	0.10
Flame color	yellowish	blue

The expansion of the preparative chemistry of trifluorophosphinemetals was made possible only by the development of a special high-pressure technique [14]. Since large quantities of pure trifluorophosphine were required, an economical laboratory preparation of PF_3 was developed at the same time [8]. This method is based on the fluorination of phosphorus trichloride with zinc fluoride [9]:

$$2\ PCl_3 + 3\ ZnF_2 \rightarrow 2\ PF_3 + 3\ ZnCl_2$$

The preparation is carried out in a modified Kipp's apparatus connected to washing and drying apparatus, and permits the generation of 150 to 200 ml of pure liquid trifluorophosphine per day with a single charge of reactants and without supervision

Trifluorophosphine can also be prepared by fluorination of PCl_3 with AsF_3 [10], HF [11], or benzoyl fluoride [12], by cleavage of $P(OC_6H_5)_3$ with benzoyl fluoride [12a], and by the reaction of red phosphorus with HF at 500 °C [13].

The high-pressure reactions are carried out as described earlier [14] in copper- or silver-coated electrically heated rotating autoclaves. Since the P–F bonds of trifluorophosphine and its metal compounds are slowly hydrolysed in moist air, the investigations are carried out in an atmosphere of dry nitrogen.

III. Metal(0) Trifluorophosphines [15]

The structure of the metal trifluorophosphines $[M(PF_3)_n]_x$ ($x = 1$ or 2 in all compounds known at present) is substantially identical with that of the metal carbonyls. Their stoichiometric composition can therefore be explained by *Sidgwick*'s "effective atomic number rule" [16], according to which stable complexes with trifluorophosphine must exist if the central metal atom can achieve an effective electronic configuration corresponding to that of the next inert gas in the periodic system by accepting the electron pairs from the phosphorus atoms of n PF_3 groups.

Metals with even atomic numbers should therefore give mononuclear metal trifluorophosphines, as was in fact found for all the metals of Group 6 B and Group 8 (see Table 2). These mononuclear complexes are diamagnetic and coordinatively saturated. The trifluorophosphine complexes of metals having odd atomic numbers (Groups 5 and 7, and some of Group 8), according to this structural principle, must be at least binuclear (*e.g.* by formation of a metal-metal bond as in the formula $(PF_3)_nM–M(PF_3)_n$ [17]) for the central metal atom to achieve the inert gas configuration. For reasons of time alone, however, only three crystalline diamagnetic trifluorophosphine complexes of such metals have so far been prepared; these are the violet, highly volatile cobalt compound $[Co(PF_3)_4]_x$ [18], the orange-red tetrakis(trifluorophosphine)rhodium(0), which is binuclear [19a, 19b], and the colorless pentakis(trifluorophosphine)rhenium(0), which is also dimeric [19c] (see Table 2). The cobalt and rhenium complexes have not yet been so thoroughly characterized as the rhodium compound, but studies on these complexes are in progress.

Though there are still some gaps among the trifluorophosphines of metals having odd atomic numbers, it can already be seen that the transition metals that form trifluorophosphine complexes occupy a closed field in the periodic system.

1. Methods of Preparation

Several methods with very different scopes have been found for the preparation of metal(0) trifluorophosphines:

1. The only metal trifluorophosphine known prior to 1963 was tetrakis(trifluorophosphine)nickel, prepared by *Wilkinson* [4] by halogen exchange:

$$Ni(PCl_3)_4 \xrightarrow{SbF_3/SbCl_5} Ni(PF_3)_4$$

In 1961, *Seel et al.* [7] perfluorinated tetrakis(trichlorophosphine)nickel [20] with potassium fluorosulfinate (KSO_2F). However, this method can be used only in the case of nickel, since no homogeneous PCl_3 or PBr_3 complexes of the other metals are known.

2. The classic method for the preparation of the metal carbonyls of the iron metals is based on the direct action of carbon monoxide on the metal [21]. Consequently, after the discovery of tetrakis(trifluorophosphine)nickel, a direct synthesis was attempted under various conditions of temperature and pressure, but at first without success [4, 22]. Recently, however, tetrakis-(trifluorophosphine)nickel was obtained quantitatively at a PF_3 pressure of only 70 atm from nickel powder prepared by thermal decomposition of nickel oxalate [23]:

$$Ni + 4\ PF_3 \xrightarrow[100\ C°]{\geqslant 70\ atm} Ni(PF_3)_4$$

This reaction represents the only direct synthesis of a metal trifluorophosphine so far, and is a further example of the rare direct formation of a nickel(0) complex, NiL_4, from metallic nickel and a compound of trivalent phosphorus [24].

3. A more general preparation involves displacement reactions of suitably coordinated complexes [25]. Ligand exchange under a high PF_3 pressure is particularly successful in the preparation of hexakis(trifluorophosphine)-chromium [26] and hexakis(trifluorophosphine)molybdenum [14]:

$$M(C_6H_6)_2 + 6\ PF_3 \xrightarrow[100-200\ °C]{>200\ atm} M(PF_3)_6 + 2\ C_6H_6\ (M = Cr, Mo)$$

Tetrakis(trifluorophosphine)nickel can also be obtained by ligand displacement:

$$NiL_4 + 4\ PF_3 \xrightarrow{80-300\ atm} Ni(PF_3)_4 + 4\ L$$
$$(L = PCl_3\ [4, 23, 23a],\ L = CO\ [23])$$

and, under mild conditions of temperature and pressure, from $(\pi\text{-}C_5H_5)_2Ni$ and trifluorophosphine [23b, 44].

Except in the case of tetracarbonylnickel, the CO cannot be completely displaced from metal carbonyls (M = Co, Fe, Mn, Cr, Mo) by PF_3 under pressure alone. However, UV irradiation of a mixture of PF_3-substitution products of pentacarbonyliron, $Fe(CO)_{5-x}(PF_3)_x$, or of hexacarbonylmolybdenum, $Mo(CO)_{6-x}(PF_3)_x$, in the presence of trifluorophosphine leads to pentakis(trifluorophosphine)iron [27] or hexakis(trifluorophosphine) molybdenum [27a]. Similar photochemical substitution reactions of metal carbonyls had already been achieved with π [28] and n donors [29]. It may be expected that other metal trifluorophosphines $M(PF_3)_n$ will become available from the metal carbonyls by reaction with PF_3 under pressure to form carbonyltrifluorophosphine-metal complexes (cf. Section VII), followed by photochemically induced total substitution by PF_3 under pressure:

$$M(CO)_n \xrightarrow[>1]{PF_3} M(CO)_{n-x}(PF_3)_x \xrightarrow{PF_3,\ h\nu} M(PF_3)_n.$$

4. The most important method of synthesis, particularly with respect to simplicity of the starting materials, applicability to a wide range of metals, and high yields, is the "reductive fluorophosphination" of metal salts [30]. This method enabled the preparation of the wide range of trifluorophosphine complexes now known (see Table 3)

This high-pressure method is based on the following principle:

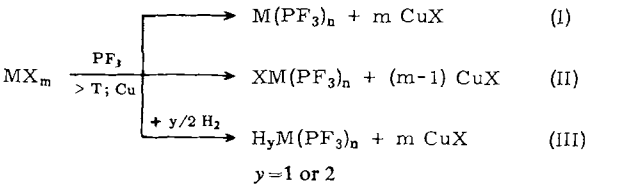

Table 3. Trifluorophosphine complexes prepared by reductive fluorophosphination of metal salts.

Compound	Starting materials and reaction conditions	Yield (%)	Ref.
$Mo(PF_3)_6$	$MoCl_5/Cu,PF_3$ (300 atm) [a],250 °C	15	[31]
$W(PF_3)_6$	WCl_6/Cu, PF_3 (300 atm), 250 °C	12	[32]
$Fe(PF_3)_5$	FeI_2/Cu (Zn),PF_3 (400 atm), 180 °C	70	[33]
$Ru(PF_3)_5$	$RuCl_3/Cu$, PF_3 (400 atm), 270 °C	50	[31]
$Ni(PF_3)_4$	NiI_2/Cu, PF_3 (135 atm), 100 °C	100	[23]
$Pd(PF_3)_4$	$PdCl_2/Cu$, PF_3 (300 atm), 100 °C	*ca.* 80	[34]
$Pt(PF_3)_4$	$PtCl_4/Cu$, PF_3 (40 atm), 100 °C	94	[34]
$[Re(PF_3)_5]_2$	$ReCl_5/Cu,PF_3$(320 atm), > 160 °C	*ca.* 50	[19c,37]
$[Rh(PF_3)_4]_2$	$RhCl_3/Cu,PF_3$ (250 atm), >150 °C	30	[19b]
$HRe(PF_3)_5$	$ReCl_5/Cu$, PF_3 (250 atm), H_2 (100 atm), 300 °C	40	[34a]
$HCo(PF_3)_4$	CoI_2/Cu, PF_3 (50–300 atm), H_2 (100 atm), 170 °C	100	[32]
$HRh(PF_3)_4$	$RhCl_3/Cu$, PF_3 (90 atm), H_2 (100 atm), 70 °C	100	[19a]
$HIr(PF_3)_4$	$IrCl_3/Cu$, PF_3 (160 atm), H_2 (45 atm), 215 °C	100	[35]
$H_2Fe(PF_3)_4$	FeI_2/Zn, PF_3 (300 atm), H_2 (100 atm), 250 °C	traces	[31]
$H_2Ru(PF_3)_4$	$RuCl_3/Cu$, PF_3 (300 atm), H_2 (100 atm), 270 °C	*ca.* 70	[31]
$H_2Os(PF_3)_4$	$OsCl_3/Cu$, PF_3 (400 atm), H_2 (100 atm), 270 °C	*ca.* 80	[31]
$Co(PF_3)_4I$	CoI_2/Cu, PF_3 (70–300 atm), 20 °C	30[b]	[18]
$Re(PF_3)_5Cl$	$ReCl_5/Cu$, PF_3 (250 atm), 160 °C	45	[36,37]
$Fe(NO)_2(PF_3)_2$	$[Fe(NO)_2Br]_2/Cu$, PF_3 (200 atm), 75 °C	90	[38]
$CoNO(PF_3)_3$	$[Co(NO)_2Cl]_2/Cu$, PF_3 (300 atm), 70 °C	46	[38]

[a] Initial pressure at room temperature. [b] Crude yield about 70 %.

An anhydrous metal halide is reduced in an autoclave by a halogen-accepting metal (generally copper or zinc), addition of trifluorophosphine to the metal liberated taking place at the same time under high PF_3 pressure (route I). The temperature and pressure required for this dry reaction depend on the metal. By route II, the process gives a monohalogenated PF_3 complex, particularly with metals having odd atomic numbers; in the presence of other reactants (*e.g.* H_2 or NO), these may even add on to or remain on the metal. The compounds that have been prepared in this way are listed in Table 3.

This process has greatly enriched our knowledge of zerovalent metal complexes, particularly those of ruthenium, osmium [39], palladium, and platinum. Among the homologues of iron, the only known compounds with oxidation state zero were the metal carbonyls $M(CO)_5$ [40] and $M_3(CO)_{12}$ [41], to which were added recently a number of phosphine complexes of ruthenium(0) [42].

The most important outcome of this method was the synthesis of tetrakis(trifluorophosphine)palladium and -platinum [43]; this synthesis can be carried out with $PtCl_4$ [44], $PdCl_2$ [44], $Pd(C_6H_5CN)_2Cl_2$ [23], and $Pd(CO)_2Cl_2$ [45] at relatively low PF_3 pressures and even in the absence of a secondary metal, since trifluorophosphine itself acts as a halogen acceptor in some cases.

These noble metal trifluorophosphines are noteworthy, since only a few other authentic compounds [2] of tetracoordinate Pd(0) and Pt(0) remained when the triphenylphosphine complexes, originally thought to be compounds of Pt(0), were found to be dihydrides of Pt(II) [46]; further, these other tetracoordinate Pd(0) complexes are very unstable. Moreover, no *volatile* complexes of the type M^0L_4 (M = Pd and Pt) have previously been found.

The existence of these tetrakis(trifluorophosphine) complexes also refutes the view [47] that ligands which rely on strong π back-donation are less suitable for the stabilization of the oxidation state zero of palladium and platinum than complex anions such as $[CN]^{\ominus}$ [48] and $[C\equiv C-C_6H_5]^{\ominus}$ [49].

2. Structure and Properties

Though no detailed X-ray or electron diffraction investigations have been reported, it is fairly certain that the monomeric metal trifluorophosphines are sterically similar to the analogous metal carbonyls. The regular tetrahedral arrangement of the PF_3 groups in tetrakis(trifluorophosphine)nickel was deduced from the Raman spectrum [50]. This is supported by the fact that the IR spectrum, like that of trifluorophosphine itself and those of $Pd(PF_3)_4$ and $Pt(PF_3)_4$ (cf. Table 8), contains only two P–F stretching vibrations. Thus the metal in the tetrakis(trifluorophosphine) complexes is in the sp^3-hybridized state. The infrared spectra of the hexakis(trifluorophosphine) complexes of the chromium group also contain only two P–F stretching bands, demonstrating the regular octahedral coordination of the d^2sp^3-hybridized central atom. The pentakis(trifluorophosphine) complexes of iron and its homologues must be assumed to have a trigonal-bipyramidal structure, simply on the grounds of the strong mutual repulsion of the PF_3 groups. Further evidence of this structure is provided by the absence of a dipole moment and by the ^{19}F-resonance spectrum of the iron compound [31].

The principal physical properties of the mononuclear metal trifluorophosphines are given in Table 2. The strong similarity to the corresponding metal carbonyls is obvious [51]. Features common to all the compounds are their nonpolar behavior and their remarkable stability towards oxidizing agents and moisture. Where their thermal stability is sufficiently high, the trifluorophosphines listed in Table 2 can be steam-distilled without appreciable losses. These heavy metal compounds are distinguished in particular by their volatility which probably results from a mutual repulsion of the molecules due to the high electron density on the ligands. The vapors have musty, stifling odors and cause difficulty in breathing; consequently, care must be exercised in working with volatile trifluorophosphine complexes.

The thermal stability of the metal trifluorophosphines, which is always greater than that of the comparable metal carbonyls should also be emphasized. This stability reaches a maximum with hexakis(trifluorophosphine)tungsten, and decreases from left to right in the periodic table. A striking feature is the stability minimum with the 4d metals. The only metal trifluorophosphine that is unstable at room temperature is $Pd(PF_3)_4$. The thermal decomposition of most of the metal trifluorophosphines leads to deposition of the metal; pentakis(trifluorophosphine)ruthenium appears to give a polynuclear red metal trifluorophosphine above 155 °C.

The compounds are soluble to varying extents in polar and nonpolar organic solvents, but not in water. Only $Fe(PF_3)_5$ exhibits almost unlimited solubility in liquid trifluorophosphine at −105 °C. Dilute or concentrated acids attack the metal trifluorophosphines only when hot, and then only slowly; bases, on the other hand, rapidly hydrolyse the P–F bonds. Ammonolysis of tetrakis(trifluorophosphine)nickel [7] in liquid ammonia leads initially to a colorless solution of the triaminophosphine complex of nickel(0); when this solution is

$$Ni(PF_3)_4 + 24\ NH_3 \rightarrow Ni(P(NH_2)_3)_4 + 12\ NH_4F$$

concentrated, the complex undergoes polycondensation with liberation of NH_3 to form a viscous mass which is evidently the highly polymeric nitride $[Ni(PN)_4]_x$. Similar condensations have been observed with primary amines such as isopropylamine [7].

The most interesting of the complex-chemical properties is the possibility of replacement of the PF_3 groups by donor ligands. Preliminary experiments with the tetrakis(trifluorophosphine) complexes and pentakis(trifluorophosphine)iron showed that the PF_3 groups can be replaced by isonitriles, phosphines, phosphites, tertiary N bases, and even carbon monoxide. The degree of substitution depends on the donor and acceptor properties of the entering ligand, increasing with the acceptor strength.

For example, triphenylphosphine gives the crystalline products $M(PF_3)_{4-x}(PPh_3)_x$ (Ph = phenyl; M = Ni: x = 1 and 2 [23]; M = Pd: x = 2 [52]; M = Pt: x = 1 and 2 [52]) and $Fe(PF_3)_3(PPh_3)_2$ [31]. The weaker donor triphenylphosphite replaces up to three PF_3 groups in tetrakis(trifluorophosphine)nickel, and up to four in tetrakis(trifluorophosphine)platinum. These phosphine and phosphite derivatives (cf. Table 7) are colorless or weakly colored diamagnetic nonelectrolytes, and are therefore true substitution products, in which the characteristic volatility of the metal trifluorophosphines has been lost.

Carbon monoxide, on the other hand, can replace all the PF_3 ligands in tetrakis(trifluorophosphine)nickel [23], (cf. also Section VII).

$$Ni(CO)_4 + 4\ PF_3 \underset{CO(350\ atm)}{\overset{PF_3(350\ atm)}{\rightleftharpoons}} Ni(PF_3)_4 + 4\ CO$$

Even in the final stages of the reactions with triphenylphosphine, the remaining trifluorophosphine can still be displaced by carbon monoxide under pressure.

The ease of substitution of metal trifluorophosphines again increases from left to right in the periodic table. Ease of substitution therefore varies inversely with the stability of the M–PF_3 bonds and the screening of the metal. Thus tetrakis(trifluorophosphine)nickel reacts smoothly with triphenylphosphine, even in boiling benzene, to form the disubstitution product; pentakis(trifluorophosphine)iron gives $Fe(PF_3)_3(PPh_3)_2$ on simultaneous irradiation of the mixture with UV light; and hexakis(trifluorophosphine)chromium is stable towards this donor ligand even under vigorous conditions (150 °C, UV irradiation) [31].

Finally, the reaction of $Pt(PF_3)_4$ with CO under pressure is particularly interesting, since it yields a colorless liquid which

[50] *L. A. Woodward* and *J. R. Hall*, Nature (London) *181*, 831 (1958); Spectrochim. Acta *16*, 654 (1960).

[52] Unpublished work by *Th. Kruck* and *K. Baur*.

is unstable at room temperature (decomposes above about −20 °C), and probably is $Pt(CO)_4$ [36,52]. In view of the stability relationships among the tetrakis(trifluorophosphine) complexes of Ni, Pd, and Pt on the one hand and tetracarbonylnickel and -platinum on the other, it is unlikely that tetracarbonylpalladium can exist under normal conditions, and it is probably obtainable only at low temperatures and high CO pressures.

IV. Trifluorophosphinemetal Hydrides [52a] [*]

The PF_3 complexes of cobalt, rhodium, and iridium are characterized by a strong tendency to form hydrides $HM(PF_3)_4$, which are unusually stable thermally and chemically (see Table 4). The M–H group (M = Co, Rh, or Ir) may be regarded as a "pseudometal atom" (Ni, Pd, or Pt respectively), and the complex hydrides $HM(PF_3)_4$ correspond in many of their physical properties to tetrakis(trifluorophosphine)nickel, -palladium, and -platinum. Tetrakis(trifluorophosphine)ruthenium dihydride and -osmium dihydride, which have only recently been prepared, fit in well, particularly with regard to ease of formation and high thermal stability, with the above compounds $HM(PF_3)_4$, which are the most thoroughly studied so far. Pentakis(trifluorophosphine)rhenium hydride has also been prepared and characterized. The homologous manganese hydride [34a] and even tetrakis(trifluorophosphine)iron dihydride [31] have recently been identified by IR spectroscopy (see Table 4).

[52a] These results were reported to the EUCHEM Conference "Chemistry of Metal Hydrides" in Bristol (England) on April 2nd, 1966, and to the Westdeutsche Chemiedozententagung 1966 in Würzburg (Germany).

[*] *Editors' note*: Binary compounds of hydrogen are known collectively as hydrides regardless of the bonding involved. The term "trifluorophosphinemetal hydrides" for the complexes discussed in this Section is intended as an extension of this definition, without any implication about the metal-hydrogen bonding.

These diamagnetic metal hydrides are monomeric and in most cases readily obtainable by the following principal methods:

1. Reductive fluorophosphination of metal halides in the presence of hydrogen (cf. Table 3), *e.g.*

$$CoI_2 + 2\,Cu + 4\,PF_3 + \tfrac{1}{2}\,H_2 \rightarrow HCo(PF_3)_4 + 2\,CuI.$$

The hydrides of cobalt and its homologues are so readily formed that traces of moisture or any substances containing hydrogen can act as hydrogen donors.

2. Acidification of alkali trifluorophosphinemetallates. This method has also proved suitable for the preparation of the analogous deuterium compounds.

$$K[M(PF_3)_4] + D^{\oplus} \xrightarrow{D_2SO_4} DM(PF_3)_4 + K^{\oplus}.$$

However, the deuterides are also rapidly formed when the hydrogen compounds are shaken with heavy water. The great ease of formation of complex cobalt hydrides containing PF_3 is shown particularly clearly in the synthesis of carbonyltris(trifluorophosphine)cobalt hydride [53] from octacarbonyldicobalt in the presence of hydrogen fluoride or hydrogen on a platinum catalyst:

$$3/2\,[Co(CO)_4]_2 + 6\,PF_3 + 2\,HF \xrightarrow[25\,^\circ C]{500\ atm} 2\,HCo(PF_3)_3CO + CoF_2 + 10\,CO$$

$$[Co(CO)_4]_2 + H_2 + 6\,PF_3 \xrightarrow[Pt,\ 70\,^\circ C]{200\ atm} 2\,HCo(PF_3)_3CO + 6\,CO.$$

Apart from the crystalline rhenium hydride, these substances [including $HCo(PF_3)_3Co$] have low melting points and are mobile liquids under normal conditions. Owing to their high volatility, they can be distilled or sublimed at normal pressure (though losses occur in the case of the rhodium compound). They dissolve readily and without dissociation in nonpolar organic solvents; the solubility in liquid trifluorophosphine decreases in the order Ir, Rh, Co. Their colorless vapors have stifling odors.

Unlike most complex hydrides of transition metals [54], particularly the comparable carbonylmetal hydrides, the trifluorophosphinemetal hydrides and their deuterium analogues are rather inert and have a surprisingly high thermal stability, those of Co, Ir, Ru, and Os being among the most thermostable hydride complexes of the transition metals. For example, Table 5 shows the increase in stability with increasing PF_3 content for cobalt.

Only the rhodium complex slowly loses its hydrogen and part of the trifluorophosphine, even at room temperature, with formation of a deep red, volatile, and apparently polynuclear trifluorophosphinerhodium complex. The relative instability of the metal(0) trifluorophosphines of the second transition series in relation to the lower

[a] Total decomposition. [b] Dehydrogenation.

and higher homologues is thus again found in the hydrogen compounds.

The stability of the trifluorophosphinemetal hydrides towards oxidizing agents is surprising. They generally remain unchanged for several days in dry air; the cobalt compound can even be refluxed for several hours with manganese dioxide without appreciable reaction.

The reactions known at present can be divided into two categories:

1. Formation of Trifluorophosphinemetallates

Except in the case of $HRh(PF_3)_4$, the thermal liberation of hydrogen occurs only at high temperatures and with complete decomposition of the molecule; however, the proton can be removed from all trifluorophosphinemetal hydrides even by weak bases, B, such as tertiary amines, water, tetrahydrofuran, and acetone, with formation of the trifluorophosphinemetallates [19a, 32, 35, 53]. In these bases, the compounds exhibit good electric conductivity, which is due to partial (tetrahydrofuran) or complete dissociation, *e.g.*

$$HM(PF_3)_4 + B \rightarrow [BH]^{\oplus} + [M(PF_3)_4]^{\ominus}.$$

In aqueous systems, the complex hydrides $HM(PF_3)_4$ (M = Co, Rh, Ir) are found to be equally strong acids, comparable in strength to tetracarbonylcobalt hydride. The trifluorophosphinemetal hydrides of the iron group and $HRe(PF_3)_5$ are much less acidic. The anions formed in accordance with the above equation can be precipitated from their solutions by the addition of bulky cations such as $[Cr(C_6H_6)_2]^{\oplus}$ or $[Fe(o\text{-phenanthroline})_3]^{2\oplus}$. The quaternary ammonium trifluorophosphinemetallates, $[NR_3H]$ $[M(PF_3)_4]$, are precipitated when solutions of the complex hydride and of the tertiary amine in petroleum ether are mixed. The colorless pyridinium salt $[C_5H_5NH]$ $[Co(PF_3)_3CO]$ can be sublimed at 40 °C/10^{-3} mm, evidently as a result of thermal dissociation into C_5H_5N and $HCo(PF_3)_3CO$ [59] and recombination on the cooling surfaces [60].

In petroleum ether, the trifluorophosphinemetal hydrides of the cobalt group react even with the very weak Lewis base triphenylphosphine to give the crystalline phosphonium salts $[HP(C_6H_5)_3]$ $[M(PF_3)_4]$, which are also colorless [69].

Thus the acidic nature of the trifluorophosphinemetal hydrides also confirms that PF_3 is similar in its complex chemistry to CO and not to the numerous other phosphine ligands PR_3 (R = organic group), the complex metal hydrides of which possess neither acidic nor basic properties [60a].

In particular, however, the hydrogen of all the trifluorophosphinemetal hydrides can be replaced by alkali metals. The colorless alkali trifluorophosphinemetallates $M_y^I[M(PF_3)_n]$ (y = 1 or 2) are obtained, without cleavage of the P–F bonds, when a solution of a complex hydride in ether is shaken with an alkali metal amalgam; the potassium salts, which crystallize well, are formed readily and mostly quantitatively, *e.g.*:

$$HM(PF_3)_4 + KHg \xrightarrow[20\,^{\circ}C]{(C_2H_5)_2O} K[M(PF_3)_4] + {}^1/_2\,H_2.$$

The carbonyltrifluorophosphinemetal hydrides can be converted similarly into carbonyltrifluorophosphinemetallates, *e.g.* $[Co(PF_3)_3CO]^{\ominus}$ [53].

Trifluorophosphinemetallates can also be obtained by reduction of halogenometaltrifluorophosphines [18, 34a, 37] and of metal(0) trifluorophosphines [19b] with potassium amalgam, *e.g.*

$$ClRe(PF_3)_5 \xrightarrow{KHg} K[Re(PF_3)_5] + KCl$$

$$[Rh(PF_3)_4]_2 \xrightarrow{KHg} 2\,K[Rh(PF_3)_4].$$

The ionic structure of the potassium trifluorophosphinemetallates has been shown by conductivity measurements in acetone, by magnetochemical studies, and by precipitation reactions. The alkali metal salts are diamagnetic; complex salts with the paramagnetic cation $[Cr(C_6H_6)_2]^{\oplus}$ have a magnetic moment of 1.7 B.M. Thus the trifluorophosphinemetallate anions $[M(PF_3)_4]^{y-}$

($y = 1$ or 2) are isoelectronic and presumably also isosteric with the tetrakis(trifluorophosphine) complexes of nickel and its homologues

Surprisingly, the potassium salts dissolve in ether, but without dissociation. They are very soluble in water, and give neutral solutions (pH $\approx$ 7). The P–F bonds of these anions readily undergo hydrolytic cleavage, particularly in the case of the rhodium and iridium complexes.

Mention should be made of the stability of the trifluorophosphinemetallates towards oxidizing agents. Even the alkali metal salts can be kept for several days in dry air. This behavior is interesting, since all previously known complexes in which the central metal carries a negative charge, including the carbonylmetallates [61], are extremely sensitive to oxygen, and are often even pyrophoric. The reducing action of the trifluorophosphinemetallates is much weaker than that of the carbonylmetallates. It is not surprising, therefore, that complex salts such as $[M^{+I}(CO)_6][Co^{-I}(PF_3)_4]$ (M = Mn and Re) are stable, whereas the analogous complexes $[M(CO)_6]$ $[Co(CO)_4]$ containing only CO ligands lose CO to form the mixed metal carbonyls $(CO)_5MCo(CO)_4$ even at 20 °C (M = Mn) or 60 °C (M = Re) [62].

The inertness of this complex hydride towards the donor $P(C_6H_5)_3$ is thus in striking contrast to the ease of substitution of the iodine complex $Co(PF_3)_4I$ having the same structure type (cf. Section VI). It is also noticeable that the replacement of the PF_3 group is accompanied by a decrease in thermal stability, whereas the introduction of the ligand $P(C_6H_5)_3$ into $HCo(CO)_4$ increases the stability [56] (cf. Table 5).

The colorless $HCo(PF_3)_3P(C_6H_5)_3$, which is stable in air, reacts quantitatively with potassium amalgam to give potassium tris(trifluorophosphine)triphenylphosphinecobaltate(–I), $K[Co(PF_3)_3P(C_6H_5)_3]$ [18]. The crystalline salt is stable in air, and is hydrolysed by water to the hydrophobic hydride, which is therefore a much weaker acid than $HCo(PF_3)_4$.

3. Structural Relationships

All the trifluorophosphinemetal hydrides exhibit a proton magnetic resonance absorption, characterized by a strong chemical shift to higher field strengths in relation to tetramethylsilane as the internal standard (cf. Table 6). Thus the ^{1}H–NMR signals occur in a range that is generally characteristic of complex transition metal hydrides. These findings indicate that the protons are situated in the immediate neighborhood of the central metal atom, and therefore experience strong diamagnetic shielding. Finally, the splitting of the ^{1}H signal of the rhodium compound as a result of the nuclear spin of the ^{103}Rh nucleus confirms that the hydrogen-metal bonding is covalent.

The covalent nature of the M–H bond in all trifluorophosphinemetal hydrides is confirmed by the M–H stretching vibrations in the 5 μ region of the infrared spectra. The assignment of these weak to medium bands is corroborated by the IR spectra of the deuterium compounds (cf. Table 6).

Table 6. IR and ^{1}H–NMR data for the metal-hydrogen bond in trifluorophosphinemetal hydrides [31, 34a, 35].

Compound	^{1}H-Resonance signal (against $Si(CH_3)_4$)		IR stretching vibrations		$\tilde{\nu}_{M-H}/\tilde{\nu}_{M-D}$	Force constant

2. Substitution Reactions

Replacement of a PF_3 group in tetrakis(trifluorophosphine)cobalt hydride with triphenylphosphine could be effected by heating for several hours, and was possible only because of the thermal stability of the hydrido complex:

$$HCo(PF_3)_4 + P(C_6H_5)_3 \xrightarrow[\text{Xylene}]{135\,^\circ C} HCo(PF_3)_3P(C_6H_5)_3 + PF_3.$$

[61] For a review, see: *W. Hieber, W. Beck,* and *G. Braun,* Angew. Chem. *72*, 795 (1960).

[62] *Th. Kruck* and *M. Höfler,* Chem. Ber. *97*, 2289 (1964); *Th. Kruck, M. Höfler,* and *M. Noack, ibid. 99*, 1153 (1966); Angew. Chem. *76*, 787 (1964); Angew. Chem. internat. Edit. *3*, 701 (1964).

Evidence of the overall structure of hydrides having an ML_4 molecular skeleton was provided by a comparison of the IR spectra of the isoelectronic complexes $HCo(PF_3)_3L'$ and $Ni(PF_3)_3L'$ [L' = $P(C_6H_5)_3$] [18]. These are identical in the number and intensity of the P–F bands. Since the nickel compound has C_{3v} symmetry, it can be deduced that the complex cobalt hydride has a trigonal-bipyramidal arrangement of the five ligands about the dsp^3-hybridized cobalt atom, the H atom and the triphenylphosphine being situated at opposite ends of the trigonal axis.

The compounds $HM(PF_3)_4$, whose IR spectra are identical in the region of the P–F stretching vibrations (cf. Table 8), indicating a similarity of structure, probably have a similar molecular geometry (C_{3v} symmetry). Finally, the results of the IR and ^1H–NMR studies of the trifluorophosphinemetal hydrides $H_2M(PF_3)_4$ suggest that the d^2sp^3-hybridized central metal atom in these compounds has an "octahedral" environment, with *cis* arrangement of the two hydrogen atoms (C_{2v} symmetry).

In all hydrido complexes of transition metals whose structures have been established by X-ray diffraction (cf. in particular [60a]), the complex ligands adjacent to the hydrogen are displaced towards them. It therefore seems reasonable to assume that the PF_3 ligands in the trifluorophosphinemetal hydrides are also displaced towards the H atoms; the $M(PF_3)_4$ skeletons of the complex hydrides $HM(PF_3)_4$ and $H_2M(PF_3)_4$ thus have a distorted tetrahedral configuration as shown in Fig. 1. In any case, even the rather qualitative results obtained so far in structural investigations show that the H atoms of the trifluorophosphinemetal hydrides do not disappear among the electrons surrounding the central metal, but occupy a normal coordination site on the metal.

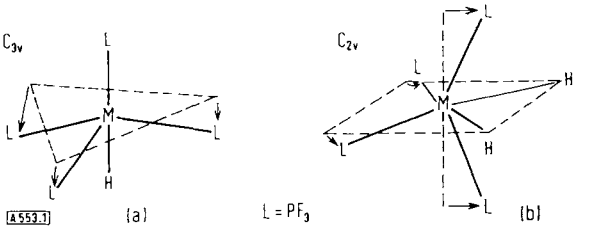

Fig. 1. Structural models for the trifluorophosphinemetal hydrides $HM(PF_3)_4$ (M = Co, Rh, Ir) (a) and $H_2M(PF_3)_4$ (M = Fe, Ru, Os) (b).

V. Nitrosyltrifluorophosphinemetal Complexes

In the metal(0) trifluorophosphines, trifluorophosphine can be partially replaced by the three-electron donor nitric oxide to give mononuclear inner-orbital complexes, in which the inert gas configuration of the metal is preserved. The diamagnetism of the complexes and the position of the N–O stretching vibrations (1788 to 1844 cm^{-1}), which is characteristic of coordinately bonded "$NO^{\oplus}$", indicate that the bonding of the nitric oxide to the metal involves both the σ electron pair on the nitrogen and the unpaired electron. Back-donation M → NO involving π* orbitals of the ligand also make a considerable contribution to the bonding state of the M–N–O linkage, as follows:

Two NO groups correspond electronically to three PF_3 ligands. The uptake of one or two unpaired NO electrons by cobalt or iron respectively gives a pseudonickel atom. (Corresponding remarks apply to metals of the 2nd transition series.)

This leads to the following isoelectronic and apparently isosteric (tetrahedral) series of compounds, the members of which have the general formula $M(NO)_x(PF_3)_{4-x}$ (x = 0, 1, 2, or 3 [63]):

$Fe(NO)_2(PF_3)_2$	$Co(NO)(PF_3)_3$	$Ni(PF_3)_4$
	$Rh(NO)(PF_3)_3$	$Pd(PF_3)_4$

Thus the "nitrosyl displacement law" formulated by *Seel* [64] is evidently also valid for these metal trifluorophosphine derivatives.

The hydrophobic nitrosyltrifluorophosphinemetal complexes, like the "classical" complexes $Co(NO)(CO)_3$ [65] and $Fe(NO)_2(CO)_2$ [66], are red, mobile, and very volatile liquids, which solidify only at low temperatures, and which can be distilled at normal pressure without decomposition. Some of their physical properties are listed in Table 7. Their thermal and chemical stabilities decrease with increasing NO content, but are always greater than those of the analogous nitrosylcarbonylmetal complexes [67]. Their intensely yellow vapors are almost odorless. They all dissolve readily in the common organic solvents, and to a moderate extent in liquid trifluorophosphine. Only the iron compound is rapidly decomposed by water.

The nitrosyltrifluorophosphinemetal complexes can be prepared by a wet or by a dry method. The latter is based on a modified method of reductive fluorophosphination. Thus if the halogenonitrosyl complexes of iron and cobalt are used as the starting materials (cf. Table 3), one or both NO groups remain attached to the metal even under very high PF_3 pressures, and the nitrosyltrifluorophosphine complexes are obtained in good yields, *e.g.*

$$[Fe(NO)_2Br]_2 + 2\ Cu + 4\ PF_3 \rightarrow 2\ Fe(NO)_2(PF_3)_2 + 2\ CuBr$$

A particularly useful preparation may be carried out at atmosheric pressure with the trifluorophosphinemetallates as starting materials [68]. When carbon dioxide is

[63] The existence of a nitrosyltrifluorophosphine complex $M(NO)_3PF_3$ of a metal of Group 7 B is still uncertain.

passed into aqueous solutions of the potassium tetrakis-(trifluorophosphine)metallates containing nitrite, the nitrosyltris(trifluorophosphine) complexes of cobalt and of rhodium are obtained in yields of 50—60%, but not the iridium complex:

$$[M(PF_3)_4]^{\ominus} + NO_2^{\ominus} + CO_2 \rightarrow M(NO)(PF_3)_3 + PF_3 + CO_3^{2\ominus}$$

The complex is removed from the reaction mixture by the current of CO_2, dried with $CaCl_2/P_2O_5$ while still gaseous, and condensed. It is interesting that only one PF_3 group is eliminated in the reaction of $K[Co(PF_3)_3CO]$; the physical properties of nitrosylcarbonylbis(trifluorophosphine)cobalt $Co(NO)(CO)(PF_3)_2$ [69] are as expected from those of the parent compound $Co(NO)(PF_3)_3$.

The reduction of $Fe(NO)_2(PF_3)_2$ with potassium amalgam in cooled ether yields the yellow potassium nitrosyltris(trifluorophosphine)ferrate(−I), $K[Fe(NO)(PF_3)_3]$ which is unstable in air [69a]. The anion is isoelectronic and isosteric with $Co(NO)(PF_3)_3$. Acidification of the crystalline potassium salt with 50% sulfuric acid leads almost quantitatively to nitrosyltris(trifluorophosphine) iron hydride, $HFe(NO)(PF_3)_3$ [69a], an orange, mobile liquid (m.p. −86 °C, b.p. *ca.* 80 °C/720 mm, decomp. 175 °C). The IR and ^1H-NMR spectra (cf. Table 6) of this surprisingly stable nitrosylmetal hydride indicate a structure as shown in Figure 1a, with the H atom and the NO group *trans* to each other on the threefold molecular axis.

VI. Halogenotrifluorophosphinemetal Complexes

Trifluorophosphine complexes in which the central metal atom is positively charged are particularly interesting from the point of view of bond theory, since the stability limits of metal-PF_3 bonds for higher oxidation states of the central metal atom can be found with the aid of these complexes. In addition to the true cationic complexes of the type $[M(PF_3)_6]^{\oplus}$ [M = Mn(I) and Re(I)], the synthesis of which is being investigated at present, they include the halogenotrifluorophosphinemetal complexes $X_mM(PF_3)_n$ (X = Cl, Br, or I; m = 1 or 2), in which the electron-attracting PF_3 groups have a strongly electronegative competitor. Such complexes of platinum, cobalt, iridium, iron, and rhenium have now been prepared and characterized [70].

1. Syntheses at Atmospheric Pressure

As early as 1891, *Moissan* [71] prepared the first trifluorophosphine complex of a transition metal (though he did not recognize it as such) by the reaction of phosphorus pentafluoride with platinum black. The compound he regarded as "$PtPF_5$" has the formula $[(PF_3)PtF_2]_2$ [22], corresponding to the dimeric complex $[(PCl_3)PtCl_2]_2$ [72]. Thus this is one of the very rare compounds in which fluorine functions as a bridge.

[70] Evidence has also been found for the formation of very unstable PF_3 adducts with CuCl and AuCl [22].

[71] *H. Moissan*, Bull. Soc. chim. France *1891*, 454.

[72] *M. Schützenberger*, Bull. Soc. chim. France *1872*, 482; *K. A. Jensen*, Z. anorg. allg. Chem. *231*, 365 (1937).

In 1951, shortly before the discovery of tetrakis(trifluorophosphine)nickel, *Chatt* [22] synthesized two other halogenotrifluorophosphineplatinum complexes. When PF_3 is passed over platinum(II) chloride at 200–220 °C, the colorless *cis*-dichlorobis(trifluorophosphine)platinum, $Cl_2Pt(PF_3)_2$, and the orange-yellow *trans*-dichlorotrifluorophosphineplatinum, $[(PF_3)PtCl_2]_2$, which is bridged by two chlorine atoms, immediately sublime. Both of these compounds have physical properties very similar to those of the halogenocarbonyl complexes $Pt(CO)_2Cl_2$ and $[(CO)PtCl_2]_2$, but are more volatile and more stable. At the boiling point of the monomer (240 °C) vigorous liberation of PF_3 and formation of the binuclear complex occurs.

The dihalogenotetrakis(trifluorophosphine)iron complexes can be obtained by direct reaction of pentakis(trifluorophosphine)iron with halogens. The deep red iodine compound is formed at 0 °C in pentane; the orange bromine compound and the amber chlorine compound are readily obtained in the gas phase:

$$Fe(PF_3)_5 + X_2 \rightarrow Fe(PF_3)_4X_2 + PF_3.$$

In contrast to the easy, quantitative synthesis [73] of $Fe(CO)_4I_2$ from FeI_2 and CO (6 atm) at 18 °C, attempts to make PF_3 (>200 atm) react with anhydrous iron(II) halides were unsuccessful even with reaction times of several weeks. It appears that in the stepwise addition to the doubly positive iron, the acceptor PF_3 does not encounter sufficient back-donation.

The yellow iodotetrakis(trifluorophosphine)iridium and the red-brown iodotetrakis(trifluorophosphine)cobalt are obtained by the action of iodine on potassium tetrakis(trifluorophosphine)iridate(−I) [37] and by iodination of tetrakis(trifluorophosphine)cobalt hydride with iodoform respectively [18]:

$$K[Ir(PF_3)_4] + I_2 \xrightarrow[-80\,^\circ C]{(C_2H_5)_2O} Ir(PF_3)_4I + KI$$

$$HCo(PF_3)_4 + I_3CH \xrightarrow[0\,^\circ C]{C_5H_{12}} Co(PF_3)_4I + I_2CH_2$$

2. Syntheses Under Pressure

Whereas the reductive fluorophosphination of tungsten hexachloride leads to hexakis(trifluorophosphine)tungsten, the reduction of the pentachloride of its right-hand neighbor in the periodic system, rhenium, under the usual conditions for the high-pressure synthesis of trifluorophosphinemetals (cf. Table 3) essentially stops after four chlorine atoms have been replaced [37]:

$$ReCl_5 + 4\,Cu + 5\,PF_3 \rightarrow Re(PF_3)_5Cl + 4\,CuCl$$

In addition to $Re(PF_3)_5Cl$, another colorless, but less volatile substance was recently isolated from the reaction products and identified as dimeric pentakis(trifluorophosphine)rhenium, $[Re(PF_3)_5]_2$.

It is interesting that cobalt gives a halogeno complex containing the maximum number of PF_3 groups, $Co(PF_3)_4X$, whereas with carbon monoxide only the addition compound $CoI_2 \cdot CO$ is known [74], which is stable under CO pressure only. At room temperature and under a relatively low pressure of PF_3 (about 50 atm), a mixture of anhydrous cobalt(II) iodide and copper powder avidly absorbs trifluorophosphine until a final pressure of about 10 atm is reached [18] (cf. Table 3); the resulting $Co(PF_3)_4I$ can be removed from the autoclave under vacuum.

3. Properties

All the halogen derivatives of this series must be regarded as purely covalent; they show the typical metal(0) trifluorophosphine character. They have definite melting points and dissolve readily in the common organic solvents.

Their volatility is striking, being greatest in iodotetrakis(trifluorophosphine)cobalt and -iridium, and decreasing slightly in the halogenotrifluorophosphineiron complexes in the order Cl, Br, I.

On the whole the halogenotrifluorophosphinemetal complexes are much less stable, chemically and thermally, than the trifluorophosphine complexes of the metals having valence 0 or −1. They tend to decompose rapidly in solution (particularly in polar solvents) and in air. Their thermal stabilities lie between wide limits, the most stable being the compounds of rhenium and platinum. However, the monomeric halogenotrifluorophosphine complexes of the 5d metals exhibit a strong tendency to polymerize. The thermal stabilities of the halogenotrifluorophosphineiron complexes are distinctly lower, but comparable among themselves, and one of the principal properties of $Co(PF_3)_4I$ is the loss of all the PF_3 groups above 7 °C. If the PF_3 liberated is continously removed, a brown substance having the composition "CoI" is finally produced. This substance, which is amorphous to X-rays and still sensitive to heat and air, is probably the hitherto unknown cobalt(I) iodide. The only trifluorophosphine complexes known at present whose metal-PF_3 bonds are unstable under normal conditions are $Co(PF_3)_4I$ and $Pd(PF_3)_4$.

The halogenotrifluorophosphinemetal complexes are very reactive towards donor ligands, since the entry of such ligands into the molecule makes the metal more negative and so strengthens the metal-PF_3 bond. The monohalogeno complexes $Re(PF_3)_5Cl$ and $Co(PF_3)_4I$ [18] exchange one and two PF_3 groups, respectively, for triphenylphosphine; this leads to a considerable increase in thermal and chemical stability, particularly for the disubstitution product of cobalt. At room temperature, the dihalogeno complexes of iron lose all their trifluorophosphine to form $Fe(PPh_3)_2X_2$. Similarly one can explain the fast reduction of the air-sensitive complexes iodotetrakis(trifluorophosphine)cobalt and -iridium to form the much more stable potassium tetrakis(trifluorophosphine)metallates(−I) [18,37]:

$$M(PF_3)_4I + 2\,K\,(Amalgam) \xrightarrow{10\,^\circ C} K[M(PF_3)_4] + KI$$

(M = Co, Ir)

VII. Carbonyltrifluorophosphinemetal Complexes

This interesting class of substances can be obtained by two routes:

1. The action of trifluorophosphine or carbon monoxide (generally under pressure, with simultaneous UV irradiation) on metal carbonyls or on metal trifluorophosphines, respectively, leads to mixtures of carbonyltrifluorophosphinemetal(0) complexes,

$$M(CO)_n + x\ PF_3 \rightarrow M(CO)_{n-x}(PF_3)_x + x\ CO$$
$$M(PF_3)_n + x\ CO \rightarrow M(PF_3)_{n-x}(CO)_x + x\ PF_3,$$

which, owing to their almost identical volatilities and solubilities, can be separated only by gas chromatography.

The ability of trifluorophosphine to displace carbon monoxide was first observed in tetracarbonylnickel [22]. The ease of this exchange on nickel was later confirmed by *Bigorgne* [75], who found by IR spectroscopy that all the substitution products $Ni(CO)_{4-x}(PF_3)_x$ are formed when trifluorophosphine is simply passed into tetracarbonylnickel. All three carbonyltrifluorophosphinenickel complexes ($x = 1$ to 3) were recently isolated by gas chromatography and identified as colorless liquids with low freezing points [76]. It was also found that ligand exchange takes place in the system $Ni(CO)_4$/$Ni(PF_3)_4$ even on gentle heating, and that when one pure carbonyltrifluorophosphinenickel complex is heated, all five species $Ni(PF_3)_{4-x}(CO)_x$ ($x = 0$ to 4) are eventually formed [76]. Evidence of such commutations and dismutations had been found earlier [14, 26] with the carbonyltrifluorophosphine complexes $M(PF_3)_{6-x}(CO)_x$ of chromium and molybdenum.

The degree of substitution in these equilibria is to a first approximation a function of the quantities of trifluorophosphine and carbon monoxide present. For example, if the reaction of nickel carbonyl with trifluorophosphine is carried out under pressure (350 atm), tetrakis(trifluorophosphine)-nickel is formed in a yield of about 80 %, together with all the intermediate substitution products (see also Section III.2). When the carbon monoxide liberated has been removed, a further reaction of the mixture with PF_3 under pressure leads almost quantitatively to the homogeneous trifluorophosphine complex. The same behavior is found in the reaction of $Ni(PF_3)_4$ with CO under pressure. Comparison of the infrared spectra [75] of the carbonyltrifluorophosphinenickel complexes with those of the colorless liquid products of reactions of tetrakis(trifluorophosphine)platinum with CO under pressure [44] shows that all the intermediate substitution products $Pt(PF_3)_{4-x}(CO)_x$ are formed also in the latter system. Their stability decreases with increasing CO content; the pure products have not yet been prepared.

The CO ligands of pentacarbonyliron can also be progressively replaced by trifluorophosphine to give all the possible substitution products [27]. All the compounds of the series $Fe(CO)_{5-x}(PF_3)_x$ ($x = 1$ to 4) have been isolated; they are light yellow liquids, whose stability towards air and light increases with the PF_3 content.

In reactions of hexacarbonylchromium and -molybdenum with PF_3 under pressure [14,26], it was again found that carbon monoxide can be readily replaced by trifluorophosphine, but in this case the colorless, waxy products were found to be mixtures. The substitutions tend to stop at the stage of the tris(trifluorophosphine) derivatives. Recently, however, all nine complexes $Mo(CO)_{6-x}(PF_3)_x$ ($x = 1$ to 6, including three pairs of *cis-trans* isomers) have been prepared from $Mo(CO)_6$ [77].

2. In the synthesis of specific carbonyltrifluorophosphinemetal complexes, substitution products of metal carbonyls with other relatively loosely bound ligands are subjected to the action of PF_3 under pressure at moderate temperatures (to avoid dismutation) [14,26]:

$$Cr(CO)_3(NH_3)_3 + 3\ PF_3 \xrightarrow[20\,^\circ C]{350\ atm} Cr(CO)_3(PF_3)_3 + 3\ NH_3$$

$$Mo(CO)_3(C_9H_{12}) + 3\ PF_3 \xrightarrow[80\,^\circ C]{350\ atm} Mo(CO)_3(PF_3)_3 + C_9H_{12}$$

(C_9H_{12} = Mesitylene)

The molybdenum compound can also be obtained from $Mo(CO)_3(PCl_3)_3$ by halogen exchange with potassium fluorosulfinate (KSO_2F) [78]. The colorless, crystalline, and very volatile tricarbonyltris(trifluorophosphine) complexes of chromium(0) and molybdenum(0) have octahedral structures with an all-*cis* arrangement of the three PF_3 ligands. Since it is more strongly bonded to the metal, the mesitylene in tricarbonylmesitylene-chromium(0) is eliminated only above 100 °C [26], again giving mixtures of $Cr(CO)_{6-x}(PF_3)_x$.

The carbonyltrifluorophosphinemetal complexes are almost identical with the corresponding metal trifluorophosphines and metal carbonyls in their physical properties such as color, volatility, solubility, *etc.* (cf. Table 7).

Thus trifluorophosphine and carbon monoxide can replace each other unrestrictedly and reversibly in the metal(0) compounds, the resulting mixed complexes being similar in character to the homogeneous metal trifluorophosphines and metal carbonyls. This property of the two monodentate ligands is unique.

In general [79], in reactions of metal carbonyls with Lewis bases B, substitutions are preferred to base reactions (in the sense of a valence disproportionation of the metal carbonyl, *e.g.* $3M^0 \rightarrow 2M^{-I} + M^{+II}$) with increasing tendency of B to enter into M–B back-donation. Thus the strong back-donating tendency of trifluorophosphine can be seen from the fact that only replacement is observed in its reactions with metal carbonyls.

VIII. π-Aromatictrifluorophosphinemetal Complexes

The first member of this group to be studied in any detail was bis(trifluorophosphine)cyclopentadienylcobalt [80], which can be obtained from dicyclopentadienylcobalt in 20 to 30 % yield by a displacement reaction:

$$Co(\pi\text{-}C_5H_5)_2 + 2\ PF_3 \xrightarrow[170\,^\circ C]{350\ atm} Co(PF_3)_2(\pi\text{-}C_5H_5) + [C_5H_5].$$

[80] *Th. Kruck*, *W. Hieber*, and *W. Lang*, Angew. Chem. *78*, 208 (1966); Angew. Chem. internat. Edit. *5*, 247 (1966).

The red, oily liquid may be regarded as a compound of Co(I); like $Co(PF_3)_4I$, therefore, it is extremely sensitive to oxidation. Its diamagnetism and the ^1H-NMR and IR spectra are in agreement with a π-bonded symmetrical ring.

Tris(trifluorophosphine)mesitylenemolybdenum(0) [80a], $Mo(PF_3)_3(C_9H_{12})$, was obtained when a suspension of $Mo(PF_3)_6$ in mesitylene was irradiated with UV light for several hours, *i.e.* by the direct action of an aromatic compound on a metal(0) trifluorophosphine complex. The volatile product (cf. Table 7) is stable even towards concentrated alkali solutions and dilute acids.

The existence of a tris(trifluorophosphine)benzenechromium(0) has also been reported [77]. This substance, which has not yet been characterized fully, is obtained in an interesting manner: thus, while the aromatic ligand of tricarbonylbenzenechromium(0) is replaced by three PF_3 ligands under high PF_3 pressures, irradiation in hexane solution with UV light in the presence of trifluorophosphine leads to the stepwise replacement of CO by PF_3. However, the only product that could be isolated was the stable $Cr(PF_3)_3(C_6H_6)$.

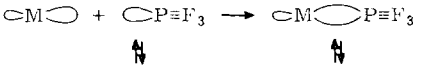
This photochemically induced reaction throws light on the bonding in the derivatives $Cr(CO)_2L(arene)$ (L = compounds of trivalent phosphorus, amines, *etc.*) and emphasizes the special position occupied by trifluorophosphine as a result of its back-donating power. The photochemical primary reaction [81] of metal carbonyls and their π-arene derivatives leads to a species, A, that contains less CO and is therefore strongly electrophilic, and can then add on a wide range of ligands in the secondary step.

$$Cr(CO)_3(C_6H_6) \xrightarrow[-CO]{h\nu} \underset{A}{\{Cr(CO)_2(C_6H_6)\}} \xrightarrow{+L} \underset{S}{Cr(CO)_2L(C_6H_6)}.$$

When L = $P(C_6H_5)_3$, pyridine, *etc.*, the substitution stops at this first stage, since these donors increase the bond order of the M–C bonds of the remaining CO groups, *i.e.* they increase the contribution of the limiting structure $M{=}C{=}\ddot{O}$; disubstitutions are rare, and trisubstitution has not been observed. On the other hand, if the coordination vacancy in A is filled by the acceptor PF_3, the M–CO bond in the monosubstitution product S is weakened (increased contribution of the structure $M{-}C{\equiv}O^{\oplus}$:), since the $M \rightarrow PF_3$ π bond takes up more of the charge transferred from the aromatic ligand onto the metal. This effect ultimately leads to complete substitution of the carbon monoxide.

Though only three metal trifluorophosphine complexes containing aromatic rings are known at present, their stability and ease of preparation leads one to expect as large a diversity of compounds as in the class of aromatic-ring metal carbonyl complexes.

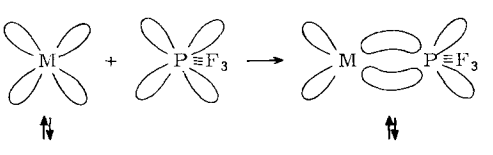
IX. Bonding



The available chemical, spectroscopic, and magnetochemical data permit only qualitative consideration of the bonding in trifluorophosphine complexes.

The nature of the metal-PF_3 bond is fundamentally the same as that of the metal-CO bond, since the bonding possibilities of the two ligands are similar. However, there are slight differences, which ultimately lead to the marked differences in behavior described above. Some understanding of the complex-chemical behavior of trifluorophosphine can be gained simply from a comparison of its electronic structure (schematic notation) with that of other complex ligands that also form stable bonds with d metals in low oxidation states.

$$:P{\equiv}F_3 \qquad :C{\equiv}O: \qquad :N{\equiv}O: \qquad :C{\equiv}N: \qquad :C{\equiv}N{-}R$$



A common feature of these molecules is the presence of a lone pair of electrons and unoccupied π orbitals on the more electropositive donor atom.

In the coordinate bonding of trifluorophosphine to a transition metal atom, the doubly occupied sp^3 orbital of the phosphorus and, above all, its $3d_\pi$ orbitals are of decisive importance. Overlap of the doubly occupied sp^3 orbital of the phosphorus with suitably directed free hybrid orbitals of the metal leads initially to a weak donor σ bond.

Proof of the donor function of trifluorophosphine is provided by the adduct $F_3P \rightarrow BH_3$ with the strong Lewis acid monoborane, even though this adduct is unstable [82]. In boron trifluoride [83], on the other hand, the electrophilic action of the p_z orbital of boron, which already participates in the B–F double bonds, is no longer sufficient for coordinate bonding of the very weak Lewis base PF_3, but can effect bonding with the stronger donor PCl_3 [84], though even the adduct $Cl_3P \rightarrow BF_3$ can exist only up to −6 °C.

The low electric dipole moment [85] of the Pt–PF_3 bond in $Pt(PF_3)_2Cl_2$ is enough to show that this cannot be a simple [86] donor σ bond. The surprising stability of the trifluorophosphine complexes is therefore undoubtedly due to a strong d_π–d_π bond formed by donation from occupied orbitals of the central metal atom to the 3d orbitals of phosphorus; this effect is strengthened by the high electronegativity of the fluorine atoms, since these lower the energy of the 3d orbitals of the phosphorus:

The overall result, however, is probably a synergic type of bonding, since this π bonding increases the electron density on the phosphorus, and hence also its basicity (but cf. [87]).

A deeper insight into metal-trifluorophosphine bonding is provided by the P–F stretching bands in the 10 to 12μ

region. Tne IR vibrations of free PF_3 reappear as group frequencies in the IR spectra of its metal complexes, and since they are characteristically altered, they may be used as an important criterion for distinguishing between different types of compounds. The P–F stretching vibrations in the metal(0) trifluorophosphines, trifluorophosphinemetal hydrides, and halogenotrifluorophosphinemetal complexes always occur at higher wave numbers than in free trifluorophosphine, while they are displaced to much lower wave numbers in the trifluorophosphinemetallates and in the substitution products with donor ligands. The P–F stretching vibrations in isosteric compounds are directly comparable (cf. Table 8, columns d and f).

Table 8. Comparison of the P–F stretching vibrations of some trifluorophosphinemetal complexes.

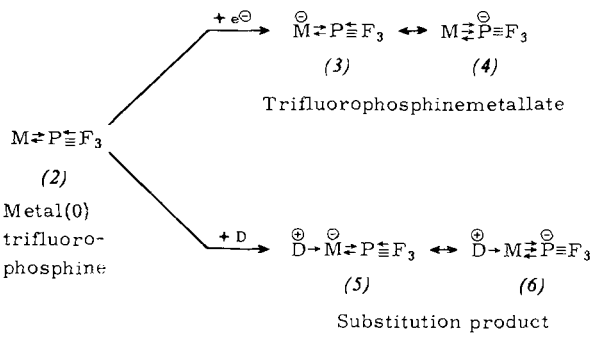
These observations can be readily explained if the P–F bond in trifluorophosphine is assumed to possess double-bond character, which is influenced by the metal-phosphorus bond. The superposition of a π bond on the P–F σ bond results from the overlap of occupied 2p orbitals of fluorine with the 3d orbitals of the phosphorus, so hat limiting structures such as

[88]



make a considerable contribution to the bonding in trifluorophosphine. This bonding is represented in the following discussion by the formulation $:P \overleftarrow{\equiv} F_3$.

For a given internuclear distance, the value of the overlap integral for p_π–d_π bonds of this type is greatest when the d_π orbital is more diffuse than the p_π orbital [89], *i.e.* has a higher principal quantum number. Since this is the case with the combination phosphorus-fluorine, π bonding plays a considerable part in the overall bonding in trifluorophosphine, though not in any other phosphorus trihalides. This view [53] is supported by the ^{31}P nuclear magnetic resonance of PF_3 [90], since despite the high electronegativity of fluorine, which should lead to an *ionic* bonding component, the diamagnetic shielding of phosphorus is stronger in PF_3 than in any other phosphorus trihalide. Finally, chemical evidence of the existence of F→P π bonding is provided by the considerable stability of trifluorophosphine towards hydrolysis, in comparison with that of the other phosphorus trihalides.

When trifluorophosphine *(1)* is linked to a metal in the zero oxidation state (see Scheme 1), the donor σ bond leads to a decrease in the electron density on the phosphorus, and this necessarily leads to an increase in the π-bond order of the P–F bonds. However, this effect can be only weak, since it is distributed over three P–F bonds, and since it is opposed by the simultaneous metal→phosphorus back-donation *(24)*. Nevertheless, the P–F force constant in $Ni(PF_3)_4$ is 7.73 mdyne/Å, compared with 5.38 mdyne/Å in free PF_3 [50]. However, if the metal is given a (formal) negative charge (*e.g.* by reduction to the trifluorophosphinemetallate or by the introduction of donors D), this is absorbed by the M–P π bond with an increase in the electron density on the phosphorus, with the result that the π-bond component of the P–F bonds decreases [*(4)* or *(6)*]. Thus a displacement of the P–F absorption bands towards lower wave numbers is an indication of an increase in the bond order of the M–PF_3 bond. This is strongest in the hetero-anion $[Co(PF_3)_3P(C_6H_5)_3]^{\ominus}$ (Table 8), since in this case there are two factors that tend to make the metal more negative.

The shift of the M–P stretching frequencies towards higher wave numbers for the trifluorophosphinemetallates and the substitution products of the metal(0) trifluorophosphines as expected from *(4)* and *(6)* has also been experimentally confirmed [91].

It should be stressed that *e.g.* the double arrow of the M–PF_3 bond *(2)* is only a symbol for the bonding, and

Scheme 1. Bonding in trifluorophosphinemetal(0) complexes, in their substitution products, and in trifluorophosphinemetallates.

does not denote a true double bond (*e.g.* as in olefins). The strength of the M–PF_3 linkage resulting from the combined action of the donor σ bond and the acceptor

[88] Cf. *E. Fluck*, Z. Naturforsch. *19b*, 869 (1964).

[89] *L. E. Sutton*: Chemische Bindung und Molekülstruktur. Springer-Verlag, Berlin 1961.

[90] *H. S. Gutowsky* and *D. W. McCall*, J. chem. Physics *22*, 162 (1954).

[91] These spectroscopic studies will be fully reported in the near future.

π bond corresponds only to that of a single bond, as is shown by the Ni–P force constant ($k_{Ni-P} = 2.71$ mdyne/Å [50]) in $Ni(PF_3)_4$, [compare $k_{Ni-C} = 2.52$ mdyne/Å in $Ni(CO)_4$].

By influencing the occupation of the d_π orbitals of the phosphorus, the available charge density on the metal atom affects not only the strength of the P–F bonds and hence their stretching frequencies, but also the physical properties and chemical behavior of the trifluorophosphine complexes.

This $M-PF_3$ bonding type explains the fact that the P–F bond order in the hydridotrifluorophosphine complexes of cobalt and its homologues is higher than that in the isoelectronic tetrakis(trifluorophosphine) complexes of nickel, palladium, and platinum. The central atoms of the complex hydrides, partly because of their lower nuclear charge and partly because one electron of the metal is fixed in the covalent M–H bond, have effectively fewer electrons available for back-donation to the PF_3 than nickel and its homologues in the pure metal trifluorophosphines.

The electron-attracting action of trifluorophosphine extends over the metal to other ligands present in the complex and so affects their bonding. The halogenotrifluorophosphinemetal complexes for example, are only formally analogous to the corresponding halogenocarbonylmetal complexes. Their nonpolar character and high volatility suggest covalent M–X bonding. In addition, the wave number of the Re–Cl stretching in $Re(PF_3)_5Cl$ is 37 cm^{-1} higher than that for the corresponding carbonyl complex [37]. This higher M–X bond order is evidently due to an X→M π bond, which is induced by the PF_3 groups, and which is superimposed on the polarized M–X σ bond:

(7) *(8)* *(9)*

A considerable contribution is therefore made by the structures *(8)* and *(9)*.

The extent of the charge transfer from other ligands to the metal, and hence the increase in the $M-PF_3$ bond order in the substituted trifluorophosphine complexes (see Table 9, *(5)* and *(6)*) is naturally also determined by the donor and acceptor properties of the substituents [23]. This explains the fact that the reaction of tetrakis(trifluorophosphine)nickel with triphenylphosphine stops at the stage of $Ni(PF_3)_2(PPh_3)_2$, whereas the weaker donors $P(OR)_3$ readily give trisubstitution, and carbon monoxide, whose acceptor power approaches that of trifluorophosphine, can replace all the PF_3 groups.

The bonding of the trifluorophosphine to the metal is also stronger in the anionic trifluorophosphine complexes than in the metal(0) trifluorophosphines [see Scheme 1, *(4)*]. The surprising chemical stability of the trifluorophosphinemetallates, which contrasts with the ease of oxidation of the carbonylmetallates, is due mainly to the outstanding acceptor strength of this ligand, which leads to extensive withdrawal of the negative charge from the metal.

Thus the π-acceptor power of trifluorophosphine is clearly greater than that of any of the usual ligands, with the exception of the $NO^{\oplus}$ ion. This is impressively shown by its complex-chemical behavior, and has also been repeatedly confirmed by IR spectroscopic studies [14,53,92]. Thus we find a (naturally abridged [93]) sequence of monodentate neutral ligands with decreasing tendency to form acceptor π bonds:

$$PF_3 > CO > PCl_3 > P(OR)_3 > CNR > PR_3 \gg NR_3.$$

The ligands on the right are pure or predominant donors, and have little or no available π-orbital accommodation for the acceptance of M→L back-donation [94]; they therefore preferentially form stable bonds with positively charged metal ions. On the left, however, we find the strongest π acceptors, which mainly stabilize the oxidation state zero or even low (formal) negative valences of transition metals.

I am indebted to K. Baur, A. Engelmann, Dr. W. Lang, and Dr. A. Prasch for their collaboration, and to N. Derner, B. Griesel, M. Negele, and M. Stadler. I am grateful to Prof. W. Hieber and to Prof. E. O. Fischer for their interest in this work and for their generous support. Acknowledgement is also due to the BASF, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie for financial support.

[94] Therefore NF_3 cannot be a ligand comparable to PF_3, even apart from its strong fluorinating properties.

Chemistry of the Incandescent Lamp[**]

BY A. RABENAU[*]

Halogen lamps have been on the market for some time; they are replacing the conventional lamp in many fields except general service (domestic) applications. Their relatively small bulbs contain small amounts of halogen in addition to an inert gas. The mode of action of the iodine lamp, which depends on the presence of traces of oxygen, has been elucidated. Tungsten evaporating from the filament is returned to it by a cyclic process involving a tungsten oxide and WO_2I_2. No tungsten is ever deposited on the bulb wall of such a lamp. A regenerative cycle in which the vaporized tungsten is deposited on the hottest (and hence most vulnerable) parts of the filament can, in principle, be realized by the use of fluorine compounds.

1. Basic Principles

The incandescent lamp is a thermal radiator. The filament, which is normally protected from the atmosphere, is heated to high temperatures by the direct passage of a current. The luminous efficiency[***] is determined by the Stefan-Boltzmann law, according to which the energy of the emitted radiation increases with the fourth power of the absolute temperature, and by Wien's displacement law, according to which the maximum of the energy curve is displaced into the visible region with rising temperature (Fig. 1). The

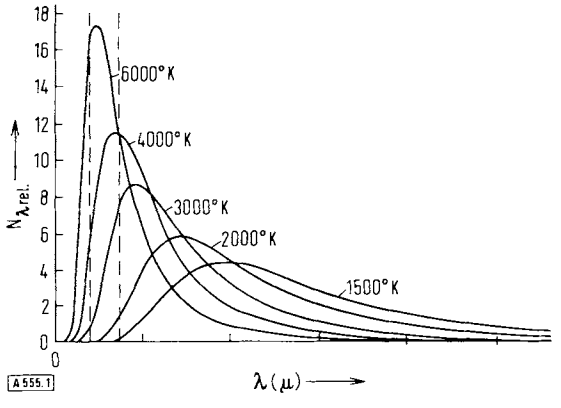

Fig. 1. Spectral energy distribution of a black body. The radiation emitted $N_{\lambda rel}$ is given in arbitrary units. The broken lines indicate the limits of the visible region.

luminous efficiency is highest at about 6000 °K, which corresponds roughly to the surface temperature of the sun. For a black body it is 95 lm/W; by way of comparison, a monochromatic radiator of wavelength λ_m = 555 mμ, the sensitivity optimum of the human eye, has a luminous efficiency of 682 lm/W. The considerable temperature-dependence of the luminous efficiency, brightness, and hence the life of a tungsten filament can be seen from Table 1.

Table 1. Characteristic data for an uncoiled incandescent tungsten filament (diameter 0.01 mm) in vacuum (< 10^{-5} mm).

Temp. (°K)	Brightness (cd/cm²)	Luminous efficiency (lm/W)	Life (hr)
2400	157	9.37	1.17×10^3
2600	347	14.28	3.86×10^1
2800	694	20.43	1.9
3000	1257	27.10	0.15
3200	2110	34.6	—
3400	3370	42.6	—

2. Filament Materials

Filament materials must have a high melting point, a low vapor pressure, and a low rate of evaporation. Moreover, it must be possible to produce filaments having adequate mechanical strength from the materials. This last point in particular has been a deciding factor in the development of the incandescent lamp[1].

Table 2. Compounds and elements with melting points close to or above 3000 °C.

Phase	M.p. (°C)	Phase	M.p. (°C)	Phase	M.p. (°C)
TaC	3880	HfB_2	3250	NbB_2	3000
C	3870	TiN	3205	ThO_2	3050

pressure of carbon limits the maximum useful working temperature to about 2100 °K, since at higher temperatures blackening of the envelope leads to excessive light losses. A search was therefore made for other materials. The Nernst lamp, in which the filament material was a mixed oxide (85 % ZrO_2 + 15 % Y_2O_3), did not become widely used. Owing to the complicated method of ignition, which involves preheating, it was ousted by the metal-filament lamps that appeared on the market in rapid succession. Though tungsten was considered as a filament material at a very early stage [1a], it was many years later that the metallurgy of this metal was mastered. The first filaments were produced from tungsten powder, which was mixed with an organic binder and forced through fine diamond orifices. The binder was then evaporated off in an inert gas, and the metal powder sintered at about 2500 °C. One great disadvantage of lamps containing filaments of this type was their low shock resistance, so that despite their advantages they could not fully replace the carbon-filament lamp.

A turning point was reached with the introduction of the drawn tungsten filament by *Coolidge* in 1908. Rods of compressed tungsten powder are heated by direct passage of a current to temperatures near the melting point and forged into thick wires, from which filaments can be drawn. Following this development, tungsten became generally accepted as a filament material. The dominant position of tungsten is understandable: its vapor pressure at 3000 °C is more than 1000 times lower than that of carbon.

Owing to its outstanding shock resistance, the carbon-filament lamp is still used to a limited extent, *e.g.* in ships and underground railways. Other filament materials such as carbides (Table 2) have been discussed, but have not so far been used.

3. Life of an Incandescent Lamp

The life of an incandescent lamp is determined essentially by two factors: blackening of the bulb and "burning out" of the filament. Both processes are related to the vapor pressure (rate of vaporization), which therefore determines the maximum working temperature.

a) Blackening of the Bulb

During operation vaporized filament material is deposited on the bulb wall, leading ultimately to unacceptably high light losses. To minimize light losses, the bulb must be relatively large. The decrease in luminous efficiency with time is the main problem with carbon lamps and vacuum lamps in general.

b) "Burning out" of the Lamp

While the lamp is burning, thinner parts ("hot spots") are formed in the filament, and these points of high resistance ultimately carry practically the entire load. An increase in temperature, and hence increased vaporization, results and after a time the filament fuses at these points. Though this a random process, the life of a lamp is closely related to its working conditions.

c) Influence of Residual Gases

Reactions caused by impurities, particularly by residual gases, can lead to a considerable transfer of material from the filament to the bulb wall, and so shorten the life of the lamp.

Tungsten reacts with water vapor at the filament temperature as follows:

$$W + x\,H_2O \rightleftharpoons WO_{x(g)} + x\,H_2 \qquad (a)$$

At low temperatures the reaction proceeds from right to left. In vacuum lamps [3] tungsten passes in this way to the bulb wall, while in lamps filled with inert gases [4] it is transferred mainly from hotter to cooler parts of the filament (Fig. 2). The water formed is then used to repeat the process.

Fig. 2. Transport of tungsten from hotter (T_2) to cooler (T_1) parts of an incandescent tungsten coil in the presence of a little water vapor (after [4]). (Magnification 100×; filament temperature about 2500 °K).

In carbon-filament lamps traces of oxygen react with the carbon filament to form CO [5]. This decomposes on the wall to carbon and CO_2, which reacts with the filament to form further CO. Both these processes are examples of chemical transport reactions.

The life and luminous efficiency (working temperature) of incandescent lamps can be improved in two ways: 1. by decreasing the rate of evaporation; and 2. by elimination of the damage caused by vaporization (material transport).

4. Rate of Evaporation

Even in the early stages of development of the incandescent lamp, attempts were made to reduce the rate of evaporation by filling the bulb with inert gases. However, it was found that the additional losses due to

[3] *I. Langmuir*, Trans. Amer. Inst. Electr. Engrs. *32*, 1394 (1913).
[4] *C. J. Smithells*, Trans. Faraday Soc. *17*, 485 (1921).
[5] *H. Schäfer*: Chemical Transport Reactions. Academic Press, New York 1964, Weinheim/Bergstr. 1962, p. 41.

thermal conduction and in particular to convection outweigh the advantages of the use of inert gases. Only after a detailed study of the heat losses [6] could gases be used to advantage. *Langmuir* [6] found that an incandescent body is surrounded by a quasi-stationary layer of gas, because of the increase in gas viscosity with increasing temperature. Heat is lost from this layer only by radiation and conduction. The heat loss W, in watts, due to conduction can be expressed approximately by equation (b) [7],

$$W = Cl\,(a/B)^{0.3} \times 4.19 \int_{T_1}^{T_2} k \, dt \qquad (b)$$

where C is a constant, l is the length and a the diameter of the wire, B is the thickness of the Langmuir layer, and k is the coefficient of thermal conductivity of the gas. The ratio a/B is in the range 0.02–0.2. The equation shows that the heat losses depend largely on the length of the filament, but only to a small extent on its diameter. Thus a short thick wire should be particularly suitable. Since the length is fixed by the specified voltage and power, *Langmuir* coiled the wire so that Langmuir layers of adjacent turns overlapped. A filament of this type behaves like a short cylindrical one whose diameter is the same as the outside diameter of the coil. The "coiled-coil" filament was introduced in the 1930's [8]. Another property of the Langmuir layer, and one of particular importance in the most recent developments, is the fact that thermal conduction inside this layer is independent of the gas pressure.

The lower coefficient of thermal conductivity of gases with higher molecular weight led to the use of argon instead of nitrogen in gas-filled lamps. General-service lamps with powers greater than 40 W nowadays contain 93 % argon and 7 % nitrogen, the nitrogen being added to prevent arcing. Krypton and xenon are used only in special lamps, owing to their high cost.

5. Technology of the Filament

One problem that is particularly noticeable with coiled filaments is "sagging" of the wire. The drawn polycrystalline tungsten wire recrystallizes under working conditions, with the result that slip can occur at grain boundaries that are almost perpendicular to the wire surface, so that the wire sags and finally breaks (Fig. 3).

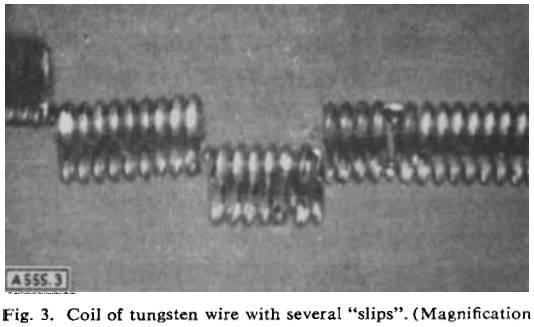

Fig. 3. Coil of tungsten wire with several "slips". (Magnification 65×)

Attempts to avoid this sagging led first to the use of monocrystalline wires (Pintsch wire). However, apart from technological difficulties, the wire sags particularly readily at the points where two monocrystals are joined. Present-day filaments have a staple-fiber structure (Fig. 4), in which the grain boundaries form only a small angle with the surface [9]. This recrystallization structure is obtained by addition of small quantities of sodium or potassium silicate to the tungstic acid before reduction [10].

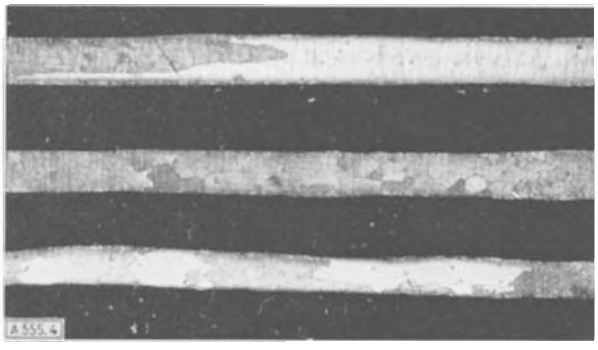

Fig. 4. Crystal structure of recrystallized tungsten wires 180 μ in diameter. The wires were produced from:
top: **doped W powder (staple-fiber structure);**
center: **doped and undoped W powder (1:1);**
bottom: pure W powder.

6. Getters

The examples in Section 3c show that the quality of incandescent lamps depends to a large extent on the care taken in their manufacture. This is particularly true of the quality of the vacuum. *Malignani* used red phosphorus as a getter as early as 1894. Small quantities of red phosphorus are vaporized in the lamp after it has been evacuated and sealed; the phosphorus reacts with residual gases such as water and oxygen to form compounds with low vapor pressures. This discovery was a great advance in lamp technology. Red phosphorus is still used both in vacuum lamps and in gas-filled general-service lamps. It is applied to the coil as a paste, together with other substances, and vaporized.

The first getter specially intended for tungsten lamps was phospham, $(PN_2H)_x$. It was later suggested that this should be replaced by phosphorus nitride, P_3N_5, to avoid the introduction of hydrogen, which causes arcing. The barium (1916) and zirconium getters (1938) also deserve mention in view of their practical importance [11b].

7. Wall Reactions

Conversion of the light-absorbing carbon or tungsten deposits into transparent compounds such as halides or oxides was also attempted long ago. Thus as early as 1882, introduction of small quantities of chlorine into carbon-filament lamps was suggested [11]. The "Novak" lamp (with a carbon filament), which was introduced in 1894, contains small quantities of bromine. However, this does not have the desired effect on the life of the lamp, since the small quantities of halogen are consumed in unavoidable side reactions [12].

Large quantities of chlorine, on the other hand, cause lamp failure, *Skaupy* [12] therefore suggested the use of compounds over which there is a low vapor pressure of the active gas, which would consequently maintain reaction with the deposits over long periods. The compounds suggested include thallium(III) chloride, potassium hexachlorothallate, and platinum(II) chloride.

Later, compounds as stable as sodium chloride and cryolite were successfully used in metal-filament lamps, even though the halogen vapor pressure of these compounds is negligible. Compounds such as K_3TlCl_6 react [13] as expected by *Skaupy*. Sodium chloride and cryolite, on the other hand, are effective only when deposited in a finely divided form on the wall and when tungsten vapor comes into contact with them. This effect has not yet been fully explained, but it is thought that these substances affect the structure of the deposit. Cryolite is nowadays added to the phosphorus getters in vacuum lamps.

8. "Positive" Cyclic Processes

Langmuir [14] took two tungsten wires in a tube to different temperatures under low chlorine pressures. It was found that at suitable temperatures, the hotter wire became thicker and the cooler wire thinner. A deposit of tungsten deliberately produced in a lamp disappeared on reaction with atomic chlorine, produced by the dissociation of Cl_2 on the hot wire. This demonstrated the fundamental possibility of transport of material from cooler to hotter zones ("positive" transport).

These results formed a basis for further thought and experimental studies on ways of making practical use of this process [15]. The only gases that can be considered are halogens, since only tungsten compounds containing halogen are sufficiently volatile at relatively low temperatures [eq. (c)]. (Carbonyls cannot be used for this purpose).

$$W + n\,X \rightleftharpoons WX_n \qquad (c)$$

[11] *E. A. Scribner*, US.-Pat. 254780 (March 7th, 1882).

[12] *F. Skaupy*, Ger. Pat. 246820 (Dec. 7th, 1909).

The "inversion temperature" depends on the stability of the tungsten compounds formed, and decreases from fluorine compounds to iodine compounds. All parts of the lamp that can react under the experimental conditions, such as leads and supports, must be at a temperature above the inversion temperature. Cooler parts corrode, and this ultimately leads to failure of the lamp. However, the use of reactions with low inversion temperatures is limited by the low reaction rates. On the other hand, it was impossible to maintain the required temperature of a few hundred degrees at all parts of the lamp.

One interesting technical result of this work is the production of metals such as zirconium and titanium by the iodide process developed by *van Arkel, deBoer*, and *Fast*.

During the development of the high-pressure mercury arc between 1930 and 1950, the introduction of the technique of sealing tungsten into quartz lamps enabled the required temperatures to be maintained, and it was only then that the technical production of the halogen lamp became possible. It was described in a patent as early as 1949 [16], but details of the first commercial lamp were not published until 1959 [17]. Iodine was used as the filling on the basis of the (incorrect) thermodynamic data available at that time [18]. The inversion temperatures for the other halogens are too high.

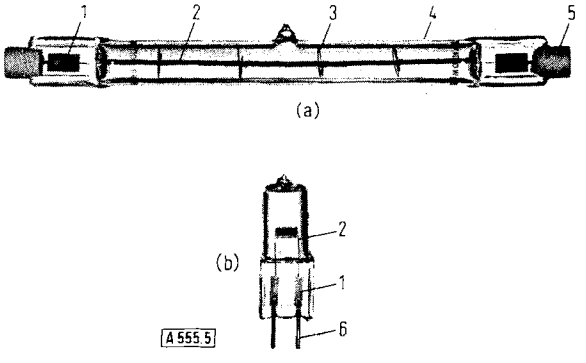

Fig. 5. (a) Halogen photo lamp 220 V, 1000 W; (b) halogen projector lamp, 24 V, 150 W; both lamps half size.

1. Molybdenum foil; 2. tungsten filament; 3. tungsten support; 4. quartz tube; 5. porcelain; 6. nickel pin.

The design of lamps of this type is shown in Figs. 5a and 5b. The cyclic process requires constructions and working conditions different from those of conventional lamps [19]. Thus elongated lamps (Fig. 5a) must be operated within an angle of $\pm$ 4° from the horizontal, since thermal diffusion otherwise causes a depletion of halogen in the upper part of the lamp, leading to premature failure. The envelope, which is made of quartz or a high-melting hard glass, is situated as close as possible to the tungsten coil. The wall temperature is about 600 °C, so that no volatile compounds can condense and be withdrawn from the cycle. The concentration of the iodine vapor is about 0.25 µmole/ml.

[19] *T. M. Lemons* and *E. R. Meyer*, Illuminating Eng. *59*, 723 (1964).

This construction offers a number of advantages. Since the lamp does not blacken during its working life[19a], there is no need for a large bulb, which would also make the high wall temperatures impossible to maintain. The resulting small volume, about 1 % of the volume of a conventional lamp, permits the economical use of the heavier but expensive inert gases. Since the cross section of the cylinder is roughly the same as the thickness of the Langmuir layer, the heat losses are independent of the pressure, as pointed out earlier. These lamps can therefore be operated at high gas pressures. This is made technically feasible by the increase in mechanical strength resulting from the smaller diameter. Both of these measures lead to a decrease in the rate of evaporation. This possibility can be utilized in two ways: the life of the lamp under comparable conditions may be increased, or the filament temperature may be raised, thus giving a higher luminous efficiency and brightness for the same working life (Table 1).

The most recent developments have been directed away from the iodine lamp. Owing to the color of iodine, the iodine concentration must not exceed 0.25 μmole/ml, since light losses otherwise occur owing to absorption. Since it is also difficult to dose small quantities of iodine in the production of these lamps, attempts were made to replace iodine with other halogens. However, the other halogens can hardly be used in the elementary form, since even bromine attacks the cooler leads and supports. Instead of bromine, it is possible to use hydrogen bromide, which is formed by decomposition of easily dosed dibromomethane on the filament[20]. Lamps of this type are already on the market. The small quantity of carbon formed during the decomposition has no effect on the quality of the lamp. In principle, hydrogen chloride may also be used. Absorption is negligible in either case.

Owing to their special properties, the use of halogen lamps is steadily growing[21,22], particularly in photography, as well as in outdoor lighting and in automobile headlights. Many types of lamps (50 to about 10000 W) are in use.

9. Chemical Reactions in Incandescent Lamps

Tungsten diiodide is assumed to be formed in the iodine lamp[17,22–24]:

$$W + I_2 = WI_2 \qquad (d)$$

This assumption is based on the sparse and outdated literature on tungsten iodides[25], and on estimated thermodynamic data on equilibria in tungsten halides[18]. However, more recent calorimetric measurements on tungsten chlorides[26] and bromides[27] have shown considerable deviations from the estimated values (which were not based on any experimental data, with the exception of an incorrect value for WCl_6). Moreover, no experimental evidence has been found for the formation of a binary tungsten iodide under the conditions prevailing in the iodine lamp[28]. An indication of the true state of affairs was provided by the observation that the cyclic process in the iodine lamp requires the presence of small quantities of oxygen.

Various interpretations were offered for this discovery[29], until the stable tungsten dioxide diiodide, WO_2I_2, was prepared[30]. The cyclic process in an iodine lamp containing no oxygen can be started by the introduction of WO_2I_2. On the basis of experiments and observations in the laboratories at Aachen and Eindhoven[*], it is concluded that the reactions shown in Fig. 6 occur in the iodine lamp. This suggestion does not conflict with practical experience[28].

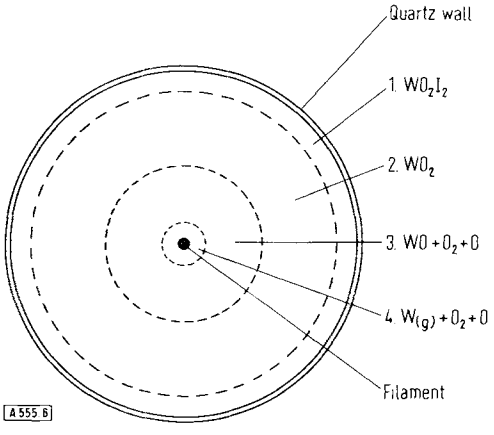

Fig. 6. Transport in an iodine-oxygen lamp. Diagram of the reaction zones with the predominant molecules. The inert gas and iodine, which are present everywhere, are not indicated.

In the neighborhood of the filament (temperature about 3000 °K), tungsten and oxygen react to form a tungsten oxide. Near the wall, the oxide reacts with iodine to form an oxide iodide, which remains gaseous at the high wall temperatures. Owing to the excess of iodine present, WO_2I_2 cannot decompose with deposition of WO_2, which would condense on the wall. It is not yet known whether the oxygen cycle also occurs in the bromine lamp (tungsten bromides are known).

10. The Regenerative Cycle

We have seen that there is no deposition of tungsten in halogen lamps during operation, and hence no blackening of the bulb wall, and that the luminous efficiency

remains practically constant throughout the life of the lamp. The question now arises whether the life of the lamp is also prolonged.

The life of the lamp could be increased only if the tungsten were preferentially transported back to the hottest parts, so preventing the development of hot spots. This condition is certainly not satisfied in the iodine and bromine lamps. The compounds responsible for the deposition of tungsten are completely dissociated before they reach the filament, owing to the high temperature of the latter. The tungsten should therefore be preferentially deposited on the cooler parts of the coil; this ultimately corresponds to an axial transfer of material from hotter to cooler parts of the filament. This process has been demonstrated by tracer techniques [31]. A model lamp contained three filaments the center one having been activated in a reactor. After 220 hours of operation, most of the ^{185}W had been deposited near the ends of the unactivated filaments (Fig. 7).

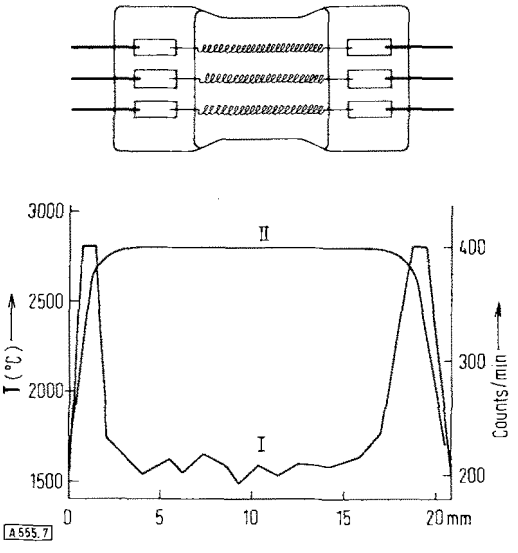

Fig. 7. Transport of tungsten along the filament in a lamp filled with iodine and 0.6 atm of xenon [31]. Top: experimental arrangement, schematic. The center coil contains ^{185}W. Bottom: activity (curve I) of ^{185}W after a burning time of 220 hours, and temperature (curve II) along one of the unactivated coils.

The outstanding improvements achieved with the new lamps are due to the prevention of blackening and the increase in working life resulting from the use of high gas pressures [32, 33] but not to regeneration of the filament. Only the most stable compounds of tungsten can take part in a regenerative cycle. This led *J. Schröder* to study the fluorine cycle in our laboratory [34]. Since fluorine reacts with tungsten even when cold, blackening is prevented even at low temperatures, and any blackening present is reversed.

For example, the blackening on the wall of a tungsten lamp (burning time 10 hours at 3000 °C in argon at 500 mm) could be removed by the introduction of WF_6 (burning time 15 min at 3100 °C, 500 mm of argon + 2 mm of WF_6). Despite considerable experimental difficulties, it could be shown that fluorine has a true regenerative effect. Fluorine is introduced as NF_3, which decomposes on the filament. The glass bulb is protected by a thin layer of MgF_2 and CoF_2. A tungsten loop, the thickness of which has been reduced over half of its length by etching, is heated to high temperatures (Fig. 8a). (The thicker part, which is cooler, is not visible in the photograph). After a burning time of 15 minutes in an atmosphere of WF_6 the loop becomes uniform (Fig. 8b). Microscopic examination shows that its thickness is constant over its entire length. Fig. 9 shows how the temperature along a tungsten coil becomes uniform on treatment with fluorine. In principle, therefore, fluorine satisfies the requirements for a regenerative cycle. Thus while the conditions for a "fluorine lamp" are by no means satisfied, in view of the extreme technological difficulties encountered in the protection of the cooler parts against attack by fluorine, these experiments nevertheless substantiate the above views on the regenerative cycle.

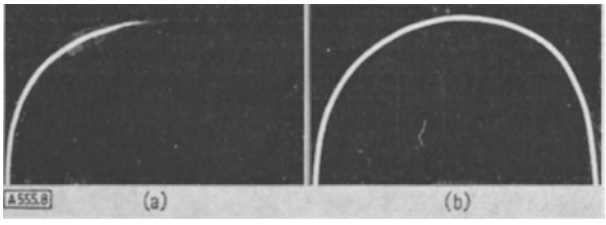

Fig. 8. (a) Tungsten loop immediately after the lamp is switched on. The left-hand side is thinner than the right-hand side. The temperature on the left is 3100 °C, on the right 2800 °C. (b) The same loop after burning for 10 min in 500 mm of Ar + 2 mm of WF_6. The geometry and temperature of the wire have become perfectly uniform (magnification 4×).

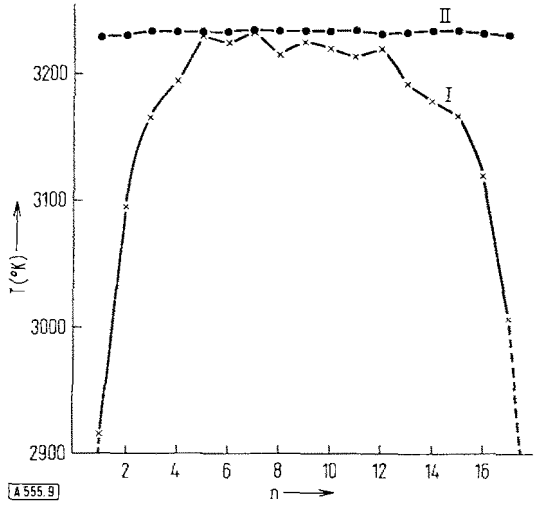

Fig. 9. Temperature along a tungsten filament (n = number of turns). I. No previous treatment. II. Same type of coil, after burning for 5 min in 200 mm of Ar + 4 mm of NF_3.

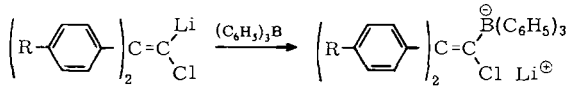
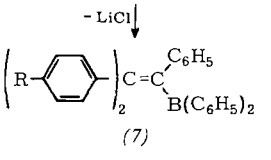
Borate Complexes Derived from Lithium Carbenoids — Mechanism of the "Inverse Stevens Rearrangement" [1]

By *G. Köbrich* and *H. R. Merkle* [*]

Jäger and *Hesse* [2] have contrasted the nitrogen ylides and their ability to undergo the cationotropic Stevens rearrangement, with the boron ylides *(3)* because several anionotropic rearrangements of boron ate-complexes can be ascribed to the fact that the arrangement of their charges is the reverse of that in *(1)*. It has been an open question whether this "inverse Stevens rearrangement" is really to be ascribed to a boron ylide intermediate stage.

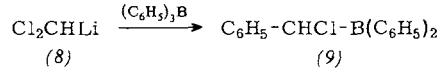


(1) *(2)*



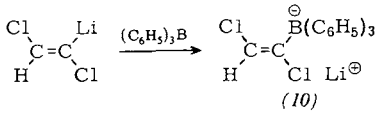
(3) *(4)*

We observed inverse Stevens rearrangements when we treated stable lithium carbenoids *(5)* [3] with triphenylboron. ate-Complexes *(6)* were slowly formed which rearranged to boranes *(7)* with elimination of lithium chloride when the mixture was warmed to room temperature or boiled in tetrahydrofuran.

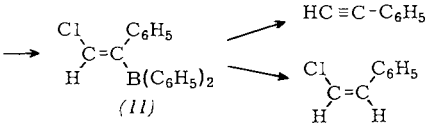


(5) *(6)*

(a), R = H
(b), R = Cl
(c), R = CH_3

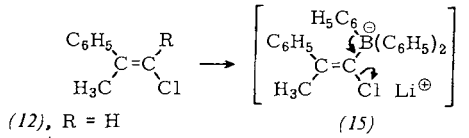


(7)

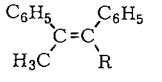


Use of dichloromethyl-lithium *(8)* gives the corresponding (chlorobenzyl)diphenylborane *(9)* The ate-complex *(10)* formed from *trans*-dichlorovinyl-lithium decomposes at −100 °C into pure *cis*-styryl chloride and phenylacetylene (molar ratio about 1:3); presumably the borane *(11)* is first formed.

(8) *(9)*



(10)



(11)

The ate-complex *(14)* formed from *trans*-methylstyryl chloride *(12)* *via* the *trans*-carbenoid compound *(13)* [4] affords 99% pure *cis*-α-methylstilbene *(17)* [yield 65%, calculated on *(12)*] on rearrangement and acid hydrolysis. The *cis*-isomer of compound *(12)* gives 98 % pure *trans*-α-methylstilbene (yield 71 %). These findings exclude a boron ylide intermediate common to the two isomers. The steps *(12)* → *(13)* → *(14)* and *(16)* → *(17)* are electrophilic reactions at the unsaturated carbon atom with retention of configuration. It then follows that the rearrangement step *(14)* → *(16)* occurs with inversion by rear attack *(15)* of the phenyl group on the carbon atom carrying the chlorine substituent.

(12), R = H
(13), R = Li

Ethyl Diazoiodoacetate and its Decomposition to Ethoxycarbonyliodocarbene

By *F. Gerhart, U. Schöllkopf,* and *H. Schumacher* [*]

Halogenodiazomethanes are of interest as precursors of halogenocarbenes and as preparative reagents [1]. We obtained ethyl diazoiodoacetate *(2)*, the first characterized halogenodiazoalkane [2], in about 80% yield when we treated diethyl mercuribisdiazoacetate *(1)* [3] in ether with rather less than 2 equivalents of iodine. The filtrate was concentrated (water-pump, room temperature, rotary evaporator) and the residue was digested with petroleum ether (b.p. 40 °C) to remove the last traces of mercuric iodide. Compound *(2)* is a red oil, stable for days at 0–5 °C, giving IR bands at 2080 and 1680 cm^{-1}. Triphenylphosphazine derivative: m.p. 109 to 112 °C (decomp.; precipitated from benzene by petroleum ether).

(1) *(2)*

(3)

We formulate scission of the carbon-mercury bond by iodine as an S_Ei process, depicted in *(3)* [4]. Since this should proceed also with other reagents, it should be possible to prepare further hetero-substituted diazoacetic esters from the compound *(1)* [5].

Photolysis of *(2)* (450 W Hanovia lamp, Pyrex filter) gave ethoxycarbonyliodocarbene *(4)*, from which we obtained ethyl 1-iodo-2,2-dimethylcyclopropanecarboxylate *(5)* (b.p.

(4) *(5)*

45 °C/0.4 mm; yield 40%; NMR signals of the cyclopropane protons as an AB spectrum at $\tau = 8.7$ with $J_{AB} \approx 6$ Hz) on irradiation of *(2)* in isobutene until evolution of nitrogen ceased. Products formed by insertion in the C–H bond were not detected [6]. We conclude that the carbene *(4)* is more selective than ethoxycarbonylcarbene.

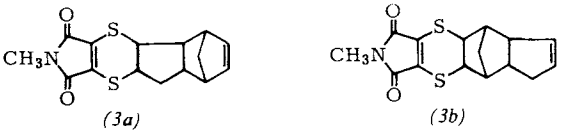
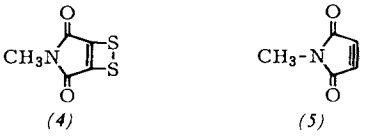
Evidence for the Intermediate Occurrence of Acetylenedicarboxyimide

By *W. Draber*[*]



When 1,4-dithiintetracarboxydiimides *(1)* are heated in pyridine at 120 °C, mellittriimides *(2)* are obtained in yields of up to 50% together with sulfur and unidentified brown products. Small quantities of mellittriimide were also occasionally obtained in the preparation of the dithiins *(1)* from dichloromaleimides and H_2S in the presence of a material such as $CaCO_3$ [1] to neutralize the acid formed. Heating the dithiins without pyridine or in indifferent solvents such as xylene or ethanol does not lead to formation of triimides *(2)*.

(1) *(2)*



R = H, CH_3, C_6H_5-CH_2

An indication of the course of the reaction was given by the formation of a yellow compound, m.p. 137.5–138 °C, yield 7%, that could be isolated chromatographically together with the mono- and di-adducts of cyclopentadiene to *(1)* and 24% of *(2)*, after the dithiin *(1)* had been heated with an excess of dicyclopentadiene and pyridine under nitrogen for 16 hr at 110 °C. The composition and molecular weight correspond to an adduct of 2 moles of cyclopentadiene to one of maleimide and 2 g-atoms of sulfur. IR spectrum in KBr: 1765, 1715, 1700 cm^{-1} (imide-CO); 1600 (C=C); 1550 (imide-C=C). UV spectrum in ethanol: 240 mμ (log ε = 3.38), 267 (3.85), 424 (3.34). These results indicate a dimercaptomaleimide system. The NMR spectrum at 90 MHz in $CDCl_3$ [τ = 4.34 (2 olefinic protons), 6.97 ($N-CH_3$), 8.42 (1 H), poorly resolved multiplet at τ = 6.4 to 7.9 (9 H)] does not permit unambiguous decision between the structures *(3a)* and *(3b)*.

(3a) *(3b)*

The formation of *(3a)* or *(3b)* is preferred to an asymmetrical decomposition of *(1)* to a compound *(4)* [2] and acetylenedicarboxyimide *(5)*, from which *(2)* is then obtained. The Diels-Alder adduct of cyclopentadiene to *(5)*, not hitherto described, would probably not be stable under the reaction conditions.

(4) *(5)*

Attempts to prepare the Diels-Alder adduct of cyclopentadiene to acetylenedicarboxylic anhydride from the corresponding acid by dehydration with acetic anhydride gave a substance that polymerized rapidly even at room temperature.

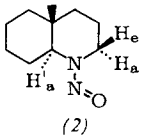
Anisotropic Effects in Heterocyclic Nitrosamines

By *Y. L. Chow*[*]



The restricted rotation about the partial N–N double bond of a nitrosamino group derived from a symmetrical amine gives rise to different NMR chemical shifts for the *cis*- and *trans*-α-methylene protons [**]. A conformationally "frozen" heterocyclic nitrosamine should allow direct observation of the long-range shielding of the nitrosamino group, provided that inversion at the amine center is slow.

The 4-substituted *N*-nitrosopiperidines *(1b)* and *(1c)* give four well-separated signals, corresponding to the four α-protons in different environments (see Table 1). The signals were assigned on the basis of their splitting pattern and coupling constant [1] and by decoupling experiments at 100 MHz. The equatorial protons H_e and H'_e, being coplanar, or nearly so, with the $C_\alpha-N-N-O$ plane, absorb at approximately the same (lower) field [2], whereas the axial protons H_a and H'_a absorb at higher fields. Since H_a is situated inside the semi-circular shielding zone of the nitrosamino group, its signal appears at a far higher field. This anisotropy is even better manifested by an unusually large

chemical shift difference ($\Delta\delta$ = 2.4–2.9 ppm) between the axial (H_a) and equatorial (H_e) protons of the *cis*-methylene group. In contrast, the corresponding chemical shift difference of the *trans*-methylene group is much smaller ($\Delta\delta'$ = 1–1.4 ppm).

(1a), R = H
(1b), R = CH_3
(1c), R = CH_2-C_6H_5

(2)

The conformationally rigid and unsymmetrical *trans*-decahydroquinoline gives the *anti*-nitrosamine *(2)* as the sole nitrosation product. The Dreiding model shows that the rigidly held equatorial proton of the β-methylene group in the cyclohexane ring is close to the oxygen in the *syn*-configuration and thus destabilizes this configuration. The chemical shifts of the *cis*-α-methylene protons and particularly the large difference (2.73 ppm) between the shifts of the axial and equatorial protons lead unambiguously to the *anti*-configuration assignment for the nitrosamine *(2)*.

The NMR spectrum of conformationally mobile *N*-nitrosopiperidine *(1a)* is considerably simplified due to rapid interconversion of the conformers, whereby the axial and equatorial protons give an average signal. Since the two conformers are energetically equivalent, the signal of the *cis*-α-methylene protons should occur half-way between the H_a and H_e signals. The observed signal at τ = 6.35 is therefore assigned to *cis*-α-methylene protons and that at τ = 5.87 to *trans*-α-methylene protons. In acyclic nitrosamines *cis*-α-methylene protons also absorb at a higher field than *trans*-α-methylene protons[3].

Table 1. NMR data of nitrosamines at 60 MHZ (τ values, Varian A 56/60 spectrometer, $(CH_3)_4Si$ as internal standard).

Compound	Solvent	H_a	H_e	$\Delta\delta$ [a] (ppm)	H'_a	H'_e	$\Delta\delta'$ (ppm)
(1b) [b]	CCl_4	7.50	5.15	2.35	6.35	5.38	0.87
	C_6H_6	7.83	5.18	2.65	6.80	5.57	1.23
(1c) [b]	CCl_4	7.62	5.17	2.45	6.47	5.38	1,09
	C_6H_6	8.05	5.18	2.87	7.02	5.62	1.40
(2)	CCl_4	7.63 [c]	4.90 [d]	2.73	6.68	—	—
	C_6H_6	7.67	4.83	2.84	7.11	—	—
(1a)	CCl_4		6.35			5.87	
	C_6H_6		6.57			6.23	

[a] $\Delta\delta = \tau(H_a) - \tau(H_e)$.

[b] The axial protons show a triplet, each split into doublets, $J_{gem} \approx J_{aa} \approx$ 12–13 Hz, J_{ae} = 3–4 Hz. The equatorial protons show a doublet that is further split into multiplets. J_{gem} = 13 Hz; $W^1/_2$ = 6–7 Hz.

[c] Determined by decoupling experiments.

[d] Each doublet is further split into multiplets, J_{gem} = 14 Hz and $W^1/_2$ = 7 Hz.

1,5-Diazabicyclo[5.4.0]undec-5-ene, a New Hydrogen Halide Acceptor

By *H. Oediger* and *Fr. Möller*[*]

1,5-Diazabicyclo-4.3.0]non-5-ene *(1)* can be used to introduce double bonds by removal of hydrogen halide[1,2]. We have now found that 1,5-diazabicyclo[5.4.0]undec-5-ene *(2)*, obtained, analogously to *(1)*[1,3] from caprolactam and acrylonitrile by way of compounds *(3)* and *(4)*, is considerably superior to the base *(1)* for this purpose.

(1)

(3) *(4)* *(2)*

As shown in the table, the yields of alkene are considerably improved by use of the base *(2)*.

Bromoalkane	Alkene	Yield (%) on use of *(1)*	Yield (%) on use of *(2)*
4-Bromoheptane	3-Heptene	60	91
2-Bromoheptane	1- and 2-Heptene (*ca.* 1:4) [a]	36	78
2-Bromooctane	1- and 2-Octene (*ca.* 1:4) [a]	40	84

[a] Molar proportions.

Method: A mixture of equimolar amounts of bromoalkane and base is warmed to 80–90 °C and the alkene formed is distilled off. A solvent such as dimethyl sulfoxide may be added.

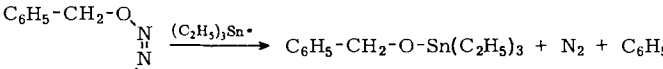
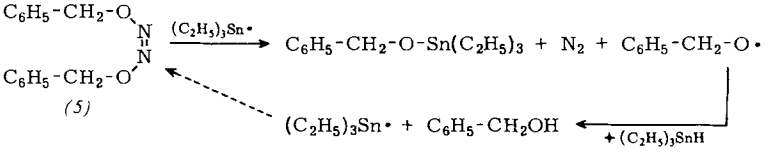
Free-Radical Decomposition of Azo Compounds Induced by Organotin Hydrides



By *W. P. Neumann* and *H. Lind*[*]

We have observed a radical-induced decomposition of the azo compounds R–N=N–X–R′ and R–X–N=N–X–R′, where X is a covalently bound polar group.



Homolysis of phenyl phenylazo sulfone *(1)*[1] in dilute toluene solution is accelerated ten-fold, even at 80 °C, if an organotin hydride is present ($t_{1/2}$ = 8 min). Benzene, N_2, and a stannyl phenylsulfinate *(2)*, m.p. 67 °C, are formed in equimolar amounts. Occurrence of free phenylsulfonyl radicals can be excluded; they would afford the sulfinic acid and, with further hydride, H_2. Stannyl radicals *(3)* induce the acceleration and their covalent attachment to the sulfonyl group is synchronous with the detachment of the azo group (S_R2 mechanism).

A side reaction is the free-radical hydrostannation of *(1)* at the azo group to the hitherto unknown *N'*-phenyl-*N*-phenylsulfonyl-*N*-stannylhydrazines, *e.g. (4)*, m.p. 116 °C, the yield of which depends on the relative amounts of the reagents and on the temperature.

Homolysis of dibenzyloxydiimide *(5)* [2] cannot be induced in solution, either by increasing the concentration of the diimide, or by the radical scavengers galvinoxyl [**], iodine, chloranil, methanol, or *p*-t-butylthiophenol. It is first order in benzene, chloroform, and chlorobenzene, giving 1.0 mole of N_2, 0.50 mole of benzyl alcohol and, contrary to previous assumption [2], only 0.25 mole of benzaldehyde, together with a resin of average composition $(C_6H_5{-}CHO)_4$ and some benzyl benzoate. Evidently the benzaldehyde captures benzyloxy radicals.

However, in dilute benzene solution at 30 °C the homolysis of the diimide *(5)* is accelerated eight-fold if an organotin hydride is added ($t_{1/2}$ = 22 min). This effect is largely eliminated by the powerful radical-trapping agent galvinoxyl. An S_R2 mechanism operates here also, attachment of a benzyloxy group to the attacking stannyl radical being synchronous with its detachment from the azo group. The other benzyloxy group is liberated as a radical and then is trapped by the hydride. N_2 is also formed.

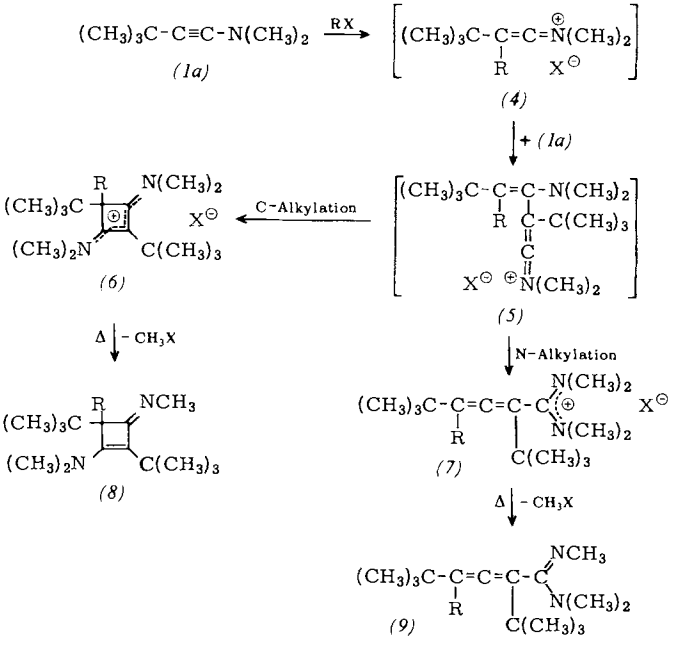
Acylation, Alkylation, and Protonation of Alkynylamines [1]

By *H. G. Viehe, R. Buijle, R. Fuks, R. Merényi*, and *J. M. F. Oth* [*] [2]



On acylation with acyl chlorides (such as C_6H_5COCl. CH_3COCl, $COCl_2$) in toluene at room temperature alkynylamines (ynamines) *(1)* afford 2-acyl-1-chloroalkenylamines *(2)*, which are hydrolysed to 2-acylcarboxamides *(3)* by water even at room temperature.

R^1	R^2	Ac	R^3	*(2)*	*(3)*
$(CH_3)_3C$	CH_3	COCl	CO_2H	B.p. 76–78 °C/0.5 mm, yield, 85 %	M.p. 127 °C, yield 94 %
C_6H_5	C_2H_5	COC_6H_5	COC_6H_5	Not isolated	M.p. 112 °C, yield 88 %
CH_3	$R^2_2 = (CH_2)_5$	$COCH_3$	$COCH_3$	Not isolated	B.p. 93 °C/0.2 mm, yield 91 %

Alkylation of (3,3-dimethyl-1-butynyl)dimethylamine *(1a)* with methyl bromide and reaction with a second molecule of alkynylamine gives the salts *(6)* and *(7)*. The ketene iminium salt of type *(4)* is probably first formed and reacts with further alkynylamine to afford the iminium salt *(5)* and this is then stabilized by intramolecular *N*- or *C*-alkylation. When 5.3 g (42 mmoles) of compound *(1a)* is heated with 3.4 g (36 mmoles) of methyl bromide without a solvent in a sealed tube for 30 hr at 90 °C, a solid salt mixture (yield 73 %) is formed that contains 35 % of the "cyclobutanecyanine" *(6)*, R = CH_3, and 65 % of the amidinium salt *(7)*. These products can be separated by recrystallization from acetone. Both salts lose methyl bromide on distillation, *(6)* giving an 80 % yield of the iminocyclobutenylamine *(8)* at 250 °C/0.2 mm, and *(7)* giving a 94 % yield of the allenecarboxamidine *(9)* at 225 °C/0.2 mm.

On protonation of the alkynylamine *(1a)* with HCl or HBF_4, only the cyclobutanecyanine *(6)*, R = H, is formed. A solution of 3 mmoles of HCl in 20 ml of dichloromethane is added slowly to 6 mmoles of compound *(1a)* in 5 ml of dichloromethane at −5 °C. The salt *(6)*, R = H, X = Cl, remains on evaporation of the solution and is recrystallized from alcohol/

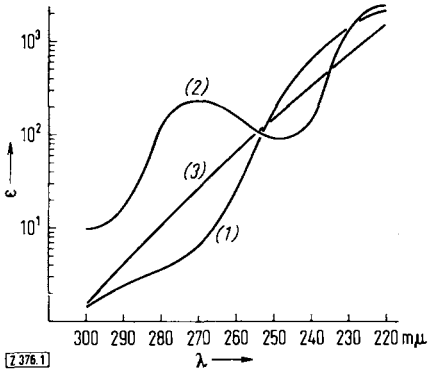
Synthesis of Hexamethylprismane

By *W. Schäfer, R. Criegee, R. Askani,* and *H. Grüner* [*]

If a solution of 80 g of hexamethyl(Dewar benzene) *(1)* [1] in 450 ml of anhydrous ether is irradiated for 170 hr at *ca.* 3 °C by UV light of wavelength 254 mμ (33W low-pressure immersion lamp; Hanau, type PL 368-NK 6/20), a mixture of hexamethylbenzene *(2)* (yield, 11 g = 14%) and hexamethylprismane *(3)* (yield, 4 g = 5%) is obtained and 80% of the starting material is recovered.

(1)

(2) *(3)*



The ether is distilled off at atmospheric pressure, the main part (8–9 g) of the product *(2)* is filtered off, and the filtrate is distilled in a water-pump vacuum, yielding a mixture, b.p. 58–60 °C/18 mm, of *(1)* and the prismane derivative *(3)* which is readily volatile because of its spherical shape [distillation residue *ca.* 1.5 g of *(2)*]. The mixture, which has solidified after 12 hr in a refrigerator, melts on warming slowly to room temperature on a Buchner funnel under nitrogen. Hexamethylprismane *(3)* forms the filter cake and is recrystallized from, *e.g.*, ethanol.

Irradiation of a 1% ethereal solution of *(1)* at 0 °C for 3 hr with a 100W low-pressure mercury lamp (Gräntzel, Karlsruhe) gives a mixture of *(3)* 7%, *(1)* 47%, and *(2)* 45%. After distilling off the ether the residue is treated with ethanol (25 ml for 5 g of mixture). Hexamethylprismane distils in a rotary evaporator with the alcohol at 25 °C/30 mm and crystallizes out when the receiver is cooled to −30 °C.

Hexamethylprismane forms colorless prisms of m.p. 91 °C. It is sensitive to shock and deflagrates when rubbed in a mortar or placed in a flame. It explodes when placed in a melting-point capillary on a block heated at 250 °C or when concentrated sulfuric acid or iodine is added to it in a test tube.

As expected, the NMR spectrum shows only one singlet τ = 9.03.

The IR spectrum, which contains few lines, is characterized by bands (measured for a molten film) at 2850–2950 (s), 2722 (w), 1440 (s), 1375 (m), 1085 (w), 1045 (s), and 803 (s) cm^{-1} [2].

UV spectrum of hexamethylbenzene *(2)*, hexamethyl(Dewar benzene) *(1)*, and hexamethylprismane *(3)* in isooctane.

The UV absorption of *(3)* is unexpectedly intense, as is that of *(1)*, in the region where aromatic and conjugated systems absorb.

Pyrolysis of *(3)* in *o*-dichlorobenzene can be followed by means of the NMR spectrum. At 110 °C half of it has reacted after 2 hr to give a mixture containing 62% of *(2)* and 38% of *(1)*. Since the half-reaction time for the con-

version *(1)* → *(2)* is 2 hr only at 150 °C, the pyrolysis *(3)* → *(1)* + *(2)* must proceed to some extent by way of an intermediate of high energy.

Hexamethylprismane is the third prismane derivative to become known[3,4].

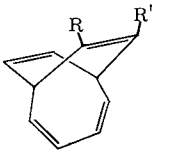
Preparation of Derivatives of Bicyclo[4.2.2]deca-2,4,7,9-tetraene from Tricarbonylcyclooctatetraeneiron

By *U. Krüerke*[*]

We have prepared derivatives of bicyclo[4.2.2.]deca-2,4,7,9-tetraene *(1)* by addition of alkynes to the monocyclic form of cyclooctatetraene. Our starting material was tricarbonylcyclooctatetraeneiron *(2)* in which the metal atom is π-bonded to two of the double bonds[1].

When an equivalent amount of tolan is slowly (1 hr) added to the complex *(2)* in boiling mesitylene under nitrogen a hydrocarbon $C_{22}H_{18}$, m.p. 147–148 °, whose NMR spectrum is in accordance with the structure *(4a)* is formed, besides hexaphenylbenzene and $Fe_2(CO)_6(C_{28}H_{20})$ *(3)*[2]. Repeated chromatography on Al_2O_3 (eluent hexane/benzene-5 %) was necessary to separate the products *(3)* and *(4)*. Passage of carbon monoxide during the reaction increased the yield of *(4a)* to 35 %. The carbon monoxide stabilises the tricarbonyliron group in its complex *(2)* and almost wholly prevents the carbonylmetal-catalysed trimerisation[3] of tolan. No further increase in yield results when the carbon monoxide is under slight pressure (2–4 atm). Free cyclooctatetraene does not react with tolan over a period of 2 hr at 160 °C.



The compounds *(4b)* (m.p. 53 °C; yield 15 %) and *(4c)* (m.p. 74 °C; yield *ca.* 10 %) are formed from the complex *(2)* and methyl phenylpropiolate or trimethyl(phenylethynyl)silane, respectively. Attempted synthesis by reaction of *(2)* with $CH_3C{\equiv}CCH_3$, $C_6H_5C{\equiv}CH$, $C_6H_5C{\equiv}CCN$, and $CH_3OOCC{\equiv}CCOOCH_3$ was unsuccessful since trimerisation of the alkyne, formation of organoiron carbonyls, and decomposition predominated. Some 2,3-dimethylnaphthalene was obtained in the reaction with $CH_3C{\equiv}CCH_3$. $C_6H_5C{\equiv}CH$ yielded, besides a little 2-phenylnaphthalene, as main product a carbonyliron complex *(5)*, m.p. 180–181 °C (with slow decomp.), whose NMR spectrum indicated the presence of 9,10-dihydro-2-phenylnaphthalene as ligand.

Occurrence of the naphthalene derivatives demonstrates the primary formation but thermal instability of derivatives of bicyclo[4.2.2]decatetraene also in these reactions. In fact, the compound *(4a)* decomposes at 170–180 °C in a sealed and evacuated (*ca.* 10^{-3} mm) tube, mainly to 2,3-diphenylnaphthalene and diphenylbicyclo[3.3.2]deca-2,6,9-triene *(6)*, m.p. 110 to 116 °C. It was not possible to isolate the further products that were shown by thin-layer chromatography. The NMR spectrum of a non-crystalline hydrocarbon mixture gave no evidence for the presence of diphenylbullvalenes.

The compound *(6)* gives a very complicated NMR spectrum, so that the positions of the phenyl groups could not be determined unambiguously; but positions 2,6, 3,7, and 9,10 can be excluded on symmetry grounds. Since the melting point of the compound is unsharp a mixture of isomers may be present alongside a main component.

After irradiation of compound *(4a)* in cyclohexane with UV light for 5 hr at 20 °C, column chromatography on Al_2O_3 (eluent hexane/benzene -50 %) led to isolation of unchanged *(4a)* (40 %) and a viscous oil of composition $C_{22}H_{18}$ whose NMR spectrum was temperature-dependent and which thus probably contained diphenylbullvalene. It has not yet been possible to separate the components disclosed by the NMR spectrum; all the components of the oil decompose rapidly on thin-layer chromatography on SiO_2.

We have been unable to confirm the formation of bullvalene from the complex $(C_{10}H_{10})Fe_2(CO)_6$[4] which contains the ligand *(1)*.

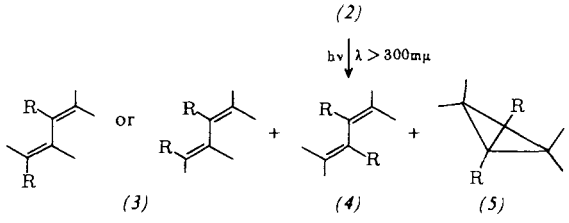
Double 1,3-Dipolar Addition to a Triple Bond to give the Bicyclo[1.1.0]butane System

By *M. Franck-Neumann*[*]

Acetylenes and secondary diazoalkanes give 3*H*-pyrazoles[1], pyrolysis of which leads to cyclopropenes[2]. We have found that dimethyl acetylenedicarboxylate and the very reactive 2-diazopropane[3] afford dimethyl 3,3a,6,6a-tetrahydro-3,3,6,6-tetramethylpyrazolo-[4,3-*c*]pyrazole-3a,6a-dicarboxylate *(2)* together with dimethyl 3,3-dimethyl-3*H*-pyrazole-4,5-dicarboxylate *(1)*:

(1) *(2)*

The compound *(2)*, m.p. 59 °C, is obtained in 85 % yield by using an excess of 2-diazopropane under the following conditions: Dimethyl acetylenedicarboxylate is added dropwise to a well stirred, red solution of 2-diazopropane in ether/xylene at −20 °C until discoloration occurs. A further amount of diazopropane (50% of the amount previously employed) is added to the mixture which is then allowed to stand at room temperature until it becomes colorless. It is then filtered and the solvents are removed from the filtrate by evaporation *in vacuo*, whereupon the compound *(2)* crystallizes on standing.



The product *(1)* has a strong IR absorption band at 1735 cm^{-1} (α,β-unsaturated ester) and a further strong band at 1635 cm^{-1} characteristic of 3*H*-pyrazoles [4], but *(2)* absorbs only at 1745 cm^{-1} (ester) and 1560 cm^{-1} (azo group). UV spectra (in C_2H_5OH) confirm the structures assigned [*(1)*: λ_{max} = 358 mμ (ε = 168), 244 mμ (ε = 4450); *(2)*: λ_{max} = 328 mμ (ε = 237)].

NMR spectra of compounds *(1)* to *(5)* (tetramethylsilane as internal standard; δ values in ppm; unspecified signals are singlets; q = quartet)

Compound	CH_3 on sat. C atom	CH_3 on double bond	$R-CO_2-$	Intensity ratio

[*] With J = 1.5 Hz.

On irradiation of the pyrazolopyrazole in benzene with a high-pressure Hg lamp, N_2 was evolved and three isomers *(3)*, *(4)*, and *(5)* (ratio 1:2:2; total yield 50 %) of composition $C_{12}H_{18}O_4$ were formed, as well as other products which were not obtained pure. The three isomers were separated by column and gas chromatography (silicone column, 150 °C). UV spectra: *(3)*, λ_{max} = 216 mμ (ε ≈ 21000); *(4)*, λ_{max} = 219.5 mμ (ε ≈ 18000); *(5)*, λ_{max} = 213.5 mμ (ε ≈ 8000). The IR spectra of *(3)* and *(4)* indicate an α,β-unsaturated ester group (C=O and C=C bands), but *(5)* gives only one band, at 1725 cm^{-1} (ester), in the 1500 to 2000 cm^{-1} region. From these data and the NMR values given in the table the structures illustrated are assigned to compounds *(3)*, *(4)* and *(5)*.

(3) *(4)* *(5)*

As expected [5], compound *(5)* is thermally unstable; when it is heated at 150 °C, it affords, besides other compounds, the substance *(4)* which is the sole gaseous pyrolysis product at 270 °C. The half-reaction time for ring opening of *(5)* at 150 °C is about 3 hr (NMR analysis in perchlorobutadiene).

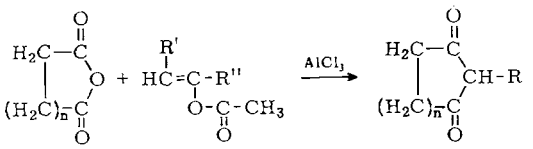
Synthesis of 2-Alkyl-1,3-cycloalkanediones by Friedel-Crafts Acylation

By *H. Schick, G. Lehmann*, and *G. Hilgetag* [*]

2-Alkyl-1,3-cyclopentanediones are important intermediates in the total synthesis of steroids [1–3]. They have hitherto been prepared by multistage processes [4–6].

We have found that 2-alkyl-1,3-cyclopentanediones *(1)*, n = 1, are obtained in a single step by condensation of succinyl chloride with carboxylic acids under Friedel-Crafts conditions.

(1)



(1), R	*n*	Yield (%)	M.p. (°C)
CH_3	1	35 [a] 45 [b] 25 [c]	214–216
C_2H_5	1	30 [b]	175–177
CH_3	2	40 [b]	204–206

[a] In 500 ml of 1,2-dichloroethane. [b] In 300 ml of nitromethane. [c] In 300 ml of nitrobenzene.

When glutaryl chloride is used in place of succinyl chloride, 2-alkyl-1,3-cyclohexanediones *(1)*, n = 2, are formed. Nitromethane, nitrobenzene, and 1,2-dichloroethane are suitable solvents.

Succinic anhydride or succinyl chloride react analogously with enol acetates of aldehydes, methyl alkyl ketones, symmetrical dialkyl ketones, or cyclic ketones to give 2-alkyl-1,3-cyclopentanediones *(2)*, n = 1, in a single step. Use of glutaryl chloride instead of succinic acid derivatives yields 2-alkyl-1,3-cyclohexanediones *(2)*, n = 2.

2-Methyl-1,3-cyclopentanedione: 1) 155 g (1 mole) of succinyl chloride and 148 g (2 moles) of propionic acid are added to a suspension of 320 g (2.4 moles) of $AlCl_3$ in 300 ml of nitromethane with cooling and exclusion of moisture. The mixture is heated for 3 hr at 80 °C, then cooled to 10 °C and poured

onto 500 g of ice. After cooling to about 0 °C, the crude 2-methyl-1,3-cyclopentanedione that has separated is filtered off, washed with 50 ml of cold water, and recrystallized from water (with charcoal). The aqueous phase of the filtrate is boiled with charcoal, filtered, and continuously extracted with ether. A second fraction crystallizes after concentration of the ether extract. Total yield, 50 g (45 %).

2) Methyl ethyl ketone enol acetate (114 g; 1 mole) is added over 10 min to a solution of 264 g (1 mole) of sublimed $AlCl_3$ and 100 g (1 mole) of succinic anhydride in 500 ml of anhydrous nitromethane with exclusion of moisture and cooling in ice; the temperature rises to 30–40 °C. The mixture is heated for $3^1/_2$ hr at 80 °C, then cooled to about 10 °C and poured onto 400 g of ice. The crude 2-methyl-1,3-cyclopentanedione deposited is filtered off, washed with 50 ml of cold water, and recrystallized from water with charcoal. A further crop can be obtained by boiling the aqueous phase of the filtrate with charcoal, filtering, and extracting with ether. Total yield, 56 g (50 %).

A New Ring-Closure Reaction

By *H. J. Bestmann* and *E. Kranz* [*]

Dihalogen compounds of type *(1)* react with methylenetriphenylphosphorane *(2)* in boiling benzene to give phosphonium salts *(3)*, which at once react with a second molecule of the phosphorane *(2)*, yielding by "transylidation" [1] the ylides *(5)* and methyltriphenylphosphonium halide *(4)* [2]. The alkylidenephosphoranes *(5)* give the cyclic phosphonium salts *(6)* by intramolecular *C*-alkylation [2,3].

	Y	(8), R = C_6H_5 B.p. (°C/mm) or m.p. (°C)	(8) Yield (%)

9	$-(CH_2)_2-$	145 [a]	64
10	$-(CH_2)_3-$	184 [a]	71
11	$-(CH_2)_4-$	62–64/3	61

[a] M.p. of dinitrophenylhydrazone.

In the examples 5–8 of the table, the bromomethyl group in the corresponding dihalogen compounds *(1)* must be in the *cis* position with respect to the ring. Example 5 then gives the bicyclic compound *(10)*, example 8 leads to the oxygen-bridged compound *(11)*. The synthesis of the compound *(12)* *via* example 4 demonstrates the possibility of preparing spiro compounds by means of the new ring closure method.

The structures of the compounds *(8)* and *(9)* were proved by elemental analyses and UV, IR, and NMR spectra.

The intermediates *(3)* and *(5)* were not isolated. The mixture of salts *(4)* and *(6)* is precipitated from the reaction medium. Since *(4)* readily dissolves in water it can usually be easily separated from the less soluble *(6)*. In many cases, however, this separation is unnecessary before further reaction. The yields of *(6)* or of the mixture of *(4)* and *(6)* amount to 75–95 %.

The salt *(6)* can again be converted by bases into an ylide *(7)*, which can be used in various reactions [2,4]. Thus the Wittig reaction [5] of the ylide *(7)* with aldehydes gives cyclic

compounds with exocyclic double bonds *(8)*, and on autoxidation [6] it gives cyclic ketones *(9)*.

Experimental:

A solution of 1 mole of the dihalogen compounds *(1)* in benzene is added to a salt-free solution of 2 moles of the ylide *(2)* in pure benzene [4] (the addition is carried out dropwise and slowly while the reactants are stirred under reflux). After a short time a mixture of *(4)* and *(6)* begins to precipitate, the reaction being completed as soon as the yellow color of the ylide has disappeared.

A salt-free solution of the ylide *(7)* in absolute tetrahydrofuran is prepared from the salt *(6)* or the mixture *(4)* and *(6)* (if these have proved inseparable). On addition of an aldehyde *(7)* undergoes a Wittig reaction [5] or autoxidation of the solution occurs [6]. After evaporation of the solvent the residue is extracted with a little ether, whereupon a large part of the triphenylphosphine oxide produced remains undissolved. The remaining triphenylphosphine oxide is removed from the ether extracts on an alumina column (activity: Grade II; eluent ether). After evaporation of the eluted solvent, the products *(8)* and *(9)* are obtained by fractional distillation.

All operations in which the ylide is present must be carried out in an atmosphere of dry nitrogen.

Synthesis of 7-Amino-6-methoxy-5,8-quinolinedione

By *T. K. Liao, W. H. Nyberg*, and *C. C. Cheng* [*]

The antitumor antibiotic streptonigrin *(1)* [1] contains a 5,8-quinolinedione system, the attempted synthesis of which has so far yielded only 7-amino-6-hydroxy-5,8-quinolinedione *(2a)* [2].

(1)

(2), X = OCH_3, Z = NH_2
(2a), X = OH, Z = NH_2
(3), X = OCH_3, Z = Br
(4), X = NH_2, Z = Br
(5), X = OCH_3, Z = N_3

We have now synthesised 7-amino-6-methoxy-5,8-quinolinedione *(2)*. On bromination [3] of 6-methoxy-5,8-quinolinedione [4], 7-Bromo-6-methoxy-5,8-quinolinedione *(3)*, m.p. 185 to 187 °C (decomp.), was formed in quantitative yield. However, ammonolysis of *(3)* in water or ethanol at room temperature did not yield *(2)*, but gave exclusively 6-amino-7-bromo-5,8-quinolinedione *(4)* m.p. 314 °C (decomp.) by the nucleophilic attack [3,5] of NH_3 at the 6-position. When compound *(3)* was treated with an equimolar amount of sodium azide in 50 % aqueous ethanol at room temperature, a near quantitative yield of 7-azido-6-methoxy-5,8-quinolinedione *(5)* [orange-yellow flakes; m.p. 145 °C (decomp.); IR bands at 1270 (aromatic ether), 1652 and 1680 (carbonyl), 2130 cm^{-1}, (azide)] was obtained, possibly by nucleophilic attack [5] and addition of an azide ion at the 6-position whereupon a triazol ring closure, $Br^{\ominus}$ loss, and synchronous ring opening take place at the 7-position.

Hydrogenation [6] of *(5)* in methanol at room temperature with hydrogen and platinum oxide affords 7-amino-6-methoxy-5,8-quinolinedione *(2)* as dark purple flakes [m.p. 202–203 °C (decomp.), from ethylacetate; λ_{max} (at pH = 1 and 11) = 232 mμ (ε = 16300 and 17000), 271 (13700 and 17400), 475 (2550 and 2800); IR bands: 1270 (aromatic ether), 1700 (carbonyl), 3250 (hydroxyl), 3500 cm^{-1} (amino)].

The further synthesis of streptonigrin *(1)* from *(2)* can be outlined as a multistep addition of *(2)* to 4-[2-alkoxy-3,4-dimethoxy]-5-alkylamino-6-lithium-3-methyl-2-pyridinecarboxylate.

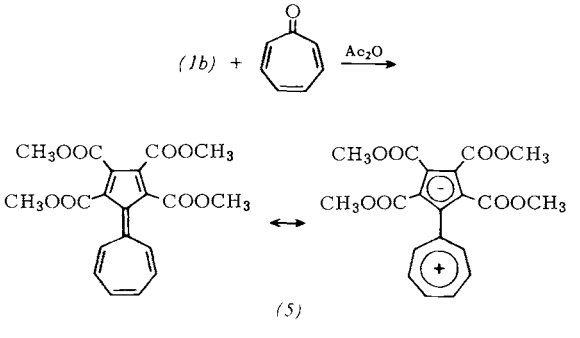
				452	(4.46) Sh	

[a] In methylene chloride. Only the longest-wavelength bands are recorded. Sh denotes shoulder

We have found that substituted cyclopentadienes such as tetrachlorocyclopentadiene *(1a)*[2] and tetramethyl 1,2,3,4-cyclopentadienetetracarboxylate *(1b)*[3] react with 4-pyrones *(2a)* to *(2c)* in acetic anhydride even at room temperature, yielding deeply colored cyclopentadienylidenepyrans *(3)*. After 12 hr the precipitated crystals are collected and recrystallized from acetonitrile or dimethylformamide.

The compounds *(3)* exchange oxygen for nitrogen with primary amines, smoothly yielding *N*-substituted 1,4-dihydro-4-cyclopentadienylidenepyridines *(4)*. The mixture of amine and pyran is warmed in dimethylformamide; when it is cooled the product crystallizes and can be recrystallized from dimethylformamide [*(4c)* from methanol].



(4)

	X	Y	R	M.p. (°C)	λ_{max} (mμ)	(log ε)	Yield (%)
(4a)	Cl	CH_3	CH_3	>150 (decomp.)	432	(4.58)	48
(4b)	Cl	CH_3	$CH_2C_6H_5$	>170 (decomp.)	436	(4.64)	42
(4c)	$COOCH_3$	CH_3	CH_3	238	424	(4.34)	25

Attempts to replace the oxygen of *(3)* by sulfur with sodium sulfide or sodium hydrogen sulfide were unsuccessful. However, *(1a)* can also be converted in acetic anhydride to the cyclopentadienylidenethiopyrone corresponding to *(3b)* with 2,6-diphenyl-1-thiopyrone (yield 43%, m.p. 264 °C, λ_{max} = 505 mμ, log ε = 4.55 in CH_2Cl_2).

Tetramethyl 7,8,9,10-sesquifulvalenetetracarboxylate *(5)*, which is iso-π-electronic with the cyclopentadienylidene-pyrans and -dihydropyridines, was obtained in 60% yield from *(1b)* and tropone; it crystallizes from the reaction mixture as permanganate-colored needles with a metallic luster, m.p. 209 °C (decomp.), λ_{max} = 540 mμ (log ε = 4.39), 251 (4.48) in CH_2Cl_2. The NMR spectrum of *(5)* (in D_3CSOCD_3, tetramethylsilane as internal standard) shows two sharp singlets (intensity 6) at 3.70 and 3.75 ppm for the

(5)

12 methoxy protons. The signal for the six protons of the tropylium system at 8.46 ppm is a broad singlet; it shows that the hydrogen atoms are almost equivalent. The shift to lower fields indicates a high contribution of the ionic limiting structure to the ground state of the molecule.

A New Synthesis of Isothiazoles [**]

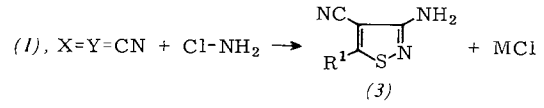
By *K. Hartke* and *L. Peshkar* [*]

Active methylene groups can be thioacylated[1,2] with esters of dithiocarboxylic, thionocarboxylic, trithiocarbonic, or xanthic acid in anhydrous ethanol in the presence of an equimolar amount of alkali alkoxide as catalyst within a few hours at room temperature. The hitherto unknown salts *(1)* that are formed (in yields of over 70%) either separate or can be isolated after evaporation of the solvent. In order to characterize these salts, some of which are hygroscopic, they are

(1)

(2)

R = S-Alkyl, O-Alkyl
M = Na, K



(2)	X	Y	R^1	B.p. (°C/mm) or m.p. (°C)	Yield (%)
(a)	CN	CN	CH_3	36.5	60
(b)	CN	CN	C_6H_5	98	60
(c)	CN	CN	$C_6H_5CH_2$	73.5	95
(d)	CN	CN	SCH_3	80	50
(e)	CN	CN	OC_2H_5	47	60
(f)	CN	$CONH_2$	CH_3	149	60

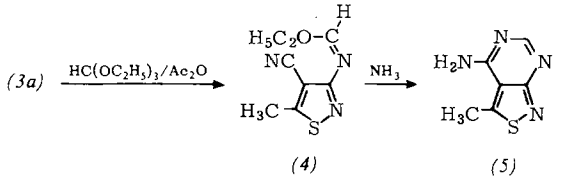
methylated to the sulfides *(2)*. The salts are dissolved or suspended in ethanol and left with a small excess of methyl iodide at room temperature for about 1 hr; after evaporation of the ethanol and addition of water the crystalline sulfides *(2)* are filtered off, or the liquid ones are extracted with ether.

Compounds *(1)* and *(2)* are of interest as intermediates for the preparation of heterocyclic compounds. Thus, in reactions analogous to those of the corresponding enol ethers, the sulfides *(2)* give pyrimidines with amidines or guanidines, pyrazoles with hydrazines, isoxazoles with hydroxylamines, and pyrroles with 2-amino carboxylic esters. Owing to the great reactivity of the unsaturated sulfides *(2)* towards nucleophilic reagents these condensations occur within a few hours at room temperature. The resulting heterocycles either separate out or can be isolated after evaporation of the solvent (ethanol). The salts *(1)* are alkylated also by α-chloro ketones, or α-chloro carboxylic esters or nitriles (reaction conditions as for methyl iodide); the resulting sulfides cyclize to thiophenes when warmed for ½ hr on the water-bath after addition of triethylamine.

Salts of type *(1)* containing two nitrile groups[3] yield isothiazoles *(3)* when treated with aqueous chloramine solution: 0.015 mole of aqueous chloramine solution[4] is added to a solution of 0.01 mole of *(1)* in 10 ml of water, and the resulting immediate crystalline precipitate is filtered off after 2 hr and recrystallized from ethanol. The derivatives *(3a)* and *(3c)* are obtained also on using hydroxylamine-*O*-sulfonic acid under the same conditions and in about the same yields, but attempts to prepare *(3b)* and *(3d)* with hydroxylamine-



O-sulfonic acid gave products of as yet unclarified structure. The isothiazole structure *(3)* follows from the IR and UV spectra and from elemental analyses.

(1), X=Y=CN + Cl-NH_2 → *(3)* + MCl

(3)	R^1	M.p. (°C)	Yield (%)
(a)	CH_3	176	86
(b)	OC_2H_5	198	77
(c)	SCH_3	176	72
(d)	$C_6H_5CH_2$	144	93

As α,β-amino nitriles the isothiazoles *(3)* can undergo further reactions. For instance, when 0.01 mole of *(3a)* is heated with 40 ml of an equimolar mixture of ethyl orthoformate and acetic anhydride[5] on the water-bath for 3 hr, evaporation affords the derivative *(4)*, m.p. 76 °C, in 90% yield, which with an excess of alcoholic ammonia at room temperature gives compound *(5)*, decomp. *ca.* 230 °C, in 85% yield. This is the first isothioazolo[3,4-*d*]pyrimidine reported.

(3a) $\xrightarrow{HC(OC_2H_5)_3/Ac_2O}$ *(4)* $\xrightarrow{NH_3}$ *(5)*

Preparation of Substituted Oxaboroles from Sodium 1-Alkynyltrialkylborates and Acyl Chlorides

By *P. Binger*[*]

Sodium triethyl-1-propynylborate and acetyl chloride give only about 35% of methyl propynyl ketone and triethylborane, since about 50% of the borate is converted into the alkyl derivative *(2a)* of the hitherto unknown 2,3-dihydro-1,2-oxaboroles. Other possible products, such as methyl ethyl ketone and diethylpropynylborane, could not be detected.

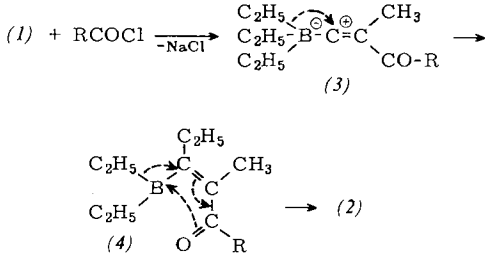
$Na[(C_2H_5)_3BC{\equiv}C\text{-}CH_3]$ + RCOCl $\xrightarrow[-NaCl]{5\text{-}10\,°C}$ *(2)* + $R\text{-}CO\text{-}C{\equiv}C\text{-}CH_3$ + $B(C_2H_5)_3$

(1)

(a), R = CH_3

(b), R = C_6H_5

A solution of 32 g (0.2 mole) of *(1)* in 60 ml of dichloromethane is added dropwise and slowly at 5–10 °C, with cooling in ice-water, to 15.6 g (0.2 mole) of acetyl chloride. A yellow color develops and sodium chloride separates. Distillation of the filtrate gives, apart from the solvent, two fractions. Fraction I (8.4 g, b.p. 32–33 °C/12 mm) contains 71% of methyl propynyl ketone (gas-chromatographic analysis); fraction II (17.5 g, b.p. 68–69 °C/12 mm) is almost pure *(2a)*.



Benzoyl chloride and the salt *(1)* under the same conditions afford 2,3,3,4-tetraalkylated 5-phenyl-2,3-dihydro-1,2-oxaborole *(2b)* (b.p. 68 to 70 °C/10^{-3} mm) in up to 30% yield together with some phenyl propynyl ketone (6%) and ethyl phenyl ketone (7%). The remainder consists almost wholly of dark, tarry products.

The structure of the compound *(2a)* is proved by the mass spectrum (molecular weight 180, one boron atom), the infrared spectrum ($\nu_{C=C}$ = 1690 cm^{-1}), and the ^1H-NMR spectrum [1 C_2H_5 (on B): τ = 8.99 ppm; 2 C_2H_5 (on C-3): τ_{CH_2} = 8.6 ppm (quartet), τ_{CH_3} = 9.44 ppm (triplet); 1 CH_3 (on C-4): τ = 8.59 ppm; and 1 CH_3 (on C-5): τ = 8.07 ppm].

The reaction can be extended to other sodium alkynyltrialkylborates; *e.g.* $Na[(C_3H_7)_3BC{\equiv}C\text{-}CH_3]$ and acetyl chloride yield 4,5-dimethyl-2,3,3-tripropyl-2,3-dihydro-1,2-oxaborole, with methyl propynyl ketone.

The substituted oxaboroles are sensitive to oxygen but are not attacked by substances containing active protons (water, ethanol, ethylene glycol) up to about 100 °C. They do not form stable addition compounds with tertiary amines.

Like 1,2-diborylated alkenes, the compounds *(2)* are formed probably by way of "borenylides" *(3)*[1]. The ketones *(4)* initially formed can be isolated only when trapped with pyridine. The free compounds evidently rearrange readily to *(2)*.

(1) + RCOCl $\xrightarrow[-NaCl]{}$ *(3)* → *(4)* → *(2)*

Two New Syntheses of Arylhydrazines

By *W. Burkhardt* and *Th. Kauffmann*[*]

Since a high temperature is required in the synthesis of phenols or arylamines from arenesulfonates and alkali hydroxides or alkali amides, it did not appear promising to attempt an analogous synthesis of arylhydrazines by means

of sodium hydrazide[2] because of the thermolability of the hydrazide. Surprisingly, however, sodium hydrazide reacts rapidly with sodium arenesulfonates in a hydrazine-ether mixture (about 1:10 v/v)[3] even at 35 °C, giving, in most cases, almost quantitative yields of the corresponding hydrazine derivative. Since no di- or tri-arylhydrazine or, as in the reaction of sodium *p*-toluenesulfonate *(1)*, position isomers of the arylhydrazine are formed, the reactions occur by the addition-elimination mechanism of nucleophilic aromatic substitution and not by the aryne mechanism.

(1)

(2)

The reaction of sodium benzenesulfinate shows that the arenesulfinates also give arylhydrazines *(2)*.

Sodium salt	Reaction time (hr)	Hydrazine formed	Yield (%)
Benzenesulfonate	1 [a]	Phenyl	97
Benzenesulfinate	1 [a]	Phenyl	93.5
o- or *p*-toluenesulfonate	1 [a]	*o*- or *p*-Tolyl	92 or 98
2,4-, 2,5-, or 3,4-Dimethylbenzenesulfonate	1	2,4-, 2,5-, or 3,4-Dimethylphenyl	90, 89, or 94
2,4,6-Trimethylbenzenesulfonate	2	2,4,6-Trimethylphenyl (+ 73 % of mesitylene)	15
4-Biphenylsulfonate	3	4-Biphenylyl	75
2-Naphthalenesulfonate	1	2-Naphthyl	98
1,3-Benzenedisulfonate	1.5	*m*-Sulfophenyl	91

[a] Molar ratio, sulfonate (or sulfinate): $NaNH-NH_2$: NH_2-NH_2 = 1:5:5; in other cases, 1:5:25.

Synthesis of Dienes from Vinyl Halides *via* Organocopper Compounds [1]

By *Th. Kauffmann* and *W. Sahm* [*]

Tetrahydrofuran solutions of vinylmagnesium halides are readily accessible from vinyl halides[2]. On dropping such solutions into a suspension of CuCl in tetrahydrofuran under nitrogen at −60 to −40 °C we obtained intensely green or red mixtures which presumably contain vinylcopper(I) compounds. When such mixtures are warmed to +20 °C, conjugated dienes are formed in good yield, the intense color disappearing and elemental copper separating[3].

Conversions Effected:

Vinylmagnesium chloride → 1,3-butadiene[5] (yield[4] 60.5 %; green intermediate). 2-Methylpropenylmagnesium bromide → 2,5-dimethyl-2,4-hexadiene (yield 97 %; deep green intermediate). *cis*- and *trans*-Propenylmagnesium bromide (4.8:1) → mixture (yield 81 %; red intermediates) of *cis,cis*-, *cis,trans*-, and *trans,trans*-2,4-hexadiene (14.4:7.3:1).

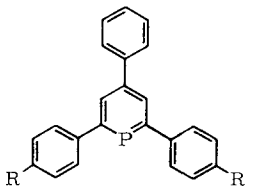
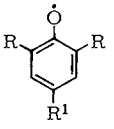
A New, Stable Phosphorus Radical



By *K. Dimroth*, *N. Greif*, *H. Perst*, and *F. W. Steuber* [*]
With the cooperation of *W. Sauer* and *L. Duttka*

While oxidation or reduction of phosphamethinecyanines[1] (the first compounds with delocalized C=P−C bonds) gives a number of radicals not yet identified, reaction of 2,4,6-triphenylphosphabenzene *(1a)*[2] with 2,4,6-triphenylphenoxyl *(2a)*[3] in benzene leads to immediate decoloration of the red phenoxyl solution and formation of a stable greenish-yellow, weakly fluorescing solution which, as shown by its ESR spectrum (see Figure), contains a phosphorus radical.



The phosphorus coupling constant a_P amounts to 23.2 gauss. The same spectrum is obtained on treatment of *(1a)* with 2,6-bis(pentadeuterophenyl)-4-phenylphenoxyl *(2b)*, 2,4,6-tris(pentadeuterophenyl)phenoxyl *(2c)*[4], 4-t-butyl-2,6-diphenylphenoxyl, or [^{17}O]-2,4,6-triphenylphenoxyl. This shows that the ESR spectrum of the new radical is independ-

ent of the oxidizing phenoxyl radical and that the oxygen, since it is not coupled with the phosphorus, is probably not chemically bound to it.

(1a) R = H
(1b) R = OCH_3

(2a) R = R^1 = C_6H_5
(2b) R = C_6D_5, R^1 = C_6H_5
(2c) R = R^1 = C_6D_5

The phosphabenzene *(1a)* does not react with 2,4,6-tri-t-butylphenoxyl or 2,6-di-t-butyl-4-phenylphenoxyl. Whether this is because the redox potential of these radicals is too low[5] or because the *ortho*-t-butyl groups hinder the reaction sterically is being studied. If the redox potential of *(1a)* is lowered by introduction of two *p*-OCH_3 groups into the phenyl rings at C-2 and C-6 *(1b)*, then oxidation can be effected even with lead dioxide and an analogous phosphorus radical is obtained. The fine structure of the doublet in its ESR spectrum is poorly resolved, but the coupling constant a_P is almost the same as that for the radical from *(1a)*.

The new phosphorus radical is stable in benzene at 0 °C when air is excluded: no decrease in radical concentration was observed after storage for 14 days.

A Simple Synthesis of Phospholes

By *G. Märkl* and *R. Potthast* [*]

Phospholes *(1)* are analogous to pyrroles and are thus of interest because they may have aromatic bonding character.

Previous syntheses of phospholes[1] are restricted to special cases. We have now found a general phosphole synthesis in the reaction of butadiynes with phenylphosphine, which is analogous to the syntheses of pyrroles[2] and thiophenes[3]. Whereas only traces of phospholes are formed in thermal or free-radical reactions, the cycloaddition can be effected under conditions in which intermediate phenylphosphine anions are formed. Reaction of bis(hydroxymethyl)phenylphosphine (easily accessible from phenylphosphine[4]) with butadiyne in boiling pyridine yields phospholes (method A); phenylphosphine itself adds smoothly to butadiynes in benzene even at room temperature in the presence of catalytic amounts of phenyl-lithium (method B).

(1)

(1), R	B.p. (°C/mm) or m.p. (°C)	Yield (%) A	Yield (%) B	NMR spectrum in $CDCl_3$
Phenyl	184—186	20.5	60	Complex band at τ = 2.45 to 3.0
2-Naphthyl	230—231	17.5	89.5	
p-Tolyl	194—196	29	59	Singlet at τ=7.75(6H) Complex band at τ = 2.49 to 3.16 (15 H)
p-Bromophenyl	200—202	16.5		Complex band at τ = 2.67 to 2.90
CH_3	66—69/0.2	0	51	Doublet at τ = 8.02 (6 H), J_{P-CH_3} = 10 Hz [a] Doublet at τ = 3.61 (2 H), J_{P-H} = 12.5 Hz [a] Complex band at τ = 2.59 to 2.92 (5 H)

[a] The weak coupling H—C=C—CH_3 leads to formation of a shoulder.

2,5-Dimethyl-1-phenylphosphole is the first phosphole without aryl groups attached to the ring C atoms. Comparison of the chemical shift of the NMR signals of the protons on C-3 and C-4 with the shift in 2,5-dimethylfuran ($\tau_{3,4-H}$ = 3.61, τ_{CH_3} = 7.86), 2,5-dimethylthiophene ($\tau_{3,4-H}$ = 3.61, τ_{CH_3} = 7.70), and 1,2,5-trimethylpyrrole ($\tau_{3,4-H}$ = 4.41, $\tau_{2,5-CH_3}$ = 7.99)[5] is not inconsistent with the assumption of aromatic bonding in phospholes *(1)*.

Method A (1-phenyl-2,5-di-p-tolylphosphole): 0.8 g (3.5 mmole) of 1,4-di-*p*-tolyl-1,3-butadiyne is added to a solution of bis-(hydroxymethyl)phenylphosphine [prepared[4] from 0.55 g (5 mmole) of phenylphosphine] in 4 ml of anhydrous pyridine, and the mixture is refluxed for 5 hr. Crystallization of *(1)*, R = *p*-CH_3—C_6H_4, is completed by addition of water; yield 0.35 g.

Method B (2,5-dimethyl-1-phenylphosphole): 2.34 g (30 mmole) of 2,4-hexadiyne is added at room temperature to a solution of 3.3 g (30 mmole) of phenylphosphine and 8 mmole of phenyl-lithium in 15 ml of benzene/tetrahydrofuran (1:1 v/v). The product is distilled off under nitrogen 18 hr after the vigorous reaction has ceased; yield 2.7 g of colorless liquid.

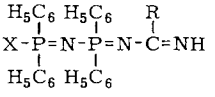
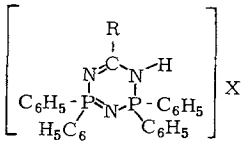
Tetraphenyldiphospha^{V}-1,3,5-triazines and their Salts[1]



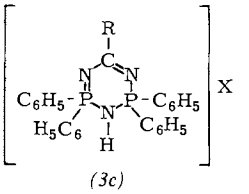
By *A. Schmidpeter* and *J. Ebeling*[*]

Amidinium chlorides *(1)* condense with tetraphenylimidodiphosphinic trichloride chloride *(2)*[2] with elimination of 3 mol. equivalents of HCl when equimolar amounts are heated together in a vacuum. Structures *(3a)* to *(3c)* (X = Cl)



$$[RC(NH_2)_2]Cl + [N((C_6H_5)_2PCl)_2]Cl \longrightarrow 3\ HCl + RC((C_6H_5)_2P)_2N_2HCl$$

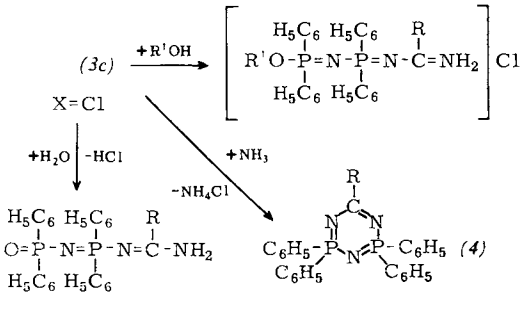
(1) *(2)* *(3)*



must be considered for the condensation products. Convertibility into a tetraphenylborate [X = $B(C_6H_5)_4$] indicates an ionic and thus a cyclic structure.

(3a)

(3b)



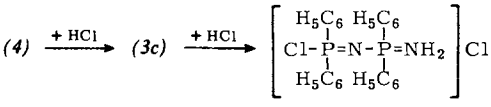
(3c)

Equivalence of the two phosphorus atoms and thus the symmetrical structure *(3c)* follow from the ^{31}P–NMR spectra and from splitting of the proton signal of the *C*-substituent (R=CH_3 or C_6H_5–CH_2) to a triplet[3]. The location of the proton at position 3 is surprising in view of the difference in basicity between amidine-nitrogen (pK ≈ 12[4,5]) and phosphazene-nitrogen (pK ≈ 2[6]) and indicates extensive equalization of electron density throughout the ring skeleton.

(3c) R	X	M.p. (°C)	$\delta^{31}P$ [a] (ppm)	$\delta^{1}H$(NH) (ppm)	$\delta^{1}H$(CH aliphatic) (ppm)	J_{PH} (Hz)
CH_3	Cl	192–195	−19.0	−15.2	−2.63	1.8
CH_3	$B(C_6H_5)_4 \cdot 2\ CH_3CN$	114–116 (decomp.)	−20.4		−1.80	1.6
C_6H_5–CH_2	Cl	182–184	−19.9	−14.2	−4.22	2.6
C_6H_5	Cl	218–225 (decomp.)	−21.9			

[a] The chemical shifts were measured for CH_2Cl_2 solutions [7] and are given as negative for lower fields with reference to 85 % H_3PO_4 or tetramethylsilane. The strongly negative chemical shift of the signal for the proton attached to nitrogen confirms its 3-position. The NH signal of protonated cyclophosphazenes had previously [8] been anticipated at −12.5 ppm, by analogy with that of protonated organic nitrogen heterocycles.

Diphospha^{V} -1,3,5-triazinium chlorides *(3c)* readily undergo hydrolysis and alcoholysis with opening of the ring between positions 1 and 2. However, diphospha^{V}-1,3,5-triazine



bases *(4)*[9] are liberated by ammonia. When R = C_6H_5 removal of HCl from *(3c)* may be effected by prolonged heating in vacuum.

(4), R	M.p. (°C)	$\delta^{31}P$ [a] (ppm)	$\delta^{1}H$(CH aliphatic) (ppm)	J_{PH} (Hz)
CH_3	175–177	−15.6	−2.17	2.7
C_6H_5–CH_2	113–114	−15.9	−3.67	3.2
C_6H_5	239–241	−17.3		

[a] $\delta^{31}P$ was measured in CH_2Cl_2 or C_6H_5Cl, and $\delta^{1}H$ in CCl_4.

A solution of a diphospha^{V}-1,3,5-triazine *(4)* absorbs HCl at atmospheric pressure, reversing the synthetic route, but the extent of this reaction depends on the nature of the substituents that determine the basicity: one equivalent is absorbed when R = C_6H_5, but two when R = CH_3:

The compounds *(4)* prepared are soluble in polar organic solvents and in aromatic compounds, and sparingly soluble in ether, aliphatic hydrocarbons, or water. Diphospha^{V}-1,3,5-triazines are stable towards water and bases but are decomposed by aqueous acids to *(1)* and tetraphenylimidophosphinic acids $(C_6H_5)_2OP$–NH–$PO(C_6H_5)_2$.

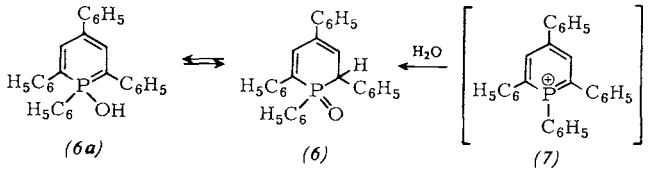
Electrophilic Reactions of 2,4,6-Triphenylphosphabenzene

By *G. Märkl*, *F. Lieb*, and *A. Merz*[*]

Whereas we were unable to alkylate triphenylphosphabenzene *(1)*[1] with methyl iodide or $[(C_2H_5)_3O]BF_4$, it reacts with nucleophilic reagents such as lithium alkyls and aryls in benzene even at room temperature.

In contrast to the course of comparable nucleophilic substitutions of pyridine[2,3], the base adds directly to the phosphorus, whose valence shell expands to a decet [as in *(2)*]. Hydrolysis of the deep indigo solutions obtained gives 1-alkyl and 1-aryl-1,2-dihydrophosphabenzenes *(3)*, which are isolated by freeze-drying.



(3), R = C_6H_5 (recrystallization from ethanol under nitrogen), m.p. 144–145 °C, yield 64 %, λ_{max} = 327 mμ, ε = 7300 (in benzene); ^{1}H–NMR: quartet at τ = 5.79 (benzyl-H), J_{P-CH} = 13 Hz, $J_{Ha/Hb}$ = 4 Hz; doublet at τ = 3.6 (1 H), J = 4 Hz; complex band at τ = 2.15 to 3.15 (21 H).

(3), R = n-butyl (chromatography on Al_2O_3 under nitrogen), pale yellow oil, yield 52 %; ^{1}H–NMR: quartet at τ = 5.96 (benzyl-H), J_{P-CH} = 8 Hz, $J_{Ha/Hb}$ = 4 Hz; doublet at τ = 3,78 (1 H); complex band art τ = 2.1 to 3.1 (16 H) and at τ = 8.5 to 9.6 (9 H).

The phosphonium salts *(4)* (R = C_6H_5, R^1 = CH_3, $X^\ominus$ = $I^\ominus$; m.p. 160–162 °C that are readily obtained from *(3)* yield the red, non-crystalline, 1,1-disubstituted PV-phosphabenzenes *(5)*[4] when treated with dilute aqueous NaOH at room temperature. Compounds *(2)* react in benzene solution directly with alkyl iodides, *e.g.* CH_3I, yielding solutions of the ylides *(5)*.

Oxidation of the dihydro-compound*(3)*, R = C_6H_5, with H_2O_2 at 0 °C affords the oxide *(6)* as bundles of fine, colorless needles, m.p. 156–158 °C, λ_{max} = 332 mμ (ε = 6300–6600; in benzene); ^{1}H–NMR: quartet at τ = 5.72 (benzyl-H), J_{P-CH} = 16.5 Hz, $J_{Ha/Hb}$ = 4 Hz; quartet at τ = 3.6 (1 H), J_{P-CH} = 16.5 Hz, complex band at τ = 2.2 to 3.0 (21 H). The oxide *(6)* is also obtained (on chromatography of the reaction mixture) from phenylphosphine and 2,4,6-triphenylpyrylium fluoroborate[5], being formed by reaction of the intermediate 1-phenylphosphabenzene cation *(7)* with water.

The ultraviolet spectrum of the oxide *(6)* in methanol shows an isosbestic point at 372 mμ and two maxima at 340 and 432 mμ, which indicate the equilibrium *(6)* ⇄ *(6a)*. Even with weak bases and in water, *(6a)* gives the brilliant red, resonance-stabilized anion (λ_{max} = 348, 365, and 475 mμ in benzene).

Synthesis of Silyl Phosphinites [**]

By *K. Issleib* and *B. Walther* [*]

According to their ^{31}P–NMR and IR spectra, secondary phosphine oxides have the structure $R_2P(O)H$ and not that of a "phosphinous acid" R_2POH; but when heated with alkali metals in aprotic solvents they evolve an equivalent amount of hydrogen to yield compounds of type R_2POM.

If a salt R_2POK (R = n-C_4H_9[1] or C_6H_5[2]), prepared by heating $R_2P(O)H$ with potassium in dioxane, is dropped onto $(CH_3)_3SiCl$ (method A), compounds *(1)* and *(5)* are formed. Organosilanes containing more chlorine give inhomogeneous products in this reaction.

When secondary phosphine oxides are heated directly with various substituted organo-chlorosilanes in benzene in the presence of triethylamine (method B), subsequent filtration and concentration of the solutions, followed by distillation in a vacuum or by recrystallization from n-hexane, give the compounds *(1)* to *(7)* in good yields. The spectra and chemical behavior of these compounds prove the silyl phosphinite structure and exclude the formation of tertiary phosphine oxides $[R_2P(O)]_nSiR'_{4-n}$.

		Method	B.p. (°C/mm) or m.p. (°C)	Yield (%)	Chem. shift [a] (ppm)

[a] Calc. relative to 85 % aqueous orthophosphoric acid. We thank Dr. *E. Fluck*, Heidelberg, for the ^{31}P–NMR measurements.

Germyl and stannyl phosphinites can be prepared in the same way, as is shown by the formation of *(8)* and *(9)* by method A. Compound *(9)* is also obtained from $R_2P(O)H$ and tributyldiethylaminostannane.

The ^{31}P–NMR spectra of compounds *(1)* to *(9)* all show only one resonance line, whose large negative chemical shift is of the same order of size as those of other P compounds of coordination number 3. IR spectroscopy does not disclose any P=O stretching vibration between 1150 and 1250 cm^{-1}. Unlike alkyl and aryl phosphinites, the compounds *(1)* to *(7)* do not isomerize to tertiary phosphine oxides when heated with iodine as catalyst. Attempts to prepare isomers of *(4)* and *(7)* by treating $R_2P(O)Cl$ (R = n-C_4H_9 or C_6H_5) with $LiSi(C_6H_5)_3$ in tetrahydrofuran led to $(C_6H_5)_6Si_2$ and $R_4P_2(O)_2$ as the result of metal-halogen exchange. Compounds *(1)* to *(7)* react with alkyl iodides in the sense of an Arbusov reaction, yielding tertiary phosphine oxides and organo-iodosilanes (a), and they are hydrolysed by water (b).

$$(R_2P{-}O{-})_nSiR^1_{4-n} + n\,R^2I \rightarrow n\,R_2R^2P(O) + SiI_nR^1_{4-n} \quad (a)$$

$$(R_2P{-}O{-})_nSiR^1_{4-n} + n\,H_2O \rightarrow n\,R_2P(O)H + Si(OH)_nR^1_{4-n} \quad (b)$$

Heating compounds *(1)* to *(7)* and *(9)* with sulfur in benzene gives the corresponding silyl and stannyl thiophosphinites.

Treatment of $(n\text{-}C_4H_9)_2P(O)H$ with $SiCl_4$ in the molar ratio 4:1 by method B does not yield silyl tetrakis(di-n-butyl phosphinite) but instead tetrabutyldiphosphine monoxide *(10)*, R = n-C_4H_9 (75% yield), and silica. This product *(10)*

$$4\,R_2P(O)H + SiCl_4 \xrightarrow{N(C_2H_5)_3} 2\,R_2P{-}P(O)R_2 + 4\,HCl + SiO_2$$

(10)

was prepared for ^{31}P-NMR-spectral comparison from $(n\text{-}C_4H_9)_2P(O)H$ and $(n\text{-}C_4H_9)_2PCl$ in benzene in presence of $N(C_2H_5)_3$ (64% yield). It is a colorless liquid, b.p. 120–125 °C/0.01 mm, and gives a derivative, $(n\text{-}C_4H_9)_2P(O){-}P(O)(n\text{-}C_4H_9)$, b.p. 150–152 °C/0.01 mm. The ^{31}P-NMR spectrum of *(10)*, R = n-C_4H_9, has an AB structure, giving signals at 55.6, 46.7, −45.3, and −54.8 ppm with J_{PP} = 216 Hz.

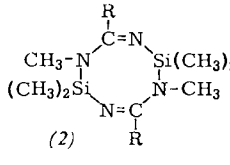
Silicon-Nitrogen Heterocycles containing C=N Double Bonds

By *O. J. Scherer* and *P. Hornig* [*]



No Si–N ring system incorporating C=N bonds has been reported hitherto and those with C=C bonds can be prepared only in the form of mono- or di-*o*-phenylene derivatives [1].

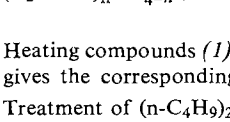
We have prepared Si–N heterocycles incorporating C=N bonds by treating the addition product *(1)* of benzonitrile and lithium methylamide with dichloro(dimethyl)silane in the presence of triethylamine.

$$R{-}C{\equiv}N + LiNHCH_3 \rightarrow R{-}C(=NLi){-}NHCH_3$$

(1)

$$2\,(1) + 2\,(CH_3)_2SiCl_2 + 2\,(C_2H_5)_3N \rightarrow$$

$$+ 2\,LiCl + 2\,(C_2H_5)_3N \cdot HCl$$



(2)

R = C_6H_5

The product of this reaction, 1,2,2,5,6,6-hexamethyl-4,8-diphenyl-1,3,5,7-tetraaza-2,6-disila-3,7-cyclocatadiene *(2)*, forms colorless crystals which are very sensitive to moisture, readily soluble in ether, benzene, or CCl_4, and moderately soluble in petroleum ether. M.p. 77–79 °C; yield, 43 %.

If lithium methylamide is also present during the reaction, a six-membered heterocycle is formed containing only one C=N bond, namely, 1,2,2,3,4,4-hexamethyl-6-phenyl-1,3,5-triaza-2,4-disila-5-cyclohexene *(3)*, in 45 % yield. This forms colorless crystals, of m.p. 62–64 °C, which are also very sensitive to moisture and dissolve readily in ether, benzene, CCl_4, or petroleum ether.

(1) + 2 $(CH_3)_2SiCl_2$ + 2 $(C_2H_5)_3N$ + $LiNHCH_3$ →

+ 2 LiCl + 2 $(C_2H_5)_3N \cdot HCl$

(3)

R = C_6H_5

Whereas the protons of the product *(3)* give five sharp ^1H-NMR signals [τ = 9.90 and 9.78 (CH_3Si), τ = 7.51 and 7.43 (CH_3N), τ = 2.78 (C_6H_5) (Varian A 60, 60 MHz; 10% solution in CCl_4; tetramethylsilane as internal standard)], the spectrum of product *(2)* at room temperature has sharp signals only at τ = 7.32 (CH_3N) and τ = 2.74 (C_6H_5). At 30 °C the protons of the dimethylsilyl group afford two broad signals [τ = 10.12 and 9.49 (CH_3Si)], at *ca.* 0 °C two sharper signals, and at *ca.* 50 °C one broad signal, behavior indicating the presence of conformational isomers. The relative areas observed for the two compounds agree well with calculated values.

Bands at 1620 cm^{-1} in the IR spectra of *(2)* and *(3)* can be assigned to C=N, and are accompanied in both cases by two weaker bands at 1600 and 1580 cm^{-1}.

Reaction of both products with ethanol is exothermic. With *(2)* it gives *N*-methylbenzamidine (identified as hydrochloride) and diethoxy(dimethyl)silane with quantitative cleavage of the Si–N bonds. Reaction of *(3)* gives, besides

$$(3) + 2\,C_2H_5OH \rightarrow R{-}C(=NH){-}NHCH_3 + \left[C_2H_5O{-}Si(CH_3)_2{-}\right]_2 NCH_3$$

(4)

the amidine derivative, *N*-methyl-bis[ethoxy(dimethyl)silyl]-amine *(4)* in 60% yield [τ = 9.89 (CH_3Si), τ = 8.85(t) and 6.38(q) (C_2H_5), τ = 7.52 (CH_3N)] as a colorless liquid of b.p. 50–53 °C/0.1 mm.

Experimental:

Synthesis of *(2)*: 3.1 g (100 mmoles) of CH_3NH_2 is dissolved in 50 ml of ether and metalated at −70 °C with 6.4 g of butyl-lithium in hexane (100 mmoles in 44 ml of solution) (stirring; exclusion of moisture; N_2-atmosphere). The suspension is treated at 0 °C with 10 g (97 mmoles) of C_6H_5CN in 35 ml of ether and stirred for 2 hr at room temperature. After addition of 10.1 g (100 mmoles) of $(C_2H_5)_3N$, 12.9 g (100 mmoles) of $(CH_3)_2SiCl_2$ in 30 ml of ether is added dropwise, resulting in vigorous boiling. The mixture is stirred for 2 hr, filtered, washed with ether, and fractionally distilled. B.p. 174–176 °C/0.1 mm, m.p. 77–79 °C (recrystallized from pentane). Yield 43 %, calculated on the C_6H_5CN used [forerun, *ca.* 40 %, a mixture of C_6H_5CN and *(3)*].

Synthesis of *(3)*: The compound is prepared under the same conditions as *(2)*, except that only 5 g (48.5 mmoles) instead of 10 g of C_6H_5CN is used. Product *(3)* is isolated on fractionation as a turbid oil, b.p. 103–106 °C/0.1 mm, and is purified by dissolution in ether, filtration, and a second distillation. B.p. 104 °C/0.1 mm; m.p. 62–64 °C. Yield 45 %, calculated on the C_6H_5CN used [forerun, *ca.* 5 % of C_6H_5CN; residue, *ca.* 30 % of *(2)*].

Preparation of Phosphoryl Difluoride Isothiocyanate and Phosphoryl Fluoride Diisothiocyanate

By *H. W. Roesky* [*]

Phosphoryl fluoride isocyanates were previously unknown. They can be used as starting materials for the preparation of new phosphorus compounds.

For the synthesis of phosphoryl difluoride isothiocyanate *(2)*, difluorophosphoric anhydride *(1)* [1] was stirred vigorously with potassium thiocyanate (molar ratio 1:1.2) for 12 hr at 25 °C. After filtration, the liquid was fractionated under reduced pressure. The yield of *(2)* (b.p. 35–36 °C/87 mm, mol. wt. 142.5 by Regnault's method, 168 cryoscopically in benzene) was 50 %. By-products of the reaction are POF_3, $(SCN)_2$, and $(SCN)_x$.

$$\underset{(1)}{F_2P(O)-O-P(O)F_2} + KSCN \longrightarrow \underset{(2)}{F_2P(O)NCS} + K[PO_2F_2]$$

If the difluoride *(2)* is heated for an hour under nitrogen at 65 °C and atmospheric pressure, phosphoryl trifluoride *(3)* and phosphoryl fluoride diisothiocyanate *(4)* are obtained,

$$2\ \underset{(2)}{F_2P(O)NCS} \longrightarrow \underset{(3)}{POF_3} + \underset{(4)}{FP(O)(NCS)_2}$$

the latter in 40 % yield (b.p. 64–65 °C/3.5 mm, mol. wt. 203, cryoscopically in benzene). $(SCN)_x$ is formed as a by-product. Compounds *(2)* and *(4)* are colorless liquids. Traces of moisture decompose them, with yellow to brown coloration. Reaction of potassium cyanate with compound *(1)* (molar ratio 1.2:1) at 25 °C gives phosphoryl difluoride isocyanate

$$(1) + KOCN \longrightarrow \underset{(5)}{O{=}P(F)_2{-}NCO} + K[PO_2F_2]$$

(5) [2], which after filtration of the reaction mixture is obtained by distillation (b.p. 69 °C; yield 50 %).

Synthesis of Thiophosphoryl Difluoride Isothiocyanate and Thiophosphoryl Fluoride Diisothiocyanate

By *H. W. Roesky* [*]

Thiophosphoryl fluoride isothiocyanates have not previously been described. As starting material for their synthesis we used thiophosphoryl triisothiocyanate *(1)* [1]. If antimony trifluoride *(2)* is treated dropwise, at 100 °C and a pressure of 1 to 2 mm, with triisothiocyanate *(1)* (molar ratio 1.5:1), thiophosphoryl difluoride isothiocyanate *(3)* and thiophosphoryl fluoride diisothiocyanate *(4)* are formed.

$$\underset{(1)}{2\,SP(NCS)_3} + \underset{(2)}{SbF_3} \rightarrow \underset{(3)}{SPF_2NCS} + \underset{(4)}{SPF(NCS)_2} + Sb(NCS)_3$$

The product *(4)* is distilled off during the reaction (yield 45 %, b.p. 66–67 °C/1.5 mm), whereas *(3)* is collected in a cold trap (–78 °C; acetone-dry ice), which is placed after the first collecting vessel, and is purified by subsequent fractionation (yield 18 %, b.p. 89.5–90 °C/760 mm).

Elemental analysis proves the composition of *(3)* and *(4)*. Molecular weights are 159.1 (Regnault), 160 (cryoscopic in benzene) for *(3)* and 199 (cryoscopic in benzene) for *(4)*.

From the temperature-dependence of the vapor pressure of *(3)* it is possible to obtain the vapor pressure equation

$$\log p = (-1756.3/T) + 7.7150,$$

an extrapolated boiling point of 90.1 ± 0.5 °C, a latent heat of evaporation of L = 8.049 kcal/mole, and a Trouton constant of 22.2 cal/degree.

Both compounds are pale liquids that decompose in the presence of traces of water with yellow to brown coloration.

N-Cyaniminosulfur Difluoride

By *W. Sundermeyer* [*]

On treating bis(trimethylsilyl)carbodiimide [1] with sulfur tetrafluoride we obtained *N*-cyaniminosulfur difluoride *(1)* in a smooth reaction [2].

$$R_3Si{-}NCN{-}SiR_3 + SF_4 \rightarrow \underset{(1)}{F_2S{=}N\ CN} + 2\,R_3SiF \quad (R = CH_3)$$

The product is formed quantitatively if the reactants (on a 2-molar scale, slight excess of SF_4) are heated at 50 °C in a closed vessel (200 ml) for 2 hr. The trimethylfluorosilane and the excess of sulfur tetrafluoride can be separated by low-temperature vacuum-distillation, the pure product *(1)* remains behind as a clear colorless liquid (b.p. 58 °C/100 mm, 43 °C/49 mm; vapor pressure = 14 mm at 20 °C). The boiling point (extrapolated to atmospheric pressure) is 111 °C. The compound partly decomposes above 50 °C and becomes yellow. Melting point −34 °C. Molecular weight (Dumas) = 111.

The mass spectrum shows typical fragments FSNCN (*m/e* = 96), SNCN (72), SF_2 (70), and SF (51), as well as the molecule ion (110). The ^{19}F–NMR spectrum includes a singlet at −48.1 ppm ($CFCl_3$ as external standard). The IR spectrum, measured for the NaCl and KBr region, shows absorption bands (with tentative assignments) at 2255 (s, ν_{as}NC–N[3]), 1463 (m), 1337 (vs, νS=N), 844 (vs, ν_sNCN), 764 (vs, ν_{as}SF), 725 (vs, ν_sSF), 615 (m), and 527 (m). The spectroscopic data are in accordance with the structure assigned and with the data for *N*-cyaniminosulfur difluoride prepared by a different method[4].

Of the isoelectronic compounds

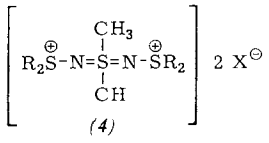
(1)

the dialkylsulfur diimides *(1)* have been known for only a short time[2]. We have now found that reactive *N,N'*-dihalogeno-*S,S*-dialkylsulfur diimides *(2)* can be prepared, some of them in good yield, by halogenation of *(1)* in aqueous solution buffered by potassium carbonate.

(2)

	X	M.p. (°C)	Decomp. pt. (°C)	Yield (%)
(2a)	Cl	58	60	19
(2b)	Br	150	152	76
(2c)	I		134–136	97

Preparation of N,N-dibromo-S,S-dimethylsulfur diimide (2b): 7.6 g of bromine in 100 ml of methanol is added dropwise, with stirring, over 30 min, to a solution of 1.8 g of *S,S*-dimethylsulfur diimide and 10.4 g of potassium carbonate in 400 ml of water. The mixture is stirred for a further 30 min and the dibromo compound is filtered off.



This is washed with a little water and methanol and dried in a vacuum. Yield: 3.8 g.

N,N-Dihalogeno derivatives of the higher dialkylsulfur diimides are accessible by the same method. Methylene chloride, ethyl acetate, and acetonitrile are suitable as solvents for compounds *(2a)* and *(2b)*; *(2a)* also dissolves in alcohols and nitromethane; *(2c)* is only sparingly soluble in the usual solvents.

Compounds *(2a)* to *(2c)* have the usual properties of *N*-halogeno compounds. This is so for halogenations as well as for oxidations. They undergo nucleophilic substitution with phosphines and sulfides, the halogen being lost as anion and the compounds *(3)* and *(4)* formed. The salt-like character of *(3)* and *(4)* was proved by determination of ionogenic halogen and by conductivity measurements. The structures of *(3)* and *(4)* were confirmed by analysis and chemical reactions.

(3)

(4)

Large quantities of *(2a)* should not be prepared since even amounts of less than 1 g often explode spontaneously at 0 °C. Compound *(2b)* detonates when struck but, like *(2c)*, can be kept for months without decomposition.

Tricarbonylhexamethylborazolechromium[1]

By *R. Prinz* and *H. Werner*[*]

Borazole complexes analogous to dibenzenechromium[2] and tricarbonylbenzenechromium[3] were previously unknown. The synthesis of tricarbonylhexamethylborazolechromium according to eq. (a)

$$(CH_3CN)_3Cr(CO)_3 + B_3N_3(CH_3)_6 \xrightarrow{\text{dioxane}} [B_3N_3(CH_3)_6]Cr(CO)_3 + 3\,CH_3CN \qquad (a)$$

represents the first preparation of such a complex. The composition of the complex was established by elemental analysis, and osmometric molecular-weight determination in benzene

gave a value of 297. (The preparation of $(CH_3CN)_3Cr(CO)_3$ was as described by *Tate*[4].) Reaction conditions: stirring at 30 °C and 15 mm/Hg for some hours.

Table 1. Comparison of tricarbonylhexamethylborazolechromium with a typical π-complex and a Lewis-base complex.

	$B_3N_3(CH_3)_6Cr(CO)_3$	$C_6(CH_3)_6Cr(CO)_3$	$(C_6H_{11}NH_2)_3Cr(CO)_3$

^{14}N—NMR [b]	+299 ppm		+252 ppm	

[a] Varian A 60, 60 MHz, in $CDCl_3$ with $CHCl_3$ as internal standard.
[b] Varian HR 100, 7,22 MHz, 23490 gauß; reference signal: NO_3-group of NH_4NO_3 as external standard. Standardisation by side-band technique. Solvent: dioxane.

The following ions were determined by mass spectrometry[7].

$B_3N_3(CH_3)_6Cr(CO)_3^{\oplus}$, $B_3N_3(CH_3)_6Cr(CO)^{\oplus}$, $B_3N_3(CH_3)_6Cr^{\oplus}$ and $B_3N_3(CH_3)_6^{\oplus}$.

Atlas CH 4 mass spectrometer, 50 eV; the calculated and observed isotope ratios $^{10}B:^{11}B$, $^{14}N:^{15}N$ agree.

The chemical properties and spectroscopic data indicate that hexamethylborazolechromium tricarbonyl is analogous to the aromatic metal tricarbonyl complexes. An X-ray crystallographic study should provide further information on this point.

Work in progress indicates that the analogous molybdenum and tungsten complexes of hexamethylborazole are probably also obtainable.

Oxygen Complexes of Zerovalent Nickel, Palladium, and Platinum

By *G. Wilke*, *H. Schott*[1], and *P. Heimbach*[*]

Oxygen reacts at −78 °C with olefinbis(triphenylphosphine)-nickel(0) complexes and also with tetrakis(triphenylphosphine)nickel(0), in ether or toluene, giving a compound of composition $[(C_6H_5)_3P]Ni{\cdot}O_2$ which is stable in solution below −35 °C. It is probably the bis(triphenylphosphine)-nickel(0), which is present at least in traces in all the equilibrium mixtures, that enters into these reactions.

The analogous complexes $[(C_6H_{11})_3P]_2Ni{\cdot}O_2$ and $[(C_5H_{10}N)_3P]_2Ni{\cdot}O_2$, which are stable up to about −5 °C and −30 °C, respectively, were prepared from ethylenebis(tricyclohexylphosphine)nickel(0) and ethylenebis(tripiperidinophosphine)nickel(0), respectively. The increase in stability of

$$Ni^0(TPP)_4 \underset{+2\,TPP}{\overset{-2\,TPP}{\rightleftharpoons}} [Ni^0(TPP)_2] \underset{-Olefin}{\overset{+Olefin}{\rightleftharpoons}} (TPP)_2Ni(Olefin)$$

$$[Ni^0(TPP)_2] \xrightarrow{+O_2} (TPP)_2Ni{\cdot}O_2$$

TPP = $(C_6H_5)_3P$

the complexes in the order triphenylphosphine < tripiperidinophosphine < tricyclohexylphosphine parallels the increase in stability of the analogous ethylene complexes[2].

Analogous complexes were also obtained by the action of oxygen on $Pd^0(TPP)_4$ and $Pt^0(TPP)_4$ in benzene at 20 °C.

$$M^0(TPP)_4 + O_2 \rightarrow (TPP)_2M{\cdot}O_2 + 2\,TPP\ (\text{in part TPPO})$$

TPPO = $(C_6H_5)_3PO$

These complexes (M = Pd or Pt) are more stable than the nickel complex, but they nevertheless decompose when stirred for days, *e.g.* in benzene, at 20 °C. The decomposition of all the complexes takes place according to the scheme:

$$(TPP)_2M{\cdot}O_2 \rightarrow M + 2\,TPPO$$

M = Ni (rapid reaction above −35 °C).
M = Pd or Pt (rapid reaction above +90 °C, slow reaction even at +20 °C in solution).

The metal that is liberated can be trapped as a M(0) complex by addition of an excess of triphenylphosphine.

$$(TPP)_2M{\cdot}O_2 + 4\,TPP \rightarrow 2\,TPPO + M^0(TPP)_4$$

M = Ni (−35 °C, yield 56%).
M = Pd (+50 °C, yield 85%).

The $M^0(TPP)_4$ formed can again react further with oxygen, giving $(TPP)_2M{\cdot}O_2$. If a mixture of $Ni^0(TPP)_4$ and an excess of TPP in toluene is allowed to react with oxygen at such a temperature (above −35 °C for Ni) that the oxygen compounds decomposes again, then the TPP is oxidized catalytically to TPPO by molecular oxygen. With Ni^0 complexes, 50 molecules of TPP can be oxidized per Ni atom present. For Pd the ratio is at least 1:500. The maximal catalytic yield has not been determined.

Hydrolysis of $(TPP)_2Ni{\cdot}O_2$ with water-saturated ether and acetylacetone at −78 °C gives H_2O_2 in 83.5% yield, as well as TPP. Bromine reacts with $(TPP)_2Ni{\cdot}O_2$ at −78 °C or with $(TPP)_2Pd{\cdot}O_2$ at 0 °C in ether, liberating 31 and 83%, respectively, of the oxygen that was bound in the complex.

Infrared spectra could be obtained for the relatively stable complexes $[(C_6H_{11})_3P]_2Ni{\cdot}O_2$, $[(C_6H_5)_3P]_2Pd{\cdot}O_2$, and $[(C_6H_5)_3P]_2Pt{\cdot}O_2$. Besides the bands from triphenylphosphine, the Pd and Pt compounds gave bands at *ca.* 875 and 830 cm^{-1}, respectively, which can be ascribed to the O—O vibration of the complex-bound oxygen molecules. The O—O

band cannot be recognized in the spectrum of the Ni compound because tricyclohexylphosphine absorbs in the same region. In this connection mention should be made of the complex $O_2IrCl(CO)(TPP)_2$ which has been synthesised by *L. Vaska* [3].

Dicyclopentadienyltechnetium Hydride

By *E. O. Fischer* and *M. W. Schmidt* [*]

In contrast to earlier work [1], we have obtained dicyclopentadienyltechnetium hydride $Tc(C_5H_5)_2H$ in 14% yield, and not the dimeric dicyclopentadienyltechnetium $[Tc(C_2H_5)_2]_2$, from the reaction of technetium tetrachloride with cyclopentadienylsodium in tetrahydrofuran (THF) and in the presence of sodium tetrahydridoborate. This hydride is analogous to the known dicyclopentadienylrhenium hydride [2].

Cyclopentadienylsodium NaC_5H_5 (10.5 g) was added to a suspension of $TcCl_4$ (3.9 g) in THF (60 ml) at −50 °C. After warming to 20 °C, $NaBH_4$ (1.0 g) was added to the purple reaction mixture which was then stirred at 50 °C for 10 hours. Evaporation of the solvent and sublimation of the residue at 40–60 °C/10^{-2} mm gave a yellow solid. A further small quantity of the sublimate was obtained after a second treatment of the residue with THF. Resublimation and recrystallization from toluene, gave golden-yellow, pure platelets. Dicyclopentadienyltechnetium hydride is very sensitive to air, but thermally stable. The solid, which melts without decomposition at 150 °C, is readily soluble in benzene and toluene but less so in hexane. The molecular weight [3] was found osmometrically in benzene to be 225 (calc. 230.2).

The infrared spectrum of $Tc(C_5H_5)_2H$ in KBr shows the following bands which are characteristic of π-cyclopentadienyl complexes (in cm^{-1}) [4]: 3045 m, 2910 w (ν_{CH}); 1400 s, 1097 s (ω_{CC}); 995 s (δ_{CH}); 803 m, 773 vs (γ_{CH}). [c.f. $Re(C_5H_5)_2H$ 3062 m, 2910 w, 1408 m, 1392 s, 1095 s, 998 s, 987 s, 816 s, 795 s]. The Tc–H stretching vibration occurs at 1930 m (KBr) and 1923 (CS_2 solution). [cf. ν(Re–H) in $Re(C_5H_5)_2H$ 2032 w, 2000 m (KBr); 2016 (CS_2)]. The force constant k(Tc–H) is calculated to be 2.20 mdyn/Å [cf. k(Re–H): 2,41 mdyn/Å]. The metal-hydrogen bond in $Tc(C_5H_5)_2H$ is thus somewhat weaker than in the rhenium analogue. The same difference is found for $Mo(C_5H_5)_2H_2$ and its tungsten analogue [5].

The NMR spectrum [6] of a saturated benzene solution of $(C_5H_5)_2TcH$ shows a singlet at $\tau = 5.6$ (halfwidth 1.7 Hz) and a broad signal in the hydride region at $\tau = 17.8$ (halfwidth 40 Hz) at 25 °C. The relative intensity of these signals is approximately 10:1. $Re(C_5H_5)_2H$, however, shows a doublet at $\tau = 5{,}75$ (splitting 1.2 Hz) and a sharp signal at $\tau = 23.0$ (halfwidth 6 Hz), at 25 °C. The low field shift of the Tc–H signal compared with that of Re–H indicates a weaker shielding in the former. This may be explained by a decreased negative charge on the hydrogen attached to technetium [7].

The mass spectrum [8] of $(C_5H_5)_2TcH$ shows strong peaks at *m/e* 230 and 229 which may be assigned to the molecule-ion and to the ion $[Tc(C_5H_5)_2]^+$ respectively. The two peaks are of approximately equal intensity. In the mass spectrum of $Re(C_5H_5)_2H$ measured under similar conditions, the ion $[Re(C_5H_5)_2]^+$ has only ~ 65% of the intensity of the molecule-ion. This change in intensity is a further indication of a weakening in the metal-hydrogen bond in the technetium compound. Other mass peaks are weak in comparison to the two mentioned and nothing was observed at *m/e* 458 which would correspond to $[Tc(C_5H_5)_2]_2$.

Dicyclopentadienyltechnetium hydride is a typical base. It may be extracted from benzene into 2 N aqueous HCl. Neutralisation of the aqueous solution of dihydridodicyclopentadienyltechnetium chloride with 2 N NaOH yields the free hydride again.

$$Tc(C_5H_5)_2H \underset{NaOH}{\overset{HCl}{\rightleftharpoons}} [Tc(C_5H_5)_2H_2]Cl$$

The dihydridodicyclopentadienyltechnetium cation may be precipitated as the rather insoluble white hexafluorophosphate $[Tc(C_5H_5)_2H_2]PF_6$, which may be purified by crystallisation from acetone/hexane, from aqueous solutions of the chloride.

The infrared spectrum of this compound in KBr shows the normal vibrations (in cm^{-1}) of the cyclopentadienyl ligands at 3130 s, 2915 vw, 1428 s, 1410 s, 1108 w, 1022 m, 1003 m, 764 vs, broad [cf. $[Re(C_5H_5)_2H_2]PF_6$ 3140 s, 2922 vw, 1451 m,sh, 1412 s, 1110 w, 1031 m, 1001 m, 784 sh]. The Tc–H vibration appears as a weak absorption at 1984 cm^{-1} [cf. Re–H 2058 cm^{-1}].

The NMR spectrum [6] of $[Tc(C_5H_5)_2H_2]PF_6$ in deuteroacetone shows a signal at $\tau = 4.11$ (triplet, splitting 0.2 Hz) and a barely recognisable signal in the hydride region at $\tau = 17.7$. [cf. $[Re(C_5H_5)_2H_2]PF_6$: $\tau = 4{,}17$ and $\tau = 24{,}6$].

We suggest that $Tc(C_5H_5)_2H$ has a bent structure similar to that of $Re(C_5H_5)_2H$.

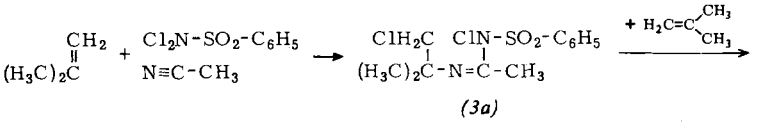
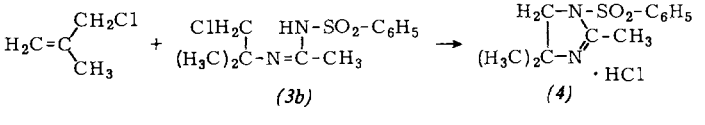
Coupled Addition to the Carbon-Carbon Double Bond

By *W. Theilacker* [*]

In kinetic studies of the addition of HOCl to cyclohexene from aqueous solution with acetonitrile as co-solvent, it was found that the acetonitrile takes part in the reaction and *N*-(2-chlorocyclohexyl)acetamide *(2)* [R + R′ = $(CH_2)_4$; here X = OH] is formed in a coupled reaction.



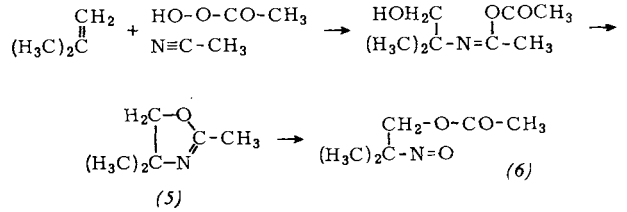
X = OH, Cl *(1)* *(2)*



This reaction can be extended to other olefins and nitriles, and chlorine and water can be used in place of HOCl. *Cairns, Graham, Barrick,* and *Schreiber* [1] have added chlorine to olefin-nitrile mixtures with exclusion of water, obtaining imidoyl chlorides *(1)*, X = Cl, which can be converted into amides *(2)* by hydrolysis. The addition proceeds more smoothly and in better yield in the presence of water.

When α,β-unsaturated acids (R′ = COOH) are used in place of olefins, chlorine in aqueous acetonitrile affords, after hydrolysis, the β-amino-α-hydroxycarboxylic acids in yields of up to 70 % (*e.g.* isoserine, isothreonine, isoallothreonine, isohydroxyvaline).

Coupled addition also occurs with *N,N*-dichlorobenzenesulfonamide instead of HOCl or Cl_2. The amidines thus formed give imidazoline hydrochlorides *(4)* in yields of 30 to 90 %, sometimes spontaneously, sometimes when heated in solvents, sometimes under the influence of bases.



(3a)

(3b) *(4)*

The olefin and the nitrile components may be varied within wide limits; *N,N*-dichlorobenzenesulfonamide may be replaced by ring-substituted analogues or *N,N*-dichloromethanesulfonamide. Moreover, *N,N*-dichlorocarboxamides, if stable, may be used. Only one chlorine atom takes part in the addition, the second being used for chlorination of the olefin at the allyl position, whence a method for chlorination of olefins at the allyl position may be developed.

Olefins of the isobutene type also react with nitriles and peracetic acid, giving nitroso compounds such as *(6)* by way of oxazolines such as *(5)*.

(5) *(6)*

Since these nitroso compounds are further oxidized by peracetic acid, the reaction conditions must be closely controlled.

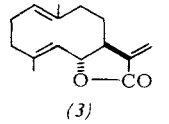
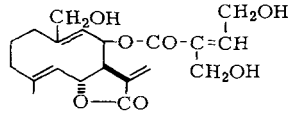
Sesquiterpenoids with Ten-Membered Rings

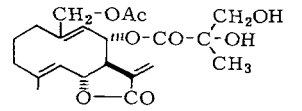


By *F. Šorm* [*]

Sesquiterpenoids are now known to include many diverse structures. Some sesquiterpenes, such as caryophyllene and humulene, also contain carbon rings of medium size, whose occurrence in nature was earlier considered unlikely. The most frequently encountered sesquiterpenoids are those with a ten-membered ring, which are derived from 4-isopropyl-1,7-dimethylcyclodecane (germacrane).

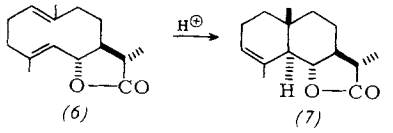


The presence of this ten-membered ring was first established in the lactone pyrethrosin *(1)* [1], and the first compound for which a complete determination of structure was presented was the ketone germacrone *(2)* [2]. Other lactones of this group were later isolated from plants of the family Compositae; they were named germacranolides. Together with the santanolides and the newly discovered guaianolides, ambrosanolides, and eremophylanolides they form an additional group of sesquiterpene lactones. The natural germacranolides are either simple unsaturated lactones such as costunolide *(3)*, or they contain an additional free (balchanolide, iosbalchanolide) or esterified hydroxyl group (acetylbalchanolide, eupatoriopicrin). Compounds containing two free or esterified hydroxyl groups have also been identified *e.g.* the bitter substances arctiopicrin *(4)*, cnicin *(5)*, scabiolide, and salonitolide.



(1)

(3)



(4)

(5)

The structure and stereochemistry of all the germacranolides named above have been elucidated and it has been shown that they are closely related to the santanolides and guaianolides. It is noteworthy that the germacranolides are readily converted into compounds of the santonin series by stereospecific transannular ring closure; for instance, dihydrocostunolide *(6)* yields santenolide *(7)* in an acid medium.

(6) *(7)*

The cyclodecadiene system of natural germacranolides also undergoes other interesting chemical changes: thus β-elemenone *(8)* is formed on pyrolysis of germacrone *(2)*.

(2) *(8)*

Analogous changes presumably take place in nature and compounds of the germacrane type may well be precursors of the santanolides and guaianolides, and perhaps of the elemane type. The elemane series have an irregular linkage of isoprene residues that is difficult to explain in any other way.

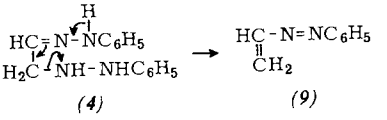
Recent Studies of Mechanism in the Carbohydrate Field

By *H. Simon*[*]

In connection with the Amadori rearrangement[1] and the hydrolysis of glycosylamines[2] we have studied transglycosidation by measuring the exchange rate of an *N*-glucoside with a free amine. This free amine was labeled with tritium and was chemically identical with that bound to the glycoside.



Reaction of *N-p*-nitrophenyl- *(1)*, *N-p*-tolyl- *(2,)* and *NN*-pentamethylene-D-glucosides *(3)* with the corresponding amines obeys second-order kinetics. The rate shows the same strong dependence on pH as that of the hydrolysis. Maximum rates are: for *(1)* in the strongly acidic region; for *(2)* at pH 1.5; and for *(3)* at pH 5.0. The mechanistic conclusions drawn for hydrolysis[2] can thus be extended to the present reactions.

Kinetic and tracer experiments have been made on glycolaldehyde and six of its derivatives, particularly on phenylhydrazinoacetaldehyde phenylhydrazone *(4)*, a type of compound not yet studied, although it is postulated as an intermediate in osazone formation. The hydrazone *(4)* cannot be dehydrogenated to the osazone by iodine, 2,6-dichlorophenolindophenol, oxygen, or Fe^{3+} ions; thus it is very improbable that phenylhydrazine can effect dehydrogenation in an intermolecular reaction; kinetic experiments have also provided evidence against such a supposition. The aniline eliminated during osazone formation also plays no decisive role; it is split off in an azaallyl elimination *(5)* → *(6)* which has parallels in the easy loss of amine from derivatives of an aminopropenol *(7)* → *(8)*[3]. A corresponding elimination of aniline occurs if glycoaldehyde is treated under osazone formation conditions.

(5) *(6)* *(7)* *(8)*

Compound *(4)* undergoes elimination of phenylhydrazine *(4)* → *(9)* as well as the decomposition *(5)* → *(6)*:

(4) *(9)*

The very rapid osazone formation from *(4)* in an anhydrous medium without addition of phenylhydrazine is therefore explained by assuming the reaction *(5)–(6)* and formation of the osazone by *(6)* and the phenylhydrazine which is liberated *via (4)–(9)*. α,β-Unsaturated azo compounds of type *(9)* probably are also produced during osazone formation from aldoses. Mannose phenylhydrazone gives the azo compound *ca.* 10 times faster than glucose phenylhydrazone – at least in pyridine/acetic anhydride – as was ascertained on use of labeled material. In this way the large difference in osazone formation shown by epimeric aldoses can be explained.

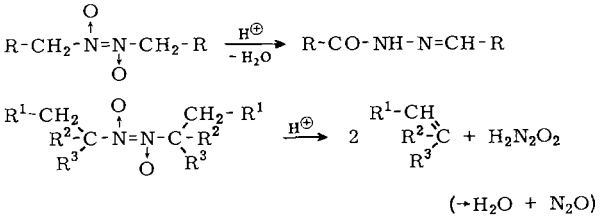
Acid-Catalysed Reactions of Aliphatic Nitroso Compounds

By *W. Pritzkow*[*]

Monomeric nitroso compounds may react with strong acids by prototropic rearrangement (route 1), by nucleophilic 1,2-migration of an organic group (route 2), or by fragmentation (route 3).



Reaction by route 1 is easily realized: it is the normal reaction of secondary nitroso compounds with acids. Route 3 is used when $R^{\oplus}$ is a relatively stable carbonium ion, *e.g.*:

In such cases prototropic rearrangement often takes second place to fragmentation.

No example has hitherto been found for route 2, nucleophilic 1,2-rearrangement, leading to nitrones.

For dimeric nitroso compounds with nitroso groups bound to primary carbon the reactions formulated above are accompanied by a disproportionating rearrangement, and for those with a nitroso group bound to tertiary C by an elimination:

(→H_2O + N_2O)

Lecture at Marl-Hüls (Germany), on November 2nd, 1966 [VB 29 IE]

Substitution Effects in Organosilicon Compounds

By *G. Schott*[*]

After a review of the most important categories of substitution constants [*e.g.* σ^H(*Hammett*), σ^* (*Taft*), σ' (*Roberts*), σ^0 (*Taft*)] and a discussion of the relationships existing between them, the applicability was investigated of these parameters to compounds in which the reactive center constitutes a silicon atom carrying a reactive substituent. Various test reactions were carried out [*e.g.* a) to c)], partly of nucleophilic and partly of electrophilic nature, and of different orders. The results obtained for about 80 organosilicon compounds can therefore be considered as of a general nature.

a) $R_3Si{-}O{-}CO{-}R' + ROH \longrightarrow R_3Si{-}OR + R'{-}CO{-}OH$

b) $R_3Si{-}H + Br_2 \longrightarrow R_3Si{-}Br + HBr$

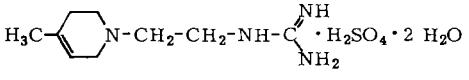
c) $R_3Si{-}H + H_2O \longrightarrow R_3Si{-}OH + H_2$

It was found that:

1. In substituted alkyl-Si compounds the σ^* constants (*Taft*) are experimentally confirmed; deviations were observed when the substituents were able to interact with the Si atom through $d\pi$-resonance.

2. In substituted phenyl-Si compounds, only the σ^0 constants (*Taft*) were applicable not the σ^H values of Hammet.

The conclusions made as to the bonding on Si atoms agree with the results obtained by spectrometry.



Lecture at Hamburg (Germany), November 11th, 1966 [VB 37 IE]

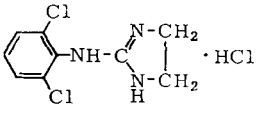
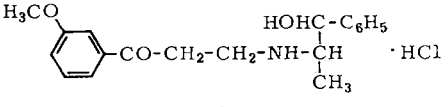
Therapy Congress and Pharmaceutical Exhibition



The 18th GermanTherapyWeek took place from August 27th to September 3rd, 1966 in Karlsruhe, in conjunction with an exhibition of drugs in which 285 firms participated. Examples of pharmaceuticals that contain new synthetic active components or components that are new to the German market, are described below; new combinations of known substances are not reported.

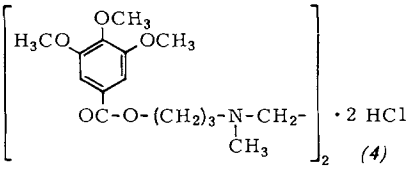
New antihypertonics were introduced by Farbenfabriken Bayer, Leverkusen, and by C. H. Boehringer, Ingelheim. Leron® from Bayer contains 1,2,3,6-tetrahydro-1-(2-guanidinoethyl)-4-methylpyridine sulfate dihydrate *(1)* (generic name: cyclazenin) as active component; it is a colorless, crystalline substance, m.p. 231–233 °C; the solution in water is neutral. Leron is suitable in particular for therapy of medium to severe hypertonicity when treatment with the usual antihypertonic drugs – even in combination with salidiuretics – is insufficient.



(1)

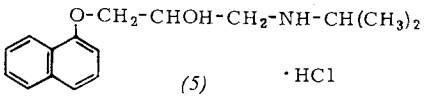
Catapresan® from C. H. Boehringer contains a new active component from the imidazoline group, namely 2-(2,6-dichloroanilino)-2-imidazoline hydrochloride *(2)*, which is readily soluble in water and alcohol. Catapresan differs both in its mode of action and in its structure from the imidazoline derivatives known hitherto, for the latter either decongest the mucous membranes (vasoconstrictors) or are strong vasodilators. It is suitable for treatment of pathological hypertension, even in advanced cases.

(2)



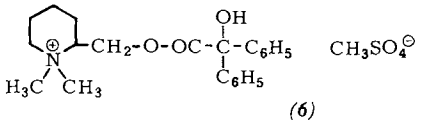
A new drug for treatment of coronary insufficiency, angina pectoris, myocardial infarction – particularly if there are also symptoms of cardiac weakness or incipient cardiac insufficiency and strengthening of the heart is desired – ildamen® from Chemiwerk Homburg, Frankfurt/M. contains as active component ω-[(β-hydroxy-α-methylphenethyl)-amino]-*m*-methoxypropiophenone hydrochloride *(3)* (generic name: oxyfedrin), m.p. 192–194 °C.

(3)



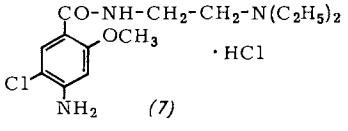
Ustimon® is a drug for strengthening the myocardium in treatment of coronary diseases; it was developed by Österreichische Stickstoffwerke, Linz, and introduced by Byk-

Gulden Lomberg GmbH., Constance. It contains *N,N'*-dimethyl-*N,N'*-bis-[3-(3,4,5-trimethoxybenzoyloxy)propyl]-ethylenediamine dihydrochloride *(4)* (generic name: hexobendin), a white, crystalline, water-soluble, bitter substance, m.p. 180 °C. Ustimon is suitable for treatment of circulatory disorders in the coronary vasicles and the myocardium, for prophylaxis and therapy of cardiac thrombosis, for treatment of postinfarction conditions, and for basic treatment of organic coronary diseases.



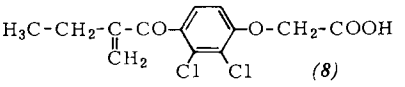
(4)

A novel product for the treatment of angina pectoris is Dociton®, produced by ICI Ltd., England, and marketed in Germany by Rhein-Pharma Arzneimittel GmbH., Heidelberg. Its active component is 1-(isopropylamino)-3-(1-naphthyloxy)propan-2-ol hydrochloride *(5)* (generic name: propanolol hydrochloride), a colorless substance, m.p. 163–164 °C, readily soluble in water and ethanol. Dociton acts by selective and reversible blocking of the β-receptors in the heart. In this way the heart is protected from the consequences of undesired sympathetic irritation (adrenalin and similar substances); the heart activity is thus economized by influencing the heart frequency, the myocardial tone, and the oxygen consumption.



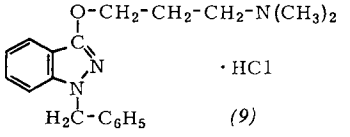
(5)

Acabel® from Chemie Grünenthal GmbH., Stolberg/Rheinland, is a new spasmolytic of the benzilic ester series. It consists of 2-(benziloylmethyl)-1,1-dimethylpiperidinium methyl sulfate *(6)* (generic name: piribenzil methylsulfate). Acabel is a parasympatholytic with marked musculotropic and neurotropic properties and is characterized by strong, rapid, and long-lasting spasmolysis and alleviation of pain with good tolerance and low dosage rates.



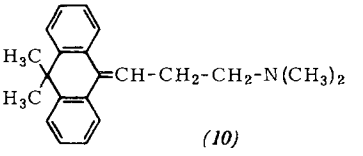
(6)

A new type of regulator for the motor function of the digestive tract, with simultaneous antiemetic action, has come on the market in the form of Paspertin® from Kali-Chemie AG., Hannover. The active component, 4-amino-5-chloro-*N*-[2-(dimethylamino)ethyl]benzamide hydrochloride *(7)* (generic name: metoclopramid), has no chemical relation to substances previously used for treatment of functional disturbances of the digestive tract and of nausea: it is a procaine amide derivative. Indications for Paspertin are nausea, vomiting, feeling of repletion, pressure on the stomach, epigastric pains, *etc.*



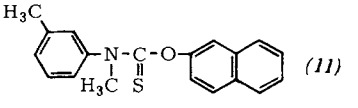
(7)

Hydromedin®, introduced by Sharp and Dohme GmbH., Munich, is a new sulfonamide-free diuretic suitable for treatment of edema at all stages and of the most varied origin. It contains [2,3-dichloro-4-(2-ethylacryloyl)phenoxy]-acetic acid *(8)* (generic name: etacrynic acid), a white, crystalline substance, m.p. about 122 °C, which is sparingly soluble in water.



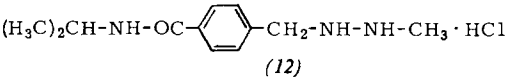
(8)

Kali-Chemie AG., Hannover, and Troponwerke, Cologne, jointly introduced the antiphlogistic tantum®. This preparation contains 1-benzyl-3-(3-dimethylaminopropoxy)-1*H*-indazole hydrochloride *(9)* (generic name: benzydamin hydrochloride) and has antiphlogistic, decongestive, and analgetic action on inflamed tissues. It is suitable for the treatment of postoperative or posttraumatic inflammations and swellings, inflammatory conditions of supporting and motor apparatus, and unspecific inflammation of the upper respiratory tract.



(9)

A new thymoleptic, Trausabun® from Byk-Gulden Lomberg GmbH., Constance, has both psychomotor stimulating and sedating components and consists of 9-[(3-dimethylamino)-propylidene]-9,10-dihydro-10,10-dimethylanthracene *(10)* (generic name: melitracen).

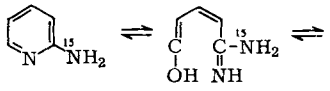


(10)

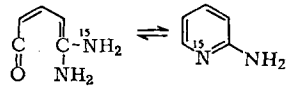
A new antimycotic has been introduced by Byk-Essex Pharmateuzische GmbH., Munich. Tonoftal® is a 1% solution of 2-naphthyl-*N*-methyl-*N*-(*m*-tolyl)thiocarbamate *(11)*, a colorless, odorless, oil-free liquid, suitable for local application in infections by *Trichophyton rubrum, Tr. mentagrophytes, Tr. tonsurans, Microsporon canis, M. audouini, Epidermophyton floccosum,* and *Malassezia furfur*; it is inactive against *Candida albicans.*

(11)

Natulan® belongs to a new class of cytostatics, the methylhydrazine derivatives. It is *N*-isopropyl-*p*-[(2-methylhydrazino)methyl]benzamide hydrochloride *(12)*, introduced by Hoffmann-La Roche AG., Grenzach/Baden. Natulan is



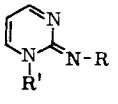
(12)



particularly suitable for treatment of lymphogranulomatosis, but successes have also been obtained against other malignant neoplasia. [VB 44 IE]

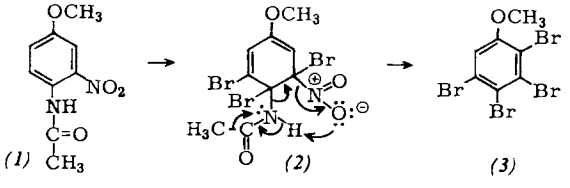
German version: Angew. Chem. 79, 102 (1967)

Reversible hydrolytic ring opening of 2-aminopyridine *(1)* was studied by *M. Wahren*. Prolonged heating of *(1)* with ^{15}N-labeled amino-nitrogen in hydrochloric acid or ammonium hydroxide results in hydrolysis to *(2a)*. Its tautomer *(2b)* provides the starting material *(1)*, with both nitrogens labeled.



(1a) *(2a)*

(2b) *(1b)*

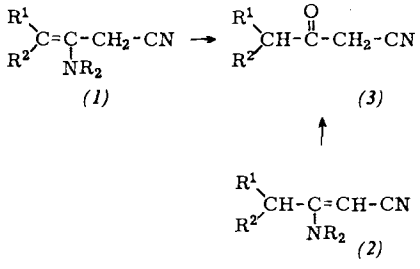


The exchange could be followed only up to about 4% of the expected equilibrium condition, because of the fast substitution of the amino group resulting in the formation of 2-hydroxypyridine. In the Dimroth rearrangement of iminodihydroheteroaromatic compounds to amino-heterocycles, an open-chain intermediate corresponding to *(2)* is also involved. For example, in aqueous sodium hydroxide 1-ethyl-1,2-dihydro-2-iminopyrimidine *(3a)* gives 2-ethylaminopyrimidine.

(3a): R = H; R' = C_2H_5
(3b): R = CH_3; R' = C_2H_5
(3c): R = C_2H_5; R' = CH_3

Interestingly, *(3b)* cannot rearrange to a stable aromatic structure, so that an equilibrium results between *(3b)* (40%) and *(3c)* (60%), as shown by *D. J. Brown, B. T. England*, and *J. S. Harper* on the basis of NMR studies. With different substituents R and R' the equilibrium lies on the side in which R in *(3)* is more bulky or a stronger electron attractant. / Z. Chem. *6*, 181 (1966); J. chem. Soc. (London) C *1966*, 1165 / –Bu. [Rd 543 IE]

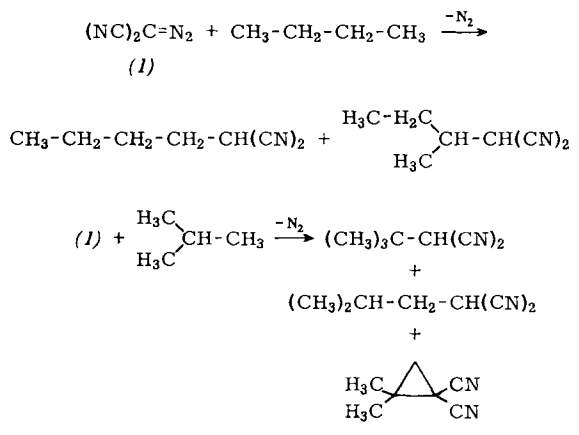
The concerted elimination of an acetamido and a nitro group was observed by *C. R. Harrison* and *J. F. W. McOmie* when they brominated 4-acetamido-3-nitroanisole *(1)* in acetic acid in the presence of a little pyridine. The product, 2,3,4,5-tetrabromoanisole, m.p. 140–141 °C, previously unknown, can be isolated in 57% yield. 4-Amino-3-nitroanisole, however, is brominated as expected in the 5-position. The reaction mechanism clarifies some earlier reactions, *e.g.* the loss of an acetamido group during bromination of anilides in HBr/HNO_3.



(1) *(2)* *(3)*

First *(1)* is brominated in 5-position followed by the addition of one molecule of bromine, resulting in *(2)*, which eliminates HNO_2 and methyl isocyanate and is again brominated to give *(3)*. / J. chem. Soc. (London) C *1966*, 997 / –Bu. [Rd 545 IE]

An alternative to the Sandmeyer synthesis of aromatic bromo-compounds is suggested by *J. I. G. Cadogan, D. A. Roy*, and *D. M. Smith*. Instead of adding the diazonium salt to a HBr/CuBr solution, substituted anilines can be diazotized with amyl nitrite in bromoform at 100 °C. This procedure is not suitable for chloro-compounds, as chlorine radicals are less easily abstracted. Examples: 4-bromoaniline gives 69% of 1,4-dibromobenzene; methyl 2-aminobenzoate yields 71% of methyl 2-bromobenzoate. / J. chem. Soc. (London) C *1966*, 1250 / –Bu. [Rd 546 IE]

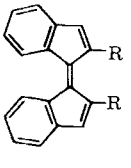


The synthesis of enamines from allenes was studied by *P. M. Greaves* and *S. R. Landor*. Amines add to 1-cyanoallenes with small alkyl substituents in a fast exothermic reaction. 1-Cyanoallenes with larger substituents must be heated with the amines. The enamines are formed in 80 to 90% yield. Addition takes place in the 1,2 or 2,3 position; diethylamine adds predominantly in the 1,2 position, and piperidine preferentially in the 2,3 position. The two types of enamines *(1)* and *(2)* do not isomerize, and evidently are formed by

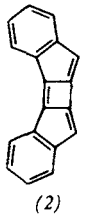
(1) *(3)* *(2)*

two different routes. They can be quantitatively hydrolysed to the same β-oxonitriles *(3)*, so providing a new synthesis of these compounds. / Chem. Commun. *1966*, 322 / –Ma. [Rd 551 IE]

The reaction of dicyanocarbene, which is liberated from dicyanodiazomethane *(1)*, with alkanes, alkenes, and alkynes has been studied by *E. Ciganek*. The carbene is inserted into the primary, secondary, and tertiary C–H bonds of n-butane and isobutane in the relative ratios of 1:4.6:12. The addition of the carbene to *cis*- and *trans*-2-butenes is not stereospecific.

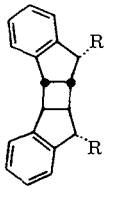


At high dilution, both isomers give a mixture of 70% of *trans*- and 30% of *cis*-2,3-dimethyl-1,1-dicyanocyclopropane. Compound *(1)* adds to alkynes to give 3,3-dicyanocyclopropenes. / J. Amer. chem. Soc. *88*, 1979 (1966) / –Ma. [Rd 552 IE]



2-Pyridinecarbaldehyde oximes have been prepared by *F. A. Daniher, B. A. Hackley*, and *A. B. Ash* in a one-step reaction from 2-chloromethylpyridines and a buffered aqueous-ethanolic solution of hydroxylammonium chloride, using a method described by *S. Forman*. Examples: 5-chloro-2-chloromethylpyridine gave 63 % of 5-chloro-2-pyridinecarbaldehyde oxime (m.p. 194–195 °C); ethyl 6-chloromethyl-3-pyridinecarboxylate gave 72 % of ethyl 6-hydroxyiminomethyl-3-pyridinecarboxylate (m.p. 128–129 °C). These compounds, which could previously be obtained only by syntheses involving several steps, are precursors of *N*-methyl-2-hydroxyiminomethylpyridinium iodides, which are of interest as antidotes for poisoning by organic phosphines. / J. org. Chemistry *31*, 2709 (1966) / –Bu. [Rd 563 IE]

Trifluoromethylated and chlorodifluoromethylated 1,3,5-oxadiazines and 1,3,5-dioxazines can, according to *M. E. Hermes* and *R. A. Braun*, be obtained in good yields by condensation of hexafluoroacetone or 1,3-dichlorotetrafluoroacetone with cyanamides. For example, from hexafluoroacetone and an excess of dimethylcyanamide at 175 °C, these authors obtained 91 % of 4,6-bis(dimethylamino)-2,2-bis(trifluoromethyl)-2*H*-1,3,5-oxadiazine (m.p. 136 °C, b.p. 250 °C), while with an excess of hexafluoroacetone at 150 °C, 6-dimethylamino-2,2,4,4-tetrakis(trifluoromethyl)-4*H*-1,3,5-dioxazine is obtained as an unstable liquid in 96 % yield. The oxadiazines and dioxazines with unsubstituted amino groups (obtained from cyanamide) undergo thermal rearrangement to form dihydrotriazines and dihydrooxadiazines, e.g. 4,6-diamino-2,2-bis(chlorodifluoromethyl)-2*H*-1,3,5-oxadiazine → 4-amino-2,2-bis(chlorodifluoromethyl-1,2-dihydro-1,3,5-triazin-6-ol (m.p. 298 to 299 °C, λ_{max} = 212 mμ, ε = 2820). / J. org. Chemistry *31*, 2568 (1966) / –Bu. [Rd 564 IE]



A symmetrical dibenzofulvalene (1a) was obtained by *A. G. Anastassiou, F. L. Setliff*, and *G. W. Griffin* in an (unsuccessful) attempt to prepare *(2)*. Indene was irradiated with long-wave UV light for 24 hours to obtain *syn,trans*-tuxane *(3a)*, which reacted with *N*-bromosuccinimide to form *(3b)*. Treatment of *(3b)* with potassium amide in liquid ammonia yields 27 % of biindenyl and about 2 % of *(1a)*, the structure of which was proved by analysis, NMR spectrometry, and comparison of the UV spectrum with that of *(1b)*, which was known. Unlike the parent compound fulvalene, *(1a)* is very

(1a) R = H
(1b) R = Br

(2)

(3a) R = H
(3b) R = Br

stable. (Calculated delocalization energy 6.73 β; m.p. of the gold-yellow leaflets > 300 °C). / J. org. Chemistry *31*, 2705 (1966) / –Bu. [Rd 565 IE]

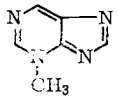
L-Lysine oxygenase from *Pseudomonas fluorescens* has been crystallized by *H. Takeda* and *O. Hayaishi*. The enzyme, which catalyses the decarboxylation of lysine with oxidation, by atmospheric oxygen, to δ-aminovaleramide, has a mole-

$$NH_2-(CH_2)_4-CHNH_2-COOH + O_2 \rightarrow NH_2-(CH_2)_4-CONH_2 + CO_2 + H_2O$$

cular weight of 191 000; each molecule contains 2 molecules of flavin-adenine dinucleotide (FAD), which can be readily removed with ammonium hydrogen sulfate. The apoenzyme can be reactivated to the extent of 50 to 80 % by 10^{-6} M FAD. No iron or copper could be detected in the enzyme; the detection limits were 0.05 and 0.01 mole, respectively, per mole of FAD. / J. biol. Chemistry *241*, 2733 (1966) / –Hö. [Rd 567 IE]

Cytochrome C peroxidase from baker's yeast mitochondria has been obtained as crystals having maximum dimensions of 5×0.2×0.2 mm³ by *T. Yonetani, B. Chance*, and *S. Kajiwara*. These authors made use of the fact that the concentrated enzyme is much less soluble in distilled water than in buffer solutions. The crystallization took place during the dialysis of an approximately 0.2 mM solution in phosphate buffer against water, with the addition of seed crystals. The crystals showed no change in crystal form or loss of enzyme activity on storage for 5 hours at 23 °C in an atmosphere saturated with water vapor. Substrates such as H_2O_2, CH_3OOH, and C_2H_5OOH were absorbed by the crystals to form the enzyme-substrate complex, with no observable change in crystal form. The enzyme and the enzyme-substrate complex are isomorphous, the color merely changes from brown to red-brown. / J. biol. Chemistry *241*, 2981 (1966) / –Hö. [Rd 568 IE]

5'-Hydroxypolynucleotide kinase has been characterized and concentrated from phage-infected (T1 and T5) *Escherichia coli* by *A. Novogrodsky*. The enzyme catalyses the phosphorylation of free 5'-hydroxyl groups in polynucleotides. Nucleosides and 2'-substituted nucleosides are not phosphorylated. The phosphate donors are ATP, GTP, UTP, and CTP. The characterization of the enzyme is based on the following observations: 1. Micrococcus nuclease, an endonuclease, which produces fragments having free 5'-hydroxyl groups from DNA and RNA, increases the phosphate receptor activity of DNA and RNA. 2. Alkaline phosphatase and phosphomonoesterase split off ^{32}P-phosphate from polynucleotides that have been labeled with ^{32}P-phosphate in the 5' position by the kinase. 3. Polyriboadenylate and polyribocytidylate that have been labeled as in 2 give labeled 2'(3')-5'-adenosine diphosphate and 2'(3')-5'-cytidine diphosphate on alkaline degradation. 4. During the degradation of a polynucleotide from the 3' end (by snake venom phosphodiesterase), ^{32}P-phosphate is incorporated at the 5' end by the kinase. The kinase was also detected in rat liver cell nuclei, but not in uninfected *E. coli*. / J. biol. Chemistry *241*, 2923, 2933 (1966) / –Hö. [Rd 569 IE]



The conditions for the binding of mRNA on ribosomes have been studied by *P. B. Moore*. The experiments were carried out with ribosomes from *Escherichia coli* and with synthetic homopolynucleotides (poly-U and poly-C). The optimum magnesium ion concentration was 10^{-2} M, but Mg^{2+} could be replaced by Ca^{2+} and Mn^{2+}, and even by spermidine (polycation, 10^{-3} M). It is therefore unlikely that the cations act as complex formers. Each ribosome can bind only poly-U or poly-C, pointing to the existence of only one mRNA-binding site per ribosome. The binding of mRNA never required the presence of other cofactors such as tRNA, GTP, or the transferases. In view of the pretreatment of the ribosomes, it is very unlikely that these factors could still have been bound. / J. molecular Biol. *18*, 8 (1966) / –Hö. [Rd 570 IE]

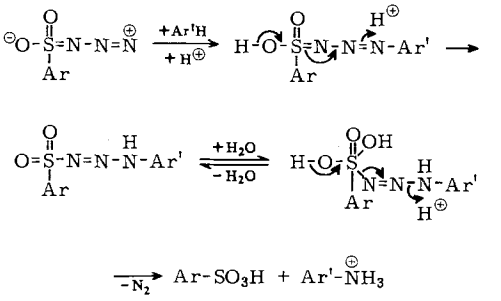
Desensitization of fructose-1,6-diphosphatase by chemical modification has been achieved by *O. M. Rosen* and *S. M. Rosen*. The enzyme catalyses the dephosphorylation of fructose-1,6-diphosphate. It is reversibly and non-competitively inhibited by AMP, whereas the enzyme phosphofructokinase, which catalyses the reverse reaction, is activated by AMP. The inhibition by AMP is hindered (desensitization) if the enzyme is treated with 1-fluoro-2,4-dinitrobenzene in the presence of fructose-1,6-diphosphate. This is not accompanied by any

loss of activity. The desensitization is irreversible. The enzyme is irreversibly deactivated when it is treated with the fluorodinitrobenzene in the absence of fructose-1,6-diphosphate. On total hydrolysis of the enzyme after treatment with fluorodinitrobenzene, *o*-dinitrophenyl-tyrosine and ε-dinitrophenyllysine were found in equal quantities. The enzyme can be reversibly desensitized by *p*-chloromercuribenzoate or urea. / Proc. nat. Acad. Sci. USA *55*, 1156 (1966) / –Hö. [Rd 577 IE]

Evidence of the interaction between aminoacyl-tRNA and transferase I has been obtained by *F. Ibuki, E. Gasior,* and *K. Moldave.* The transfer of amino acids from aminoacyl-tRNA to peptides requires the presence, not only of ribosomes and mRNA, but also of guanosine triphosphate, a thiol, and the aminoacyltransferases I and II. The very labile transferase I is relatively stable in the reaction mixture. This stabilization is attributed entirely to the interaction with aminoacyl-tRNA, whose influence is lost on removal of the amino acid. No specificity for the tRNA species can be detected. Conversely, transferase I protects the aminoacyl-tRNA against hydrolysis. It appears that a transferase I-aminoacyl-tRNA complex is formed, in which the components stabilize each other. / J. biol. Chemistry *241*, 2188 (1966) / –Hö. [Rd 578 IE]

3-Methylpurine *(1)*, the only *N*-methyl isomer of purine that had not previously been described, has been synthesized by *B. Townsend* and *R. K. Robins.* 3-Methylpurine is of interest as a model substance for a series of naturally occurring 3-substituted purines. (Thus glycosidization of synthetic 6-dimethylaminopurine nucleosides, which are related to puromycin, takes place, not in position 7, but in position 3 of the purine). The compound *(1)* is prepared by desulfuration of 3-methyl-6-methylthiopurine in hot methanol with Raney nickel. 3-Methylpurine forms crystals having m.p. 184–185 °C (from n-heptane/benzene) and is stable for several months, but is rapidly decomposed by 1 N alkalis.

(1)



3-Methylpurine and its derivatives are more reactive than the other methylpurines, this is due to the possibility of formation of many polar structures. / J. heterocyclic Chem. *3*, 241 (1966) / –De. [Rd 590 IE]

Lean $H_2/N_2/O_2$ flames containing alkali metal have been studied spectrophotometrically at about 2000 °K by *M. J. McEwan* and *L. F. Phillips.* These authors found that considerable quantities of NaO_2 are formed as a result of the reaction

$$Na + O_2 + M = NaO_2 + M \qquad M = \text{Collision partner}$$

By measurement of the equilibrium constants of this reaction, the dissociation energy $D^0_{Na-O_2}$ was found to be 65 ± 3 kcal/mole. Potassium behaves similarly but, owing to the greater stability of KO_2, the dissociation energy could not be determined in this case. / Trans. Faraday Soc. *62*, 1717 (1966) / –Hz. [Rd 593 IE]

Acid-catalysed amination of aromatic compounds can be achieved with arenesulfonylazides, according to *G. S. Sidhu, G. Thyagarajan,* and *U. T. Bhalerao.* (The synthesis was discovered in the study of the Schmidt reaction on chromones). The following reaction proceeds in good yield (see Table) in concentrated H_2SO_4 even below 25 °C:

Ar	Ar'–NH_2	Yield (%)
C_6H_5	C_6H_5–NH_2	60–65
p-CH_3–C_6H_4	C_6H_5–NH_2	60–65
C_6H_5	*o*- and *p*-CH_3–C_6H_4–NH_2	55–60
p-CH_3–C_6H_4	*o*- and *p*-Cl–C_6H_4–NH_2	35–40

Since substituents in the nucleus of the arenesulfonylazide evidently have no influence, the authors conclude that the reaction involves direct electrophilic substitution of the substrate Ar'H by the azide $ArSO_2N_3$. / Chem. and Ind. *1966*, 1301 / –Jg. [Rd 594 IE]

BOOK REVIEWS

Gmelins Handbuch der anorganischen Chemie (Gmelin's Handbook of Inorganic Chemistry), 8th completely revised edition. Published by the Gmelin-Institut für anorganische Chemie und Grenzgebiete in der Max-Planck-Gesellschaft zur Förderung der Wissenschaften. Initiated by *R. J. Meyer*, continued by *E. H. Erich Pietsch*. Verlag Chemie GmbH., Weinheim/Bergstr.

The output of "Gmelin" for 1964 amounted to seven volumes containing a total of 3521 pages and 1078 illustrations at a total price of DM 2898; these are impressive figures, both editorially and from the point of view of price.

System No. 3: Oxygen. Vol. 6: Ordinary Water (electrochemical behavior, systems with organic solvents), isotopic varieties of water, ions of water. 1964, iv, xxiii, 364 pp. with 60 illustrations. Cloth DM 278.–. Revised by *Anna Bohne-Neuber, Erna Brennecke, P. Koch, Margarete Lehl-Thalinger, Gertrud Pietsch-Wilcke.*

The present Vol. 6 continues the description of the compounds of oxygen started in Vol. 5 (1963) [*]. In accordance with the "Gmelin principle", the only compounds of oxygen are water and hydrogen peroxide.

The chapter on ordinary water is first concluded with two sections "Electrochemical behavior" (17 pp.) and "Systems with organic solvents" (70 pp.). In the former, particular attention is given to the specific conductance of natural and distilled water and to the electro-kinetic phenomena occurring in liquid water. The second presents a general review of the behavior of mixtures of organic solvents with water, particularly from the point of view of phase theory, the discussion being confined to a few particularly important solvents (benzene, methanol, ethanol, diethyl ether, dioxane, acetic acid).

Most (about $^2/_3$) of this volume deals with the isotopic varieties of water (237 pp.). Corresponding to the three hydrogen isotopes ^1H = H, ^2H = D, and ^3H = T and the three oxygen isotopes ^{16}O, ^{17}O, and ^{18}O, there are 18 possible varieties of water. Of these, only "heavy water" D_2O (O =

[*] Cf. Angew. Chem. *76*, 930 (1964).; Angew. Chem. internat. Edit. *3*, 710 (1964)

natural mixture of oxygen isotopes), together with HDO, which is always present in mixtures with H_2O but is unstable in the pure liquid phase, is of any practical importance; consequently, 205 pages (more than $^6/_7$) of this chapter are devoted to D_2O and HDO, while the remaining 32 pages deal with the other varieties of water, special attention being given to the heavy water $H_2{}^{18}O$ and the super-heavy (radioactive) water T_2O. Special mention should be made of the data on the formation of D_2O (and HDO) from H_2O by nuclear reaction, by synthesis from the elements, and by isotope exchange between water and hydrogen and between water and hydrogen compounds, on the concentration and purification of D_2O on the laboratory and industrial scales – electrolytic dissociation of water, fractional distillation of water and of hydrogen, isotope exchange between hydrogen, hydrogen compounds (hydrogen sulfide, mercaptans, ammonia, cyclohexane, benzene) and water, with discussion of the fundamental principles and illustrations of apparatus –, on the physical and chemical properties of D_2O and HDO, on the behavior of heavy water as a solvent, and on the analysis of heavy water.

The last chapter, "Ions of water" (40 pp.) deals with the H_3O^+ and OH^- ions, including their hydrated and deuterated forms.

The literature is fully covered up to the end of 1949, and further references are cited to bring the literature up to the present, though these references are not exhaustively utilized in every case. The System No. "Oxygen", including the present volume, now covers 2096 pages and contains 372 illustrations (total price DM 1311.–).

System No. 16: Phosphorus. Part B: Technology, physiological damage, the element. 1964, iv, xxx. 458 pages with 32 illustrations. Cloth DM 350.–. Revised by *M. Atterer, Vera Haase, G. Hantke, A. Hirsch, G. Kirschstein, H. K. Kugler, A. Kunze, Gertrud Pietsch-Wilcke, K. Rumpf, F. Seuferling, Ph. Stiess, Hildegard Wendt.*

The present Part B is the first volume of the 8th edition on the important element phosphorus, which has not been revised since the (385 pp.) corresponding volume of the last edition (1911). It deals with the technology of phosphorus and phosphoric acid (86 pp.), physiological damage due to phosphorus and its compounds (11 pp.), and elementary phosphorus (361 pp.).

The chapter "Technology" is concerned in particular with the methods for the wet decomposition and thermal reduction of crude phosphates, and for the oxidation of phosphorus, the working-up (purification, concentration) of technical phosphoric acid, the production of white phosphorus, and its conversion into the red form.

The section "Physiological damage" deals with damage (*e.g.* burns, poisoning) by white phosphorus and phosphorus compounds (phosphine, phosphoric acids, phosphorus halides, phosphorus sulfides, radioactive phosphorus).

Most (80 %) of the volume is devoted to elementary phosphorus. Following a brief note (6 pages) on general properties, position in the periodic table, valence, and atomic weight, the formation and preparation of the element in the laboratory are d scussed (4 pp.). In view of the growing scientific and practical importance of the radioactive isotopes ^{32}P (half-life 14.3 days) and ^{33}P (half-life 25.0 days) over the last few decades, the formation, concentration, and separation of these isotopes, as well as the classification of the phosphorus isotopes in general, are reported at length (53 pp.). The sections on the atom and atom-ions, molecules and molecule-ions, and forms of phosphorus report in detail (72 pp.) on the properties of the atom in the ground and excited states (optical spectra, X-ray spectra, absorption and scattering of X-rays and γ-rays), the interactions in the valence activity of phosphorus, the P_2 and P_4 molecules, and the transitions between the white, red, violet, and black forms of phosphorus. In the chapter on physical properties (26 pp.), the macrophysics of elementary phosphorus is subdivided in the usual manner according to physical states and modifications. The chapter on chemical behavior (80 pp.), contains particularly interesting notes on the behavior of white phosphorus towards light, heat, and oxygen, on the reactions of phosphorus with acids, non-metals, compounds of non-metals, metals, and compounds of metals, and on the solutions of phosphorus in inorganic and organic solvents. Detailed data are also given in the chapter "Detection and determination" (120 pp.). Since the volumes of *Fresenius-Jander*'s handbook of analytical chemistry dealing with the qualitative (1956) and quantitative (1953) analysis of phosphorus have already been published, this chapter is confined to period between about 1950 and the end of 1960.

The present Part B, which contains numerous illustrations and (in keeping with the practice followed for some years) has German/English indices and marginal notes in English, was followed by two further volumes in 1965; these will be reviewed in the future.

System No. 19: Bismuth. Supplement 1964, iv, lviii, 866 pages with 212 illustrations. Cloth DM 652.–. Revised by *Hildegard Banse, Elisabeth Bienemann-Küspert, G. Czack, H. Engst, Inge Flachsbarth, H. Golder, Eleonore Kirchberg, G. Kirschstein, Marie-Luise Klaar, K. Koeber, Imberta Leitner, Ellen von Lindeiner-Schön, Wolfgang Müller, Gertrud Pietsch-Wilcke, N. Polutoff, H. Rieger, K. Rumpf, W. Schaffernicht, P. Schubert, F. Seuferling, Hildegard Wendt.*

The present supplement to the 229-page principal volume "Bismuth", which appeared in 1927, covers literature published up to the end of 1960, and deals in the usual manner with the occurrence of bismuth, physiological damage due to bismuth, elementary bismuth, and the compounds of bismuth.

The occurence of bismuth, which covers only a few pages in the principal volume, is now subjected to a new and lengthy discussion (153 pp.), which is subdivided as usual into the sections extraterrestrial occurrence, geochemistry, topography, and minerals.

Following a few data on physiological damage due to elementary bismuth and its compounds (8 pp.), the main chapter (more than half of the text) contains a description of elementary bismuth (460 pp.). This part begins with short discussions (3 pp.) on the position of bismuth in the periodic table, its valence, and its atomic weight, and then goes into details of the formation and preparation of the element (46 pp.). This section deals with the technology of bismuth (working-up of the crude material, isolation of the metal from bismuth ores, purification of crude bismuth and reactor bismuth, preparation of pure bismuth, purity testing, use) as well as with the preparation of special forms of bismuth (particularly colloidal solutions, thin layers and films, single crystals). In the discussion of the physical properties (251 pp.), the handbook takes the modern development into account, and deals with the properties of the atomic nucleus, the atom, the atom-ions, the molecule and the molecule ions (total 98 pp.) separately from those of the bulk metal (153 pp.). Thus this chapter begins with a description of the 18 known bismuth isotopes (the natural isotopes ^{209}Bi, ^{210}Bi (RaE), ^{211}Bi (AcC), ^{212}Bi(ThC), and ^{214}Bi (RaC) being discussed together with all the other nuclides, in contrast to the principal volume), and the formation, concentration and separation, the decay and nuclear reactions of the bismuth isotopes, and the behavior of Bi activities in practically weightless quantities are discussed. This is followed by data on the arc and X-ray spectra of the bismuth atom, the absorption, scattering, and reflection of X-rays and γ-rays, positive and negative bismuth ions, and the Bi_2 molecule and the Bi_2 anion. The section on bulk bismuth begins with data on the one-component system bismuth (constitution diagram, vaporization and condensation, latent heats), and then proceeds in the usual manner with a discussion of the macrophysics of bismuth, which concentrates largely on the structural-crystallographic, mechanical-thermal, and electric-magnetic properties, and on

the electrochemical behavior (potentials, cells, behavior as electrode, electrolytic deposition of bismuth from solutions and melts).

The chapter on the chemical behavior (40 pp.) also takes into account the investigations (behavior of the melt towards metals, alloys, and other reactor materials) carried out in recent years in connection with the use of molten bismuth in reactor technology. The survey of the chemical behavior of the bismuth ion is also valuable. The chapter on the detection and determination of bismuth (99 pp.) follows the chapters on the qualitative (1956) and quantitative (1951) analysis of bismuth in *Fresenius-Jander*'s handbook of analytical chemistry, and deals mainly with the literature published between 1950 and the end of 1960. In accordance with the Gmelin principle, the only alloys of bismuth discussed are the Bi/Sb alloys (21 pp.).

In accordance with the same principle, the bismuth compounds discussed (245 pp.) are those with hydrogen, oxygen, nitrogen, halogens, chalcogens, boron, carbon, silicon, phosphorus, arsenic, and antimony. The sections on bismuth halides and chalcogenides are particularly detailed, and account for 80 % of the chapter.

With the present bismuth volume, there is now available a complete, up to date description of the elements of Group V of the periodic system.

System No. 21: Sodium. Supplement, Vol. 1: Technology of sodium and its compounds. 1964. iv, xxiv, 399 pages with 35 illustrations. Cloth DM 304.–. Revised by *K. Beeker, E. Best, H. Bitterer, G. Hantke, A. Hirsch, H. K. Kugler, A. Kunze, F. Plessmann.*

The present Vol. 1 of the supplement to the 992-page principal volume "Sodium", which appeared in 1928, deals with the technology of sodium and its compounds, the literature up to and including 1960 being fully covered. The volume clearly shows the development trends during this period.

In the isolation of metallic sodium, the transition from the electrolysis of molten sodium hydroxide (Castner method) to that of molten sodium chloride (Downs method) has been almost completed: in 1925, 75 % of the world production (15240 t) were still produced by the Castner method, while in 1957, 98 % of the world production, which had increased in the meantime by a factor of more than ten (203708 t) were produced by the Downs method.

The process that was formerly almost exclusively used for the preparation of sodium hydroxide solution, *i.e.* the calcination of soda, has been largely replaced by the electrolysis of sodium chloride solutions, particularly by the amalgam process; the chlorine, which was occasionally regarded as an undesirable by-product, is steadily becoming the principal product (with a resulting over production of NaOH).

The section on the production of sodium nitrate deals *inter alia* with the Guggenheim process of cold-leaching of caliche, which had to be adopted during the 1930's because of competition from synthetic saltpeter.

The description of the production of sodium chloride contains interesting sections on modern flotation processes, advances in the preparation, purification, and concentration of brines, and controlled crystallization. The section on sodium salts of the oxo acids of chlorine reports *inter alia* on the production of dilute sodium hypochlorite solutions (mainly used for the bleaching of paper and textiles), the preparation of sodium chlorite (introduced around 1940 as a bleach for fibers and textiles), and progress in the electrochemical isolation of sodium chlorate (which is important as an oxidizing agent) and of sodium perchlorate (used as an intermediate in industrial inorganic chemistry).

Most of the section on sodium sulfide is devoted to the classical method of reduction of sodium sulfate with coal. In the section on sodium salts of oxo-acids of sulfur, mention should be made of the notes on the regeneration of sodium sulfite from cellulose brines, on the production of sodium sulfate from brines, and on the technology of sodium thiosulfate and sodium dithionite.

The description of the large-scale production of $NaBH_4$, which is finding increasing use as a selective reducing agent and as a starting material for the production of boranes, is particularly interesting.

The discussion of the production of soda shows the extensive development, both theoretical and practical, of the Solvay process. The section on the technology of sodium cyanide deals mainly with progress in the Castner process (preparation from ammonia, sodium, and coal) and in the Bucher process (preparation from atmospheric nitrogen, soda, and coal).

The section on the preparation of sodium silicate (water glass) describes, not only the method normally used at present, *i.e.* fusion of the raw materials and dissolution of the product, but also the numerous suggestions for production by a wet process.

An important section in the description of the technology of sodium phosphates deals with the condensed sodium phosphates, which have grown in importance since about 1925, and which now account for more than 75 % of the total phosphate output.

The section on the peroxo compounds of sodium deals in particular with sodium peroxide, sodium peroxosulfate, and the peroxohydrates of sodium borate, carbonate and phosphate.

A final section discusses physiological damage due to sodium and sodium compounds (working hazards in the production and use of metallic sodium, sodium hydride, oxide, peroxide, hydroxide, amide, *etc.*, radioactive sodium). Volume 2, which was published in 1965, will be reviewed later.

System No. 58: Cobalt. Supplement, Part B, Vol. 2: Complex compounds of trivalent cobalt. 1964, iv, xxxix, 507 pages with 71 illustrations. Cloth DM 471.–. Revised by *K.-Chr. Buschbeck, H. Feicht, R. Gagarin, Ursula Hettwer, G. Krause, Irmingard Kreuzbichler, H. Lehl, W. Schaffernicht, (the late) G. Schleitzer, Edith Schleitzer-Steinkopf.*

The present Vol. 2 completes the supplement to the principal Vol. B of the System No. "Cobalt", the 314-page Vol. 1 (Complex compounds of mono- and bivalent cobalt) having appeared a year earlier.

The volume is divided into two parts: Part 1 (317 pp.) deals with the complex Co(III) compounds with normal bonding of the ligands, and Part 2 (142 pp.) with complex Co(III) compounds with inner-orbital bonding of the ligands. The volume is introduced by three pages on taxonomy, configuration notation, and the *trans*- and *cis*-effect, and concludes with a 45-page appendix containing addenda, a list of abbreviations for commonly-occurring ligands, and a particularly welcome formula and alphabetic index of the organic complex formers occurring as ligands and addends in the principal volumes Cobalt A (1931/32) and Cobalt B (1930) and in the two corresponding supplements A (1961) and B (1963/64).

Part 1 of the text, which is divided into mononuclear and polynuclear complexes, begins the section on mononuclear complexes (297 pp.) with compounds of the hexammine type $[CoA_6]^{3+}$ (86 pp.) having six (similar or dissimilar) neutral ligands A. Corresponding to the coordination number 6 of cobalt, this is followed by complexes of the pentammine type $[CoXA_5]^{2+}$ (74 pp.) having one acid ligand X, the tetrammine type $[CoX_2A_4]^{+}$ (108 pp.) having two, the triammine type $[CoX_3A_3]$ (14 pp.) having three, the diamminecobaltate(III) type $[CoX_4A_2]^{-}$ (14 pp.) having four, and the monoamminecobaltate(III) type $[CoX_5A]^{2-}$ (1 p.) having five (similar or dissimilar) acid ligands X[**]. In the section on polynuclear complexes (20 pp.), the discussion starts with dinuclear cobalt(III) compounds having one, two, and three bridge

[**] The cobaltates(III) of the type $[CoX_6]^{3-}$ having six acid ligands X were described earlier in Supplement A (1961).

bonds, and then proceeds *via* the tri- and tetranuclear complexes to the polymeric polynuclear compounds. The discussion covers not only the preparation and the physical and chemical properties of the various complexes, but also questions relating to the stereoisomerism of such compounds with optically inactive and optically active ligands; very complicated situations occasionally arise in the latter case (*e.g.* eight stereoisomeric forms of tris(propylenediamine)-cobalt(III) complexes $[Copn_3]^{3+}$).

Part 2 deals with cobalt(III) complexes with inner-orbital bonding of the complex formers, (*e.g.* porphyrins, amino acids, ethylenediaminetetraacetic acid, dimethylglyoxime), *i.e.* simultaneous bonding to the cobalt by neutral and acid groups of the ligands. The complexes in this part are grouped, not according to complex types, as in Part 1, but according to ligands, by analogy with the arrangement of Vol. 1 of Supplement B. Special mention should be made of the cobalt complexes with α-amino acids and peptides (with their isomerism and optical activity), the complexes with ethylenediaminetetraacetic acid (which have recently been studied to an increasing extent, and in which the ligand may be hexa- and pentadentate), and the complexes with Schiff bases, with dimethylglyoxime (*Chugaev*'s reagent), with biguanide and its derivatives, and with cysteine.

The literature is fully covered up to the end of 1949, with extensive supplements for the period 1950 to 1960 taking into account developments up to the present time. With the present volume, the System No. "Cobalt" now contains 2585 pages and 342 illustrations, and costs a total of DM 1718.–. Alloys containing cobalt are described in System No. 59 "Iron", Part D, 2nd Supplement (magnetic materials).

System No. 59: Iron. Gmelin-Durrer: Metallurgy of iron, 4th completely revised edition, Vol. 1: Historical, definitions, general physicochemical principles, thermal pretreatment of iron ores (at the same time supplement to the principal volume "Iron", Part A, Vols. 3 to 5). Vol. 1a: 1964, iv, vii, xxii, 583 pages; Vol. 1b: 1964, iv, 344 pages with 668 illustrations. Cloth, total DM 843.–. Revised by *F. Cappel, E. Franke, B. Ilschner, W. John, H. Meiler, K. Meyer, H. Rausch, F. Rex, Brigitte Schenkel, G. von Struve, H. Viereck, Hertha Winkler.*

With the present Vol.1 of the 4th edition of "Gmelin-Durrer", the Gmelin-Institut resumes the discussion of the wide topic of the metallurgy of iron, which was started in the 1st edition in 1933, and which has now been expanded to four volumes. The work also represents a supplement to Vols. 3 (1930), 4 (1932), and 5 (1933) of Part A of the Gmelin principal volume "Iron", which also deals with the metallurgy of iron. As a deviation from the practice previously followed, each of the four volumes planned is subdivided into a text volume (a) and an illustration volume (b), since the number of illustrations is so large (in Vol. 1, for example, there are 668 illustrations to 583 pages of text) that they could not be conveniently arranged in the text.

Vol. 1, in which the state of knowledge is described by four Gmelin authors and eight outside experts, is characterized in that each complete field is preceded or followed by a survey containing no references, so that this work is not simply an exhaustively revised handbook, but also an orientating textbook.

Following short general notes (13 pp.) on the history and definitions of "iron" and "steel", a 16 page chapter first discusses the physicochemical principles of the processes used in ironworks, dealing on the one hand with the "states" (thermodynamic concepts and designations, thermochemical values relating to the metallurgy of iron, the structure of the liquid metals and slags, phase-boundary equilibria), and on the other with "processes" (fundamentals of the kinetics of metallurgical processes, diffusion in liquid metals and slags, viscosity of liquid metals and slags, special problems in reactions with porous solids and in reactions of gases with solid fuels and reducing agents). In this discussion, the special case of iron often takes second place to the general problem, *e.g.* of the liquid state, the binary system, the diffusion-controlled process, since wherever data for iron are not yet available, results obtained with other substances and systems are considered.

The following 405-page main part (70 % of the text volume) is devoted to the thermal pretreatment and the lumping of ores. The thermal pretreatment is deliberately restricted to preparation in the narrower sense, *i.e.* to the drying of ores and their calcination and magnetizing roasting; the general principles, the furnaces and equipment, their operation, the operating data, and the thermal energy balances are discussed in all three cases. The subsequent discussion of the lumping of ores deals with briquetting (general considerations, briquettes with and without fuel and binder, industrial briquetting procedure), extrusion (fundamental data, extrusion procedure), sintering (processes in sintering, influence of variables, behavior of the accessory elements, additives, special processes, sintering apparatus), pelletizing (general principles, production of pellets, firing of the pellets, fire aggregates), and the binding of iron ore by coking with coal (production of iron coke, other binding processes).

The text volume 1a is accompanied by an illustration volume 1b, the figures of which impressively illustrate the discussions in the text volume. This Volume 1b, contrary to the usual practice, contains a detailed subject index in German and English covering 166 pages, and including about 7000 subjects, as well as the 22-page content index. This is particularly useful, since the extremely wide range of aspects considered cannot be presented to the user by the content index. The next three volumes will also contain a subject index of this type.

On the whole, the seven volumes of "Gmelin 1964" reviewed here again represent an imposing output by the Gmelin editorial staff, which is attempting to increase the speed of reporting in future by new information methods. We must await with keen anticipation the planned "Rapid Information", which will analyse the original publications for all substances and subjects mentioned in the original (and not only in its title), and make these available to the user a few weeks after its publication. *E. Wiberg* [NB 537 IE]

Katalytische Hydrierungen im Organisch-Chemischen Laboratorium (Catalytic Hydrogenation in the Organic Chemistry Laboratory). By *F. Zymalkowski.* Ferd. Enke Verlag, Stuttgart 1965. 1st ed., viii, 360 pp., 15 illustrations, paper DM 80.–, cloth DM 86.–.

The book provides a survey of the methods of catalytic hydrogenation. The first, general section contains a detailed description of the methods and of hydrogenation catalysts, the industrial processes being deliberately excluded. The comprehensive special section deals with the use of catalytic hydrogenation, the material being arranged according to reduction steps. The possibilities and limitations of the method are illustrated with the aid of numerous characteristic examples. Considerable space is given to the discussion of the sterio course of the hydrogenation. Numerous procedures are interspersed in the text, so that this book is a particularly successful combination of a monograph and a laboratory handbook. The value of the book is enhanced by more than 1000 well-chosen references. The book fills a gap in the German literature, and should be of great value to all preparative organic chemists. Its purchase can be wholeheartedly recommended. *H. Stetter* [NB 513 IE]

Analgetics, Chemistry and Pharmacology. Vol. 5 of the series: Medicinal Chemistry. Edited by *G. de Stevens.* Academic Press, New York-London 1965. 1st edit., viii + 475 pp., numerous figs., $17.–.

Three years have elapsed since the appearance of the first volume in this series, and during that time it has earned a

secure place in the technical literature. In distinction from other series, the individual volumes treat large areas of drug research in the form of monographs and offer the reader a comprehensive review. The fifth volume is also written in this way: eight chapters deal with an introduction (I), the physiology and pharmacology of pain and its treatment (II), clinical measurement of pain (III), morphine and its derivatives (IV), synthetic analgetics with morphine-like action (V), isoquinoline analgetics (VI), pyrazole derivatives (VII), and synthetic analgetics in general (VIII), as well as the most important aspects of analgetics in respect of general relationships.

In an introduction *A. Burger* gives an excellent review of the historical development and present trends of analgetics research.

The second chapter (*C. A. Winter*) gives a clear and comprehensive account of the physiology and pharmacology of pain. The pharmacological and clinical testing of analgetics continues to pose numerous problems; *Winter*'s review and the next chapter by *R. W. Houde, S. L. Wallenstein,* and *W. T. Beaver* on the clinical apprehension of pain provide the active researcher with valuable help towards further progress.

The other five chapters deal with chemical aspects of the individual groups of analgetics. *E. L. May* and *L. J. Sargent* treat morphine and its derivatives; in this, the oldest area of analgetics research, the repetition of much that has been included in other reviews was unavoidable. Synthetic analgetics with morphine-like action (*R. A. Hardy jr.* and *M. G. Howell*) and isoquinoline analgetics (*A. Brossi, H. Besendorf, L. A. Pirk,* and *A. Rheiner*) form topical subjects whose presentation is very welcome. *W Krohs*, the author of the monograph "Pyrazolone und Dioxopyrazolidine gives a very good, brief survey of pyrazole derivatives which however could be equally ob ained from his book. Finally, the editor treats synthetic compounds with analgetic action in general at the end of the special part of the book. This last chapter gave the reviewer particular pleasure; it is brief and clear, introduces much new material, and will certainly be stimulating to those working in the field.

In summarizing, it may be stated that the monograph "Analgetics" is successful. Pharmacological, physiological, clinical, and chemical aspects are equally well treated, and the book will surely remain the best review of analgetics for a long time. The reviewer warmly recommends it to all interested chemists, biochemists, pharmacologists, physiologists, and clinicians, congratulates the editor on a valuable contribution to the literature on drug research, and wishes this series the success that it deserves.

E. Jucker [NB 502 IE]

Modern Textbook of Organic Chemistry. By *G. P. Ellis.* Butterworth & Co. Ltd., London 1966. 1st Edit., xii + 466 pp., numerous illustrations, bound, £ 2/17/6.

The aim of the present textbook is to point out the relationships in organic chemistry and reduce the amount of pure learning involved.

An introduction deals with chemical bonds, the principal types of reactions, and the fundamentals of spectroscopy (UV, IR). In the subsequent chapters, the usual subdivision of material into aliphatic and aromatic compounds is dropped in favor of subdivision by functional groups. The book starts with hydrocarbons, grouped into alkanes, cycloalkanes, alkenes, cycloalkenes, alkynes, and aromatic hydrocarbons, then proceeds to halogen compounds, alcohols and phenols, ethers, and aldehydes, emphasis being placed on the influence of the ligand (*e.g.* aliphatic and aromatic) on the functional group. This is followed by chapters on stereochemistry, carboxylic and sulfonic acids and their derivatives, nitro and nitroso compounds, amines and diazo compounds, amino acids, carbohydrates, and heterocyclic compounds.

Each chapter is subdivided into a general introduction and sections on nomenclature, bonding problems, UV and IR spectra (with illustrations), general reactions, and methods of preparation, as well as a discussion of some important specific compounds. Problems are given at the end of each chapter. A pleasing feature, particularly in the case of heterocycles, is the inclusion of summaries of the reactions of various compounds.

As a whole, the book gives a very unfinished impression and contains many errors. On page 14, for example, enolization is indicated as a hydride shift, and on page 229 the author describes a mechanism for the Cannizzaro reaction that corresponds to the fourth-order rate equation, which is observed in only a few cases. The aldehyde group here carries a dot whose meaning is obscure. The use of symbols, in fact, is somewhat confusing throughout. A dot is used in one case for a single electron in free radicals (p. 19), and then a few pages later for a pair of electrons (p. 21, chloroacetic acid). The manner in which, *e.g.*, the nitration of benzene is represented on p. 17 is questionable. An entire side chain is omitted from vitamin B on page 405.

A book claiming to be modern should discuss nuclear magnetic resonance spectra as well as IR and UV spectra. Mention of the Cahn-Ingold-Prelog rules in the discussion of stereochemistry would also have been desirable. As would the use of more energy-level diagrams in the discussion of reaction mechanisms.

The overall approach of the book is very welcome, but it would have to be thoroughly revised before it could really be recommended.

H. J. Bestmann [NB 541 IE]

Sulfonation and Related Reactions. By *E. E. Gilbert.* Interscience Publishers, a Division of John Wiley & Sons Ltd., London 1965. 1st ed., xi, 530 pp., 1 illustration, 71 tables, cloth, £6.6.0.

The author, *E. E. Gilbert*, an employee of Allied Chemical Corp., has for some time been well known to those interested in this field as a result of his experimental papers and reviews (cf., *e.g.*,"The Reactions of Sulfur Trioxide and of its Adducts with Organic Compounds" in Chemical Reviews *62*, 549 (1962)). The book is intended to follow on from *C. M. Suter*'s book "The Organic Chemistry of Sulfur", which covers the literature in this field up to 1941.

The book is divided into eight chapters. The first describes the reagents used for the sulfonation and sulfation of organic compounds, while the second chapter deals with the sulfonation of aliphatic, aromatic, and heterocyclic compounds with the compounds described in the first chapter.

The introduction of the sulfo group into organic compounds of various classes by means of sulfur dioxide, *e.g.* in the sulfochlorination and sulfoxidation of aliphatic compounds, or by means of bisulfites, *e.g.* in the Strecker synthesis or the addition of bisulfites to olefins, is reported in the third chapter.

The next chapter deals with the oxidation of organic compounds containing sulfur with formation of sulfo compounds. Indirect methods for the sulfonation of organic compounds, such as sulfoalkylation or sulfoarylation, are described in Chapter 5. The sixth chapter is concerned with sulfation, *i.e.* the preparation of compounds with sulfur joined to carbon *via* oxygen (esters of sulfuric acid and their derivatives). *N*-Sulfonation and desulfation, *i.e.* the reverse of sulfonation, are described in the last two chapters.

The individual sections of the book are characterized by a clear presentation of the material discussed. Evidently, this work was written by an outstanding authority with very wide knowledge and great practical experience. The literature (up to mid-1964) is adequately covered by about 3000 references. The book, which closes a gap in the literature on sulfonation and related reactions, can be wholeheartedly recommended to all those interested in this field.

F. Asinger [NB 510 IE]

The Structure of Small Molecules. By *W. J. Orville-Thomas.* Series of monographs: Principles of Modern Chemistry. Elsevier Publishing Company, Amsterdam-New York 1966. 1st ed., vii, 189 pp., 55 illustrations, bound, Dutch fl. 26.–

This book is the first of a series of monographs intended to serve as a basis for a one-semester course of two lectures a week.

The volume is specially concerned with the use of quantum-chemical concepts to obtain an understanding of the electronic structure and bonds in "small" polyatomic molecules, *i.e.* those containing up to about 5 atoms. Though this is a very narrow selection from the entire field of application of quantum chemistry, it is justified methodically. The models suitable for these molecules, with their wide range mcom position and geometry, indeed are different from those used *e.g.* for the rather uniform group of the planar aromatic hydrocarbons.

The treatment is aimed at chemists. The *Hückel* version of the molecular orbital method (HMO method) is used. A short introduction is followed by sections on the basic concepts of the chemical bond and the properties of such bonds (bond lengths, angles, and energies, force constants, and bond moments) and another section giving a survey (though only rudimentary) of quantum mechanics. This is followed by a section on stereochemistry and its quantum-chemical interpretation, and a final chapter (which in the reviewer's opinion is the most interesting) on the electronic structures of a large number of individual molecules, organized on the basis of a theoretical ordering principle. The substance index is also very useful.

The book is not very suitable as an introduction to quantum chemistry as a whole, nor is it intended as such. However, it does provide a source of information on the numerous molecules with which it deals.

Sulfines and Sulfenes — the *S*-Oxides and *S,S*-Dioxides of Thioaldehydes and Thioketones

BY G. OPITZ [*]

Four sulfines have so far been prepared by elimination of HCl from sulfinyl chlorides with triethylamine and by oxidation of diaryl thioketones with peracid. They are colored, crystalline compounds, which slowly decompose at room temperature. Attempts to prepare sulfenes have not yet been successful, but mesylsulfene [1] has been isolated as the trimethylamine adduct. It can be shown by interception reactions that sulfenes are formed as intermediates by the action of trialkylamines on aliphatic sulfonyl chlorides and by the action of sulfur dioxide on diazoalkanes. They react with ROD to form monodeuterated sulfonates, with diazoalkanes to give three-membered rings, with enamines, dienamines, ketene O,O-, O,N-, and N,N-acetals, and chloral, and in some cases with vinyl ethers, to give four-membered rings. They also react with nitrones to give five-membered rings, and with β-aminovinyl ketones and dienamines to give six-membered rings.

A. Introduction

Sulfines are the *S*-oxides and sulfenes [2] the *S,S*-dioxides of thioaldehydes and thioketones. They are formally the inner anhydrides of sulfinic and sulfonic acids respectively, just as ketenes are inner anhydrides of carboxylic acids. *S*-oxides and *S,S*-dioxides of thiocarboxylic acid derivatives such as chlorides or amides are not regarded as sulfines or sulfenes.

Alkylidene	sulfide	sulfoxide	sulfone	ketone
Inner anhydride of a	sulfenic acid	sulfinic acid	sulfonic acid	carboxylic acid
Usual name	thioketone (or thioaldehyde)	sulfine	sulfene	ketene

Sulfines (like sulfinic acids and dialkyl sulfoxides) have a lone pair of electrons on the S atom, whereas in the sulfenes (as in sulfonic acids and dialkylsulfones), all the electrons of the S atom are involved in bonding. Sulfenes are derivatives of sulfur trioxide, and sulfines are derivatives of sulfur dioxide, one O atom in each case being replaced by an alkylidene group.

Wedekind and *Schenk* [3] first used the name sulfenes to express the relationship [4] to the ketenes. This was formally logical, but it precluded the possibility of using endings to indicate the state of oxidation, as is usual with the acids (sulfenic, sulfinic, sulfonic acids). Nevertheless, *Sheppard* and *Diekmann* [5] chose the name sulfines for alkylidene sulfoxides [6].

[4] *H. Staudinger*: Die Ketene. F. Enke, Stuttgart 1912, pp. 92, 129.

[5] *W. A. Sheppard* and *J. Diekmann*, J. Amer. chem. Soc. *86*, 1891 (1964).

[6] In this paper sulfines and sulfenes are named generally as derivatives of sulfine (CH_2=SO) and sulfene (CH_2=SO_2), by analogy with the ketenes, and occasionally as oxides or dioxides of thioaldehydes or thioketones. If the C atom of the CH_2 group forms part of a ring, the groups =SO and =SO_2 should be designated by the prefixes "sulfinyl" and "sulfonyl", respectively. Thus *(5)* is called 9-sulfinylfluorene. This suggestion is based on the rule for ketenes (=CO = carbonyl when the CH_2 group forms part of a ring).

The differences between carbonyl and thiocarbonyl groups are explicable on the basis of differences in polarizability, size, and electronegativity of the heteroatoms [7] (Table 1).

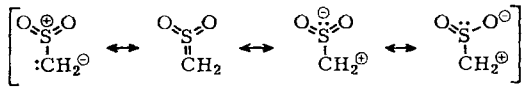

Table 1. Electronegativity according to

	Pauling	*Mulliken*	*Allred* and *Rochow* [8]
C	2.60	2.63	2.50
O	3.50	3.17	3.50
S	2.60	2.41	2.44

With its relatively strong 2p-2p π bond the carbonyl group is strongly polar but difficult to polarize; most aldehydes and ketones are stable in the monomeric form. The thiocarbonyl group with its more diffuse 2p-3p π bond is weakly polar, but easily polarizable; all thioaldehydes and most thioketones are unstable, mainly because of their pronounced tendency to di-, tri-, and polymerize. That carbonyl and thiocarbonyl groups react differently with sodium hydrogen sulfite, zinc and hydrochloric acid, diazomethane, and sodium acetylide [9] suggests that the S atom may even carry a partial positive charge:

$R_2C^{\delta\oplus}=O^{\delta\ominus}$; $R_2C^{\delta\ominus}=S^{\delta\oplus}$

What effect does *S*-oxidation have on the reactivity of the CS double bond? It might be thought that the presence of the more electronegative O atoms on the S atom would increase the carbonyl reactivity, particularly since, in addition to the "carbonyl" canonical structure *(1c)* of sulfene, a 1,3-dipolar formulation such as *(1d)* is possible, in which the oxygen has taken over the negative charge [10].

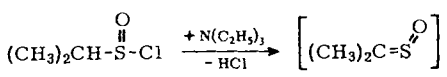
(1a) ylide like; *(1b)* cumulative; *(1c)* carbonyl like; *(1d)* 1,3-dipolar

Canonical structures of sulfene

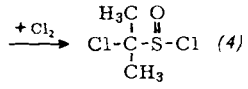
If we imagine *(1d)* to be cyclized to *(2)*, the sulfur clearly has assumed the same oxidation state as in a sulfinic acid.

(2) hydroxymethanesulfinic acid — inner ester of — *(3)* hydroxymethanesulfenic acid

In the "ylide" canonical structure *(1a)*, on the other hand, the oxidation state of the S atom is the same as in a sulfonic acid. Thus the cumulative formulation *(1b)*, which is neutral locally as well as overall, conceals the ability to react in two directions, on the one hand to form derivatives of methanesulfonic acid, and on the other to give derivatives of hydroxymethanesulfinic acid. We shall see that both types of reaction do occur.



However, by far the most common mode of reaction is that corresponding to the "ylide" structure *(1a)*. Thus, the sulfonyl group exhibits electrophilic and the methylene nucleophilic character; the sulfenes consequently resemble the ketenes in their reactions. The question of whether the sulfines behave analogously cannot be answered until further reactions are known. No evidence of the existence of the three-membered rings *(2)* and *(3)* has been found as yet.



The fact that no sulfenes, and only four sulfines, have so far been isolated clearly shows that the instability of the thiocarbonyl compounds is further increased by *S*-oxidation. The relationship between structure and stability probably follows the same rules as for the thiocarbonyl compounds. Thus it is no accident that the *S*-oxides of thioamides [11] were discovered before the sulfines, whereas no *S*,*S*-dioxides of thioamides are known at present, and that three of the four sulfines that have been isolated are diarylsulfines. An interesting but as yet unanswered question is that of the extent of the similarity of the sulfenes to the ketenes, *e.g.* whether the sulfenes exhibit differences in dimerization properties and in sensitivity to oxygen such as exist between aldoketenes and ketoketenes.

B. Sulfines

I. Elimination of HCl from Sulfinyl Chlorides

Attempts to prepare the simplest sulfine, thioformaldehyde *S*-oxide, by the action of triethylamine on methanesulfinyl chloride or to intercept it by cycloaddition to ketene acetals [12] or to enamines [13] have been unsuccessful. The report [5] that NEt_3 forms a salt with methanesulfinyl chloride, but does not split off HCl, is in marked contrast to the vigorous reaction of NEt_3 with 2-propanesulfinyl chloride in dichloromethane at −20 °C, in which NEt_3–HCl is reported to be precipitated in quantitative yield [5] (according to the author's observations, 5.6 g of NEt_3–HCl dissolve in 100 ml of CH_2Cl_2 at −20 °C). Dimethylsulfine (thioacetone *S*-oxide) could not be detected either directly or by interception with reactive olefins or dienes. However, its presence in the filtrate, which undergoes an exothermic reaction on warming to room temperature, is indicated by the presence of NMR signals of chemically non-equivalent methyl groups, and by the formation of 2-chloro-2-propanesulfinyl chloride *(4)* on addition of chlorine [5].

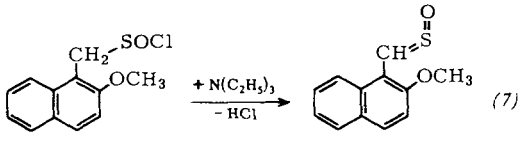
[13] *S. Schüring,* Diploma Thesis, Universität Tübingen, 1963.

The first thioketone *S*-oxide was prepared by *Sheppard* and *Diekmann*[5] by the addition of NEt_3 to the unstable 9-fluorenesulfinyl chloride in ether at room temperature. NEt_3–HCl was precipitated immediately, and thiofluorenone *S*-oxide (9-sulfinylfluorene) *(5)* was isolated from the filtrate in a crude yield of 75%.

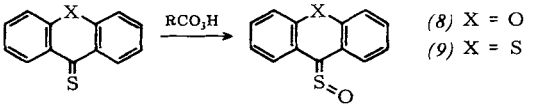


(5)

(6)

The sulfine *(5)* (orange-red needles, m.p. 111–112 °C) shows an additional fine structure of the aromatic signals in the NMR spectrum as compared with fluorene. This is to be expected, since the CSO group, which lies in the plane of the ring, forms an angle at the sulfur atom, so that the protons in the two benzene rings experience different levels of magnetic shielding. The UV spectrum is similar to that of fluorenone, but the bands show a slight hypsochromic shift. *(5)* decomposes slowly at room temperature and rapidly at its melting point, with loss of SO_2 and formation of a brown mass, from which 48% of bifluorenylidene and a few percent of fluorenone have been isolated. However, it does not appear to be affected by boiling benzene, THF, or cyclohexene, even when heated in these liquids for days. It reacts with *N*-(1-cyclohexenyl)morpholine to form a crystalline adduct which is assumed to have the zwitterion structure *(6)*[5] because of its strong IR absorption at 1710 cm^{-1}.

Barely eight weeks later, *Strating*, *Thijs*, and *Zwanenburg*[14] reported the preparation of the first thioaldehyde *S*-oxide, the brilliant yellow 2-methoxy-1-naphthylsulfine *(7)*, by the same method.



(7)

The anisotropy of the magnetic shielding by the sulfine group is shown in the NMR spectrum by a strong displacement of the aldehyde proton signal to lower fields (in $CHCl_3$, $\Delta\tau = -0.53$). *(7)*, which melts at about 90 °C with decomposition, reacts with a sulfuric acid solution of 2,4-dinitrophenylhydrazine to form the 2,4-dinitrophenylhydrazone of 1-formyl-2-methoxynaphthalene with liberation of H_2S, and on UV irradiation in CH_2Cl_2 it gives the aldehyde itself together with sulfur.

II. Oxidation of Thioketones

Strating, *Thijs*, and *Zwanenburg*[15] also prepared the diarylsulfines *(5)*, *(8)*, and *(9)* in yields of 97, 84, and 83% respectively, by oxidation of the thioketones with monoperoxyphthalic acid in ether or methylene chloride. The reaction proceeds very rapidly at room temperature, the color of the thioketones disappearing almost instantaneously.

(8) X = O
(9) X = S

Whenever the thiocarbonyl compound is obtainable in the monomeric form, as it is in these cases, then this should be the best method for the preparation of sulfines. *(8)* and *(9)*, like *(5)*, form orange-red needles which slowly decompose at room temperature. Treatment of *(9)* in ethanol with a trace of sulfuric acid gives thioxanthone in 81% yield and hydrogen sulfide, showing that the oxygen has added to the thione sulfur, and not to the sulfide sulfur.

Some IR and UV data for *S*-oxides of thioaldehydes, thioketones, thioacyl chlorides, and thioamides are given in Table 2. The sulfines give two strong IR bands at 1019–1078 and 1065–1128 cm^{-1} which are assigned to the C=S=O grouping. Owing to the variation in the position of the thiocarbonyl vibration, it is probable that these ranges will later prove to be too narrow.

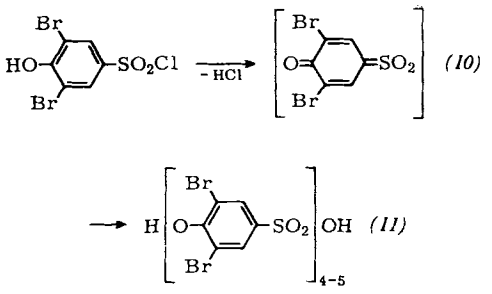
Table 2. IR and UV absorptions of sulfines and related compounds.

Compound	IR (cm^{-1})	UV (mμ (log ε))
(5) [5]	1019, 1120	362 (4.18) in dioxane
(7) [14]	1040, 1065	398 (4.16) in dichloromethane
(8) [15]	1068, 1128	410 (4.02) in cyclohexane
(9) [15]	1078, 1093	420 (3.85) in cyclohexane
cis-Thiobenzoylchloride-*S*-oxide [16, 22]	1025, 1145	229 (3.90), 323 (3.95)
trans-Thiobenzoylchloride-*S*-oxide [16, 22]	1005, 1120	226 (3.90), 328 (4.10)
Thioamide-*S*-oxides [11]	900–1100	
Thioacetamide-*S*-oxide [11]	916	290 (3.95) in water

C. Sulfenes

I. Elimination of HCl from Sulfonyl Chlorides (Sulfonyl Chloride Acting as Sulfene Interceptor)

1. Elimination of HCl from 2,6-Dibromophenol-4-sulfonyl Chloride



In 1908, *Zincke* and *Brune*[17] observed that 2,6-dibromophenol-4-sulfonyl chloride loses HCl when treated with soda or potassium acetate in aqueous acetone. They attributed the transient intense yellow coloration to the formation of quinoid sulfene *(10)*, and assumed the colorless precipitate that gradually separates to be a dimer or trimer of *(10)*.

[17] *T. Zincke* and *R. Brune*, Ber. dtsch. chem. Ges. *41*, 902 (1908).

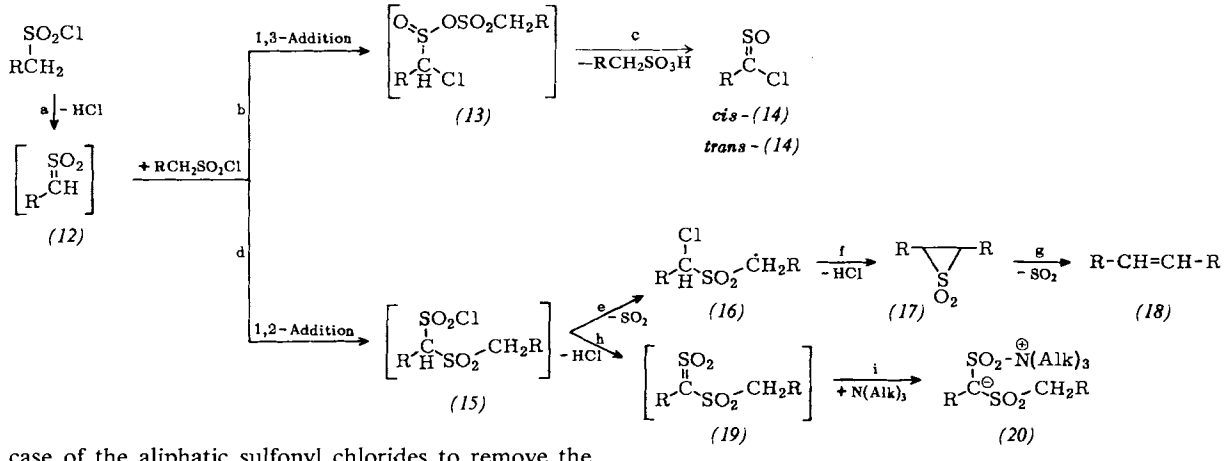
(10)

(11)

According to *Hall*[18], the yellow color is due to the phenoxide anion of the sulfonyl chloride. It is possible that the phenoxide anion is converted into the precipitate, which according to *Oae* and *Kiritani*[19] has the constitution *(11)*, without initial formation of the sulfene.

2. Elimination of HCl from Primary Sulfonyl Chlorides and Mesyl Chloride

While the proton of the phenolic hydroxyl group is easily removed in the formation of *(10)*, which in the light of the vinylogy principle is reminiscent of the reaction $HO-SO_2Cl \rightarrow HCl + SO_3$, it is necessary in the case of the aliphatic sulfonyl chlorides to remove the much more firmly bound α-CH proton. This is achieved with trialkylamines under conditions that lead to ketene secondary products in the reaction of carboxylic acid chlorides[20]. The real incentive in the search for sulfenes was provided in 1911 by the discovery, by *Wedekind* and *Schenk*[3], that triethylamine removes HCl from phenylmethanesulfonyl chloride, even in cold benzene. These authors obtained NEt_3–HCl, SO_2, and stilbene, and concluded that the phenylsulfene intermediate (thiobenzaldehyde *S,S*-dioxide) had lost SO_2 and that the resulting phenylcarbene had dimerized. In a repetition of this work, *King* and *Durst*[21] also isolated triethylammonium phenylmethanesulfonate and thiobenzoyl chloride *S*-oxide *[(14)*, R = C_6H_5], which they resolved into its geometric isomers by chromatography[22,16].



This reaction shows a peculiar dependence on the solvent (Table 3). In ether or dichloromethane it yields stilbene, but no thiobenzoyl chloride *S*-oxide, while in cyclohexane it gives thiobenzoyl chloride *S*-oxide, but no stilbene.

Table 3. Products of the reaction of phenylmethanesulfonyl chloride with triethylamine [16] (+ present — absent).

Solvent	NEt_3–HCl	SO_2	*trans*-Stilbene	*cis*-Stilbene episulfone	NEt_3–$C_6H_5CH_2SO_3H$	$C_6H_5C(Cl)=SO$
Ether	+	+	+	+	trace	trace
CH_2Cl_2	+	+	+	+	trace	trace
Benzene	+	+	+	+	+	+
Cyclohexane	+	trace	trace	—	+	+

The dependence on the structure of the primary sulfonyl chloride is also surprising. Whereas *p*-nitrophenylmethanesulfonyl chloride in cold ether gives *trans-p,p'*-dinitrostilbene (44%)[12,23], the reaction of 10-camphorsulfonyl chloride with triethylamine or pyridine yields the thiocarbonyl chloride *S*-oxide *(24)*, but no olefin[24]. Other primary sulfonyl chlorides and bromides of the camphor series react in a similar manner[25,27].

The products obtained can be explained by the assumption that the sulfene *(12)*, liberated by dehydrochlorination of the sulfonyl chloride, immediately adds to unreacted sulfonyl chloride either in the 1,3-position (route b) or in the 1,2-

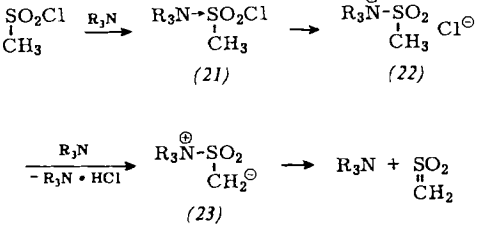
position (d) (Scheme 1). *Strating*[28] explains the formation of the thiocarbonyl chloride *S*-oxide *(14)* by 1,3-addition to the mixed anhydride *(13)* of a sulfonic acid and an α-chlorosulfinic acid, followed by 1,2-elimination (c) of the sulfonic acid. The olefin *(18)* is formed by 1,2-addition (d) of the sulfonyl chloride to the sulfene to form an α-sulfonylsulfonyl chloride *(15)*, elimination of SO_2 to form the α-chlorosulfone *(16)*, and a Ramberg-Bäcklund reaction *via* the three-membered ring sulfone *(17)*[29]. Carbenes are not involved in the formation of the olefins[30,12,16].

a) *Step a*

When triethylamine is used as halogen hydride acceptor, step a proceeds rapidly for sulfonyl chlorides and bromides[16,27,28]. With sulfonyl fluorides, however, the reaction is so slow[16,31] under these conditions that it is of no preparative value.

Although phenylmethanesulfonyl fluoride and chloride are converted into mono-, di-, and trisulfones, as well as olefines[32], by the base phenyl-lithium, it is conceivable that such products are produced *via* α-metalated sulfones, phenylsulfenes playing no part in this reaction.



The sulfene allegedly[33] formed from 2-methylanthraquinone in boiling chlorobenzene has proved to be the sulfonic acid[34].

Dehydrohalogenation can best be carried out by means of trialkylamines in most[24,26,28,35,36], but not in all, cases[24,37,38] pyridine and similar cyclic imines are also suitable reagents. Triethylamine is most commonly used for this purpose and has many advantages; it is easy to purify and to add to, and to remove from, the reaction mixture. Its hydrochloride is easily separable since it is not hygroscopic, and is only sparingly soluble in petroleum, ether, benzene, ether, THF and at −40 °C, in acetonitrile.

Remarkable differences in behavior with aliphatic[39] and aromatic[40,41] sulfonyl chlorides exist between trimethyl- and triethylamine in spite of their having almost the same basicity. Thus, mesyl chloride adds to NMe_3, in ether at −20 °C, to give a sparingly soluble adduct (presumably *(21)*, R = CH_3), which with aniline yields *N*-mesylaniline and with enamines, sulfones having four-membered rings (cf. Section C V 1). The IR spectrum and the formation of mesyl chloride and NMe_3–DCl on treatment of this compound with DCl demonstrate that the mesyl group has remained intact. Elimination of HCl, accompanied by formation of NMe_3–HCl as well as various unidentified secondary products, occurs when the labile adduct is allowed to stand.

With NEt_3, however, no adduct can be detected and elimination of HCl starts immediately. The precipitate formed in ether reacts neither with aniline[42] nor with enamines[42]. No experimental evidence exists for the suggested[43,16] presence of a polysulfene. On the contrary, it is typical of the sulfenes that they react with one of the reaction components from which they are formed, in this case with sulfonyl chloride, instead of di-, tri- or polymerizing as do ketenes. Time will show whether the short lifetime of sulfenes is an adequate explanation.

The formation and reactions of the mesyl chloride-trimethylamine adduct would suggest that the 1,2-elimination of HCl with other amines proceeds *via* a labile sulfonyl chloride-amine adduct *(21)* or an acylammonium salt *(22)*.

This is not supported by the fact[31] that enamines also react with primary and secondary sulfonyl chlorides to give sulfones with four-membered rings in good yields when ethyldiisopropylamine is used in place of trimethylamine. The only observable effect is that the reaction proceeds more slowly. The formation of adducts analogous to *(21)* or *(22)* can be excluded on steric grounds.

The question of whether the sulfene is liberated or remains attached to the amine as in *(23)*[23] cannot be answered at present. In our opinion, the formation of trialkylammonium salts of the sulfonyl chlorides

$(Alk)_3NH^{\oplus}\ {}^{\ominus}CR_2-SO_2Cl$, as formulated by *Fusco* [29] and *King* [21], is unlikely. The smooth elimination of HCl from secondary sulfonyl chlorides by NEt_3 in acetonitrile at −40 °C is important in view of the complications encountered in cycloaddition experiments under other conditions [44].

A convincing argument for the occurrence of sulfenes as intermediates is the formation of monodeuterated sulfonates in the presence of deuterated alcohol.

$$RCH_2-SO_2Cl + AlkOD \xrightarrow[-HCl]{NEt_3} RCH_2-SO_2OAlk + R-CHD-SO_2OAlk$$

R = H, CH_3, C_2H_5, CH_2=CH, C_6H_5, *p*-$O_2N-C_6H_4$; Alk = CH_3, C_2H_5 [37,45]

R = C_6H_5; Alk = CH_3, $CH(CH_3)_2$, $C(CH_3)_3$ [35,36]

If the deuterium were incorporated at the sulfonyl chloride or ester stage by base-catalysed H,D exchange, the other α-H atoms would also be replaced to some extent. However, as was shown independently by *King* and *Durst* [35,36] for phenylmethanesulfonyl chloride and by *Truce, Campbell,* and *Norell* [37,45] for a series of primary sulfonyl chlorides, mesyl chloride, mesyl bromide, methanesulfonic anhydride, and 2-propane- and 1-propene-1-sulfonyl chloride, the products appear to contain only undeuterated and monodeuterated esters, but no polydeuterated esters. Phenylmethanesulfonyl chloride and an excess of CH_3OD or the dideuterated sulfonyl chloride and an excess of CH_3OH give only monodeuterated esters at 25 °C (within a minute), but only in the presence of a base such as NEt_3. In the absence of a base, the esterification proceeds much more slowly ($t_{1/2}$ = 90 min at 50 °C) and without H,D exchange [36].

$$C_6H_5-CH_2-SO_2Cl \xrightarrow[\text{in } CH_3OD]{+NEt_3}$$

$$C_6H_5-CHD-SO_2OCH_3 \xleftarrow[\text{in } CH_3OH]{NEt_3} C_6H_5-CD_2-SO_2Cl$$

It must be concluded from the above findings that, in the presence of NEt_3, the monodeuterated ester is formed by the elimination-addition mechanism *via* the sulfene. According to *Truce* [45], the normal product results from an S_N2 reaction *via* a sulfonyltriethylammonium salt, which could also be formed by "collapse" [45] of the sulfene with the NEt_3–HCl.

$$RCH_2-SO_2Cl + N(C_2H_5)_3 \xrightarrow{E2} RCH{=}SO_2 + \overset{\oplus}{N}H(C_2H_5)_3Cl^{\ominus} \xrightarrow{+AlkOD} RCHD-SO_2OAlk$$

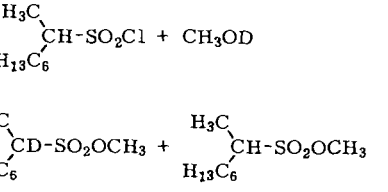
$$RCH_2-SO_2Cl + N(C_2H_5)_3 \xrightarrow{S_N2} RCH_2-SO_2-\overset{\oplus}{N}(C_2H_5)_3Cl^{\ominus} \xrightarrow{+AlkOD} RCH_2-SO_2OAlk$$

This hypothesis would explain the isotope distribution in the case of 1-propene-1-sulfonyl chloride and the migration of the double bond can be explained by preferential 1,2-addition to the vinylsulfene that is liberated as an intermediate.

$$CH_3-CH{=}CH-SO_2Cl + Alk\ OD \xrightarrow[-H(D)Cl]{+NEt_3} CH_3-CH{=}CH-SO_2OAlk + CH_2{=}CH-CHD-SO_2OAlk$$

(a) *(b)*

Alk = CH_3; ratio *(a)*:*(b)* = 33:67



Alk = C_2H_5; ratio *(a)*:*(b)* = 9:91

Further evidence opposing a 1,4-addition, which is hindered by the inductive effect of the sulfonyl group, is provided by the uniform product obtained with 2-propene-1-sulfonyl chloride.

$$CH_2{=}CH-CH_2-SO_2Cl \xrightarrow[-HCl]{N(C_2H_5)_3} \left[CH_2{=}CH-\overset{\ominus}{C}H-\overset{\oplus}{S}O_2 \leftrightarrow \overset{\ominus}{C}H_2-CH{=}CH-\overset{\oplus}{S}O_2 \right]$$

$$\xrightarrow{+AlkOD} CH_2{=}CH-CHD-SO_2OAlk$$

Secondary sulfonyl chlorides such as 2-octanesulfonyl chloride show less readiness to undergo an elimination-addition type of reaction (ratio of deuterated: normal ester = 87:13 where the total yield is 40%).

2-Octanesulfonyl azide does not react under the above conditions. The elimination of HN_3 is, however, initiated by the addition of potassium methoxide and the deuterated ester is produced in 61% yield after a reaction time as short as 5 min. The degree of the participation of the sulfene mechanism in amide formation from [2-D]-(+)-2-octanesulfonyl chloride may be assessed from the amount of deuterium lost; dimethyl amine 46%, aniline 8%, *N*-methylaniline 0% D loss [46].

The mild and rapid introduction of sulfonyl groups into hydroxy and amino compounds *via* sulfenes is of preparative interest, at least when this cannot be achieved with aromatic sulfonyl chlorides, as is the case with some oximes [47] and with *N*-t-butoxycarbonylsedridine [48] [*N*-t-butoxycarbonyl-2-(2-hydroxypropyl)-piperidine].

In the synthesis of cephalosporin C, *Woodward* [49] accomplished the *O*-acylation of a sensitive 5-hydroxythiazolidine by using mesyl chloride/ethyldiisopropylamine.

b) *Steps b and c*

Steps b and c are supported by reactions in the presence of tosyl chloride [28]. Since the sulfonyl chloride that adds to the sulfene in the 1,3 position is "lost" as the sulfonic acid in step c, it can in principle be replaced by another sulfonyl chloride. If this replacement is successful, more thiocarbonyl chloride *S*-oxide *(14)* must be formed. In fact, the yield of *(24)* in the reaction of 10-camphorsulfonyl chloride with pyridine can be increased from 38 to 70% by the addition of an equimolar quantity of tosyl chloride. When 10-camphorsulfonyl bromide

reacts with tosyl chloride in pyridine, only the chlorine compound *(24)* is obtained.

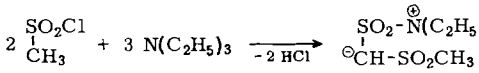
(24)

This shows that a halogen-free intermediate must be involved, and so disproves *Wedekind*'s hypothesis [24] that the sulfene removes water from the sulfonyl halide in the formation of *(24)*.

It has not yet been proved that the 1,3 addition (b) does in fact take place, but if so, it is the only known reaction in which the sulfenes react as expected from the 1,3-dipolar resonance structure *(1d)*.

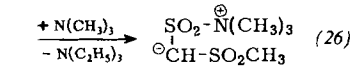
c) *Steps d, e, f, and g*

Step d, which should also take place with any other sulfonyl chloride, leads by a 1,2 addition to an α-sulfonylsulfonyl chloride *(15)*. The corresponding addition of carbonyl chlorides to ketenes is apparently possible only in a few cases [4]. Like all sulfonyl chlorides having unsaturated groups (vinyl, aryl, acyl) on the α-C atom, *(15)* tends to lose SO_2.



Mesylmethanesulfonyl chloride [*(15)*, R = H, m.p. = 106–108 °C], which has been known for only a short time [50], is relatively stable, but unsuccessful attempts [3, 25] to prepare diphenylmethanesulfonyl chloride and 9-fluorenesulfonyl chloride show that two phenyl groups in the α position cause SO_2 to be eliminated from a sulfonyl chloride, even at room temperature. The combination phenyl + sulfonyl in *(15)* [R = C_6H_5] probably has a similar effect.

After the elimination of SO_2 (e), the presence of the α-chlorosulfone [*(16)*, R = C_6H_5] and the trialkylamine satisfies the conditions for the Ramberg-Bäcklund reaction [51,52], *i.e.* the 1,3 elimination of HCl (f) to give the three-membered ring sulfone *(17)* with subsequent loss of SO_2 (g) to give the olefin *(18)*.



More recent work shows that the reaction has a wide range of application [53–56]. NEt_3 is satisfactory as the base for bis-(α-bromobenzyl)sulfone [57]; it is not yet known whether this is also true of purely aliphatic α-halogenosulfones. In boiling D_2O/NaOD, the H/D exchange of the α-protons in α-chlorodiethylsulfone [*(16)*, R = CH_3] is faster than the formation of 2-butene (97% of olefinic D), but slower in the case of the three-membered ring sulfone [*(17)*, R = CH_3] (5% of olefinic D) [54]. The proportion of the *cis*-olefin formed with 2N KOH increases with decreasing size of the group R in the α-chlorosulfone *(16)* (CH_3 78, C_2H_5 56, C_3H_7 53% of the *cis*-olefin). The values show practically no change when the Cl atom is replaced by Br or I. This can be explained by step f, which involves anionization on the halogen-free side and intramolecular nucleophilic substitution analogous to the cyclopropanone ring closure in the Favorskii reaction, since the elimination of SO_2 (g), which is slow at room temperature and fast at high temperatures, is stereospecific [16,52], even in the presence of 2N KOH [54].

d) *Steps h and i*

The α-position of the original sulfonyl chloride is strongly activated by conversion into the α-sulfonylsulfonyl chloride *(15)*. This must facilitate the elimination of HCl (h) to form the α-sulfonylsulfene *(19)*. In view of the relatively high acidity (1,3-disulfones dissolve in dilute alkali), it seems surprising that the elimination of SO_2 (step e) can compete with the elimination of HCl (step h) at low temperatures, and the latter step has never been discussed until now. The first sulfene was recently isolated as the trimethylamine adduct *(26)* by the route a, d, h, i [58,59].

(25)

(26)

When NEt_3 is added to mesyl chloride in acetonitrile at −40 °C, NEt_3–HCl is precipitated quantitatively, and on filtering the mixture the mesylsulfene-triethylamine adduct *(25)* is present in the filtrate; this can be isolated as a colorless powder by freeze-drying, but it is preferentially converted into the much more stable NMe_3 adduct *(26)*, which is sparingly soluble in acetonitrile. If NMe_3 is used in the initial reaction, a mixture of *(26)* and NMe_3–HCl is precipitated.

The secondary reactions of the simple sulfene when mesyl chloride reacts with NEt_3 in ether or petroleum ether at −10 to +20 °C are unknown. However, it is certain that neither a polysulfene nor thiiran dioxide is formed. In aqueous solution, the precipitate gives an acid reaction and evolves SO_2, and when heated with PbO it forms PbS. The formation of SO_2 suggests route d, e, and the formation of H_2S suggests route b, c; the latter route should lead to the thioformyl chloride *S*-oxide [*(14)*, R = H], which is presumably unstable. The probability of side reactions occurring is very high in the case of mesyl chloride. Thus the sulfonyl chloride *(15)* and mesyl chloride must be expected to add on in both the 1,3- and the 1,2-position in the sulfenes *(12)* and *(19)*. In this way the groups R=CH_3–SO_2 and CH_3–SO_2–CH_2–SO_2 can be introduced into thioformyl chloride *S*-oxide [*(14)*, R = H] and into mesylsulfene [*(19)*, R = H]. Other reactions may follow.

3. Elimination of HCl from Secondary Sulfonyl Chlorides

Fusco et al. [29] have studied tne reaction of 2-propanesulfonyl chloride with NEt_3. For secondary sulfonyl chlorides, Scheme 1 can be simplified by the omission of

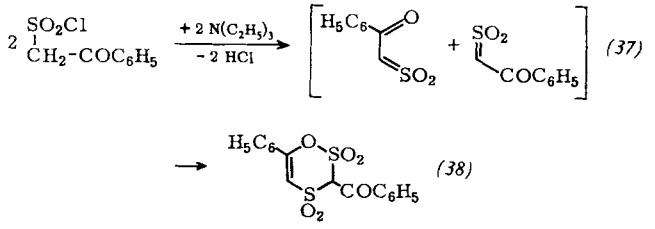
steps c, h, and i (Scheme 2 with secondary reactions). Nothing is known about step b. The formation of the α-sulfonylsulfonyl chloride *(29)* can be deduced from two secondary reactions. On the one hand *(29)* is a tertiary sulfonyl chloride, and so very readily loses SO_2 (e) to form the α-chlorosulfone *(30)* (t-butylsulfonyl chloride loses SO_2 at 35 °C with $t_{1/2}$ = 34 hours [60]). On the other hand, 1,2-addition (k) of *(29)* to the sulfene *(27)* yields the new α-sulfonylsulfonyl chloride *(33)*. This in turn forms the α-chlorodisulfone *(34)* by loss of SO_2 (l), and the α-chlorotrisulfone *(36)* by 1,2-addition (m) to the sulfene *(27)* followed by loss of SO_2 (n). The reaction can clearly continue with formation of $R_2CH(SO_2CR_2)_nSO_2Cl$ and $R_2CH(SO_2CR_2)_nCl$.



Scheme 2. Reaction of secondary sulfonyl chlorides with trialkylamine

(30), *(34)*, and *(36)* were isolated from the reaction products of 2-propanesulfonyl chloride (R = CH_3). With 2-butanesulfonyl chloride and cyclohexanesulfonyl chloride, on the other hand, only the sulfones [*(30)*, R_2 = CH_3, C_2H_5 or $(CH_2)_5$] were isolated; these did not give the olefin *(32)* (route f, g) under the conditions of the reaction (cold ether or boiling dioxane), but did so on subsequent heating with 2N NaOH.

Though it is still largely unknown how the secondary reactions of the sulfenes depend on the structure of the sulfonyl chloride and the reaction conditions, it may be assumed that the formation of products having low molecular weights will be favored by heat, unsaturated substituents, and a high degree of branching in the α position, all of which promote the elimination of SO_2. In any case, it can be seen from Schemes 1 and 2 that the elimination of SO_2 terminates the reaction sequences. The assumption [29] that the chlorodisulfone *(34)* can also be formed by addition of the α-chlorosulfone *(30)* to the sulfene *(27)* is opposed by the inertness of α-halogenosulfones [61].

4. Elimination of HCl from Benzoylmethanesulfonyl Chloride

The long sought dimerization of a sulfene was finally observed by *Fusco et al.* [29] in the reaction of NEt_3 with benzoylmethanesulfonyl chloride.

The triethylammonium salt of the dimer *(38)* is obtained in 45% yield in chloroform [29] and in 60% yield in acetonitrile [62]. The above authors formulated the cyclization as a Diels-Alder reaction of the benzoylsulfene *(37)*. This, like all sulfenes, can act as a dienophile [63,64], and by invocation of the keto group, it can also function as a heterodiene. No other examples of the dimerization or polymerization of sulfenes are known.

II. Reaction of Diazoalkanes with Sulfur Dioxide (Diazoalkane or SO_2 Acting as Sulfene Interceptors)

A second method for the production of sulfenes *in situ* was discovered by *Staudinger* and *Pfenninger* [65] during an attempt to prepare diphenylsulfene [*(42)*, R = C_6H_5, Scheme 3] from diphenyldiazomethane and sulfur dioxide. The sulfene is formed very rapidly at −20 to +20 °C, with evolution of N_2; the diazonium sulfinate *(39)* would appear to be a more probable intermediate than the cyclic azo compounds *(40)* and *(41)*. However, the sulfene again escapes direct detection by immediate reaction with one of the starting materials.

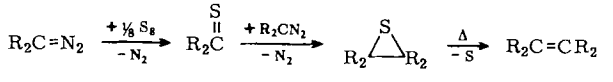
[65] *H. Staudinger* and *F. Pfenninger*, Ber. dtsch. chem. Ges. *49*, 1941 (1916).



Scheme 3. Reaction of diazoalkanes with sulfur dioxide.

The reaction with an excess of SO_2 gives benzophenone, in yields up to 90% together with products containing sulfur. The authors therefore concluded that it involved a 2+2 cycloaddition (c) of the sulfene to SO_2 followed by cleavage of the four-membered ring (d) to form benzophenone *(44)* and S_2O_3 which decomposes into SO_2 and S.

If, on the other hand, SO_2 is passed into a solution of diphenyldiazomethane, the diazoalkane acts as a sulfene interceptor (e). The three-membered ring sulfone *(50)* is formed *via* an intermediate that was not isolated, but which Staudinger formulated as Δ^2-[1,2,3]-thiadiazoline-1,1-dioxide *(47)*. When *(50)* is heated, it partly loses SO_2 to form tetraphenylethylene *(51)*, and partly undergoes a rearrangement that is of no interest in this context, with formation of five-membered ring sulfones and other diphenylanthracene derivatives [65,66].

If the reaction is carried out in the presence of water, alcohols, ammonia, alkylamine, or dialkylamine, it yields diphenylmethanesulfonic acid or its esters or amides. Aniline, *p*-toluidine, and *p*-anisidine do not act as sulfene interceptors in this reaction [65,67,68].

The reaction sequence a, b, e, h corresponds to the reaction of diaryldiazomethanes with sulfur (or thioketones) to form episulfides [69,70], and steps e and h to the reaction of ketene

with diazomethane to form cyclopropanone [71], though in this case the ketene cannot be produced from diazomethane and CO [72].

The Staudinger-Pfenninger reaction for the synthesis of three-membered ring sulfones *(50)* or olefins *(51)* has now been applied to other diazo compounds: diazomethane [73,74], diazoethane [54], phenyldiazomethane [57,75], aryldiazoalkanes [73,76,77], and cycloalkyldiazoalkanes [78,79]. 2-Diazopropane gave only acetoneazine, while diazoacetic ester did not react with SO_2 [77]. With diazomethane as starting material, thiirane-*S*,*S*-dioxide [*(50)*, R = H, m.p. 19 °C, b.p. 64 °C/0.3 mm Hg] was isolated from the reaction products (yield 70%) and characterized. Diazoethane yields *cis*- and *trans*-2-butene in approximately equal amounts. The crystalline epithio dioxide of the *cis*-olefin can be separated from the oily *trans* derivative at low temperatures. On heating the former neat, in isopropanol, or in 2 N NaOD/D_2O, it is converted into *cis*-2-butene. The stereospecificity of the elimination of SO_2 is lost in the presence of potassium t-butoxide/$(CH_3)_3COD$, and H,D exchange takes place at the same time (20 parts of *cis*- to 80 parts of *trans*-H_5C_2–CD=CD–C_2H_5). The reaction of phenyldiazomethane with both liquid and aqueous SO_2, also afforded the epithio dioxide of *cis*-stilbene only, together with *trans*-stilbene and benzylidenazine. At 90 °C, the epithio dioxide gives pure *cis*-stilbene in 83% yield, whereas a mixture of 61 parts of *trans*- and 39 parts of *cis*-stilbene is formed when it is heated to 50 °C in 0.2N NaOH. The elimination of SO_2 is complete after 2 days at room temperature. The *trans*-stilbene is probably also formed *via* its epithio dioxide, without the participation of phenylcarbene [75].

While the reaction of diaryldiazomethanes and aryldiazoalkanes with SO_2 leads to three-membered ring sulfones *(50)* in good yields, or to olefins *(51)* and relatively small quantities of ketazine *(49)*, the ketazines predominate in the products obtained from cycloalkyldiazoalkanes. Cyclic azosulfones, which occur as pairs of

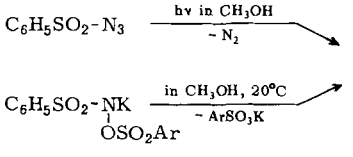
[77] *E. Reichold*, Dissertation, Universität Erlangen, 1955.

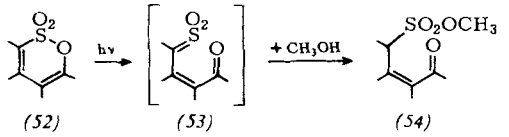
stereoisomers and are regarded as Δ^3-[1,3,4]-thiadiazoline 1,1-dioxides *(45)*, are also formed, probably by 3+2 cycloaddition (e) of sulfenes and diazoalkanes. However, the isomeric Δ^2-[1,2,3]-thiadiazoline structure *(47)* can not yet be definitely ruled out. The best known product is the crystalline substance *(45)* with $R_2 = C_2H_5$, C_6H_{11}, which is obtained from 1-cyclohexyl-1-diazopropane and SO_2 [78,79]. The stereoisomers have identical UV and IR spectra, with sulfone bands at 1150 and 1300 cm^{-1}. When a solution of the isomers of *(45)* in petroleum ether is filtered through Al_2O_3, SO_2 is lost (f), whereby the ketazine *(49)* is formed.



When the stereoisomers are heated slowly, the same reaction occurs at temperatures above 120 °C. Immersion of the reactants in a bath at 240 °C leads also to the liberation of nitrogen and formation of 3,4-dicyclohexyl-3-hexene *(51)* in 8% yield. In such cases the yield of olefin cannot be increased beyond 25% even when a special technique (flow pyrolysis) is used [79].

It may be assumed from these observations that the three-membered ring sulfones *(50)* are formed, not *via* the [1,3,4]-thiodiazolines *(45)*, but *via* the previously unknown Δ^2-[1,2,3]-thiadiazoline 1,1-dioxides *(47)* or *via* the zwitterions *(46)* or *(48)*. The elimination of N_2 from *(46)* to form the three-membered ring sulfone *(50)* would correspond to the elimination of the chloride ion in the Ramberg-Bäcklund reaction.

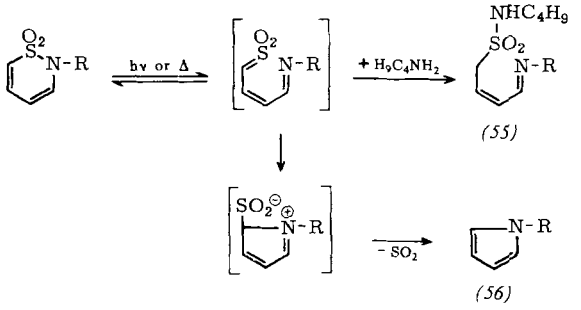
(46) *(50)*



Neureiter [54] considers the variable steric course of the reaction to be incompatible with this mechanism [73,75,80]. Thus the preferential formation of the *cis*-olefin epithio dioxide is

not observed in the reaction of diazoethane with SO_2, as it is in the reaction of α-halogenated diethylsulfone with 2N KOH. However, this argument is not very convincing, in view of the great ease with which the diazonium group is split off.

III. Photochemical Ring Cleavage of Sultones

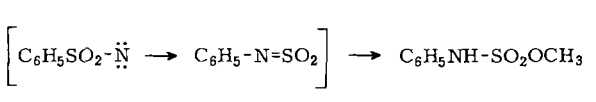


Doubly unsaturated δ-sultones *(52)* are converted into the sulfonates *(54)* on UV irradiation in methanol.

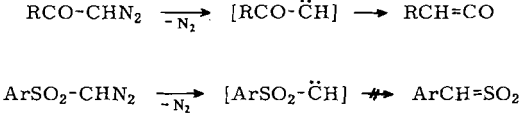
(52) *(53)* *(54)*

In the presence of benzylamine, the *N*-benzylsulfonamides are formed. Since these reactions do not take place in the dark, it is assumed that they proceed by photochemical ring cleavage to form the ketovinylsulfenes *(53)* [34].

The corresponding sultams react analogously when irradiated with UV light in the presence of butylamine.



(55) *(56)*



The reaction products are the *N*-butylsulfonamide *(55)* and the pyrrol *(56)* which is formed by loss of SO_2. *Durst* and *King* [81] interpret the formation of pyrrol, which is the main reaction in photolysis in cyclohexane, ether, or methanol, as well as in pyrolysis, as nucleophilic addition of the N atom of the imine on the C atom of the sulfene group and subsequent loss of SO_2. Nucleophilic addition can take place at the S atom (normal case, reversion to sultams) or at the C atom (exceptional case, reduction in ring size).

IV. Elimination of Nitrogen from α-Diazosulfones

Curtius and Lossen degradations can also take place in the sulfonic acid series [82] (23 and 67% yield respectively):

Similarly, the elimination of N_2 from α-diazosulfones could lead to sulfenes by a reaction akin to the Wolff rearrangement.

However, in the heat-, light-, or Ag_2O-induced decomposition of *p*-methoxybenzenesulfonyldiazomethane [83] and benzenesulfonyldiazomethane [84], only reactions of the arylsulfonylcarbene could be detected.

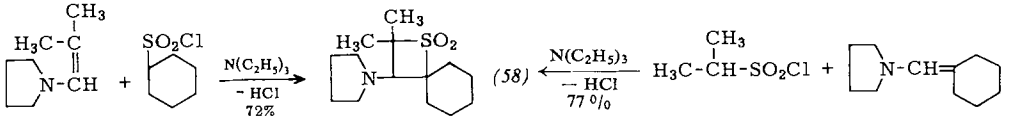
V. Cycloadditions with Sulfenes Produced *in situ*

Attempts to prepare sulfenes have resulted in interception by the sulfonyl chloride, diazoalkane, or SO_2. A component that is introduced deliberately can assume the role of interceptor only if the sulfene reacts more rapidly with this component than with sulfonyl chloride (*e.g.* with H_2O, D_2O, AlkOD, $(Alk)_2NH$, $ArNH_2$ [36,45], and tosyl chloride, but not with tosyl fluoride [28]) or than with diazoalkane or SO_2 (*e.g.* with H_2O [65,73], but cf. [75], and with AlkOH [65], NH_3, $AlkNH_2$, and $(Alk)_2NH$ [67], but not with $ArNH_2$ [67] or acetone [73]). Moreover, if the sulfene is produced from diazoalkane $+SO_2$, the intercepting component must not react with either of these components. The number of possible interceptors is therefore small, and it is at least partly understandable that unlike ketenes [85], sulfenes undergo cycloaddition only with strongly nucleophilic olefins and other very reactive partners. The high reactivity of the diazoalkanes is a great drawback and for this reason cycloadditions are generally carried out with sulfenes produced *in situ* from sulfonyl chloride and NEt_3.

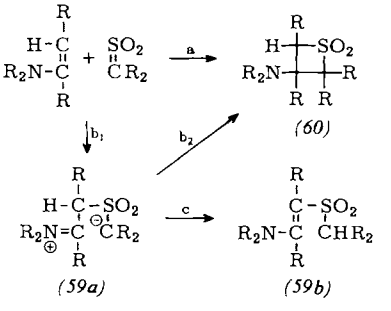


1. Enamines

The resumption of sulfene research in 1960 after a break of several decades was due to the observation [86,87] that *N*-(1-propenyl)piperidine is not *C*-acylated by mesyl chloride/NEt_3 in cold ether, but is converted into 2-methyl-3-piperidinothietane 1,1-dioxide *(57)* (yield 88%).

(57)

Mesyl chloride (methanesulfonic anhydride may also be used [38]) and primary sulfonyl chlorides react with enamines of aldehydes and ketones in the same orientation, and no obvious restrictions have been found regarding solvent and temperature [30,88,23,43,50,89–96]. Even more surprising is the fact that secondary sulfonyl chlorides do not react under a wide range of conditions, whereas the reaction proceeds smoothly in acetonitrile at −40 °C. The formation of the same product *(58)* from *N*-(2-methyl-1-propenyl)pyrrolidine and cyclohexanesulfonyl chloride and from *N*-(cyclohexylidenemethyl)pyrrolidine and 2-propanesulfonyl chloride proves the constitution of the fourmembered ring sulfones [44].



(58)

As in the analogous cycloaddition of enamines to ketenes [97] and isocyanates [98–100], high basicity of the enamine favors initiation of the reaction under mild conditions, while the formation of open-chain sulfones [*e.g. (59b)*] is favored by increasing α-substitution of the sulfonyl chloride and of the enamine. Thus the cycloaddition of dimethylsulfene to *N*-(2-methyl-1-propenyl)-pyrrolidine proceeds in 85% yield, whereas the yield in the cycloaddition to *N*-(2-methyl-1-propenyl)morpholine is only 10% [44]. *N*-Vinylcarbazole does not react with sulfene [96]. In general, open-chain sulfones are formed with sulfene and monosubstituted sulfenes only with enamines from ketones [30,95,23,101] and of disubstituted sulfenes with enamines from aldehydes and ketones [44].

In view of the difficulties encountered [102,103] in the conversion of enamines into open-chain sulfones by β-*C* acylation with aromatic sulfonyl chlorides, it may be assumed that cycloaddition and *C*-acylation proceed *via* sulfenes. Cycloaddition and subsequent ring opening can, however, be mistaken for direct *C*-acylation and this must be borne in mind when considering four-membered ring sulfones carrying substituents, such as vinyl, aryl, and aminomethyl groups, which are conducive to ring cleavage. The possibility that the four-membered ring is formed by addition of the sulfonyl chloride to the double bond of the enamine followed by dehydrochlorination, either directly or *via* the *C*-acylated enamine, has been ruled out experimentally [43,23,39].

It is unknown whether the cycloaddition is a one-step multicenter reaction (a) or a two-step addition (b).

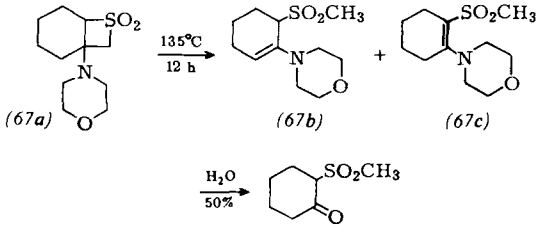
Path b is probably preferred in view of both the selection rules [104] for multi-center cycloadditions and the observation [105] that even in the 2+2 cycloaddition to the non-polar cyclohexene, diphenylketene reacts rather more rapidly with the carbonyl group than with the diphenylmethylene group. This route provides a better explanation of the single orientation and of the fact that only strongly nucleophilic olefins are attacked by sulfenes. It also enables us to establish a relationship between the extent of *C*-acylation and the stabilization of the charges in the zwitterion *(59a)*. However, the expected solvent-dependence is lacking in the reaction of β-pyrrolidinostyrene with mesyl chloride/NEt_3. The yield of open-chain sulfone is the same (4%) in acetonitrile as in ether, though the yields of the cycloadduct are 75 and 35% respectively [95].

Route a should be stereospecific, while route b should be stereoselective only if the life of the zwitterion *(59a)* is very short. Owing to the lability of the *cis* enamines [106], it is more difficult to obtain any information in this case than in the stereospecific [107,108] cycloaddition of ketoketenes to vinyl ethers. Since the possibility of a *cis-trans* rearrangement of the enamine before addition cannot be ruled out, no conclusions can be drawn from the observation [109] that *trans-N*-(1-propenyl)morpholine yields only one four-membered ring sulfone on reaction with mesyl chloride/NEt_3, whereas the *cis*-enamine gives a mixture of two stereoisomers.

These experiments should be distinguished from the reactions of the bicyclic enamines *(61)* with CH_3SO_2Cl/NEt_3 and chloromethanesulfonyl chloride/NEt_3 [90,91]. The NMR spectra of these compounds show that they exist to the extent of 80–90% in the form shown.

(61) *(62a)* *(62b)*



The cycloaddition of the sulfenes, which attack from the *exo* side, is stereoselective in that the amino group predominantly occupies the sterically favored position *(62a)*, *(62b)*, in which, unlike the H atom shown, it does not lie under the bicyclo system. The distance between the amino group and the olefinic protons, whose NMR signals appear as two doublets and not as a triplet, differs only in the stereoisomers shown. As expected, thioformyl chloride *S,S* dioxide gives two stereoisomeric cycloadducts [*(62a)* and *(62b)*, R = Cl] in which the Cl atom is *cis* and *trans* to the amino group respectively.

The enamine from pyrrolidine and isobutyraldehyde gives the same four-membered ring sulfone *(63)* with diazomethane/SO_2 as with mesyl chloride/NEt_3, as well as the disulfone *(64)* [39,42,110].

It seems doubtful, at least for *(64)*, whether the products in this case are formed by cycloaddition of the enamine to sulfene. It is possible that the reacting species is, not the enamine, but its SO_2 adduct *(65)*. This could react as an immonium sulfinate [111,112] with diazomethane to form the four-membered ring *(63)*, and with the adduct *(66)* of sulfene and diazomethane [cf. *(46)* in Scheme 3] to form the six-membered ring *(64)*.

The 3-aminothietane 1,1-dioxides are generally weakly basic compounds that crystallize well. Difficulties are sometimes encountered in their reduction with $LiAlH_4$ to form 3-aminothietanes [88,43,30,95] and in the elimination of amine [94,89,92,95] *via* the quaternary salt *(Hofmann)* or *via* the amine oxide *(Cope)* to form the 3-aminothietene 1,1-dioxide.

The thermal stability of the 3-aminothietane 1,1-dioxides depends on the nature and the number of substituents. 2-Ethyl-3-morpholinothietane 1,1-dioxide, 2-methyl-3-piperidinothietane 1,1-dioxide, and similar alkyl-substituted four-membered ring sulfones can be distilled or sublimed in a high vacuum. While ring cleavage takes place at room temperature [113] for the adduct of *N*-(1-cyclohexenyl)morpholine and ketene [*(67a)*, CO in place of SO_2], the sulfene cycloadduct *(67a)* must be heated for several hours at 135 °C [43]. *(67b)* and *(67c)* are formed in the ratio 67:33.

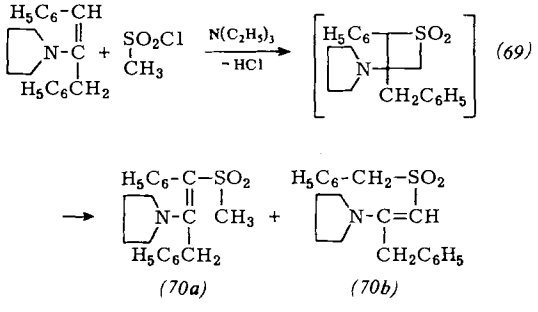
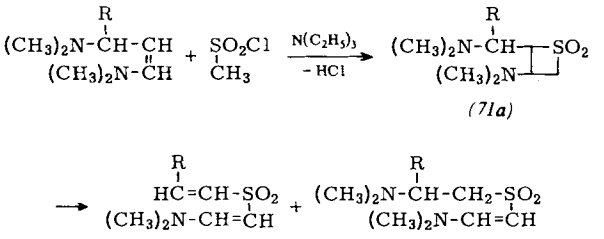
[113] *G. Opitz* and *F. Zimmermann*, Liebigs Ann. Chem. *662*, 178 (1963).



This reaction is of preparative interest, since the direct *C*-sulfonylation of *N*-(1-cyclohexenyl)morpholine with mesyl chloride is unsatisfactory even in the absence of NEt_3 [43].

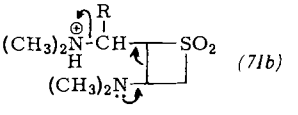
Ring cleavage in 2-phenyl-3-dimethylaminothietane 1,1-dioxide has been achieved by heating with aqueous-methanolic sodium hydroxide solution [95]. The phenyl group probably promotes the reaction by delocalization of the negative charge.

(68)



The enamine produced from dibenzyl ketone and pyrrolidine yields two open-chain sulfones *(70a)* and *(70b)*, and not the expected four-membered ring sulfone, when treated with mesyl chloride in ether.

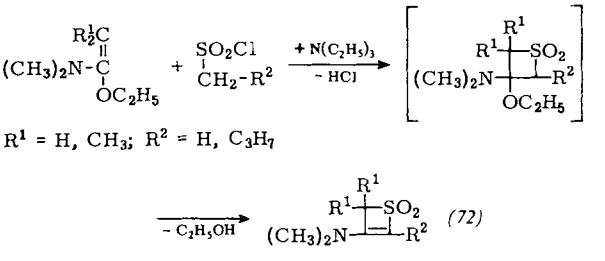
(69)



(70a) *(70b)*

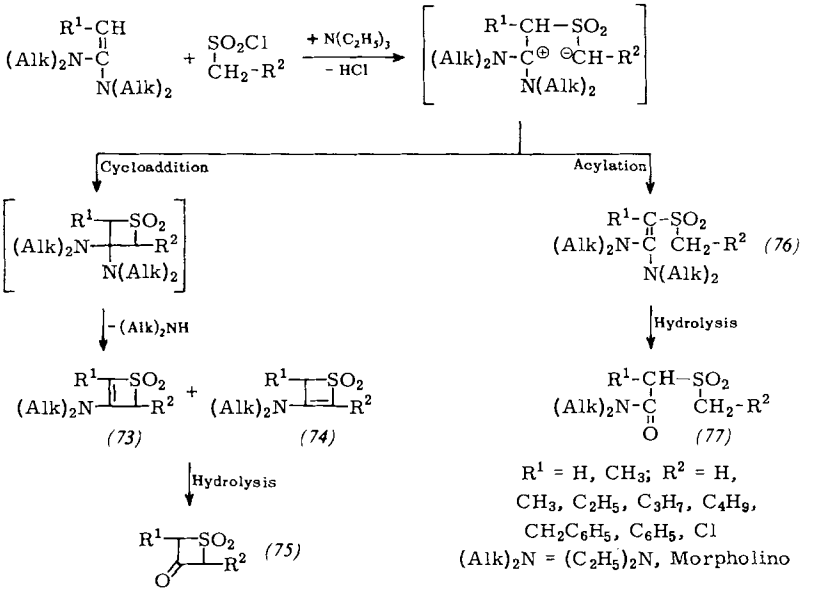
Whereas the formation of the benzylsulfone *(70b)* is explicable only by assuming *(69)* to be intermediate, the isomeric methylsulfone *(70a)* can also be produced by direct *C*-sulfonylation of the enamine. Primary sulfonyl chlorides react analogously with this enamine [101]. Ring cleavage of the four-membered ring sulfones *(71a)*, which are obtained from γ-amino enamines, proceeds as readily (in THF at −20 °C) as for enolizable 3-amino-cyclobutanones [93].

(71a)



The reason for this probably lies in the ready fragmentation *(71b)* of the protonated diamine *(71a)* [93].

(71b)



2. Ketene *O,N*- and *N,N*-Acetals

The cycloaddition of ketene *O,N*-acetals to sulfene is followed by spontaneous elimination of alcohol, leading to the formation of 3-dialkylaminothietene 1,1-dioxide *(72)* [114, 115].

(72)

Ketene *N,N*-acetals react similarly with elimination of dialkylamine, which reacts with part of the sulfonyl

(73) *(74)* *(75)* *(76)* *(77)*

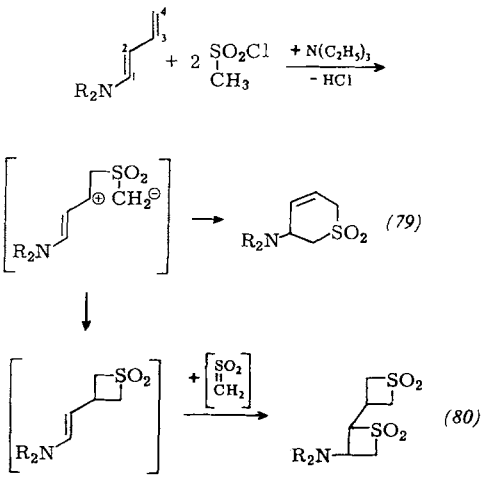
chloride. The unsaturated four-membered ring sulfones, which occur as mixtures of the isomers *(73)* and *(74)* when $R^1 \neq R^2$, are enamines, and can therefore be hydrolysed. The hydrolysis must be conducted carefully [114, 115], since 3-oxothietane 1,1-dioxide [*(75)*, $R^1 = R^2 = H$] is readily hydrolysed to mesylacetic acid [116]. The cycloaddition is accompanied by formation of open-chain sulfones; this is not surprising in view of the stabilization of the positive charge in the zwitterion [114–118] (with ketene instead of sulfene, only acylation is observed [119]). 1,1-Bis-(*N*-methylanilino)-2-methyl-1-propene is too inert for either reaction [116].

Since ketene *N,N*-acetals react with SO_2, the sulfenes cannot be produced from diazoalkane and SO_2 in this case [42].

The formation of open-chain sulfones is promoted by $R^1 = H$, by groups R^2 that, like C_6H_5, can accommodate the negative charge on the zwitterion, by substitution of the sulfene H atoms, as well as by polar solvents or solvents such as chloroform that dissolve the NEt_3–HCl. Thus the reaction of 1,1-dimorpholinoethylene and mesyl chloride/NEt_3 in ether, THF, or benzene gives 3-morpholinothietene 1,1-dioxide [*(73)*, $R^1 = R^2 = H$] in 69–92% yield, while in acetonitrile, DMF, or chloroform the same components give 1,1-dimorpholino-2-mesylethylene [*(76)*, $R^1 = R^2 = H$]. Primary sulfonyl chlorides, even in non-polar solvents, give open-chain sulfones as the main products, while these are the only products obtained with secondary sulfonyl chlorides. The formation of the very stable ketene *N,N*-acetal hydrochlorides [118, 103] gives rise to difficulties in the isolation of products, and in the hydrolysis of the sulfones *(76)* with hydrochloric acid to give the mesyl acetamides *(77)*.



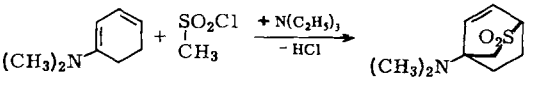
(78)

With 2-propanesulfonyl chloride the α-chlorosulfone *(78)* is formed as well as the normal product [*(78)*, H instead of Cl] [115]. According to recent observations [31], enamines can react analogously with secondary sulfonyl chlorides. Probably the zwitterionic primary adduct of olefin and sulfene is chlorinated by remaining sulfonyl chloride.

3. Dienamines

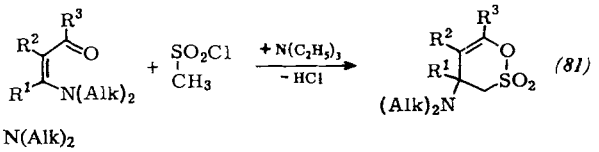
The butadienylamines, which give a Diels-Alder reaction even at 0 °C with ethyl acrylate, acrolein, acrylonitrile [120], and ketene [103], exhibit very interesting behavior on addition to sulfene. A 4+2 cycloaddition to give *(79)* competes fairly successfully with the double 2+2 cycloaddition leading to *(80)* [64, 93].

If electrophilic attack in position 4 is followed by ring closure in position 3, the product is an enamine, which reacts further with sulfene to form *(80)*. The cyclization in position 1, which is favored by a *cisoid* conformation



(79)

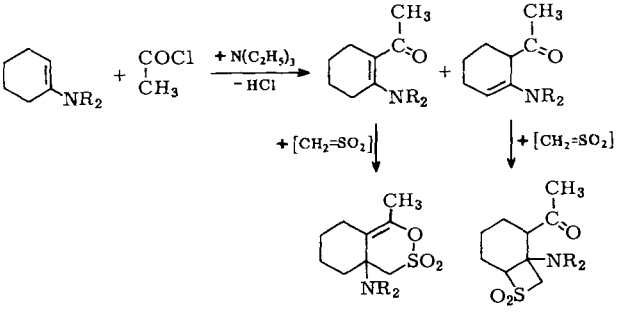
(80)



R_2N = Dimethylamino, diethylamino, pyrrolidino, piperidino, morpholino.

of the dienamine, leads to the stable allylamine *(79)*. If the cisoid structure is fixed, only the Diels-Alder reaction is observed [121].

4. β-Aminovinyl Ketones



Sulfene acts as a dienophile toward β-aminovinyl ketones [63], giving good yields of the crystalline enol sultones *(81)*; the yield is low only when $R^1 = CH_3$, owing to side reactions [121]. The ring closure corresponds to the formation of α-pyrones with ketene [122].

(81)

$N(Alk)_2$				
Piperidino;	$R^1 = H$;	$R^2 = CH_3$;	$R^3 = CH_3$;	80%
Pyrrolidino;	$R^1 = H$;	$R^2 = H$;	$R^3 = CH(CH_3)_2$;	75%
Dimethylamino;	$R^1 = CH_3$;	$R^2 = H$;	$R_3 = CH_3$;	7%

With the aid of this 4+2 cycloaddition and the 2+2 cycloaddition of sulfene to enamines, it can be shown that the acetylation of cyclohexenylamines leads to mixtures of the vinylogous carbonamide and the unconjugated isomer [63].

NR_2 =			
Pyrrolidino	32%	8%
Piperidino	9%	57%
Morpholino	5%	66%

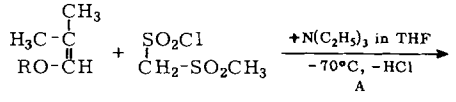
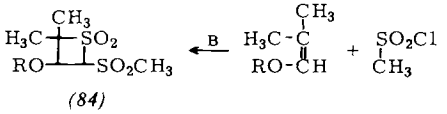
5. Vinyl Ethers

Vinyl ethers undergo 2+2 cycloaddition with mesylsulfene to give the four-membered ring sulfones *(82)*, together with small quantities of the enol ethers *(83)* [123].



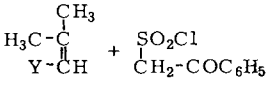


(82) *(83)*

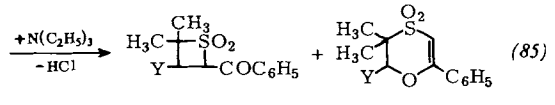
$R^1 = C_2H_5$; $R^2 = H$	60%	22%
$R^1 + R^2 = (CH_2)_3$	70%	little

The fact that the mesylsulfene can be produced *in situ* either from mesylmethanesulfonyl chloride/NEt_3 in THF at −70 °C (route A) or from mesyl chloride/NEt_3 in acetonitrile at −40 °C (route B) shows that vinyl ethers do not react with simple sulfenes, since route B proceeds *via* sulfene (see Scheme 1). In the convenient and successful route B, the polar acetonitrile favors the formation of open-chain sulfones. This reaction is not so important in route A, which is little used at present.

With alkyl isobutenyl ethers, which cannot form open-chain sulfones, the cycloaddition by route B is almost quantitative, though the mesyl chloride must first be converted by at least three reaction steps into mesylsulfene.



(84)

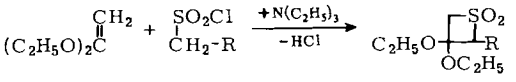


$R = CH_3$	A 75%; B 85%
$R = C_2H_5$	A – ; B 90%

The four-membered ring sulfones, which form beautiful crystals, are unstable to alkalis. 3-Ethoxy-2-mesylthietan 1,1-dioxide *[(82)*, $R^1 = C_2H_5$, $R^2 = H$], which is particularly sensitive to alkalis, is degraded to dimesylmethane $(CH_3{-}SO_2)_2CH_2$ by 2N NaOH.

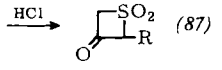
Vinyl ethers evidently undergo cycloaddition with strongly electrophilic sulfenes only.

Methoxycarbonyl sulfene does not react [96]. Benzoyl sulfene undergoes 4+2 cycloaddition with the enol ether



(85)

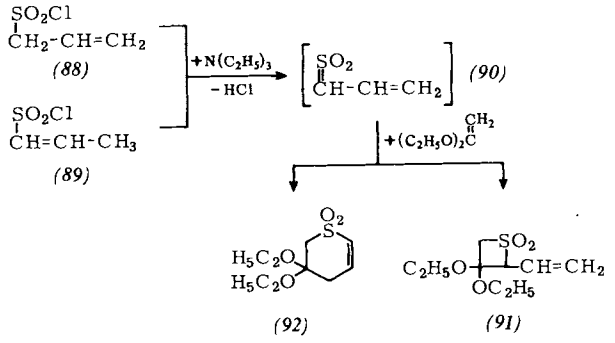
Y = 1-Pyrrolidinyl	40%	0%
Y = C_2H_5O	0%	42%



from isobutyraldehyde to give *(85)* [Y = alkoxy] and not 2+2 cycloaddition, as with the corresponding enamines [62].

6. Ketene Acetals

The more reactive ketene diethyl acetal adds to sulfene [124,43], which must be produced from mesyl chloride/NEt_3, since only thiirane dioxide is obtained when diazomethane/SO_2 is used [42]. The yield (24–68%) of 3,3-bis(ethoxy)thietane 1,1-dioxide *[(86)*, R = H], which is hydrolysed to 3-oxothietane 1,1-dioxide *[(87)*, R = H, yield 70%] by concentrated hydrochloric acid [125, 126], exhibits an unexpected dependence on the solvent [12]. In the absence of NEt_3 other products are formed [127].



R = H, Ar, Cl, CF_3 *(86)*

(87)

Cycloaddition with primary sulfonyl chlorides occurs only if R is aromatic or electron-attracting [12, 118]. The particularly reactive *p*-nitrophenylmethanesulfonyl chloride gives 54% of the cycloadduct together with a little 4,4′-dinitrostilbene. Nothing is known about acylations.

An indication of the intermediate formation of sulfenes is provided by the observation by *Truce* and *Norell* [12] that the isomeric propenesulfonyl chlorides *(88)* and *(89)* give the four-membered ring sulfone *(91)* [46% from *(88)* and 51% from *(89)*] and the six-membered ring sulfone *(92)* [7% from *(88)* and 8% from *(89)*] in mixtures having almost the same composition.

(88) *(89)* *(90)* *(92)* *(91)*

Corresponding to its formation by 1,2- and 1,4-elimination, vinylsulfene *(90)* can undergo 1,2- and 1,4-cycloaddition. Its low tendency to enter into 1,4 addition with ketene acetal to form *(92)* and AlkOD (see Section C I 2a) is explained by the inductive effect of the SO_2 group.

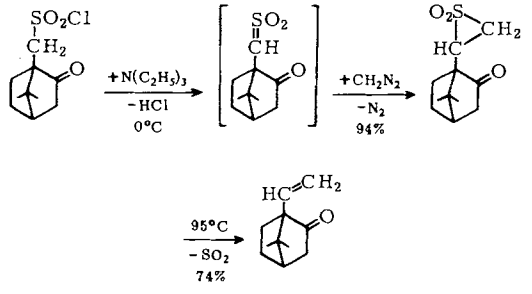
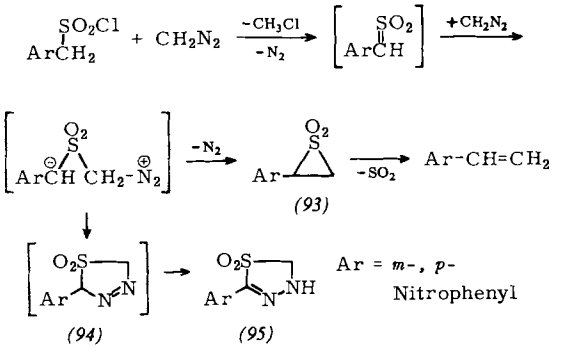
[127] *W. E. Truce, D. J. Abraham*, and *P. S. Radhakrishnamurti*, Tetrahedron Letters *1963*, 1051.



7. Chloral

The cycloaddition of sulfene to chloral corresponds to the formation of β-lactones from ketene and carbonyl compounds that undergo spontaneous hydration. In cold ether, the β-sulfone is obtained in 42% yield [128].



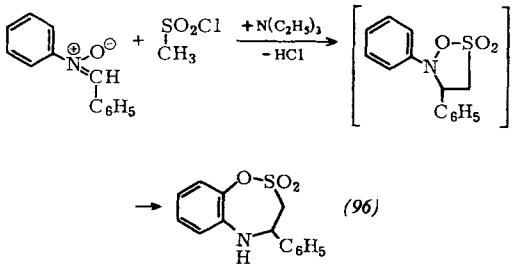
8. Diazoalkanes

The preparative disadvantage of the Staudinger-Pfenninger reaction (see Section C II), *i.e.* the fact that it yields only symmetrical olefins, can be overcome by the production of another sulfene from sulfonyl chloride and NEt_3 in the presence of a diazoalkane [129]. The sulfene is immediately intercepted by the diazoalkane, showing that diazoalkanes are much more reactive sulfene interceptors than sulfonyl chlorides.

Both symmetrical and unsymmetrical olefins, as well as their epithio *S,S*-dioxides, can be prepared in this way from mesyl chloride or primary sulfonyl chlorides and diazomethane, diazoethane, 1-diazo-2-methylpropane, and 2-diazobutane [39,129,130,42,56]. As in the reaction of diazoalkanes with SO_2, there appears to be no preference for the formation of the *cis*-olefin [130].

With *m*- and *p*-nitrophenylmethanesulfonyl chloride, the addition of triethylamine is unneccessary, since excess diazomethane acts as the HCl acceptor. In cold ether the reaction yields the epithio *S,S*-dioxide of nitrostyrene *(93)* and 2-nitrophenyl-Δ^2-[1,3,4]-thiadiazoline 1,1-dioxide *(95)*, which forms nitrobenzonitrile on hydrolysis [80].

[128] *D. Borrmann* and *R. Wegler*, Chem. Ber. *99*, 1245 (1966).



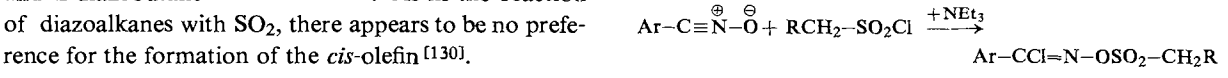
[129] *G. Opitz* and *K. Fischer*, Angew. Chem. *77*, 41 (1965); Angew. Chem. internat. Edit. *4*, 70 (1965).

[130] *G. Opitz* and *N. Fischer*, unpublished.

In view of the properties (see Section C II) of 2,5-diethyl-2,5-dicyclohexyl-Δ^3-[1,3,4]-thiadiazoline 1,1-dioxide [*(45)*, $R_2 = C_2H_5$, C_6H_{11}], it is unlikely that *(94)* can be converted into the three-membered ring sulfone *(93)* before isomerization to form *(95)*. This reaction therefore provides a further argument in favor of the view that the olefin *(51)* (Scheme 3) is not formed *via* the Δ^3-[1,3,4]-thiadiazoline 1,1-dioxide *(45)*.

9. Nitrones

Sulfene acts as a dipolarophile toward *N*-benzylideneaniline *N*-oxide. This can be deduced from the formation of the [1,2,5]-oxathiazepine *S,S*-dioxide derivative *(96)* in 63% yield [131].



(96)

The migration of a sulfonyloxy group from the N atom of aniline into the *o* position following the 3+2 cycloaddition has also been observed with the benzoyloxy group [132].

10. Unsuccessful Interception Attempts

The reaction of nitrile oxides with methane- or phenylmethanesulfonyl chloride/NEt_3 leads to sulfonates of hydroxamyl cnlorides. No 1,3-dipolar cycloadditions have been achieved [47,133,134].

The structure of the products obtained with Schiff bases [42] has not yet been estaolished. Attempted cycloadditions of sulfenes produced *in situ* with anthracene and cyclohexene [43], with acrolein, ethyl acrylate, hexachlorobutadiene, trifluorochloroethylene, 1-ethoxy-1-ethylthioethylene, 1,1-bis-(*p*-methoxyphenyl)ethylene, 1,1-bis-(*p*-dimethylaminophenyl)ethylene, and phenylimino diethyl carbonate [12], with diphenylketene, 1,1-bis-(ethylthio)ethylene, 1,1-dichloroethylene, cyclopentadiene, and *p*-tolylthioethylene [124], with phenylacetylene, 1-methoxy-1-buten-3-yne, and 1,2-bis(ethoxy)ethylene [42], and with benzylideneaniline [12,42], vinyl ethyl ether [124,42], ethoxyacetylene [43,124], and tetramethoxyethylene [135] were unsuccessful.

VI. Reactions of the Mesylsulfene-Trimethylamine Adduct

As was described in Section C I 2d, mesylchloride reacts with trialkylamines in acetonitrile at −40 °C to form mesylsulfene, which adds on to an excess of amine [58,59]. Trimethylamine stabilize the mesylsulfene to such an extent that the adduct *(26)* can be isolated at room temperature in air as a white, finely crystalline powder (yield 60%) which decomposes at 126–130 °C. The NMR spectrum, with singlets at $\tau = 5.6$ (CH), 6.9 (CH_3SO_2), and 7.0 [$N(CH_3)_3$] in the ratio 1:3:9, shows the ammonium character of the adduct [$N(CH_3)_3$:τ = 7.9; $^{\oplus}N(CH_3)_4$:τ = 6.7] and the small influence of the negative charge on the chemical shift of the methine proton [$CH_3SO_2\underline{C}H_2SO_2N(CH_3)_2$:$\tau$ = 5.6]. The hydrolysis with water to form trimethylammonium mesylmethanesulfonate *(97)* is complete only after about 5 hours at 36 °C, so that the reaction can be conveniently followed by IR and NMR spectroscopy.

(26), and the analogous mesylsulfene-triethylamine adduct, react with aniline, dimethylamine, and pyrrolidine to form the amides *(98)*. The reaction of *(26)* with p-O_2N–C_6H_4–OD gives the ester *(99)* of mesylmethanesulfonic acid, which is monodeuterated in the methylene group, and with *N*-(2-methyl-1-propenyl)-pyrrolidine and 2*H*-dihydropyran to give the fourmembered ring sulfones *(100)* and *(101)* respectively. The same compounds are formed when the mesylsulfene-amine adducts are replaced by CH_3SO_2–CH_2–SO_2Cl/NEt_3 [50].

VII. Future Prospects

56 years after the first experiments by *Wedekind* and *Schenk* [3], the concept of the formation of sulfenes from sulfonyl chlorides by dehydrochlorination with trialkylamine may be assumed to have been vindicated. The indirect proof of the existence of sulfenes by interception reactions has now been followed by direct proof in the isolation of a sulfene as the trimethylamine adduct. The next step must be the detection and isolation of free sulfenes. Only then will it be possible to answer the questions that still remain open: How does the life of free sulfenes depend on structure and temperature? What is the nature of the bonding? Why do sulfenes fail to polymerize? Do simple sulfenes also form amine adducts?

I am grateful to my co-workers Dr. H. Adolph, D. Bücher, Dr. N. Fischer, Dr. M. Kleemann S. Mächtle H.-R. Mohl, K. Rieth, Dr. H. Schempp, F. Schweinsberg, G. Stephan, Dr. E. Tempel, and G. Walz, who have made important contributions in this field. Thanks are also due to the Verband der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, the Chemische Werke Hüls AG/Marl, and the Georg Schumacher GmbH/Haunsheim for their support of this work.

Nickel-Catalysed Reactions of Allyl Halides and Related Compounds

BY G. P. CHIUSOLI AND L. CASSAR [*]

Allyl compounds react with carbon monoxide, or with carbon monoxide and acetylene, in the presence of tetracarbonylnickel as catalyst. These catalysts are involved also in coupling reactions and addition reactions of activated olefins and ketones. Reactions of this type can be used for the preparation of unsaturated aliphatic acids, esters, nitriles, hydrocarbons, alicyclic ketones, keto acids, keto esters, diketones, lactones, phenols, and other compounds. The reactions proceed via π-allylnickel complexes.

1. Preparation of Unsaturated Acids and Esters from Allyl Compounds, Acetylene, and Carbon Monoxide

a) Reaction of Allyl Halides

In earlier publications [1,2] we described two reactions for the preparation of unsaturated acids or esters by "carbonylation" with tetracarbonylnickel as the catalyst:

$$RCH{=}CH{-}CH_2X + CO + R'OH \xrightarrow[Ni(CO)_4]{} RCH{=}CH{-}CH_2{-}COOR' + HX \quad (a)$$

$$RCH{=}CH{-}CH_2X + HC{\equiv}CH + CO + R'OH \xrightarrow[Ni(CO)_4]{} RCH{=}CH{-}CH_2{-}CH{=}CH{-}COOR' + HX \quad (b)$$

R = alkyl, aryl, H; R' = alkyl, aryl, H; X = Cl, Br, I; some of the hydrogen atoms in the allyl group may be replaced by alkyl groups.

Reaction (a) gives β,γ-unsaturated compounds, while reaction (b) yields compounds with double bonds in both the α,β and δ,ε positions, the α,β substituents being *cis* to each other.

Reaction (a) is carried out at room temperature and at 2–3 atm pressure. The reaction is suppressed at higher pressures unless the temperature is also raised, whereas lower pressures favor dimerization of the allyl groups. Generally the yields do not exceed 50%. Reaction (b) is best carried out at room temperature and at atmospheric pressure (yield up to 80%). In both cases, the start of the reaction is characterized by a strong reddish coloration of the reaction mixture, which changes to green toward the end of the reaction.

If the compound is a secondary halide that can rearrange to a primary halide, it reacts in the primary form; *e.g.* $CH_3{-}CHCl{-}CH{=}CH_2$ reacts as $CH_3{-}CH{=}CH{-}CH_2Cl$ [2a]. The same is true of tertiary halides, which do not react as such, even under the usual mild conditions (0–50 °C), but rearrange first to give secondary halides.

When inert solvents (*e.g.* ethers or aromatic hydrocarbons) are used, the products are acyl halides [2a, 3b]. Reactions (a) and (b) are best carried out in dilute solution in the presence of an excess of tetracarbonylnickel (more than 1 mole per mole of allyl compound). Table 1 shows some methyl esters obtained *via* equation (b). No attempt was made to determine the optimum conditions for their syntheses.

Table 1. Methyl esters of 2-*cis*-5-dienoic acids obtained at 20 °C in methanol in accordance with eq. (b).

R''CH=CH–COOCH$_3$ R''– =	B.p. (°C/mm)	Yield (%)
$CH_2{=}CH{-}CH_2{-}$	62–63/28	70
$CH_3{-}CH{=}CH{-}CH_2{-}$	73–75/20	81
$CH_2{=}C(CH_3)CH_2{-}$	62–63/16	80
$CH_3{-}CH{=}CH{-}CH(CH_3){-}$	75–78/20	40
$CH_3{-}C(CH_3){=}CH{-}CH_2{-}$	85–86/12	35
$CH_3{-}(CH_2)_2{-}CH{=}CH{-}CH_2{-}$	69–70/2	62
$CH_3{-}(CH_2)_4{-}CH{=}CH{-}CH_2{-}$	68–70/0.4	73
$CH_3{-}(CH_2)_6{-}CH{=}CH{-}CH_2{-}$	103–104/1	64
$CH_3{-}(CH_2)_{14}{-}CH{=}CH{-}CH_2{-}$	150–156/0.2	48
$CH_3{-}C(CH_3)_2{-}CH_2{-}CH{=}CH{-}CH_2{-}$	97–100/8	55
$H_3COCO{-}CH{=}CH{-}CH_2{-}$	79–81/1	40
$H_3COCO{-}CH_2{-}CH{=}CH{-}CH_2{-}$	126–130/6	32
$H_3COCO{-}CH{=}CH{-}CH_2{-}CH{=}CH{-}CH_2{-}$	140–141/5	80
$H_3COCO{-}CH{=}C(CH_3){-}CH_2{-}$	81–82/1	45
$H_3C{-}COO{-}CH_2{-}CH{=}CH{-}CH_2{-}$	115–117/5	35
$NC{-}CH_2{-}CH{=}CH{-}CH_2{-}$	133–134/7	79
2-Cyclopenten-1-yl	92–96/12	50
2-Cyclohexen-1-yl	105–108/12	50
$C_6H_5{-}CH{=}CH{-}CH_2{-}$	155–160/5	54
$H_3COCO{-}CH{=}CH{-}CH_2{-}CH{=}CH{-}CH_2{-}CH_2{-}CH{=}CH{-}CH_2{-}$	150–155/0.3	19

Part of the tetracarbonylnickel enters into non-catalytic side reactions in which it is converted into nickel halide, *e.g.* with dimerization [eq. (c)], or hydrogenation [eq. (d)] of the allyl group.

$$2\,RCH{=}CH{-}CH_2X + Ni(CO)_4 \longrightarrow RCH{=}CH{-}CH_2{-}CH_2{-}CH{=}CHR + NiX_2 + 4\,CO \quad (c)$$

$$RCH{=}CH{-}CH_2X + Ni(CO)_4 + H_2O \longrightarrow RCH_2{-}CH{=}CH_2 + NiOHX + 4\,CO \quad (d)$$

Reaction (b) may also yield by-products, such as acrylic acids or esters, from acetylene and carbon monoxide; however, the formation of these products can be suppressed by neutralization of the hydrogen chloride liberated.

3-Chloro-1-propyne (propargyl chloride) reacts with carbon monoxide, water, and tetracarbonylnickel to give 2,3-butadienoic acid and itaconic acid. The similarity between this and the reaction of allyl chloride is, however, purely formal. *Jones et al.* interpreted this reaction as a variant of the oxo synthesis [3].

Generally allyl halide groups can be produced easily in olefins *e.g.* by "substitutive chlorination" with chlorine. An atom of bromine can be introduced into the allyl position in an olefin by means of *N*-bromosuccinimide, while an allyl H atom can be replaced by a hydroxyl or acetoxy group on oxidation with air in the presence of *e.g.* $PdCl_2$ [51] or cobalt acetate [52].

b) Reactions of Other Allyl Compounds

Unsaturated acids and esters [2d, 2g] can also be synthesized by reaction (b) when allyl alcohols, ethers, and esters [eq. (e)] are used, *e.g.*

$$RCH{=}CH{-}CH_2OH + CH{\equiv}CH + CO \xrightarrow[HCl]{Ni(CO)_4} RCH{=}CH{-}CH_2{-}CH{=}CH{-}COOH \qquad (e)$$

($RCH{=}CH{-}CH_2{-}CH{=}CH{-}COOCH_2{-}CH{=}CHR$ is a by-product in water/acetone).

These reactions are carried out in the presence of less hydrogen chloride than is required for the formation of allyl chlorides. The yields ($\approx$ 80–85%) are generally higher than when allyl chlorides are used [eq. (b)], since the latter reaction is impeded by the nickel chloride which is formed in the side reaction (c).

If higher temperatures ($\approx$ 130 °C) are used, allyl esters react with tetracarbonylnickel, even in the absence of hydrogen chloride, to form allyl groups, carbon monoxide, and nickel salts [3a]. An example of the use of allyl esters is the reaction of 4-chloro-2-butenyl acetate. When *cis*-1,4-dichloro-2-butene is treated with tetracarbonylnickel, carbon monoxide, and acetylene in methanol it decomposes, mainly into *cis*-2-butene and butadiene; if one of the chlorine atoms is replaced by an acetoxy group, the resulting compound reacts with acetylene, carbon monoxide, and methanol (with careful neutralization of the hydrogen chloride liberated) to form methyl 7-acetoxy-2,5-heptadienoate *(1a)* [catalyst $Ni(CO)_4$].

$$H_3C{-}CO{-}O{-}CH_2{-}CH{=}CH{-}CH_2{-}CH{=}CH{-}COOCH_3 \quad (1a) \quad + HC{\equiv}CH + CO \xrightarrow[HCl]{Ni(CO)_4} H_3COOC{-}CH{=}CH{-}CH_2{-}CH{=}CH{-}CH_2{-}CH{=}CH{-}COOCH_3 \quad (1b)$$

The "acetoxyallyl" group (of 1a) can then be made to react in the presence of hydrogen chloride to give dimethyl 2,5,8-decatrienedioate *(1b)*, which forms dimethyl sebacate on hydrogenation [4]. A further example is the use of allyl acrylate instead of allyl halides. Allyl acrylate can be obtained directly from two molecules of acrolein; it reacts with carbon monoxide, methanol and acetylene in the presence of hydrogen chloride and tetracarbonylnickel to give methyl acrylate and methyl 2,5-hexadienoate [5].

c) Catalysis under Pressure

The use of acetylene and carbon monoxide under pressure permits catalysts to be employed which do not decompose in secondary reactions. Using salts such as nickel benzenesulfonate, and complexes such as that of nickel bromide with acetylacetone, 2,5-dienoic acids can be prepared from allyl halides, alcohols, ethers, and esters. According to *Reppe*, esters of acrylic acid are formed under these conditions from acetylene and carbon monoxide [5a]. However, this reaction can be suppressed by the use of low partial pressures of acetylene [2h, 6].

For example, allyl alcohol in methanol (previously saturated with 8 atm of C_2H_2 and 38 atm of CO at 15 °C) at 170 °C is converted into methyl 2,5-hexadienoate (16% conversion) in 4 hours; the product is partly isomerized to methyl 3,5- and 2,4-hexadienoate. The yield is 80% if methyl allyl ether and diallyl ether are recycled in the system.

d) New Catalysts

A new method which we have developed, and in which finely divided nickel and thiourea or iron powder, nickel chloride, and thiourea is used as catalyst, seems even more advantageous [2e, 2h]. With these systems the reaction can be carried out at or even below room temperature (−30 °C with Raney nickel/thiourea) and at atmospheric pressure in the absence of tetracarbonylnickel. This new method is useful for the preparation of esters according to equation (b); on the other hand, tetracarbonylnickel is recommended for the synthesis of acids (equation (b) where R′ = H). Tetracarbonylnickel can be conveniently prepared from carbon monoxide, iron powder, nickel chloride, and sulfides in water [2e, 2h, 7]:

$$Fe + NiCl_2 + 4\,CO \longrightarrow Ni(CO)_4 + FeCl_2$$

2. Properties of the 2,5-Dienoic Acids and their Esters

a) Isomerization

The 2,5-dienoic acids and esters obtained according to equation (b) have the *cis* configuration about the α,β double bond. On treatment with cold alkalis the compounds rearrange, first into the less stable, and then into

the more stable dienoic acids or esters [8]. (In the case of straight-chain compounds, the 3,5-isomers are the less stable and the 2,5-isomers the more stable compounds.) This agrees with the principle that the first product in kinetically controlled reactions is the thermodynamically least stable product [8a].

Investigation of the tautomerism of these "five-carbon systems" activated by carboxyl or alkoxycarbonyl groups, enabled us to isolate 3,5- and 2,4-dienoic acid derivatives. Some of these derivatives, *e.g.* sorbic acid (2,4-hexadienoic acid), are important commercial products.

Prolonged treatment of the 2,5-dienoic esters with an excess of ammonia yields tautomeric amides, generally the amides of the 3,5-dienoic acids [9]. The amides of the 2,5-dienoic acids are best prepared by careful reaction of the 2,5-dienoic ester with thionyl chloride and ammonia [9a]. The derivatives of the 3,5- and 2,4-dienoic acids give Diels-Alder adducts with maleic anhydride; with 3,5-dienoic acids such adducts are formed immediately the components are mixed.

2,5-Diene derivatives having a *cis* configuration about the α,β double bond can be converted into the *trans* form by treatment with sulfide radicals [10]. The properties of some *cis-trans*-isomeric methyl dienoates are listed in Table 2.

Table 2 Properties of *cis-trans*-isomeric methyl 2,5-dienoates [10]; for UV and IR absorptions of the 3,5 and 2,4 derivatives see [8, 50].

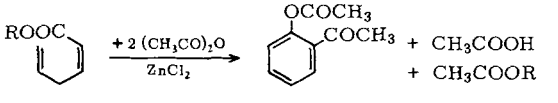
b) Cyclization

cis- or *trans*-Dienoic acids and their esters can be cyclized to form phenols by heating in acidic or alkaline media or preferably in acetic anhydride [11]. Phenols are also formed, generally in very small quantities, during the synthesis according to eq. (b) from allyl halides, acetylene, and carbon monoxide.



When 2-*cis*-5-hexadienoic acid, in the absence of solvent, is brought into contact with zinc or aluminum chloride or with other chlorides used as catalysts in the Friedel-Crafts reaction, a vigorous reaction, which is difficult to control, takes place and moderate quantities of phenol are formed. The reaction proceeds less vigorously in acetic anhydride and almost quantitative yields of phenol (as the acetate) are obtained.

3,5-Hexadienoic acid reacts in a similar manner, whereas 2,4-hexadienoic acid does not react under these conditions; 5-methyl-2-*cis*-5-hexadienoic acid yields *m*-cresol acetate in a remarkably pure state.

ω-Alkylhexadienoic acid derivatives do not react under these conditions to give phenols, whereas ω-carboxy derivatives do so. For example, salicyclic acid (as the acetate) can be obtained on treatment of 2,5- or 3,5-heptadiendioic acid with $ZnCl_2$ in acetic anhydride.

The system sodium acetate/acetic anhydride has been found suitable for the ω-alkyl compounds; it is possible in this way to obtain excellent yields of *o*-cresol by cyclization of 2,5- or 3,5-heptadienoic acid, and of 1,5-dihydroxynaphthalene by cyclization of 2,5,8- or 3,5,7-decatriendioic acid (products as acetates; catalyst: zinc chloride). The reaction of 2,5-hexadienoic esters in acetic anhydride leads to *o*-acetylation of the nucleus [12].

Phenols are formed when 2,5-dienoyl chlorides are allowed to react in the presence of finely divided metals, *e.g.* iron or palladium, in solvents such as benzene [12]. Thus, the reaction of 2,5-hexadienoyl chloride in the presence of palladium in boiling benzene yields phenol and HCl.

3. Substitutive Hydrogenation

Allyl halides with electron-attracting substituents such as $COOCH_3$, CN, or $CONH_2$ on the allyl carbon atoms [*] do not react with carbon dioxide in aqueous alcohol; instead, the halogen atom is replaced by a hydrogen atom from the solvent [2f]. Allyl rearrangement leads mainly to the less stable of the two tautomers. This is illustrated by reaction (f).

$$ClCH_2-CH=CH-CN + Ni + H_2O \longrightarrow CH_2=CH-CH_2-CN + NiOHCl \quad (f)$$

The reaction proceeds rapidly and the yields of $CH_2=CH-CH_2-CN$ are almost quantitative. The equilibrium between the two tautomers is established more quickly if the allyl carbon atoms carry alkyl substitutents.

2-Chloro-4-phenyl-3-butenonitrile gives the compound $C_6H_5-CH=CH-CH_2-CN$ almost quantitatively.

It is immaterial whether the halogen is attached to the C-1 or the C-3 carbon atoms of the allyl group; thus $CH_2=CH-CH(Cl)CN$ and $ClCH_2-CH=CH-CN$ [in eq. (f)] give the same product. This suggests the possibility of the following reaction:

$$RCH=CH-CHO \xrightarrow{HCN} RCH=CH-CHOH-CN \xrightarrow[Ni(CO)_4]{HCl} RCH_2-CH=CH-CN \text{ or } RCH=CH-CH_2-CN$$

4. Dimerization

Allyl halides form linear dimers on reaction with tetracarbonylnickel in alcohols. Allyl halides with electron-attracting substituents, however, do not form dimers in aqueous alcohol since the halogen is replaced by a hydrogen atom. If required, the dimers can be obtained in good yields in benzene, ether, *etc.* Irrespective of the steric nature of the allyl halide, the final product is predominantly *cis,cis* and *cis,trans* or *trans,trans* and *cis,trans*, depending on the nature of the electron-attracting substituents [13]. For example, when heated with tetracarbonylnickel in diethyl ether, 4-chloro-2-butenonitrile yields about 64% of *cis,cis*- and about 30% of *cis,trans*-2,6-octadienodinitrile, while methyl 4-chloro-2-butenoate yields about 38% of dimethyl *trans,trans*- and about 62% of dimethyl *cis,trans*-2,6-octadienoate *(2)*.

$$H_3COCO-CH=CH-CH_2-CH_2-CH=CH-COOCH_3 \quad (2)$$

For recent progress in this field see [13a,29a].

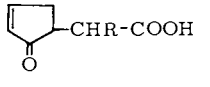
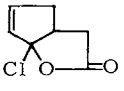
5. Preparation of Derivatives of Cyclic Ketones and of Phenols



While the reaction of allyl halides having electron-attracting substituents with tetracarbonylnickel in benzene, ether, *etc.*, leads mainly to dimerization with very little uptake of carbon monoxide, direct carbonylation can be achieved, though in low yields (≈ 30–40% under CO at a high pressure and at 100 °C), in aliphatic, alicyclic, or aromatic ketones (water content < 1%) and even (though less satisfactorily) in esters. Side reactions include dimerization [14]. Dienoic acids are formed in the reaction with carbon monoxide and acetylene (yields of 40–50%) as well as cyclic compounds. In the reaction of nitriles coupling predominates. Thus from 4-chloro-2-butenonitrile with acetylene and carbon monoxide in ketones or esters, and in the presence of tetracarbonylnickel, 6-cyano-2,5-hexadienoic acid is formed in a yield of only 8–10%, the principal product being 1,6-dicyano-1,5-hexadiene.

Cyclic compounds are obtained as the main products when allyl halides, having no substituents or alkyl substituents on the allyl carbon atoms, are allowed to react with acetylene and carbon monoxide in inert solvents such as ketones, esters, or ethers. On the other hand, the formation of straight-chain acids (such as occurs in aqueous or alcoholic solution) becomes less important [15,16]. The initially formed acyl halides cyclize readily.



In the simplest case (allyl chloride), reaction with carbon monoxide and acetylene in moist acetone (0.5% water) leads to *(3)*, (which can isomerize to *(9)*) and *(4)* as well as *(26a)* and phenol. The acid *(4)* exists mainly in the form of the chlorinated lactone *(4a)*. Products such as *(7)* and *(8)* are also present.

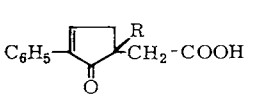
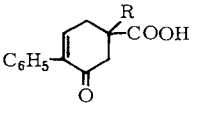
Crotyl chloride in moist acetone yields mainly *(5)* and *(6)*, while methallyl chloride gives mainly *m*-cresol together with the cyclic compounds *(10)–(12)*[16b].

(10)

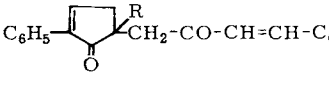


(11)



(12)

In diethyl ether or its homologues, the principal products of the reaction of allyl chloride with carbon monoxide and acetylene [in the presence of $Ni(CO)_4$] are *trans*-1-(2-oxo-3-cyclopentenyl)-3,6-heptadien-2-one *(24a)* [16a] and the acid *(4)*. An interesting by-product is the ketone *(24b)*. Ethyl acetate is intermediate between acetone and diethyl ether in its action.



The stability of the complex formed from the alkyne and the nickel compound increases on going from acetylene to its higher homologues, and the use of anhydrous solvents is no longer necessary *e.g.* in the case of phenylacetylene. (Fewer side reactions take place in solvents containing water). The reaction of phenylacetylene, tetracarbonylnickel, carbon monoxide, and allyl chloride in acetone/water (4:1) yields *e.g.* the compounds *(13)–(16)* [17,21] [*(13)*, m.p. 110–111 °C; *(15)*, m.p. 104–105 °C]. Replacement of allyl chloride by methallyl chloride leads to the products *(13a)*, *(14a)*,

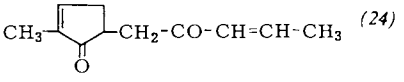
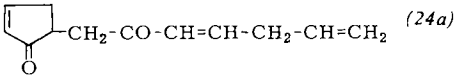
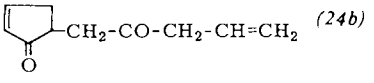
With allyl chloride, the use of propyne instead of phenylacetylene leads to the compounds *(21)–(24)*.



(21)

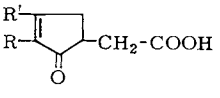


(22)

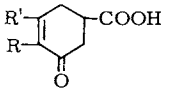


(23)

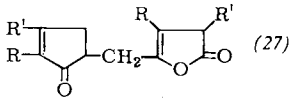
(24)



(24a)

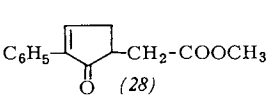


(24b)

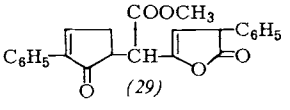


With alkylacetylenes (R,R′ = alkyl or H; RR′ = alkylene), the principal products are *(25)–(27)*.

(25)



(26); *(26a)*, R = R′ = H



(27)

Even allyl derivatives with electron-attracting substituents react in inert solvents such as acetone. Under such conditions, the reaction of methyl 4-bromocrotonate, phenylacetylene, carbon monoxide, and tetracarbonylnickel yields *(28)* and *(29)*.

(28)

(29)

$HOOC-CH=CH-CH_2-CH=CH-COOCH_3$ *(29a)*

$H_2C=CH-CH_2-COOCH_3$ *(29b)*

The stoichiometry of the reactions leading to the compounds *(3)–(29)* is rather complex. Tetracarbonylnickel acts catalytically in the formation of acids or esters or of phenols [eq. (g) and (h)], but stoichiometrically in the other reactions [equations (i), (j), and (k)].

Though equation (h) is formulated as a catalytic process, the nickel consumption at room temperature is closer to that of a stoichiometric reaction. This is due to the formation of a nickel complex with H and Cl, which,

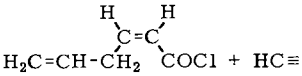
6. Carbonylation of Acyl Halides to form Lactones and Cyclopentenone Derivatives

Acyl halides react with acetylene and carbon monoxide under the same conditions as allyl halides to form lactones *(30)* [17a]. Ketones are used as solvents, esters being less suitable.

[17a] *L. Cassar* and *G. P. Chiusoli*, Tetrahedron Letters *1966*, 2805.

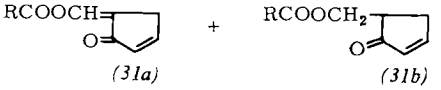


$$RCOCl + HC{\equiv}CH + Ni(CO)_4 + H_2O \longrightarrow$$

$$+ NiOHCl + 3\ CO$$

(30)

The behavior of 2,5-hexadienoyl chloride (and bromide) is rather interesting. The *cis* isomer cyclizes in acetone at 20 °C to give *(3)* [16a, 17a], while the *trans* isomer reacts "normally" to form *(30)* with R = *trans*-$CH_2{=}CH{-}CH_2{-}CH{=}CH$.



$$+ NiOHCl + 2\ CO$$

(3)

2-*cis*-5-Hexadienoyl chloride and its nickel complex are formed directly from allyl chloride, acetylene, and tetracarbonylnickel. This has been shown spectroscopically (in ether) by *Heck* [35], and is further substantiated by the fact that hexadienoic acid is obtained in part on hydrolysis of the reaction mixture. The compound 2-*cis*-5-hexadienoyl chloride cyclizes readily (the main product being *(3)*) and can be isolated only in traces.

When a halide of an organic acid reacts with carbon monoxide, acetylene, and tetracarbonylnickel in the presence of an α,β-unsaturated aldehyde, the products obtained are esters of oxocyclopentenylidenemethanol or of oxocyclopentenylmethanol, depending on whether hydrogen is given off or taken up. For example, acrolein gives *(31a)* and *(31b)* [17a].

$$RCOCl + CH_2{=}CH{-}CHO + HC{\equiv}CH + Ni(CO)_4 \longrightarrow$$

(31a) *(31b)*

7. Reactions with Activated Olefins

We have seen that an addition induced by the allyl group can terminate with the uptake or loss of hydrogen. This is generally observed when the carbon atoms of the allyl group carry an electron-attracting substituent.

The same phenomenon is found in the addition of such allyl compounds to activated olefins such as acrylonitrile or methyl acrylate [eq. (l)].

$$CH_2{=}CH{-}CH_2X + CH_2{=}CHZ + H_2O + Ni \longrightarrow CH_2{=}CH{-}CH_2{-}CH_2{-}CH_2Z + NiOHX \quad (l)$$

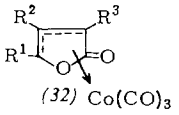
This reaction proceeds in ethanol at about 40 °C [18]. In solvents such as benzene and with tetracarbonylnickel as the catalyst [19], the reaction yields a mixture of compounds formed by uptake or loss of hydrogen, which can be isolated by distillation of the crude products without the addition of water.

For example, methyl 5-hexenoate and methyl 2-*trans*-5-hexadienoate are obtained from allyl bromide and methyl acrylate. (The product obtained from acetylene according to eq. (b) is in the *cis* form.) The fact that the two products are formed in varying ratios indicates that they are formed independently of each other.

Acrylonitrile reacts with allyl halide and tetracarbonylnickel to form a nickel complex [19a], which yields 5-hexenonitrile on treatment with water or acids. Pyrolysis of the complex, on the other hand, gives a mixture containing 2-*trans*-5-hexadienonitrile together with 5-hexenonitrile and other linear isomers of hexadienonitrile.

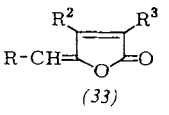
8. Carbonylation of Other Organic Halogen Compounds

a) Reactions of Aromatic Iodine Derivatives



Other aliphatic halides, and even benzyl chloride, do not react under the very mild conditions used for reactions with tetracarbonylnickel. However, at temperatures above 100 °C, iodobenzene and other aromatic iodine derivatives react with tetracarbonylnickel and acetylene to form γ-keto acids or their esters [20], which may be

$$C_6H_5I + HC{\equiv}CH + Ni(CO)_4 + 2\,H_2O \longrightarrow C_6H_5{-}CO{-}CH_2{-}CH_2{-}COOH + NiOHI + 2\,CO$$

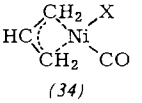


regarded as hydrolysis products of β,γ-unsaturated γ-lactones or as hydrogenation products of α,β-unsaturated γ-keto acids or esters. The α,β-unsaturated γ-keto acids or esters are hydrolysed under the conditions of the reaction, but owing to the presence of electron-attracting substituents, they do not take up CO.

b) Related Reactions with Other Catalysts

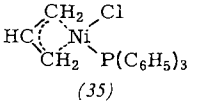
Even saturated halogen compounds react with carbon monoxide when the carbonylcobalt anion is used as the catalyst [22]. *Heck* has synthesized unsaturated lactone complexes such as *(32)* in systems consisting of acylcarbonylcobalt complexes and alkynes in an inert solvent.

(32) $Co(CO)_3$



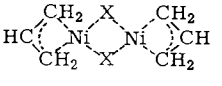
(33)

If R^1 contains an activated CH_2 group, addition of a base leads to the loss of a proton, followed by catalytic formation of a diene *(33)*. We have also carried out a stoichiometric synthesis of γ-keto acids with the carbonylcobalt anion in solvent/water mixtures, *e. g.* acetone/water [21]. Allyl halides react with carbon monoxide in the presence of palladium chloride [23–28] or a platinum complex [29] as a catalyst. A review of allylnickel complexes has been published by *Wilke* [29a]; for other reviews see [29b–29e].



9. Investigations on the Course of the Reaction

a) Nature and Formation of the Catalytically Active Intermediate



We at first formulated the reaction (for $CH_2{=}CH{-}CH_2X$) as proceeding *via* a complex $[C_3H_5{-}CO{-}Ni(CO)_3]^{\oplus}X^{\ominus}$ [2a, 30]. After the isolation of allyl complexes of other transition metals [54, 55], we suggested the structure *(34)* for the complex (X = halogen), by analogy with π-allylcobalt and π-allylcarbonylmanganesecomplexes. The isolation of the complex *(35)* led *Heck*, *Chien*, and

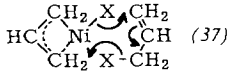
Breslow [31] to the same theoretical conclusions. *Fischer* and *Bürger*, who had isolated dimers *(36)* [32] (X = halogen), considered such compounds to act as catalysts [33].

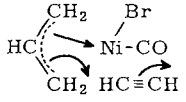


The existence of intermediates such as those with the structures *(34)* and *(35)* would explain the formation of methyl 3-butenoate by carbonylation of allyl chloride in methanol [34] and of 3-butenoyl chloride in ether, as well as the formation of 2,5-hexadienoic acid derivatives in the presence of acetylene [35]. The intermediate *(34)* could be formed from alcohols, allyl ethers, or allyl esters and hydrogen chloride as follows [2g]:

(34)

The catalytic systems iron/nickel halide/thiourea and nickel powder/thiourea may give a similar complex in the presence of the allyl halide. Thiourea favors the reduction of the nickel halide and permits the formation of a π-allyl complex.

It was not known at first whether the allyl group reacts under the usual conditions, in the π-form or in the σ-form. The results of our investigations with ^{14}C-labeled allyl bromide ($1-^{14}C]CH_2=CH-CH_2Br$) show that the allyl group always undergoes an allyl rearrangement in the reaction with tetracarbonylnickel. However, this rearrangement is not due to fast equilibration of the σ-forms before the reaction (for example, in the reaction of allyl acetate with acetylene and carbon monoxide in methanol, allyl acetate with only 10% of [3-^{14}C] could be recovered). It may therefore be concluded that the reaction proceeds *via* a π-allyl complex. Allyl halides can be isomerized by monohalogenonickel complexes *via* an independent reaction as in *(37)* [3a]. The isolation of nickel acetate and methyl hexadienoate in the $Ni(CO)_4$-catalysed reaction of allyl acetate with acetylene and carbon monoxide shows that the nickel cleaves the $-CH_2-O-$ bond, as was also found by *Bauld* in the dimerization of allyl esters with tetracarbonylnickel [36].



(37)

b) Reaction of Allyl Compounds with Acetylene and Carbon Monoxide and with Other Compounds

Acetylene is polymerized by (^{14}C-labeled) π-allylnickel bromide dissolved in benzene; we were unable to isolate any product formed from one mole of allyl bromide and one mole of acetylene. Although the polymer contained labeled allyl groups, it was not possible to decide whether the first step involved the addition of the allyl group to acetylene or the dimerization of two allyl groups to give 1,5-hexadiene, which then reacted with acetylene. (Labeled allyl groups have also been detected in the copolymer of acetylene with 1,5-hexadiene [19]). If carbon monoxide is present, treatment with water yields 2,5-hexadienoic acid.

This behavior suggests that CO and acetylene first add to the π-allylnickel bromide; the coordinately bound components then react as indicated in *(34a)*.

(34a)

The addition of halogens and CO to olefinic ligands in the presence of palladium chloride [23] is thought to proceed in the same manner [37]. Instead of CO and C_2H_2, activated olefins, such as methyl acrylate and acrylonitrile, can react with π-allylnickel bromide [19]. The selective formation of the dimerization products may also be explained by the reaction of the π-allylnickel bromide with one molecule of allyl halide [13].

c) Formation of Acids and Esters

The acyl nickel compound, which is formed by the addition of the allyl group to the carbonyl group attached to nickel (with or without the introduction of acetylene), is cleaved by water or alcohols into hydrogen halide and acid or ester.

The reaction may proceed in two stages, *i.e.* addition of halogen to form the acyl halide, followed by hydrolysis or alcoholysis. We have demonstrated the formation of the acyl chloride in benzene by isolating this product [2a].

Heck detected 3-butenoyl chloride and 2,5-hexadienoyl chloride by IR spectrometry of π-allylnickel halide in ether solution in the presence of carbon monoxide and of carbon monoxide and acetylene [35]. However, it was not known whether acyl halides are formed also as the initial products in water or alcohol. We have investigated the *Reppe* synthesis [5a] of acrylic compounds from alkynes and carbon monoxide, in which an acyl compound of this type is split off. Such syntheses proceed smoothly with acetic acid [38] instead of hydrogen chloride; it was therefore to be expected that an acid anhydride would be formed, and would be detectable, even in alcoholic solution, by virtue of its greater stability.

When a mixture of 1-octyne, tetracarbonylnickel, and acetic acid was heated in methanol for a few minutes at 60 °C, the mixed anhydride of acetic and α-hexylacrylic acid could be detected by IR spectroscopy and by chemical methods (as acetanilide and α-hexylacrylanilide) [39].

This suggests that acyl halides also occur as intermediates when the reaction is carried out with hydrogen halide in alcohol.

It seems that halide ions compete with alcohol to cleave the acyl nickel halide.

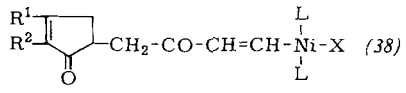
d) Cyclization to Form Derivatives of Ketones and Phenols

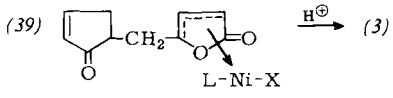
The cleavage of the 2,5-dienoic acids from nickel complexes such as *(34a)* can be prevented by the use of inert solvents such as ketones, esters, and ethers (see Section 5). In solvents containing hydroxyl groups, the liberation of the 2,5-dienoic acids is also suppressed by the use of higher alkynes which form much more stable nickel complexes.



Ketones have a stronger stabilizing action than the other solvents. This action is particularly evident in the formation of the unsaturated lactone in the reaction of allyl compounds, or acyl halides, with acetylene, and tetracarbonylnickel. The tendency of the ketones or aldehydes to stabilize acyl groups by attack on the oxygen has been observed in the formation of enol esters from acyl halides and ketones [20] and of complexes from acylcarbonylcobalt complexes and aldehydes [53]. The stabilizing action on the acyl group is even more evident in the case of compounds having electron-attracting substituents on the allyl group; these compounds form dienoic acids more readily in ketonic than in "inert" solvents such as ether, ethyl acetate, or acetonitrile. Exceptions are observed with substituents which (like the CN group) tend to interact with the metal and favor the formation of products such as 1,6-dicyano-1,5-hexadiene and small quantities of dienoic acids.

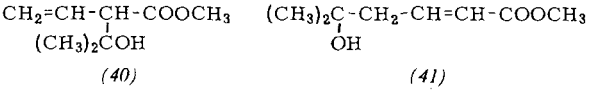
After its formation on the nickel complex, the hexadienoyl group forms a cyclic, ketonic ligand containing five or six carbon atoms. A cyclohexenone or a phenol can be split off from the ligand containing six carbon atoms. Ring closure to form alicyclic ketones has also been observed when acyl cobalt complexes, such as 5-hexenoylcarbonylcobalt, are heated [40]. The tendency toward phenol formation with loss of hydrogen is strongest in the methallyl halides. Allyl halides and their straight chain homologues give little phenol; the reaction leads mainly to the formation of a cyclopentenone ring, which adds on further carbon monoxide. Hydrolysis of the acyl nickel complex yields mainly the acid *(4)* and its homologues.

The cyclization of 2,5-hexadienoyl chloride to form phenol can take place in the absence of CO, but transition metals such as palladium must be present. The intermediate is probably similar to that formed in the Rosenmund reaction [12,41]. The reaction proceeds catalytically and in almost quantitative yield. When the cyclization is carried out with tetracarbonylnickel at room temperature, the products contain very little phenol and a large quantity of (4).



e) Other Reactions with Acetylene and Carbon Monoxide

The initially formed cyclopentenone and cyclohexenone complexes tend to react further with acetylene and carbon monoxide, probably to form complexes such as *(38)* and *(39)* (L = *e.g.* CO). *(39)* is similar to the complex *(34)*. The products isolated also require the formation of *(38)* and *(39)*.



(38)

In the reaction of allyl chloride with carbon monoxide and phenylacetylene, we isolated the diketone *(15)* as the main product. Propyne reacts to give the analogous product *(24)*. When the reaction was carried out in ether, we also obtained *(24a)*, which is presumably formed by the reaction of allyl halide with *(38)*. In the reaction with acetylene, in slightly moist (< 0.5% water) ketones, a second carbonyl group can be readily introduced to form unsaturated β,γ-lactone derivatives such as *(3)* [42]. *(3)* is less stable than the α,β tautomer *(9)*.

The π-allyl intermediate *(39)* was assumed to react with ketones in a Reformatsky-type reaction. To check the validity of this supposition, methyl 4-bromocrotonate and acetone were made to react in the presence of tetracarbonylnickel (instead of zinc as used by *Reformatsky*) [16]. The esters *(40)* and *(41)* were obtained in the ratio 88:12.

(40) *(41)*

Unsaturated γ-lactone structures and cyclic structures with five or six carbon atoms are generally obtained in reactions with acetylene or other alkynes and carbon monoxide. (See [43–49] for reactions with iron, cobalt, and nickel complexes).

f) Stability of the Acyl Carbonyls

We have shown that in the reaction of allyl halides with tetracarbonylnickel and acetylene, the allyl group adds on to acetylene, while the other groups, such as 2-oxo-3-cyclopentenylmethyl or -phenyl (in the reactions of

the aromatic iodine derivatives) react with carbon monoxide. This is due to the instability of the 1-oxo-3-butenyl group formed from the allyl group. For example, the reaction of 3-butenoyl chloride with tetracarbonylnickel in tetrahydrofuran yields 1,5-hexadiene, with liberation of carbon monoxide.

$$2\ CH_2{=}CH{-}CH_2{-}COCl + Ni(CO_4) \longrightarrow CH_2{=}CH{-}CH_2{-}CH_2{-}CH{=}CH_2 + NiCl_2 + 6\ CO$$

Most acyl carbonyls are too stable to split off carbon monoxide; they add on acetylene and carbon monoxide to form lactones *(30)*.

We are grateful to Prof. A. Quilico for the interest which he has shown in our work.

Chemical Effects of Nuclear Transformations in Solids

BY HORST MÜLLER [*]

Nuclear reactions and radioactive transformations offer the possibility of investigating the chemical reactions of "bare" nuclei. The interest in such chemical processes following nuclear transformations has already led to two international symposia [1, 2]. In solids, the chemical reactions of recoil nuclei having energies lower than 1 keV proceed not via molten states, but via regions of little disorder.

I. Introduction

Nuclides produced in nuclear reactions or resulting from radioactive decay can escape from their parent molecule and enter into chemical reactions by virtue of their kinetic energy and charge. The study of such reactions, *i.e.* of the behavior of an atom from the time of the nuclear transformation to the instant at which it finally forms a new chemical bond, is possible if the new nucleus is radioactive and therefore can be distinguished from the large numbers of atoms which remain unchanged.

In 1934, *Szilard* and *Chalmers* [3] found that the ^{128}I formed by the nuclear reaction $^{127}I(n,\gamma)^{128}I$ in the neutron activation of ethyl iodide can be separated from the far greater amount of unchanged organically bound iodine by extraction into aqueous media. A similar "Szilard-Chalmers process" was frequently used to obtain radioactive nuclides of high specific activity – ideally in the carrier-free state. The separation of active from inactive isotopes is possible only with elements that occur in at least two oxidation states (*e.g.* BrO_3^-/Br^-) or types of bonding (*e.g.* covalently bound iodine/I^-); moreover, there must be no exchange between these two forms.

The chemical reactions following isomeric transitions, *e.g.* $^{80m}Br \rightarrow {}^{80}Br$, are very similar to the Szilard-Chalmers process. These subsequent reactions offer the only method known at present for the separation of nuclear isomers.

The greatest success has been achieved so far in the study of gases, especially of tritium atoms from the nuclear processes $^3He(n,p)^3T$ and $^6Li(n,\alpha)^3T$ and ^{11}C atoms from $^{12}C(\gamma,n)^{11}C$ and other nuclear reactions [4–8]. Investigations on liquids, mainly organic halogen compounds, have been less successful [9]. Least of all is known about the chemical effects of nuclear transformations [**] in solids [10–14].

II. Nuclear Recoil [15]

The energy of the compound nucleus formed by the capture of a thermal neutron is 6 to 8 MeV higher than that of the nucleus in the ground state. Most of the excess energy is emitted as γ radiation. A γ-quantum of energy E_γ has a momentum

$$p = E_\gamma/c \qquad (1)$$

(c = velocity of light).

Owing to the conservation of momentum, the product nucleus receives an equal and opposite momentum. The kinetic (recoil) energy E_R of a nucleus having mass M and velocity v is found to be

$$E_R = Mv^2/2 = p^2/2\,M = E_\gamma^2/2Mc^2 \qquad (2)$$

The kinetic energy of (n,γ)–recoil nuclei is therefore between 100 and 1000 eV.

However, most compound nuclei emit not one, but on average three γ quanta, and proceed by various routes to the ground state *via* intermediate states; these intermediate states accumulate close to the ground state. The total momentum and hence also the recoil energy become smaller as a result of the splitting, and for two γ quanta having energies $E_{\gamma 1}$ and $E_{\gamma 2}$, for example,

$$E_R = (Mc^2/2)\,(E_{\gamma 1}^2 + E_{\gamma 2}^2 + 2\,E_{\gamma 1}\,E_{\gamma 2}\cos\Theta) \qquad (3)$$

(Θ is the angle enclosed by γ_1 and γ_2).

If the various γ cascades and their frequencies are known, the distribution of the recoil energies can be calculated by stochastic methods, under the (not strictly valid) assumption that the distribution of the γ quanta is isotropic. The most accurate calculation so far has shown that for $^{35}Cl(n,\gamma)^{36}Cl$, the average recoil energy is about 75 % of the maximum possible value found from equation (2), and that low recoil energies are very rare [16]. The various γ quanta are not emitted simultaneously, since the intermediate states have lifetimes of between 10^{-16} and 10^{-12} sec or longer. Consequently, a recoil atom may already have lost the kinetic energy resulting from the first γ emission before it is set in motion again by a second emission. From equation (1), the velocity v after a γ emission is

$$v = E_\gamma/Mc \qquad (4)$$

After a 2 MeV γ emission, a recoil atom of mass number 100 would travel 12.5 Å in 2×10^{-13} sec. This distance is greater than the mean free path in a solid. The loss of energy of recoil atoms as a result of collisions has been detected in nuclear resonance experiments [17]. Owing to the non-uniform distribution of the intermediate states, most of the kinetic energy is derived from the first step of the γ cascade. For nuclear isomers decaying to the ground state by γ emission, the recoil calculated from equation (2) is small since the γ energy of such transitions is only of the order of 100 keV; for a nucleus of mass number 100, E_R = 0.054 eV.

Nuclear isomers can decay, not only by γ emission, but also by internal conversion. Instead of a γ quantum, a shell electron is emitted with an energy E_β equal to the difference of the energy of the isomeric state and the binding energy of the electron emitted from the K, L, ... shell. The ratio of the number of electrons emitted to the number of γ quanta emitted is known as the conversion factor α. The recoil energy of the nucleus is

$$E_R = \frac{m_0 + m_e}{2\,M}\,E_\beta \qquad (5)$$

where m_0 and m_e are the rest mass and the relativistic mass of the electron, respectively.

For a mass number of 100 and E_β = 80 keV (binding energy of the K electron about 20 keV), it is found that E_R = 0.47 eV.

In β^- decay, the recoil energy is given by vectorial addition of the contributions of the emitted electron [eq. (5)] and of the neutrino. The resulting recoil energy has a distribution between 0 and E_R(max); the maximum value is found by insertion of the maximum β energy in equation (5); for medium-heavy atoms and E_β = 1 MeV values around or below 10 eV are obtained. The average recoil energy is about half of the maximum.

For nuclear reactions involving particles with energies greater than those of thermal neutrons, the recoil energies are always greater than a few tens of keV; recoil energies of between 50 and 100 MeV are obtained for fragments produced by nuclear fission. A particularly interesting class of nuclear reactions consists of those involving fast neutrons, n_f *i.e.* (n_f, 2n) and (n_f, γ), as well as the (γ,n) reaction, which, like the (n,γ) reaction, give isotopic nuclei and permit the study of the influence of the recoil energy.

The recoil energy is distributed between the translational energy and the internal energy of the molecule; in diatomic molecules, the increase in internal energy corresponds to the fraction $m/(M+m)$ of the recoil energy (M = mass of the recoil atom, m = mass of the second atom [18]; in polyatomic molecules, the mass of the rest of the molecule may be used, to a rough approximation, for m). The recoil atom can be liberated only if the vibrational component of the internal energy (the rotational component in polyatomic molecules is small) is greater than the energy (about 2–3 eV) of the bond between the recoil atom and the rest of the molecule [19, 20]. These observations are strictly valid for gases; corrections are to be expected in solids, owing to the hindrance of translation and the fact that the rest of the molecule is bonded to other atoms in the lattice, so that the error involved in an estimate based on the total recoil energy should be small.

It follows that only about 1 % of the recoil atoms keep their bonds intact in the (n,γ) process. In isomeric transitions without internal conversion, on the other hand, practically all the molecules concerned "survive". In β^- decays, the maximum recoil energy is often of the same order of magnitude as, or smaller than, the bond energy, so that a considerable fraction of the bonds may remain intact.

III. Influence of Charge[15]

In β^- decay, the nuclear charge increases by +1, so that the product nucleus is in the form of a singly charged positive ion. Fast rearrangement of the electron cloud sometimes also leads to excitation and to a loss of electrons, particularly from the outer shells, which is known as "shake-off". In the case of heavy atoms, ionization also occurs as a result of collision of the β^- particle with electrons in the inner shells. As a result, 10–20 % of the product nuclides have a charge of +2, higher charges rapidly becoming less common. In β^+ decay, the primary products are singly negatively charged ions which can give neutral (sometimes excited) atoms and positive ions by electron loss.

A molecule in which one of the atoms undergoes β decay may survive this change if the recoil is too weak to break the bond and if the new chemical compound resulting from the change in the atomic number of the atom in question is stable. The reaction sequence

$$-{}^{14}CH_3 \xrightarrow{\beta^-} -{}^{14}NH_3^+ \xrightarrow{-H^+} -{}^{14}NH_2$$

for labeled ethane, toluene, or ethylbenzene yields 47 % of methylamine, 98 % of aniline, or 82 % of benzylamine respectively[21,22]. Similar reactions take place in solids:

Reaction	Yield (%)	Ref.
$Cs^{51}MnO_4 \xrightarrow{\beta^+} \square^+Cs^{51}CrO_4$[*]	99.6	[23]
$^{99}Mo(C_6H_6)_2 \xrightarrow{\beta^-} {}^{99m}Tc(C_6H_6)_2^+$	80—90	[24]
$M_2^{125}SnCl_6 \xrightarrow{\beta^-} M^{125}SbCl_6 + M^+ (M = K, NH_4)$	76—78	[25]
$^{144}Ce(acac)_3 \xrightarrow{\beta^-} {}^{144}Pr(acac)_3^+ + e^-?$ $\longrightarrow {}^{144}Pr(acac)_3$	100	[26]
$K^{131}IO_4 \xrightarrow{\beta^-} {}^{131m}XeO_4\,(?) + K^+$	40	[27]
$K^{131}IO_3 \xrightarrow{\beta^-} {}^{131m}XeO_3\,(?) + K^+$	>40	[27]
$^{105}Ru(C_5H_5)_2 \xrightarrow{\beta^-} {}^{105}Rh(C_5H_5)_2^+ + e^-?$ $\longrightarrow {}^{105}Rh(C_5H_5)_2$	*ca.* 10	[28]
$^{239}U(C_5H_5)_3X \xrightarrow{\beta^-} {}^{239}Np(C_5H_5)_3X^+ + e^-?$ $\longrightarrow {}^{239}Np(C_5H_5)_3X$ (X = F, Cl)	$\geqslant$ 90	[29]
$C_5H_5{}^{99}Mo(CO)_3 \xrightarrow{\beta^-} C_5H_5{}^{99m}Tc(CO)_3^+ + e^-?$ $\longrightarrow C_5H_5{}^{99m}Tc(CO)_3$		[30]

[*] $\square^+$ = Cation vacancy.

The high yields obtained in most cases indicate retention of the bond. The β^--active sandwich compounds were prepared directly by neutron activation of the inactive substances. The methods indicated were the first known syntheses of the benzenetechnetium(I) cation and of rhodocene.

Similar processes have been suggested for the preparation of rare gas compounds that are not yet known[31,32]:

$$KTF_2 \xrightarrow{\beta^-} K^+ + {}^3HeF_2$$

$$^{22}NaF \xrightarrow{\beta^+} {}^{22}NeF^- \xrightarrow{-e^-?} {}^{22}NeF$$

$$^{131}IX_n \xrightarrow{\beta^-} {}^{131m}XeX_n^+ \xrightarrow{+e^-?} {}^{131m}XeX_n$$

X = Halogen

However, anomalous charge states cannot be produced in association with nuclear transformations. For example the reaction

$$^{51}MnCO_3 \xrightarrow{\beta^+} {}^{51}Cr^+ + CO_3^{2-}$$

does not take place; instead, 70 % of Cr^{3+} and 30 % of CrO_4^{2-} are obtained[23].

The vacancy formed, generally in the K or L shell, as a result of the internal transition of nuclear isomers may be filled by electrons from higher shells with emission of X-ray quanta. However, the excess energy may also be used to emit another shell electron. This process may be repeated several times, progressing in an outward direction, and finally yielding an atom with a multiple positive charge. In the mass spectrometer, a maximum of the charge distribution is found between +5 and +10. This process is known as the Auger process (or vacancy cascade), and is completed in 10^{-15} sec. It can also be studied for non-radioactive atoms if vacancies in inner electron shells are produced by X-ray or electron radiation[33]. A molecule containing such an Auger atom decomposes as a result of the loss of bonding electrons and Coulombic repulsion following distribution of the positive charge to other atoms of the molecule. The fragments of the molecule can easily have kinetic energies of between 10 and 100 eV, *i.e.* much greater than the recoil energy resulting from the emission of shell electrons as given by eq. (5).

In isomeric transitions without internal conversion the atom gains no charge, and according to eq. (2), there is only a very slight recoil, so that the molecules remain intact; in this case the isomers cannot be separated. Well known examples are $^{69m}Zn(C_2H_5)_2$, $^{127m}Te(C_2H_5)_2$, and $^{129m}Te(C_2H_5)_2$. With conversion coefficients of 0.06, ~ 100, and ~ 100, 95 %, 0 %, and 0 %, respectively, of the starting substance remains unchanged[34,35].

The positive charge of atoms after internal conversion is not reflected in the charge state that is finally found, despite the unambiguous mass spectrometric results. Thus on decay in an

electric field, the final products are mainly found at the anode[36,37]. ^{80}Br formed from ^{80m}Br does not react as an electrophile[38].

Low-energy intermediates of the (n,γ) process decay, not only by γ emission, but also by internal conversion followed by the Auger effect, so that the recoil atoms also carry considerable positive charges. Since γ transitions and internal conversion proceed differently for each nuclide, even nuclei having the same atomic number behave differently, so that an isotope effect may be observed.

The following proportions of positively charged recoil atoms were found on neutron irradiation of gaseous ethyl bromide and ethyl iodide: 12 % of ^{80m}Br, 18 % of ^{80}Br, and 25 % of ^{82}Br, and 50 % of ^{128}I[39]. About 50 % of the recoil atoms ejected from the surfaces of indium, gold and manganese or from compounds of these metals are positively charged[40,41]. Of the products formed in the reaction of recoil ^{128}I atoms with methane, 25 % are formed *via* I^+ (spectroscopic state: $^1D_2$)[42]. Since the lifetimes of the lower states of the compound nucleus are greater (about 10^{-10} sec) than those of the higher, the charge arises only after the recoil atom has already acquired most of its kinetic energy and is no longer associated with its neighbors. If the recoil and the charging took place simultaneously, the recoil atoms ejected from metals would necessarily be neutral.

Thus while a considerable proportion of the (n,γ) recoil atoms are positively charged, a large part of the positively charged atoms resulting from internal conversion possess kinetic energy due to Coulombic repulsion. These facts explain why such nuclides generally exhibit a qualitatively similar behavior.

In solids, however, the (n,γ) process accompanied by internal conversion does not generally lead to a transition into a higher valence state, as was found for compounds of Sb^{3+}, As^{3+}, Ce^{3+}, Cr^{3+}, and Tl^{1+}[43]. An electron exchange probably takes place. Similarly the high initial positive charges of the high-energy fragments formed by nuclear fission have only a small influence on their ultimate chemical fate.

Of the iodine isotopes formed by the nuclear fission of uranium in neutron-irradiated uranyl iodate, 14 % of the ^{131}I and 18 % of the ^{133}I are found in the reduced form (I^-, I_2, IO^-), and the remainder as iodate; on the other hand, ^{135}I is reduced to the extent of 67 %. Consideration of the properties of the iodine atom and its environment offers a ready explanation of these observations. Since iodine has a relatively high ionization potential, it should be found mainly in the reduced form, as is the case with the primary fission product ^{135}I. ^{131}I and ^{133}I are formed as secondary products in a β^- decay chain involving Sn, Sb, and Te as precursors. These elements, particularly Sn, have low ionization energies, and in the bulk of the uranyl iodate they will therefore be preferentially converted into an oxidized form, which may be retained in the subsequent β^- decays[44].

The general conclusion is that the chemical fate of the recoil atom is determined only after it has lost most of its kinetic and electronic energy. The chemical consequences of (n,γ), (γ,n), and (n_f,2n) nuclear processes are therefore generally very similar. Even the unexpected results concerning the charge state in the internally converted isomeric transition and in the (n,γ) process accompanied by internal conversion can be explained in this way. The chemistry of the system is more important than the primary effects.

IV. Fundamental Observations

The proportion of radioactive atoms present in a new chemical form after irradiation of a suitable compound with thermal neutrons and subsequent dissolution is the *yield*. The proportion of the radioactive atoms that remain chemically unchanged in the starting material is the *retention*. The definition of the retention should be rigidly adhered to, so that even species that are closely related to the starting compound should be included in the yield. If no secondary radiolytic changes take place, the yield fraction is free from carrier, and only the retention fraction is mixed with the mass of the unactivated starting substance. Some examples are shown in Table 1.

Since it is not known *a priori* what compounds are present, no assumptions should be made in the chemical separation of the irradiated substances, *i.e.* no carriers should be added. Methods such as chromatography, gas chromatography, ion exchange, and ionophoresis have proved suitable, whereas precipitation, solvent extraction, and distillation are generally inadequate.

Fig. 1 represents schematically the Szilard-Chalmers process for bromates. A number of recoil atoms return to the initial potential and remain as bromates, while others are trapped in higher potential troughs. Dissolution of the solid leads to the liberation of such atoms, which then undergo further reaction, possibly with the solvent, to give the form having the lowest energy, *i.e.* bromide. If the irradiated material is heated before

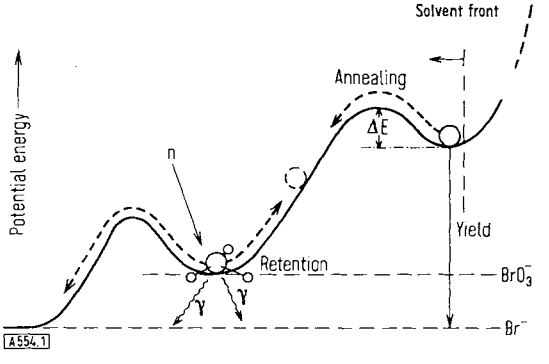

Fig. 1. Simplified scheme of the Szilard-Chalmers process in bromates.

being dissolved, atoms from the higher potential troughs return to the potential of the bromate. Thus this "annealing" decreases yields and increases retentions. This phenomenon refutes the otherwise tempting assumption that the recoil atoms that are not in the

retention form are immediately converted into the yield form. There are also systems in which this is impossible on chemical grounds; thus hexahalogenorhenates(IV) K_2ReX_6 give ReO_4^- as the yield fraction, the oxygen clearly coming from the solvent. If the yield form is particularly stable, it may also be formed directly, as indicated by the arrow over the left-hand potential barrier; this fraction, *e.g.* the $^{13}N^{14}N$ from the nuclear reaction $^{14}N(n_f,2n)^{13}N$ of NaN_3, would not be susceptible to annealing [85].

In systems that give several yield forms, it is generally not clear which of these are formed in the solid state and which are formed only on dissolution. Apart from the Mössbauer effect (see Section XII), however, there is no method that permits the investigation of the state of the atoms in the solid phase itself.

Important problems are:

1. How is the kinetic and electronic energy of the recoil atom lost? How far does the recoil atom travel, what reactions does it undergo, and what changes does it bring about in its environment?

2. What is the chemical, electronic, spatial, and energetic structure of the disturbed regions containing the recoil atom after it has come to rest?

3. What types of reactions take place during the annealing?

4. When end products are not formed in the crystal itself, how are they formed on dissolution out of the defect centers?

5. How are questions 1. to 4. affected by the compound under investigation?

V. The Retention

The retention consists of the primary retention and the secondary or reaction retention. The primary retention includes molecules that have not been disrupted in spite of excitation by the nuclear process. Reaction retention results from the reaction of temporarily free recoil atoms with their surroundings.

In the Szilard-Chalmers process in gases, *e.g.* organic halides, the primary retention is generally less than 1 %. The addition of a large excess of free-radical scavengers (*e.g.* NO + I_2, Br_2) inhibits recombination of recoil atoms to form the starting substance [86]. In

solids, recombination of the fragments of a disrupted molecule may be facilitated by a cage effect. Thus disruption is no longer decided solely by the strength of a chemical bond, but also depends on the energy required to move an atom from one lattice site to another (roughly 25 eV, cf. Section VII.3). Nevertheless, it may be assumed that even in solids, the primary retention (including the cage effect) is very small, since systems are known to exist in which the total retention is very small (cf. Table 2).

Table 2. Systems with low retention [45–47, 50, 87].

Irradiated substance	Retention (%)
$LiMnO_4 \cdot 3H_2O$	3
KIO_4	4
$NaClO_3$	1.5–5
$KClO_3$	4
$LiClO_3$, $NaClO_4$, $KClO_4$	0

To determine the primary retention in K_2CrO_4, mixed crystals of this substance with K_2BeF_4 were studied [88]. The retention decreases from about 70 % for pure K_2CrO_4 to 25 % (which is still a very high value) at high dilutions. Tris(acetylacetonato)cobalt(III) has a retention of 19.8 %, which falls to 2.8 % on dilution with tris(acetylacetonato)aluminum(III) [89]. This value may correspond to the primary retention, but it is not clear why the cobalt recoil atoms do not also react with fragments from the similar aluminum compound.

There is seldom a clear relationship between the retention and the properties of the substance under investigation. Thus no simple relationship could be recognized on variation of the cation and the content of water of crystallization in permanganates [87], arsenates [90], and chromates (cf. Table 3), or of the central atom in phthalocyanines and porphins [78, 80]. The same is true of the influence of the anion in cobaltammine complexes [59]. Dipseudocumene-, di-

Table 3. Retention in chromates [73, 91, 92].

Irradiated substance	Retention (%)	Irradiated substance	Retention (%)
Li_2CrO_4	66.0	$K_2Cr_2O_7$ mcl.	82.4
Na_2CrO_4	73.6	$K_2Cr_2O_7$ tricl.	89.5
$Na_2CrO_4 \cdot 2H_2O$	72.7	$(NH_4)_2CrO_4$	17.5
$Na_2CrO_4 \cdot 4H_2O$	87.8	$^{24}MgCrO_4$	56.7
K_2CrO_4	60.8	$^{26}MgCrO_4$	52.7
		$ZnCrO_4$	34.6

mesitylene-, dibenzene-, benzenetricarbonyl-, and hexacarbonyl-chromium showed no relationship between retention and the number of ligands, heat of formation, aggregation state, bond strength, and mass of the ligands [81]. The decrease in retention in ammonium salts and salts containing water of crystallization is explained by the reducing properties of H_2O and NH_4 [93]. No decrease in retention is observed in acid salts and ammine complexes. In complexes such as cobalt phthalocyanine, where the screening of the cobalt atom by the organic ligands is not the same on all sides, the Co retention is lower than in *e.g.* the fully shielded tris(acetylacetonato)cobalt(III) [57].

For some oxo anions, there is a relationship between the retention and the oxidation potential (cf. Fig. 2) [72]. This comparison is open to the objection that the processes considered take place in the solid whereas redox potentials are measured in solution. The relationship is not valid for phosphates and solid solutions such as K_2CrO_4/K_2SO_4, $KMnO_4/KClO_4$, and KH_2PO_4/KH_2AsO_4.

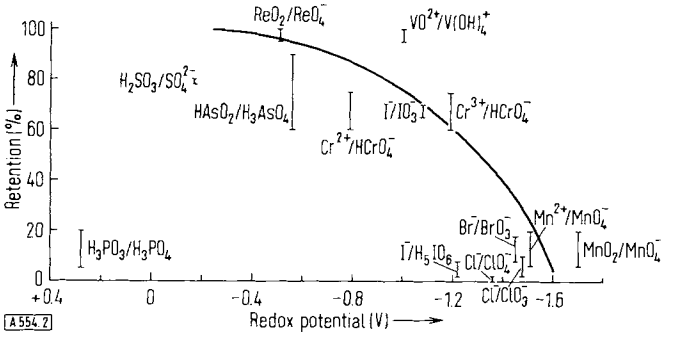

Fig. 2. Relationship between retention and redox potential.

In complicated organic compounds containing P, S, Co, or Se, the retention is usually extremely small. Thus ^{60}Co-labeled vitamin B_{12} [94], ^{32}P-labeled DNA and ATP [95, 96], and ^{35}S-labeled cysteine [97] cannot be prepared by direct activation. High retention values [98–103] are probably due to radioactive impurities.

Annealing can take place even below room temperature, and also can be induced by ionizing radiation. In order to prevent annealing and so to avoid changes in the retention, it is necessary not only to carry out the activation at the lowest possible temperature (−196 °C) and with the smallest possible dose, but also to carry out the dissolution at a low temperature. Temperatures down to −95 °C have been attained with organic solvents, and down to −55 °C with a eutectic $LiCl/H_2O$ mixture. The retention for $KMnO_4$ then falls from 20 % to 5 %, and that for $Na_2CrO_4 \cdot H_2O$ from 89 % to 39 % [104].

These experiments show that it is not possible to speak of an intrinsic retention value, since it may be assumed that substances irradiated and dissolved slightly above 0 °K would have extremely low retentions.

VI. Older Models of Recoil Chemistry

1. The Billiard-Ball Model

According to *Libby*[105], retention is due to displacement of an unactivated atom by an activated atom of the same element. This mechanism proceeds even when the collision is not central, provided that the residual energy is not sufficient to disrupt the newly formed molecule. The maximum energy ΔE that can be transferred in a central collision is

$$\Delta E = 4\, E_R\, M_1 M_2/(M_1 + M_2)^2 \qquad (6)$$

(M_1, M_2 = masses of the colliding species).

On average, half of this energy is transferred on collision. The recoil atom also loses considerable energy in collisions with atoms of different masses; thus for a mass ratio $M_1/M_2 = 0.5$, $\Delta E/E_R = 0.89$, whereas for $M_1 = M_2$, $\Delta E/E_R = 1.00$.

There are many observations that cannot be explained by the billiard-ball model. For example, the retention for some compounds is very low; higher retentions in other compounds appear to be due to annealing. It is also not clear how recoil atoms in complexes can reach other central atoms without disturbing the ligands. Secondly, a billiard-ball collision can occur only if the range of the recoil atom is at least equal to the distance to the nearest atoms of the same type, and appreciable retention values would be possible only if the range were many times this distance, since the nearest neighbors occupy only a fraction of the space angle 4π. However, the range of (n,γ)-recoil atoms is only of the order of 10 Å (Section VII, 7 and 8). The billiard-ball model is also contradicted by the results of experiments with mixed crystals K_2CrO_4/K_2SO_4[72,73,88], $KMnO_4/KClO_4$[106], and KH_2PO_4/KH_2AsO_4[107](Szilard-Chalmers component named first). In all these cases, the retention should be lower than in the pure compound since the recoil atom still retains some energy, even on central collision; however, the retention increases.

2. The Ligand-Loss Model

The ligand-loss model, which is also due to *Libby*[108], is based on the hypothesis that central atoms of complex ions that undergo an (n,γ) process lose some of their ligands. Though the model has often been used, the mechanism of this ligand loss has not been discussed.

According to *Libby*, ligand-*ions* are split off from the complex ions of metals. Irradiation of $KMnO_4$, for example, leads to the following forms:

$$Mn^{VII}O_4^- \xrightarrow{-O^{2-}} Mn^{VII}O_3^+ \xrightarrow{-O^{2-}} Mn^{VII}O_2^{3+} \xrightarrow{-O^{2-}} Mn^{VII}O^{5+} \xrightarrow{-O^{2-}} Mn^{7+}$$

On dissolution in water, these forms are either reduced (giving yield) *e.g.*

$$4\, MnO_3^+ + 2\, H_2O \longrightarrow 4\, MnO_2 + 3\, O_2 + 4\, H^+ \qquad (a)$$

or hydrated (giving retention) *e.g.*

$$MnO_3^+ + H_2O \longrightarrow MnO_4^- + 2\, H^+ \qquad (b)$$

In complex anions of nonmetallic elements, the nuclear process is assumed to lead to the removal of ligand-*atoms*, *e.g.* for bromate

$$Br^{V}O_3^- \xrightarrow{-O} Br^{III}O_2^- \xrightarrow{-O} Br^{I}O^- \xrightarrow{-O} Br^-$$

The ligand-loss model fails to explain the results of a large number of experiments. The pH-dependence of the retention is only approximately compatible with equations (a) and (b); furthermore, these two reactions must have the same activation energy, since the retention is not affected by a temperature rise of 40 °C[87]. The retention is also unchanged by the use of acetone as the solvent, though hydration in accordance with eq. (b) is then impossible[108,109]. It was recently shown that the yield fraction consists mainly of Mn^{2+}, which is adsorbed on added manganese dioxide, but can be separated in strongly acidic solution[71]. With bromates, Br^0 is found as well as Br^-, but no BrO^- or BrO_2^-[48].

The species required by the ligand-loss model have never yet been detected in the crystal itself. The solution reactions that relate these species to the end products are hypothetical.

VII. High-Energy Atoms in Solids

Formerly, the chemical phenomena accompanying nuclear reactions in solids were considered from a purely chemical viewpoint whereas more consideration now is given to the physical changes.

The changes brought about by high-energy atoms in solids are known as radiation damage[110–113]. Metamict minerals exhibit such damage and, although of crystalline appearance, they are internally largely isotropic. This is due to the high-energy recoil atoms (*ca.* 100 keV) resulting from the α decay of the uranium or thorium present in the mineral. Extensive study of radiation damage became possible only after the construction of accelerators and reactors. However, such investigations immediately assumed great importance in nuclear technology since radiation-resistant materials are necessary in the construction of power reactors.

1. Production of Primary Atoms

Atoms with kinetic energy are produced in solids by collision of high-energy particles such as protons, deuterons, helium nuclei, fast neutrons, electrons, or

fragments from nuclear fission, or even as a direct result of nuclear processes. If the energy transferred is greater than a limiting value E_d (about 25 eV), known as the displacement energy, the lattice atom concerned is displaced. This displacement energy was estimated by *Seitz* [114] as early as 1949, *i.e.* before measurements had been carried out. It is approximately four times the sublimation energy; one factor of 2 is due to the fact that, unlike surface atoms, the lattice atoms are bonded on all sides, and the second factor of 2 results from the irreversibility of the collision process. The displaced lattice atom is known as a primary atom. If its energy is sufficiently high, it can displace further lattice atoms, so that secondary and tertiary atoms give rise to a cascade of lattice defects.

2. Nature of the Lattice Defects

A displaced lattice atom leaves a vacancy and generally comes to rest as an interstitial atom, as shown schematically in Fig. 6. A vacancy and an interstitial atom together form a Frenkel pair. Another form of interstitial atom is the static crowdion, in which a lattice row that is normally occupied by n atoms contains $n+1$ atoms.

Defects are present even at thermal equilibrium. In copper, the energy of formation of a vacancy is 1 eV, and that of an interstitial atom is 4 eV. At 1000 °C, the vacancy concentration is 0.01 %. Such defects lead macroscopically to changes in the specific heat, density, lattice parameters, optical properties, and electric conductivity.

3. Displacement Energy

The displacement energy E_d is best determined by collision experiments with electrons ($E_e \sim 0.5$ MeV). The maximum energy $E_p(\max)$ that can be transferred to a lattice atom of mass M is

$$E_p(\max) = 2\,(E_e + 2\,m_0\,c^2)\,E_e/M\,c^2 \qquad (7)$$

(E_e = energy of the electron, m_0 = rest mass of the electron).

The electron energy E_e that just causes a measurable change, *e.g.* in conductivity, is measured; $E_p(\max)$ in eq. (7) corresponds to the desired energy E_d. In Table 4, the expected value $E_d \sim 25$ eV is confirmed, except in the case of semiconductors and the ordered alloy phase.

Table 4. Displacement energies found experimentally from equation (7) [111, 115, 116].

Substance	E_d (eV)
Graphite	25
Si	13
Al	32
Ag	28
Cu	22
Fe	24
Ni	24
Cu_3Au (ordered)	≈ 10 [a]
GaAs	9.1 (Ga); 9.5 (As)

[a] Migration energy, not displacement energy (see Section VII.5).

4. Number of Displacements

The calculation of the number of displacements $\nu(E_p)$ produced by a primary atom of energy E_p is roughly as follows: A primary atom of energy $E_p < E_d$ does not produce any change. Primary atoms having an energy $E_d < E_p < 2E_d$ displace an atom after the transfer of at least E_d; however, their remaining energy is then less than E_d, and the atom remains at the point of collision, so that effectively no new vacancy is formed. Only primary atoms with $E_p > 2E_d$ can transfer the energy E_d to an atom with which they collide and still retain the energy E_d, so that a new vacancy is produced. This reasoning leads to the expression

$$\nu(E_p) = E_p/2\,E_d \qquad (8)$$

The same result was obtained by *Kinchin* and *Pease* [117] by a mathematically more formal method. The energy stored in the vacancies is about 5 eV per Frenkel pair in metals, and so amounts to only 10 % of the energy required for their formation.

5. Replacement

In the calculation of the number of displacements, though primary atoms with $E_d < E_p < 2E_d$ cause the displacement of a new atom, they themselves remain trapped at the collision site. This process is known as replacement. *Kinchin* and *Pease* [118] consider such replacements possible even at energies as low as 0.1 E_d.

Whereas replacement reactions in metals and disorded alloys cause no observable changes, in ordered alloy phases such as $MnNi_3$ or Cu_3Au they lead to a more statistical arrangement of the atoms even at energies below E_d (cf. Table 4).

6. Thermal Spikes

Instead of describing individual defects, *Seitz* and *Koehler* [119] considered the damage process collectively in their thermal-spike model. In a displacement, only a small part of the energy is stored in defects, the remainder being liberated as heat. If a quantity of heat Q is liberated at a lattice point in a collision at time $t = 0$, then the temperature T at a distance r from this point at time t is

$$T(r,t) = \frac{Q}{8\,\pi^{3/2}\,c_p d} \cdot \frac{1}{(Dt)^{3/2}} \cdot \exp\,(-r^2/4\,Dt) \qquad (9)$$

where the heat diffusion coefficient D is given by $D = C/c_p d$

(C = thermal conductivity, c_p = specific heat, d = density).

[119] *F. Seitz* and *J. S. Koehler*, Solid State Physics *2*, 305 (1956).

Fig. 3 shows such a temperature distribution at various times.

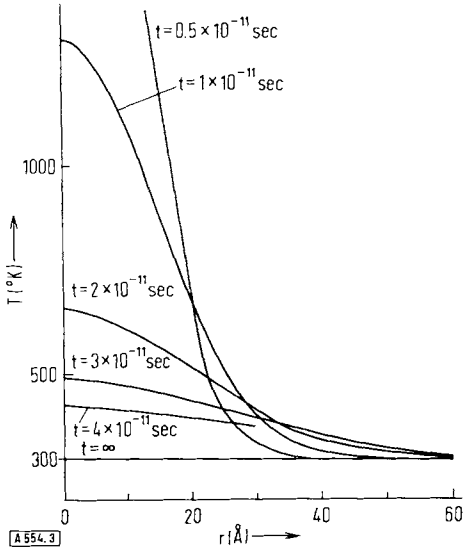

Fig. 3. Local temperature distribution in a thermal spike in Cu (D = 0.001 cm²/sec; Q = 1000 eV). According to G. H. Vineyard (personal communication), Q = 300 eV in the original is a misprint [110].

For an event with Q = 300 eV, which approximately corresponds to the recoil energy in (n,γ) processes, a region of about 10 atomic diameters (about 1000 atoms) is heated for 10^{-11} sec to about 1000 °K, *i.e.* approximately to the melting point. However, the diffusion of heat in atomic regions is probably faster than would be expected from eq. (9) and the time and the size of the thermal spike so calculated are therefore too large. Differences of opinion exist as to whether the hot region can be regarded as a true melt or simply as a superheated solid without appreciable mixing of the atoms. According to *Seitz* and *Koehler*, at least the central part of the spike is in thermal equilibrium, and so can be treated as a macroscopic melt.

The problems of interpretation should have no bearing on processes that can be thermally activated in the excited region, such as the conversion of ordered alloy phases into disordered phases, the transition from low-temperature to high-temperature phases, segregation, thermal production of Frenkel pairs, *etc.*. However, attempts to detect such thermal processes, *e.g.* the transition from gray to white tin[120] or the transition from metastable tetragonal ZrO_2 into the monoclinic form[121] on irradiation with fast neutrons, have been largely unsuccessful. The transition from ordered into disordered alloy phases is better explained by the replacement model. However, spikes were detected at higher energies, for example with the fragments from nuclear fission. When monoclinic ZrO_2 is bombarded with fission fragments in the presence of stabilizing foreign atoms such as V, Cr, or Ta, it is converted into the cubic high-temperature modification[122,123]. Near the surface in *e.g.* uranium and plutonium, evaporation takes place at a rate of the order of 1000 atoms per fission fragment[124]. The rate of evaporation is reduced if the surface is coated with oxide.

7. Energy Loss and Range of Primary Atoms

Bohr[125] proposed the expression (10) for the interaction potential between primary and lattice atoms.

$$V(r) = (Z_1 Z_2 e^2/r) \exp(-r/a) \qquad (10)$$

(Z_1, Z_2 = nuclear charges of the two particles concerned, r = distance between the particles, a = the screening parameter). $a = a_H/(Z_1^{2/3} + Z_2^{2/3})^{1/2}$

(a_H = 0.529 Å, radius of the Bohr hydrogen atom in the ground state).

For primary atoms having Ep (eV) $< 30\,Z^{7/3}$, the electron clouds scarcely penetrate each other, and the scattering is given by a hard-sphere model. Above this energy limit, the Rutherford scattering model (which will not be described here) is valid[111]. For energies above E_i (eV) $=10^3\,M$, energy is lost mainly by ionization of the surroundings.

To summarize, it may be said that most primary atoms lose their energy by hard-sphere scattering, while fission fragments and accelerated particles lose their energy mainly by ionization. Whereas the ionization causes no permanent changes in metals, electronic defects are produced in semiconductors and nonconductors.

The path length of a primary atom is found by summation of the various free paths. For elements ($Z_1 = Z_2 = Z$), *Holmes* and *Leibfried*[126] equated the Bohr potential of equation (10) to the energy of the primary atom:

$$2\,V(R) = E_p = \frac{2Z^2e^2}{R} \exp(-R/a) = E_B \frac{a}{R} \exp(-R/a) \qquad (11)$$

$E_B = 2Z^2e^2/a$, R is the interaction distance in such a collision, *i.e.* the "diameter of the sphere". It can be seen that R increases as E_p decreases.

According to the kinetic gas theory, the collision cross-section is

$$\sigma_p = \pi R^2 \qquad (12)$$

and the mean free path L_p of a primary atom is

$$L_p = 1/N_A \pi R^2 \qquad (13)$$

(N_A = number of atoms in the unit volume). Fig. 4 shows the relationship between L_p and E_p for Cu primary atoms in copper. Summation of the individual free paths L_p, assuming that the energy of the primary particle is halved at each collision, shows that the mean total path $\bar{L}$ is given by

$$\bar{L} = L_p\,(3/2 + R/a), \qquad (14)$$

and the mean maximum range by

$$\overline{(R^2_{max})}^{1/2} = L_p\,(7/2 + 2\,R/a)^{1/2} \qquad (15)$$

The maximum range is the greatest distance from the starting point that is ever reached by the primary atom, while the

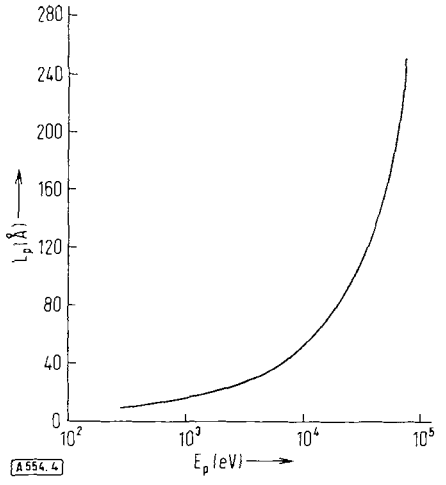

Fig. 4. Relationship between the mean free path L_p and the energy E_p of a primary atom in copper [111].

vector range is the distance between the atom after it has come to rest and the starting point. The penetration depth is the projection of the vector range in the original direction.

The Bohr potential gives only a moderately good description of the interaction. The agreement between theory and experiment is generally not very satisfactory.

8. Experimental Determination of Ranges

The range of the high-energy fragments from nuclear fission ($\sim$ 2–12 mg/cm^2 $\sim$ 0.007–0.045 mm in Al) is determined by allowing the fragments produced in a very thin layer to penetrate a series of thin foils which are then analysed individually to find their content of radioactive fission fragments. In nuclear reactions producing atoms of lower primary energies and correspondingly smaller ranges, layers of target material and of catcher material are pressed together alternately. The range R in the target material is then (for $d \gg R$)

$$R = 2\,df. \qquad (16)$$

d = thickness of target layer, f = proportion of the radioactive atoms penetrating the catcher foils [127].

The maximum range is found if the atomic number of the atoms of the catcher material is significantly lower than that of the target material, since atoms that have left the target layer cannot return to this layer by backscattering. Instead of the foils, powdered target material may be mixed with solid catcher materials or suspended in liquids (cf. Table 5).

Table 5. Recoil ranges of target nuclei in the target material, after *Pauly* and *Süe* [128–131].

Target	Nuclear reaction	Catcher	Recoil energy (MeV)	Range (Å)	Range (μg/cm²)
P_{red}	$^{31}P(\gamma,n)^{30}P$	Tetralin	0.16	800	19
P_{red}	$^{31}P(\gamma,n)^{30}P$	Tetralin	0.40	2300	54
$CuSO_4 \cdot 5H_2O$	$^{63}Cu(\gamma,n)^{62}Cu$	$CaCO_3$	0.20	2600	59
Cu	$^{63}Cu(\gamma,n)^{62}Cu$	NaCl,$BaCl_2 \cdot 2H_2O$	0.20	600	53
NaCl	$^{35}Cl(n,\alpha)^{32}P$	Naphthalene, paraffin	0.59	5000	105
NH_4Cl	$^{35}Cl(n,\alpha)^{32}P$	SiO_2	0.59	7000	107
NaCl	$^{35}Cl(n,p)^{35}S$	Naphthalene, paraffin	0.12	500	10
NH_4Cl	$^{35}Cl(n,p)^{35}S$	SiO_2	0.12	700	11
S_8	$^{32}S(n,p)^{32}P$	H_2O	0.6	6500	135
NaCl	$^{37}Cl(d,p)^{38}Cl$	$CaCO_3$	0.48	3200	66
NaCl	$^{23}Na(d,p)^{24}Na$	$CaCO_3$	0.82	3700	76

A few years ago, another method of range determination became prominent. In this method radioactive ions (*e.g.* ^{24}Na, ^{86}Rb, ^{133}Xe, ^{222}Rn), which have acquired a definite energy by passage through an electric field, are used to bombard the catcher material (generally aluminum). The penetration and distribution are then determined by successive dissolution of thin layers of the catcher. Fig. 5 shows the penetration probability for ^{85}Kr in aluminum at energies between 2 and 600 keV [136].

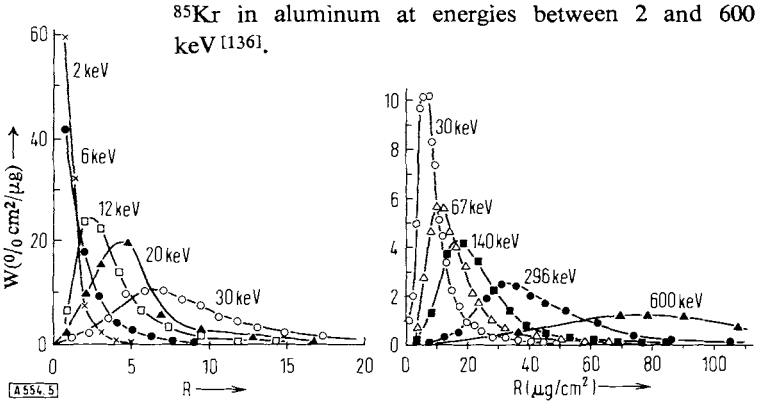

Fig. 5. Relationship between penetration probability W and the penetration R of ^{85}Kr in aluminum for energies between 2 and 600 keV [136].

(W = percentage of ^{85}Kr atoms which come to rest in layers of thickness 1 μg/cm² at a distance R from the surface).

Aluminum is anodically oxidized and the oxide film is dissolved by hot phosphoric acid/chromic acid solution. The thickness of the oxide film is proportional to the formation voltage; it is possible to dissolve away layers as thin as 1 μg/cm² $\triangleq$ 37 Å [132]. The process can also be used with

tungsten and with silicon [133,134]. Reproducible removal of thin layers can also be achieved by cathode sputtering [135].

The range of (n,γ) recoil atoms is extremely small. In the case of indium and gold foils, only those recoil atoms that are produced in the outermost monoatomic layer emerge; thus the range is approximately one lattice layer [40]. On neutron irradiation of a slurry of sulfur particles of radius 0.8 μ in water, 0.26% of the ^{35}S atoms were found in the water; this corresponds to a range of 40 Å for the recoil atoms [128,137]. The ranges of the ^{28}Al produced in aluminum and in Al_2O_3 by the reaction $^{27}Al(n,\gamma)$ were 11 and 4.4 Å respectively, and the range of the ^{56}Mn resulting from the $^{55}Mn(n,\gamma)$ reaction in iron containing Mn was 35 Å [138,139].

9. Focusons, Dynamic Crowdions

So far we have not considered the fact that the atoms at rest have a strict geometrical arrangement. The real crystals were replaced by a random distribution of atoms, *i.e.* were regarded as amorphous. Consideration of the lattice structure leads to some entirely new aspects of the behavior of atoms travelling through solids.

Close-packed atoms along a lattice row can behave as a row of billiard balls in contact with one another. A collision directed along this line leaves all the balls in their original position except the last, which moves away. This is the case in the crystal lattice when the lattice row is interrupted *e.g.* by a small or light foreign atom, a vacancy, or a grain boundary, and the ejected atom enters an interstitial site. If the lattice row is not interrupted, the collision process stops after about 100 interatomic distances owing to loss of energy.

The angle between the collision direction and the lattice direction becomes smaller with each collision. Thus the energy transport becomes focused along lattice lines without any transport of material [140,141]. This phenomenon is referred to as focusing collisions (cf. Fig. 6).

There is an upper energy limit E_F for focusons, since the atomic diameter becomes steadily "smaller" as the energy increases [cf. eq. (11)], until the lattice rows are apparently no longer close-packed. This limit for copper in the ⟨110⟩ direction is about 50 eV.

If the energy of a primary atom is greater than the focusing energy E_F, or if the lattice rows are less closely packed, each atom in the collision chain moves into the position of its nearest neighbor, leaving a vacancy at the origin of the collision chain. Focusing mainly occurs because the moving atoms are held in the direction of the line by adjacent lattice rows. This process is known as a dynamic crowdion (cf. Fig. 6). Thus, such a crowdion transports both energy and material, whereas a focuson transports only energy. The crowdions in ordered lattices replace the Kinchin-Pease replacement reactions. A crowdion can change into a focuson when its energy falls below E_F.

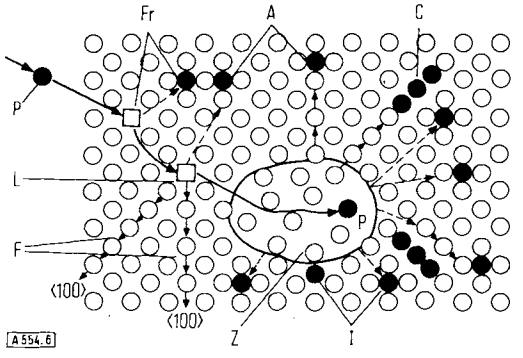

Fig. 6. Scheme of a depleted zone after *Seeger* [142].
P = primary atom (originating in a lattice region that is not shown); L = vacancy; F = focusons; Z = depleted zone; I = interstitial atoms; C = crowdion; A = replacement collisions; Fr = Frenkel pair.

Crowdions and focusons lose, to the lattice, small amounts of energy, which is no longer available for the production of radiation damage. Owing to the fast transport of energy from the point of collision, the formation of thermal spikes becomes less likely, and interstitial atoms can be expected at greater distances from the starting point.

10. Depleted Zones

For lattice structures, *Seeger* [142] has developed a defect model that is more probable than the thermal-spike model. An essential feature of the Seeger model is the occurrence of dynamic crowdions which transport the energy and material away from the surroundings of the primary atom coming to rest. At a certain distance this gives rise to defects, *e.g.* a static crowdion resulting from the "freezing-in" of the dynamic crowdion, or an interstitial atom resulting from the ejection of the excess atom. A depleted zone is formed around the rest position of the primary atom. Frenkel pairs and focusons (cf. Fig. 6) are also formed directly. The maximum diameter of the depleted zone is 20 Å.

11. Kinematics of High-Energy Atoms in Solids

In order to be able to follow the behavior of primary atoms in detail, *Vineyard* [143] used a computer in a study of the changes occurring when a single copper atom in a Cu lattice moves with a certain energy in a definite starting direction (*e.g.* see Fig. 7).

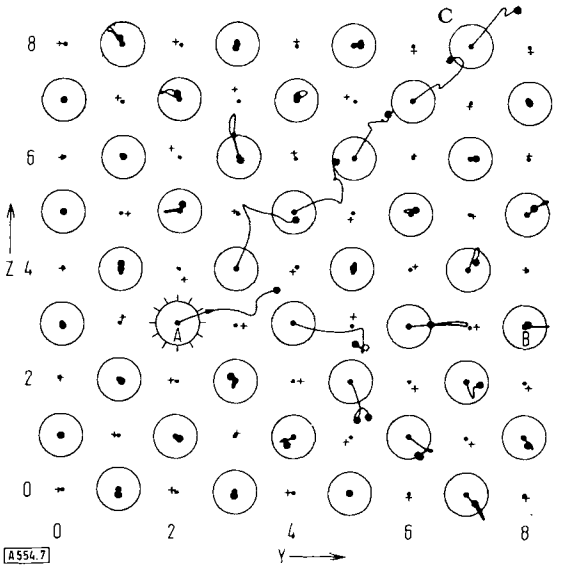

Fig. 7. Changes in the (100) plane of a copper lattice 3.24×10^{-13} sec after the transfer of an energy of 40 eV to the atom A (energy vector at an angle of 22.5° to the y axis). Large circles with medium-bold centers denote the starting positions of the atoms, and bold dots indicate the final positions. The routes travelled by the atoms are shown. Small dots show the starting positions of the atoms of the next-lower plane, and crosses indicate their final position. The event leads to the transient formation of three vacancies and two interstitial atoms in the neighborhood of A, resulting in one stable vacancy. A dynamic crowdion in the direction AC, after four changes of position, leads to the formation of an interstitial atom in the neighborhood of C. A focuson is observed in the direction AB [143].

The threshold energy E_d for the formation of a Frenkel pair is clearly dependent on direction and is 25 eV for the ⟨100⟩ direction, 25 to 30 eV for ⟨110⟩, and about 85 eV for ⟨111⟩. Thus the electron collision experiments give not an average value, but the minimum value of E_d. For a 400 eV event, the vacancies are found in the neighborhood of the point of origin, in agreement with Seeger's depleted-zone model, but the interstitial atoms are farther away.

Vineyard[144] used the kinetic energies obtained by computer calculations to calculate temperatures. He found no gradually spreading region of relatively uniform temperature, but temperature maxima in the vicinity of the collision chains. In a 100 eV event, the temperature maxima fell to below the melting point in only 10^{-12} sec, and after 1.65×10^{-12} sec the temperature was substantially that of the surroundings. Though there are similarities to the thermal-spike model, the initial fall in temperature is much faster.

12. Radiation Damage in Heteropolar Compounds

Processes such as those described above probably also occur in non-metallic solids. However they are less important than electronic processes, which already belong to the field of radiation chemistry. The essential measurable changes are the rupture of chemical bonds and the formation of color centers.

When irradiated inorganic substances are dissolved, it is possible to detect decomposition products, *e.g.*

a) $NO_3^- < NO_2^- + 1/2\ O_2$

b) $ClO_3^- < Cl^- + 3/2\ O_2$

c) $BrO_3^- < BrO_n^- + (3-n)/2\ O_2 \quad 2 \geqslant n \geqslant 0$

d) $IO_3^- < I^- + 3/2\ O_2$

e) $SO_4^{2-} < SO_3^{2-} + 1/2\ O_2$

f) $NaN_3 < Na + 3/2\ N_2$

Annealing can take place at least in cases a), b), and c).

VIII. New Models

1. Hot-Spot Model

Yankwich[145] and *Harbottle*[146] have discussed the chemical effects of nuclear transformations in solids on the basis of the thermal spike model. The recoil atom produces a hot spot (or a displacement spike) with displaced atoms. Thermodynamic considerations show that reactions with activation energies of about 1 eV can proceed in good yield in this hot spot. Exchange reactions lead to retention; other reactions lead to yield forms, generally with high chemical stability. The theory allows at least a qualitative understanding of annealing. Defects remain in the rapidly cooling hot spot, and these react further only when the temperature is raised. However, it is not clear why annealing nearly always leads to an increase in retention.

2. Disorder Model[70,147]

The disorder model is based on *Vineyard*'s computer calculations[143] the result of which is also regarded as an adequate model of the chemical effects of nuclear transformations. According to this model, an (n,γ) recoil atom having an energy of about 100 eV loses its kinetic energy very quickly and comes to rest only a few interatomic distances away from its starting point. Retention of the original molecular group or complex ion would be possible *e.g.* if a focuson were formed (primary retention). The general damage to the lattice is small, *i.e.* only a few atoms change places with neighboring atoms or become interstitial atoms. The process does not involve an intermediate liquid-like state.

The changes taking place, including those of a purely electronic nature, cannot be described in detail. Simulation by computer calculations has not so far been possible.

After having lost its energy, the recoil atom is in a new environment. From the chemical point of view, this state may have the character of a compound, which may remain intact on dissolution or may enter into a purely chemical reaction with the solvent. Other atoms are in metastable states, and with their surroundings they constitute the disorder center; these give yield forms,

[144] *G. H. Vineyard*, Discuss. Faraday Soc. *31*, 7 (1961).

[145] *P. E. Yankwich*, Canad. J. Chem. *34*, 301 (1956).

[146] *G. Harbottle* and *N. Sutin*, J. physic. Chem. *62*, 1344 (1958).

[147] *H. Müller* in [2], *2*, 359 (1965).

or may be annealed to give retention (cf. Fig. 1) [68]. The defects in this model formally resemble the intermediate forms of the ligand-loss model (cf. Section VI, 2). Since the disorder center is formed only when the recoil atom is nearly at rest, it is not determined by the initial energy of the recoil atom. Melting processes can occur only at recoil energies greater than 10 keV.

Even for substances with a retention of 100 %, for which no Szilard-Chalmers process is observed, some of the recoil atoms may well be found in defects. The difference in the arrangement of the surrounding atoms can lead to a change in the angular correlation of coincident γ quanta of the decaying nucleus. This effect was first observed for ^{188}Re from the nuclear reaction $^{187}Re(n,\gamma)^{188}Re$, in which $K^{188}ReO_4$ with all the ^{188}Re in crystallographically known sites was compared with neutron-activated $KReO_4$ [148].

The disorder model differs from the hot-spot model in that the reaction region is smaller and less disturbed, thus resulting in no appreciable mixing of the contents, and that the temperature rise is smaller and of shorter duration.

IX. Annealing [93, 149]

Annealing is the disappearance of defects (*e.g.* Frenkel pairs or dislocations) in solids. The defect centers produced in chemical compounds by nuclear reactions can be annealed, not only by the action of heat and ionizing radiations, (electrons, γ quanta), but also by pressure [150], UV irradiation [68, 151], or ultrasonics [152]. Fig. 8 shows the course of thermal annealing in calcium bromate at various temperatures [153]. This type of curve,

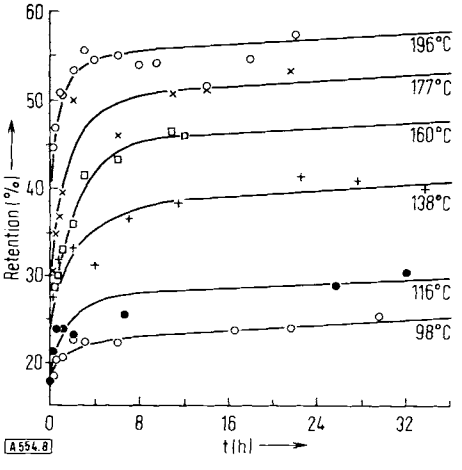

Fig. 8. Thermal annealing of calcium bromate [153].

which rises rapidly to a temperature-dependent pseudo-plateau, is quite common, though curves containing maxima [154], and/or minima [155] are also found as well as families of curves with the same pseudo-plateau for a range of temperatures [84]. The annealing curves become very complicated when different processes are combined. The curves should reflect the properties of the defect and thus be of use in its characterization.

The Maddock defect theory [156] applied to K_2CrO_4 explains annealing as an interaction of the Szilard-Chalmers center with a lattice defect, *e.g.* a vacancy. The fast annealing (steep part of the curve) corresponds to annealing of centers situated close to such a defect; the extent of the annealing increases with temperature and the process is of the first order. The pseudo-plateau region corresponds to annealing by the diffusion of a defect towards the center; since the number of defects is large in comparison with the number of Szilard-Chalmers centers, this recovery process is of the zeroth order. If new defects are produced at this stage, some of these will be situated very close to Szilard-Chalmers centers, so that a new phase of fast annealing can occur. The initial retention is also influenced by defects, such as can be produced by doping with foreign atoms or even by quenching or crushing [157]. The defect theory explains the frequently observed dependence of the Szilard-Chalmers phenomena on the properties of the starting material.

According to the defect theory, radiation annealing is due to the action of an exciton (electron hole + electron) on the Szilard-Chalmers center; electron holes or electrons, however, can also be active. The radiation annealing tends towards saturation, since the irradiation itself produces defects, which compete with the Szilard-Chalmers centers for the excitons. However these defects can be thermally eliminated even at temperatures at which the Szilard-Chalmers centers are not affected.

A theory related to that of Maddock was developed for C_2Br_6 [84]. Here the recoil atom is again regarded solely as an indicator for the changes in the defect center.

The action of electronic effects becomes clearest in experiments on KCl, in which the phosphorus produced by the reaction $^{35}Cl(n,\alpha)^{32}P$ is found mainly in the reduced form (not P^{5+}), but is converted into $^{32}P^{5+}$ on annealing [158]. No annealing occurs when the neutrons are produced by the D–T reaction and not in a reactor. Such neutrons are free from γ-radiation, which produces the electronic defects.

If $Ca(IO_3)_2$ doped with $^{131}I^-$ or K_2CrO_4 doped with $^{51}Cr^{3+}$ is heated, the charge transfers $^{131}I^- \rightarrow {}^{131}IO_3^-$ and $^{51}Cr^{3+} \rightarrow {}^{51}CrO_4^{2-}$ exhibit strong resemblance to the annealing curves of neutron-activated $Ca(IO_3)_2$ and

K_2CrO_4 respectively [159–161]. The same is true of the system $KBrO_3/^*Br^-$ [162]. The obvious interpretation is that annealing is due to simple chemical transfer reactions in these cases.

The interpretation of this annealing mechanism according to the disorder model is that the defect property (*e.g.* abnormal charge, abnormal coordination of neighboring atoms) is not associated permanently with the primary defect atom, but can be passed on to other atoms in the manner of a transfer. The greater the number of atoms (only one of which is radioactive) involved in this exchange, the greater is the retention, which may in the extreme case be as high as 100 %. Conversely, the number n of atoms involved in the transfer can be calculated from the maximum retention at temperature T, *i.e.* $R_\infty(T)$, using the expression $n = 1/(1-R_\infty(T))$.

A possible example of this process is given by *Schmidt*'s experiments [163] on the chemical effects of the isomer transition $^{80m}Br \rightarrow {}^{80}Br$ in the complexes $[Rh(NH_3)_5{}^{80m}Br]X_2$ and $[Ir(NH_3)_5{}^{80m}Br]X_2$ (X = Cl, Br). In these experiments the retention decreased from an initial value of between 45 and 55 % to 34 % on annealing above 200 °C. This behavior can be most easily explained as an activated transfer, in which ^{80}Br occupies one of a total of three halogen sites with equal probability. Normal annealing curves with increasing retention, however, were found for the nitrates (X = NO_3). Thus halide and nitrate cannot undergo transfer, probably on steric grounds.

In activated NH_4Cl (nuclear reaction $^{14}N(n,p)^{14}C$), 10 % of the ^{14}C is in the form of HCOOH, HCHO, and CH_3OH, even after sublimation of the material. Thus the precursors of these substances do not anneal, even on complete reformation of the lattice [164].

The annealing in $[Co(NH_3)_6]Cl_3$ is attributed to a purely chemical reaction [165]:

$$[^{60}CoCl(NH_3)_5]Cl_2 \xrightarrow{NH_3} [^{60}Co(NH_3)_6]Cl_3$$

X. Experimental Support for the Disorder Model

The neutron irradiation of anhydrous Na_2HPO_4 gave 10 % retention together with 11 % each of triphosphate and diphosphate, 26 % of isohypophosphate, 3 % of hypophosphate, and 9 % each of diphosphite, phosphite, and hypophosphite. In view of the absence of large quantities of polyphosphate, the hot-spot model may be ruled out. Isohypophosphate is not labeled randomly, but as $P^5-O-{}^{32}P^3$. These experiments were taken as the first evidence that the disorder is only slight [55]. It is assumed that triphosphate, isohypophosphate, and hypophosphate [166] are formed in the crystal, and not on dissolution. The fact that 80 % of the triphosphate is in the form $P-O-{}^{32}P-O-P$, *i.e.* is labelled in the center, indicates a high steric specificity of the reaction; thus the triphosphate is formed by the insertion of a ^{32}P recoil atom between two PO_4^{3-} tetrahedra. Accordingly, the triphosphate yield decreases on neutron irradiation of hydrated orthophosphates, since the distance between the PO_4 groups is greater in this case. Triphosphate obtained from diphosphates is labeled mainly in the terminal position [167].

On irradiation of rhombic sulfur, the active sulfur from the reaction $^{34}S(n,\gamma)^{35}S$ (maximum recoil energy *ca.* 750 eV) remains in the rhombic sulfur, whereas the phosphorus atoms from the reactions $^{32}S(n,p)^{32}P$ and $^{32}S(n,p)^{33}P$ (recoil energies 45 and 15 keV respectively) are found in the S_μ fraction [168]. However, this enrichment is due to adsorption of phosphorus-oxygen compounds, and so does not support the hot-spot theory even for the high energies mentioned [169].

On neutron activation of white phosphorus, 66 % of the ^{32}P is found in the red phosphorus, which amounts to only about 1 % of the total. However, this transmutation is brought about, not only by heat, but also by the rupture of the bonds in the P_4 molecule as a result of the recoil. When the irradiated product is heated, the annealing reaction $^{32}P_{red} \rightarrow {}^{32}P_{white}$ is masked by the polymorphous transition $P_{white} \rightarrow P_{red}$ [170]. These results also favor the disorder model.

Following the nuclear reaction $^{80}Se(n,\gamma)^{81m}Se$ in red selenium, only 2 % of the recoil atoms are found in the gray and vitreous selenium; the hot-spot model predicts a higher proportion [171].

Annealing reactions can follow a very specific course. After the nuclear reaction $^{59}Co(n,\gamma)^{60}Co$, the initial retention of (+)-$[Co(en)_3](NO_3)_3 \cdot 3H_2O$ is 4.5 %, while that of the (−)-form amounts to 0.4 %. On prolonged annealing at 80 °C, these values increased to 69.2 and 3.1 % respectively, *i.e.* on annealing the original optical isomer is reformed [58]. Similar behavior is found for *cis-trans* isomers of $[Co(en)_2Cl_2]NO_3$ and $[Co(en)_2Br_2]NO_3$ [172–174].

The hot-spot theory explains this phenomenon as being due to recrystallization of the molten region during which the matrix that has remained unchanged impresses its own structure on the recrystallized material. However, there is no parallel for such a process in inorganic chemistry. According to the disorder model, only very slight changes occur, so that the starting material can be readily reformed. At higher recoil energies, however, greater damage is expected; the formation of an isomer that was not originally present indicates rearrangement.

This was in fact found for 100 keV ^{58}Co recoil atoms from the nuclear reaction $^{59}Co(n_f,2n)$ in *cis*- and *trans*-$[Co(en_2)Cl_2]NO_3$ [175]. Migration of the recoil atom back to its original place is unlikely. For *cis-trans* complexes containing only monodentate ligands such as $Co(NH_3)_4(NO_2)_2^+$ and $Co(NH_3)_2(NO_2)_4^-$, the stereospecificity of the annealing process is low even at low recoil energies, *i.e.* rearrangements can take place more readily [61,63].

Many elements give two or more active nuclides on (n,γ) activation. The chemical secondary reactions of such isotopes may differ quantitatively. This is referred to as an isotope effect, and can result from: 1. differences in the recoil energy, 2. differences in the charge as a result of the Auger effect, 3. differences in the masses of the recoil atoms.

It is not generally possible to attribute an isotope effect definitely to any one of these factors. However, an exception is found in zinc phthalocyanine [79]. The retention was 28.9 % for ^{65}Zn and 41.6 % for ^{68m}Zn; the values for the dipyridine complex Zn(phthalocyanine)(pyridine)$_2$ are 4.7 % and 14.3 % respectively. Thermal annealing is observed only for ^{69m}Zn. From the γ spectra of the compound nuclei, it can be estimated that the recoil experienced by ^{65}Zn is approximately twice as strong as that experienced by ^{69m}Zn, so that the former travels farther. Thus recombination of the organic residue with ^{65}Zn becomes less likely; the retention decreases and annealing by recombination does not take place. The lower retention values for the dipyridine complex are explained by hindrance of recombination by the pyridine or its fragments.

A wealth of information was obtained in the study of the nuclear reaction $^{185}Re(n,\gamma)^{186}Re$ in homogeneous mixed crystals K_2ReBr_6/K_2SnCl_6 and K_2ReBr_6/K_2OsCl_6 containing 1 to 28 and 6 to 20 mole-% of K_2ReBr_6 respectively [70,147]. In mixed crystals containing little K_2ReBr_6, primary retention would give $^{186}ReBr_6^{2-}$; retention *via* a billiard-ball collision would yield $^{186}ReCl_6^{2-}$, since the recoil atom would probably displace Sn or Os. According to the hot-spot and disorder models, however, mixed bromochlororhenates should also be expected.

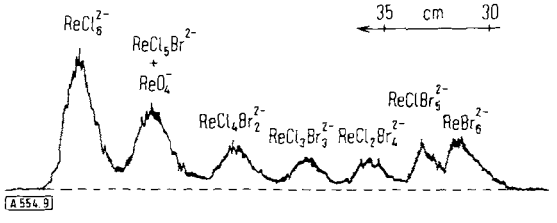

Fig. 9. ^{186}Re activity after ionophoretic separation of neutron-irradiated K_2ReBr_6/K_2SnCl_6 mixed crystals (see also Table 6) [70].

The various species were separated by ionophoresis; an example of an activity distribution is shown in Fig. 9; numerical values are given in Table 6. Normal ligand exchange occurs neither during the preparation of the mixed crystals nor during the ionophoretic separation [176,177]. Most of the recoil atoms are in the form of mixed bromochlororhenates, which must therefore

Table 6. Products of the nuclear process $^{185}Re(n,\gamma)^{186}Re$ in mixed crystals. The figures are expressed as percentages of the total ^{186}Re content.

Ion found	K_2ReBr_6 in K_2SnCl_6 (molar prop. 1:>100)	K_2ReBr_6 in K_2OsCl_6 (molar prop. 1:>100)
$^{186}ReBr_6^{2-}$	13	13
$^{186}ReBr_5Cl^{2-}$	7	5
$^{186}ReBr_4Cl_2^{2-}$	6	8
$^{186}ReBr_3Cl_3^{2-}$	8	12
$^{186}ReBr_2Cl_4^{2-}$	11	13
$^{186}ReBrCl_5^{2-}$	13	11
$^{186}ReCl_6^{2-}$	32	3
$^{186}ReO_4^-$	10	35

have been formed according to either the hot-spot or the disorder model (the forms $^{186}ReCl_6^{2-}$ and $^{186}ReBr_6^{2-}$ can also be formed in this way). The billiard-ball mechanism can be abandoned as a general model, since only 3 % of $^{186}ReCl_6^{2-}$ was found in the system K_2ReBr_6/K_2OsCl_6. Similarly, $^{186}ReBr_6^{2-}$ is thought to result from annealing, and not to represent the primary retention.

Even when very dilute solid solutions are used (up to 1 and 6 %, respectively, of K_2ReBr_6), bromide accumulates in the ligands around the recoil nuclei to concentrations of 34 % in K_2ReBr_6/K_2SnCl_6 and 53 % in K_2ReBr_6/K_2OsCl_6, based on the total number of ligands. This is not due to any preference of the recoil atom for bromine, since in the mixed crystal K_2ReCl_6(2 mole-%)/K_2SnBr_6, 48 % of the ligands in the recoil products are chloride. The only explanation for the enrichment is that a small reaction zone, in consequence of a small recoil range, is situated around the locality of the nuclear event so that the six original ligands form a considerable proportion of all the halogen atoms available for recombination with the recoil atom. From the number of Br ligands in excess of the statistical probability, it is calculated that 18 halogen atoms are involved for K_2ReBr_6/K_2OsCl_6. The unit cell of the matrix substance, which has a volume of about 1000 Å^3, contains 24 halogen atoms; thus the reaction zone of the Szilard-Chalmers process is calculated to have a volume of 500 to 700 Å^3 and an average radius of about 5 Å. This value is also a measure of the recoil range, and agrees with the figures given in Section VII.8.

The size of the reaction zone is about one order of magnitude smaller than predicted by the hot-spot model, but is approximately as expected from the computer calculations [143]. This supports the disorder model. The idea of a "melt" is also opposed by the fact that the distribution of all possible bromochlororhenates is not statistical, relative to the halogen atoms in the reaction zone; it reflects instead the special position of the recoil atom after the loss of its energy and the smallness of the changes in the arrangement of the other atoms. The fact that only 3 % of $^{186}ReCl_6^{2-}$ is found for K_2ReBr_6/K_2OsCl_6, as compared with 32 % for K_2ReBr_6/K_2SnCl_6, shows that the recoil range in the former system is just small enough to prevent the recoil atom passing into the pure chloride environment of the K_2OsCl_6 matrix, probably because of the greater mass of osmium and the stronger bonding between the osmium and its ligands. This difference cannot be explained by the hot-spot model. All the changes described take place in the crystal before dissolution.

A reaction zone of only one or two molecular diameters was also found in experiments on the chemical effects of the isomeric transition $^{80m}Br \rightarrow {}^{80}Br$ in solid alkyl bromides [178].

XI. Other Experimental Results

The $^{59}Co(n,\gamma)^{60}Co$ reaction in $[Co(NH_3)_6][Co(CN)_6]$ and in $[Co(NH_3)_6][Fe(CN)_6]$ leads to all of the seven possible complexes $[^{60}Co(CN)_n(NH_3)_{6-n}]^{3-n}$ $(0 \leq n \leq 6)$, but this result cannot be interpreted in the same manner as for the hexahalogenometalate mixed crystals (see Section X) [179].

In the complex salts $[CoX_n(NH_3)_{6-n}]Y_{3-n}$ ($X = NO_2$; $Y = NO_2$, NO_3; $n = 1,2,3$), $K[Co(NO_2)_4(NH_3)_2]$, and $NH_4[Co(NO_2)_4(NH_3)_2]$, further nitro groups, but no NH_3 groups, enter the coordination sphere [60]. In cobalthexammine salts, the entry of a free ion into the coordination sphere is observed: $[Co(NH_3)_6]X_3 \rightarrow [^{60}CoX(NH_3)_5]X_2$ ($X = Cl$, Br) (as well as after the isomeric transition $^{80m}Br \rightarrow {}^{80}Br$) [62, 165, 180]; the tetrammine complexes $[^{60}CoX_2(NH_3)_4]^+$ are no longer stable. On annealing, the pentamminehalogeno complexes disappear in favor of the starting substance. The same is true of nitroammine complexes $[Co(NO_2)_n(NH_3)_{6-n}]^{3-n}$ ($n = 2, 3, 4$) [63]. In these cases, therefore, the chemical difference of the ligands does not allow the simple requirements of the disorder model to become effective. In activated K_2ReBr_6/K_2ReCl_6 mixed crystals, on the other hand, annealing leads to the formation of all the mixed bromochlororhenates (IV) [147].

Entry of ions into the ligand sphere also takes place in the bromine activation $^{79}Br(n,\gamma)^{80m}Br$ of $[CoX(NH_3)_5]Br_{2\text{ or }3}$ and $[CoX_2(en)_2]Br_{1\text{ or }3}$ ($X = NH_3$, NCS, NO_2, H_2O, ONO, ONO_2, F, Cl, Br, I); the products are $[Co^*Br(NH_3)_5]^{2+}$ and $[CoX^*Br(en)_2]^{1+\text{or}2+}$ [181, 182]. In the neutron irradiation of sparingly soluble hydroxo salts such as $4Co(OH)_2 \cdot Mn(OH)Cl$ or $4Zn(OH)_2 \cdot Ni(OH)Br$ with disordered intermediate layers of basic hydroxides, some of the ^{60}Co and ^{65}Zn recoil atoms accumulate in the disordered layers, and can be removed by ion exchange [183].

The nuclear reaction $^{35}Cl(n,p)^{35}S$ in alkali metal chlorides sublimed under vacuum or drawn from the melt leads to more than 50 % of a precursor that can be obtained as sulfide on dissolution in aqueous sulfide solution. This precursor is probably in the form of neutral atomic sulfur (possibly also of S^+ or S^-). The life of the fragment in question in the solution must be at least 10^{-6} sec, since owing to the low sulfide carrier concentration, the protective transfer reaction, can

$$^{35}S^0 + S^{2-} \longrightarrow {}^{35}S^{2-} + S^0$$

occur on average only after 10^{-6} sec. Sulfur can be extracted from the irradiated crystals; on annealing, it appears to accumulate on the crystal surface. The sulfide yield is increased by the incorporation of cation vacancies, by electron irradiation before activation, and by the use of alkali metal chloride containing F centers. On dissolution in sulfide-free water, or if analytically pure alkali metal chloride is used without pretreatment, the main product is sulfate, together with a little sulfite [53, 184–186].

When a mixture of a uranium compound with a catcher substance is irradiated with neutrons, fission fragments can be used for syntheses [28, 187–189]. The following reactions have been carried out (the yields are given in brackets; the uranium compound is not indicated:)

$$Cr(CO)_6 \longrightarrow {}^{99}Mo(CO)_6\ (60\,\%),\ {}^{99m}Tc(CO)_6$$
$$Fe(C_5H_5)_2 \longrightarrow {}^{103}Ru(C_5H_5)_2\ (60\,\%),\ C_5H_5FeC_5H_4{}^{131}I$$
$$C_6H_6 \longrightarrow C_6H_5{}^{131}I\ (60\,\%)$$
$$C_6H_5X \longrightarrow C_6H_5{}^{131}I,\ C_6H_4X{}^{131}I$$
$$\beta\text{-}C_{10}H_7Br \longrightarrow \beta\text{-}C_{10}H_7{}^{131}I\ (40\,\%)$$
$$CH_3COONH_4 \longrightarrow CH_3{}^{131}I$$
$$LiF \longrightarrow Xe\text{–}F\ \text{compounds.}$$

The first reaction permitted the rapid separation of the previously unknown nuclides ^{103}Mo, ^{104}Mo, and ^{105}Mo [190–192]. The decisive synthetic step in the labeling with fission fragments is the β^- decay of the precursor [193]. Syntheses induced by β decay are also known for liquids [194–196].

XII. Mössbauer Effect

Probably the greatest obstacle to an understanding of the chemical effects of nuclear transformations in solids is ignorance of the state of the recoil atom when it has come to rest. All the usual methods fail because of the low concentration of the defect centers.

However, it has now been found that the position and structure of the Mössbauer resonance lines depend on chemical bonding, *i.e.* on the charge and environment of the Mössbauer nucleus [197]. It is therefore possible to study the structure of individual atomic defects in the solid [198, 199]. In

contrast to the usual Mössbauer investigations, the compound to be investigated must be used as the Mössbauer radiation source, and not as the absorber.

^{57}Co decays ($\tau_{1/2}$ = 267 days) with electron capture to give an excited (14.4 keV) ^{57}Fe state. About one third of the new nuclides have the same charge as the ^{57}Co used and the rest have a higher positive charge, owing to the Auger effect. The excited ^{57}Fe state decays to the ground state with an average life of about 10^{-7} sec. Investigation of this transition by means of the Mössbauer effect provides information about the chemical state, *i.e.* the charge, of an iron atom 10^{-7} sec after its formation from ^{57}Co. The atomic environment of the 14.4 keV ^{57}Fe is the same as that of the original ^{57}Co, since the recoil after the decay of the latter is too small to cause displacements.

^{57}Co-doped CoO, ZnF_2, and NaF[200,201], as well as $^{57}CoCl_2$ that has separated out in NaCl[202], contain only Fe^{2+}, while isolated $^{57}Co^{2+}$ cations in NaCl give some Fe^{+}[203]. Both Fe^{2+} and Fe^{3+} are found in $^{57}Co^{III}(acac)_3$[204], $[^{57}Co^{III}(C_5H_5)_2]B(C_6H_5)_4$[205], (Fe, $^{57}Co)(NH_4)_2(SO_4)_2 \cdot 6H_2O$[201], $^{57}CoCl_2 \cdot 6H_2O$, $^{57}CoSO_4 \cdot 7H_2O$, $^{57}Co(NH_4)_2(SO_4)_2 \cdot 6H_2O$, and $^{57}CoSiF_6 \cdot 6H_2O$[206]. Small quantities of Fe^{4+} are also found in $^{57}Co(NH_4)_2(SO_4)_2 \cdot 6H_2O$ and $CoSiF_6 \cdot 6H_2O$.

^{129}I decays with β^- emission ($\tau_{1/2} = 1.6 \times 10^7$ years), to give an excited (40 keV) state of ^{129}Xe, which goes to the ground state with an average lifetime of 10^{-9} sec. The chemical state of the xenon depends on the starting compound[207].

$$^{129}I_2 \longrightarrow {}^{129}Xe^0?$$

$$Na^{129}I \longrightarrow {}^{129}Xe^0$$

$$Na^{129}IO_3 \longrightarrow {}^{129}XeO_3$$

$$K^{129}IO_4 \longrightarrow {}^{129}XeO_4$$

$$Na_3H_2{}^{129}IO_6 \longrightarrow \text{6 O octahedrally arranged around } {}^{129}Xe$$

$$K^{129}ICl_4 \cdot H_2O \longrightarrow {}^{129}XeCl_4 \ (\geqslant 75\,\%)$$

$$K^{129}ICl_2 \cdot H_2O \longrightarrow {}^{129}XeCl_2$$

(Nothing can be said about the stability of the $XeCl_4$ at a later time; $XeCl_2$ has recently been synthesized[208]).

The chemical effects of nuclear transformations would be directly comparable only with the results of Mössbauer investigations on nuclei produced by a nuclear process in the substance under investigation. However, all that is known is that the ^{56}Mn nuclei formed from $KMnO_4$ in (n,γ) reactions are in the form of Mn^{7+}, Mn^{4+}, and $Mn^{<4+}$, while ^{119m}Sn from both SnO_2 and SnO is entirely in the form of Sn^{4+}[209].

New Methods of Preparative Organic Chemistry V[1]

Organic Syntheses with Imides of Sulfur Dioxide

BY G. KRESZE AND W. WUCHERPFENNIG [*]

Cycloadditions and other reactions of compounds containing the groups N=SO and N=S=N are reviewed.

Two series of imides are derived from sulfur dioxide, *i.e.* the *N*-sulfinyl compounds R–N=SO and the sulfodiimides[1] R–N=S=N–R'. In the organic derivatives, R and R' may be alkyl or aryl groups, or organic groups attached to the N atom *via* heteroatoms.

The first compound of this class to be identified as such by *Michaelis* and *Herz*[2] was *N*-sulfinylaniline ("thionylaniline") *(1a)*, which was obtained by the reaction of aniline with $SOCl_2$:

$$C_6H_5{-}NH_2 + SOCl_2 \longrightarrow C_6H_5{-}NSO + 2\,HCl \qquad (1a)$$

This compound had been described even earlier by *Böttinger*[3], but its constitution had not been given.

In recent years the properties and behavior of such compounds have been reinvestigated by several research groups. It was found that these compounds, and particularly the extremely reactive *N*-sulfinylsulfonamides[4,5], can undergo

a wide variety of reactions and can be used for many syntheses. This use of the *N*-sulfinyl compounds is discussed below. Reviews dealing with the reactivity of the compounds, their physical properties, and their molecular structure have already been published [4,6]. These questions are not discussed here, nor is the chemistry of unsubstituted thionylimide HNSO [7]. Experimental details of the methods of preparation and reactions of *N*-sulfinyl compounds, which are only summarily referred to here, have been given in the first review article [4].

The first sulfodiimides were prepared in 1956 [8]. Benzo-2,1,3-thiadiazole (piazthiole) [9] could be formally regarded as a sulfodiimide, but the properties of this highly aromatic system are quite different from those of the "open-chain" sulfodiimides. In particular, piazthiole does not give the reactions of the N=S linkage that are characteristic of the other N=S=N compounds.

The classes of compounds that can be synthesized by reactions with imides of sulfur dioxide are listed in Table 1.

1. *N*-Sulfinyl Compounds

N-Sulfinyl compounds known so far are derived from aliphatic or aromatic amines, hydrazines [10,11,12], *O*-substituted hydroxylamines [13], acid hydrazides [12, 14,15], thiosemicarbazide [14], hydroxamide *O*-ethers $R{-}C(NOR')NH_2$ [16], sulfenamides [4], sulfonamides [4, 5], and dialkyl phosphoramidates $(RO)_2P(O)NH_2$ [17].

The *N*-sulfinylsulfonamides and the *N*-sulfinylamines have hitherto been most widely used for synthetic work and the preparation of these compounds will be described in detail. The *N*-sulfinyl derivatives of acid hydrazides

and thiosemicarbazide are thermally unstable [12,14,15], while with the hydrazones of benzaldehyde and benzophenone, nitrogen is liberated even under mild conditions during the preparation of the *N*-sulfinyl compound [12,16]. The *N*-sulfinylhydrazines, which are very stable to hydrolysis, have been used as acaricides [18,23].

1.1. Preparation of *N*-Sulfinylamines and *N*-Sulfinylsulfonamides

1.1.1. *N*-Sulfinylamines

N-Sulfinylamines are generally prepared from the amines with thionyl chloride in ether or benzene.

Treatment of aromatic amino acids [20], or their Pb or Ag salts [21], with $SOCl_2$ yields *N*-sulfinylaminoacyl chlorides.

The *N*-sulfinyl derivatives of sensitive amines can be advantageously prepared by "transsulfinylation", which is based on the equilibrium

$$R{-}NH_2 + R'{-}NSO \rightleftharpoons R{-}NSO + R'{-}NH_2.$$

The lower the basicity of the amino compound $R'{-}NH_2$ and the higher the basicity of $R{-}NH_2$, the farther is this equilibrium displaced to the right. Consequently, *N*-sulfinylsulfonamides $R{-}SO_2{-}NSO$ *(2)* are excellent sulfinylating agents (cf. also Section 1.2.4.3.).

1.1.2. *N*-Sulfinylsulfonamides

Sulfonamides *(3)* can also react with thionyl chloride [4],

$$\underset{(3)}{R{-}SO_2{-}NH_2} + SOCl_2 \longrightarrow \underset{(2)}{R{-}SO_2{-}NSO} + 2\,HCl.$$

The reaction proceeds smoothly when the sulfonamide is heated with an excess of thionyl chloride in the absence of solvents; in benzene it proceeds much slower than the reaction of amines, but gives good yields if the reaction mixture is heated under reflux for several days. The sulfinylation is complete when the sulfonamide has dissolved and (except in the case of the *p*-nitrobenzene derivative) is not reprecipitated even after the reaction solution has cooled.

Instead of the sulfonamides *(3)*, the Na salts of the *N*-chlorosulfonamides

$$R{-}SO_2{-}NClNa + SOCl_2 \longrightarrow \underset{(2)}{R{-}SO_2NSO} + NaCl + Cl_2,$$

or the *N,N*-dichlorosulfonamides may be treated with $SOCl_2$ to obtain *N*-sulfinylsulfonamides *(2)* [5].

$$R{-}SO_2{-}NCl_2 + SOCl_2 \longrightarrow \underset{(2)}{R{-}SO_2{-}NSO} + 2\,Cl_2$$

Table 2. Examples of *N*-sulfinylsulfonamides $R{-}SO_2{-}NSO$ *(2)*.

R	M.p. (°C)	Yield (%)	Method
CH_3	[a]	86	B

p-$NO_2{-}C_6H_4$	115–117	96	C

[a] B.p. = 80–81 °C/10^{-4} mm.

Procedures

N-Sulfinyl-p-toluenesulfonamide (2a) (method A)

100 g of *p*-toluenesulfonamide *(3a)* is refluxed for 8 h with 180 ml of $SOCl_2$. The excess of thionyl chloride is removed by distillation and the residue is then distilled at about 0.1 mm Hg. M.p. 53 °C, yield 75–80%.

N-Sulfinyl-p-chlorobenzenesulfonamide [4] (method B)

31 g of *p*-chlorobenzenesulfonamide and 13.5 ml of $SOCl_2$ are refluxed in 50 ml of dry benzene in the absence of moisture. After three days the sulfonamide has completely dissolved and is not reprecipitated on cooling. The solvent is removed at about 10 mm Hg and the brown, liquid residue is distilled in a high vacuum. 34 g (88%) of a yellow oil distils over and solidifies on cooling. B.p. 122–125 °C/10^{-4} mm, m.p. 52–53 °C.

N-Sulfinylarylsulfonamides (2) from Na Salts of N-Chloroarylsulfonamides [5] (method C)

0.15 mole of $SOCl_2$ is added dropwise to a suspension of 0.1 mole of the dry Na salt of *N*-chloroarylsulfonamide in benzene or CCl_4. The reaction mixture slowly becomes warm. After a time the precipitate of NaCl is removed by filtration and the solvent and excess of $SOCl_2$ are removed from the filtrate by distillation at reduced pressure. The oily residue of *N*-sulfinylarylsulfonamide crystallizes on cooling. Some examples of *N*-sulfinylsulfonamides prepared by methods A–C are given in Table 2.

N-Sulfinylarylsulfonamides (2) from N,N-Dichloroarylsulfonamides [5] (method D)

A mixture of 0.1 mole of *N,N*-dichloroarylsulfonamide and 0.15 mole of $SOCl_2$ is heated at 80–100 °C until the liberation of chlorine stops (2–4 h). The excess of $SOCl_2$ is distilled off under vacuum. The oily residue of *N*-sulfinylarylsulfonamide crystallizes on cooling. The yields are almost quantitative.

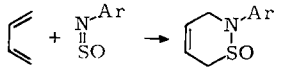
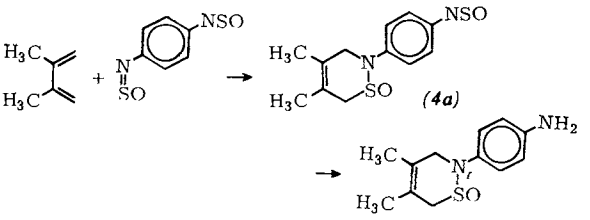
1.2. Reactions with *N*-Sulfinylamines and *N*-Sulfinylsulfonamides



1.2.1. General

The physical properties of the *N*-sulfinylaniline derivatives show that the S=N bond of the *N*-sulfinyl compounds is to be regarded as a four-electron bond, and can enter into conjugative interaction with adjacent π-electron systems [4]. The bond is also polar, with the S atom as the positive end and the N atom as the negative end of the dipole. These structural considerations offer an explanation of the reactions of the *N*-sulfinyl compounds. Thus the substances enter into many cycloadditions with formation of six-membered, five-membered, or four-membered rings; they can add on reagents of the form HX and their analogues by a polar mechanism; and they can react with electrophilic or nucleophilic reagents in general. These reactions are discussed in the following section. In preparative work it should be noted that the primary addition products are often unstable and are readily converted into other compounds.

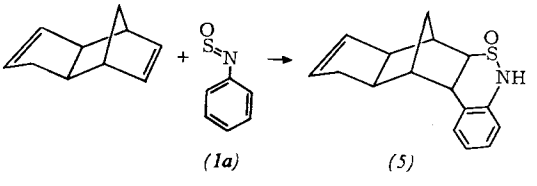
1.2.2. Cycloadditions



1.2.2.1. Preparation of 3,6-Dihydro-1,2-thiazine Derivatives, δ-Sultams, *N*-Alk-3-enylsulfonamides and *N*-Arylpyrroles

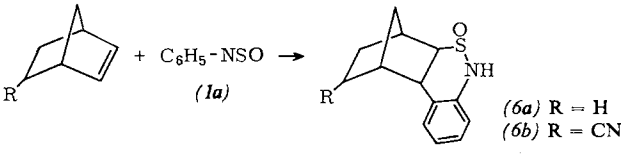
The diene synthesis with *N*-sulfinylarylamines as dienophiles was described by *Wichterle* and *Roček* in 1953 [25–27].

(1) *(4)*



This addition takes place with all aromatic *N*-sulfinylamines *(1)*; aliphatic *N*-sulfinylamines do not react. The reactants are heated in the absence of a solvent, since the reaction is very slow in solution. An excess of diene is generally beneficial. The product often darkens when heated and vigorous decomposition sometimes occurs at higher temperatures. Polar (and probably also steric) effects of substituents on the benzene nucleus of the *N*-sulfinylarylamines have no apparent influence on the reaction. Though the *N*-sulfinylnitroarylamines react somewhat faster than N-sulfinylaniline *(1a)*, adducts are formed even by derivatives having donor substituents (such as *N*-sulfinyl-*p*-anisidine). The bis-*N*-sulfinyl derivative of *p*-phenylenediamine forms only a monoadduct *(4a)*, which reacts with water to give the amino compound.

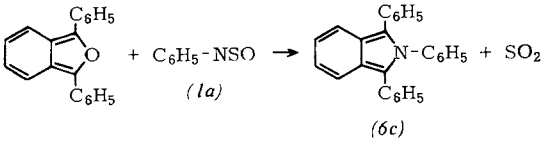
(4a)



On the other hand, the steric hindrance due to substituents in positions 1 and 4 of the diene component greatly affects the rate of reaction, as do polar effects. Thus butadiene and 2-substituted and 2,3-disubstituted derivatives react normally, while butadienes with substituents at the ends of the diene system react only with difficulty, if at all. Though adducts of 1-methyl- and 1-*p*-nitrophenylbutadiene are known [28], no Diels-Alder adducts have so far been isolated with 1-acetoxybutadiene, sorbic acid (2,4-hexadienoic acid), ethyl sorbate, sorbic alcohol (2,4-hexadien-1-ol), or cyclohexadiene.

According to *Collins* [29], the 2:1 adduct obtained by the reaction of dicyclopentadiene with *N*-sulfinylaniline *(1a)* [28] has the structure *(5)*.

(1a) *(5)*



Norbornene and its 5-cyano derivative react analogously to give *(6a)* and *(6b)* respectively.

(1a) *(6a)* R = H *(6b)* R = CN

In these cases the *N*-sulfinylaniline acts not as a dienophile, but as a diene.

The reaction of *N*-sulfinylaniline *(1a)* with 1,3-diphenylisobenzofuran is anomalous [30]. The reaction without a solvent yields 46% of 1,2,3-triphenylisoindole *(6c)*. The same compound is formed in a higher yield when the reactants are heated for 13 hours in benzene in the presence of $BF_3 \cdot O(C_2H_5)_2$.

(1a) *(6c)*

The adducts *(4)* can be converted into *N*-aryl-δ-sultams *(7)*, while reduction with $LiAlH_4$ leads to 3,6-dihydro-1,2-thiazines *(8)*.

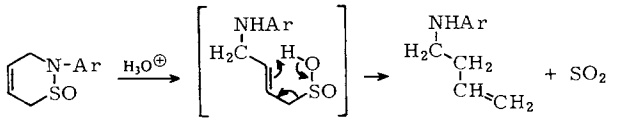
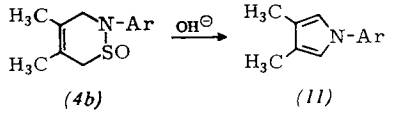
[30] *M. P. Cava* and *R. H. Schlessinger*, J. org. Chemistry *28*, 2464 (1963).



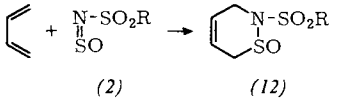
(7) (4) (8)

Desulfuration of the adduct *(6a)* with Raney nickel in ethanol yields the hexahydrocarbazole derivative *(9)* (70% yield).



(6a) (9)

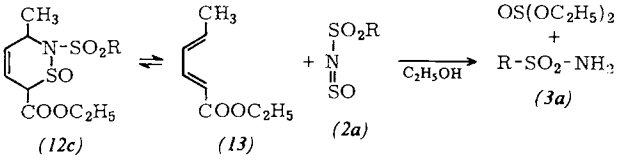
On acid hydrolysis, the *N*-aryl-3,6-dihydro-1,2-thiazine 1-oxides *(4)* lose SO_2 and the double bond migrates to give *N*-alk-3-enylarylamines *(10)*, the formation of which has been explained by *Wichterle* [25,26] as follows:



(4) (10)

The alkaline hydrolysis of the adducts *(4)* also follows an anomalous course. When the adducts are heated with alcoholic KOH, the pyrrole derivatives *(11)* are obtained, the yield being practically quantitative in the case of the 2,3-dimethylbutadiene adducts *(4b)* [25,26,31].

(4b) (11)

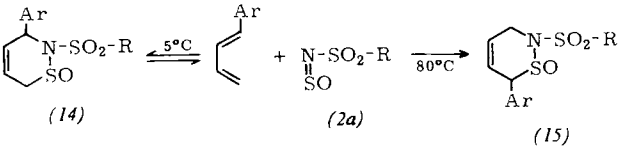


The reactivity of the NSO group in cycloadditions is generally increased by strongly electron-attracting substituents on the N atom, and is sometimes even qualitatively changed [4]. This is observed in particular in the diene synthesis with *N*-sulfinylsulfonamides *(2)* [4,24,32]. In nearly every case, these add readily and in excellent yield. The reaction is generally exothermic, and when carried out without a solvent can lead to an explosion. It is therefore recommended that an inert solvent such as benzene should be used, and that the reaction mixture should be cooled initially. The reaction is allowed to proceed to completion by prolonged standing at room temperature or by heating, and in many cases the adducts *(12)* crystallize out.

(2) (12)

All the *N*-sulfinylsulfonamides *(2)* studied so far are very reactive in the diene synthesis. However, the structure of the diene has the same influence as in the Diels-Alder reaction with *N*-sulfinylamines *(1)*. Thus butadiene, isoprene, 2,3-dimethylbutadiene, 2-chlorobutadiene, and cyclohexadiene react rapidly at room temperature, 2,3-dichlorobutadiene and 1-*p*-nitrophenylbutadiene react at a moderate rate, and ethyl sorbate reacts very slowly. 2-Chlorocyclohexa-1,3-diene reacts only on standing for several months. No adducts are obtained with hexachlorocyclopentadiene, either at room temperature or on heating.

The Diels-Alder reaction is reversible in some cases. Thus the adduct *(12c)* of ethyl sorbate *(13)* and *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* is converted back into the starting materials when heated in alcoholic solution, *p*-toluenesulfonamide *(3a)* and diethyl sulfite being formed by a secondary reaction.



(12c) (13) (2a) (3a)

R = p–CH_3–C_6H_4

The adduct of cyclopentadiene and *N*-sulfinylbenzenesulfonamide can be isolated at low temperatures, but decomposes into its components at room temperature. *Hamer* [33] found the following data for this equilibrium in CH_2Cl_2:

25 °C	$K = 11.21$	$\Delta H° = -13.9$ kcal/mole
20 °C	$K = 18.81$	$\Delta G°_{25} = -1.4$ kcal/mole
15 °C	$K = 23.78$	$\Delta S°_{25} = -41.9$ e.u.
10 °C	$K = 35.87$	

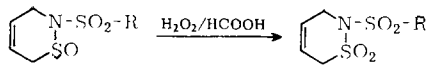
This reversibility can also be seen in the mutual orientation assumed by the components in the Diels-Alder reaction. Thus 1-arylbutadienes react in benzene with *N*-sulfinyl-*p*-toluenesulfonamide in the cold to give 3-aryldihydrothiatine derivatives *(14)*, whereas the reaction under reflux leads to 6-aryldihydrothiazines *(15)*. The isomers *(15)*, which can be obtained from *(14)* by heating in benzene, are the thermodynamically more stable products, probably because of mutual hindrance of the aryl- and toluenesulfonyl groups in *(14)* [34].

(14) (2a) (15)

R = p–CH_3–C_6H_4

The 3-aryldihydrothiazine derivatives *(14)* and the adducts of the *N*-sulfinylsulfonamides *(2)* with 2-substituted butadienes (2-methyl-, 2-chloro-, and 2-phenylbutadiene) obey the empirical rule for orientation in the Diels-Alder reaction, which had been established in the analogous cycloadditions of nitrosobenzenes [35]. According to this rule, the orientation corresponds to that of a diene synthesis with a vinyl compound CH_2=CHX if the C^1 of the vinyl compound is replaced by the N atom of the *N*-sulfinylsulfonamide and C^2 by the S atom.

Like the *N*-aryldihydrothiazines *(4)*, the *N*-arylsulfonyldihydrothiazines *(12)* give sultams *(16)* on oxidation, preferably with H_2O_2 in acid media.



[31] *J. Roček*, Chem. Listy *47*, 1781 (1953); Coll. czechoslov. chem. Commun. *19*, 275 (1954), Chem. Abstr. *49*, 1055b (1955).

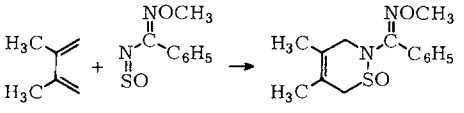
[33] *J. Hamer* and *A. Macaluso*, J. org. Chemistry *31*, 3049 (1966).

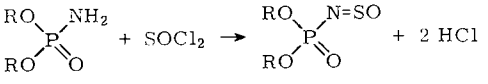
[34] *G. Kresze, U. Wagner*, and *W. Wucherpfennig*, unveröffentlicht.

[35] *G. Kresze* and *J. Firl*, Tetrahedron Letters *1965*, 1163.



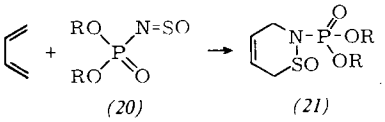
(12) (16)

However, reduction of *(12)* to the 3,6-dihydro-1,2-thiazines has not so far been observed. *(4)* and *(12)* also differ in their behavior on hydrolysis. Both acidic and alkaline hydrolysis of *(12)* lead to the same products, *N*-alk-3-enylsulfonamides *(17)* [cf. the formation of *(10)* or *(11)* from *(4)*].



(12) (17)

N-Sulfinylbenzhydroxamide-*O*-methyl ether *(18)* can also react as a dienophile; with 2,3-dimethylbutadiene it forms the adduct *(19)* [16].



(18) (19)

The activation is not so pronounced in the case of the dialkyl *N*-sulfinylphosphoramidates *(20)* which result from the reaction of the esters *(20a)* with $SOCl_2$ [17].

(20a) (20)

The diethyl compound does not react with dienes at room temperature, but gives a Diels-Alder adduct *(21)* when butadiene is passed through a boiling solution in benzene.

(20) (21)

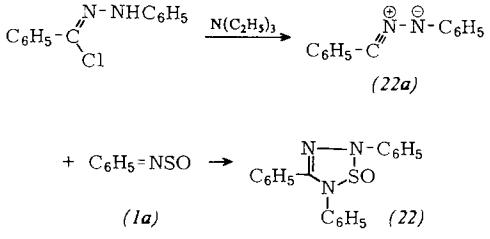
Procedures [*]

4,5-Dimethyl-2-phenyl-3,6-dihydro-1,2-thiazine [25, 26]

2.2 g of 4,5-dimethyl-2-phenyl-3,6-dihydro-1,2-thiazine 1-oxide is extracted for 45 min in an extraction apparatus with a boiling solution of 0.2 g of $LiAlH_4$ in 50 ml of anhydrous ether. 3 ml of water are added to the cooled reaction mixture to destroy the unreacted $LiAlH_4$. Removal of the ether by evaporation leaves 1.94 g of a yellowish oil which slowly crystallizes. Repeated recrystallization from methanol yields large rhombic plates having m.p. 93–94 °C.

1-o-Tolyl-3,4-dimethylpyrrole ((11), Ar = o-Tolyl) [31]

2.35 g of 2-*o*-tolyl-4,5-dimethyl-3,6-dihydro-1,2-thiazine 1-oxide is heated for 1.5 hours with 2 g of KOH in 25 ml of ethanol. The reaction mixture is poured into water and extracted with ether; the ether phase is then dried and evaporated to dryness. Yield 96%, m.p. 52–53 °C (coarse needles from methanol/water).

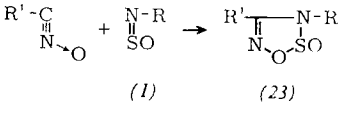


[*] The procedures given here are supplementary to those which appeared in the previous review [4]

1.2.2.2. Preparation of 2,5-Dihydro-1,2,3,5-thiatriazoles, 1,2,3,5-Oxathiadiazoles, *N*-Arylsulfonylformamidines, and Carbodiimides

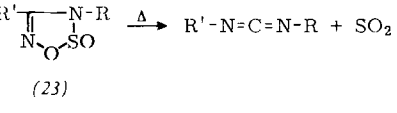
Both *N*-sulfinylamines and *N*-sulfinylsulfonamides undergo 1,3-dipolar additions readily and give good yields. If the initially formed five-membered heterocyclic compound loses SO_2, the products of thermolysis rearrange.

The following components have been used so far:



a) The nitrilimine *(22a)* (prepared *in situ* from benzoyl chloride phenylhydrazone and triethylamine) combines with *(1a)* to form 2,4,5-triphenyl-2,5-dihydro-1,2,3,5-thiatriazole 1-oxide *(22)* in 87% yield [36].

(22a)



(1a) (22)

b) Nitrile oxides react exothermically with *N*-sulfinyl compounds to form 3*H*-1,2,3,5-oxathiadiazole 2-oxides *(23)*, in some cases quantitatively [37, 38].

(1) (23)

The 1,3-dipole component may be prepared *in situ*, aromatic components being prepared from the hydroxamyl chlorides and triethylamine, and the aliphatic components from the corresponding nitro compounds and isocyanates [38]. Pyrolysis of the oxathiadiazoles *(23)* leads almost quantitatively to carbodiimides, which can generally be synthesized by this route.

(23)

c) The primary adducts formed in the reaction of nitrones with *N*-sulfinylsulfonamides *(2)* are so unstable that, owing to the strongly exothermic nature of the reaction, only the secondary products, arylsulfonylformamidines *(24)*, can be isolated even at low temperatures [39, 40].

(2)

(24)

Procedures

4-(p-Chlorophenyl)-3-(p-toluenesulfonyl)-1,2,3,5-oxathiadiazole 2-Oxide ((23), R' = p-Cl-C_6H_4, R = p-CH_3-C_6H_4-SO_2) [37b]

5.1 g of anhydrous triethylamine is added rapidly, with vigorous stirring, to an ice-cooled solution of 9.5 g of *p*-chlorobenzhydroxamyl chloride in 250 ml of anhydrous ether. After a few minutes the trimethylammonium chloride is filtered off and washed with a little anhydrous ether. 10.9 g of *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* is added to the combined filtrates. The mixture is allowed to stand at room temperature for two hours and is then filtered, the filtrate is evaporated to dryness under vacuum, and the residue is recrystallized from n-hexane. Yield 8.5 g, m.p. 89–90 °C.

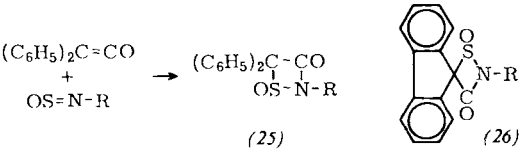
Carbodiimides [37b]

1,2,3,5-Oxathiadiazole 2-oxide in a small flask is heated at, or slightly above, its melting point in an oil bath. Moisture is excluded and a slow current of nitrogen is passed through the tube until the evolution of SO_2 stops. The flask is allowed to cool and the carbodiimides are recrystallized from hexane or benzene/hexane; liquid carbodiimides are isolated by distillation.

2,4,5-Triphenyl-2,5-dihydro-1,2,3,5-thiatriazole 1-Oxide (22) [36]

1.5 ml of triethylamine is added to a solution of 0.92 g of benzoyl chloride phenylhydrazone and 1.85 g of *N*-sulfinylaniline *(1a)* in 10 ml of boiling benzene; triethylammonium chloride is precipitated. The reaction mixture is heated for 1 hour and is then kept at room temperature for 2 hours. The reaction mixture is filtered and the filtrate is evaporated to dryness under vacuum. The crystalline residue is recrystallized from ethanol; yield 87%, m.p. 122.5–123.5 °C.

N^2-Benzene sulfonyl-N^1,N^1-diphenylformamidine [40]

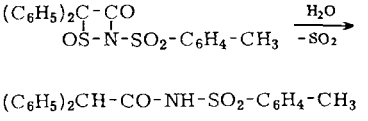


A solution of 2.5 g of *C*,*N*-diphenylnitrone in 10 ml of anhydrous benzene is added to a solution of 2.5 g of *N*-sulfinylbenzenesulfonamide in 30 ml of anhydrous benzene. The mixture becomes warm and SO_2 is evolved. After a few minutes the product begins to crystallize. Crude yield 2.5 g (59%), m.p. 187–188 °C. The substance can be recrystallized from acetone/dioxane (2:1).

1.2.2.3 Preparation of 1,2-Thiazetidin-3-one 1-Oxides

Aliphatic or aromatic *N*-sulfinylamines *(1)* and *N*-sulfinylsulfonamides *(2)* react with diphenylketene, generally at room temperature, to give *N*-substituted 4,4-diphenyl-1,2-thiazetidin-3-one 1-oxides *(25)* in good yields [4,41].

[41] *H. Beecken* and *F. Korte*, Tetrahedron *18*, 1527 (1962).

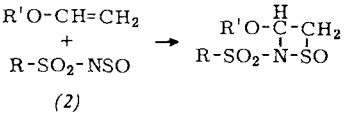


Biphenyleneketene (9-carbonylfluorene) reacts in the same way with *N*-sulfinylamine to give the spiro compounds *(26)* [41].

(25)

(26)

The diphenylketene adduct of *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* can be readily hydrolysed to form *N*-(diphenylacetyl)-*p*-toluenesulfonamide *(26a)* [4].



(26a)

N-Substituted diphenylacetamides are obtained from the sulfinylamine adducts by treatment with concentrated hydriodic acid or with methanolic KSH [41].

No ketene adducts of sulfinylaniline or sulfinylcyclohexylamine have so far been isolated; in the second case, sublimation in a high vacuum gave *N*-cyclohexylacetamide and *N*,*N*-dicyclohexyloxamide as secondary products.

The addition of *N*-sulfinylsulfonamides *(2)* to enol ethers is exothermic and takes place under mild conditions. In contrast to the *N*-(arylsulfonyl)isocyanate/enol ether adducts, which are readily converted into β-alkoxyacrylamides [42], the 3-alkoxy-1,2-thiazetidine 1-oxide derivatives are stable [43].

(2)

1.2.3. Reactions with Carbonyl and Sulfinyl Compounds and their Analogues

The reactions of *N*-sulfinylsulfonamides *(2)* with the groups >C=O, >C=N–, >C=S, >S=O, or >P=O vary according to the other substituents on the reactants. In many cases the reaction consists in the replacement of the *N*-aryl-(or alkyl)-sulfonylimino group by the O or S atom or by the NR group of the other reactant. On the basis of the reaction products and the feasibility of the intermediate formation of a four-membered ring, these reactions have been referred to as "quasi-Wittig reactions" [44–46]. The mechanism of the reactions is

[42] *F. Effenberger* and *R. Gleiter*, Chem. Ber. *97*, 1576 (1964).

[43] *F. Effenberger* and *R. Gleiter*, Angew. Chem. *75*, 1117(1963); Angew. Chem. internat. Edit. *3*, 142 (1964); Chem. Ber. *99*, 3963 (1966).

[44] *G. Kresze* and *R. Albrecht*, Angew. Chem. *74*, 781 (1962); Angew. Chem. internat. Edit. *1*, 595 (1962).

[45] *G. Schulz* and *G. Kresze*, Angew. Chem. *75*, 1022 (1963); Angew. Chem. internat. Edit. *2*, 736 (1963).

[46] *A. Senning*, Acta chem. scand. *18*, 1958 (1964).

still largely uncertain. A mechanism similar to that of a Wittig reaction cannot be assumed in the reaction with thionamides[14], and the stereochemistry of the sulfoxide reaction also indicates a different course[47].

1.2.3.1. Preparation of Sulfonylimines, Tetrahydropyridines, Pyridines, and Azetidines

When *N*-sulfinylsulfonamides *(2)* are heated with aldehydes having no α-H atoms, SO_2 is eliminated and *N*-sulfonylimines *(27)* are formed in good yields[44,48].

$$R\text{-}SO_2\text{-}NSO + R\text{-}CH{=}O \longrightarrow R\text{-}SO_2\text{-}N{=}CH\text{-}R' + SO_2$$
(2) *(27)*

The reaction is often catalysed by $AlCl_3$, BF_3, HCl, or similar substances. The *N*-*p*-toluenesulfonylimine of n-butyl glyoxalate [*(27a)*, R = *p*-CH_3–C_6H_4, R′ = $COOC_4H_9$] can also be obtained by this method[49]. Aliphatic aldehydes give poorer yields of 1,1-bis(arylsulfonamido)alkanes, as does polymeric trifluoroacetaldehyde. However, the sulfonylimine can be obtained by an indirect route; the hydrate of trifluoroacetaldehyde reacts with *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* to form *N*-(2,2,2-trifluoro-1-hydroxyethyl)-*p*-toluenesulfonamide, whose *O*-acetyl derivative loses acetic acid on vacuum distillation to give 2,2,2-trifluoroethylidene-*p*-toluenesulfonamide *(27b)*[50].

$$CF_3\text{-}CH(OH)_2 + R\text{-}SO_2\text{-}NSO \rightarrow CF_3\text{-}\underset{\displaystyle OH}{\underset{|}{CH}}\text{-}NH\text{-}SO_2\text{-}R$$
(2a)

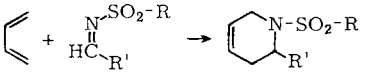
$$\xrightarrow{(CH_3CO)_2O} CF_3\text{-}\underset{\displaystyle OCOCH_3}{\underset{|}{CH}}\text{-}NH\text{-}SO_2\text{-}R \rightarrow CF_3\text{-}CH{=}N\text{-}SO_2\text{-}R$$
(27b)

R = p-CH_3-C_6H_4

N-Sulfinylaniline *(1a)* reacts with benzaldehyde on heating to give benzylideneaniline. However, this reaction is slower than the analogous reaction of the *N*-sulfinylsulfonamides *(2)*; an earlier report[51] of a fast exothermic reaction with formation of crystalline products could not be confirmed[48].

The reactivity of the C=N double bond in the *N*-sulfonylimines *(27)* is higher in some cases and lower in others than in normal imines. The C=N bond of the compounds derived from aromatic aldehydes is often cleaved on addition of HX, *e.g.* in the reaction with acetic acid or water. Stable adducts are obtained with thiophenol and esters of thioglycolic acid; sodiomalonic ester can also be added as an active methylene component.

$$R\text{-}SO_2\text{-}N{=}CH\text{-}R' \xrightarrow{C_6H_5SH} R\text{-}SO_2\text{-}NH\text{-}\underset{\displaystyle SC_6H_5}{\underset{|}{CH}}\text{-}R'$$
(27)

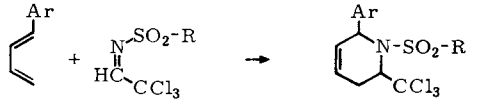


$$\downarrow CH_2(COOC_2H_5)_2 \qquad HSCH_2\text{-}COOC_2H_5 \searrow$$

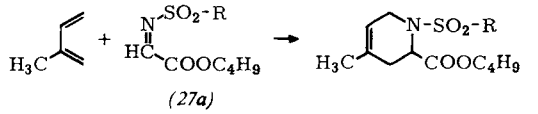
$$R\text{-}SO_2\text{-}NH\text{-}\underset{\displaystyle CH(COOC_2H_5)_2}{\underset{|}{CH}}\text{-}R' \qquad R\text{-}SO_2\text{-}NH\text{-}\underset{\displaystyle SCH_2\text{-}COOC_2H_5}{\underset{|}{CH}}\text{-}R'$$

R″ = Ar

The compound derived from chloral [*(27)*, R′ = CCl_3] also gives stable adducts with water, ethanol, aniline, and *p*-toluenesulfonamide.



Electron-accepting substituents on a multiple bond generally increase the reactivity of this bond in Diels-Alder reactions. This effect is also observed with the *N*-sulfonylimines *(27)*. Sulfonylimines containing an aromatic group do not form adducts when heated in benzene with dienes, despite the electron-attracting action of the sulfonyl group; however, if the C atom of the CN bond also carries an electron-attracting group, as in *(27a)*, *(27b)*, and *(27c)*, adducts *(28)* are formed under the above conditions[50].

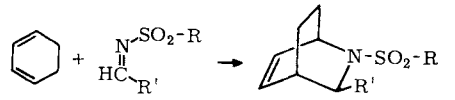


(27) *(28)*

(a) R′ = $COOC_4H_9$, R = *p*-CH_3–C_6H_4
(b) R′ = CF_3, R = *p*-CH_3–C_6H_4
(c) R′ = CCl_3, R = *p*-CH_3–C_6H_4

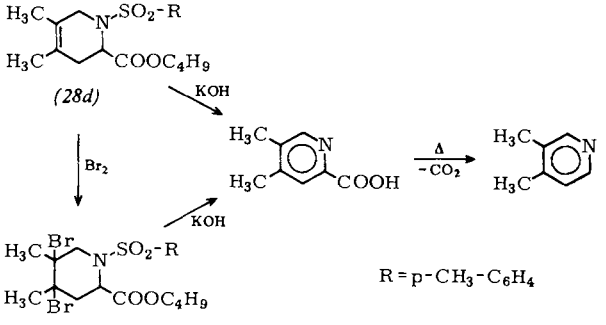
1-Arylbutadienes[34] and isoprene[49] form only one of the two possible isomeric adducts.

(27c)



(27a)

R = p-CH_3-C_6H_4

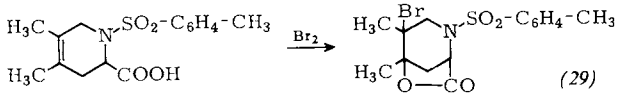


If, as is suggested by the addition reactions of the sulfonylimines, the C atom of the sulfonylimines is regarded as the positive end of the CN bond dipole and is taken to be equivalent to the β-C atom of CH_2=CHX dienophiles, the observed orientation is again in agreement with our empirical rule[35] (cf. Section 1.2.2.1).

The sulfonylimines *(27b)* and *(27a)* derived from trifluoracetaldehyde and from butyl glyoxalate react with cyclohexa-1,3-diene to form the 2-azabicyclo[2.2.2]oct-5-ene system[49, 50].

(27)

While acid hydrolysis of butyl *N*-*p*-toluenesulfonyl-1,2,3,6-tetrahydropyridine-2-carboxylate *(28a)* yields the carboxylic acid, alkaline hydrolysis also leads to elimination of *p*-toluenesulfinic acid and disproportionation; thus alkaline hydrolysis of the isoprene adduct followed by decarboxylation gives γ-picoline, while the 2,3-dimethylbutadiene adduct



(28d)

R = p-CH_3-C_6H_4

(28d) gives 4,5-dimethylpyridine-2-carboxylic acid, and hence 3,4-lutidine [49]. The yields can be improved if the adduct is first brominated and then hydrolysed with alkali; the pyridine ring system is then formed by simultaneous elimination of sulfinic acid and HBr [34].

Bromination of the free carboxylic acid corresponding to *(28d)* yields the bicyclic bromolactone *(29)* [52].

(29)

The sulfonylimines *(27)* also undergo cycloaddition with keteneaminals or enamines. 2-Aminoazetines or azetidines can be obtained in this way [53].

Procedures

N-Benzylidene-p-toluenesulfonamide ((27), R = p-CH₃–C₆H₄) [54]

A slow current of dry HCl gas is passed through a solution of 0.1 mole of benzaldehyde and 0.1 mole of *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* in 50 ml of benzene, and the solution is heated to boiling and refluxed in the HCl stream for 1 hour. The benzene is removed by distillation under vacuum and the residue is recrystallized from ethanol. Yield 98%, m.p. 107 °C.

2-(p-Toluenesulfonyl)-3-trifluoromethyl-2-aza-bicyclo[2.2.2]oct-5-ene [50]

A mixture of 3.2 g of *N*-trifluoroethylidene-*p*-toluenesulfonamide *(27b)* and 1.1 g of cyclohexa-1,3-diene is refluxed for 7.5 hours in 7 ml of anhydrous benzene. The solvent is evaporated, and the residue is recrystallized from ethanol. Yield 4.0 g (95 %), m.p. 90 °C.

n-Butyl 4,5-Dimethyl-1-(p-toluenesulfonyl)-1,2,3,6-tetrahydropyridine-2-carboxylate (28d) [49,55]

A mixture of 14.0 g of *N*-(n-butoxycarbonylmethylene)-*p*-toluenesulfonamide *(27a)* and 4.1 g of dimethylbutadiene is heated for 10 hours in 25 ml of anhydrous benzene. The solvent is then evaporated under vacuum. The crude ester is obtained in a yield of 89%, and can be purified by chromatography on silica gel ($CHCl_3$).

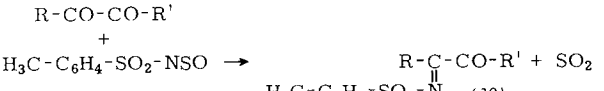
[54] *D. Sommerfeld*, Dissertation, Technische Hochschule München, 1966.

[55] *U. Wagner*, Diploma Thesis, Technische Hochschule München, 1965.

n-Butyl 4,5-Dibromo-4,5-dimethyl-1-(p-toluenesulfonyl)piperidine-2-cavboxylate [55]



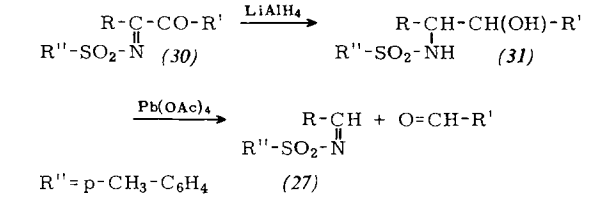
A solution of 5.7 g of bromine in 15 ml of CCl_4 is added dropwise to 13 g of n-butyl 4,5-dimethyl-1-(*p*-toluenesulfonyl)-1,2,3,6-tetrahydropyridine-2-carboxylate *(28d)* in 15 ml of CCl_4, with cooling in ice. The reaction mixture is allowed to stand overnight, the solvent is distilled off under vacuum, and the residue is extracted with 20% $Na_2S_2O_3$ solution. Yield 58.5%, m.p. 103–105 °C (from ethanol).

2-Carboxy-4,5-dimethylpyridinium Chloride Hydrate [55]

2.9 g of n-butyl 4,5-dibromo-4,5-dimethyl-1-(*p*-toluenesulfonyl)piperidine-2-carboxylate is heated for 4.5 hours with 4 g of KOH in 30 ml of absolute ethanol. Water is added and the alcohol is distilled off. The aqueous solution is extracted with ether to remove unhydrolysed material, and is then acidified with HCl and again extracted with ether. The aqueous phase is evaporated to dryness, and the residue is extracted with 50 ml of boiling ethanol. The ethanol is filtered and evaporated to dryness. The resulting residue is heated for 30 min with 10 ml of concentrated HCl, the solution is evaporated to dryness, and the residue is recrystallized from tetrahydrofuran/glacial acetic acid (1:1) with the addition of a little concentrated HCl. Yield 63%, m.p. 228 °C.

1.2.3.2. Preparation of Sulfonylimines, Sulfonylformamidines, and Nitriles

While benzophenone does not react with *N*-sulfinyl-*p*-toluenesulfonamide *(2a)*, even in the presence of $AlCl_3$, benzil reacts in the same way as benzaldehyde when heated with *(2a)* in benzene, with smooth formation of benzil mono-*p*-toluenesulfonylimine *(30a)*. Further reaction to form benzil diimine derivatives was not observed even in the presence of excess of *(2a)* [56].



(2a) *(30)*

(a) R = R′ = C_6H_5
(b) R = *p*-Cl–C_6H_4, R′ = C_6H_5
(c) R = R′ = *p*-Cl–C_6H_4
(d) R = R′ = *p*-H_3C–C_6H_4

p-Chloro-, *p,p′*-dichloro, and *p,p′*-dimethylbenzil react in a similar manner, whereas no reaction occurs with *p*-methoxy- and *p,p′*-dimethoxybenzil, the starting materials being recovered unchanged in these cases.

Derivatives of benzil mono-*N*-toluenesulfonylimine are generally more resistant to hydrolysis than the *N*-arylsulfonylimines derived from benzaldehyde; however, the benzil derivatives are readily hydrolysed by heating with dilute sulfuric acid, to give the original benzil derivative and sulfonamide. The derivative *(30c)* of *p,p′*-dichlorobenzil is relatively stable under these conditions, and unlike *(30a)*, it cannot be reduced with $NaBH_4$. All benzil mono-*N*-sulfonylimines are reduced to the amino alcohol *(31)* by $LiAlH_4$.

(30) *(31)*

(27)

[56] *G. Kresze, D. Sommerfeld*, and *R. Albrecht*, Chem. Ber. *98*, 601 (1965).

This reduction can be used for the determination of the constitution of the product *(30b)* from *p*-chlorobenzil and *N*-sulfinyl-*p*-toluenesulfonamide *(2a)*. According to Criegee [57], *N*-toluenesulfonylamino alcohols are cleaved by lead tetraacetate with formation of *N*-toluenesulfonylimines. When treated in this way, *(30b)* gave benzaldehyde and the expected *p*-chlorobenzaldehyde *p*-toluenesulfonylimine [*(27)*, R = *p*-Cl–C_6H_4], which was also synthesized for comparison from *p*-chlorobenzaldehyde and *(2a)*.

Thus electron-acceptor groups generally favor the reaction of benzil derivatives with *N*-sulfinyl-*p*-toluenesulfonamide *(2a)*. In *p*-chlorobenzil, the reaction takes place on the carbonyl group from which the electrons are more strongly withdrawn. Strong electron donor groups, such as a methoxy group in the *p*-position, hinder the reaction.

Diacetyl also reacts with *N*-sulfinyl-*p*-toluenesulfonamide *(2a)*; analysis and the IR and NMR spectra show that the *N*-(*p*-toluenesulfonyl)-enamine *(32)*, *i.e.* the tautomeric form of the *N*-(*p*-toluenesulfonyl)-monoimine, is formed in this case.

$$H_2C=C(NH-SO_2-C_6H_4-CH_3)-COCH_3 \qquad (32)$$

Formamide reacts with *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* with elimination of water and formation of hydrocyanic acid. *N,N*-Disubstituted formamides react similarly to the aromatic aldehydes, with loss of SO_2 to form N^1,N^1-disubstituted N^2-arylsulfonylformamidines *(24)* [48].

$$\underset{(2)}{R-SO_2-NSO} + O=CH-NR'_2 \longrightarrow \underset{(24)}{R-SO_2-N=CH-NR'_2} + SO_2$$

In this case the *N*-sulfinylarylsulfonamides *(2)* react similarly to *N*-arylsulfonylisocyanates [58].

The reaction of aromatic acyl chlorides with *N*-sulfinylsulfonamides *(2)* leads to *N*-sulfonylimide chlorides, which decompose under the conditions of the reaction or at higher temperatures to give a nitrile and a sulfonyl chloride [52].

$$\underset{(2)}{R-SO_2-NSO} + Ar-COCl \longrightarrow R-SO_2-N(Cl)-C-Ar + SO_2$$

$$\longrightarrow Ar-C\equiv N + R-SO_2Cl$$

Benzaldehyde azine [59] and benzylideneaniline [46] react in the same way as benzaldehyde, the reactions with *N*-sulfinylbenzenesulfonamide leading to benzylidenequenzenesulfonamide.

Procedures

Benzil Mono-N-p-toluenesulfonylimine (30a) [56]

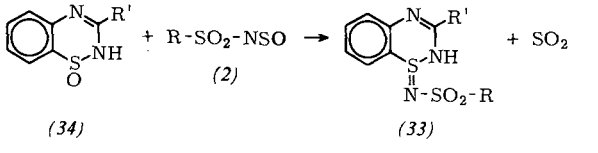
5.5 g of dry benzil and a little $AlCl_3$ are added to 11.0 g of *N*-sulfinyl-p-toluenesulfonamide *(2a)* in 15 ml of anhydrous benzene. The mixture is heated for 1.5 hours in the absence of moisture. Small quantities of $AlCl_3$ are added at half hourly intervals. The mixture is cooled, the benzene is removed by distillation under vacuum, and the residue is extracted by boiling with 150 ml of a mixture of petroleum ether and CCl_4 (2:1 v/v). When the filtered solution is cooled, 8.4 g (68 %) of benzil mono-*N*-*p*-toluenesulfonylimine crystallizes. M.p. 132 °C (from ethanol).

N^1,N^1-Dimethyl-N^2-(p-toluenesulfonyl)-formamidine [48]

A mixture of 2.0 g of *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* and 1.5 g of dimethylformamide is strongly heated for 8 min. The melt is cooled and recrystallized from ethanol. Yield 2.0 g (96 %), m.p. = 135–137 °C.

1.2.3.3. Preparation of Sulfimines and Phosphine Imides

Aliphatic sulfoxides react very readily with *N*-sulfinylsulfonamides *(2)*, in some cases exothermally, when solutions of the reactants are brought together in an inert solvent such as benzene [45].



$$R'R''SO + \underset{(2)}{R-SO_2-NSO} \longrightarrow R'R''S=N-SO_2-R + SO_2$$

In some cases the resulting *N*-sulfonylsulfimides crystallize after a short time. In the case of aromatic sulfoxides the reactants must be heated for several hours at 80 to 100 °C in benzene, or in the absence of solvents; the reaction products are not so pure, and the yields are lower. *N*-Sulfinylaniline *(1a)* and its *p*-nitro derivative do not react with sulfoxides under the above conditions. When methyl sulfoxides are used, excessively vigorous reaction can lead to the formation of methane-bis(sulfonamide) derivatives as by-products.

Sulfinyl diamides react in the same way as sulfoxides [16]:

$$[(C_2H_5)_2N]_2SO + \underset{(2)}{R-SO_2-NSO} \longrightarrow [(C_2H_5)_2N]_2S=N-SO_2-R$$

Sulfinic acid derivatives also react in this way. Thus benzothiadiazineimines *(33)* are obtained from benzothiadiazine 1-oxides *(34)* by reaction with *N*-sulfinylsulfonamides *(2)* [60].

(34) *(33)*

Triphenylphosphine oxide, sulfide, *N*-phenylimide, and *O,O,O*-triethyl thiophosphate also undergo "transsulfonylimination" [61,62],

$$(C_6H_5)_3P=X + \underset{(2)}{R-SO_2-NSO} \longrightarrow (C_6H_5)_3P=N-SO_2-R + XSO$$

$$X = O, NC_6H_5, S$$

$$(C_2H_5O)_3P=S + R-SO_2-NSO \longrightarrow (C_2H_5O)_3P=N-SO_2-R + \text{"}S_2O\text{"}$$

though the yields are low in some cases.

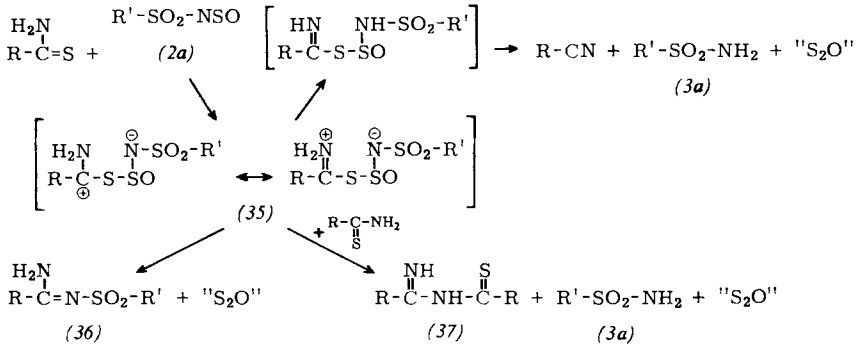
Procedures

Tetraethyl-S-(p-toluenesulfonylimino)-sulfinyldiamide [16]

A solution of 10.85 g of *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* in 50 ml of anhydrous $CHCl_3$ is added to 9.6 g of tetraethylsulfinyldiamide in 25 ml of anhydrous $CHCl_3$. SO_2 is liberated, and the solution becomes warm and assumes a red color. The reaction mixture is allowed to stand for 15 hours at room temperature, and the chloroform is then distilled off; the residue crystallizes. Yield 93%, m.p. 56–57 °C (from water).



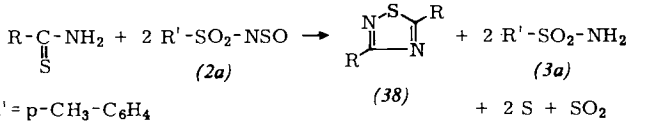
1-(p-Toluenesulfonylimino)-3-phenylbenzo-2H-1,2,4-thiadiazine ((33), R=p-CH_3–C_6H_4, R'=C_6H_5) [60]

0.7 g of 3-phenylbenzo-2*H*-1,2,4-thiadiazine 1-oxide is heated for several hours in benzene with an excess of *N*-sulfinyl-*p*-toluenesulfonamide *(2a)*. The reaction mixture is cooled and filtered, and the precipitate is extracted with ethyl acetate to remove *p*-toluenesulfonamide. Yield 0.9 g (79%), m.p. 208–208.5 °C (from dimethylsulfoxide/ethyl acetate).

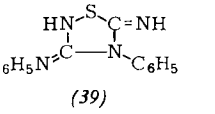
1.2.3.4. Preparation of N^2-Sulfonylamidines and 1,2,4-Thiadiazoles

Thioxo compounds can undergo "transsulfonylimination" with *N*-sulfinylsulfonamides in the same way as carbonyl compounds. However, other reaction products (nitriles or 1,2,4-thiadiazole derivatives) are often obtained as by-products or even as the main products. The course followed by the reaction depends on the nature of the thioxo compound, and the ratio of the various products evidently also depends on the solvent. All three products could be formed via the intermediate *(35)* [14].

The (strongly positive) S atom of the *N*-sulfinyl compound reacts with the negative S atom of the thioxo group. Both types of polarization have been observed



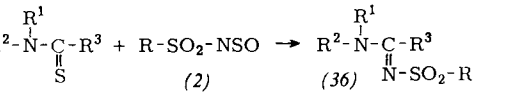
R' = p-CH_3-C_6H_4



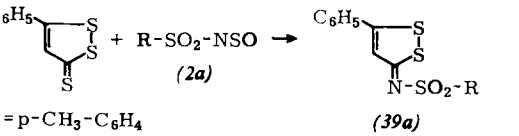
and are quite common; that of the *N*-sulfinylsulfonamides *(2)* is evident in the reaction with pyridine *N*-oxides [40], and that of the thionamides in many other reactions. The resulting dipolar product *(35)* can be stabilized in various ways:

1. by loss of S_2O to form the sulfonylamidine *(36)*,
2. by proton transfers and loss of S_2O and toluenesulfonamide to form the nitrile, and
3. by S_N reaction on the C atom with the N atom of a second molecule of thionamide. Proton transfer and subsequent loss of S_2O and toluenesulfonamide lead to the thioacylamidine *(37)*. The thioacylamidines *(37)* are readily oxidized to 3,5-disubstituted 1,2,4-thiadiazoles *(38)*.

The reaction of *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* with *N*-substituted aliphatic or aromatic thionamides lead to moderate or satisfactory yields of 1,2,4-thiadiazoles *(38)*.



The nitriles corresponding to the thionamides are sometimes also formed as by-products. The reaction of *N*-phenylthiourea yields the "Hector base" *(39)*, which can also be obtained by oxidation with H_2O_2.



(39)

The conversion of thionamides into 3,5-diaryl-1,2,4-thiadiazoles and that of thioureas into Hector bases can be carried out with many different reagents, but this method fails with aliphatic compounds. In this case the reaction with *N*-sulfinylsulfonamides *(2)* may be useful for preparative purposes.

N^2-Sulfonylamidines *(36)* are obtained in the reaction of *N*-sulfinylsulfonamides *(2)* with thioformamide, *N*-substituted thionamides [14], and *N,N*-disubstituted thioureas [46], and as by-products in the reaction of *N*-acylthioureas [63] and of an excess of thiobenzamide with *N*-sulfinylsulfonamides *(2)*. 1,2-Dithiacyclopent-3-ene-5-thiones (trithiones) also undergo transsulfonylimination with *(2a)*.

R = p-CH_3-C_6H_4 *(39a)*

[63] *A. Horn*, Dissertation, Technische Hochschule München, 1966.

Procedure

N^1,N^1-Dimethyl-N^2-p-toluenesulfonylbenzamidine ((36), $R = p\text{-}CH_3\text{–}C_6H_4$, $R^1 = R^2 = CH_3$, $R^3 = C_6H_5$) [14,63]

A solution of 2.7 g of *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* in 25 ml of chloroform is added to 2.0 g of *N*,*N*-dimethylthiobenzamide in 50 ml of anhydrous chloroform, and the mixture is heated for 16 hours. The solvent is distilled off and the residue is extracted with boiling ethanol. The product that crystallizes from the hot filtered solution can be recrystallized from ethanol and acetonitrile. Yield 2.7 g (75%), m.p. 161–162 °C.

1.2.4 Additions of Proton-Activated Compounds

Corresponding to the polarity of their S=N bond, the *N*-sulfinyl compounds react with compounds of the type HX in accordance with the scheme

$$R\text{–}NSO + HX \longrightarrow R\text{–}NH\text{–}SO\text{–}X$$

In most cases this addition product rapidly reacts further with a second mole of HX:

$$R\text{–}NH\text{–}SO\text{–}X + HX \longrightarrow R\text{–}NH_2 + X_2SO$$

The reaction leads to the transfer of a sulfinyl group. The resulting sulfinyl compound can react further in a similar manner as the primary product. This is the reason for the preparative importance of "transsulfinylation", particularly in the reactions with amidines, active methylene compounds, and thiols. The addition of HX to *N*-sulfinylsulfonamides *(2)* is generally much faster than to *N*-sulfinylamines *(1)*, and in many cases only the more reactive sulfonamide derivatives can be used.

1.2.4.1. Addition of Water, Alcohols, or Hydrogen Halides

The simplest example of the addition of HX is hydrolysis, which is evidently catalysed both by acids and by bases. *N*-Sulfinylsulfonamides *(2)* and aliphatic *N*-sulfinylamines *(1)* are more resistant to hydrolysis. *N*-Sulfinylmesidine can be steam-distilled without appreciable decomposition [64].

Alcoholysis proceeds analogously to hydrolysis and leads to the formation of sulfites $(RO)_2SO$ [65]. In this case it has been qualitatively found that the reactivity of the *N*-sulfinylamines is increased by electron-attracting substituents. The alcoholysis is assumed to lead first to esters R–NH–SOOR′, which are very unstable and immediately react further [66]. The reaction of the *N*-sulfinylamines with dry hydrogen halide is a reversal of

$$R\text{–}NSO + 2\,HCl \longrightarrow R\text{–}NH_2 + SOCl_2$$

their formation, and has been recommended for the preparation of pure thionyl chloride [67].

According to *Smith* and *King* [68], this reaction is also involved in the reaction of *N*-sulfinylamines *(1)* with carboxylic acids to form anilides, as reported by *Carré* and *Libermann* [69], since pure compounds containing no HCl or $SOCl_2$ do not react.

The *N*-sulfinylsulfonamides *(2)*, the formation of which from sulfonamides *(3)* and $SOCl_2$ is much slower than that of the *N*-sulfinylamines *(1)* (cf. Section 1.1.1.2.), are more resistant to cleavage by HCl [54].

Unlike the *N*-sulfinylamines *(1)*, however, *N*-sulfinyl-*p*-toluene-sulfonamide *(2a)* that has been distilled in a high vacuum, and which no longer contains chlorinated impurities, reacts smoothly with acetic acid to give good yields of *N*-acetyl-*p*-toluenesulfonamide [52]. It therefore seems likely that direct reaction occurs in this case:

$$\underset{(2a)}{H_3C\text{–}C_6H_4\text{–}SO_2\text{–}NSO} + CH_3COOH \longrightarrow H_3C\text{–}C_6H_4\text{–}SO_2\text{–}NHCOCH_3 + SO_2$$

It was mentioned in Section 1.2.3.1. that HCl also acts as a catalyst in the reactions of the *N*-sulfinyl compounds. Many discrepancies in the reports on the reactivities and the nature of the reactions of *N*-sulfinylamines and *N*-sulfinylsulfonamides can apparently be explained by the presence or absence of HCl or $SOCl_2$ (from the preparation of the *N*-sulfinyl compound) in the reaction mixture.

1.2.4.2. Preparation of Unsymmetrically Substituted Trisulfides

In the reaction of *N*-sulfinylamines *(1)* [70] or *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* with thiols, the first step in the "transsulfinylation" can be carried out separately:

$$R\text{–}NSO + HSR' \longrightarrow \underset{(39b)}{R\text{–}NH\text{–}SO\text{–}SR'}$$

An exothermic reaction takes place with the formation of *N*-arylamidothiosulfites (thio esters of *N*-arylsulfamic acid) *(39b)*, whose N–S bonds are easily cleaved; the reaction with thiols can be used for the preparation of unsymmetrically substituted alkyl aryl trisulfides [70]:

$$R\text{–}NH\text{–}SO\text{–}SR' + 3\,R''\text{–}SH \longrightarrow R\text{–}NH_2 + R''\text{–}S\text{–}S\text{–}S\text{–}R' + R''\text{–}S\text{–}S\text{–}R'' + H_2O$$

1.2.4.3. Preparation of *N*-Sulfinyl Compounds, 2,1,3-Thiadiazoles, 2,1,3-Thiadiazines, and Benzo-1,2,4-thiadiazines

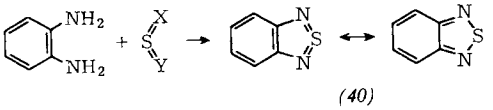
The reaction of *N*-sulfinylamines or *N*-sulfinylsulfonamides with compounds containing amino groups is useful for preparative purposes. This reaction generally leads to smooth transsulfinylation, particularly when the difference in basicity between the original and final

[64] *A. Michaelis* and *G. Junghans*, Liebigs Ann. Chem. *274*, 233 (1893).

[65] *W. T. Smith jr.*, *D. Trimnell*, and *L. D. Grinninger*, J. org. Chemistry *24*, 664 (1959); *W. T. Smith jr.* and *L. D. Grinninger*, *ibid. 26*, 2133 (1961); *L. Jannelli*, *L. Senatore*, and *C. Carpanelli*, Ann. Chimica *53*, 1150 (1963).

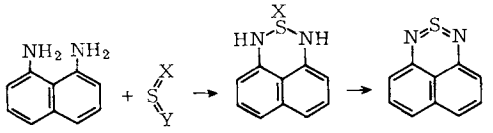
[66] *G. Zinner*, Chem. Ber. *91*, 966 (1958).

[67] *P. Carré* and *D. Libermann*, Bull. Soc. chim. France [5], *6*, 579 (1939).



[68] *W. T. Smith jr.* and *G. G. King*, J. org. Chemistry *24*, 976 (1959).

[69] *P. Carré* and *D. Libermann*, C.R. hebd. Séances Acad. Sci. *194*, 2218 (1932).

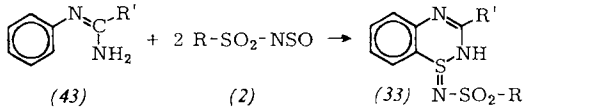


[70] *G. Kresze* and *H. P. Patzschke*, Chem. Ber. *93*, 380 (1960).

amino compounds is large[73]. The *N*-sulfinylsulfonamides *(2)* are therefore particularly suitable for the preparation of other *N*-sulfinyl compounds. Transsulfinylation with *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* and its analogues can be used not only for the preparation of sensitive *N*-sulfinylamines (cf. Section 1.1.1.) but also of *N*-sulfinylhydrazides[71], *N*-sulfinylhydroxamide *O*-ethers[72], and *N*-sulfinylsulfenamides[4].

The reaction of aromatic *o*- or *peri*-diamines with compounds of the type X=S=Y yields benzo-2,1,3-thiadiazoles [piazthioles, *(40)*][9,22,74–78] or naphtho[1,8,8*a* – *c*,*d*]thiadiazines *(41)*[79,80].

(40)



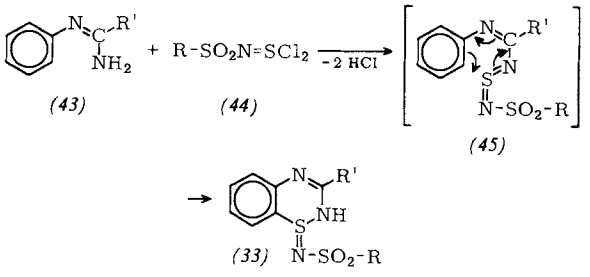
(42) *(41)*

These ring-closure reactions proceed increasingly readily with the reagents SO_2[9,76,79], $SOCl_2$[22,74], Ar–NSO[74,75,77,79,80], and $(RSO_2N)_2S$[78].

Mono-*N*-sulfinylamines[75] and the cyclic sulfinyldiamide *(42)*, X = O[79,80] have been isolated as intermediates. Numerous derivatives of *(40)* and *(41)*, some of them heterosubstituted, have been prepared in this way.

The course of the reaction of N^2-arylamidines *(43)*[81] with *N*-sulfinylsulfonamides *(2)* seems surprising. These compounds react even at room temperature in chloroform to give the 1-*N*-arylsulfonylimines *(33)* of the 2*H*-1,2,4-benzothiadiazines, often in yields of more

(43) *(2)* *(33)* N-SO_2-R



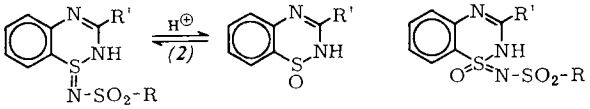
+ SO_2 + R-SO_2-NH_2

(3)

than 90%. The amidines *(43)* may also be replaced in this reaction by similar compounds such as *N*-arylguanidines (R′ = NR″$_2$), *N*-arylisoureas (R′ = OR″), and *N*-arylisothioureas (R′ = SR″).

When *(43)* and *(2)* are allowed to react in a molar ratio 1:1, the only product is again *(33)*, and half of the amidine used is recovered unchanged. The great ease with which the aromatic nucleus is attacked is particularly surprising; the reaction is not prevented even by strong electron-acceptor substituents (NO_2 in the *p*-position, SO_2–NH_2 in the *m*-position with respect to the point of attack).

The arylsulfonyliminosulfur dichlorides *(44)* react in the same way as the *N*-sulfinylsulfonamides *(2)*. In this case only 1 mole of *(44)* is required per mole of *(43)* if a base is added to remove the liberated HCl.



(43) *(44)* *(45)*

(33) N-SO_2-R

As in the reaction of the arylsulfonyliminosulfur dichlorides *(44)* with primary aromatic amines[78], it must again be assumed that the first step is the formation of a sulfodiimide *(45)*. However, this is evidently unstable, and undergoes valence isomerization and proton migration with formation of the stable benzothiadiazine derivative *(33)*. A similar mechanism was suggested recently[82] for the isomerization of imidoyl isothiocyanates to form quinazolinethiones. Thus the reaction may be compared to an intramolecular "polar" diene synthesis.

(45) could also occur as an intermediate in the reaction with *N*-sulfinylsulfonamides. This is supported by the fact that *N*-phenyl-*N*′-methylbenzamidine does not react to form the methyl-substituted benzothiadiazine. The formation of a sulfodiimide without scission of a C–N bond is inconceivable in this case.

Solvolysis of the 2*H*-benzothiadiazine derivatives *(33)* with glacial acetic acid, formic acid, or sulfuric acid leads to the formation of 2*H*-1,2,4-benzothiadiazine 1-oxides *(34)*.

(33) *(34)* *(46)*

The structure of the starting materials *(33)* was verified by oxidation of the sulfoxides *(34)* with H_2O_2 in glacial acetic acid to obtain the 2*H*-1,2,4-benzothiadiazine 1,1-dioxides, which are known. The reduction of *(34)* with zinc and glacial acetic acid proceeds abnormally, with the ring contraction to form benzothiazoles. Oxidation of the 1-sulfonylimino-2*H*-benzothiadiazines *(33)* with alkaline permanganate leads to the sulfoximine analogues *(46)*. The results obtained so far indicate that in the "sulfinylation" of the amidines *(43)*, the primary adduct *(47)* undergoes transsulfinylation with a second

mole of *(2)* (cf. Section 1.2.3.3.); the resulting guanidine analogue *(48)*, a sulfurous acid diamide imide, then loses sulfonamide to form the sulfodiimide intermediate *(45)*. In the reactions of *N*-sulfinylamines *(1a)* with phenylphosphine *(49)*[83] and with phenylarsine[84], the primary adducts again undergo complex secondary reactions.

Procedures

7-Amino-1,2,5-thiadiazolo[3,4-d]pyrimidine [75]

3 mmoles of *N*-sulfinylaniline *(1a)* is added to 1 mmole of 4,5,6-triaminopyrimidine in 10 ml of pyridine under nitrogen and in the absence of moisture, and the mixture is heated at 110 °C for 4¾ hours. The solvent is distilled off under vacuum, and to remove pyridine and aniline, ethanol/water is repeatedly added and evaporated. The residue is treated with aqueous alcohol and filtered off. Yield 94%, yellow crystals having m.p. 250 °C.

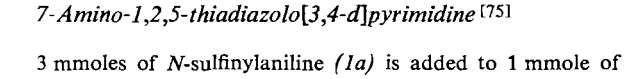
3-Phenyl-1-(p-toluenesulfonylimino)-benzo-2H-1,2,4-thiadiazine ((33), R = p-CH₃–C₆H₄, R′ = C₆H₅) [60,81]

9.8 g of solid *N*-phenylbenzamidine is added to a solution of 21.7 g of *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* in 150 ml of $CHCl_3$. SO_2 is evolved and the reaction mixture becomes warm and turns red. The mixture is allowed to stand for 6 hours at room temperature and the precipitate that separates is removed by filtration and digested with ethyl acetate at room temperature to remove *p*-toluenesulfonamide. Yield 18.8 g (95%), m.p. 208–208.5 °C (from dimethyl sulfoxide/ethyl acetate).

3-Phenylbenzo-2H-1,2,4-thiadiazine 1-Oxide ((34), R′ = C₆H₅) [60,81]

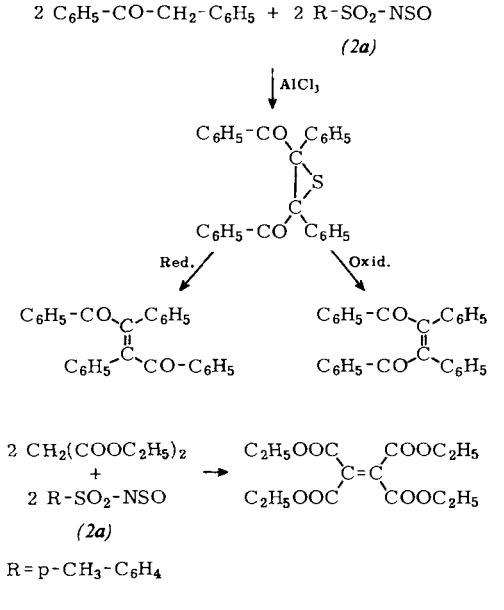
A suspension of 25 g of 3-phenyl-1-(*p*-toluenesulfonylimino)-benzo-2*H*-1,2,4-thiadiazine in 500 ml of glacial acetic acid is prepared and is heated slowly to 120 °C with stirring. The solid dissolves to give a pale yellow solution. After cooling, the solution is added to an equal amount of water and the mixture is filtered, yield 10.0 g. A further 2.7 g can be obtained by evaporation of the filtrate to dryness under vacuum and extraction of the residue with boiling water. Total yield 12.7 g (83%), m.p. 250–252 °C (from ethanol).

3-Phenylbenzo-2H-1,2,4-thiadiazine 1,1-Dioxide [60]



0.6 g of 3-phenylbenzo-2*H*-1,2,4-thiadiazine 1-oxide is dissolved in hot glacial acetic acid, and an excess of 30% H_2O_2 is added to the hot solution. The mixture is heated for 1 hour on a water-bath, allowed to stand for several hours at room temperature, and filtered. Yield 0.3 g (47%), m.p. 306–308 °C.

3-Phenyl-1-(p-toluenesulfonylimino)-benzo-2H-1,2,4-thiadiazine 1-Oxide (46) [60,81]

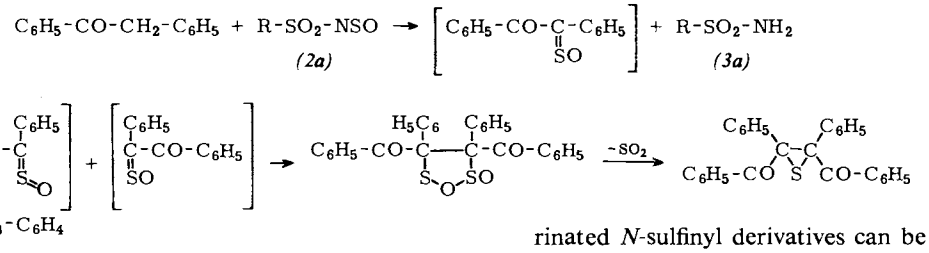


3 g of 3-phenyl-1-(*p*-toluenesulfonylimino)-benzo-2*H*-1,2,4-thiadiazine is dissolved in 60 ml of 2N NaOH. A solution of 3 g of $KMnO_4$ in 50 ml of water is added dropwise to the boiling solution with stirring. The mixture is then heated for 1 hour on a water-bath, and acidified after cooling. The MnO_2 that is precipitated is reduced with $NaHSO_3$ until the precipitate becomes colorless. It is then filtered off and washed thoroughly with water. Yield 0.9 g (29%), m.p. 248–250 °C/decomp. (from ethanol/benzyl alcohol).

1.2.4.4. Preparation of Tetrasubstituted Ethylenes

In principle, compounds containing acidic methylene groups should also undergo "transsulfinylation" with *N*-sulfinyl compounds; this reaction should lead to the formation of sulfines RR′C=SO, at least as the primary products. As was mentioned in Section 1.2.3.1., the only products found in the reaction of aliphatic aldehydes

with *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* are 1,1-bis-(*p*-toluenesulfonamido)alkanes [48], while the only product isolated so far with carbonyl compounds such as cyclohexanone is *p*-toluenesulfonamide *(3a)*. However, the reactions with malonic ester and with deoxybenzoin



[83] *L. Anschütz* and *H. Wirth*, Naturwissenschaften *43*, 16 (1956).

[84] *L. Anschütz* and *H. Wirth*, Naturwissenschaften *43*, 59 (1956).

and its derivatives in the presence of $AlCl_3$ follow a different course; the products obtained in these cases are tetrasubstituted ethylenes, or as their precursors, thiiranes [54]:

A plausible course for this oxidative dimerization of the methylene components would be as follows: (a) "Transsulfinylation" to form the sulfine, whose C=SO system acts both as a 1,3-dipole and as a dipolarophile in the second step, (b) 1,3-dipole addition, and then (c) stabilization of the five-membered heterocycle in the usual manner (cf. Section 1.2.2.2.) by elimination of SO_2 and formation of the thiirane.

The *N*-sulfinylsulfonamides often can be replaced by thionyl chloride.

Procedures

1,2-Diphenyl-1,2-dibenzoylthiiran [54]

A solution of 0.1 mole of deoxybenzoin and 0.01 mole of $AlCl_3$ in 150 ml of ether is added dropwise with stirring to 0.1 mole of *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* in 50 ml of anhydrous ether, with cooling in ice. After 2 days, the *p*-toluenesulfonamide *(3a)* that has crystallized is removed by filtration, the ether is distilled off under vacuum at a low temperature, and the oily residue is taken up in 80 ml of petroleum ether. The solution is filtered and the petroleum ether is distilled off under vacuum. The thiirane remains behind as a yellow oil. Yield 10.1 g (46.5%). The thiirane can be purified by chromatography on silica gel (benzene as eluent), m.p. 104–105 °C.

cis-Dibenzoylstilbene [54]

4 g of crude 1,2-diphenyl-1,2-dibenzoylthiirane is dissolved in 50 ml of nitrobenzene and heated for 2 hours. The nitrobenzene is removed by steam distillation and the residue is recrystallized from ethanol. Yield 85%, m.p. 211 °C.

trans-Dibenzoylstilbene [54]

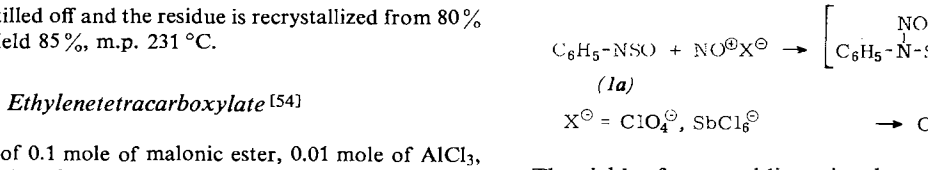
A solution of 3.4 g of triethyl phosphite in 40 ml of anhydrous ether is added dropwise to a boiling solution of 5 g of crude 1,2-diphenyl-1,2-dibenzoylthiirane in 40 ml of anhydrous benzene, and the mixture is heated for a further 4 hours. The ether is distilled off and the residue is recrystallized from 80% ethanol. Yield 85%, m.p. 231 °C.

Tetraethyl Ethylenetetracarboxylate [54]

A mixture of 0.1 mole of malonic ester, 0.01 mole of $AlCl_3$, and 0.1 mole of *N*-sulfinyl-*p*-toluenesulfonamide *(2a)* in 50 ml of nitromethane is heated for 6 hours. After cooling, the solution is filtered to remove crystals of the *p*-toluenesulfonamide *(3a)*, the nitromethane is removed by distillation under vacuum, and the residue is distilled at 10^{-2} mm Hg. Yield 38%, m.p. 52 °C.

1.2.5. Preparation of Ring Halogenated Aniline and Phenylenediamine Derivatives

The sulfinyl group has been found useful as a protective group for NH_2 in the halogenation of sensitive amines. Although the NSO group of *N*-sulfinylaniline *(1a)* is cleaved by chlorine or bromine in chloroform (the final products are 2,4,6-trihalogenoaniline and thionyl halide), chlorination in thionyl chloride as the solvent yields *N*-sulfinyl-2,4,6-trichloroaniline. Ring-halogenation of *m*- and *p*-phenylenediamine can also be achieved in this way. The resulting 2,4,6-trichlorinated or 2,3,5,6-tetrachlorinated *N*-sulfinyl derivatives can be hydrolysed to the amines with alkali or hot acid [85].



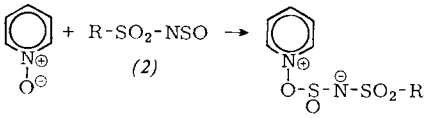
Procedure

N,N'-Disulfinyl-2,3,5,6-tetrachloro-p-phenylenediamine [85]

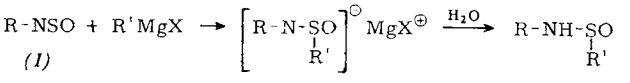
108 g (1 mole) of *p*-phenylenediamine is added in portions (over a period of 30 min) to 600 ml (8.25 moles) of $SOCl_2$, with stirring. During this addition, the temperature of the reactants is maintained at 50–65 °C in an oil bath at 50 to 55 °C. The mixture is stirred for a further 2 hours, and 281 g (7.92 moles) of chlorine passed through it at 55–65 °C for 4.5 hours. The chlorination is complete when chlorine begins to appear in the condenser. The mixture is cooled to 0 °C, and the *N,N'*-disulfinyl-2,3,5,6-tetrachloro-*p*-phenylenediamine that crystallizes is filtered off and recrystallized from CCl_4; yellow needles, yield 250 g (75%), m.p. 171 to 172 °C. Treatment with 15% NaOH at room temperature or with boiling hydrochloric acid leads to almost quantitative conversion into 2,3,5,6-tetrachloro-*p*-phenylenediamine, m.p. 224–225 °C.

1.2.6. Diazonium Salts and Sulfinamides

The reaction of *N*-sulfinyl compounds with polar or ionic, salt-like components can often be regarded as a primary reaction on one atom of the NSO system. Thus *Bott* [86] considers the formation of diazonium salts in the reaction of *(1)* with nitrosyl perchlorate, or hexachloroantimonate, in dichloroethane at −10 °C to 0 °C to proceed *via* an *N*-nitroso derivative:



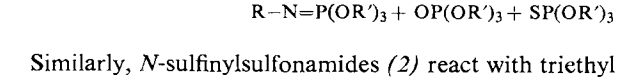
The yields of pure aryldiazonium hexachloroantimonates are higher than 90%.



[85] *G. Ottmann* and *H. Hooks*, J. org. Chemistry *30*, 952 (1965).

[86] *K. Bott*, Angew. Chem. *77*, 132 (1965); Angew. Chem. internat. Edit. *4*, 148 (1965).

Only the S atom of the *N*-sulfinyl group is attacked in the reaction of *(2)* with pyridine *N*-oxides [40].



This type of reaction is probably also involved in the additions of organometallic compounds. Additions to *N*-sulfinylamines can be carried out with Grignard compounds [19,87] and with organolithium compounds [88]. Careful hydrolysis of the adducts gives good yields of sulfinamides.

The only case in which poor yields (7% instead of 72–92%) indicate the effects of steric hindrance is the reaction of phenylmagnesium bromide with *N*-sulfinyl-t-butylamine; *N*-sulfinylmesidine, on the other hand, reacts normally [89].

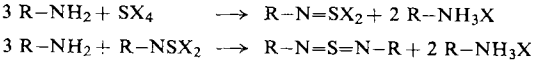
With tertiary amines, *N*-sulfinylsulfonamides *(2)* first give a brown charge-transfer complex, which then loses SO_2 with self-condensation to form a sulfodiimide (cf. Section 2.1.2.).

N-Sulfinylaniline *(1a)* and dialkyl *N*-sulfinylphosphoramidates react with trialkyl phosphites to give iminophosphates, phosphates, and thiophosphates [90].

Similarly, *N*-sulfinylsulfonamides *(2)* react with triethyl phosphite, triphenylphosphine, triphenylarsine, and triphenylstibine to give iminophosphorane derivatives and their analogues [61,62].

2. Sulfodiimides

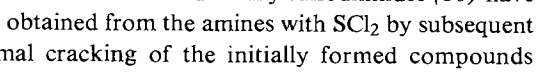
The chemistry of the sulfodiimides R–N=S=N–R′ is not yet so well developed as that of the *N*-sulfinylamines. Dialkyl- [8,91,92], diaryl- [78,93,95], disulfonyl- [96,97], and *N*-sulfonyl-*N*′-arylsulfodiimides [78,98] are known.



The stability of these compounds is strongly dependent on the organic residue [99]. Dialkylsulfodiimides decompose at, or slightly above, room temperature, only compounds containing tertiary groups being thermally stable [92]. Diaryl- and *N*-sulfonyl-*N*′-arylsulfodiimides change at high temperatures or on prolonged storage at room temperature, while disulfonylsulfodiimides are thermally stable.

Sulfodiimides are more sensitive to hydrolysis and more reactive than the corresponding *N*-sulfinylamines. Within the series of sulfodiimides, reactivity runs parallel to thermal stability.

2.1. Preparation of Sulfodiimides

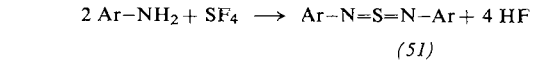


2.1.1. Dialkyl- and Diarylsulfodiimides

Dialkylsulfodiimides are prepared from alkylamines and sulfur tetrahalides at low temperatures [8,91].

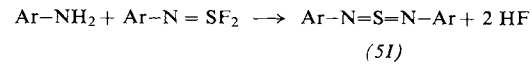
X = F, Cl

The much more stable di-t-alkylsulfodiimides *(50)* have been obtained from the amines with SCl_2 by subsequent thermal cracking of the initially formed compounds of the type $(R–NS)_x$ [92]:



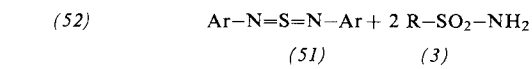
R = t-Alkyl *(50)*

Diarylsulfodiimides *(51)* were first prepared from the *N*-sulfinylamines *(1)* with sodium [93].



(1) *(51)*

Like the dialkylsulfodiimides, they are also formed in the reaction of SF_4 or aryliminosulfur difluorides with aromatic amines [94].



(51)

(51)

A very useful preparative method is the "transimidation" of the readily obtainable disulfonylsulfodiimides *(52)* with aromatic amines [95]

(52) *(51)* *(3)*

The deciding factor in this reaction (as in the analogous "transsulfinylation", cf. Section 1.1.1.) is the difference in basicity between the amine and the sulfonamide. This reaction can also readily be carried out in two steps [78].

[96] *E. S. Levtschenko* and *A. V. Kirsanov*, Ž. obšč. Chim. *32*, 2256 (1962).

[97] *W Wucherpfennig* and *G. Kresze*, Tetrahedron Letters *1966*, 1671.

[98] *E. S. Levtschenko* and *A. V. Kirsanov*, USSR-Pat. 154263 (July 24th 1963); Chem. Abstr. *61*, 1800a (1964).

[99] *E. S. Levtschenko* and *Ya. G. Bal'on*, Ž. org. Chim. *1*, 305 (1965).

1st step:

$$(R-SO_2-N)_2S + Ar^1-NH_2 \longrightarrow \underset{(52)}{R-SO_2-N=S=N-Ar^1} + R-SO_2-NH_2$$

In this (fast) step, both donor-substituted and acceptor-substituted anilines can be used. However, the course of the second (slow) step, which proceeds only with donor-substituted (strongly basic) amines, differs according to the amine component used in the first step.

2nd step:

a) Ar^1 = donor substituent, Ar^2 = donor substituent

$$R-SO_2-N=S=N-Ar^1 + Ar^2-NH_2 \longrightarrow Ar^2-N=S=N-Ar^1 + R-SO_2-NH_2$$

b) Ar^2 = acceptor substituent, Ar^2 = donor substituent

$$R-SO_2-N=S=N-Ar^1 + Ar^2-NH_2 \longrightarrow R-SO_2-N=S=N-Ar^2 + Ar^1-NH_2$$

Thus mixed diarylsulfodiimides can also be prepared by this reaction.

Dialkylsulfodiimides are bright yellow liquids, and those containing n-alkyl groups are very readily hydrolysed. Di-t-alkylsulfodiimides *(50)* are much more stable to hydrolysis. Diarylsulfodiimides *(51)* are orange to red liquids or low-melting solids having characteristic IR [94, 100] and UV spectra [94, 101]. They are slowly hydrolysed by water.

Procedures

Di-t-butylsulfodiimide ((50), $R = C(CH_3)_3$) [92]

A solution of 343 g (3.5 moles) of freshly distilled SCl_2 in 300 ml of anhydrous ether is added dropwise to 733 g (10 moles) of t-butylamine in 1250 ml of anhydrous ether at 5–10 °C. The mixture is allowed to stand for two days, and the t-butylamine hydrochloride that precipitates is filtered off and washed with ether. The filtrate is evaporated to dryness at 40 °C/0.1 mm Hg; 287 g of a yellow oil remain behind. 123 g of this oil is heated under reduced pressure. Decomposition begins at 63 °C. When the temperature reaches 160 °C, 72 g of a bright yellow oil has distilled over. Redistillation of this oil gives 70 g (56%) of pure di-t-butylsulfodiimide, b.p. 60–62 °C/15 mm Hg.

Diphenylsulfodiimide from N-Sulfinylaniline ((51), $Ar = C_6H_5$) [93]

A solution of 10 g of *N*-sulfinylaniline *(1a)* in 10 ml of anhydrous toluene is warmed with 3.2 g of Na powder (prepared by vigorous stirring of molten sodium in boiling xylene) until the exothermic reaction begins (the mixture begins to boil) and continues without further heating. When reaction has ceased, the mixture is heated for a further 15 hours, and is then cooled and filtered. The toluene solution is evaporated to dryness under vacuum at 30–40 °C, and the residue is distilled in a high vacuum. Yield about 40%.

Diarylsulfodiimides (51) from Sulfonylsulfodiimides [78]

a) 0.04 mole of arylamine in 20 ml of benzene is slowly added to a suspension of 0.02 mole of disulfonylsulfodiimide *(52)* in 30 ml of benzene. The reaction is complete within 3–4 days at room temperature but it can be accelerated by heating. The precipitated sulfonamide removed by is filtration and the filtrate is evaporated to dryness at 20–30 °C under vacuum. The diarylsulfodiimide is purified by vacuum distillation or by recrystallization from petroleum ether.

b) Diarylsulfodiimides can be obtained in 80% yield from 0.02 mole of *N*-sulfonyl-*N'*-arylsulfodiimide *(53)* in 20 ml of benzene and 0.02 mole of arylamine in 20 ml of benzene by the above procedure.

2.1.2. Disulfonyl- and *N*-Sulfonyl-*N'*-arylsulfodiimides

Disulfonylsulfodiimides *(52)* are formed by the action of tertiary amines or $AlCl_3$ on *N*-sulfinylsulfonamides *(2)* [97].

$$\underset{(2)}{2\,R-SO_2-NSO} \longrightarrow \underset{(52)}{R-SO_2-N=S=N-SO_2-R} + SO_2$$

Other syntheses use *N,N*-dichlorosulfonamides or arylsulfonyliminosulfur dichlorides *(44)* as starting materials [96].

$$2\,R-SO_2-NCl_2 + S,\ SCl_2,\ S_2Cl_2 \longrightarrow \underset{(52)}{R-SO_2-N=S=N-SO_2-R} + xCl_2$$

$$R-SO_2-NCl_2 + \underset{(44)}{R-SO_2-N=SCl_2} \longrightarrow \underset{(52)}{R-SO_2-N=S=N-SO_2-R} + 2\,Cl_2$$

$$\underset{(44)}{R-SO_2-N=SCl_2} + R-SO_2-NH_2 \longrightarrow \underset{(52)}{R-SO_2-N=S=N-SO_2-R} + 2\,HCl$$

N-Sulfonyl-*N'*-arylsulfodiimides *(53)* can be obtained by the reaction of disulfonylsulfodiimides *(52)* with one equivalent of arylamine [78].

$$\underset{(52)}{R-SO_2-N=S=N-SO_2-R} + Ar-NH_2 \longrightarrow \underset{(53)}{R-SO_2-N=S=N-Ar} + \underset{(3)}{R-SO_2-NH_2}$$

A second method is based on the use of arylsulfonyliminosulfur dichlorides *(44)* as starting materials [78].

$$\underset{(44)}{R-SO_2-N=SCl_2} + Ar-NH_2 \longrightarrow \underset{(53)}{R-SO_2-N=S=N-Ar} + HCl$$

Disulfonylsulfodiimides *(52)* are bright yellow substances which crystallize well (for IR spectra see [97]). They are extremely sensitive to hydrolysis and very reactive. *N*-Sulfonyl-*N'*-arylsulfodiimides *(53)* are yellow-orange solids; their reactivity and their sensitivity to hydrolysis are lower than those of the disulfonylsulfodiimides *(52)*.

Procedures

Disulfonylsulfodiimides (52) [97]

The *N*-sulfinylsulfonamide is dissolved in its own weight of anhydrous benzene, and 2.5 mole-% [based on *(2)*] of anhydrous pyridine (1:1 in benzene) is added. The mixture is

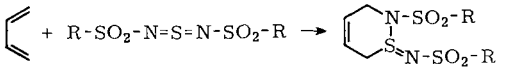
[100] *A. Foffani, G. Leandri, J. Zanon,* and *C. Carpanelli,* Tetrahedron Letters *1959*, Nr. 11, S. 21.

[101] *G. Leandri* and *A. Mangini,* Boll. sci. Fac. Chim. ind. Bologna *15*, 51 (1957).

allowed to stand overnight at room temperature, and the disulfonylsulfodiimide *(52)* that crystallizes is filtered off and washed with CCl_4. The yield is almost quantitative. The product may be recrystallized from benzene (R = aryl) or nitromethane (R = alkyl).

N-Arylsulfonyl-N'-arylsulfodiimides (53) [78]

A solution of 0.02 mole of arylamine in 20 ml of benzene is added slowly to a cooled suspension of 0.02 mole of bis(arylsulfonyl)sulfodiimide in 30 ml of benzene. The mixture is allowed to stand for 2–3 hours, the arylsulfonamide that crystallizes is removed by filtration, and the filtrate is evaporated to dryness under vacuum. A quantitative yield of the crude product is obtained.

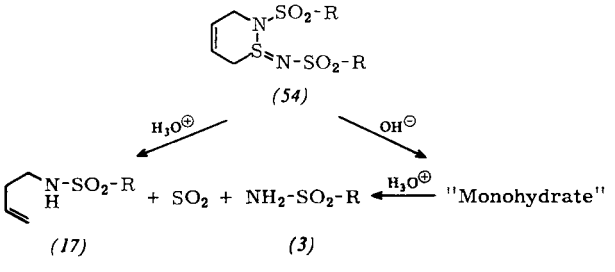


2.2. Reactions with Sulfodiimides

As might be expected, many of the reactions of sulfodiimides are similar to those of the *N*-sulfinylamines; however, in many other reactions, the sulfodiimides show a characteristically different behavior.

The only reactions of any preparative interest at present are those of the stable di-t-alkyl- *(50)*, disulfonyl- *(52)*, and *N*-sulfonyl-*N'*-arylsulfodiimides *(53)*.

2.2.1. Preparation of 1-Sulfonylimino-3,6-dihydro-1,2-thiazines

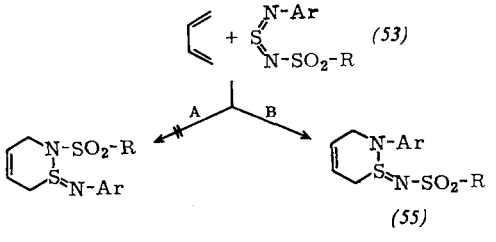


Di-*N*-sulfonylsulfodiimides *(52)* react even at room temperature with sterically unhindered dienes in solution with spontaneous liberation of heat and formation of 1-sulfonylimino-2-sulfonyl-3,6-dihydro-1,2-thiazines *(54)* [102].

(52) *(54)*

The structure of the heterocyclic compounds *(54)* was established from their IR spectra [97] and from degradation reactions [102].

Acid hydrolysis gives the *N*-alk-3-enylsulfonamide *(17)*, the sulfonamide *(3)*, and SO_2. Treatment with alkali solution [102] leads to the formation of "monohydrates" or their alkali metal salts, the structures of which are not yet known but which decompose on acid hydrolysis to form *(17)*, *(3)*, and SO_2.



Thus the acid degradation proceeds similarly to that of the 2-sulfonyl-3,6-dihydro-1,2-thiazine 1-oxides *(12)* (cf. Section 1.2.2.1.).

The *N*-sulfonyl-*N'*arylsulfodiimides *(53)* react much less readily with dienes [99]; the components must be heated for some time in benzene. Two reactions (A and B) appear possible because of the unsymmetrical substitution of the dienophilic N=S=N system.

Degradation reactions show that the course followed is path B, with formation of *(55)*. Acid hydrolysis gives the sulfonamide *(3)*, SO_2, and a "basic fraction", from which the *N*-alk-3-enylaniline *(10)* has so far been isolated in only one case [99]. Alkaline hydrolysis gives the sulfonamide *(3)* and *N*-arylpyrroles *(11)* in a smooth reaction.

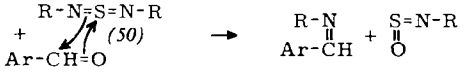
The acid and alkaline hydrolyses are completely analogous to those of the 2-aryl-3,6-dihydro-1,2-thiazine 1-oxides *(4)*.

As yet, no cycloadditions of diaryl- or dialkylsulfodiimides have been reported.

Procedures

1-Sulfonylimino-2-sulfonyl-3,6-dihydro-1,2-thiazines (54) [97]

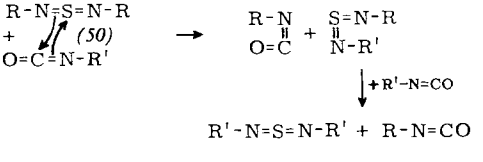
0.02 mole of disulfonylsulfodiimide *(52)* is dissolved in 10 ml of warm benzene (in nitromethane when R = CH_3). The solution is cooled and 1.1 equivalents of freshly distilled diene are added. With low-boiling dienes it is recommended that the flask should be cooled with ice. The mixture is allowed to stand overnight, and the adduct that precipitates is filtered off and washed with ether. The yield is almost quantitative. The compounds can be recrystallized from a large quantity of alcohol or from nitromethane.



1-Benzenesulfonylimino-2-aryl-4,5-dimethyl-3,6-dihydro-1,2-thiazines [99]

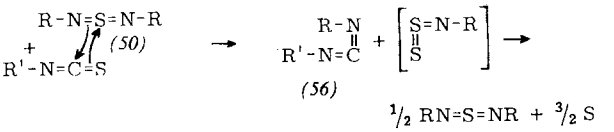
0.02 mole of *N*-benzenesulfonyl-*N'*-arylsulfodiimide is boiled with 0.02 mole of dimethylbutadiene in 20 ml of benzene. Depending on the nature of the substituents in the aryl group, the reaction is complete within 15 min (NO_2, $SO_2N(CH_3)_2$) to 3 hours (OCH_3, Cl). If the adduct crystallizes on cooling, it is filtered off, washed with ether, and recrystallized. Otherwise the benzene is evaporated under vacuum and the crystalline residue is treated as described above.

2.2.2. Preparation of Carbodiimides

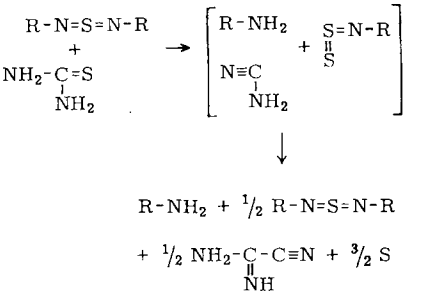


The only sulfodiimides whose reactions with polar multiple bonds have so far been investigated are the di-t-alkyl-substituted compounds *(50)* [103].

Sulfodiimides *(50)* (like the *N*-sulfinylsulfonamides *(2)*, cf. Section 1.2.3.1.) react with aromatic aldehydes to form imines.



R = t-Alkyl



Reactions with cumulative double bond systems are also interesting. The nucleophilic center in isocyanates is the N atom, and one or both groups R (depending on the reactant ratio) are replaced.

In isothiocyanates, on the other hand, the nucleophilic center is the S atom, and carbodiimides *(56)* are formed.

The reaction with thiourea probably involves a similar primary reaction, the intermediate then being stabilized by proton shift.

Procedure

N-Phenyl-N'-tert-butylcarbodiimide ((56), R = C_6H_5, R' = $C(CH_3)_3$) [103]

6.8 g of di-t-butylsulfodiimide and 10.4 g of phenyl isothiocyanate are heated at 120 °C for 4 hours. Yield 72%, b.p. 90–92 °C/4 mm Hg.

2.2.3. Transimidations

The disulfonylsulfodiimides *(52)* react with arylamines to form *N*-sulfonyl-*N'*-arylsulfodiimides *(53)*, which can react with a second mole of arylamine to form diarylsulfodiimides *(51)*. These reactions have been discussed in Section 2.1.1.

This reaction is also used for the preparation of piazthioles [78] (cf. Section 1.2.4.3.). The disulfonylsulfodiimides react faster and under milder conditions (room temperature) than any other reagent used for the cyclization of diamines.

Procedure

Benzo-2,1,3-thiadiazole (piazthiole) (40) [78]

0.015 mole of *o*-phenylenediamine in 10 ml of benzene is slowly added to a solution of 0.015 mole of bis(benzenesulfonyl)sulfodiimide in 40 ml of anhydrous benzene. An intense red color appears, and then quickly disappears. After 2 hours, the benzenesulfonamide that has crystallized is filtered off and the filtrate is evaporated to dryness under vacuum. Yield quantitative, m.p. 43–44 °C.

We thank the "Fonds der Chemischen Industrie" and Schering AG., Berlin, for supporting our investigations. Our thanks are also due to Chemische Werke Hüls AG., Marl, to BASF, Ludwigshafen, to Farbwerke Hoechst, and to Farbenfabriken Bayer, Leverkusen, for generous gifts of chemicals.

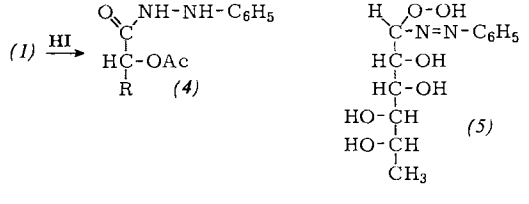
Formation and Degradation of 1-Phenylazo 1-Hydroperoxides Derived from Carbohydrates

By *Manfred Schulz* and *L. Somogyi*[*]

Geminal phenylazo-substituted organic hydroperoxides are formed by the action of oxygen on phenylhydrazones containing an NH group[1–5]. We have applied this reaction to both unacetylated and acetylated acyclic carbohydrate phenylhydrazones.



For instance, by passing oxygen into a benzene solution of penta-*O*-acetyl-D-galactose phenylhydrazone for 2 hr at room temperature we obtained 2,3,4,5,6-pentaacetoxy-1-phenylazo-D-*galacto*-hexyl hydroperoxide *(1)* in 80 % yield [m.p. 117–120 °C (decomp.); from benzene/petroleum ether; $[\alpha]_D^{21} = -30.8°$ (c = 1, in benzene)]. This compound crystallizes rapidly after treatment of the reaction mixture with petroleum ether. Its structure follows from elemental analysis and iodometric determination of the active oxygen, as well as from UV data: λ_{max} (in ethanol) = 217 mμ, ε = 11182; 275 mμ, ε = 11150; 412 mμ, ε = 153.

As in peroxyglycosides[6], the grouping $-O-\overset{|}{C}-\overset{|}{C}-O-O-$ proved liable to fragmentation. On treatment with 0.01 N methanolic $NaOCH_3$ at room temperature, compound *(1)* decomposes in a few hours to a sugar having one less carbon atom (D-lyxose) *(2)* as the main product, which can be isolated in 60 % yield (identified by paper-chromatographic comparison with authentic D-lyxose). *N*-Formyl-*N'*-phenyldiazene *(3)* should also be formed in this decomposition;

its hydrolysis products, methyl formate (identified by gas chromatography) and phenyldiazene (UV spectrum in 0.002 M methanolic $NaOCH_3$ solution: λ_{max} = 213 mμ, ε ≈ 8000; 273 mμ, ε ≈ 6700; 401 mμ, ε ≈ 58[7]) were identified.

On reduction with zinc and acetic acid, compound *(1)* regenerates the original hydrazone, and with sodium iodide in acetic acid gives penta-*O*-acetyl-*N*-phenyl-D-galactonohydrazide *(4)*[8] (yield 90 %).

2,3,4,5-Tetrahydroxy-1-phenylazo-L-*manno*-hexyl peroxide *(5)* [yield 60 %; m.p. 110–118 °C (decomp.); $[\alpha]_D^{22} = -71.0°$ (c = 1, in methanol); UV data: λ_{max} (in dioxane) = 240 mμ, ε = 7000; 272 mμ, ε = 7440; 400 mμ, ε = 92.6] is obtained from L-rhamnose phenylhydrazone by treatment with oxygen (in acetone; room temperature; 19 hr); it fragments to 5-deoxy-L-arabinose (yield 90 %; identified by paper-chromatographic comparison with authentic 5-deoxy-L-arabinose).

The following carbohydrates were similarly treated: D-glucose, D-xylose.

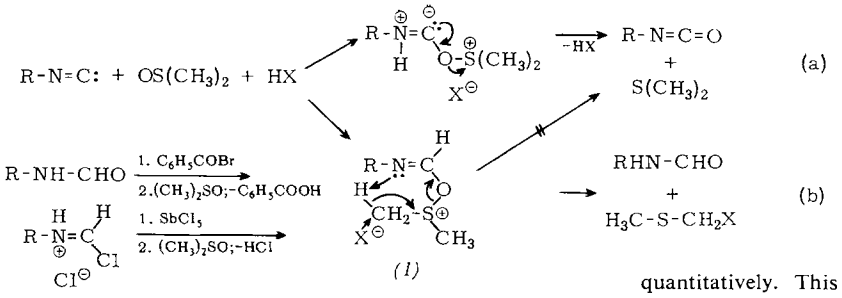
Acid-Catalysed Oxidation of Isocyanides with Dimethyl Sulfoxide



By *D. Martin* and *A. Weise*[*]

Pure dimethyl sulfoxide does not react with isocyanides. However, isocyanate and dimethyl sulfide are formed after about 24 hr if 5 mole-% of bromine is added to a boiling chloroform solution of an isocyanide and dimethyl sulfoxide[1]. This is presumably a chain reaction, involving primarily the isocyanide dibromide.

We have found that in oxidation of isocyanides with dimethyl sulfoxide, catalysis with Brönsted acids (*p*-toluenesulfonic acid; anhydrous HCl) or triphenylmethyl perchlorate is more convenient. The exothermic reaction requires only a short time for completion at 50 to 80 °C in the absence of a solvent. It gives the isocyanates in 50 to 90 % yield, together with dimethyl sulfide (40–60 %)[**] and relatively small amounts of resin.

This new method of oxidation helps to clarify the problem of whether the nitrogen or the carbon atom of the isocyanide group is the more basic: the smooth isocyanate formation is understandable only if we assume primary *N*-protonation of the isocyanide group (eq. a), as was postulated[2] for acid-catalysed reactions of isocyanides.

By model experiments[***] we have shown that the *O*-sulfonium formimidates *(1)* that would result from *C*-protonation do not decompose to isocyanates, dimethyl sulfide, and acid under comparable conditions, but, like the adducts of other nitrilium salts[3], react with dimethyl sulfoxide in accordance with the mechanism of the Pummerer reaction[4] to give amides and α-substituted dimethyl sulfides (eq. b); formamides were not found after reaction in the presence of catalytic amounts of acid. *C*-Protonation does occur to some extent when the isocyanide–dimethylsulfoxide mixture is added dropwise to an equimolar amount of anhydrous *p*-toluenesulfonic acid, but even then up to 50 % of isocyanate is formed.

Examples: A mixture of 50 mmole of isocyanide and 55 mmole of dimethyl sulfoxide is treated with 5 mmole of *p*-toluenesulfonic acid or 1 mmole of triphenylmethyl perchlorate. The temperature is kept at 50 to 80° by periodic cooling and two or three additions of a little acid; dimethyl sulfide distils off, and after disappearance of the isocyanide odor (about 30 min) the residue is fractionated in a water-pump vacuum. Products are tabulated below.

	Yield (%)	
	$(CH_3)_2S$	Isocyanate (b.p.)
n-C_4H_9	55	85 (115–120 °C)
Cyclohexyl	46	92 (62–68 °C/15 mm)
C_6H_5–CH_2	49	90 (88–91 °C/12 mm)
p-CH_3–C_6H_4	64	52 (75–78 °C/15 mm)

The behavior of isocyanides towards alkylating and arylating agents in dimethyl sulfoxide indicates that only "hard"[5] electrolytes tend to attack the nitrogen atom.

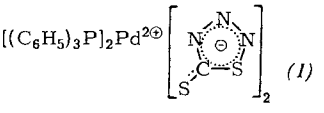
Ligand Addition and Redox Reactions of Azido-Metal Complexes

By *W. Beck* and *W. P. Fehlhammer* [*]

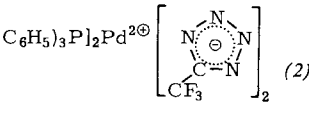


Metal carbonyls, *e.g.* $W(CO)_6$, react with azide ions, giving isocyanate complexes[1].

We have found that isocyanates also arise when azido-metal complexes are treated with free carbon monoxide. Thus when CO is passed at 20 °C into a chloroform solution of diazido-

$$M{-}CO + N_3^- \longrightarrow [M{-}NCO]^- + N_2$$
$$M{-}N_3 + CO \longrightarrow M{-}NCO + N_2$$

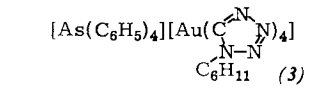
bis(triphenylphosphine)palladium(II), $[(C_6H_5)_3P]_2Pd(N_3)_2$[2], the isocyanate complex $[(C_6H_5)_3P]_2Pd(NCO)_2$ is obtained quantitatively. This pale yellow compound [decomp. at 216 °C; $\nu_{as}(NCO) = 2218$, $\nu_s(NCO) = 1347$ cm^{-1}, suspension in Nujol] is also obtained directly from $K_2[Pd(NCO)_4]$ and triphenylphosphine in ethanol/water[3]. A CO pressure of 200 atm (at 20 °C) is necessary for complete conversion of the platinum(II) compound $[(C_6H_5)_2P]_2Pt(N_3)_2$[2] into the analogous isocyanate complex [$\nu_{as}(NCO) = 2234$ cm^{-1}]. However, no cyanate could be detected after CO had been passed (at 200 atm and 20 °C) into an aqueous solution of sodium azide. The reaction $N_3^- \rightarrow NCO^-$ does occur when Pd(II) nitrate is added [1.5 g of NaN_3, 0.1 g of $Pd(NO_3)_2$, in water], the Pd(II) being reduced to metallic palladium.



If an excess of carbon disulfide is allowed to act on solid $[(C_6H_5)_3P]_2Pd(N_3)_2$ for several days at 20 °C, CS_2 is added to the azide group and the complex *(1)* is formed. This pale yellow substance (decomp. at 119–120 °C) was also obtained from Pd(II) nitrate, $Na[CS_2N_3]$ ("azidodithiocarbonate")[4], and

(1)

$P(C_6H_5)_3$ in ethanol/water. The characteristic IR absorption bands of the coordinately bound 1,2,3,4-thiatriazole-5-thiolate ion lie at 1295(m), 1223(s), 1067(s), 1020(m), and 932(m) cm^{-1} (KBr disk). The decomposition products arising from *(1)* in chloroform solution at 20 °C give an intense IR band at 2095 cm^{-1} indicating an isothiocyanate complex.



Reaction of $[(C_6H_5)_3P]_2Pd(N_3)_2$ with trifluoroacetonitrile in CH_2Cl_2 (1 atm, 0 °C, 1 hr) also leads to formation of a compound in which a five-membered ring system is bonded through a nitrogen to the palladium. This reaction is analogous to the 1,3-dipolar cycloadditions of organic azides[5].

(2)

The pale yellow tetrazolato complex *(2)* formed (decomp. at 258 °C) is sparingly soluble in CH_2Cl_2 and its IR spectrum (KBr disk) shows the bands of the 5-trifluoromethyltetrazolate anion[6]: 1507(s) ν(C–CF_3); 1242(s), 1191(s), 1182(m), 1168(s), 1156(s), 1143(s) $\nu(CF_3)$; 746 (s) $\delta(CF_3)$; 1401(w), 1312(w), 1040(s), and 1024(s) (ring vibrations).

A tetrazolato complex, possibly containing a metal-C bond, is also formed on treatment of $[As(C_6H_5)_4]$ $[Au(N_3)_4]$[2] with cyclohexyl isocyanide (molar proportions 1:4.5) in CH_2Cl_2 at 20 °C for about 1/2 hr. On addition of petroleum ether shiny, colorless leaflets of tetraphenylarsonium tetra-(cyclohexyltetrazolato)aurate(III) *(3)* are obtained [m.p. 184 °C (decomp.)]. The ^1H–NMR spectrum (in $DCCl_3$)

(3)

includes three signals (intensity ratio 5:1:10) which can be assigned to the 20 phenyl protons ($\tau = 2.4$), the four tertiary H atoms ($\tau = 5.2$), and the 40 methylene protons ($\tau = 8.3$) of

the cyclohexyl ring. The IR spectrum (Nujol suspension) contains the characteristic bands of 1-cyclohexyltetrazole, except for the ν(CH) vibration [7].

The red solution of $[As(C_6H_5)_4]$ $[Au(N_3)_4]$ in tetrahydrofuran rapidly becomes colorless in daylight, an intramolecular redox reaction occurring:

$$[As(C_6H_5)_4]\ [Au^{III}(N_3)_4] \xrightarrow[THF]{h\nu} [As(C_6H_5)_4]\ [Au^{I}(N_3)_2] + 3\,N_2.$$

The diazidoaurate(I) complex [decomp. at 127 °C; $\nu_{as}(N_3)$ = 2039 cm^{-1}, $\nu_s(N_3)$ = 1285 cm^{-1}, KBr disk] is precipitated in crystalline form by petroleum ether. It can also be obtained directly from Au(I)Cl, NaN_3, and $[As(C_6H_5)_4]Cl$ in CH_2Cl_2.

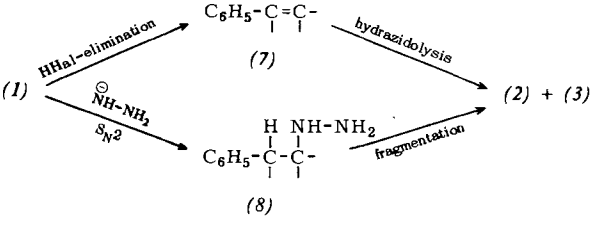
Cleavage of β-Halogeno-α-phenylalkanes by Sodium Hydrazide

By *Th. Kauffmann, W. Burkhardt*, and *E. Rauch* [*]

On reaction with sodium hydrazide, phenylalkyl halides of types *(1)*, *(4)*, and *(5)* [2] formally should be convertible by elimination of hydrogen halide into olefins that can be cleaved by the hydrazide [1]. If the elimination of HHal is faster than competing reactions, then the action of sodium hydrazide should lead to scission between the C atoms that are α and β to the phenyl group and thus to formation of a hydrocarbon *(2)* and a hydrazone *(3)*.

We have found that under the conditions of hydrazidolysis of C=C bonds [1] (in a hydrazine/ether mixture at 35 °C or in a hydrazine/benzene mixture at 60 °C; excess of sodium hydrazide) this cleavage does occur to a large extent with halides of type *(1)*. With *(4)* or *(5)* it occurs only to a small extent, the main reactions being replacement of the halogen by hydrogen, or a hydrazine group respectively.



(1) *(2)* *(3)*

(4) *(5)* *(6)*

Reactant	Temp. (°C)	Yield (%) after 5 hr[3]
Type (1):		
Phenethyl chloride, bromide, iodide	60	Toluene 74, 80, 67
β-Methylphenethyl bromide	35	Ethylbenzene 67
α-Methylphenethyl chloride, bromide, iodide	35	Toluene 89, 85, 73
Type (4):		
α-Methylbenzyl bromide	35	Toluene 2, ethylbenzene 35
α-Ethylbenzyl bromide	35	Toluene 1, phenylpropane 41
Type (5):		
3-Phenylpropyl bromide	35	Toluene 16, 3-phenylpropylhydrazine 47, phenylpropane 6.

For cleavage of compounds of type *(1)* we must consider not only the route *via* the olefin *(7)*, but also that *via* the hydrazine derivative *(8)*, since hydrazines of this type decompose in the presence of sodium hydrazide according to *(8)* → *(2)* + *(3)* [4].

In favor of the route *via (7)* are the facts that β,β-dimethylphenethyl chloride *(6)*, which cannot yield a styrene derivative by elimination of HHal, gives no trace of isopropylbenzene on treatment with sodium hydrazide in ether at 35 °C or in benzene at 60 °C, but remains largely unattacked (22 % or 8 % resp. of t-butylbenzene being formed).

Stereoselective Synthesis of 1-Butene with Lithium Sulfate as Elimination Catalyst [1]

By *H. Noller, M. Rosa-Brusin*, and *P. Andréu* [*]

In our studies of the elimination of hydrogen halide on solid catalysts we have always obtained mixtures of the three linear butenes from n-butyl chloride or bromide, *cis* + *trans* 2-butene being formed in large excess [2]. Recently, however, using lithium sulfate and a microcatalytic technique (a pulse technique) at temperatures between 320 and 370 °C, we obtained 1-butene exclusively from n-butyl bromide [3]; at 390 °C some 10 %, and at 420 °C some 50 %, of 2-butene was formed.

A nitrogen stream (35 ml/min), saturated at 70 °C with n-butyl bromide, was passed through a horizontal glass tube (inner diameter 2 cm) holding *ca.* 50 g of catalyst, then through a

trap cooled in ice and water (to remove unchanged butyl bromide), and finally through a soda-lime tube (to remove HBr).

The lithium sulfate used as catalyst ($LiSO_4 \cdot H_2O$ cryst., Merck) is advantageously tempered for 11 hr at 160 °C[3]. The butenes produced were analysed by gas chromatography (column 3.5 m long, 1/4 inch diameter; packing, 30 % dinonyl phthalate on 60–80 mesh Chromopak from Curtin, USA; room temp.; carrier gas, 120 ml of He per min; flame ionization detector).

The 1-butene obtained on use of 45 g of lithium sulfate at 270 °C contained *ca.* 50 % of 2-butene; the selectivity is thus less on a preparative scale. The proportion of 2-butene can be kept below 10 % only by using a mixture of lithium sulfate 30 g and soda-lime 15 g (for removal of the HBr that favors isomerization) at 270 °C; under these conditions the conversion is about 20 % of the butyl bromide passed over the catalyst. At 300 °C the conversion is higher, but so is the proportion of 2-butene (*ca.* 30 %).

The composition of the product is almost unchanged when the experiment is run for several hours. A recirculating reactor of the type described by *Schwab* would probably be very suitable for continuous operation[4].

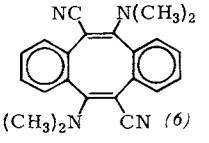
Stable *o*-Quinodimethanes [1]

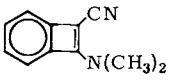
By *R. Gompper, E. Kutter,* and *H. Kast* [*]

In contrast to their simple analogues, ω,ω-hetero-substituted (SR, NR_2, OR, or Hal) quinonemethides are stable[2]. The same structural principle[3] is incorporated in some stable *p*-quinodimethanes. Thus it was to be expected that suitable substituents would also stabilize *o*-quinodimethanes sufficiently to prevent the normal valence isomerization to bicyclo[4.2.0]octatrienes.



(1), R = H *(2)*, R = H

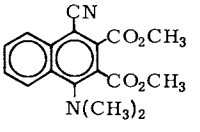
(4), R = H *(3)*, R = H



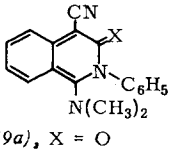
(5), R = *o*, *p*-$C_6H_3(NO_2)_2$

o-(Cyanomethyl)benzoic acid and PCl_5 in ether give the crystalline acid chloride (in CH_2Cl_2 an isoquinoline is formed[4]), which without further purification, is treated in benzene with aqueous dimethylamine, thus yielding the amide *(1)*[5] (a pale yellow oil, b.p. 128 °C/0.005 mm). Heating this amide with P_2S_5 in pyridine affords impure *o*-(cyanomethyl)thiobenzamide *(2)* (b.p. 140–145 °C/0.01 mm) as a deep red oil, which with methyl iodide yields the colorless quaternary salt *(3)* (m.p. 168–171 °C). If a solution of the salt *(3)* in dimethylformamide (DMF) at −40 °C is treated with a strong base (e.g. NaH, K t-butoxide, or C_2H_5MgI), it at once becomes deep blue; the following reactions, as well as the color[3], indicate the formation of the *o*-quinodimethane, 5-(cyanomethylene)-6-[(dimethylamino)(methylthio)methylene]-1,3-cyclohexadiene *(4)*.

If the temperature of the blue solution of compound *(4)* in DMF rises to −10 to 20 °C, the color changes to yellowish-brown, and if the mixture is then poured into water 5,11-dicyano-6,12-bis(dimethylamino)dibenzo[*a,e*]cyclooctatetraene *(6)* is isolated in *ca.* 50 % yield [colorless crystals, m.p. 236–238 °C; ν(CN) = 2195 cm^{-1}].

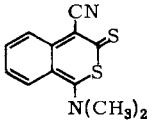


(6)



(7)

Elemental analysis, osmometric determination of the molecular weight in chloroform, and IR and NMR spectra confirm the structure given. We assume that compound *(6)* arises directly by dimerization of *(4)* and loss of CH_3SH from the primary product, since there is no indication of intermediate formation of the benzocyclobutadiene *(7)*. The *o*-quinodimethane *(5)*, which is stable even at room temperature, is obtained by treatment of *(4)* in DMF at −40 °C with 1-fluoro-2,4-dinitrobenzene, forming reddish-violet crystals with a golden-yellow sheen, m.p. 146–148 °C, λ_{max}(DMF) = 540 mμ.



Compound *(4)* is the starting material for many cycloadditions (all effected in DMF at −40 °C, the reaction mixture subsequently being poured into water at 20 °C). Dimethyl acetylenedicarboxylate and *(4)* yield dimethyl 1-cyano-4-(dimethylamino)-2,3-naphthalenedicarboxylate (pale yellow needles, m.p. 131–133 °C; λ_{max}(DMF) = 377 mμ). 2,3-Dihydroisoquinolines *(9)* are formed in good yields on treatment of *(4)* with phenyl isocyanate [*(9a)*, orange prisms, m.p. 240–242 °C], phenyl isothiocyanate [*(9b)*, red

Dehydration of 3-Acetonylglutaric Acid

By *E. Winterfeldt*[*]

The preparation of the anhydride *(2)* [1] by heating 3-acetonyl glutaric acid *(1)* with acetyl chloride (2 hr, *ca.* 51 °C) gives an approximately 20 % yield of a by-product that has a much higher melting point (170 °C) and is much less soluble in ether than *(2)*. The IR spectrum of this compound shows no anhydride band but has a broad carbonyl band at 1750 cm^{-1} and intense bands at 940, 1050, and 1130 cm^{-1}. Our assumption that the dilactone *(3)* had been formed was confirmed by elemental analysis and the NMR spectrum.

The signal of the methyl group appears as a singlet at τ = 8.28, and that of the two identical protons H_D as a broad singlet (half-width 4.5 Hz) at τ = 7.78 (intensity ratio 3:2), as expected since coupling with H_C is only slight. The protons H_A and H_B constitute a distorted AB quartet in which the two inner lines are almost superposed at τ = 7.25 (J_{AB} = 19 Hz); here also only slight coupling with H_C is observed.

The lactone *(3)* can be converted by methanolic hydrochloric acid into dimethyl 3-acetonylglutarate *(4)* (IR: 1730, 1150 cm^{-1}; NMR: τ_{OCH_3} = 6.39, τ_{OC-CH_3} = 7.90, τ = 7.4–7.7, intensity ratio 6:3:7), which is also obtained within 5 min when the dicarboxylic acid is allowed to react with diazomethane in ether at room temperature.

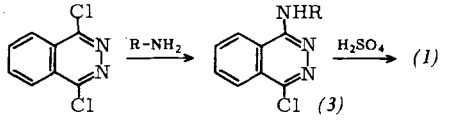
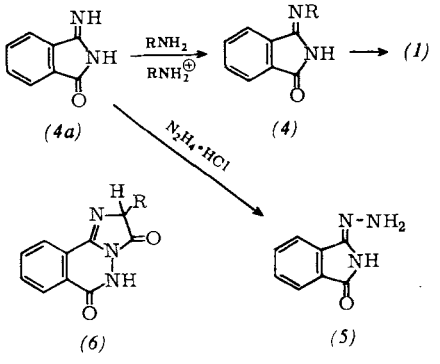
Synthesis of 4-Amino-1-phthalazinones [1]



By *W. Flitsch* and *H. Peters* [*]

The Ing-Manske reaction of *N*-substituted phthalimides with hydrazine affords primary amines and 1,4-phthalazinedione *(2)* [2]. Except for the parent compound *(1a)* with R = H [4], 4-amino-1-phthalazinones *(1)*, which have been assumed to be intermediates in this reaction [3], have remained hitherto unknown.



4-Amino-1-phthalazinones can be prepared in the following ways:

1. Reaction of 1,4-dichlorophthalazine [5,7] with primary amines and hydrolysis of the 1-amino-4-chlorophthalazines *(3)* by concentrated sulfuric acid, insofar as the group R is stable (*e.g.* H or CH_3).

2. A more generally useful synthesis is acid-catalysed transamination of 3-iminoisoindolin-1-one *(4a)* to yield 3*N*-substituted 3-iminoisoindoline-1-ones [6,8] and reaction thereof with hydrazine, which, contrary to the assumption made by *Elvidge* and *Linstead* [6], leads to 4-amino-1-phthalazinones *(1)*.

We used acid-catalysed reaction of compound *(4a)* and hydrazine to obtain the 3-hydrazonoisoindolin-1-one *(5)* described by *Elvidge* and *Linstead*. Compounds *(4c)* and *(4d)* react with hydrazine, affording imidazo[2,1-*a*]phthalazines *(6)* which are hydrolysed by alkali to the 4-amino-1-phthalazinones *(1d)* and *(1e)*. The structure of *(6)* was proved by elemental analysis and IR spectra.

The 4-amino-1-phthalazinones described are not converted into 1,4-phthalazinedione *(2)* either under the conditions of the Ing-Manske reaction (heating with dil. HCl) or by means of conc. HCl and thus cannot be intermediates in this reaction.

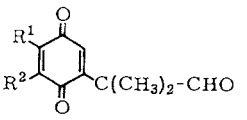
Simple Method for Introduction of a Formylalkyl Group into Quinones



By *K. Ley* and *R. Nast* [*]

Enamines react smoothly with quinones, yielding 1:1 adducts [1]. Even in aqueous suspension, the resulting hydroxycoumarans *(1)* can be converted into formyl alkylquinones *(2)*, with loss of the amino group, by oxidizing agents such as $FeCl_3$, $CuCl_2$, nitric acid, and nitrous acid. Smooth oxidation requires that one of the positions *ortho* to the hydroxyl group in the coumaran *(1)* shall be substituted. Yields are greater than 70 %.

R^1	R^2	M.p. (°C)	Color of solid
H	$C(CH_3)_2$–CHO	91–92	Yellow
CH_3	$CHCH_3$–CHO	154–156	Yellow
H	1-Formyl-4-methyl-3-cyclohexenyl	140–142	Yellow

R^1	R^2	M.p. (°C)	Color of solid
$(CH_3)_3C$	H	87–88	Violet [a] (yellow in CH_3OH, CH_3CN)
CH_3	CH_3	60–62	Yellow
C_6H_5	H	142–143	Yellow
Cl	Cl	77–79	Yellow

[a] The solid compound gives an ESR signal.

Synthesis of compound (1):

149 g of isobutenylmorpholine is added dropwise to an ice-cooled suspension of 158 g (1 mole) of 1,4-naphthoquinone in 700 ml of methanol at 15–22 °C, with stirring. The mixture is stirred for 1 h at room temperature, and then filtered under suction; the crystalline filter cake is washed with 3 litres of methanol/water (2:1), and dried at 50 °C. Yield 224 g. M.p. 160–163 °C. The product can be used without further purification.

Synthesis of Compound (2):

540 g of $FeCl_3 \cdot 6H_2O$ in 750 ml of water is added dropwise to a well-stirred suspension of 299 g (1 mole) of compound *(1)* in 1 liter of water. Stirring is then continued for 1 h at room temperature and the mixture filtered. The filter-cake is washed with water, and recrystallized from iso-propanol. Yield 196 g = 86 %.

A New Synthesis of Aliphatic Isothiocyanates [1, 2]

By *J. C. Jochims* and *A. Seeliger* [*]

Carboxylic, phosphoric [3], and sulfonic acids [4] react intermolecularly with carbodiimides, yielding anhydrides; however, carbodiimide cleaves H_2S intramolecularly from dithiocarbamic acids, and isothiocyanates are obtained:

$$R{-}NH_2 + R'{-}N{=}C{=}N{-}R' + CS_2 \longrightarrow R{-}N{=}C{=}S + R'{-}NH{-}CS{-}NH{-}R'$$

This reaction, in a neutral aqueous medium at low temperature, can be used for the preparation of aliphatic isothiocyanates under milder conditions than are required for previously known isothiocyanate syntheses.

Experimental: 1/10 mole of a primary aliphatic amine is added to 1/10 mole of dicyclohexylcarbodiimide (or some other carbodiimide) and 40 ml of CS_2 in 100 to 200 ml of ether (or tetrahydrofuran) at −10 °C, with stirring, and the temperature is allowed to rise to 20 °C during 3 h. After the mixture has been kept for 12 h at room temperature it is filtered and the residue (dicyclohexylthiourea) washed with ether; the filtrate is concentrated and the alkyl isothiocyanate obtained (cf. table) is recrystallized or distilled in a vacuum. The poorer yields of 9-fluorenyl isothiocyanate are due to partial decomposition.

R–N=C=S R	Yield (%)	B.p. (°C/12 mm) or m.p. (°C)
Benzyl	90	125–126
$(C_2H_5O)_2CH-CH_2$	87	102–103
Phenylisobutyl	99	137–138
Diphenylmethyl	81	(59, from ethanol)
9-Fluorenyl	70	(91–92; from benzene/light petroleum)

In contrast to primary aliphatic amines, 1 mole of the more weakly basic α-naphthylamine uses only $^1/_2$ mole of carbodiimide under the usual conditions and 1,3-di-(α-naphthyl)-thiourea is obtained quantitatively.

The formation of the isothiocyanate thus depends on the relative velocities of competing reactions of the amine, namely, a) that with carbon disulfide to give the dithiocarbamic acid and b) that with the isothiocyanate formed to give the thiourea. With strongly basic aliphatic amines, reaction a) is faster and yields mainly alkyl isothiocyanates; with aromatic amines reaction b) is faster, yielding only the thioureas. However, even with aliphatic amines, reaction b) cannot be entirely suppressed, *i.e.* some 1,3-dialkylthiourea RHN–CS–NHR is formed and it is precipitated with the dicyclohexylthiourea. Therefore, when stoichiometric amounts are used the residual carbodiimide must be separated from the alkyl isothiocyanate by fractional distillation or washing with pentane; it is advantageous to begin with somewhat less than 1 mole of carbodiimide.

Attempts to prepare isocyanates by an analogous method gave ureas only.

Metal Complexes of Diethylthiophosphinic Acid

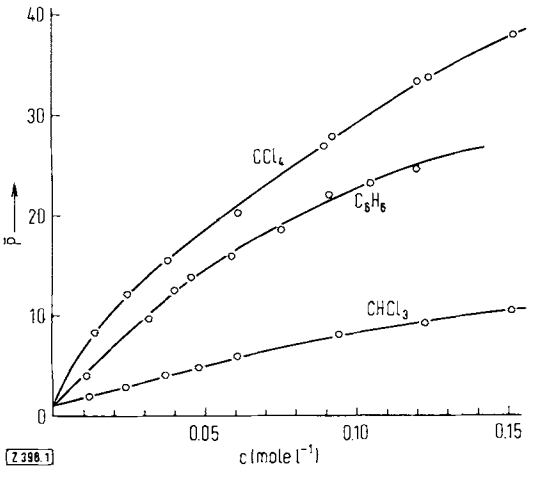
By *W. Kuchen* and *H. Hertel*[*]

Metal complexes of diethylthiophosphinic acid show a greater tendency to associate in solvents free from electron donors than do the corresponding dithiophosphinato complexes[1,2]; the influence of various factors on the association thus becomes more evident. To prepare the complexes we used sodium diethylphosphinate, $(C_2H_5)_2P(S)ONa\cdot 3H_2O$, which was obtained as colorless leaflets (m.p. 58–59 °C) by neutralization of thiophosphinic acid[3] $(C_2H_5)_2P(S)OH$, evaporation, dissolution of the residue in acetone, and precipitation with ligroin.

Complexes of type *(1)* were precipitated when sodium diethylthiophosphinate was added to aqueous solutions of a metal salt, and they were recrystallized from 2-propanol. Complexes with Zn(II) (m.p. 186–188 °C), Cd(II) (m.p. 119–122 °C), In(III) (m.p. 133 °C), or Pb(II) (m.p. 99–102 °C) as the central atom formed colorless crystals which, as is shown by thermogravimetric analysis, melt with decomposition.

A mixture of stoichiometric quantities of $(C_2H_5)_2P(S)OH$ and $CoCO_3$ in boiling benzene gives, after several hours, a viscous, deep blue solution of the Co(II) complex, which is obtained as intensely blue crystals (m.p. 186–188 °C) from 2-propanol and forms mixed crystals with the Zn(II) complex.

All these complexes dissolve readily in organic solvents such as benzene, carbon tetrachloride, chloroform, alcohols, and acetone. Osmometric determination of the molecular weights shows that the *octahedral* In(III) complex is present only as a monomer in benzene over a wide range of concentrations (from *ca.* 0.005 to *ca.* 0.1 mole l^{-1}), whereas the *tetrahedral* complexes are strongly associated. With rising concentration the degree of association of the tetrahedral complexes approaches a limiting value which depends on the solvent (see Fig. 1) and on the central atom (see Table 1); extrapolation to infinite dilution always leads to the monomer. Viscometric studies[5] of the Co(II) and Zn(II) complexes in benzene disclosed a very steep rise in the reduced viscosity η_{spec}/c with rising concentration. The nature of the chalcogen atom also influences the association. For instance, the degree of association of the Cd(II) complexes increases in the order $Cd[(C_2H_5)_2P(Se)Se]_2 < Cd[(C_2H_5)_2P(Se)S]_2 < Cd[(C_2H_5)_2P(S)S]_2 < Cd[(C_2H_5)_2P(S)O]_2$ from 1.75 to 2.5 (at $c = 0.07$ mole/l, osmometrically in benzene at 37 °C).



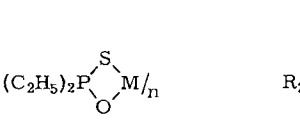


Fig. 1. Degrees of association $\bar{P}$ calculated from the osmometrically [4] determined apparent number average molecular weights of $Co[(C_2H_5)_2P(S)O]_2$ at 37 °C in CCl_4, C_6H_6, and $CHCl_3$ (mol. wt. of monomer 333.27).

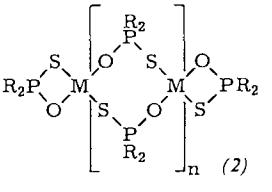

Table 1. Mean degree of association of complexes $M[(C_2H_5)_2P(S)O]_2$ in benzene at 37 °C.

mol/l	Cd(II)	Co(II)	Zn(II)
0.01	2.2	4.0	5.6
0.05	2.5	14.0	17.4
0.10	2.5	22.6	23.6
0.15	–	27.4	27.6

We assume that association involves formation of chelate bridges as in formula *(2)*, which was previously postulated or proved for metal complexes of the dialkyldithiophosphinic acids[1,2] and for phosphinic acids[6]. The influence of hybridization of the metal ions and the radii of the donor atoms, in particular, favor our view that bridged structures of low strain are formed for steric reasons[1]. That there is no tendency towards a higher coordination number on association could be shown for the Co(II) complex: the intensities and positions of the absorption maxima in the electronic spectra ($\lambda_{max} = 605$ mμ, $\log \varepsilon = 2.591$), measured for benzene and carbon tetrachloride solutions of various concentrations,

(1)

(2)

indicate in all cases tetrahedral coordination of the metal[7], which is clearly present also in the crystals since a magnetic moment of μ_{eff} = 4.63 B.M. was found[8].

The Co complex is monomeric in pyridine, which acts as an electron donor, the electronic spectrum (λ_{max} = 515 mμ, log ε = 1.496) here indicating octahedral coordination of the Co[7]. In agreement with this, we were able to isolate the pink bis(diethyl thiophosphinato)tetrapyridinocobalt(II), $[(C_2H_5)_2P(S)O]_2Co(C_5H_5N)_4$ (m.p. 63–64 °C; μ_{eff} = 4.98 B.M.[8]; non-electrolyte in pyridine), in which the phosphinato group acts as unidentate ligand.

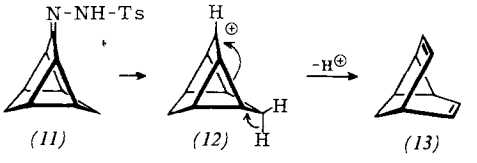
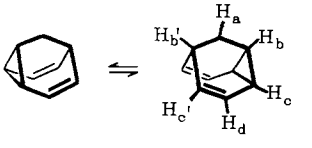
Rearrangements of the Triasterane System [1]

By *U. Biethan*, *H. Klusacek*, and *H. Musso* [*]

The cyclopropane rings of triasterane *(3)* are parallel and particularly favorably situated for rearrangements induced by conversion of a methylene bridge into an anion, radical, cation, or carbene. For instance, the Wolff-Kishner reduction of triasteranone *(1)* gives 29 % of triasterane *(3)*, 8.5 % of bicyclo[3.3.1]nona-2,6- and -2,7-diene, as well as 0.9 %[2] of tricyclo[3.3.1.$0^{2,8}$]non-3-ene *(5)*[1]. The formation of *(5)* can be explained by homoallylic rearrangement of the anionic intermediate *(2)* to the anion *(4)* and protonation of the latter.



(1) *(2)* *(3)* *(4)* *(5)* *(6)*



(7) R = Cl *(9)* R = O
(8) R = CHN_2 *(10)* R = N-NH-Tosyl

The olefin *(5)* can be hydrogenated over platinum in glacial acetic acid to the hydrocarbon *(6)* and thence further to bicyclo-[3.3.1.]- and -[3.2.2]-nonane[1]. The structures of the products *(5)* and *(6)* are proved by comparison with the products of the following syntheses. 3-Cyclohexenylacetic acid yields its acid chloride *(7)* (b.p. 90–92 °C/15 mm, 95 %) and thence a diazo ketone *(8)* which is decomposed by copper powder in boiling cyclohexane to yield the ketone *(9)* (colorless crystals, m.p. 92–94 °C, yield 52 %). Heating the tosylhydrazone *(10)* (m.p. 203–205 °C, 80 %) with sodium glycolate in ethylene glycol affords a crude product, 85 % of which is compound *(5)* and the remainder contains six compounds of unknown structure[3]. The compound *(5)* can be isolated from this mixture in 6 % yield[2] as colorless volatile crystals, m.p. 68–70 °C. Wolff-Kishner reduction of the ketone *(9)* gives the hydrocarbon *(6)* as colorless crystals with a pleasant smell (m.p. 128–129 °C, yield 63 %[2]).

According to the mechanism of the Bamford-Stevens reaction[4] the cation *(12)* should be accessible as a product from the tosylhydrazone *(11)* and should become stabilized by loss of a proton. If this hydrazone *(11)* (m.p. 202–204 °C, 79 %) is treated in the way described for *(10)*, then tricyclo-[3.3.1.$0^{2,8}$]nona-3,6-diene *(13)* is formed. The sublimed product (m.p. 37–44 °C, 57 %) contains 97 %[3] of *(13)* which, when purified by gas chromatography, forms light-sensitive, colorless crystals (m.p. 46 °C, 43 %[2]) with an unpleasant odour[5].

(11) *(12)* *(13)*

The NMR spectrum[6] of *(13)* in $CCl_4/CDCl_3$ at room temperature confirms the constitution assigned and indicates rapid exchange between the structures of equal energy content, for it shows only four signals in the intensity ratio 2:2:4:2, namely: H_a 1.06 ppm (triplet, J = 2.5 Hz), H_b 2.33 ppm (multiplet), H_c 3.97 ppm (triplet, J = 7.5 Hz), and H_d 5.63 ppm (triplet, J = 7.5 Hz).

Hydrogenation of *(13)* over platinum in glacial acetic acid leads, as in the case of *(3)*, to a mixture of *(6)* and bicyclo-[3.3.1]- and -[3.2.2]-nonane[3].

Compound *(8)* was not purified. Results obtained in the analysis of the other new compounds were consistent with the constitutions assigned. Compatible IR, NMR, and mass spectra were also obtained.

Synthesis of D-Gulose from D-Glucose

By *W. Meyer zu Reckendorf*[*]

The hydrate *(1)* of 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-3-hexulofuranose, which is readily accessible from glucose[1], is, surprisingly, acetylated by acetic anhydride in pyridine (16 h, 60 °C) to the enol acetate *(2)* [yield 81 %, m.p. 62 to 63 °C, $[\alpha]_D^{20} = -33.0°$ (c = 1 in $CHCl_3$)]. The position of the double bond in *(2)* was established by the ^{1}H–NMR spectrum [τ values; solvent: $CDCl_3$ with tetramethylsilane as external standard: H–1 6.06; H–2 5.41; H–5 4.68; 2 H–6 4.09 (all doublets); CH_3CO 2.21 (singlet); 4 CH_3 1.39–1.54, $J_{1,2}$ 5.5 Hz], by results of the following experiments, and by steric considerations: the dioxolane ring does not permit a double bond between C–2 and C–3.

(1) *(2)* *(3)* *(4)*

Reduction of the product *(2)* with $NaBH_4$ in methanol occurs stereospecifically from the β-side, giving 1,2:5,6-di-*O*-isopropylidene-α-D-gulofuranose *(3)* [yield 60 %, m.p. 105–106 °C, $[\alpha]_D^{20} = +7.5°$ (c = 1 in $CHCl_3$)], which affords a quantitative yield of D-gulose *(4)* on hydrolysis with Lewatit S 100 H^+[2] (30 min, 90 °C). The product *(4)* was found to be pure on thin-layer chromatograms and was identified as the phenolhydrazone[3] [m.p. and mixed m.p. 142–143 °C (lit.[3] 143 °C) with a sample prepared from authentic D-gulose[4]].

The 5,6-*O*-isopropylidene group of *(2)* is labile in alkali and is removed by the $NaBH_4$ in a side reaction. This reaction is being investigated.

Contrary to statements in the literature[1], the hydrate *(1)* undergoes rapid and marked mutarotation in $CHCl_3$, this depending on loss of water of hydration. Simultaneously a strong positive Cotton effect becomes evident in the rotatory dispersion.

(1) in $CHCl_3$ (c = 10)			*(1)* in $CHCl_3$ (c = 10), dried by mol. sieve 3 A [a]	
λ (mμ)	[α] (°)	Lit. [1]	[α] (°)	Lit. [1]

Synthesis of Indium Phosphide from Indium and Phosphorus Pentoxide

By *M. Kuisl*[*]

As an $A^{III}B^V$ compound, indium phosphide is of interest as semiconductor material[1]. It was first prepared by *Iandelli*[2] who heated the elements for 350 to 400 h in a sealed tube at 700 °C. We have found that phosphorus pentoxide reacts with indium, yielding indium phosphide, in an appreciably shorter time.

The reaction occurs at 850 °C within 8 h according to the equation:

$$3.5\ P_4O_{10} + 14\ In \longrightarrow 5\ In_2P_2O_7 + 4\ InP.$$

Indium turnings and phosphorus pentoxide are weighed into a quartz ampoule with exclusion of moisture and are mixed. The ampoule is then sealed and heated. The products can be separated by sublimation of the InP above 650 °C in a high vacuum. Use of non-stoichiometric proportions of the starting materials does not lead to any other indium phosphate. If more metal is used, the excess remains unattacked even after 100 h. If too much P_4O_{10} is present, phosphorus is formed and is deposited as a yellow or red film on the walls of the ampoule and it may inflame when the ampoule is opened. To obtain pure InP one thus starts with an excess of indium, since indium has a very low vapor pressure at 650 °C whereas at this temperature phosphorus can pass over into the sublimate.

InP was characterized by Debye-Scherrer diagrams. $In_2P_2O_7$ is formed as white crystals, which dissolve slowly in acids with evolution of gas; presence of a P_2O_7 anion is indicated by the IR spectrum as well as by elemental analysis (the IR bands lie within 20 to 30 cm^{-1} of those of $Na_4P_2O_7$, and the intensities are similar[3]). Indium is formally bivalent in the formula $In_2P_2O_7$, but, by analogy with In_2Br_4 and Ga_2Cl_4, a composition $In^{I}In^{III}P_2O_7$ can be assumed; ESR measurements seem to confirm this[4].

Synthesis of Oxalactams (2-Morpholinones) from Aziridinium Tetrafluoroborates and Hydroxy Esters

By *E. Pfeil* and *U. Harder* [*]

The reactivity of the aziridinium cation towards the hydroxyl group of alcohols and phenols makes possible a simple synthesis of 2-alkoxyethylamines [1].

If the reaction is carried out with α-hydroxy esters *(1)* and aziridinium tetrafluoroborate *(2)*, one obtains first the salts *(3)* and then, by loss of alcohol, 2-substituted 3-oxapentane-5-lactams (2-morpholinones) *(4)* together with linear polyamides.

(2) *(1)* *(3)* *(4)*

R	R^1	R^2	*(4)*, M.p. (°C)	*(4)*, B.p. (°C/mm)	*(4)*, Yield (%)	*(4)*, IR νC=O (cm^{-1})
C_4H_{11}	H	H	106	142/7	33.6	1667
C_2H_5	CH_3	H	61–62	152/12	18.4	1667
CH_3	CH_3	CH_3	115	133/8	33.0	1672
C_2H_5	C_6H_5	H	144–145	—	27.6	1678, 1647

Although the yields are low the range of applicability and the simplicity of the process make it a useful route to the morpholinones which have hitherto been little investigated.

A compound of the type *(1)* is treated at 100 °C with one molar equiv. of the salt *(2)*. The mixture is heated for about 20 h at 100 °C, allowed to cool, and then dissolved in ether. Treatment with a two- to three-fold excess of piperidine or potassium ethoxide, extraction with ether, and distillation or recrystallization from cyclohexane yields the products *(4)*. The structures of the compounds produced are established by elemental analysis and IR spectra.

Ethyl DL-3-hydroxybutyrate gives analogously DL-3-methyl-4-oxahexan-6-lactam, b.p. 145–150 °C/10 mm, m.p. 109 °C, $\nu_{C=O}$ = 1678 cm^{-1}, in 29% yield.

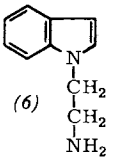
[1] *L. B. Clapp, E. A. Rick, W. B. Moniz,* and *V. B. Schatz,* J. Amer. chem. Soc. *77*, 5116 (1955); *U. Harder, E. Pfeil,* and *K. F. Zenner,* Chem. Ber. *97*, 510 (1964).

2-Aminoethylation of Indole and of 2-Methylindole



By *E. Pfeil* and *U. Harder* [*]

Aminoalkylated indoles are of importance because of their physiological properties and their use as intermediates in the synthesis of natural products, so that numerous multi-stage syntheses have been developed for them. We have succeeded in introducing the (protonated) aminoethyl group directly into the indole ring by means of the readily accessible [1] aziridinium tetrafluoroborate *(3)*, which reacts exothermally with indole *(1)* and 2-methylindole *(2)*. With the methyl compound *(2)* the reaction gives 2-methyltryptamine *(5)* in 80–90% yield, this being the simplest and fastest process for preparation of this substance.

(1) R = H *(3)* *(4)* R = H
(2) R = CH_3 *(5)* R = CH_3

The salt *(3)* and indole afford tryptamine *(4)*, 1-(2-aminoethyl)indole *(6)*, and numerous other products, including tryptamines with several aminoethyl side-chains. The ratio

(6)

of the yields of *(4)* and *(6)* depends on the temperature: at 70 °C one obtains 40% of *(4)* and 4% of *(6)*, but at 130 °C 20% of *(4)* and 20% of *(6)*.

The structures of the products are proved by elemental analysis and IR, NMR, and UV spectra, and by comparison with authentic material by thin-layer chromatography. The products can be separated by distillation or by chromatography on silica gel with chloroform-methanol-ammonia (85:15:2).

Tryptamine

23.4 g (0.2 mole) of indole is heated to 70 °C and treated, with stirring, with 26.3 g (0.2 mole) of the salt *(3)* over a period of 20 min; after a further 10 min the reaction is complete and the mixture solidifies. The bases are liberated by addition of 33.6 g (0.6 mole) of KOH in 50 ml of water. The mixture is then extracted with benzene for 20 h. Fractional distillation of the extract gives 12.9 g (40.3%) of tryptamine (b.p. 143–146 °C/0.75 mm, m.p. 118 °C; hydrochloride, m.p. 251–253 °C) as well as 1.3 g of 1-(2-aminoethyl)indole *(6)* [b.p. 125–126 °C/0.75 mm, n_D^{20} = 1.6092; IR, 3370 cm^{-1} (νNH_2); UV (ethanol), λ = 219 nm (ε = 28900), 273 (5080), 280 (5130), 292 (4100); ^{1}H–NMR: NH_2, τ = 9.25 (s); CH_2–NH_2, τ = 7.25 (t); CH_2–N(indole), τ = 6.15 (t); indole-β-H, τ = 3.50 (d); indole-α-H, τ = 2.95 (d); phenyl, τ = 2.85–2.50 (m); hydrochloride, m.p. 213–214 °C (decomp.); monopicrate (yellow), m.p. 211–212 °C; dipicrate (red), m.p. 160–162 °C].

2-Methyltryptamine

20.0 g (0.15 mole) of the salt *(3)* is added to 10.0 g (0.15 mole) of *(2)* at 110 °C. Liberation of bases with 25.2 g (0.45 mole) of KOH, in 50 ml of water, extraction for 10 h with benzene, and distillation gives 23.3 g (87%) of 2-methyltryptamine *(4)*, b.p. 155 °C/0.05 mm, m.p. 107 °C (picrate, m.p. 218 °C).

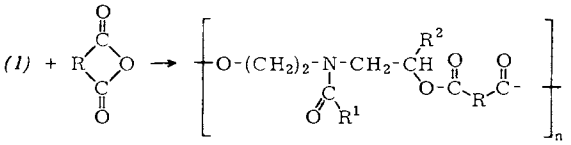
Reaction of Bicyclic Amide Acetals with Carboxylic Acids and their Anhydrides

By *R. Feinauer* [*]

Brechbühler et al. [1] recently reported a new method of esterification by treatment of carboxylic acids with acetals of *N,N*-dimethylformamide. The bicyclic amide acetals *(1)* [2], which have recently become readily accessible from epoxides and 2-oxazolines, react analogously with carboxylic acids or their anhydrides, yielding ester amides *(2)* of diethanolamine.

(1)



(2)

The components – a 5-fold excess of the acid or anhydride is used – are heated without a solvent for 2 h at 120 °C, and the ester amides are isolated by distillation. The products are viscous oils, whose structures can be established by elemental analyses, molecular-weight determinations, and by IR spectra.

R^1	R^2	R^3	*(2)*, Yield (%)	*(2)*, B.p. (°C/mm)	*(2)*, n_D^{20}
C_2H_5	C_6H_5	H	60	198/0.4	1.5152
C_2H_5	C_6H_5	CH_3	95 [a]	177/0.1	1.5052
C_2H_5	C_6H_5	C_2H_5	66	179/0.1	1.5038
C_2H_5	$CH_2OC_6H_5$	H	92	228–230/1.7	1.5159
C_2H_5	$CH_2OC_6H_5$	CH_3	92 [a]	205/0.3	1.5052
C_2H_5	$CH_2OC_6H_5$	C_2H_5	84	207/0.1	1.5055
C_6H_5	C_6H_5	CH_3	82	245/1	1.5450

[a] On use of acetic anhydride.

If equimolar amounts of the bicyclic amide acetals *(1)* are heated with dicarboxylic acid anhydrides *(3)* for 2 h at 120 to 140 °C with stirring and passage of dry nitrogen, a polyaddition to yield polyester amides of structure *(4)* occurs

rapidly, even in the absence of a catalyst. These polymers are purified by reprecipitation from chloroform/ether (1:10 v/v) and their structures determined by elemental analyses, molecular-weight determinations, and IR spectrometry.

If dicarboxylic acids are used in place of the anhydrides *(3)*, condensates of structure *(4)* but with lower molecular weights are obtained. If the temperature is raised or the reaction time prolonged, these polymers react by transamidation with loss of monocarboxylic acid R^1COOH to cross-linked resins.

Synthesis of *N*-(Fluorosulfonyl)iminosulfur Difluoride

By *O. Glemser, H. W. Roesky,* and *P. R. Heinze*[*]

Fluorosulfonamide *(1)*, prepared by ammonolysis of sulfuryl difluoride[1], reacts with tetrafluorosulfur at room temperature in the presence of sodium fluoride as HF-trapping agent, to yield 72% of *N*-(fluorosulfonyl)iminosulfur

$$\underset{(1)}{FSO_2NH_2} + SF_4 \longrightarrow \underset{(2)}{FSO_2N{=}SF_2} + 2\,HF$$

difluoride *(2)*. Its ready accessibility makes the product *(2)* suitable for preparation of further N,S compounds.

Compound *(2)* is a colorless liquid that is decomposed by traces of water with loss of HF; b.p. 105.5 °C (with partial decomposition), m.p. 77–78 °C.

Its composition is proved by the results of elemental analysis and determination of the molecular weight [164 (cryoscopically in benzene); calc 167].

The ^{19}F–NMR spectrum of *(3)* includes the triplet expected for the FSO_2 group and a doublet (spin-spin coupling of the F atoms) for the SF_2 group. N–F coupling is not observed at room temperature. The nitrogen merely broadens the bands, but at −50 °C sharper signals are obtained. The coupling constant is $J_{FF} = 9$ Hz.

	Chemical shifts (ppm) [a]			
	30 °C	−50 °C	Multiplicity	Intensity
δSF_2	−40.0	−35.7	Doublet	2
δSF	−62.2	−44.0	Triplet	1

[a] With respect to Freon 11 (CCl_3F) as external standard.

The IR spectrum of a capillary film in the NaCl region shows strong bands at 1443, 1258, 1222, 848, 795, 735, and 684 cm^{-1}, which are ascribed to the seven possible stretching vibrations, and other strong bands at 552, 473, 408, and 305 cm^{-1}, which are ascribed to deformation vibrations.

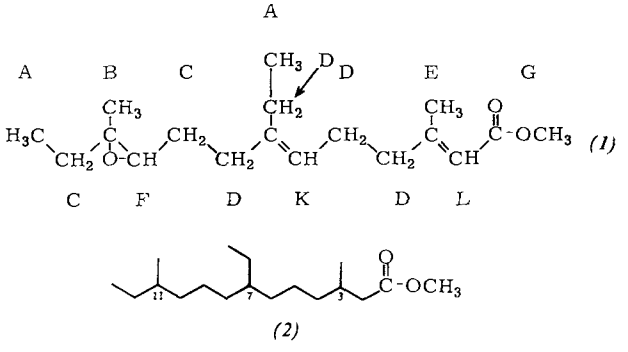
The Structure of the Juvenile Hormone



By *H. Röller, K. H. Dahm, C. C. Sweely,* and *B. M. Trost*[*]

The postembryonic development of insects is controlled by the molting hormone (ecdysone)[1], the juvenile hormone and an adenotropic factor (brain hormone). Previously we have isolated the juvenile hormone from abdomens of adult male *Hyalophora cecropia*, the giant silkworm moth[2].

Catalytic hydrogenation of 20 μg of juvenile hormone *(1)* in ethanol with palladium black gave a product *(2)* which has the empirical formula $C_{18}H_{36}O_2$ as calculated from its mass spectrum (molecular ion at *m/e* 284). The most abundant fragments at *m/e* 101 and 74 and the ion at M–31 show the presence of a methoxycarbonyl group on an aliphatic chain with a methyl branch at C-3. The mass spectrum provided no evidence of another functional group. Ions of relative high intensity at *m/e* 143, 185, and 153 (185–32) indicate an ethyl or dimethyl branch at C-7. The mass spectrum of *(1)*

contains the molecular ion at *m/e* 294 and fragments at *M*−18, *M*−31, and *M*−32. Comparison with *(2)* gives the empirical formula $C_{18}H_{30}O_3$ for *(1)*. Therefore, the hormone *(1)* has three double bonds or rings which can be hydrogenated and an oxygen that is easily eliminated. Catalytic hydrogenation of 30 μg of *(1)* with a poisoned catalyst (palladium on barium sulfate with triethylamine) gave several products with molecular ions at *m/e* 296 and 298. One spectrum shows an abundant ion at *m/e* 211 (298−87) indicating loss of the fragment $C_5H_{11}O$.

Cleavage of 15 μg of *(1)* with osmium tetroxide and periodic acid gave levulinic aldehyde which has been identified by gas chromatography. Another cleavage product has a peak in the gas chromatogram corresponding to a homologue of levulinic aldehyde.

(2)

The NMR-spectrum of 200 μg of *(1)* contains the signals (δ values with tetramethylsilane as internal standard): (A) 0.96 ppm, triplet, 6 H; (B) 1.16 ppm, singlet, 3 H; (C) 1.22–1.70 ppm, unresolved multiplet, 4 H; (D) 1.80–2.30 ppm, broad adsorption; (E) 2.12 ppm, narrow doublet, *J* 0.8 Hz, (D) and (E) together 11 H; (F) 2.46 ppm, triplet, 1 H; (G) 3.59 ppm, singlet, 3 H; (K) 4.96 ppm, unresolved multiplet, 1 H; (L) 5.46 ppm, broad singlet, 1 H.

Since the positions of branches and of double bonds have been determined by mass spectrometry and cleavage, the juvenile hormone can be identified as methyl 10-epoxy-7-ethyl-3,11-dimethyl-2,6-tridecadienoate. From the coupling constant J_{EL} and the chemical shift of E, the conjugated double bond has the *trans* configuration. The halfband width of the proton K signal compared with the absorption of similar terpene protons suggests the *trans* configuration also for the second double bond. Nothing can be said about the stereochemistry of the oxirane ring.

Detection of Hydrogen Bridges between Inosine and Other Nucleosides by NMR Spectroscopy

By *K. H. Scheit* [*]

Occurrence of a hydrogen bridge can be recognized in the NMR spectrum of a compound by a shift of the signals of the protons concerned to lower field strengths [1]. *Penman et al.* [2] and *Miles et al.* [3] were thus able to demonstrate hydrogen bridges between guanosine and cytidine, between thymine and adenine, and between uracil and adenine. 4-Thiouridine and inosine are present in t-RNS as rare nucleosides; their function has not yet been clarified. We have tried to determine with which nucleosides 4-thiouridine and inosine can associate by means of hydrogen bridges. For detection of weak hydrogen bridges it is essential to use an inert solvent such as deuterochloroform ($CDCl_3$). We therefore prepared the protected nucleosides *(1)*–*(6)* which are sufficiently

(1) Base = Adenine, R = $-CO-CH_3$
(2) Base = Uracil, R = $-CO-CH_3$
(3) Base = 4-Thiouracil, R = $-CO-CH_3$
(4) Base = Hypoxanthine, R = $-CO-CH_3$
(5) Base = Cytosine, R = $-CH(OC_2H_5)-CH_3$
(6) Base = Guanine, R = $-CH(OC_2H_5)-CH_3$

soluble in deuterochloroform. The NMR spectra of mixtures, each of two nucleosides, in $CDCl_3$ were compared with the spectra of the components at the same concentrations, and in some cases we found a shift of the NH signals to lower field strengths. This shift (interaction shift) denotes a hydrogen bridge between the bases of the nucleosides.

	Concn. (mole l^{-1})	Interaction shifts (τ-values) [b]
(1) + *(2)* [a]	0.4	ANH_2 −0.38; UN^3-H 3.34 [c]
	0.2	ANH_2 −0.56; UN^3-H −3.08
(1) + *(3)*	0.4	ANH_2 −0.38; TUN^3-H −2.90
	0.2	ANH_2 −0.54; TUN^3-H −2.70
(1) + *(4)*	0.4	ANH_2 −0.18; HN^1-H +0.1
	0.2	ANH_2 −0.28; HN^1-H no signal
(2) + *(4)*	0.4	HN^1-H +0.37; UN^3-H 0.75
	0.2	HN^1-H +0.32; UN^3-H −0.55
(2) + *(3)*	0.4	UN^3-H −; TUN^3-H −
(3) + *(4)*	0.4	HN^1-H +0.35; TUN^3-H −1.42
	0.2	HN^1-H +0.32; TUN^3-H −1.22
(3) + *(5)*	0.4	CNH_2 −; TUN^3-H −
(3) + *(6)*	0.4	GN^1-H −; GNH_2 −; TUN^3-H −

[a] Molar ratios 1:1 in all cases.

[b] Perkin-Elmer apparatus, 32.4 °C; tetramethylsilane ($\tau CH_3 = 10$) as internal standard. Negative values denote a shift to lower field strengths, positive values a shift to higher field strengths.

[c] ANH_2 = Adenine-6-NH_2; UN^3-H = Uracil-N^3−H; TUN^3-H = 4-Thiouracil-N^3−H; HN^1-H = Hypoxanthine-N^1−H; CNH_2 = Cytosine-4-NH_2; GN^1-H = Guanine-N^1−H; GNH_2 = Guanine-2-NH_2.

The table shows that 4-thiouridine *(3)* in $CDCl_3$ can associate with adenosine *(1)* and with inosine *(4)* but not with cytidine *(5)* or guanosine *(6)*. 4-Thiouridine has the same specificity as uridine in respect of its formation of hydrogen bridges with other nucleosides [2]. Inosine *(4)* apparently associates with adenosine *(1)* as well as with uridine *(2)*. The ability of the nucleobase hypoxanthine to form hydrogen bridges with purines and pyrimidines may be one reason for the presence of inosine in t-RNS. From the values of the

interaction shifts it may be concluded that the hydrogen bridges of adenosine-inosine, uridine-inosine, and 4-thiouridine-inosine are weaker than those of adenosine-uridine, and adenosine-4-thiouridine.

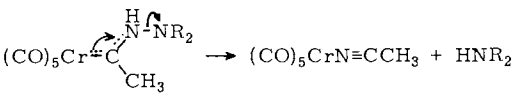
Novel Rearrangement Processes of Transition Metal Carbene Complexes

By *E. O. Fischer* and *R. Aumann* [*]

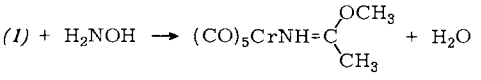
The reaction of (methoxymethylcarbene)pentacarbonylchromium(0) *(1)* [1] with substituted hydrazines of the type H_2N-NR_2, in water-free ether at room temperature, produces acetonitrilepentacarbonylchromium(0) *(2)* in high yield. The compound, which crystallizes as yellow platelets (m.p. 71 °C), gives IR and NMR spectra which are identical with those of the complex formed [2] from $Cr(CO)_6$ and CH_3CN



(1)

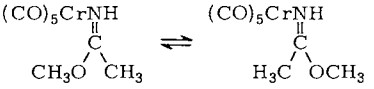
$$(CO)_5CrN{\equiv}CCH_3 + CH_3OH + HNR_2$$

(2)



R = CH_3, C_6H_5

It is probable that the reaction proceeds *via* the hydrazinomethylcarbene complex *(3)*, which immediately loses the amine group.



(3)

The reaction of anhydrous hydroxylamine with *(1)*, in ether at room temperature, produces the yellow (methyl acetimidato) pentacarbonylchromium(0) *(4)* in almost quantitative yield.

(4)

The structure of this novel complex was established by elemental analysis, NMR-, IR-, and mass spectra [3]. The methyl acetimidate can be split off by thermal decomposition of the compound at 200 ° and subsequently identified by gas chromatography. We assume that the ligand is bound at the nitrogen since Cr—N fragments are observed in the mass spectrum. The compound *(4)* exists in two forms which are in equilibrium with each other. NMR measurements at different temperatures showed that the two forms interconvert reversibly. The isomer ratio of the compounds *(4a)* and *(4b)* is 1.1:1 at 30 °C; 1.8:1 at 50 °C and 2:1 at 70 °C.

(4a) *(4b)*

The NMR spectrum [4] of the compound *(4a)* (saturated solution in C_6D_6 measured relative to the proton signal of the solvent at 436 Hz) shows two signals of equal intensity at 142 Hz and 100 Hz; the NMR spectrum of the compound *(4b)* shows two signals at 167 Hz and 44 Hz respectively.

CONFERENCE REPORTS

Drying of Paint Films in Steam

W. Funke and *K. Hamann*, Stuttgart (Germany)

Films of baking enamel are usually hardened by heat or infrared radiation. An attempt has been made to achieve cross-linking with superheated steam led over the laquered samples.

Considerable acceleration of the setting process was observed with binding agents which are cross-linked by condensation reactions. Thus the setting times of phenolic, urea, and melamine resins were shortened by 80%, or for the same setting time the necessary temperature was correspondingly reduced. Similar results were obtained for water-soluble baking enamels based on these binding materials. However, with films containing binders that dry oxidatively, drying is delayed by steaming. This result can be explained as being due to lack of the oxygen needed for hardening.

The acceleration of drying by superheated steam is probably caused by the rapid heating due to heat liberated on condensation of steam on the surface and to faster removal of solvent from the film.

Lecture at Freudenstadt (Germany), Sept. 29th, 1966 [VB 26a IE]
German version: Angew. Chem. 79, 192 (1967)

Adsorption on, and Desorption from, Pigments

K. Nollen, Stuttgart (Germany)

Isotherms for adsorption of substances of low molecular weight (fatty acids, amines) from organic solvents on oxide pigments can be described approximately by the Langmuir equation up to certain concentrations.

Studies of desorption showed that the adsorption is not reversible: some of the adsorbed material cannot be desorbed. The

amount of material that resists desorption depends on the temperature, solvent, and pigment and, above a certain concentration, is independent of the amount adsorbed. After adsorption of acid the amount resisting desorption is greater the more basic the pigment. It must thus be assumed that at least part of the non-desorbable acid is bound chemically to the pigment surface.

Reactive compounds do not lose their reactivity when firmly bound to the surface. For instance, the acrylic or methacrylic acid that cannot be desorbed from titanium dioxide (rutile) copolymerizes with styrene. The polymer, which is firmly bound to the pigment surface by its carboxyl groups, was identified by elemental analysis and IR spectroscopy.

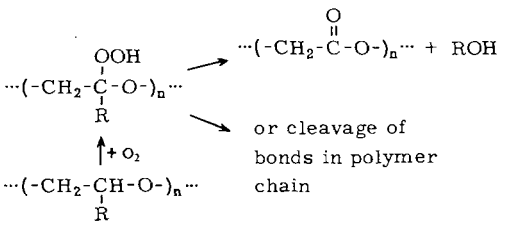
Autoxidation of Polyepoxides



L. Dulog, Mainz (Germany)

Substituted polyethylene oxides of the general formula $(-CH_2-CHR-O-)_n$ have been prepared from the monomers by use of modified organometallic catalysts, such as partly hydrolysed aluminum alkyls subsequently treated with acetylacetone. In each case the polymers have been separated by solvent-extraction, *e.g.* with ether or acetone, into a tactic and an atactic fraction. The difficultly soluble or insoluble fractions are the isotactic ones according to X-ray diffraction and IR spectra. This is in agreement with literature data.

Isotactic polypropylene oxide, isotactic poly-1-butene oxide, and isotactic polystyrene oxide, as well as polyethylene oxide were subjected in undiluted form to autoxidation in air as well as in oxygen at temperatures from 50 to 150 °C and for times from a few minutes to several hours. Degradation of the substituted polyethylene oxides sets in at once (recognizable by a loss in weight), with simultaneous decrease in the molecular weight (observable as a decrease in solution viscosity); cross-linking does not occur. Only small amounts of volatile products are formed from polyethylene oxide and there is barely any decrease in molecular weight; degradation occurs at higher temperatures (*ca.* 145 °C) than for the substituted polymers.

The volatile products were identified by gas chromatography. The first to volatilize from substituted polyethylene oxides are the alcohols ROH derived from the substituent R, the methyl ketones $R-CO-CH_3$ isomeric with the monomer, and the secondary alcohol $R-CHOH-CH_3$ formally derivable from these by reduction. Water was the only volatile product observed to be formed from polyethylene oxide.

The mechanism of the oxidation with molecular oxygen can be interpreted as formation and decomposition of ether hydroperoxides in the first step:

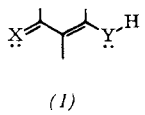
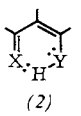
Symposium on Heterocyclic Chemistry



The Institut für Organische Chemie of the Technische Hochschule Stuttgart (Germany) was host to the 1st German Symposium on Heterocyclic Chemistry from the 5th to the 7th of October, 1966.

From the lectures:

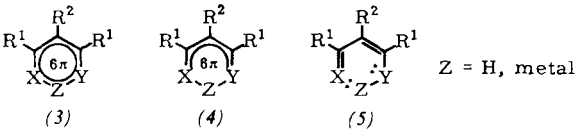


The Aromatic Character of Six-Membered Ring Chelates

E. Daltrozzo and *K. Feldmann*, Munich (Germany)

Compounds of type *(1)* can form hydrogen-bridged chelates *(2)* containing a six-membered ring in which the bridging hydrogen can be replaced by metals.

(1)



(2)

X,Y = NR, PR O, S etc.

Such cyclic 6 π-electron systems may be classified as being either cyclically conjugated *(3)* or not cyclically conjugated *(4)*. The characteristic difference between the aromatic *(3)* and the "quasiaromatic"[1] system *(4)* is in the shift of the NMR signals of the ring protons which is caused by the ring current.

[1] Nomenclature according to *D. M. G. Lloyd* and *D. R. Marshall*, Chem. and Ind. *1964*, 1760.

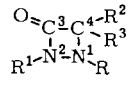
(3) *(4)* *(5)*

Z = H, metal

The possibility of aromatic *(3)* or "quasiaromatic" character *(4)* has been investigated in a series of H-bridged and metal chelates of structure *(5)* (X = Y = NR or O; R^1, R^2 = H, alkyl, aryl, or aralkyl). In all cases, UV and NMR results, when compared with those for model substances in which the existence of cyclic or non-cyclic π-electron conjugation is established, favor structure *(4)*, *i.e.* π-electron interaction does not occur across the bridging atom Z.

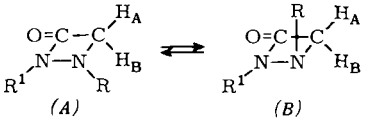
This is the case for (a): the H-bridged chelates (Z = H; X = Y = NR, where R = benzyl, phenyl, C_2H_5, or cyclohexyl; R^1, R^2 = H, alkyl, or aryl)[2,3], (b): the cyclic acetylacetonates [Z = H, Be, Zn, Al, Ga, In, Sc, Y, Co(III), Zr(IV), Th(IV), $SnCl_2$, $SnBr_2$, SnI_2, or Rh] for which aromatic character has often been suggested, and (c): for compounds *(5)* with X,Y = NR and Z = Li, Na, K, Cs, MgR_2, BR, ZnR_2,

[2] *L. C. Dorman* recently (Tetrahedron Letters *1966*, 459) assigned aromatic character to *N*-(3-benzylimino-1-methyl-1-butenyl)benzylamine (X = Y = N–CH_2–C_6H_5, R^1 = CH_3, R^2 = H). The conclusions drawn from the UV and NMR spectra of this compound and its salts are erroneous.



[3] Bases of type *(1)* exist as *cis-trans* equilibrium mixtures *(1)* ⇌ *(2)* and the position of the equilibrium is strongly dependent upon both the nature of the substituents and the solvent. The same is true also for the metal derivatives. This should be borne in mind when discussing the aromatic character of these compounds.

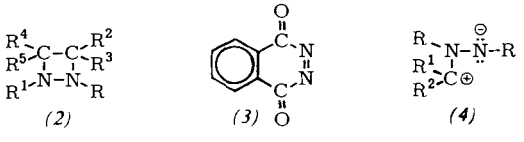
etc., in which N and C^{α} are in aromatic rings as in, *e.g.* di-2-pyridyl-, di-2-quinolyl-, and di-9-phenanthridinyl-methane. The term "quasiaromatic" was applied to compounds of structure *(4)* primarily because of their ready electrophilic substitution. S_E reactions are, however, no criterion for aromatic character, as is shown by the many examples of S_E reactions now known for polymethines (cyanines) and even for polyenes. There is thus no reason to designate the ring structure *(4)* as quasiaromatic; compounds containing it belong rather to the polymethine series.



Preparation and Reactions of Diazetidine Derivatives

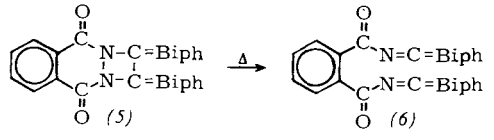
E. Fahr, W. Fischer, H. P. Flemming, A. Jung, K. H. Keil, K. Königsdorfer, J. Markert, Liselotte Sauer, F. Scheckenbach, and *R. Thiedemann*, Würzburg (Germany)

A number of 1,2-diazetidinones of types *(1a)* to *(1c)* have been prepared by addition of azo compounds to ketenes. IR spectroscopic investigation of the 1,2-diazetidinones *(1b)* has shown that the CO stretching vibration band lies between 1780 and 1785 cm^{-1} and is influenced by the substituent on the phenyl nucleus R^3, as is the ^1H–NMR signal of the C^4–H group.



(1a), $R^2 = R^3 = H$
(1b), $R^2 = H, R^3$ = substituted phenyl
(1c), R^2, R^3 = substituted phenyl etc.

(A) *(B)*



Inversion at the N^1 atom *(A)* ⇌ *(B)* was proved by the temperature-dependence of the NMR spectra[4] of the 1,2-diazetidinones; it occurs relatively slowly (coalescence temperature for R = *o*-, *m*-, and *p*-CH_3–C_6H_4 between 262 and 280 °K).

1,2-Diazetidines *(2)* were prepared by the reaction of cyclic α-oxoazo compounds, *e.g.* *(3)*, with indene. Study of the

(2) *(3)* *(4)*

products of reaction of azopyridine or azoquinoline with diazo compounds, in which diaziridines or 1,2-diazetidines should result [5], showed that deep red azomethine imines *(4)* were formed[6]. Only in one case – treatment of diazofluorene with compound *(3)* – could we identify a diazetidine derivative *(5)*; it is thermally unstable and isomerizes to *(6)*.

(5) *(6)*

Biph = 2,2'-Biphenylylene

[4] With the collaboration of Dr. *A. Mannschreck*, Heidelberg (Germany).

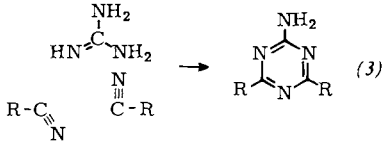
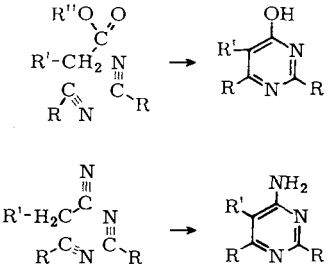
Syntheses of Triazines, Pyrimidines, and Pyridines from Nitriles

H. J. Kabbe, Leverkusen (Germany)



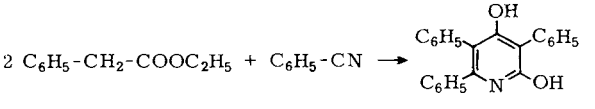
Barbiturates *(1)* are accessible from guanidine and dialkylmalonodinitriles; they rearrange above 200 °C to 2-amino-1,3,5-triazines *(2)*.

(1)



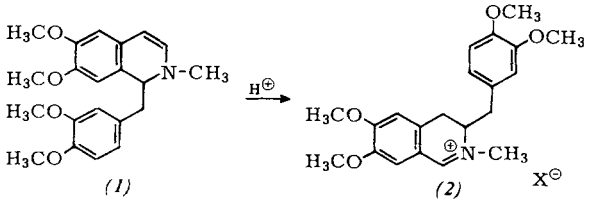
(2)

An alkoxide-catalysed synthesis of 2-amino-1,3,5-triazines *(3)* from numerous aliphatic, aromatic, and heterocyclic nitriles with guanidine is based on this reaction. Yields of up to 80 % are obtained.



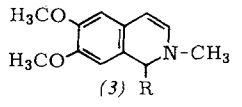
(3)

If esters (or nitriles) of the general formula R'–CH_2–COOR'' (R'–CH_2–CN) are used in place of guanidine, 4-hydroxy- or 4-amino-pyrimidines, respectively, are obtained; for this reaction the particularly reactive heterocyclic nitriles, such as 2- and 4-pyridinecarbonitriles or 2-furancarbonitrile, are generally used as the nitrile.



On the other hand, 3,5,6-triphenyl-2,4-pyridinediol is obtained from, *e.g.*, benzonitrile and ethyl phenylacetate:

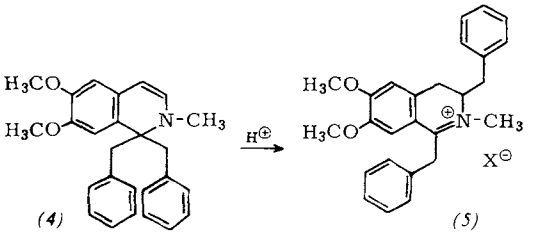
Rearrangement of Dihydroisoquinolines



J. Knabe, Saarbrücken (Germany)

We have found that 1,2-dihydro-2-methylpapaverine *(1)* rearranges to *(2)* under the influence of dilute acids.

(1) *(2)*

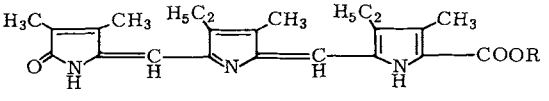


The 1-benzyl derivative corresponding to *(1)* also rearranges in a similar, unusual reaction. However, 1-alkyl-1,2-dihydro- and 1-phenyl-1,2-dihydro-isoquinoline *(3a)–(3d)* disproportionate in dilute acid to 1-substituted isoquinolinium salts and the corresponding tetrahydroisoquinolines.

(3) R

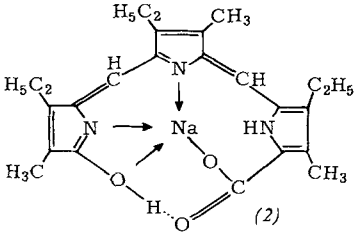
(a), R = C_6H_5
(b), R = n-C_4H_9
(c), R = CH_3
(d), R = CH_2-CH_2-C_6H_5

Treatment of 1,1-dibenzyl-1,2-dihydro-2-methylisoquinoline *(4)* with acid gives the 1,3-dibenzyl-3,4-dihydro-2-methylisoquinolinium salt *(5)*; but 1,1-diethyl-1,2-dihydro-6,7-dimethoxy-2-methylisoquinoline dimerizes.



(4) *(5)*

To clarify the mechanism of the rearrangement *(1)* → *(2)*, a mixture of *(1)* and the corresponding tetraethoxy compound was made to react. Four rearrangement products were formed (structures proved by synthesis), thus proving that the rearrangement is intermolecular.



Metal Complexes of Oxotripyrrene-α-carboxylic Acid Derivatives

H. Plieninger, B. Kanellakopulos, and *K. Stumpf,*
Heidelberg and Karlsruhe (Germany)

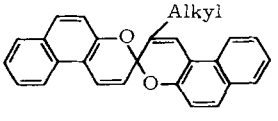
When a chloroform solution of the deep purple acid *(1)* is shaken with aqueous alkali hydroxide, the acid does not pass into the aqueous phase; the latter remains colorless while the chloroform layer turns violet. If the chloroform solution is then evaporated in the presence of methanol, Na, K, Rb, Cs, and even ammonium salts are obtained as fine needles. The crystalline salts are then barely soluble in chloroform or other organic solvents, and are insoluble in water. Analysis of the Na salt indicates a 1:1 complex and on the basis of its remarkable properties we assigned to it the structure *(2)* containing coordinately quadrivalent Na.

(1), R = H
(1a), R = C_2H_5

(2)

In the Ca, Sr, and Ba salts, which were prepared similarly, one bivalent metal ion is bound to two oxopyrrenic acid molecules. Measurements with solutions of radioisotope-labeled Na, Ca, Ba, and Sr hydroxides and stoichiometric amounts of oxopyrrenic acid in chloroform showed that the ions of alkaline-earth metals pass completely, and the ions of alkali metals only partly, into the organic phase.

The positions of the UV absorption bands of the salts differ only slightly from those of the free acid. The IR carbonyl absorption of the ester *(1a)*, the acid *(1)*, and the salts is at 1720 cm^{-1}; the absence of carboxylate absorption for the "salts" indicates an undissociated chelate, as does the chemical behavior.



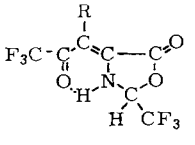
With Cu, Co, Cd, Ni, Mn, and, particularly, Zn ions the color of oxotripyrrene-α-carboxylic acid shows a shift towards blue and complex salts are formed whose UV and IR spectra are quite different from those of the salts with alkali and alkaline-earth metals. The zinc complex of ethyl oxotripyrrene-α-carboxylate *(1a)*, which gives a blue solution, contains the components in the ratio 1:1 and has strong red fluorescence. The acid *(1)* is suitable for detection of zinc in μg quantities; it is not yet known to what extent other metals interfere.

Isomerism of Spirans

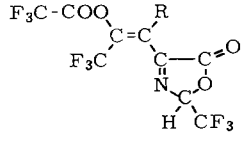
C. Schiele, Ulm (Germany)

Consideration of Dreiding models indicates that asymmetrically substituted spiropyrans should be obtainable in four stereoisomeric forms.

In agreement with this expectation, work with 3-substituted spirobi(2*H*-benzopyrans) and 2-substituted spirobi(3*H*-naphtho[2,1-*b*]pyrans) such as *(1)* has led to isolation of such previously unknown stereoisomers by fractional crystallization [7]. The products were identified by IR spectroscopy [8].



(1)

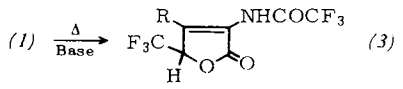


Preparation of Heterocyclic Compounds by Treatment of Amino Acids with Trifluoroacetic Anhydride

W. Steglich and *V. Austel,* Munich (Germany)

On treatment of α-amino acids with an excess of trifluoroacetic anhydride, various types of compounds result according to the reaction conditions and the nature of the amino acid. Substituted 4-trifluoroacetylmethylene-2-trifluoromethyl-5-oxazolidinones *(1)* and enol trifluoroacetates *(2)* are

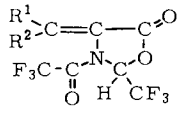
(1)
R = H, CH_3, C_6H_5



(2)

formed from alanine, 2-aminobutyric acid, and phenylalanine. On prolonged heating, alanine further affords the doubly trifluoroacetylated oxazolidinone *(1)* with R = $COCF_3$. The steric arrangement about the C=C double bond is not yet known.

When warmed with weak bases the oxazolidinones *(1)* rearrange to 2(5*H*)-furanones *(3)*. Compounds *(3)*, R = H or $COCF_3$, can also be prepared directly from alanine

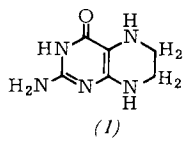


[7] *C. Schiele et al.*, Z. Naturforsch. *21b*, 292 (1966).
[8] *G. Arnold*, Z. Naturforsch. *21b*, 291 (1966).

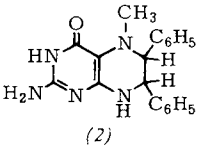
(1) (3)

and trifluoroacetic anhydride. Furanones *(3)* with R = COOR′ are particularly easily formed from aspartic β-esters[9]. A small amount of 4-ethyl-3-trifluoroacetamido-2,5-bis(trifluoromethyl)furan is obtained alongside *(2)*, R = C_2H_5, when norvaline is used.

N-Trifluoroacetylated 4-alkylidene-2-trifluoromethyl-5-oxazolidinones *(4)* are formed when an excess of trifluoroacetic anhydride reacts with amino acids such as valine, isoleucine, and leucine that are branched in the β- or γ-position.

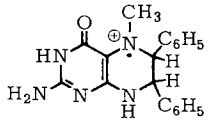


(4)

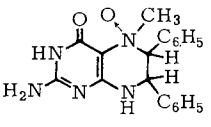


Phenyl-hydroxylation with Tetrahydropterin as Activator. — A Model for the Enzymic Synthesis of Tyrosine

M. Viscontini, Zürich (Switzerland)



An aqueous solution of tetrahydropterin *(1)* (pH 6.9) is readily oxidized by atmospheric oxygen. If phenylalanine, Fe ions, and either ethylenediaminetetraacetic acid or pyrophosphate are added to this solution, oxidation occurs in such a way that one oxygen atom is added to the phenylalanine molecule and then a 2:1:1 mixture of *o*-, *m*-, and *p*-tyrosine is formed.



(1)

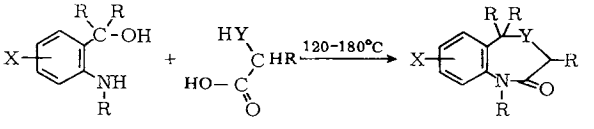
(2)

(3)

(4)

If, instead of tetrahydropterin *(1)*, tetrahydro-5-methyl-6,7-diphenylpterin *(2)* with Fe^{3+} is used in the solution, formation of an unstable complex is first observed and then, after two hr, an addition product is precipitated for which we propose the structure *(4)*. We assume that on complex formation an electron is transferred from *(2)* to Fe^{3+}, that a radical cation *(3)*[*] is formed, and that this radical adds an oxygen atom that was activated by the complexed Fe^{2+}.

On the basis of these results a novel theory of chemical and enzymic hydroxylation has been developed, involving formation of radical cations of *(1)* and of the *N*-oxide of *(1)*, rearrangement to the hydroxylamine from *(1)*, and subsequent formation of radicals of *(1)* and OH. This theory differs from the so-called mixed oxidation mechanism. The whole process may possibly occur in a complex composed of EDTA or pyrophosphate, Fe^{2+} or Fe^{3+}, *(1)*, oxygen, and phenylalanine, transfers and migrations of electrons playing a central role. If in this complex the EDTA or pyrophosphate is replaced by an apoenzyme, an enzymic reaction results in which asymmetry and stereochemistry may exert an influence on the specific course of the hydroxylation.



[9] *H. Tanner*, Dissertation, Technische Hochschule München, 1963.

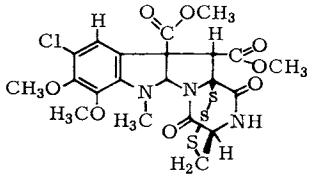
[*] *P. Hemmerich*, Universität Basel, recently demonstrated the existence of these radical cations by ESR measurements on *(2)*.

A Simple Synthesis of 2,3,4,7-Tetrabenzo-1,4-thiazepin-3-one

K. H. Weber and *K. H. Hauptmann*. Ingelheim (Germany)

In a search for psychotropic benzazepines a remarkably simple single-stage synthesis of 2,3,4,7-tetrahydrobenzo-1,4-thiazepin-3-ones *(3a)* and oxazepin-3-ones *(3b)* was discovered. These compounds were obtained in up to 98 % yield on melting 2-alkylamino-, 2-arylamino-, or 2-heteroarylaminobenzyl alcohols *(1)* with 2-mercapto or 2-hydroxy carboxylic acids *(2)*.

(1) *(2)* *(3a)*, Y = S; *(3b)*, Y = O



Since benzyl alcohol itself and 2-nitrobenzyl alcohol do not react with the SH group of 2-mercapto carboxylic acids under the above conditions, a salt-like intermediate is invoked to explain the mechanism. The yields depend greatly on the basicity of the amino group and the ease of exchange of the hydroxyl group of the substituted benzyl alcohols; as expected 2-hydroxy carboxylic acids, do not react so well.

German version: Angew. Chem. *79*, 153 (1967)

SELECTED ABSTRACTS

An unusual eight-membered ring with 3 adjacent sulfur atoms – Sporidesmin C – has been isolated by *R. Hodges* and *J. S. Shannon*. It is one of the metabolites of the fungus *Pithomyces chartarum*, which are responsible for liver damages and face eczema of sheep grazing on New Zealand pastures.

(1)

The structure was proved by degradation, NMR spectra, and particularly, mass spectrometry. / Austral. J. Chem. *19*, 1059 (1966) / –Bu. [Rd 561 IE]

***endo*-Dicyclopentadiene undergoes intermolecular rearrangement to form *exo*-dicyclopentadiene,** as has been shown by *J. E. Baldwin* with the aid of dicyclopentadiene in which an H has been replaced by a D in one of the rings. If the reaction were intramolecular, the isomerized product should remain monodeuterated, whereas an intermolecular reaction could also give doubly deuterated dicyclopentadiene. The latter is found to be the case with the *endo* compound. The labeling

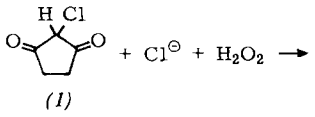
in the *exo* compound does not change under the conditions of the reaction (solution in cyclohexane in a pressure tube at 196 °C). / J. org. Chemistry *31*, 2442 (1966) / –Bu. [Rd 562 IE]

A change in the specificity of chymotrypsin was produced by *H. Weiner*, *W. Batt*, and *D. E. Koshland* by chemical modification of the enzyme. Chymotrypsin contains two methionine units, one of which is three (Met 3) and the other 15 (Met 15) amino acids away from the serine, which is the reactive group in the active site. Met 3 lies on the surface of the protein molecule, while Met 15 is situated in the interior; neither is essential to the enzymatic activity. Met 3 can be oxidized to the sulfoxide by H_2O_2 at pH 3 without additives, whereas Met 15 is oxidized only in the presence of 8 M urea. Differences between the mono- (M) and disulfoxide (D) enzymes and the native enzyme (N) include: N hydrolyses the methyl ester of acetyltyrosine three times as rapidly as M and four times as rapidly as D, and hydrolyses acetyltyrosinamide six times as rapidly as M and 400 times as rapidly as D. Benzyloxycarbonylphenylalanylleucine is hydrolysed twice as rapidly by N as by M and 59 times as rapidly as by D. / J. biol. Chemistry *241*, 2687 (1966) / –Hö. [Rd 566 IE]

The conditions for the binding of tRNA on ribosomes were studied by *C. G. Kurland*. Ribosomes from *Escherichia coli* were purified, *inter alia*, by ammonium sulfate fractionations until they no longer contained either GTP or the transferases. The binding of tRNA required only the presence of mRNA (poly-U) at a suitable salt concentration (2×10^{-2} M $MgCl_2$). The addition of GTP or transferases neither accelerated the binding of tRNA nor increased the quantity bound. No qualitative or quantitative differences were observed in the binding of phenylalanyl-tRNA and deacylated tRNA. Thus the function of the cofactors GTP and transferases I and II required for the poly-peptide synthesis is to form the peptide linkages after the ribosome/mRNA/tRNA complex has been formed. / J. molecular Bio. *18*, 90 (1966) / –Hö [Rd 571 IE]

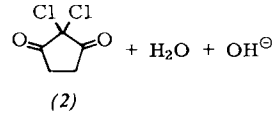
Apophosphorylase b from rabbit muscle has been studied by *E. H. Fischer et al.* The holoenzyme contains pyridoxal phosphate (PyP), and after conversion into phosphorylase a (phosphorylation by phosphorylase b kinase and ATP), it catalyses the phosphorolysis of glycogen to glucose-1-phosphate. The PyP can be removed from phosphorylase b in imidazole citrate buffer (unfolding of the protein to expose the PyP) by cysteine (removal of PyP). The apoenzyme can be crystallized in the presence of Mg^{2+}, AMP, and 2-mercaptoethanol. Unlike the holoenzyme, it tends to associate at low temperatures or at high salt concentrations, and is more labile than the holoenzyme. Incubation with PyP leads to the holoenzyme, which is indistinguishable from native phosphorylase b. Apophosphorylase b is enzymatically activated to phosphorylase a just as rapidly as phosphorylase b, the measurement being carried out after subsequent recombination with PyP. / Biochemistry *5*, 2108 (1966) / –Hö. [Rd 572 IE]

Ribulosediphosphate carboxylase from spinach leaves has been purified to a homogeneous state in ultracentrifugation experiments by *J. M. Paulsen* and *M. D. Lane*. The enzyme catalyses the reaction of ribulosediphosphate with CO_2 (or bicarbonate) to give two molecules of 3-phosphoglycerate, *i.e.* the CO_2 fixing step in the Calvin cycle in plants. The cofactor is Mg^{2+}. The incorporation of ^{14}C was used to determine the activity. The enzyme accounts for about 15 % of the total soluble protein in spinach leaves. It was purified by two ammonium sulfate precipitations and chromatography on DEAE cellulose and on hydroxyapatite. Sedimentation coefficient: 21.0 S; molecular weight by the sedimentation equilibrium method: 557000 ± 16000; molecular activity *in vitro* at 30 °C and pH 7.8 is 1300 moles of CO_2/mole of enzyme min. / Biochemistry *5*, 2350 (1966) / –Hö. [Rd 573 IE]



$$^{2\ominus}O_3POCH_2\text{–}CO\text{–}HCOH\text{–}HCOH\text{–}CH_2OPO_3^{2\ominus} + HCO^{\ominus}_3 \rightarrow 2\ {}^{\ominus}OOC\text{–}HCOH\text{–}CH_2OPO_3^{2\ominus} + H^{\oplus}$$

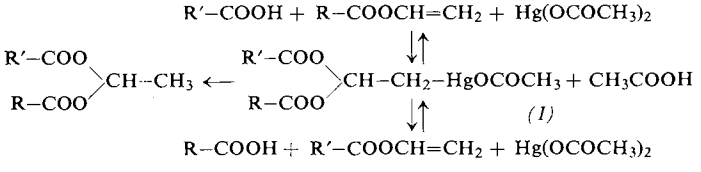
Aminopeptidase B, an *exo*peptidase with a hitherto unknown specificity, has been isolated from rat liver and enriched by a factor of 1100 by *V. K. Hopsu*, *K. K. Mäkinen*, and *G. G. Glenner*. The enzyme splits off *N*-terminal lysine and arginine; the only exception found so far was the cleavage of Gly-L-Lys. The substrates used in the activity tests were arginyl- and lysylnaphthylamides. There is no stereospecificity towards L and D forms. Gel filtration on Sephadex G 100 gives a molecular weight of about 95500, and the optimum pH is about 7. The enzyme is very specifically activated by chloride, and inhibited by complexing agents, heavy metal ions, and disulfide and thiol reagents. After treatment with complexing agents, no reactivation by metal ions was observed. / Arch. Biochem. Biophysics *114*, 557, 567 (1966) / –Hö. [Rd 574 IE]



An extraintestinal protease of bluebottles (*Calliphora erythrocephala* Meigen) has been found by *J. G. Moser*. The larvae of the flies can be kept on agar under sterile conditions. Over a period of about 100 hours they excrete a protease with their feces, whose total activity is about 100 times as high as the protease activity present in the larvae after this time, and whose specific activity is about 350 times as high as in the remainder of the larval extract. The protease differs significantly from trypsin and chymotrypsin in its specificity and in its marked sensitivity to acids. The flat pH optimum is between 7.2 and 9.4. In the oxidized B chain of insulin the following peptide linkages were cleaved: Ser-His, His-Leu, Leu-Val, Gly-Phe, and Phe-Phe. Azocasein is broken down with roughly the same kinetics as by trypsin. *N*-α-Benzoyl-arginine-β-naphthylamide (trypsin substrate) is not attacked. The maximum specific activity after concentration is comparable with that of trypsin. / Biochem. Z. *344*, 337 (1966); Umschau *66*, 570 (1966)/–Hö. [Rd 575 IE]

The enzymatic transfer of sulfur from cysteine to tRNA has been studied by *R. S. Hayward* and *S. B. Weiss* and by *M. N. Lipsett* and *A. Peterkofsky*. tRNA from *Escherichia coli* contains bases with thiol groups, as well as other uncommon bases. It has been shown that the sulfur is incorporated only when the synthesis of the tRNA molecule is complete. One of the sulfur acceptors is undoubtedly the uracil residue which is converted into the 4-thiouracil residue. The sulfur transfer requires the presence, not only of cysteine tRNA, but also of a protein fraction that has been concentrated by ultracentrifugation and ammonium sulfate fractionation, as well as magnesium ions, ATP, and pyridoxal phosphate. / Proc. nat. Acad. Sci. USA *55*, 1161, 1169 (1966) / –Hö. [Rd 576 IE]

Chloroperoxidase has been purified and crystallized by *L. P. Hager*, *D. R. Morris*, and their co-workers, and its specificity towards halides has been studied. Chloroperoxidase from *Caldariomyces fumago* is a glycoprotein having a molecular weight of about 42000 and containing iron(III) protoporphyrin IX as the prosthetic group. The enzyme catalyses the *C*-halogenation of acceptors such as β-keto acids, cyclic diketones, and substituted phenols. A suitable optical test is the conversion of 2-chloro-1,3-cyclopentanedione *(1)* into 2,2-dichloro-1,3-cyclopentanedione *(2)*, which leads to the disappearance of the high UV absorption of *(1)*. [*(1)* λ_{max} =



(1)

(2)

242, 248 mμ, ε = 20000; *(2)* λ_{max} = 277 mμ, ε = 160]. The molecular activity is 67000 mole/min/mole of enzyme for chloride, and is twice as high for bromide. Iodide also reacts, but interference occurs in this case as a result of the formation of elementary iodine. Fluoride acts as an inhibitor. / J. biol. Chemistry *241*, 1763, 1769 (1966) / –Hö. [Rd 584 IE]

The Hg(II)-catalysed vinyl exchange between vinyl acetate and carboxylic acids, according to *H. Lüssi*, proceeds by an acid-catalysed addition of Hg(II) acetate to the vinyl double bond. The organomercury intermediate *(1)* was isolated and identified. The transvinylation of carboxylic acids with vinyl esters proceeds in accordance with the following scheme:

/ Helv. chim. Acta *49*, 1684 (1966) / –Ma. [Rd 585 IE]

A method for the study of the polarity of the microenvironment of the active site in chymotrypsin has been described by *J. Kallos* and *K. Avatis*. If the *p*-nitrobenzenesulfonyl (nisyl) group is attached to the serine unit of the active center, it gives a spectrum similar to those of nisyl esters in cyclohexane. The spectrum of the nisylchymotrypsin changes when the protein is reversibly unfolded by gentle heating: it then resembles the spectra of nisyl esters in water. The serine in the native enzyme is evidently situated in a hydrophobic region, and can be reversibly exposed to the polar external environment. / Biochemistry *5*, 1979 (1966) / –Ma. [Rd 586 IE]

The histochemical detection of thiol groups can be achieved with 4-iodoacetamido-1-naphthol, which reacts with SH groups in proteins to form thioethers; these thioethers form a blue dye with diazotized 4-amino-2,5-bisethoxybenzanilide. A blue dye is also formed by the two reagents, but this can be easily washed out with organic solvents. Thus regions containing SH groups can be accurately located in histological preparations. *K. C. Tsou* and *A. M. Seligman* synthesized 4-iodoacetamido-1-naphthol from 4-amino-1-naphthol; this was converted into the 4-chloroacetamido compound, from which the end product was obtained by treatment with NaI [overall yield 20 %; pink crystals having m.p. 199 °C (aqueous methanol)]. / J. med. Chemistry *9*, 640 (1966) / –De. [Rd 587 IE]

Myxinol disulfate is the principal bile salt of the hagfish (Myxinidae) as was found by *G. A. D. Haslewood*. The Myxinidae (very primitive vertebrates) have very large gallbladders. A crystalline alcohol, myxinol, m.p. 206 °C, $[\alpha]_D$ = –15° (3β, 7α, 16α, 27-tetrahydroxy-5β-cholestane) was isolated from the hag species *Eptatretus stoutii* and *Myxine glutinosa*. This compound occurs in both species as the 3,27-bis-sulfate ester, which could be separated in the form of the Na salt (crystals from methanol), m.p. 195 °C (dec.). The salt has a very bitter taste. The Ba salt melts at 147 to 148 °C with decomposition. / Biochem. J. *100*, 233 (1966) / –De. [Rd 588 IE]

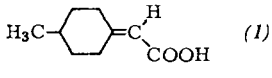
4-Hydroxy-2,3-dimethyl-2,3-dihydro-3-furanone *(1)*, an aroma component of the pineapple, has been synthesized by *D. W. Henry* and *R. M. Silverstein* by base-catalysed condensation of dimethyl oxalate and dimethyl glycolate to form the dimethyl ester of 3,4-dihydroxy-2,5-furandicarboxylic acid, conversion into the 3,4-bisbenzyloxy compound, reduction with $LiAlH_4$ to the 2,5-bishydroxymethyl derivative, and hydrogenation (Pd-C) of the dibenzoate. Compound *(1)* forms crystals having m.p. 75–78 °C. When stored under nitrogen at low temperatures *(1)* is stable for some months, whereas at room temperature in air it changes within 1–2 days into a viscous oil having a different odor. The same compound was obtained by *A. Hofmann* and *C. H. Eugster* by hydrogenolysis of acetylformoin with Pd-C/H_2 in water. / J. org. Chemistry *31*, 2391 (1966); Helv. chim. Acta *49*, Special Volume Emile Cherbuliez, 53 (1966)/–De. [Rd 589 IE]

The half-lives of the ^{129}Sn nuclear isomers were checked by *P. Chu* and *J. A. Marinsky*. These authors confirmed the existence of a nuclear isomer having $\tau_{1/2} \approx 6$ to 7 min, which had already been found by *Hagebø* and by *Dropesky* and *Orth*, but they found no evidence of the isomer having $\tau_{1/2} \approx 1$ hour postulated by *Hagebø*. After irradiation of a sample of $UO_2(NO_3)_3 \cdot 6H_2O$ with neutrons for one minute, the solution of the sample was worked up by a new method using NaI + $HClO_4$ with the addition of an Sn(IV) carrier, and ^{129}Sn was separated *via* a benzene phase. In this way it was possible to establish the existence of an isomer having $\tau_{1/2}$ = 2.0 min. These two short half lives of ^{129}Sn fit excellently with the linear log $\tau_{1/2}$-mass number relationship required for isotopes having the same spin and the same parity (^{123}Sn, ^{125}Sn, ^{127}Sn). / J. inorg. nuclear Chem. *28*, 1339 (1966) / –WG. [Rd 596 IE]

Two new syntheses of secondary phosphine sulfides are described by *Ludwig Maier*. Dialkylamino-dialkyl- and -diarylphosphines in boiling benzene react almost quantitatively with H_2S to form secondary phosphine sulfides.

$$R_2P{-}NR_2 + 2\ H_2S \rightarrow R_2P(S)H + R_2NH_2SH$$

These sulfides can also be obtained in high yields from thiophosphites and organometallic compounds. Addition of secondary phosphine sulfides to olefins or condensation with dialkylaminomethanols leads to the formation of unsymmetrical tertiary phosphine sulfides. Examples:



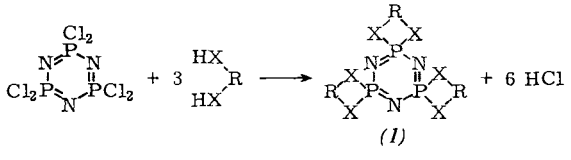
$(CH_3)_2P(S)H$, b.p. 48–50 °C/0.4 mm (yield 94 %);
$(C_6H_5)(C_2H_5O)P(S)H$, b.p. 120–127 °C/0.2 mm (54 %);
$(CH_3)_2$ (n-$C_{14}H_{29}$)PS, b.p. 186–190 °C/0.2 mm (100 %);
$(C_6H_5)_2$(cyclo-C_6H_{11})PS, m.p. 180–185 °C (77 %). / Helv. chim. Acta *49*, 1249 (1966) / –WG. [Rd 597 IE]

The preparation and structure of open-chain and cyclic polyphosphines have been described by *L. Maier*. For example, the new triphosphine $CH_3P[P(C_6H_5)_2]_2$, m.p. 130–134 °C, is obtained by the reaction of $(C_6H_5)_2PH$ with $CH_3P[N(CH_3)_2]_2$ in xylene. The structures of several known cyclic polyphosphines were corrected on the basis of molecular weight determinations and X-ray analyses. For example, $(C_6H_5P)_n$ (m.p. 149–150 °C) exists, not as a four-membered ring, but as an equilateral five-membered ring having the approximate symmetry C_s. The compound $(C_6H_5P)_6$ (m.p. 190 °C), in which the six P atoms are arranged as a six-membered ring in the chair form with the phenyl groups in the equatorial position, crystallizes in at least four forms. / Helv. chim. Acta *49*, 1119 (1966) / –WG. [Rd 598 IE]

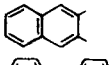
The selective cleavage of substituted phenylthio (phenylsulfenyl) protective groups in peptide syntheses has been reported by *W. Kessler* and *B. Iselin*. The *o*-nitrophenylthio group is extremely suitable for the protection of α-amino groups, particularly in complicated peptides that also contain acid-labile groups such as t-butoxycarbonyl for the protection of the side chain of trifunctional amino acids. The *o*-nitrophenylthio groups can be easily removed by nucleophilic reagents; *e.g.* $O_2N-C_6H_4-S-Lys[COOC(CH_3)_3]-OCH_3$ can be cleaved by HCN/acetic acid, SO_2/methanol/water, or thioacetamide/acetic acid to give $HLys[COOC(CH_3)_3]-OCH_3$. The use of this method in peptide synthesis on a support as described by *Merrifield* is still associated with technical difficulties. / Helv. chim. Acta *49*, 1330 (1966) / –WG.

[Rd 599 IE]

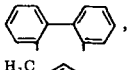
The absolute configuration of the enantiomeric 4-methylcyclohexylideneacetic acids has been determined by *H. Gerlach*.



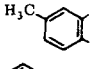
(1)



The substance *(1)* was resolved into enantiomers in 1909 by *W. H. Perkin et al.* The absolute configuration was established by correlation with (–)-isoborneol. The acid that is dextrorotatory in benzene and alcohol ($[\alpha]_{546} = +95°$ (c = 1.2; ethanol)) has *S*-chirality and the levorotatory acid has *R*-chirality. / Helv. chim. Acta *49*, 1291 (1966) / –WG.



[Rd 600 IE]



Novel phosphonitrile heterocycles were obtained by *H. R. Allcock* and *R. L. Kugel* in the reaction of phosphonitrilic chloride with diols, dithiols, and diamines in the presence of $(C_2H_5)_3N$.

(1)

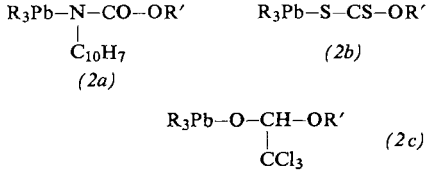
(1a): R =  , X = O

(1b): R =  , X = O

(1c): R =  , X = S

(1d): R =  , X = NH

(1a): colorless crystals, m.p. 335–336 °C (benzene). *(1b)*: white crystals, m.p. > 300 °C; can be recrystallized from xylene at 200 °C in a closed vessel. *(1c)*: colorless crystals m.p. 255–257 °C (toluene or xylene). *(1d)*: m.p. > 300 °C (aqueous acetone), insoluble in hexane, benzene, toluene, dioxane, CCl_4, and H_2O, slightly soluble in acetone, acetonitrile, and methyl ethyl ketone. The yields of *(1a)* and *(1d)* are 62 and 72 % respectively. The compounds were all characterized by analysis and by their IR, UV, and ^{1}H-NMR spectra. No evidence of interaction of the π electrons of the cyclotriphosphazane system with lone pairs of the ligands X was found. / Inorg. Chem. *5*, 1016 (1966) / –Sch. [Rd 601 IE]

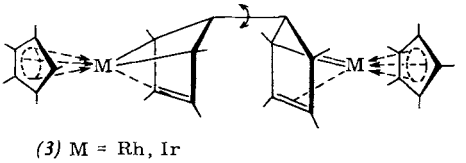


The crystal structure of dimethyltin difluoride was described by *E. O. Schlemper* and *W. C. Hamilton* as an example of octahedral coordination of tin. $(CH_3)_2SnF_2$ forms tetragonal crystals, space group I4/mm, a = 4.24, c = 14.16 Å (two formula units per unit cell). The structure consists of an infinite two-dimensional network of tin atoms and bridging fluorine atoms, with the methyl groups above and below the plane of the network. The interatomic distances are: Sn–C (2.08 ± 0.01 Å) and Sn–F (2.12 ± 0.01 Å). The crystal structure is similar to that of SnF_4. / Inorg. Chem. *5*, 995 (1966) / –Sch. [Rd 602 IE]

Additions to the lead-oxygen bond have been observed by *A. G. Davies* and *R. J. Puddephatt*. Thus novel lead-nitrogen, lead-oxygen, and lead-sulfur compounds are formed in accordance with

$$\underset{(1)}{R_3PbOR'} + A{=}B \rightarrow \underset{(2)}{R_3Pb{-}A{-}B{-}OR'}$$

$R = C_6H_5$, $R' = CH_3$



For example *(2a)* is formed from methoxytriphenyllead and AB = 1-naphthyl isocyanate, dec. p. 135–141 °C; *(2b)* is formed from *(1)* and AB = CS_2, m.p. 93–95 °C; *(2c)* is formed from *(1)* and AB = Cl_3CCHO, dec.p. 96–100 °C. The compounds are all sufficiently stable for osmometric molecular weight determinations. They are monomeric in

(2a) *(2b)* *(2c)*

0.02–0.04 M benzene solution. *(1)* reacts exothermally with hexachloroacetone in benzene. Chromatographic product recovery gives triphenyllead chloride (about 40 %), trichloromethyltriphenyllead (yield 60 %, m.p. 171–171.5 °C), and methyl trichloroacetate. The reaction with tribromoacetaldehyde yields tribromomethyl-triphenyllead having m.p. 135–140 °C. / J. organometallic Chem. *5*, 590 (1966) / –Sch. [Rd 603 IE]

Monomeric and dimeric dicyclopentadienylrhodium and -iridium have been described by *E. O. Fischer* and *H. Wawersik*. The uncharged compounds $Rh_2(C_5H_5)_4$ *(1)* and $Ir_2(C_5H_5)_4$ *(2)* were prepared for the first time by the reduction of $[Rh(C_5H_5)_2]PF_6$ and $[Ir(C_5H_5)_2]PF_6$ with molten sodium metal. *(1)* is formed in 8 % yield as an orange-yellow crystalline substance; it sublimes above 120 °C in high vacuum, decomposes above 140 °C, and is sparingly soluble in benzene, toluene, carbon disulfide, and chloroform and insoluble in hexane, methanol and water. The solid compound is moderately stable in air, but is sensitive to oxidation and to heat in solution. *(2)* is a pale yellowish substance (3 % yield), which sublimes in the monomeric form at 200 °C, and decomposes at normal pressure above 230 °C. It is sparingly soluble in benzene, toluene, and chloroform, and insoluble in hexane, methanol, and water, The paramagnetic compounds are monomeric at the temperature of liquid nitrogen only and in the gas phase above about 150 °C, and dimerize at room temperature to give the diamagnetic metal(I) complexes *(3)*. The structure was confirmed by IR and ^{1}H–NMR spectra. / J. organometallic Chem. *5*, 559 (1966) / –Sch.

Handbuch der Lebensmittelchemie (Manual of Food Chemistry). By *J. Schormüller*. Vol. II, Part 1: Analytik der Lebensmittel. Physikalische und physikalisch-chemische Untersuchungsmethoden (Analysis of foodstuffs. Physical and physico-chemical methods of investigation). Springer Verlag, Berlin-Heidelberg-New York 1965. 2nd ed., xxiv, 944 pp., DM 236.–

Physical and physico-chemical methods are of great value in the investigation of foodstuffs. Very far-reaching changes in methods have taken place since the publication of the first edition of the manual. Consequently, the first volume[*], which is devoted to the components of foodstuffs, is followed by a second volume on the analysis of foodstuffs. The 31 chapters follow the same scheme. The book starts with a theoretical introduction to the field, and this is followed by a description of the apparatus and its use, and notes on special problems of food chemistry.

H. Werner first describes sampling and associated questions (13 pp.). The descriptions are assisted by a number of good schematic drawings. The physical concept of density and its determination in liquids, solids, and gases is described by *A. Mahling* (26 pp.). The term "specific gravity" is avoided because of the confusion of the terms. The same author contributes articles on viscosity (20 pp.) and the ultracentrifuge (24 pp.). Theoretical explanations are skilfully linked with practical instructions in these articles. The same is true of the two chapters by *H. Wollenberg*, 'Ultracentrifugation, Dialysis, and Electrodialysis" (26 pp.) and "Phenomena at Phase Boundaries" (32 pp.). Theoretical explanations of the melting point, solidification point, and boiling point, and a description of the apparatus used for their determination are contributed by *H. J. Henning* (33 pp . Some mention of zone melting, which has proved an excellent method for the purification of substances would have been desirable here.

In his discussion of solubility (23 pp. *H. J. Henning* discusses open questions as well as known facts. *K. Volz* contributes a short paper on calorimetry (5 pp.). In line with the frequent use of pH measurements, these and all related questions are discussed at length by *D. Berndt* (34 pp.). Mention is also made of older methods that are less common in food chemistry. The redox potential is discussed in general and from the point of view of biology and food chemistry by *W. Heimann* and *K. Wisser* (40 pp.). The chapter is supplemented by seven tables. *K. E. Slevogt* discusses conductometry and dielectrometry (37 pp.).

In the reviewer's opinion, *K. Pfeilsticker*'s chapter (42 pp.) on emission spectral analysis passes beyond the scope of food analysis in places. The principles, technique, and value of flame photometry in the analysis of foodstuffs are described by *W. Diemair* and *K. Pfeilsticker*. Light-absorption measurements in the visible and ultraviolet regions and infrared spectra (47 pp.), color measurements (7 pp.), and luminescence analysis (20 pp.) are explained well by *J. Eisenbrand*. The reader is introduced to optical polarimetry, polarization, and (briefly) rotatory dispersion by *J. Flügge* (40 pp.). Interferometry is mentioned by *J. Eisenbrand* (5 pp.). The important topic of polarography is discussed by *W. Diemair* and *K. Pfeilsticker* (18 pp.). A good survey of the history and techniques of paper chromatography is contributed by *A. Grüne* (45 pp.), who also refers briefly to labeling with radioactive isotopes. In connection with *G. Wohlleben*'s chapter on column chromatography (9 pp.), special mention should be made of the discussion of the suitability of various inorganic and organic adsorbents. Ion exchangers and molecular sieves are also briefly described. Thin-layer chromatographic analysis (24 pp.) is discussed by *A. Seher*, starting with a short introduction and proceeding to consider various groups of substances that are of interest in food chemistry. Corresponding to the great importance of gas chromatography, *F. Drawert* (69 pp.) not only discusses in detail the theory and the structure of individual instruments and parts of instruments, but also presents many items of general interest. The chapter is supplemented by a large number of examples of applications. Electrophoresis (20 pp.) is discussed by *H. D. Behlitz*, who describes, not only methods, but also applications to various classes of substances. The authority on multiplicative distribution, *E. Hecker*, presents a concise survey of this special field (31 pp.). The increasingly important task of detecting radionuclides in foodstuffs is discussed by *K. G. Bergner* and *P. Jägerhuber* (38 pp.). The topics covered include sampling, methods of measurement, and evaluation of the measurements. The authors finally offer suggestions for the equipment of a laboratory. Under the heading "Microscopy", *H. Freund* (41 pp.) discusses microscopes, (including the electron microscope), accessories, and techniques. The microscope specimens and the staining of bacteria specimens is described by *F. Walter* (37 pp.). The calibration of measuring instruments is surveyed by *H. Johannsen* (19 pp.). *H. Ramb* presents an introduction to the fundamentals of refractometry, technical refractometry, and the application of this method to special foodstuffs (34 pp.). In the last chapter, *K. Feiling* discusses nephelometry (7 pp.). The subject index covers 29 pages.

Each chapter is accompanied by an extensive bibliography, and in almost every case by a comprehensive list of journal references. The literature is covered up to 1964. The present volume is a valuable aid to anyone who is concerned with food chemistry and who wishes to use the latest methods in his work.

HMO – Hückel Molecular Orbitals. By *E. Heilbronner* and *P. A. Straub*. Springer-Verlag, Berlin-Heidelberg-New York 1966. 1st ed., 816 pp., loose leaf DM 72.–.

It is becoming an increasingly established practice, in seeking for an understanding of the properties of molecules and in discussing possible reaction mechanisms, to turn to the results of Hückel molecular orbital (HMO) calculations rather than to write out resonance structures, as was formerly common. A systematic application of the HMO method in chemical practice seems possible only if there is no need to carry out a HMO calculation in each individual case and one may simply look up its results. The present set of tables, with a short but clear introduction on their use, is therefore very welcome.

It is not very important to the experimental chemist to understand the conditions and limitations under which the HMO theory can be derived from quantum mechanics. It is more important that he should be able to use the results of HMO calculations, and to draw chemically relevant conclusions from molecular diagrams, from the scheme of the orbital energies, and possibly also from the polarizabilities and other numerical values. This requires not only study of a textbook of MO theory, but also a certain amount of experience, and this experience can probably be built up more rapidly with the aid of the present tables.

It should be noted tha the HMO method applies only to the π-electron systems of unsaturated compounds, so that it cannot be expected to provide answers to questions specifically concerned with σ bonds. The number of possible π-electron systems is so great that it would be futile to hope for completeness. However, about 800 systems are tabulated in the book, starting with simple chains and rings, and progressing to very complex combinations of rings of various sizes and branched chains. It includes the most important

kata- and *peri*-condensed aromatics as well as many of their 5- and 7-membered ring analogues.

If one is interested in hydrocarbons that are not included in the tables, then one has simply to punch cards according to Fortran program published with the book and send it, together with data cards, to the nearest computer center.

Compounds containing hetero atoms are not included. This is understandable, since the choice of suitable heteroatom parameters is not easy, and since, for this reason as well as others (for example, because the $\sigma-\pi$ interaction is more pronounced in heteromolecules), the numerical values obtained by the HMO method for heteromolecules must be regarded much more critically than those obtained for alternant hydrocarbons.

Nevertheless, the tables can also be used for heteromolecules. To a first approximation, these can be replaced by the isoelectronic hydrocarbons, while the approximate molecular diagrams can be easily calculated (i.e. by multiplications and additions) in higher approximation from the given numerical values, particularly from the "polarizabilities". Similarly, additional cross bonds and even a possible bond alternation can be easily taken into account by means of perturbation theory. Useful as the "polarizabilities" are for expressing "perturbations" in the molecule, it is quite another question whether they will find much practical application and hence whether the space given to them is justified.

Finally, it should not be forgotten that more accurate MO calculations (*e.g.* by the Pariser-Parr method) are supposed to reproduce the HMO diagram qualitatively, but not quantitatively. However, even the most accurate calculations possible today are still far from the "ultimate truth", and in any case, this still does not detract from the usefulness of the HMO method.

The loose-leaf presentation has the advantages that the order can be changed as desired, and that new sheets can be inserted; however, it also has some disadvantages. For example, the mechanism of the reviewer's copy was damaged in transit.

W. Kutzelnigg [NB 567 IE]

Einführung in die Allgemeine Pharmakologie (Introduction to General Pharmacology). By *S. DeJong*. From the 2nd Dutch edition, translated into German by *F. Hohensee*. Urban & Schwarzenberg, München-Berlin 1965. 1st Edit. xv, 200 pp., 24 illustrations, board DM 19.80.

This booklet by the well-known Dutch pharmacologist is an attempt "to write in general terms a pharmacology for readers who know nothing of the subject"

The author gives a 20-page introduction on drugs, poisons, and stimulants (tobacco, alcohol, *etc.*) and the historical development of pharmacological research. A further 22 pages are devoted to a description of the fate of a physiologically active substance in the body after introduction in various ways, of its distribution and elimination.

The next 50 pages deal with differences in sensitivity between races and sexes, hypersensitivity, tachyphylaxis, habituation and addiction, and the cumulation of drugs; "cumulation" here refers only to the retention of a substance, and "addiction" is regarded only as psychic dependence (including that on cigarettes), while physical dependence with withdrawal symptoms is referred to as "habituation". Surprisingly, the term "drug idiosyncrasy' is used instead of the usual "sensitization", *eg.* to penicillin

In the discussion of differences in sensitivity, much too little reference is made to biological dispersion to suit the needs of beginn rs.

The difference in sensitivity is mentioned only in the testing of insulin, where "the American rabbit requires three times as much insulin as in Europe", and "the effect of insulin on rabbits varies with the time and with the weather". It would have been more useful to the beginner (for whom the book is intended) to give some examples of the difference in sensitivity of different animals to the same substance, and the resulting difficulty of applying conclusions drawn from animal experiments to humans.

Another 50 pages are devoted to a description of the relation between dose and effect with the aid of curves, the terms "probit" and "probability paper" being explained. The well-known "CT product" is given for the action as a function of time, but unfortunately is illustrated with the action of CO, which in view of the unpredictable after-effects following prolonged exposure to CO probably has nothing to do with the "CT product".

Isobolic curves are given for the combined action of substances that can reinforce or weaken each other in their action. This is followed by a number of examples illustrating "Chemical Constitution and Pharmacological Action", which show only how little is known about this subject.

A 20-page chapter shows how pharmacological effects can be calibrated and how drugs are tested for side effects (particularly for pyrogenic action), and a short note is given on the toxicological examination of drugs.

The problem of a "general pharmacology" is evident in this book. In order to understand it, one must have considerable previous knowledge, and it is impossible to agree with the author when he stresses the undemanding nature of this text. The whole book is a rather abstract affair, and the reviewer fears that, particularly among those with no medical training, it will be more confusing than useful, or may foster the misconception that the ability to manipulate terms constitutes some understanding of pharmacology. The book will make enjoyable reading for those who are experienced in pharmacological or toxicological animal experiments or in clinical pharmacology.

H. Oettel [NB 542 IE]

Manometrische Methoden und ihre Anwendung in der Biologie und Biochemie (Manometric Methods and their Use in Biology and Biochemistry). By *Arnošt Kleinzeller et al.* VEB Gustav Fischer Verlag, Jena 1965; Tschechoslowakischer Verlag für medizinische Literatur, Prague 1965. 2nd ed., 601 pp., 147 illustrations, paper DM 75.60.

The second edition, the first to appear in German, was edited by *A. Kleinzeller* and written in collaboration with seven Czechoslovakian and one English author. It contains the following chapters: 1. Warburg manometric apparatus; theory and use. 2. Methods of measurement using the Warburg apparatus. 3. Differential manometers and their use. 4. Volumetric respirometers. 5. Microrespirometers. 6. Van Slyke manometric instrument. 7. The use of electrochemical methods for the study of tissue respiration. 8. Theory of buffers and their preparation; retention. 9. Media for animal tissues. 10. Processing and preparation of biological material for manometric metabolism studies. 11. Manometric measurement of the activity of enzymes and the use of inhibitors. 12. Thunberg technique and related methods 13. The use of manometric methods in metabolic studies and interpretation of the results. 14. Analytical manometric methods.

The reader is surprised by the full and detailed treatment of the theory and use of a method whose history began with a lecture by *E. Warburg* to the *Preaßische Akademie der Wissenschaften* in 1900, and which, particularly in the hands of *O. Warburg*, has made such a significant contribution to our present knowledge of cell physiology. A particularly welcome feature of this book is the fact that the authors not only deal with pure manometry, but also describe the polarographic method for the determination of oxygen, which is an important complement to the classical method, and report at length on methods for the manipulation of biological material. Detailed procedures and lists of references dating up to 1965 are given for each technique, so providing an extremely valuable aid to both beginners and advanced workers in the field of cell physiology and enzymology.

B. Hess [NB 517 IE]

Advances in Heterocyclic Chemistry. Vol. 5. Edited by *A. R. Katritzky*, *A. J. Boulton*, and *J. M. Lagowski*; Academic Press, New York-London 1965. 1st ed., xiv, 395 pp., 395 illustrations, $16.00.

In the first article (67 pp.), *R. Zahradník* deals with theoretical considerations on the electronic structure, the resulting reactivity, and a number of physical properties of heterocyclic sulfur compounds. Starting with the model for the atomic orbitals of sulfur, calculations of the molecular orbitals for sulfur compounds are presented, and comparisons are drawn with corresponding carbocycles.

The second article (49 pp.) by *K. Zahradník* and *J. Koutecký* covers theoretical studies on the physical properties and reactivity of nitrogen heterocycles ("azines"). This article presents lucidly a tabular collection of spectral data, polarographic half-wave potentials, π-electron densities, basicities, and chemical reactivities of mono-aza heterocycles with a completeness that is unequalled elsewhere.

F. Kurzer is responsible for the article on 1,2,3-thiadiazoles (85 pp.), a class of substances that has been closely studied only in the last ten years. The syntheses developed during this time are described, those discovered by *J. Goerdeler* being particularly outstanding. Other chapters deal with the chemical and physical as well as physiological and pharmacological properties of these compounds.

R. A. Heacock wrote the article on aminochromes (85 pp.), the deep-red to violet oxidation products of 3,4-dihydroxyphenylethylamine and its derivatives (dopa amines). The possibilities of formation, the methods of preparation, and the mechanism of formation are discussed. The physical behavior, and especially chromatographic and spectral data, are presented clearly. The chemical properties, stability, and rearrangement and condensation reactions are described at length. Detailed reference is also made to the importance of the aminochromes in medicine and biology, particularly for the formation of melanine in the dark pigments or the adrenochrome metabolism.

B. S. Thygarajan discusses the aromatic quinolizines (23 pp.). He describes in detail the syntheses of the known quinolizine derivatives, the possible reactions, and the ultraviolet and infrared spectra.

The last contribution (50 pp.) by *N. Kochetkov* and *A. M. Likhosherstov*, presents a digest of 125 original publications on advances in pyrrolizidine chemistry. The syntheses described are backed up by numerous clear formulae. One chapter is devoted to the relative and absolute configuration and stereochemical transformations of the pyrrolizidine bases. The reactions and ring cleavages are reported at length. The section closes with a discussion of the biogenesis of naturally-occurring pyrrolizidines from ornithine or β-hydroxyornithine.

The book contains a balanced blend of theoretical and preparative results from research on special heterocycles. The layout of the book is again outstanding, so that it is a worthy successor to the earlier volumes, and will be a useful source of information for anyone who is interested in heterocycles.

W. Ried [NB 530 IE]

Comprehensive Biochemistry. Edited by *M. Florkin* and *E. H. Stotz*. Vol. 16: Hydrolytic Reactions; Cobamide and Biotin Coenzymes[1]. Elsevier Publishing Company, Amsterdam-London-New York 1965. 1st ed. XII, 267 pp. 10 illustrations, 37.50 Dutch florins (by subscription, 30.00 Dfl.).

Of the many reactions of enzymes a few are selected as examples and treated here in exemplary fashion; these are the reactions of the hydrolases, the action of which as acid-base catalysts has been largely elucidated in recent years, and those of the isomerizing and carboxylating enzymes that use cobamides and biotin as cofactors. A deeper insight into the arrangement of the active site of esterases has been obtained, mainly by variation of the structure of the substrate and by means of inhibitors; this is discussed by *Oosterbaan* and *Jansz*. The role of phosphatases in the synthesis and degradation of cell substances is described by *Morton* (in an article published posthumously) with his usual lucidity. A particularly topical section which, like the others, contains interesting aspects based on the personal experience of the author *(Cunnigham)*, deals with the serine proteases. Considerable space in this section is devoted to the views on the formation of active enzyme-substrate complexes, which have already been extended to other enzyme mechanisms, and the chemical and physical principles underlying these ideas are discussed.

The chapter on the cobamide (B_{12}) coenzymes, in which the essentials are presented concisely and authoritatively by *Weisbach*, *Peterkofsky*, and *Barker*, is a masterpiece of selective writing. A somewhat less balanced section is that on biotin carboxylases by *Ochoa* and *Kaziro* However, the discussion also includes all the necessary detail.

This volume is again undoubtedly well presented. However, consideration of the further progress of the enterprise raises the question of whether the completeness of this work, for which a high price must be paid, is not a luxury. The volumes should not be included in a single treatise, where there is always a desire to complete the series, but which will nevertheless not become a comprehensive manual of biochemistry; they should instead have been published as monographs, from which one could select those required, and which could be more easily kept up-to-date by publication of new editions.

L. Jaenicke [NB 539 IE]

[1] Cf. Angew. Chem. *76*, 868 (1964).

Advances in Organic Chemistry. Methods and Results. Vol. 5. Edited by *R. A. Raphael*, *E. C. Taylor*, and *H. Wynberg*. John Wiley & Sons. Ltd., New York-London-Sydney 1965. 1st Edit., vii, 337 pp., several figures and tables, cloth, 105s.

In volume 5[*] of "Advances in Organic Chemistry", *A. J. Parker* reports on the use of dipolar aprotic solvents, *R. McCrindle* and *K. H. Overton* on the chemistry of cyclic diterpenoids, and *M. Tichý* on the determination of intramolecular hydrogen bonds by IR spectroscopy and the application of such data to stereochemistry.

Parker's article (46 pp.; 232 references, of which no. 232 appears in the list of references but not in the text) is a careless piece of work and contains many mistakes. The content of the publications on which the article is based is reviewed (often distortedly) in a loose sequence instead of coordinated to form a unified picture. Consequently, there is considerable repetition with different references, while other topics are discussed in unsuitable places (*e.g.* the reaction of mercaptides with oxygen appears under "Dipolar Aprotic Solvents as Reactants", and the formation of alkyl nitrates is given as an example of the reaction $RX + R'_2N^{\ominus} \rightarrow NRR'_2 + X^{\ominus}$); with the result that the original sense is often lost (*e.g.* p. 27: preparation of nylon from isocyanates). The main value of this article would therefore lie in the reference list, but for its careless compilation: 60 references are incorrect, data on the publishers rudimentary (*e.g.* Elsevier, New York"), abbreviations of journals are sometimes inconsistent and journals that are translated into English are referred to only as the English translation. The work cited occasionally does not deal with the topic in connection with which it is referred to.

McCrindle and *Overton* review 237 papers in 67 pages. The terse discussion does not always follow *Fieser*'s "Style Guide for Chemists", and occasional incorrect (*e.g.* p. 74 under the chemistry of dihydrorosenonolactone, p. 51, two methyl groups missing; note a) of Tables I to IV is not relevant) or incomprehensible presentation (p. 80, formula of podototarin) makes it necessary to consult the original literature (spot checks indicate that the references are almost free from errors). The use of unaccustomed abbreviations is not conducive to easy reading.

Tichý deals almost exclusively with shifts in the positions of OH bands as a result of hydrogen bonding, and scattered data from 339 publications are presented on 184 pages (mainly in tables). Errors leading to distortion of meaning are comparatively rare [formulae *59* and *78* do not agree with their legends; on p. 145 *63d* appears instead of *63b*; on p. 282 one finds 2-(3,4,6- (better: 2-(2,4,5-) instead of 2-(3,4,4-trimethoxyphenyl)ethanol; on p. 157 the value of $\Delta\nu$(OH) for 2-hydroxybenzonitrile is omitted; on pages 234 and 273, the OH groups are omitted from the azomethine and biaryl formulae; a wrong formula is given on p. 178 for ascaridole glycol; the bottom formula on p. 278 (as in the original publication) carries one CH_3 group too many]. Some names of authors are also quoted wrongly (nos. 161, 209, 276, 338). On p. 200, *Tichý* uses the numbering given by *McCrindle* and *Overton* for labdandiol, while on pages 121 and 132 he uses the old system.

The reproduction of steric formulae is very arbitrary, and even includes bold dotted bonds. As before, the external presentation is excellent. *G. P. Schiemenz* [NB 577 IE]

Industrial Chemicals. By *W. L. Faith, D. B. Keyes*, and *R. L. Clark*. John Wiley & Sons, Inc., New York-London-Sydney 1965. 3rd Edit., 852 pp., 190 s.

137 of the most important industrial chemicals are decribed in alphabetic order. These include 83 organic substances and 54 inorganic substances as well as a few elements, such as oxygen, hydrogen, and chlorine. The emphasis is placed on base chemicals and intermediates. Organic "end-products" include aspirin, penicillin, polyethylene, and polypropylene.

Under each substance the book presents a brief but very lucid description of the current technical production processes (with flow diagrams and "recipes"), and the important properties, commerical grades, producers in the U.S.A., and prices are given. Processes that are important for several products, such as the oxo process and hydrodealkylation, are discussed under one of the products for which they are used. (A more detailed index would have made it easier to find such processes. For example, the alfol process is mentioned under "decyl alcohol", synthesis gas is described under hydrogen, and the oxidation of hydrocarbons under acetaldehyde; none of these processes is mentioned in the index).

The industrial chemist will be particularly interested in the "Economic Aspects". Here he will find data on the present market importance of a product, the production (in the U.S.A.) since 1944, and the prospects for further development. These sections also contain information about the relationship between production costs and plant size, the economics of combination with other processes, and the position of a product in relation to competing products.

The book offers students, teachers, and industrial chemists a wealth of facts and suggestions. Many readers may be disappointed that no literature or patents are cited. However, this was the only way in which the size and cost of the book could be kept within reasonable limits.

Catalytic Hydrogenation (Techniques and Applications in Organic Synthesis). By *R. L. Augustine*. Marcel Dekker, Inc., New York 1965. 1st ed., xii, 188 pp., several illustrations, bound $8.75.

Considerable progress has been made in recent years in catalytic hydrogenation, particularly in selective and partial hydrogenations, for which a large number of new catalysts have been discovered. Despite the existence of a number of handbooks, the literature in this field is not easy to survey. A number of authors have recently described the subject in relatively short monographs. Among these, *Augustine* stands out for his conciseness and lucidity.

The sub-title suggests that the book is intended mainly for the preparative organic chemist, with the object of assisting with hydrogenation problems; this is achieved with the aid of short hydrogenation procedures set in bold type. However, reference to the original publication often is unavoidable. Nevertheless, the brevity is a decisive aid to clarity. This is also assisted by the division of the material into: 1. Apparatus and general technical instructions (but only for the laboratory scale), 2. catalysts and general hydrogenation conditions, and 3. instructions for hydrogenations and hydrogenolyses, arranged according to functional groups, though many problems here are dealt with in a few sentences. An appendix describes the preparation of a number of common catalysts; more examples would have been welcome here.

The book may also be of interest to the hydrogenation specialist for quick orientation, though the specialist would prefer a stronger emphasis on patent literature. However, the book will be a useful aid to chemists working in the laboratory and in general research, and above all to the newcomer to the field of catalytic hydrogenation. It is concisely and clearly written, and if it is regarded as an introduction to the problems of catalytic hydrogenation, it probably serves its purpose. *M. Reich* [NB 525 IE]

The Alkaloids, Chemistry and Physiology. By *R. H. F. Manske*. Vol. VIII[1]: The Indole Alkaloids. Academic Press Inc., New York-London 1965. 1st Edit., 861 pp., bound $ 32.00.

Between 1949 and 1955, *R. H. F. Manske H. L. Holmes*, together with other well-known authors, collected the existing knowledge on the chemistry and physiology of the alkaloids n a five-volume handbook. This work became one of the most important sources of information on these natural products, and is still unsurpassed in this field. The supplementary volumes VI and VII were published in 1960. The present volume, which is particularly extensive, is devoted to the results obtained since 1960 on the indole alkaloids. The rapid development of this group of alkaloids is indicated by the size of the relevant chapters: 138 pages in Vol. II, a supplement of 200 pages in Vol. VII, and now 861 pages in Vol. VIII. This growth is due to the fact that the indole derivatives form one of the most extensive and medically most useful groups of alkaloids. Thus some 600 indole alkaloids are now known, and 50 to 100 are isolated for the first time and their structure elucidated every year. Examples of therapeutically important indole alkaloids are reserpine and the ergot and curare alkaloids.

The editor, *R. H. F. Manske*, and the eleven co-authors have made an ideal selection of material for this supplement to a handbook. The content is largely new and contains only as much material from the earlier volumes as is required to make the chapters independent. In this way the 22 chapters of the volume give impressive evidence of how much as been achieved in five years, how many new alkaloids have been elucidated, and what modern methods have been used in their elucidation. The authors themselves have made a decisive contribution to these successes.

The synthesis and stereochemistry of ergotamine are a climax of the chapter by *A. Stoll* and *A. Hofmann* on ergot alkaloids, which has grown from 28 pages in Vol. VII to 53 pages in the present volume. The description of the curare alkaloids, by *A. R. Battersby* nd *H. F. Hodson*, has also expanded considerably. In this section, due attention is paid to the elucidation of the dumeric alkaloids of calabash curare by the authors and by the research groups of *H. Schmid* and *Th. Wieland*.

The editor has written five excellent chapters on the calycanthacea and other alkaloids studied by him. This section also includes the elucidation, completed by *R. B. Woodward* and at the same time by X-ray analysis by *M. Robertson*, of

calycanthine, which is remarkable for its unusual 6-membered ring structure.

E. Schlittler describes the progress achieved in the chemistry of reserpine (which was elucidated by this author) and similar indole alkaloids. The reader learns from competent sources how *Woodward*'s total synthesis of reserpine, described in Vol. VII, has in the meantime been modified in such a way that this therapeutically active alkaloid is now as readily obtainable by synthesis as from varieties of *Rauwolfia*.

In four chapters on vinca, iboga, pentaceras, and ajmaline alkaloids, *W. I. Taylor* describes the isolation and structure elucidation of a large number of new alkaloids. These chapters also describe one of the first triumphs of mass spectrometry, which has made an outstanding contribution in this field through the work of *K. Biemann* and *C. Djerassi*. This is particularly true in the case of the detailed description of the aspidosperma alkaloids by *B. Gilbert*.

G. F. Smith, *E. Coxworth*, and *W. I. Taylor* describe the strychnos alkaloids, physostigmine, and the biogenetically important cinchonamine, fields that are now essentially complete. *J. E. Saxton* describes recent achievements in the field of the gelsemium and other alkaloids in six outstanding reviews.

Owing to the arrangement of the handbook, which was established 16 years ago, only relatively little attention could be given to advances in biogenitic studies.

There can be no doubt that in the supplementary volume VIII the editor and co-authors have produced one of the best and most stimulating monographs on the chemistry of natural products. The book will be read not only by chemists, botanists, and pharmacologists engaged in the alkaloid field, but also by all those who are interested in important mechanistic and stereochemical results and in modern methods of structure elucidation.

Hydrophobic Interactions

BY G. NÉMETHY[*]

Recent advances in theoretical and experimental studies of hydrophobic interactions are reviewed. The theory of water structure as applied to hydrophobic bonding, theoretical estimates for the free energy of unfolding of proteins, and the statistical mechanical theory of hydrophobic bonding in polyamino acids are summarized. Experimental estimates of the thermodynamic parameters of the hydrophobic bond can be obtained from solubility and dimerization data of low molecular weight compounds. Recent studies of the interaction of proteins with nonpolar solutes are discussed. Hydrophobic bonds can also be important in various other kinds of interactions involving proteins. The observed effect of urea is mentioned, although no theoretical interpretation of this effect is available yet. In conclusion the methods available for the detection of hydrophobic interactions are reviewed.

Introduction

In recent years the role of hydrophobic bonding in the maintenance of the secondary and tertiary structure of proteins (and of other macromolecules) in aqueous solution has become increasingly clear. The term "hydrophobic bonding", or more properly "hydrophobic interaction", describes the tendency of nonpolar groups to associate in aqueous solution, thereby reducing the extent of contact with neighboring water molecules. This behaviour does not arise from unfavorable energetics of the nonpolar group-water contact. On the contrary, the enthalpy of formation of a hydrophobic bond is destabilizing ($\Delta H^\circ > 0$). The formation of hydrophobic bonds is favored only because of an entropy effect: the water molecules become more ordered around exposed nonpolar solutes. When the hydrophobic bond is formed the order decreases, resulting in a favorable entropy and hence free energy of formation.

Hydrophobic bonding is often invoked in the interpretation of various observed anomalies in protein structure and reactivity. Undoubtedly, hydrophobic interactions are one of the most important effects in the stabilization of the conformation of proteins in aqueous solution. Nevertheless, restraint must be exercised in the use of this concept when experimental data are to be interpreted. Hydrophobic bonds cannot be the sole important noncovalent interaction in proteins, even though they can make a large or even the predominant contribution to the stabilization of particular conformations. They are not sufficiently specific in character to force the establishment of a unique structure: in the interaction of nonpolar groups with each other, there is little restriction upon the number of interacting groups, their mutual orientation, and the extent of their contact. Therefore, specific folding into a unique conformation presumably requires the interplay of several types of noncovalent interactions.

Theoretical Treatments of the Hydrophobic Bond

The consideration of hydrophobic bonding cannot be separated from the study of the structure of liquid water. In this connection, the most important feature of the structure of liquid water is the ability of its molecules to form spatially extended networks (clusters), by means of intermolecular hydrogen bonding (Fig. 1). Various theoretical and experimental approaches to the determination of water structure were reviewed by *Némethy* and *Scheraga*[1], and by *Kava-*

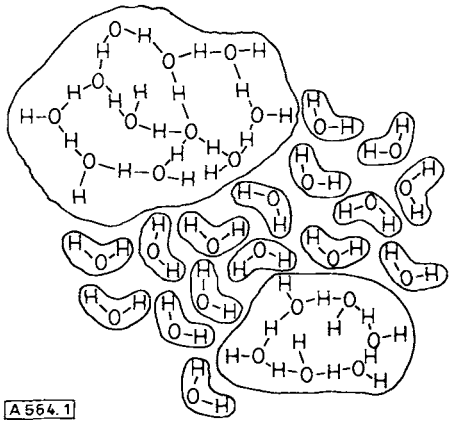

Fig. 1. Schematic representation of the structure of liquid water according to the theory of *Némethy* and *Scheraga* [1]. Hydrogen-bonded clusters and regions of non-hydrogen-bonded molecules are shown.

nau [2]. Since then, several further proposals for the structure of liquid water have been published with the aim of providing an improved description of the structure, *e.g.*, by postulating a variety of interacting multimolecular structures [3,4], or by generalizing [5,6] the use of various energy levels introduced in the theory of *Némethy* and *Scheraga* [1]. In interpretations of some recent infrared or Raman spectroscopic data, it was suggested [7–9] that the fraction of broken hydrogen bonds is small (below 10 %), *i.e.* much below earlier estimates [1,2]. Some of the problems arising in the interpretation of various observations in terms of water structure have been summarized by *Frank* [10].

Even though the details of the intermolecular structure in liquid water are still a subject of controversy, this does not detract from the prevalent picture of the effects of nonpolar solutes on water structure and on the nature of hydrophobic bonding. All evidence supports the early suggestion by *Frank* and *Evans* [11], treated later in more detail by *Kauzmann* [12] and by *Némethy* and *Scheraga* [13], that structural order increases near nonpolar solutes. Thermodynamic parameters and solubility data for various nonpolar substances can be best reconciled with the assumption that the number of hydrogen bonds per mole of water is increased near nonpolar solutes. It has been shown [13] that the presence of highly hydrogen-bonded water molecules in the immediate neighborhood of nonpolar solute molecules is favored because of the possibility of increasing the number of attractive intermolecular (van der Waals) contacts (Fig. 2). This

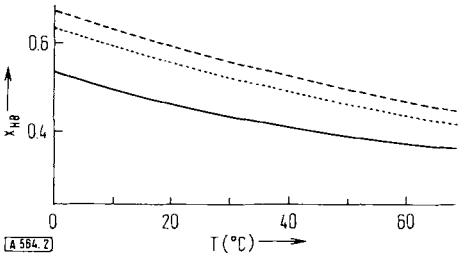

Fig. 2. The fraction of unbroken hydrogen bonds x_{HB} at various temperatures in pure water (——) and in the first layer of water molecules around aliphatic (- - - -) and aromatic (····) hydrocarbon molecules. (x_{HB} = 1 for perfectly crystalline ice.) Calculated from the theory of *Némethy* and *Scheraga* [13].

results in a stabilization of hydrogen-bonded water networks or clusters. Since this effect leads to the immobilization of more water molecules than in pure water, it results in a negative excess entropy of solution [13] and hence a large positive free energy of solution (Fig. 3), as observed. The enthalpy gained

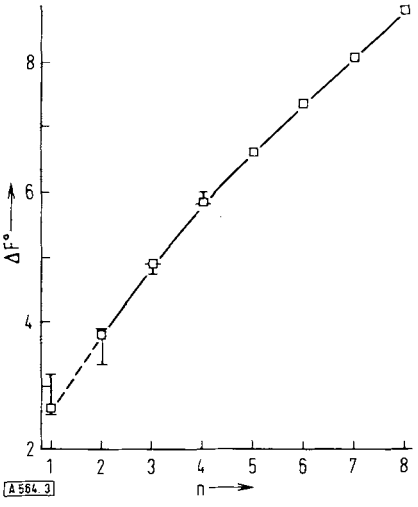

Fig. 3. Comparison of experimental (I) and theoretical (□) excess free energies (kcal/mol) of solution for the normal aliphatic hydrocarbons in water at 25 °C. *n* is the number of carbon atoms in the hydrocarbon. The curve is drawn through the theoretical points calculated by *Némethy* and *Scheraga* [13].

from the formation of the new hydrogen bonds and from the increased number of van der Waals contacts explains [13] the observation that aliphatic hydrocarbons dissolve exothermally in water.

Hydrophobic bonding can be considered essentially as the partial or complete reversal of the solution process for a hydrocarbon in water (Fig. 4). As pointed out by *Kauzmann* [12], the stable conformations of a protein in aqueous solution will be those in which nonpolar groups can come into contact with each other and are thus partially or completely removed from water [14]. This process will be accompanied by

a large negative free energy change (ΔF°), composed of a large positive entropy component (ΔS°) and zero or a small, positive enthalpy component (ΔH°), as calculated by *Némethy* and *Scheraga* [14]. The value of ΔH° is near zero for aromatic groups and positive for aliphatic groups near room temperature [14]. The free energy ΔF° describes the tendency of the non-polar groups to adhere to each other, and thus represents the strength of the hydrophobic bond.

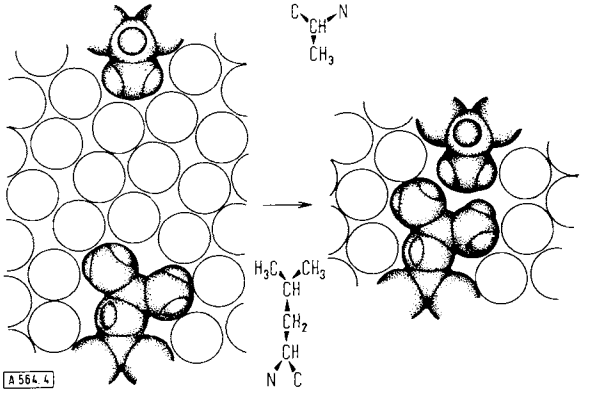

Fig. 4. Schematic representation of the formation of a hydrophobic bond between exposed alanyl and leucyl side chains on a protein. The two side chains approach each other until they touch, so that the number of nearest neighbor water molecules (shown schematically by circles, without indicating the structure) is reduced [14].

In other polar solvents, nonpolar groups also may tend to contact each other, but this happens because the energy of solvent-solvent and solute-solute interactions is more favorable than that of solvent-solute interactions. Such lyophobic [15] interactions are enthalpy-driven.

This character of hydrophobic bonds is evidenced in their temperature dependence: at low temperatures, hydrophobic bonds become stronger as the temperature increases [14,16]. The maximum strength is reached at a certain temperature which is estimated [14] to be near 58 °C for aliphatic side chains and near 42 °C for aromatic side chains.

The partial molal volume of a hydrocarbon is much smaller in aqueous solution than in nonpolar solvents ($\Delta V^\circ < 0$ for the solution process). This can be explained [13] in terms of the specific structural arrangement of water around the nonpolar solute molecules. The formation of hydrogen-bonded water aggregates is accompanied by a volume increase. However, the inert solute molecules occupy part of the cavities occurring in these water structures, resulting in a net decrease of the total volume. Conversely, the formation of hydrophobic bonds is accompanied by a volume increase [14].

A different interpretation of the effects of non-polar groups in water was proposed by *Klotz* [17,18]. According to his view, the formation of regions of ordered water in ice-like sheaths ("hydrotactoids" [18]) in the vicinity of nonpolar groups is favored, because such a structure would be stabilized by these non-polar groups, in analogy with crystalline gas hydrates [19,20]. Such ice-sheaths would lead to the masking of reactive groups. This theory involves difficulties on both thermodynamic and structural grounds. No direct evidence is available for the existence of stable, long-lived immobilized layers of water around macromolecules, as would be required for the permanent masking of groups. While exposed non-polar groups lead to ordering of water, as discussed above, the presence of large regions of this kind would lead to aggregation of the macromolecules [12], in analogy with the formation of micelles.

In the work of *Némethy* and *Scheraga* [14], attention was centered on interactions involving a limited number of amino acid side chains, such as "pairwise interactions" (Fig. 4). On the basis of hydrocarbon solubility and of the statistical thermodynamic theory developed for hydrocarbon solutions [13], lower and upper limits were estimated for ΔF°, ΔH°, and ΔS° of such interactions for all pairs of nonpolar amino acid side chains. Table 1 contains some representative examples for various types of side chains.

Table 1. Thermodynamic and structural parameters (calculated values) for the formation of pairwise hydrophobic bonds of maximum strength between selected amino acid side chains [a] at 25 °C.

Side chains	Thermodynamic parameters			Structural parameters [c]	
	$\Delta F^\circ_{H\varphi}$ kcal mol^{-1}	$\Delta H^\circ_{H\varphi}$ kcal mol^{-1}	$\Delta S^\circ_{H\varphi}$ e.u.	ΔY^s	Z_R
Ala-Ala [b]	−0.3	0.4	2.1	4	2
Ileu-Ileu	−1.5	1.8	11.1	10	5
Phe-Leu	−0.5	0.9	4.7	6	3
Phe-Phe	−1.4	0.8	7.5	12	6

[a] These values are approximately those for a hydrophobic bond of minimum strength between any two side chains.

[b] Ala = Alanine, Ileu = Isoleucine, Leu = Leucine, Phe = Phenylalanine.

[c] The meaning of ΔY^s and of Z_R is explained in the text.

The free energy of the hydrophobic bond $\Delta F^\circ_{H\varphi}$, is derived as a sum of several contributions: The free energy change (ΔF°_W) for the structural change in water, after which ΔY^s water molecules are no longer neighbors of previously exposed nonpolar groups; the difference of the van der Waals forces occuring between the nonpolar groups ($Z_R E_R$, where E_R is the attractive force for a pairwise contact, there being Z_R such pairs) and the forces occurring between the exposed nonpolar groups and the ΔY^s water molecules which were their neighbors ($\frac{1}{2}\,\Delta Y^s E_{RW}$); an entropy change due to the partial loss of flexibility of nonpolar side chains (on macromolecules) when the bond is formed ($\Sigma \Delta F_{rot}$), resulting in the expression

$$\Delta F^\circ_{H\varphi} = \Delta Y^s \Delta F^\circ_W + Z_R E_R - \tfrac{1}{2}\,\Delta Y^s E_{RW} + \Sigma \Delta F_{rot} \qquad (1)$$

The two energy parameters are $E_R = -0.15$ kcal/mole for aliphatic and −0.50 kcal/mole for aromatic groups, $\frac{1}{2}\,E_{RW} = -0.031$ kcal/mole for aliphatic and −0.16 kcal/mole for aromatic groups. ΔF_{rot} ranges from 0 to 0.3 kcal/mole for the amino acids occurring in proteins, depending on the size of the side chain.

ΔF_W° is temperature dependent. At 25 °, its value is −0.123 kcal/mole [13]. Typical values of ΔYs and of Z_R are given in Table 1.

This calculation was extended [14,21] to hydrophobic bonds involving nonpolar parts of side chains which are generally classified as polar, such as glutamic acid, glutamine, lysine, or tyrosine. It was shown [21] that such side chains can form hydrophobic bonds with other side chains or even with the peptide backbone, while their terminal polar group can be exposed to the solvent or to other polar groups. For example, in crystalline myoglobin side chains are found which lie parallel to the surface of the molecule [22].

The free energy of interactions involving more side chains was also calculated [14]. In particular, thermodynamic parameters were estimated for the transfer of nonpolar side chains from a completely aqueous environment into an existing nonpolar region [14]. Calculated values for this process are listed in columns 2–4 of Table 2, together, for comparison, with the

Table 2. Calculated thermodynamic parameters of transfer of amino acid side chains and of corresponding hydrocarbons from water into a nonpolar medium at 25 °C.

	Amino acid side chains [a]				Hydrocarbons

[d] Side chain contribution to the free energy of transfer of an amino acid from water into ethanol, calculated by *Tanford* [23].

[e] For CH_2 increment. From [13]. $\Delta H_{tr}^\circ = -0.23$ kcal/mole, $\Delta S_{tr}^\circ = +1.76$ e.u. for unbranched hydrocarbons.

free energy of transfer of hydrocarbons of similar size from water into a hydrocarbon solvent (column 6). In comparing the values for hydrocarbons and for amino acid side chains, one must bear in mind that the parameters for the transfer of a side chain from one medium to the other must always be smaller in magnitude than for the dissolution of the free hydrocarbon with the same number of carbon atoms. The steric bulk of the peptide backbone reduces the number of solvent molecules in contact with the exposed side chain.

Tanford [23–26] has applied a somewhat different approach to the estimation of the stabilization of protein conformations by hydrophobic bonding. He assumed [23] that the free energy of unfolding of a protein is given as

$$\Delta F = -T\Delta S_{conf} + \Sigma\Delta f_u \qquad (2)$$

where ΔS_{conf} is the change in conformational entropy of the polypeptide chain, and $\Sigma\Delta f_u$ is the free energy change for transfer of the small component groups of the protein molecule from their environment in the native form of the protein to their environment in the unfolded form (Fig. 5). He further assumed (a) that

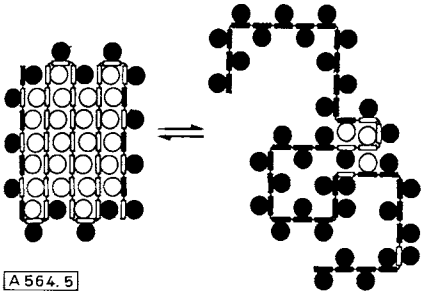

Fig. 5. Schematic diagrams of the native (left) and unfolded (right) states of a protein molecule, according to *Tanford* [25]. Rectangles represent peptide groups, circles indicate side chains. The symbols in black represent groups in contact with the solvent, symbols in white those shielded from the solvent. Reproduced, by permission of the American Chemical Society, from work by *Tanford* [25].

the major part of $\Sigma\Delta f_u$ arises from the exposure of formerly "buried" nonpolar groups to water, (b) that $\Sigma\Delta f_u$ can be calculated additively from the Δf_u values determined for the single amino acid side chains composing the protein, and (c) that Δf_u for the transfer of an amino acid side chain can be equated with Δf_t, the free energy change of the same side chain on transfer from ethanol solution to water. He calculated Δf_t for each amino acid side chain by subtracting the free energy of transfer of glycine from that of the amino acid. By determining the solubilities of the amino acids in mixed solvents, estimates of $\Sigma\Delta f_u$ were made [23,24] for solvent induced denaturation. *Tanford* describes a procedure for the numerical estimation of differences in conformational stability of proteins in various solvents, based on the comparison of Δf_u values for transfer between various solvents.

The Δf_t data determined experimentally by *Tanford* [23] for the ethanol-water transfer are listed in Table 2 for comparison with the calculated values [14]. The difference in the two sets of values may arise from two sources: where $|\Delta f_t| > |\Delta F_{tr}^\circ|$, this may reflect the difference between the free amino acid and the side chain in a bulky protein as discussed above. The nature of the solvent may also play a role. Thus the calculated values are for transfers from hydrocarbons into water, while *Tanford* and *Nozaki* used ethanol as

the organic medium. The polar OH group of the latter may account for the apparent discrepency.

While one ultimately hopes to be able to derive the free energy of stabilization of a protein conformation from the amino acid composition and the sum total of the possible interactions between the side chains, caution must be exercised in the application of eq. (2). In the native protein, not all amino acid side chains may be buried, and some nonpolar interactions presumably persist in the unfolded state [27a]. Both effects tend to diminish $\Sigma\Delta f_u$ from the value calculated purely from the Δf_t data and amino acid composition. The problem of additivity will be discussed later.

The effect of intramolecular hydrophobic bonding on the conformations of polyamino acid helices can also be studied by the methods of statistical mechanics [27]. Hydrophobic bonds can exist between sufficiently large side chains on adjacent turns of the α-helix [14], and even between a Cβ atom of an L-amino acid and the Cα atom of the fourth preceding residue along the chain in the right-handed α-helix [14]. These hydrophobic bonds can contribute to the stabilization of the α-helix [16]. The Lifson-Roig theory [28] for the helix-coil transition of polyglycine was modified [29] to include the Cβ-Cα hydrophobic bond which occurs in poly-L-alanine. For a chain length of 100 residues, the temperature of the helix-coil transition is increased by 175 °C as compared with a polyglycine of the same size. This result was based on the $\Delta F^{\circ}_{H\varphi}$ value given by *Némethy* and *Scheraga* [14]. Experimentally, it was found [29a] that a poly-L-alanine chain of about 175 residues retains the helical form at least up to 95 °C, while polyglycine (which is not water-soluble) forms no α-helix, even in nonaqueous solvents at room temperature.

In a more detailed treatment of noncovalent bonds in polyamino acids, *Poland* and *Scheraga* [27] have included hydrophobic bonding in the random coil. They showed that, while hydrophobic bonds in helical sequences can stabilize the helix greatly, the presence of such bonds in the random coil largely offsets this stabilization. The thermal transition curves in the absence of hydrophobic bonds and in the presence of such bonds in both helix and coil are very similar (Fig. 6). In the random coil, there is a relatively high probability of formation of hydrophobic bonds between side chains of adjacent residues: about 0.2 for Ala-Ala, 0.3 for Leu-Leu, 0.6 for Ileu-Ileu pairs (Table 3 in [27c]). The probability of formation of large loops in the random coil diminishes rapidly with size.

If t is the number of peptide units between the two interacting side chains, the probability becomes 0.03–0.04 for $t = 2$ and 0.02 for $t = 3$ [27c].

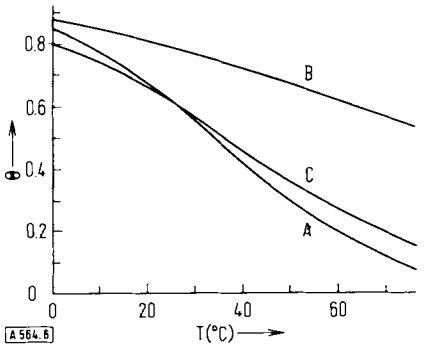

Fig. 6. Calculated helix-coil transition curves of a 20 amino-acid residue polypeptide chain (A) in the absence of hydrophobic bonds, (B) with hydrophobic bonds in the helix only, (C) with hydrophobic bonds in both the helix and the random coil. The ordinate represents the fraction of hydrogen bonds. Reproduced from work by *Poland* and *Scheraga* [27a].

Poland and *Scheraga* also showed that the helix is strongly stabilized if interhelical hydrophobic bonds are present; a sharp helix-coil transition can then occur [27b,c]. Short polyamino acid chains normally form a single, helical sequence but the probability of several shorter helices being formed is high if establishment of inter-helix side chain interactions is thereby permitted. For a particular choice of parameters, *Poland* and *Scheraga* calculated [27b] that at low temperatures (<40 °C) the most probable structure for a 20-residue poly-L-alanine chain has two parallel, interacting helices. The single chain and three interacting helices have lower probability. In the 40–80 ° range, the structure with three interacting helices is most stable, while above this temperature there is a transition to the random coil (Fig. 7). Similar results have been

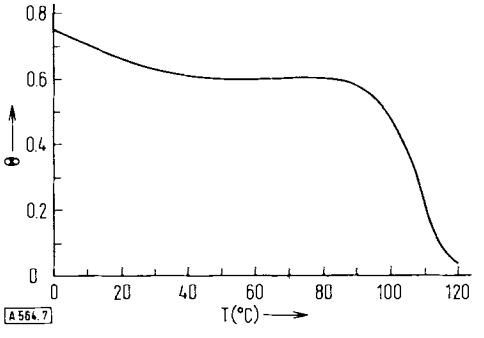

Fig. 7. Calculated helix-coil transition curve for a 20 amino-acid residue poly-L-alanine chain with interactions between helices. The ordinate represents the fraction of hydrogen bonds. Reproduced from work by *Poland* and *Scheraga* [27b].

calculated for longer helices [27c]. The calculated probabilities and transition temperatures are very sensitive to the choice of parameters.

These calculations are at present purely theoretical since no such transitions have been observed yet, possibly because they are beyond the power of present-day experimental techniques for polyamino acids. However, it was suggested by *Poland* and *Scheraga* [27c] that the triple thermal transition occurring in a copolymer of L-leucine and L-glutamic acid [30] may arise from some kind of interhelical interaction. It is notable that the calculated helix-coil thermal transition is sharpened

considerably if interhelical interactions are assumed and that it then becomes similar to the type of transition curves observed in globular proteins [27b].

Experimental Studies on Model Compounds

The main purpose of solubility studies on model compounds is the determination of free energies of transfer of nonpolar groups (a) from water to a nonpolar solution, in order to estimate the free energy of placing nonpolar groups into hydrophobic regions of proteins, (b) from water to mixed solvents, in order to estimate the contribution of hydrophobic bonds to the stabilization of proteins towards solvent denaturation.

1. Solubilities of Hydrocarbons and the Effects of Heavy Water

Determinations of thermodynamic properties of hydrocarbons provide the most direct information on behavior of nonpolar groups. For this reason, solubility data from the literature were used as standards in developing the theory of water structure and hydrophobic bonding [13,14]. More recently, *Kresheck et al.* [31] have redetermined the solubilities of propane and butane between 0 and 60 °C by a gasometric technique and confirmed their earlier measurements (cited in [13]). They also determined the solubilities of these hydrocarbons in D_2O and found them to be very slightly higher than in H_2O. The free energy of transfer, ΔF_{tr}^{o}, for the process

$$\text{RH (in } H_2O) \rightleftharpoons \text{RH (in } D_2O)$$

is about -40 ± 10 cal/mole at 0 °C and decreases to near zero at 50 °C. On the other hand, solubility measurements for amino acids in D_2O and H_2O by the same authors [31] gave small positive values of Δf_t for the side chain contributions. Micelle critical concentration data in the two solvents [31] also indicate a slightly decreased solubility of nonpolar groups in D_2O. From this *Kresheck et al.* [31] have concluded that hydrophobic bonds are slightly stronger in D_2O. The ΔF_{tr}^{o} for argon [32] has the same sign as ΔF_{tr}^{o} for the hydrocarbons. Thus, either there is a perturbing effect of the polar group to which the amino acid side chains are attached, or there is some error in the observed data for non-polar substances. However, since the solubility differences in the two solvents are very small, no large difference is expected for the strengths of hydrophobic bonds in D_2O and H_2O.

Wetlaufer et al. [33] studied the solubility of several hydrocarbons in 7 M urea and 4.9 M guanidinium chloride solutions (Fig. 8). Except for methane and ethane at low temperatures, the free energy of transfer from water into these solutions is negative (*i.e.* the solubility increases). Its main component is a large positive entropy of transfer predominating over a positive enthalpy contribution. At 25 °C, ΔF_{tr}^{o} ranges from +60 cal/mole for methane to −770 cal/mole for skatole (the analogue of tryptophan). These data agree with the solubility determinations of amino acids by *Nozaki* and *Tanford* [24], discussed below. They indicate that urea and guanidinium chloride must weaken hydrophobic bonds [34].

o—o Toluene
●—● Skatole

The use of hydrocarbons as model compounds has two drawbacks: (a) because of their low solubility in water, it is difficult to obtain sufficiently accurate data, and (b) their use may result in misleading conclusions if the polar substituents in proteins or other multifunctional solutes exert a perturbing effect, *i.e.* if there is no strict additivity of the interactions of various functional groups with water. For these two reasons, much of the work involving model compounds has been done with alcohols, amides, carboxylic acids, and amino acids.

2. Solubilities of Amino Acids

The use made by *Tanford* [23] of solubility data has been cited above. In later work, he and *Nozaki* [24,26] extended the measurements to aqueous urea and

[31] *G. C. Kresheck, H. Schneider,* and *H. A. Scheraga,* J. physic. Chem. *69,* 3132 (1965).

[32] *A. Ben-Naim,* J. chem. Physics *42,* 1512 (1965).

[33] *D. B. Wetlaufer, S. K. Malik, L. Stoller,* and *R. L. Coffin,* J. Amer. chem. Soc. *86,* 508 (1964).

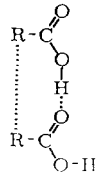
[34] The denaturing effects of urea and of guanidinium chloride may not entirely be due to the weakening of hydrophobic interactions: *Robinson* and *Jencks* [35] have concluded, from a solubility study of *N*-acetyl tetraglycine ethyl ester, that the peptide group itself becomes more soluble in the presence of these two solutes.

[35] *D. R. Robinson* and *W. P. Jencks,* J. biol. Chemistry *238,* PC 1558 (1963).

ethylene glycol solutions. They found an increased solubility for most amino acids, indicating that urea and ethylene glycol tend to weaken hydrophobic bonds. Table 3 summarizes some of their data from which it is evident that urea is a much more effective denaturing agent than ethylene glycol.

Table 3. The measured contribution of side chains to the free energy of transfer of amino acids from water into urea and ethylene glycol at 25 °C. After *Nozaki* and *Tanford* [24,26].

Side chain	Δf_t, cal/mole		
	Urea		Ethylene glycol
	6 M	8 M	30 %
Ala [a]	+ 10	+ 10	+ 30
Leu	−225	−295	−130
Met	−325	−415	− 65
Phe	−470	−600	−215
Try	−730	−920	−515
Tyr	−580	−735	−305
Gln	−190	−230	+ 10



[a] Ala = Alanine, Gln = Glutamine, Leu = Leucine, Met = Methionine, Phe = Phenylalanine, Try = Tryptophan, Tyr = Tyrosine.

As pointed out by *Wetlaufer* [33], the amino acid solubility data are to be preferred to those of hydrocarbons if the additivity of functional group effects is violated by the presence of the peptide group. However, it may even be doubted whether free amino acids are fully adequate as models for the peptides of a protein chain, since the former contain near by charged NH_3^+ and COO^--groups.

3. Interactions Involving Other Low Molecular Weight Compounds

Solubility measurements provide information analogous to the transfer of nonpolar groups from aqueous medium to the protein interior where they are "buried". In estimating the stabilization of proteins by hydrophobic bonds, it is equally important to know the interactions between nonpolar groups which are not completely buried. These correspond to the "pairwise" hydrophobic bonds for which the theory was developed by *Némethy* and *Scheraga* [14].

It was shown by *Schrier*, *Pottle*, and *Scheraga* [36] that the increase in the dimerization constants of carboxylic acids with chain length (from formic through acetic, propionic, and butyric to phenylacetic acids) in water can be explained in terms of hydrophobic bond formation between the nonpolar side chains of the dimerized acids according to formula *(1)*.

(1)

A single hydrogen bond is formed between the carboxyl groups, whereas presumably a double hydrogen bond is formed between the dimers in the gas phase where the dimerization constant is independent of chain length. The increments in dimerization constants in aqueous solution are close to the values predicted from hydrophobic bonding theory [14].

In a similar study, the thermodynamic parameters were determined [37] for the adsorption of several carboxylic acids and alcohols from water onto a polystyrene interface. While there was approximate agreement between theoretical [14] and experimental values for the effects of the nonpolar tail groups in the acids, no such agreement was found for the alcohols. Interpretation of the observed data involves several uncertainties both because of pronounced head group effects in adsorption and because the nature of nonpolar interactions in the polystyrene-adsorbent system is not so well defined as in a solution system.

The dimerization of higher carboxylic acids in terms of the formation of hydrophobic bonds has also been analyzed by *Mukerjee* [38]. He points out that the hydrophobic contribution to dimerization seems to level out after a certain size ($C_{16}H_{31}COOH$), presumably due to the coiling of long side chains and concurrent changes in the degree of exposure of methylene groups to water (cf. [13]).

Eagland and *Franks* [39] have studied the hydrolysis of fatty acid soaps and shown that the chain length dependence of the rate of hydrolysis indicates association of fatty acid molecules into the form $HX{\cdot}X^-$; the thermodynamic parameters agree with hydrophobic bonding theory [14].

Micelles

The formation of micelles gives an excellent example of the stabilization of nonpolar aggregates by hydrophobic bonding. Micelle formation involves pronounced head-group effects, as evidenced by the large observed variety of critical micelle concentrations and their sizes and shapes in different systems. However, the interaction between the nonpolar groups was recognized as one of the decisive factors in the early theories of micelle formation [40,41]. In their treatment of nonionic micelle stability, *Poland* and *Scheraga* [42] have discussed micelles in terms of hydrophobic bonding: the free energy of the micelle is shown to be composed of terms relating to the micelle as a whole, to internal freedom of motion of hydrocarbon chains in the micelle, and to solvent contri-

butions. The latter were treated in terms of the theory of hydrophobic bonding [14], which accounts well for the dependence of micelle size on concentration and temperature [43].

Micelles can also serve as models in the study of the effect of solvent additives on hydrophobic bonding. In particular, the effect of urea on micelles has been studied by several workers [45,46]. Urea raises the critical micelle concentration, indicating a weakening of hydrophobic bonds (cf. the solubility data discussed above). Studies on the association of dye molecules give similar results [47].

Proteins

1. Interactions with Nonpolar Solutes

One of the means of studying hydrophobic bonding in proteins is the investigation of their interactions with low molecular weight non-polar solutes. Binding of nonpolar solutes to nonpolar regions of proteins can have two effects: (a) the solubility of the solute can be increased, either by adsorption on the surface of the protein or by incorporation into hydrophobic regions, or (b) the solute can induce conformational changes in the protein in that the hydrophobic regions are disrupted because of the formation of stronger solute-nonpolar group hydrophobic interactions.

An example of the first effect is seen in the work of *Wishnia* [48]. He measured the solubility of ethane, propane, and butane in solutions of bovine serum albumin, hemoglobin, and lysozyme. The solubilities in the protein solutions increase several fold over those in water. The ratio of the solubilities in water and in the protein solutions is almost constant over a temperature range of 25 °C, indicating that the enthalpy of binding is small and that the solubilization is entropy-driven. A similar effect was observed for the solubilization of these hydrocarbons in micellar dodecyl sulfate solutions [49].

Wishnia and *Pinder* [50] have shown that the F-form of bovine serum albumin, stable at pH < 4, binds hydrocarbons to a much smaller extent than the N-form: the ratio of binding is 1:4 for butane and 1:5 for pentane. For the transfer of butane from water to the protein solution, $\Delta S^\circ = 17$ e.u. and ΔH° is near zero. Both values are close to those for the transfer of a hydrocarbon from water to a nonpolar solution [13]. The results were interpreted [50] as indications that the hydrocarbon binding sites are in hydrophobic regions of the protein molecule, and that the sites are altered during the conformational change because of disruption of the hydrophobic regions. From similar studies on β-lactoglobulins A and B, *Wishnia* and *Pinder* concluded [51] that in these proteins, only hydrophobic regions of limited size can incorporate hydrocarbons.

In proteins of marginal conformational stability, the binding of a nonpolar solute may induce a conformational change. *Wetlaufer* and *Lovrien* [52] have observed rapidly reversible changes in the viscosity, titration behavior, optical rotation, and ultraviolet spectrum of bovine serum albumin at alkaline pH values and of β-lactoglobulin in the neutral pH range, on addition of various hydrocarbons.

Conversely, hydrophobic bonding of small molecules on the surface of a protein molecule may protect the protein from unfolding. For example, sodium dodecyl sulfate protects bovine serum albumin from denaturation [53,54]. The protective effect requires the simultaneous binding of the anionic head group to cationic groups on the protein surface [54]. Thus the detergent acts as a bifunctional binding reagent. Presumably, this is the reason for the difference between its effect and that of the hydrocarbons.

A systematic study of the effect of nonpolar compounds on protein denaturation was undertaken by *Schrier* and *Scheraga* [55,56]. The addition of alcohols to aqueous solutions of ribonuclease lowers the temperature of thermal transition, T_{tr}. The change in T_{tr} is proportional to the alcohol concentration (up to several molar) and increases with the chain length of the alcohol (Fig. 9 and Table 4). The lowering of T_{tr} can be calculated from hydrophobic bonding theory by estimating a binding constant of the alcohol to the

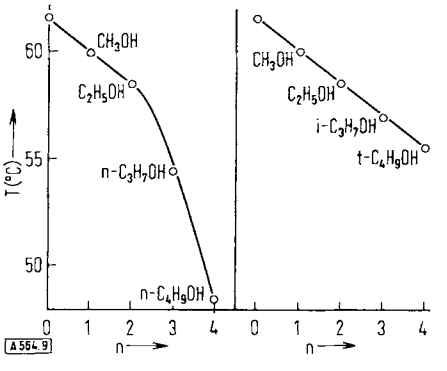

Fig. 9. The temperature of thermal denaturation of ribonuclease in 1 M alcohol solutions: (a) straight-chain, (b) branched chain (n is the number of C atoms in the alkyl chain of the alcohol). Reproduced by permission of the American Chemical Society, from work by *Schrier, Ingwall*, and *Scheraga* [56].

[43] The theory could also be extended to account for the behavior of micelles whose molecules carry charges [44].

[c] Cf. Fig. 11.

protein from the free energy $\Delta F^{\circ}_{H\varphi}$ of such bonds and from the entropy loss on association [56] (Table 4). Interestingly, the lowering of the transition temperature by branched-chain alcohols (*e.g.* iso-propanol) is closer in magnitude to that caused by the next lower straight-chain homologue (ethanol) than to the corresponding normal alcohol (n-propanol) [55]. Apparently, the nonpolar binding sites are limited in size or shape so that not all of the nonpolar tail of the branched alcohols can bind to them. One must treat the alcohols in terms of an "effective chain length", corresponding to the unbranched part of the molecule.

In a study of the effect of various solutes on the thermal transition of ribonuclease, *von Hippel* and *Wong* [57] obtained similar results for various tetraalkylammonium salts and for alcohols. The lowering of the transition temperature increases with chain length. The effective chain length differs from that of alcohols: for example, isopropanol and tetra-n-propyl ammonium salts produce nearly the same temperature change. The magnitudes of the change in T_{tr} for 1 M solutions in alcohol which were observed in the two studies are in close agreement (Table 4). *Von Hippel* and *Wong* interpret their results, not in terms of direct binding of the solute to nonpolar groups, but rather as a diminution in the availability of water molecules for "iceberg formation" about exposed nonpolar chains as a result of competition by the added solute. The model based on direct interaction between solute molecules and nonpolar groups [56] would fit *von Hippel* and *Wong*'s data better: if the action were due to the decreased availability of water, tetra-n-propyl ammonium bromide would be at least four times as effective as ethanol, since it has four, longer hydrocarbon chains.

While the effects cited can clearly be assigned to hydrophobic interactions, it is not always easy to determine the exact nature of the interaction causing denaturation for multifunctional additives, or even to predict which function of a compound will be the most important stabilizing or destabilizing factor. *Jencks et al.* [58,59] have discussed the effect of various denaturing agents for proteins and DNA, and found that denaturing strength is not correlated in all cases with the hydrophobic character of the reagent.

2. Other effects

Association of protein subunits can be stabilized by hydrophobic bonding. The polymerization of tobacco virus protein [60] is an endothermic process. It is also accompanied by the release of large amounts of tightly bound water, and an increase in partial molal volume. The association could be caused either by the formation of intermolecular ion pairs, with the release of water bound to the ions, or by the formation of intermolecular hydrophobic bonds.

Although conformational changes of enzymes, related to the effects of substrates, activators, or inhibitors, are often interpreted in terms of hydrophobic bonding, many recent papers have omitted a quantitative evaluation of the data.

The effect of hydrophobic bonding on the binding of substrates or inhibitors to enzymes has been treated quantitatively in only a few cases. An example is provided in a paper by *Anderson et al.* [61] who have studied the inhibition of yeast alcohol dehydrogenase by 1-alkyl-3-aminocarbonylpyridium chlorides, as a function of the alkyl chain length over the range C_1 to C_{11}. The effectiveness of the inhibitors, as measured by the binding constant for inhibition, increases linearly with chain length from C_3 to C_{11}. The increment in the free energy of binding is −0.37 kcal/mole per CH_2 group which is in good agreement with theoretically calculated values (Table 4, column 2).

Zahn [62] has called attention to the role of hydrophobic bonding in fibrous proteins. The results of various experiments on wool keratin and collagen, *e.g.* the weakening of the tensile strength of wool keratin fibers and the lowering of the shrinkage temperature of collagen by alcohols [62,63] parallel closely those for globular proteins. The observed chain length dependence is similar to that in the ribonuclease transition [55,56], even to the need for the use of the concept of "effective chain length". The reactivity of SH-groups in wool is enhanced by the addition of alcohols, but reduced by sodium dodecyl sulfate (cf. effects on bovine serum albumin).

3. Conformational Stability of Polyamino Acids

Hydrophobic bonds can be expected to play a role in the stabilzation of both α-helical and β-structures of polyamino acids [14] (Figs. 10 and 11). *Fasman et al.* [30] found an increase in helix content (as measured

by b_0 of the Moffitt equation) with increasing temperature for both poly-L-glutamic acid and a copolymer of L-glutamic acid and L-leucine over a limited temperature range. This inversion of thermal stability has been attributed to hydrophobic bonding [27c, 30].

Gratzer and *Doty* [64] have shown that a poly-L-alanine helix of 175 residues is very stable in water. The result can also be explained easily in terms of hydrophobic bonds [16, 27a, b, 29]. According to the theoretical treatment [27a, 29], shorter poly-L-alanine sequences should have thermal transitions in a lower temperature range; this has been qualitatively confirmed [65]. In these studies, the nonpolar polyamino acid was rendered water-soluble by flanking it at both ends with blocks of randomly coiled poly-D,L-glutamic acid or poly-D,L-lysine. *Auer* and *Doty* [66] showed that poly-L-leucine and poly-L-phenylalanine α-helices are less stable than the poly-L-alanine α-helix in chloroform solution, presumably because of steric interference of the bulky chains. Conversely, the order of stability to the helices in water is poly-L-leucine > poly-L-phenylalanine > poly-L-alanine. This can be ascribed of hydrophobic bonding between the side chains.

The Effect of Urea

At one time, the denaturing action of urea was thought to be due to its ability to compete with intramolecular peptide hydrogen bonding. However, evidence has accumulated recently which shows that urea also weakens hydrophobic bonding. Measurements of solubilities [24, 33] and of micelle stability [45, 46] indicate that nonpolar groups are more soluble in aqueous urea solutions than in water. The same effect has been observed with azo dyes for which thermodynamic data are available [67]. In a calorimetric study [68] of amino acids and peptides with nonpolar side chains, a high partial molal heat capacity C_{p2} was obtained for these solutes in water, this being in agreement with the theoretical postulate [13] of more ordered water structure around them. However, C_{p2} is lower in solutions of urea. Very likely, protein denaturation by urea involves the breaking of hydrophobic regions. In some cases there is a poor correlation between the expected effects of urea, based on the model compounds, and observed effects in proteins. Example of such discrepancies are found in the thermodynamics of denaturation of chymotrypsinogen [69], or the difference in the heat capacity of ovalbumin [68] in aqueous and urea solutions. *Tanford* [25] has made theoretical estimates of the free energy of unfolding for proteins in urea, based on the studies of model compounds [24]. While no equilibrium constant for the unfolding could be calculated *a priori*, the comparison of experimental and calculated data suggested that the unfolding may occur in several steps [25].

As yet, the mechanism of the action of urea has not been interpreted quantitatively in terms of effects on water structure or on the water-hydrocarbon interactions. *Frank* and *Franks* [70] suggest that the effect may be explained in terms of changes in the relative amounts of ordered and disordered water when urea is added. For reason of geometry, urea can mix into the disordered water regions only. In so doing it lowers the chemical potential of disordered water causing some clusters to melt in order to reestablish the equilibrium. A detailed theoretical treatment has not yet been published so that the explanation of the effect of urea on hydrophobic interactions and hence on protein denaturation remains one of the important unsolved questions in this field of research.

Experimental Studies on other Macromolecules

Very little work has been done on hydrophobic interactions in macromolecules other than proteins and polyamino acids.

It can be expected that stacking in polynucleotides and in nucleic acids involves hydrophobic interactions because of the large, partially nonpolar areas of the bases which come into contact with each other. *Fasman et al.*[71] have studied the optical rotatory dispersion of single-stranded polycytidylic acid and found that, in aqueous solution at pH 7.0, the molecule appears highly ordered. Since the order is destroyed by the addition of methanol or of ethylene glycol, evidence exists for the importance of hydrophobic interactions in stacking. On the other hand, studies on trinucleotides[72] and on polyadenylic acid[73] indicate that, for these compounds, the predominating factor in neighbor-neighbor stacking interaction is not the hydrophobic bond, although it, too, can make an important contribution.

Sinanoğlu[74] has treated the denaturation of DNA in terms of hydrophobic interactions. However, in his theory, the free energy of placing a nonpolar group into solution is interpreted in terms of the energy requirement for the creation of a solvent cavity around the group, and is correlated with the surface tension. This replaces a structural description with a discussion in terms of a macroscopic property of the liquid.

Studies of synthetic polymers in aqueous solution are rare, owing to problems of solubility. *Eliassaf*[75] has attributed the difference in some thermodynamic properties of polyacrylic acid and polymethacrylic acid solutions to the possibility of hydrophobic bond formation in the former but not in the latter.

Methods for the Detection of Hydrophobic Interactions

Most of the conclusions about the effect of nonpolar solutes on water structure, and about hydrophobic interactions in macromolecules are based on indirect evidence, primarily thermodynamic data, since no methods are available for the direct measurement of hydrophobic interactions.

It would be desirable to be able to detect the increase in water structure around nonpolar solutes directly, both in order to obtain proof for the structural theories of aqueous solutions, and to develop a tool for the detection of the formation and breaking of hydrophobic bonds. Nuclear magnetic resonance techniques have a potential for such work, since they provide information about the correlation and relative motions of neighboring molecules. Measurements of changes in the hydrogen chemical shift have produced ambiguous results which are difficult to interpret (see, for example, the discussion by *Clifford* and *Pethica*[76]). On the other hand, relaxation times of water are increased in the neighborhood of dissolved nonpolar substances by a factor of about two compared with pure water[77,78], indicating an increase in the ordering of water in the solution. On the basis of his nuclear magnetic resonance measurements[77], *Hertz* has developed a new theory[79] of aqueous solutions to explain structural changes. He gives a qualitative description, so that no full evaluation of the scope of the theory is possible yet.

The presence of hydrophobic regions inside or on the surface of a protein molecule has often been inferred from the binding of small molecules (*e.g.*[48,53,61]) or from changes in the reactivity of certain functional groups (*e.g.*[52,62]). Similarly, alterations of the UV spectra of chromophoric groups in macromolecules can be interpreted in terms of these groups being buried inside nonpolar regions of the protein, and thus becoming inaccessible to water[80,81]. The groups whose spectra are studied can occur naturally in the macromolecule, such as tyrosine or tryptophan in proteins[80], or they can be introduced artificially, whereby one obtains an easily interpretable spectrum or one can label specific sites of the molecule[82].

The fluorescence of certain dyes depends strongly on the nature of their solvent environment. The use of fluorescent dyes which can be adsorbed into nonpolar regions has been suggested[83,84] as a tool for probing hydrophobic regions of proteins. *McClure* and *Edelman*[84] have initiated a study of this effect in various solvent environments.

Conclusions

Hydrophobic interactions occur widely in aqueous solutions of both biological macromolecules and materials of low molecular weight. While the principles governing their occurrence are well understood, and it is possible to calculate their strength from theory, there are also several open problems relating to their detection and to the interpretation of their effects.

In experimental work, reliable and accurate means of the detection and measurement of hydrophobic bonding are lacking. In the interpretation of the effect of noncovalent interactions upon the thermodynamic behavior of solutes in general and upon the conformation of macromolecules in particular, the so far unsolved question of additivity must be raised: Is the total contribution of various types of noncovalent interactions the sum of the individual contributions of each of them, as determined by composition and spatial arrangement and according to parameters derived from simple model compounds, or do the various interactions perturb each other? The question has been discussed by *Némethy et al.* [21], *Tanford* [23], and *Wetlaufer et al.* [33]. It seems that the effects of various functional groups are approximately additive. However in exact quantitative treatments deviations from additivity will have to be considered explicitly.

New Methods of Preparative Organic Chemistry VI[**]

Synthesis and Reactions of Cyanic Esters

BY E. GRIGAT AND R. PÜTTER [*]

In 1963, it was found that sterically unhindered esters of cyanic acid, which had previously been considered unobtainable, could be easily prepared from phenols and cyanogen halides. Another synthesis, involving the thermolysis of thiatriazole derivatives, was discovered in 1964. The aryl cyanates in particular have since been found to have many uses as starting materials for the preparation of numerous new classes of compounds [e.g. derivatives of esters of imidocarbonic acid (esters, amides, imides, hydrazides, hydroxylamides, sulfamides, sulfhydrazides, semicarbazides); esters of imidocarboxylic acids; s-triazines, pyrimidines, tetrazoles, triazoles, triazolones, oxadiazoles, thiadiazoles, benzoxazinones, etc.], mainly by addition of nucleophilic or 1,3-dipolar reactants, or as aids e.g. in the elimination of H_2O or H_2S or in the transfer of CN groups.

The preparation of true esters *(1)* of cyanic acid, *i.e.* those in which the organic group is bonded to the oxygen, was a problem that remained unsolved for a very long time. Since cyanic acid always reacted in the iso form *(2b)* to give isocyanates *(3)* [1], attempts were made as early as the second half of the 19th century to

(1) *(2a)* *(2b)* *(3)*

synthesize the molecule *(1)* by combination of a component RO– with a component –CN. However, cyanates could not be obtained either by the reaction of esters of hypochlorous acid with cyanides [2, 3] or by the reaction of phenoxides (or alkoxides) with cyanogen halides [4–10].

In 1895 it was reported by *Nef* [9] and by *Hantzsch* and *Mai* [10] that the reaction of phenoxides (alkoxides) with cyanogen halides leads only to imidocarbonates *(4)* and cyanurates *(5)*. Though *Nef* regarded *(6)* as an intermediate in the formation of *(4)*, and considered *(5)* to result from the decomposition of *(4)* with elimination of phenol [9], it seems reasonable to assume that the products *(4)* and *(5)* are in fact formed by further reaction of an initially formed cyanate.

An exception is the reaction of sterically hindered *o*-substituted phenols with cyanogen chloride, which according to *Stroh* and *Gerber* [11] represents the first preparation of true cyanate esters. The expected

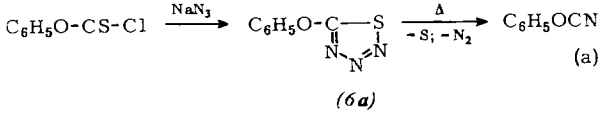
further reaction of *(1)* to form *(4)* or *(5)* does not take place because of steric hindrance by the *ortho* substituents. The cyanate structure was recognized from the IR spectra [12] and from the formation of carbamates on hydrolysis.

1. Synthesis of Cyanates



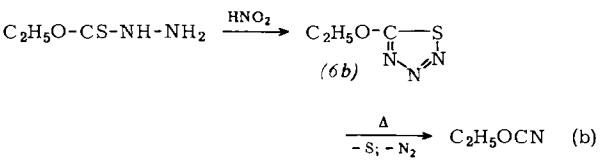
Early in 1963, we discovered a simple synthesis of cyanates by reaction of phenols with cyanogen halides (avoiding an excess of phenoxide) [13–15]. This method is successful with mono- and polyphenols as well as with a number of aliphatic hydroxy compounds, and can be easily carried out on an industrial scale. Most aryl cyanates are surprisingly stable; they are formed

$$ArOH + ClCN \xrightarrow[-\text{Base}\cdot HCl]{+\text{Base}} ArOCN \qquad (1)$$

in excellent yields, and in many cases almost quantitatively.

About a year later, but before the publication of our first patent application [13], *D. Martin*, Berlin [16], and *K. A. Jensen* and *A. Holm*, Copenhagen [17], simultaneously reported the formation of phenyl and ethyl cyanates on thermolysis of phenoxy- *(6a)* and ethoxy-1,2,3,4-thiatriazole *(6b)*.

Martin obtained phenyl cyanate in accordance with equation (a). He used this method for the preparation



(a)

(6a)

of a number of aryl cyanates [18], and later for alkyl cyanates [20].

Jensen and *Holm* obtained ethyl cyanate in accordance with equation (b), and subsequently also obtained other alkyl cyanates [19]. The yields of aryl cyanates produced by this method are generally lower than

(b)

(6b)

when phenol and cyanogen chloride are used. Alkyl cyanates are obtained in yields of only 60 % by equation (a) and 75–80 % equation (b).

Jensen and *Holm* also obtained cyanates by the elimination of H_2S from thiocarbamates with heavy metal oxides (yields: 40–57 %) [24]. Attempted syntheses using this method had hitherto proved unsuccesful [21–23].

Finally, *Kauer* and *Henderson* [25] reported the preparation of three aliphatic cyanates (cf. Table, p. 217) by the reaction of sterically hindered alkoxides or "bridgehead" alcohols with cyanogen chloride. *Hedayatullah* and *Denivelle* prepared a few cyanates by the methods known at the time (cf. Table, p. 216) [26].

2. Reactions of the Cyanates

Alkyl cyanates *(1)* readily undergo exothermic rearrangement to form alkyl isocyanates *(3)* [17,19,20,25]; the tendency toward isomerization decreases with increasing chain length of the alkyl group. The rearrangement of cyanates of bicyclic alcohols having the OH group in the bridgehead position proceeds only when catalysed by Lewis acids [25]. Cyanates of secondary alcohols (*e.g.* isopropanol) decompose into olefin and HOCN [19]. Thus alkyl cyanates behave in the same manner as the alkyl thiocyanates, which also rearrange readily to form alkyl isothiocyanates.

Because of this tendency toward isomerization, the alkyl cyanates have not yet assumed preparative importance. To verify their constitution they have been converted into known secondary products by the addition of H_2S [17,19] or alcohol [20,25], and apart from this they have been used in preparative reactions in two cases only (cf. Sections 2.1.8. and 2.2.1) [79,82].

Aryl cyanates, on the other hand, like the aryl thiocyanates, do not rearrange to form aryl isocyanates They can be used for many further reactions which will be discussed in the following survey.

Cyanates of acidic alcohols,particularly the halogeno alcohols such as β,β,β-trichloroethyl alcohol [14,15], are very similar in stability and reactivity to the aryl cyanates.

2.1. Addition of Nucleophiles to Aryl Cyanates

The carbon atom of the OCN group is strongly electrophilic because of its two electronegative neighbors. Therefore, nucleophilic reagents can react with these substances under mild conditions. The addition is catalysed by both acids (activation of the OCN group by protonation) and bases (increase in the nucleophilic strength of the other reactant by proton abstraction). The addition of nucleophiles is the most important reaction in the preparative chemistry of cyanates.

2.1.1. Nucleophiles having One Mobile Hydrogen on the O, S, or N Atom

Reagents *(7)* with a nucleophilic O, S, or N atom carrying one mobile hydrogen atom add to the CN group of the aryl cyanates under mild conditions to give adducts *(8)* that cannot be obtained in any other way. When heated, or with alkali, the adducts *(8)* generally undergo cleavage as in equation (c), with formation of the phenol from which the aryl cyanate is derived. Thus the cyanates can act as cyanide donors.

$$\underset{(1)}{ArOCN} + \underset{(7)}{HX} \longrightarrow \underset{(8)}{ArO\text{-}\overset{\overset{NH}{\|}}{C}\text{-}X} \longrightarrow \underset{(9)}{ArOH} + NC\text{-}X \quad (c)$$

X = OR, SR, NRR'

The reactions indicated by equation (c) are illustrated by the following examples:

Phenols (HX = HOAr) add smoothly to aryl cyanates in the presence of bases to give symmetrical or unsymmetrical bisaryl imidocarbonates [26–28], generally *via* both possible routes. When the substituents Ar and Ar′ are different, the decomposition of *(10)* leads to the formation of the more acidic phenol [28].

$$\begin{array}{l} ArOCN + Ar'OH \\ \qquad\qquad \searrow \\ \qquad\qquad\quad ArO\text{-}\overset{\overset{NH}{\|}}{C}\text{-}OAr' \longrightarrow ArOH + (Ar'OCN) \\ \qquad\qquad \nearrow \qquad\qquad\quad \downarrow \\ ArOH + Ar'OCN \qquad\quad (10) \qquad\qquad (Ar'OCN)_3 \end{array}$$

$$pK_{ArOH} < pK_{Ar'OH}$$

Aryl cyanates do not react with alcohols (HX = HOAlk) in the absence of catalysts. In the presence of bases and acids, the reaction yields alkyl aryl imidocarbonates *(11)*, the hydrochlorides of which are stabilized by loss of alkyl halide to form carbamates *(12)* [28–30].

$$\begin{array}{l} \qquad\qquad\qquad\qquad\qquad\qquad\quad \overset{\overset{O}{\|}}{ArOC\text{-}NH_2} + AlkCl \\ \qquad\qquad\qquad\qquad\quad \overset{\overset{NH}{\|}}{} \quad HCl \nearrow \quad (12) \\ \underset{(1)}{ArOCN} + HOAlk \longrightarrow \underset{(11)}{ArO\text{-}\overset{\overset{NH}{\|}}{C}\text{-}OAlk} \\ \qquad\qquad\qquad\qquad\qquad\quad Base \searrow \\ \qquad\qquad\qquad\qquad\qquad\qquad\quad ArOH + (NCO\text{-}Alk) \end{array}$$

An excess of alkoxide leads to decomposition of *(11)* according to the general equation (c). Loss of phenol results in the formation of alkyl cyanate which trimerizes to give cyanurate or adds alkoxide to form a symmetrical dialkyl imidocarbonate [28]. The decomposition of unsymmetrical dialkyl imidocarbonates proceeds similarly [25]. In an excess of alcohol with acid catalysis, *(1)* gives moderate yields of orthocarbonate [30].

In the reaction of aryl cyanates with mercaptans (HX = HSR) or thiophenols, the cyanide group is transferred from the oxygen to the sulfur [32] *via* the thioimidocarbonate *(13)* [31]. The transfer proceeds particularly smoothly in the case of electronegatively

$$\underset{(1)}{ArOCN} + R'SH \longrightarrow \underset{(13)}{ArO\text{-}\overset{\overset{NH}{\|}}{C}\text{-}SR'} \longrightarrow ArOH + R'\text{-}SCN$$

substituted cyanates. In many cases, the thioimidocarbonates *(13)* can be isolated as crystalline substances [32]; they were not previously available by any other route. Thus this method can be used for the introduction of a thiocyanate group under mild conditions [33].

Secondary amines (HX = HNRR′) add to *(1)* to give isoureas *(14)* [34–37].

$$ArOCN + HN\begin{matrix} R \\ R' \end{matrix} \longrightarrow \underset{(14)}{ArO\text{-}\overset{\overset{NH}{\|}}{C}\text{-}N\begin{matrix} R \\ R' \end{matrix}} \xrightarrow[Base]{\Delta} ArOH + NC\text{-}N\begin{matrix} R \\ R' \end{matrix}$$

Whereas the *O*-arylisoureas *(14)* are decomposed by heat or by alkali into phenols and cyanamides, their salts (*e.g.* hydrochlorides, sulfates) are very stable even toward heat [36]. The imino group of *(14)* can be acylated by acyl and sulfonyl halides, cyanogen halides, or even isocyanates, or alkylated with alkylating agents [36].

$$(14) + XR^2 \rightarrow ArO\text{–}C(=NR^2)\text{–}NRR' + HX$$

X = Halogen; $R^2 = COR^3, SO_2R^3, CN$

$$(14) + R^2\text{–}N{=}C{=}O \rightarrow ArO\text{–}C(=N\text{–}CO\text{–}NHR^2)\text{–}NRR'$$

$$(14) + O(C_2H_5)_3{}^{\oplus}BF_4{}^{\ominus} \xrightarrow{-O(C_2H_5)_2;\ -HBF_4} ArO\text{–}C(=N\text{–}C_2H_5)\text{–}NRR$$

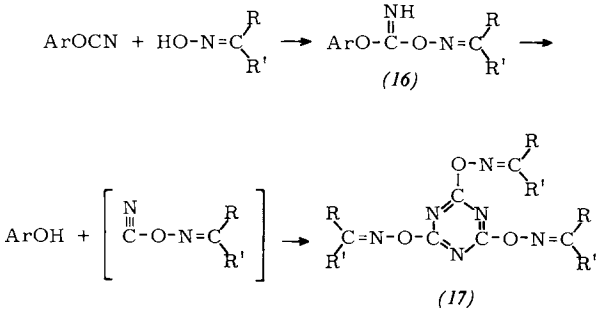
[37] Regarding the two isoureas in [30], cf. also [38] and [39].

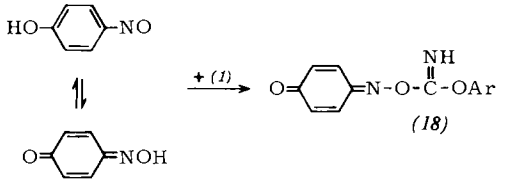


Aromatic-heterocyclic compounds containing an NH grouping also add to cyanates smoothly [34–36], *e.g.* to give the benzo[*d*][1,2,3]triazole derivative *(15)*.

(15)

Unlike the isoureas *(14)*, benzotriazoles such as *(15)* are thermally very stable (up to about 180 °C).

Cyanates react with ketoximes (HX=HON=CRR') to give initially the adducts *(16)* [40,41], which lose phenol more or less readily and trimerize to form

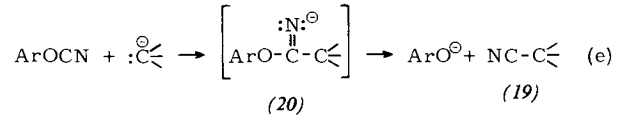


(16)

(17)

triazine derivatives *(17)*. On acidification, the oxime derivatives *(16)* undergo Beckmann rearrangement [41] according to equation (d).

$$(16) \xrightarrow{HCl} ArO{-}CO{-}NH_2 + R{-}CO{-}NHR' \qquad (d)$$



p-Nitrosophenols (= quinone monoximes) and quinone dioximes react with *(1)* in the same way as ketoximes, *e.g.* to form *(18)* [40,41].

(18)

2.1.2. Reagents having a Nucleophilic Carbon Atom

The reactions (e) of cyanates with compounds containing a nucleophilic carbon atom can be formally included in the reaction scheme (c). However,whereas the reactions in equation (c) lead to derivatives of carbonic acid, the reactions (e) result in the formation

(20) *(19)* (e)

of a C–C bond, and hence give carboxylic acid derivatives (nitriles) *(19)*, often with direct transfer of the cyanide group, so that *(20)* cannot be isolated.

Aryl cyanates *(1)* react smoothly with CH acids in the presence of triethylamine to give esters of imidocarboxylic acids [*], *e.g.* *(21a)* and *(21b)* [42,43]. The imidocarboxylate ester group loses phenol under the action of alkalis, with formation of a nitrile group [see *e.g.* *(22a)*, *(22b)*] which is formed directly when the reaction is carried out in alkaline solution [43–45]. The 1:1 adducts with malononitrile or ethyl cyanoacetate, *(21a)* and *(21b)*, can be converted by an excess of aryl cyanate into amino- and hydroxypyrimidines *(23a)* and *(23b)* [43,46–48].

The reaction of aryl cyanates *(1)* with enamines leads to the introduction of a nitrile group into the enamines; no intermediate *(20)* could be isolated [43,44] The cyano enamines *(24)* are readily hydrolysed to α-cyano ketones *(25)* [45].

(24)

(25)

[*] *Martin* has recently found that compounds of this type having at least one CN group [*e.g.* *(21a)* and *(21b)*] exist at room temperature in the tautomeric aminoethylene form [*D. Martin, K.-H. Schwarz, S. Rackow, P. Reich*, and *E. Gründemann*, Chem. Ber. *99*, 2302 (1966)].

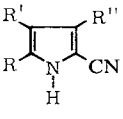
In the reaction of aryl cyanates *(1)* with Grignard compounds, no intermediate *(20)* could be isolated, the nitriles being formed directly [43–45]. An excess of Grignard compound reacts with the nitriles in the usual manner to form ketones [45].

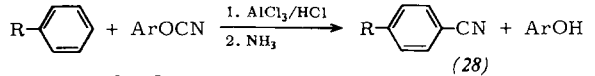
$$RMgBr + ArOCN \longrightarrow (ArO\text{-}\overset{\overset{NMgBr}{\|}}{C}\text{-}R) \xrightarrow{-\,ArOMgBr}$$



$$RCN \xrightarrow[2)\ H_2O]{1)\ RMgBr} R\text{-}CO\text{-}R$$

R = C_6H_5, C_2H_5, C_6H_5-C≡C

Pyrroles which are not substituted in the 2-position react with *(1)* in the presence of HCl only [45]. The reaction gives first the hydrochlorides of the adducts *(26)*, which then react with alkali to form 2-cyanopyrroles *(27)* [45].



(26)

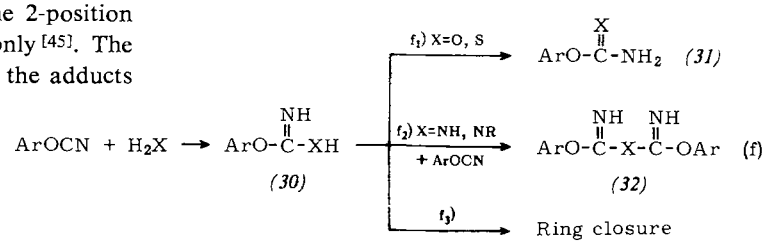
(27)

The still less nucleophilic aromatic compounds anisole and toluene only react with *(1)* on additional activation by Lewis acids. In the presence of $AlCl_3$ and HCl at 0–5 °C, the corresponding nitriles were obtained in yields of about 30 % on neutralization of the reaction solution with NH_3 [45]. No intermediates were isolated.

R = CH_3, CH_3O

(28)

Reaction of *(1)* with hydrogen cyanide in water/acetone [45,49] leads to loss of phenol and formation of dicyanogen. Depending on the reaction conditions, the product is either phenoxide [45] or iminocarbonate [45,49], the latter resulting from the reaction of the phenoxide with further aryl cyanate *(1)*; *(29)* was not isolated.



$$ArOCN + HCN \longrightarrow \left[ArO\text{-}\overset{\overset{NH}{\|}}{C}\text{-}CN\right] \longrightarrow ArOH + (CN)_2$$

(29)

[49] *E. Grigat* and *R. Pütter*, Chem. Ber. *99*, 958 (1966).

2.1.3. Nucleophiles having Two Mobile Hydrogen Atoms on the O, S, or N Atom

The reactions of aryl cyanates with nucleophiles having two mobile H aroms on the O, S, or N atom can lead to various products. The reaction may stop at stage *(30)* after the addition of one molecule of *(1)*. Where X = O or S, the 1:1 adduct is stabilized by route (f_1) with formation of the isomeric (thio)carbamate *(31)*. Where X = NH or NR, *(30)* may react with a further molecule of *(1)* to form bis(imidocarbonate)imides *(32)* (route f_2). Finally, *(30)* can also be stabilized by ring closure (route f_3).

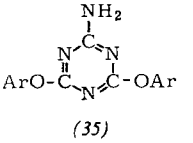
X = O, S, NH, NR

The addition of water to aryl cyanates proceeds rapidly and almost quantitatively, even in weakly acidic solution, with formation of carbamates *(33)* (route f_1) [11,16,18,26,28].

$$ArOCN + H_2X \xrightarrow{H\oplus} ArO\text{–}CX\text{–}NH_2 \qquad \begin{matrix}(33)\ X = O\\(34),\ X = S\end{matrix}$$

The reaction with hydrogen sulfide ($H_2X = H_2S$) leads equally smoothly to thiocarbamates *(34)* [50,32]. However, *(34)* can be more readily prepared from *(1)* and thiosulfates [43].

$$ArOCN + H_2S_2O_3 \xrightarrow{H_2O} ArO\text{–}CS\text{–}NH_2 + H_2SO_4$$



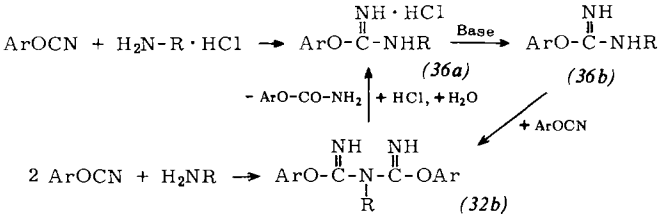
(34)

The reactions of aryl cyanates with ammonia, primary amines, hydroxylamine, and semicarbazides proceed by route f_2.

In the reaction of aryl cyanates with ammonia in anhydrous ether, the components immediately react in a molar ratio of 2:1 to form bis(imidocarbonate)-imides *(32a)* [36,51]. 1:1 adducts *(30)* could not be

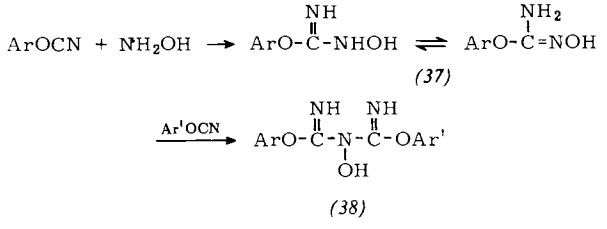
$$2\ ArOCN + NH_3 \longrightarrow ArO\text{-}\overset{\overset{NH}{\|}}{C}\text{-}NH\text{-}\overset{\overset{NH}{\|}}{C}\text{-}OAr \xrightarrow[-\,ArOH]{ArOCN}$$

(32a)



(35)

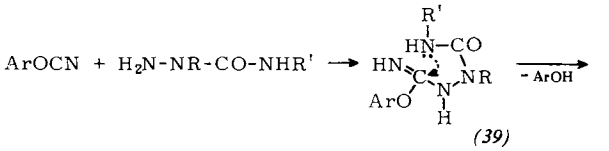
[50] *E. Grigat* and *R. Pütter*, German Pat. Appl. F 41443 IVb/12o, Farbenfabriken Bayer AG. (Nov. 30th, 1963).



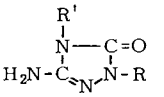
[51] *E. Grigat* and *R. Pütter*, German Pat. 1212521, Farbenfabriken Bayer AG. (Dec. 17th, 1963).

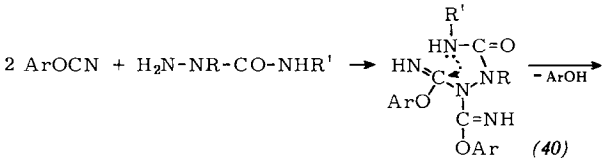
isolated. Under certain conditions (in aqueous solution with ammonium salts of weak acids) the reaction does not stop at the formation of *(32a)*, but a third molecule of aryl cyanate is added, with loss of phenol, to form the *s*-triazine derivative *(35)* [36,52].

In the reaction with primary amines ($H_2X = H_2N-R$), the initially formed *O*-arylisourea *(36b)* often reacts immediately with a second molecule of aryl cyanate to form a bis(imidocarbonate)imide *(32b)* [36,38,51]; the salts *(36a)* do not react with ArOCN. *(32b)* can be cleaved into *(36a)* and carbamate by treatment with hydrochloric acid [38].

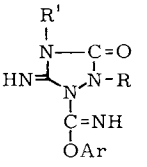


Hydroxylamine adds smoothly to aryl cyanate to form hydroxyamides of imidocarbonates *(37)* [53,54], which react with a second molecule of ArOCN on addition of alkali to form *(38)* [55]. *(37)* can be acylated at the



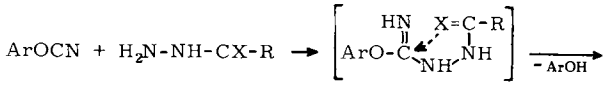


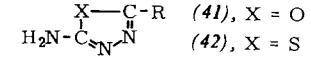
oxygen of the oxime group by the action of acyl or sulfonyl halides. The reaction of *(37)* with isothiocyanates leads to loss of phenol and formation of 5-amino-3-oxo-2,3-dihydro-1,2,4-thiadiazoles [53,56]. In the presence of alkali, *(37)* enters into a two-step reaction with chloroformates to give 3-aryloxy-5-oxo-2,5-dihydro-1,2,4-oxadiazole [53,57].



The semicarbazides ($H_2X = H_2N-NR-CO-NHR'$) formally belong to the class of compounds discussed in Section 2.1.4. However, since all the primary reactions take place on the NH_2 group, the semicarbazides will be discussed in the present section. The reactions yield two types of products, depending on substitution and reaction conditions. Reaction with 1 mole of aryl cyanate *(1)* yields *(39)* while two moles of *(1)* give the compound *(40)*.

Both *(38)* and *(40)* can lose phenol to form 1,2,4-triazole derivatives [58–60].





The reactions of *(1)* with hydrazides of carboxylic and thiocarboxylic acids are examples of the stabilization of compounds of the type *(30)* by ring closure.

Hydrazides of carboxylic acids ($H_2X = H_2N-NH-CO-R$) react with aryl cyanates, even at room temperature, to form 2-amino-1,3,4-oxadiazoles *(41)* [61]. Hydrazides

of thiocarboxylic acids react similarly to give 2-amino-1,3,4-thiadiazoles *(42)* [62].

Despite the presence of two mobile H atoms, a series of compounds H_2X add only one molecule of aryl cyanate to form stable 1:1 adducts of the type *(30)*.

The reaction of aryl- or alkylhydrazines ($H_2X = H_2N-NRR'(H)$) with aryl cyanates yields hydrazides of imidocarbonates *(43)*, which are much more stable to heat and to alkalis than the corresponding *O*-arylisoureas. They can again be readily alkylated and acylated [61,63]. Hydrazones react in the same manner as hydrazines [43,61].

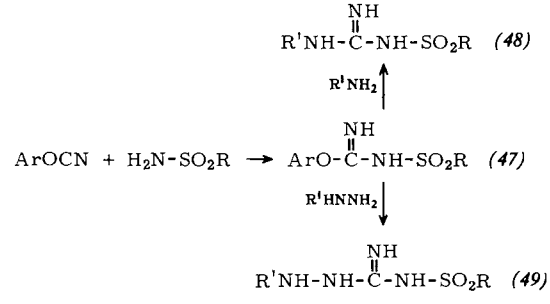
(43)

Cyanamides (H_2X = H_2N–CN, HRN–CN) also add only one molecule of aryl cyanate to the amino group to form *(44)*. Further reaction with a second molecule of ArOCN takes place in strongly alkaline media, with formation of aminobisaryloxy-*s*-triazine *(45)* [58,64].

(44)

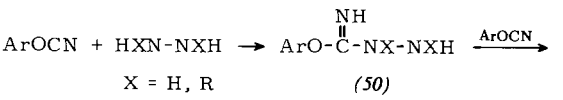
(45)



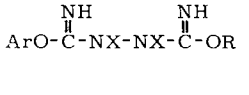
The secondary reaction *(44)* → *(45)* was not observed in the case of monosubstituted cyanamides.

Amidocarboxylic and amidosulfonic acids also add only one molecule of aryl cyanate *(1)*, with formation of *O*-arylisourea derivatives *(46)* [34,36].

(46)



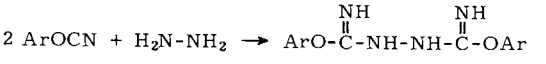
In the presence of bases, sulfonamides (H_2X = H_2N–SO_2R) add one molecule of aryl cyanate to form *(47)*. The aryloxy group in *(47)* can be readily replaced by an amino group to form *(48)* or by a hydrazino group to form *(49)* [49].



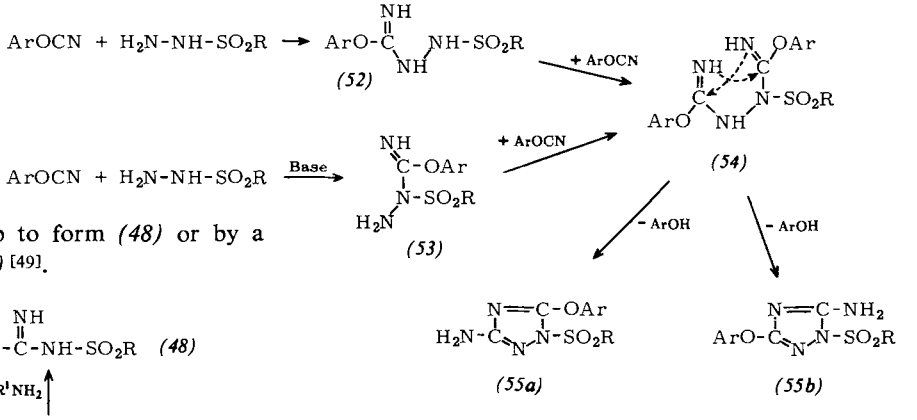
(48) *(47)* *(49)*

2.1.4. Reactants having a Second NH_2 or NH Group in Addition to an NH_2 or NH Group

In substances having a second NH_2 or NH group in addition to an amino or imino group, the first molecule of aryl cyanate *(1)* adds to one of the amino or imino groups, and a second molecule of *(1)* generally adds to the other. The reaction of semicarbazides H_2N–NR–CO–NHR′ is exception; cf. Section 2.1.3). The 1:1 adduct cannot always be isolated.

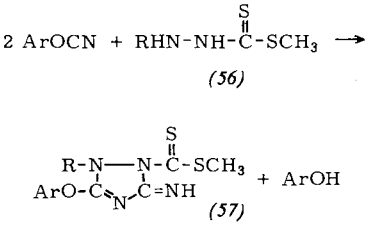


(50)



X = H, R

Hydrazine and its salts react immediately with two molecules of aryl cyanate, even when the hydrazine is present in excess, to give 1,2-bis(aryloxycarbonimidoyl)hydrazines *(51)* [61,65], which form dihydrochlorides that are only sparingly soluble in water.



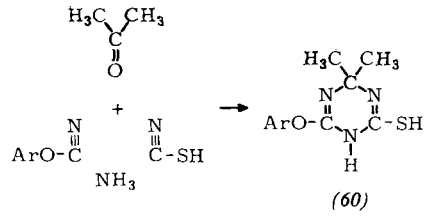
(51)

In the case of sulfonylhydrazines (H_2N–NHX = H_2N–NH–SO_2R), aryl cyanate adds on to the β-N atom in acidic and neutral media to give *O*-aryl-1-arylsulfonylisosemicarbazide *(52)*, while in alkaline media it adds on to the α-N atom to form the *O*-aryl-2-arylsulfonylisosemicarbazide *(53)*. A second molecule of ArOCN adds to the unsubstituted N atom of *(52)* or *(53)* to give *(54)* [49].

(52) *(53)* *(54)* *(55a)* *(55b)*

Ring closure of *(54)* with elimination of ArOH has been observed. This reaction yields the isomeric 3,5-disubstituted triazoles *(55a)* and *(55b)* [49].

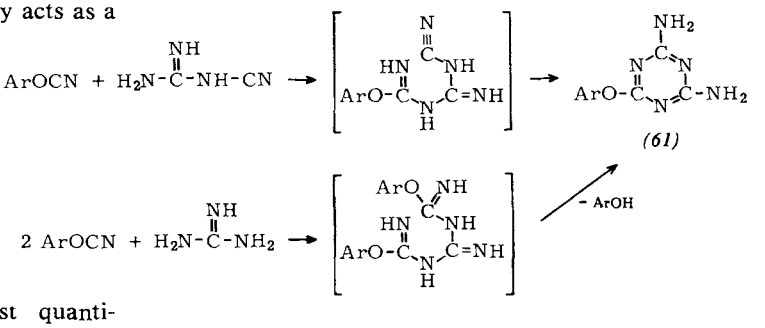
(56) *(57)*



[64] *E. Grigat* and *R. Pütter*, German Pat. Appl. F 44635 IVb/12o, Farbenfabriken Bayer AG. (Dec. 5th, 1964).

[65] *E. Grigat* and *R. Pütter*, German Publ. Pat. Appl. 1225631, Farbenfabriken Bayer AG. (Jan. 10th, 1964).

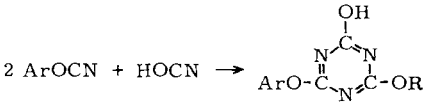
Both N atoms in the hydrazides of dithiocarbonates *(56)*, react immediately with two molecules of aryl cyanate causing ring closure to form the triazole *(57)* [43,66].



2.1.5. Direct Ring Closure to Form *s*-Triazines

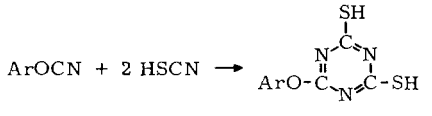
A number of reactions of aryl cyanates lead to direct ring closure and formation of *s*-triazine derivatives. These reactions will be grouped here according to the final products, irrespective of the course of the reaction. In these ring closures, one ArOCN molecule is incorporated in the ring; another frequently acts as a source of cyanide groups.

(60)



Diaminoaryloxy-*s*-triazines *(61)* are formed by the reaction of aryl cyanates with either dicyanodiamide or guanidine [70,71]; no intermediates have been isolated.

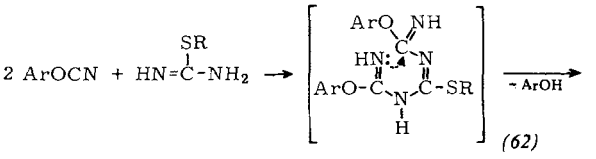
(61)



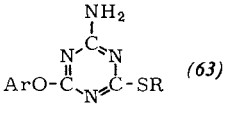
Trisaryloxy-*s*-triazines are formed almost quantitatively by trimerization of aryl cyanates [15,18,67]. The trimerization is promoted by acids, Lewis acids, and bases, as well as by the addition of phenol to the aryl cyanate.

Cyanic acid cotrimerizes with aryl cyanates to give mainly diaryl cyanurate *(58b)* together with a little monoaryl cyanurate *(58a)* [49].

(58a), R = H
(58b), R = Ar



ArOCN reacts uniformly and smoothly with thiocyanic acid, which is liberated from its salts in the reaction solution by the addition of mineral acid. The reaction gives excellent yields of aryloxydimercapto-*s*-triazines *(59)* [49,68], the SH groups of which can be alkylated or acylated, and can react with isocyanates and cyanates.



(59)

2-Aryloxy-6-mercapto-4,4-dimethyl-1,4-dihydro-*s*-triazine *(60)* has been obtained by the reaction of NH_4SCN with ArOCN in acetone [49,69].

The reaction of aryl cyanates with isothioureas gives aminoaryl(alkyl)thioaryloxy-*s*-triazines *(63)* in good yields; the intermediate *(62)* again could not be isolated [70,72].

(62)

(63)

2.1.6. Elimination of H_2O by Aryl Cyanates

Aryl cyanates can act as agents for the elimination of H_2O; in so doing they are converted into carbamates. Intramolecular dehydration takes place after the addition of the nucleophile to form the imidocarbonate derivative [*e.g. (64)*], from which the carbamate is liberated. In the intermolecular elimination of water, the very reactive primary adducts [*e.g. (68)*], which have not been isolated, act as acylating agents.

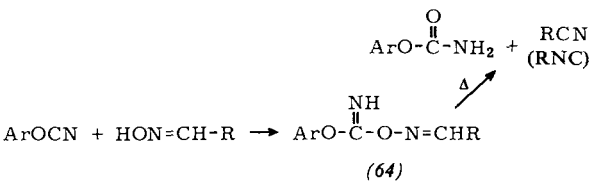
Aldoximes and aryl cyanates undergo addition reactions to form *O*-(aryloxycarbonimidoyl)aldoximes *(64)*, which break down into nitrile and carbamate when heated [41]. If the Ar residues carry strongly electron-donating groups, isonitrile is formed as well as nitrile [41,73]. At higher temperatures, (above about

[66] *E. Grigat* and *R. Pütter*, German Pat. 1219031, Farbenfabriken Bayer AG. (March 13th, 1965).

[67] *E. Grigat* and *R. Pütter*, German Pat. 1183507, Farbenfabriken Bayer AG. (May 2nd, 1963).

[68] *E. Grigat* and *R. Pütter*, German Pat. 1217965, Farbenfabriken Bayer AG. (Feb. 11th, 1965).

[69] *E. Grigat* and *R. Pütter*, German Pat. 1219939, Farbenfabriken Bayer AG. (June 5th, 1965).

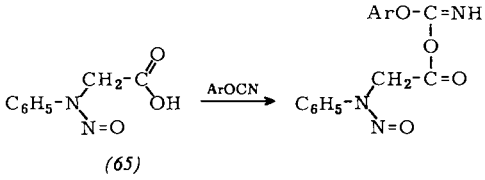


[70] *E. Grigat* and *R. Pütter*, Chem. Ber. *98*, 1168 (1965).

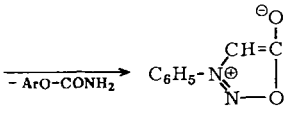
[71] *E. Grigat* and *R. Pütter*, German Pat. 1213415, Farbenfabriken Bayer AG. (July 18th, 1964).

[72] *E. Grigat* and *R. Pütter*, German Pat. 1220860, Farbenfabriken Bayer AG. (Sept. 27th, 1964).

[73] *E. Müller* and *B. Narr*, Z. Naturforsch. *16b*, 845 (1961).



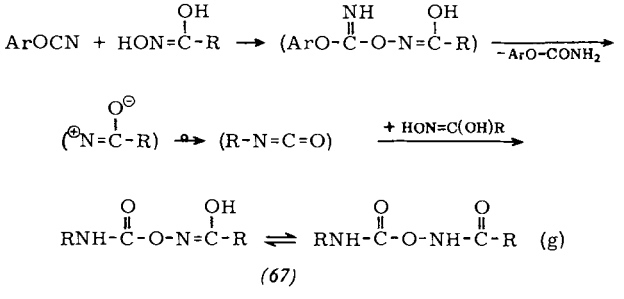
80 °C), *(64)* can no longer be isolated, and the nitrile is formed directly [39, 74].



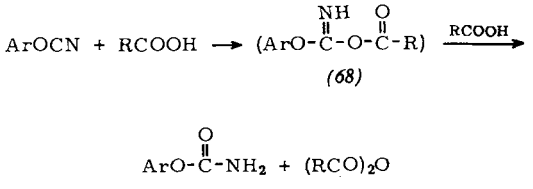
(64)

Amides are also converted into nitriles at high temperatures only [39].

N-Nitroso-*N*-phenylglycine *(65)* can be converted into *N*-phenylsydnone *(66)* in good yields at about 100 °C [39].



(65)



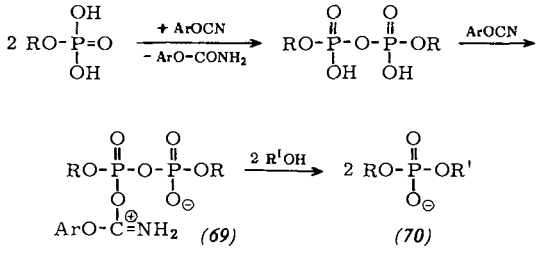
(66)

Hydroxamic acids are converted directly into *O*-carbamoylhydroxamic acids *(67)* by aryl cyanates, according to scheme (g) [62, 75].

(67)

Carboxylic acids [30, 39, 62], sulfonic acids [39, 40], and monoesters of phosphoric acid [30, 39] undergo intermolecular dehydration with formation of the anhydrides. The reaction probably proceeds *via* the mixed anhydride of *e.g.* the carboxylic acid and the monoaryl imidocarbonate, which has not been isolated and which acts as a strong acylating agent, acylating a second molecule of the acid.

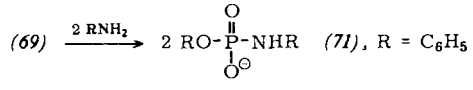
(68)



[74] *E. Grigat*, Nachr. Chem. Techn. *12*, 236 (1965).

[75] *C. D. Hurd* and *L. Bauer*, J. Amer. chem. Soc. *76*, 2791 (1954).

The reaction of some carboxylic acids (*e.g.* benzoic acid, chloroacetic acid) with aryl cyanates in the presence of alcohol yields esters of the carboxylic acids. It is not certain whether the alcohol is acylated by *(68)* or by the anhydride of the carboxylic acid [30, 39].



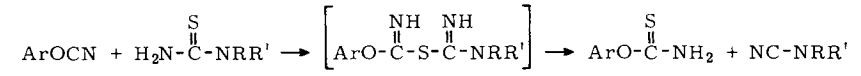
Whereas sulfonic acids solely catalyse the addition of aryl cyanates to alcohols to form the alkyl aryl imidocarbonate *(11)* [39], monoesters of phosphoric acid are further esterified to the diesters *(70)* in an excess of alcohol with *(1)*, presumably *via* an initially formed pyrophosphate [39].

(69) *(70)*

With aryl cyanate in the presence of triethylamine, orthophosphoric acid and benzyl alcohol gave only moderate yields of the monoester (35 %) and diester (14 %) [39].

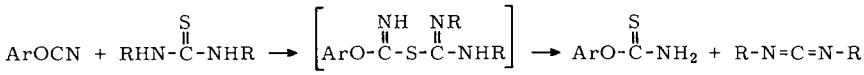
In the reaction of carboxylic acids or sulfonic acids with cyanates in the presence of amines, the addition of the amine to the cyanate to form isoureas is much faster than amide formation [30, 39, 62], whereas monophenyl phosphate, aniline, and phenyl cyanate give the phosphoramidate *(71)* *via* adducts such as *(69)* [30, 39].

2.1.7. Elimination of H_2S by Aryl Cyanates



Aryl cyanates eliminate hydrogen sulfide from organic compounds even more readily than water, the hydrogen sulfide adding to the cyanates to form thiocarbamates. The elimination of H_2S can also take place intramolecularly or intermolecularly, and like the elimination of water, proceeds *via* primary adducts of the cyanate to the S atom of the other reactant.

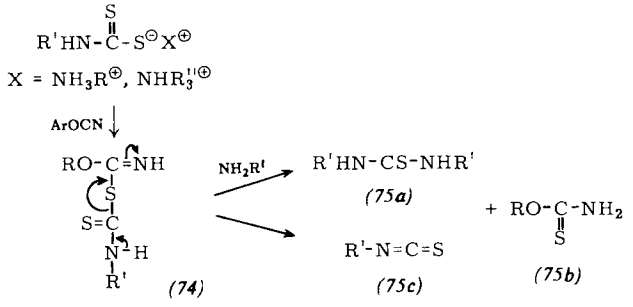
The reaction of thioureas with aryl cyanates leads to cyanamides or carbodiimides, depending on the substitution of the thiourea [70, 76]; intermediates such as *(72)* or *(73)* have not been isolated [70].



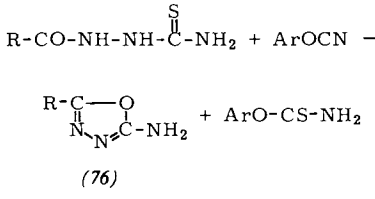
The elimination of H_2S from amides of thiocarboxylic acids proceeds smoothly, with almost quantitative formation of nitriles and thiocarbamates [62, 76].

Aryl cyanates also remove hydrogen sulfide from dithiocarbamates. In the case of dithiocarbamates of primary amines, a molecule of amine takes the place of the molecule of thiocarbamic acid *(75b)* eliminated

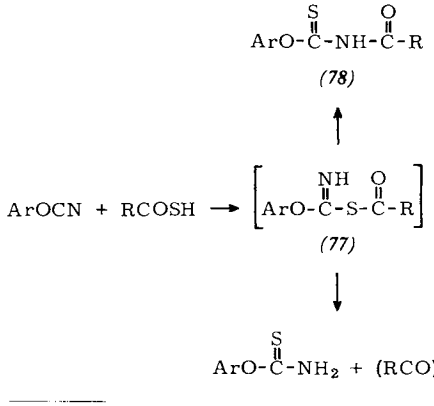
[76] *E. Grigat* and *R. Pütter*, German Pat. Appl. F 43500 IVb/12o, Farbenfabriken Bayer AG. (July 18th, 1964).



(72)



(73)

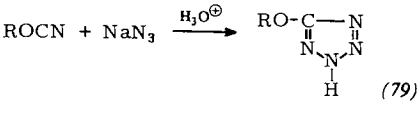


from the primary adduct *(74)* (which has not been isolated), with formation of a thiourea *(75a)*. In the reaction of dithiocarbamates of tertiary amines with *(1)*, the second proton required for the formation of *(75b)* can only come from the amido group of *(74)*, and isothiocyanates *(75c)* are formed [39].

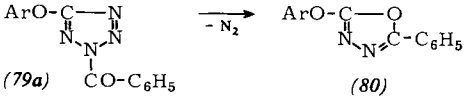
After the elimination of H_2S from 1-acylthiosemicarbazides with aryl cyanates, the residue is stabilized by ring closure to form the 2-amino-5-alkyl-1,3,4-oxadiazole *(76)* [77].

Thiocarboxylic acids [30,39,62,76] or xanthic acids, RO–CS–SH [62,76] are converted into the anhydrides under even milder conditions than are required for carboxylic acids. The primary products *(77)* [*], which cannot be isolated, again act as strong acylating agents. A transacylation *(77)* → *(78)* has been observed in one case [62]. The reaction of thiocarbonates with aryl cyanates in the presence of alcohol gives esters of carboxylic acids and thiocarbamates [39]. Unlike carboxylic and sulfonic acids (cf. Section 2.1.6.), thiocarboxylic acids react with amines and cyanates to give the amides of the carboxylic acids in good yield [39].

2.1.8. Nucleophilic Additions to the Oxygen Atom of Aryl Cyanates



In all cases described so far, the addition of nucleophiles to aryl cyanates takes place on the C atom of the OCN group. However, two groups of investigators [78,79] found that when a reaction analogous to that of trialkyl phosphites with thiocyanates [79] is carried out with cyanates, nucleophilic attack also takes place on the O atom of the OCN group. When dialkyl phosphites are used, the attack occurs exclusively on the oxygen [79]; triesters of phosphoric acid are formed in yields of up to 83 %.



2.2. 1,3-Dipolar Additions [80]

The cyanates have been found much more reactive than nitriles in additions to 1,3-dipolar compounds.

Aryl cyanates react smoothly with sodium azide to form 5-aryloxytetrazoles *(79)* [30,43,81,82]. Alkyl cyanates also undergo this reaction, but the yields are much lower (13 to 36 %) [30,82].

The 5-aryloxytetrazoles can be acylated in the 2-position; when the 2-benzoyl derivative *(79a)* was heated in dimethylformamide, it was converted into the oxadiazole *(80)*, with liberation of nitrogen [82].

[77] *E. Grigat* and *R. Pütter*, German Pat. Appl. F 49281 IVd/12p, Farbenfabriken Bayer AG. (May 25th, 1966).

[*] *(78)* can be ruled out as the primary product, since it can be prepared by another route and does not undergo the secondary reactions under the above conditions.

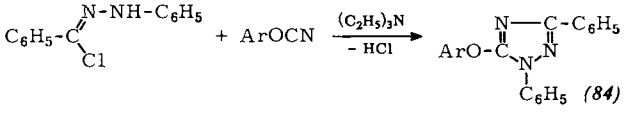
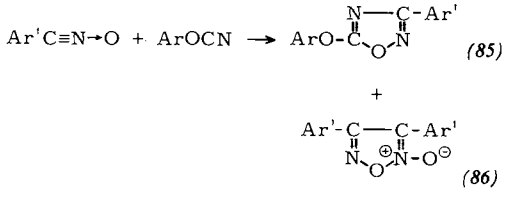
Diazomethane reacts with aryl cyanates in a molar ratio of 1:2, in ethereal solution at room temperature, to form *(81)*, which yields an aryloxytriazole *(82)* on hydrolysis [82]. Diazoacetic ester (R = $CO_2C_2H_5$) reacts in the same manner [82].

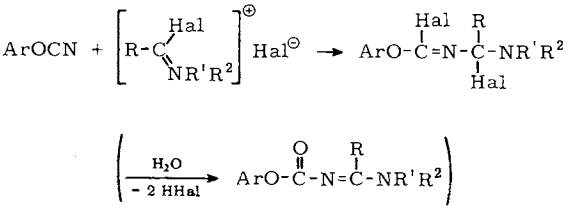


R = H, $CO_2C_2H_5$



Nitrones and aryl cyanates undergo an exothermic reaction at room temperature to form Δ^4-1,2,4-oxadiazolines *(83)* [43].

Aryl cyanates react with nitrilimines produced *in situ* to form 5-aryloxy-1,3-diphenyl-1,2,4-triazoles *(84)* [82].



Nitrile oxides, produced *in situ* from hydroxamyl chlorides or nitroalkanes, react with aryl cyanates to form 3-aryl-5-aryloxy-1,2,4-oxadiazoles *(85)* and 3,4-diaryl-1,2,5-oxadiazole-2-oxides *(86)* (dimerization products of the nitrile oxides) [30,82].

2.3. Electrophilic Addition

Electrophilic addition to the OCN group of the aryl cyanates proceeds less readily than addition to the corresponding nitriles. No reaction occurred in attempted alkylations with alkyl halides, sulfonates, and dialkyl sulfates [83]; in only one case, with triethyloxonium fluoroborate, a little phenetole was formed [84] from phenyl cyanate.

Attempted syntheses with aryl cyanates, acylating agents, and diazonium salts have also proved unsuccessful. Only two reactions with electrophilic reagents proceed smoothly. The addition of *N*-phenylnitrilium salts leads to quinazolines [84], while the addition of amide chlorides yields *N*-aminohalogenoalkylmethylimidocarbonate chlorides [85].

2.4. 2-Substituted 4*H*-1,3-Benzoxazin-4-ones

In esters of arylcarboxylic acids having a cyanato group in the *ortho* position, *e.g. (87)*, the addition of a nucleophile to the OCN group to form *(88)* is frequently (sometimes spontaneously, and sometimes on heating) followed by ring closure with the COOR group to form 2-substituted 4*H*-1,3-benzoxazin-4-ones *(89)*, which were hitherto largely unknown [86]. A second route to *(89)*, based on the ease of replacement of the

Structures and Syntheses of Carboranes

BY R. KÖSTER AND M. A. GRASSBERGER [*]

Following a discussion of bonding, the structures of the known carboranes of the clovo type and of the incompletely condensed types are described; the recently discovered carboranes with high carbon contents, such as tetracarbahexaborane ("boracarbane") are also discussed. The preparation of carboranes from polyboranes and the possibility of obtaining organo carboranes from organoboranes are then described. Some rearrangements which take place within the carborane skeleton are also mentioned.

1. Introduction

For a long time our knowledge of compounds containing boron-carbon bonds was confined to the thermally and chemically very stable boron carbide $(CB_4)_x$ [1], and to the simple, very reactive alkyl- and arylboranes containing the grouping BC_3 [2] and similar compounds.

It was possible to foresee that carbon and boron could

also form substances intermediate between these two classes of substances; however, it was only recently that the necessary foundations (the isolation and characterization of the boron hydrides [3] and a knowledge of the bonding in such compounds [4]) had been laid for the discovery of these new BC systems, which are nowadays known as carboranes [5,6]. The existence of new systems was almost simultaneously postulated by theorists [7] and recognized by experimental chemists [8–10]. It is impossible to decide how theory and practice influenced each other in this work; but it may be said that the first observations on carboranes were reported as early as 1953 [11] whereas these systems have been discussed theoretically since 1954 [12–14].

Carborane research gained momentum when decaborane [3] became available in large quantities [15,16]. The investigation of this substance led to the synthesis of a compound that was isoelectronic with the $B_{12}H_{12}^{2\ominus}$ ion [17], and whose skeleton consists of an icosahedral arrangement of two carbon atoms and ten boron atoms [18]. This compound was dicarbaclovododecaborane(12) (cf. Section 3.1.1.).

Organocarboranes [19] containing from two to five boron atoms are now readily available by several routes from organoboranes [6,20,21]. The following discussions are mainly concerned with carboranes having less than ten boron atoms, since reviews [22–24a] dealing with both the preparation and the reactions of the C_2B_{10} system have already been published.

2. Structures of Carboranes

2.1. Characterization of the Type of Compound

2.1.1. Position of the Carboranes in Relation to the Polyboranes and Aromatic Hydrocarbons

The carboranes occupy a position intermediate between the polyboranes and the aromatic hydrocarbons. If the carbon atoms of an aromatic hydrocarbon (*e.g.* benzene) are successively replaced by boron atoms, which carry a smaller number of electrons, the decrease in the number of bonding electrons leads to a progressively closer packing of the skeletal atoms, and three-dimensional structures are formed. Thus in the series $C_{6-n}B_nH_6$ ($n = 0, 2, 4$), we pass from the planar benzene, with 18 bonding electrons in the C-skeleton, *via* the pentagonal-pyramidal tetracarbahexaborane(6) $C_4B_2H_6$ (16 bonding electrons) [6], to the close-packed tetragonal-bipyramidal dicarbaclovohexaborane(6) $C_2B_4H_6$ (14 bonding electrons) [25] (cf. Fig. 1). Hexahydrohexaborate(2-), which is isoelectronic with $C_2B_4H_6$, also has the same structure [26]. As in

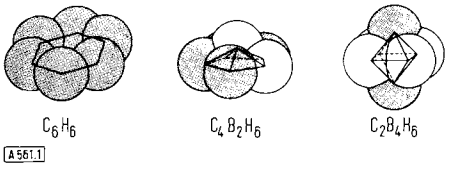

Fig. 1. Arrangement of the atoms in the series $C_{6-n}B_nH_6$ for $n = 0, 2, 4$.

the crystal lattice of the borides of bivalent metals [27], the boron atoms occupy the apices of an octahedron. LCAO–MO calculations [7,13,28] have shown that all the bonding orbitals in $C_2B_4H_6$ are filled. The completely closed and highly symmetrical three-dimensional structure, together with the particularly saturated electronic configuration, makes compounds of this type chemically and physically stable.

Between the fully condensed carboranes $C_2B_nH_{n+2}$ and the BCH compounds with polyhedral structures, which are not carboranes, there are many intermediate types; thus, the "dihydrocarboranes" $C_2B_nH_{n+4}$ [29], which contain BH_bB groups [*] on "open" sides of the BC skeleton, are a link with the polyboranes. The pentagonal-pyramidal tetracarbahexaboranes(6) [6], which are very close to the hydrocarbons, are relatively far removed from the condensed carboranes. The progressive substitution of the BH_b groups by carbon leads *e.g.* from hexaborane(10) *(1)* *via* the neutral compounds 2-carbahexaborane(9) *(2)*, 2,3-dicarbahexaborane(8) *(3)* and 2,3,4-tri-carbahexaborane(7) *(5)* to tetracarbahexaborane(6) (diborahexacarbane) *(4)*.

[29] *T. P. Onak*, *R. E. Williams*, and *H. G. Weiss*, J. Amer. chem. Soc. *84*, 2830 (1962).

[*] BH_bB denotes two boron atoms with a common hydrogen atom (bridge hydrogen atom).

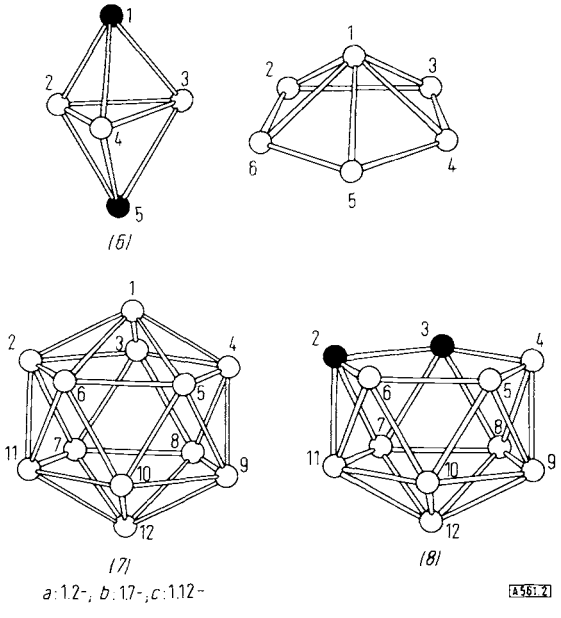
2.1.2. Nomenclature

There is as yet no uniform and generally obligatory system of nomenclature for the carboranes. Consequently, trivial names (*e.g.* "dihydrocarborane"[29]) are used side by side with semisystematic and systematic designations.

2.1.2.1. *Systematic Names*

A system that is widely used is that proposed by the Nomenclature Committee of the American Chemical Society[5]; this system, which is derived from the system used for the polyboranes, is particularly commendable for three-dimensional BC structures with high boron contents. The carbon of a carborane is regarded as a hetero atom and the compound $C_2B_3H_5$, for example, is known as dicarbapentaborane(5).

As in the case of the polyboranes, the number of hydrogen atoms attached to the carbon and boron atoms is given in brackets after the name. To emphasize the three-dimensional structure, "clovo" (from the Greek κλωβός = cage) is inserted between "carba" and "borane" in the names of carboranes of the fully condensed type $C_2B_nH_{n+2}$: *e.g.* dicarbaclovopentaborane(5). The number of hydrogen atoms need not be indicated for the clovo types. The skeletal atoms are numbered in the same way as in the polyboranes. In compounds having simple pyramidal or bipyramidal structures, numbering begins with one of the apices of the pyramids, proceeds clockwise through the base atoms as viewed from above and, in the case of a bipyramid, ends at the other apex (for exception see Section 2.3.2.1.). Thus the carborane $C_2B_3H_5$ *(6)* in Figure 2 is a 1,5-dicarbaclovopentaborane(5). It is not always possible to distinguish clearly between the apex and base atoms, as in the icosahedral dicarbaclovododecaboranes(12) *(7)*. In such cases numbering begins with a carbon atom and continues clockwise round the ring. In numbering systems containing more than one ring, the lowest index of the second ring should be among the lowest indices of the first ring. Hetero atoms (*e.g.* carbon atoms) should have the lowest indices possible.



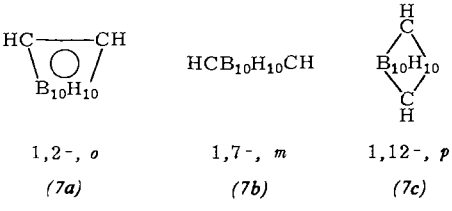


Fig. 2. Numbering of the skeletal atoms in carboranes.

Though this nomenclature can in principle also be used for three-dimensional BC structures having high carbon contents, it seems rather pointless *e.g.* to call the system $C_4B_2H_6$ *(4)* "tetracarbahexaborane(6)" since the skeleton contains more carbon atoms than boron atoms. In this case it is better to regard the boron atoms as hetero atoms, and to call the system "diborahexacarbane(6)"[6].

The anionic BC compounds with polyhedral structures are known as borates. The number of ligands outside the skeleton is given first, then the position and number of the carbon atoms in the skeleton, and finally the total number of skeletal atoms. Negative charges are given as a figure in brackets following the name. Thus the $C_2B_4H_7^{1\ominus}$ ion[29a] is a heptahydro-2,3-dicarbahexaborate(1-) ion.

2.1.2.2. *Trivial Names*

The word "carborane" itself, which was originally derived from "car(ba)borane" for the compounds $C_2B_nH_{n+2}$[8], has acquired more than one meaning. The widest meaning is now a BCH compound with carbon atoms in the skeleton and having a closed or almost closed polyhedral structure. However, the name "carborane" is often used specifically for the systems $C_2B_{10}H_{12}$ [dicarbaclovododecaboranes(12)] having an icosahedral structure, the three stereoisomers with the carbon atoms in the 1,2-position (adjacent), the 1,7-position (separated by one boron atom), and the 1,12-position (opposite apices) being distinguished as *ortho-*, *meta-*, and *para*-carboranes[5] [cf. *(7)*]. Corresponding to the hexagonal symbol for the benzene ring, the three isomers can be denoted by the formulae *(7a)–(7c)*.

1,2-, *o* (*7a*) | 1,7-, *m* (*7b*) | 1,12-, *p* (*7c*)

[29a] *T. P. Onak* and *G. B. Dunks*, Inorg. Chem. 5, 439 (1966).

Other trivial names are "barene" [30] (used only in Russian literature) for 1,2-dicarbaclovododecaborane(12), "neocarborane" [31] for 1,7-dicarbaclovododecaborane(12), and "dihydrocarborane" [29] for 2,3-dicarbahexaborane(8) *(3)*.

An advantageous combination of trivial names and systematic nomenclature provides *e.g.* the name "dicarbollide" (Spanish olla = jar or kettle) for the $C_2B_9H_{11}^{2\ominus}$ residue [32], in which the carbon and boron atoms occupy eleven corners of an icosahedron. Taking into account the vacant twelfth corner, the skeletal atoms are numbered in the same manner as the icosahedra $C_2B_{10}H_{12}$ systems, the number of the vacant position being given in brackets before the name. *(8)* in Figure 2 would be called (1)-2,3-dicarbollide.

2.2 Bonding

2.2.1. Nature of Bonding and Coordination Numbers

The skeletal atoms of the carboranes, like those of the polyboranes, generally have higher coordination numbers than the maximum valence with covalent two-center bonds. The lines drawn between the atoms of the carborane nucleus in this article are simply geometrical aids intended to show the polyhedral arrangement of the atoms. The bonds present result from the delocalization of the bonding electrons in multi-center orbitals over a large area of the molecule. The bonds in the carboranes are intermediate between covalent and metallic bonds.

The tendency to assume high coordination numbers, which is also evident in other boron compounds such as boron carbide [33,34], and particularly in elementary boron [35–37], is due to the electronic configuration of boron. A boron atom has four available orbitals, but only three bonding electrons. For example, comparison of the electronic energies in multi-center orbitals as found from LCAO calculations shows that the participation of an unoccupied atomic orbital is always accompanied by a gain in energy. The bonding energy of the three-center bond formed by the combination of three atomic orbitals is lower, *e.g.* than that of the two-center bond.

If three covalent bonds were formed, one orbital and one electron being donated to each by each of the bonded atoms, one orbital of boron would remain unoccupied. Thus in boron compounds in which there are no additional electrons available for bonding, arrangements involving close packing of the atoms are energetically favored. Such arrangements permit multiple interaction of all four orbitals of boron, and hence the formation of stable multi-center bonds.

If the "electron deficiency" of boron is compensated by the uptake of an extra electron, as in the borate ion, or by partial delocalization of a lone pair of electrons *via* a π bond (back-donation), as in compounds with elements of groups V to VII, the tendency to form multi-center bonds is lost.

2.2.2. The Three-Center Bond Theory and its Application to Carboranes [4]

The description of the π-electron system of the aromatic compounds by means of covalent bonds can also be applied to bond systems of polyboranes or carboranes if, in addition to localized two-center bonds, one also allows corresponding bonds between three atoms [12]. The simple line notation is retained. It is possible in this way, not only to represent clearly the bond systems of known boron compounds (see *e.g.* Fig. 3.), but also to make a choice on the basis of empirical rules, (cf. Sections 2.2.2.2. and 2.2.2.3.)

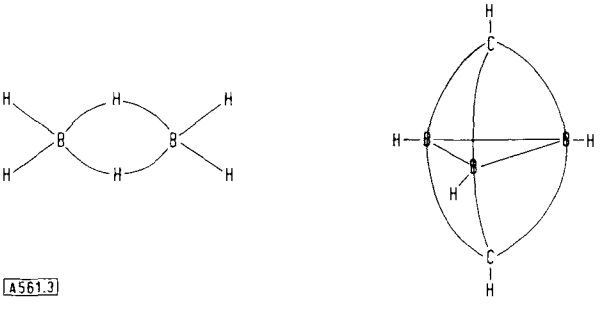

Fig. 3. Two- and three-center bonds in diborane (left) and in 1,5-dicarbaclovopentaborane(5) (right).

between several possible spatial arrangements of the atoms in compounds whose structures are unknown. Moreover, the use of the line notation also provides certain quantitative information for the estimation of charge distributions and bond orders [4]. A simple, clear representation is possible for all compounds other than those containing particularly large numbers of atoms and where the symmetry is unfavorable.

2.2.2.1. *The Three-Center Bond*

When two orbitals of two atoms interact, a bonding and an antibonding orbital are formed. The bonding orbital can accommodate two electrons, which thus constitute a covalent two-center bond. Similarly three orbitals of three atoms can also interact. The result in this case is two antibonding orbitals and one bonding orbital which can again accommodate two electrons. According to *Lipscomb* [4,12], the resulting three-center bonds exist in an open and a central (or symmetrical) type. Thus one atomic orbital may interact with an orbital of each of two other atoms (open type), or three atomic orbitals may interact with one another in the same manner (central type) (Fig. 4).

In the open type the electron distribution, to a first approximation, is $1e^-$ on the central atom and $^1/_2e^-$ on each of the outer atoms. The bond order p_{lk}, which is defined by

$$p_{lk} = 2\, c_l c_k \qquad c_l, c_k = \text{atomic orbital coefficients}$$

is $^1/_2$. In the central type the charge distribution is $^2/_3e^-$ on each of the three atoms and the bond order p_{lk} is $^2/_3$.

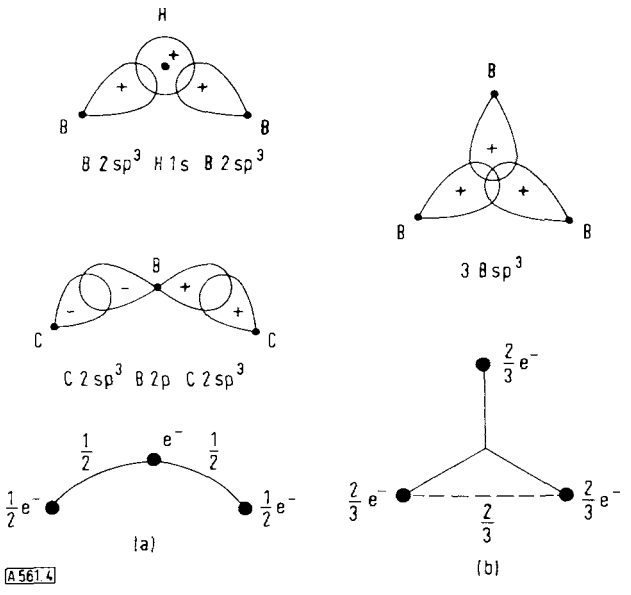

Fig. 4. Three-center bonds (a) open, (b) central. The two bottom diagrams show the electron distributions and the bond orders.

2.2.2.2. *Number of Two- and Three-Center Bonds in Carboranes*

Two electrons and three orbitals are required for a three-center bond. Since each boron atom in neutral boron compounds has one "extra" orbital available, the number of possible three-center bonds in carboranes is equal to the number of boron atoms present. Neglecting the outward-directed B–H and C–H two-center bonds, the number of electrons accommodated in the three-center bonds is equal to the number supplied by the boron atoms for bonding in the carborane skeleton. The number of two-center bonds is therefore determined by the number of C atoms and bridge H atoms. In general, for a carborane having x C atoms, y bridge H atoms, and z B atoms:

the number of three-center bonds $= z$
the number of two-center bonds $= {}^1/_2\,(3\,x + y)$.

2.2.2.3. *Resonance* [4, 38]

Owing to the localization of the electrons in bonds that extend over two or three atoms only, there are generally several possible arrangements of the calculated numbers of two- and three-center bonds. According to *Hoffmann* and *Lipscomb* [38], it is possible to distinguish between "resonance structures" and "equivalent structures". Resonance structures are arrangements that can be converted into one another by the application of symmetry operations (of the symmetry group of the molecule) Fig. 5a).

Equivalent structures are fundamentally different arrangements of the bonds and cannot be converted into one another by symmetry operations (Fig. 5b) [*]. All the resonance structures corresponding to each equivalent structure must be considered in giving complete description of a system. The number of resonance structures depends on the size and symmetry of the bond system; this number can be reduced by the following limiting conditions a–c with no appreciable decrease in its (overall) information value [38]:

a) Two atoms cannot be joined together by both a two-center and a three-center bond.

b) Two atoms cannot be joined together by both an open and a central three-center bond.

c) Two open three-center bonds cannot cross each other.

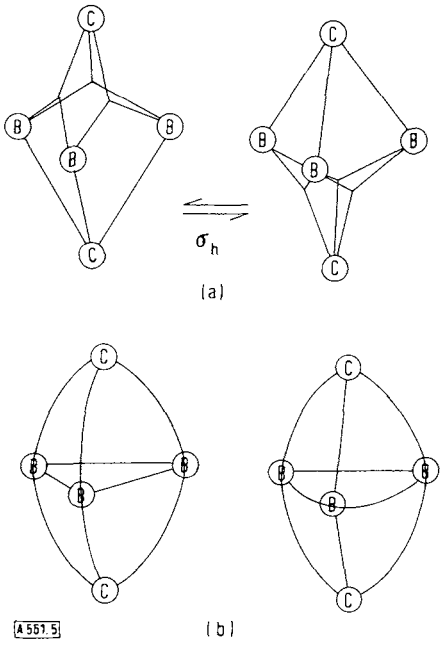

Fig. 5. Resonance structures (a) and equivalent structures (b) for the trigonal-bipyramidal 1,5-dicarbaclovopentaborane(5) *(6)*.

2.2.2.4. *Net Charges and Bond Orders* [4,38]

The net charges q_k and the bond orders p_{lk} can be estimated from the values indicated for the two three-center bonds by summation over all N resonance structures. Assuming that all the resonance structures have the same statistical weight in the combination [38]:

$$q_k = \frac{1}{N}\sum_{i=1}^{N} q_k^i \quad \text{and} \quad p_{lk} = \frac{1}{N}\sum_{i=1}^{N} p_{lk}^i$$

where q_k^i is the net charge on the atom k and p_{lk}^i is the bond order of the bond between the atoms k and l in the i-th resonance structure.

2.2.2.5. *Example*

For the isomeric dicarbaclovododecaboranes(12) *(7)*, there are three two-center and ten three-center bonds ($x=2$, $y=0$, and $z=10$). Using conditions a–c, and assuming that a two-center bond is localized between the two carbon atoms in *ortho*-carborane and that each carbon atom in *meta*- and *para*-carboranes forms one two-center bond, a total of 37 resonance structures are found for *ortho*-carborane, 93 for *meta*-carborane, and 121 for *para*-carborane [4, 28]. The charge distributions calculated from the three-center bond theory by taking into account all these structures show good qualitative agreement with those obtained from LCAO calculations [4, 28].

[38] *R. Hoffmann* and *W. N. Lipscomb*, J. chem. Physics *37*, 2872 (1962).

[*] The word "equivalent" should not be interpreted too literally here, since the structures are by no means always energetically equivalent.

2.2.3. LCAO–MO Calculations

A more accurate picture of the bond system of the carboranes can be obtained by the application of quantum-mechanical approximation methods. The extended Hückel method used by *Lipscomb* and *Hoffmann* has proved particularly successful for this purpose [28, 39–41].

2.2.3.1. *The Method* [4, 28, 39–41]

The wave functions of carboranes like those of π orbitals of aromatic systems, can be represented as linear combinations of atomic orbitals:

$$\Psi = \sum_n c_n \varphi_n$$

The coefficients of the linear combination can be calculated by the scheme of the Hückel method, taking into account the interactions, not merely between the nearest neighbors, but between all the atoms of the molecule.

In addition to the 1s orbitals of the hydrogen atoms, the combination must include four atomic orbitals per boron or carbon atom; consequently for a carborane having the general composition $C_xB_zH_{x+z}$, the combination contains a total of $5(x+z)$ terms. The coefficients c_n satisfy secular equations of the general form

$$(\alpha_n - ES_{nn})c_n + \sum_m{}' (\beta_{nm} - ES_{nm})c_m = 0$$

On introduction of the approximation

$$\beta_{nm} = KS_{nm}$$

and of the normalization condition

$$S_{nn} = 1$$

the secular equations simplify to

$$(\alpha_n - E)c_n + \sum_m{}' (K - E)S_{nm}c_m = 0$$

where

$\alpha_n = \int \varphi_n H \varphi_n \, d\tau$ (Coulomb integral)

$\beta_{nm} = \int \varphi_n H \varphi_m \, d\tau$ (resonance integral)

$S_{nm} = \int \varphi_n \varphi_m \, d\tau$ (overlap integral)

K = const.

The solutions of the secular determinants give the energy eigenvalues and the coefficients of the linear combinations for the individual molecular orbitals. With the aid of the coefficients it is possible, according to *Mulliken* [42], to estimate the electron-density distributions $n(k,l)$ between the atoms and $N(k)$ on the atoms:

$$n(k, l) = \sum_i \sum_r \sum_s n(i, r_k, s_l)$$

$$n(i, r_k, s_l) = 2\, N(i) c_{r_k i} S_{r_k, s_l} c_{s_l i}$$

and

$$N(k) = \sum_i \sum_r N(i, r_k)$$

$$N(i, r_k) = N(i) c_{r_k i} \sum_l \sum_s S_{r_k, s_l} c_{s_l i}$$

In these equations, c_{rki} and c_{sli} are the coefficients of the atomic orbitals r and s on the atoms k and l in the molecular orbital i, $S_{rk,sl}$ is the corresponding overlap integral, and $N(i)$ is the occupation number of the i-th molecular orbital.

2.2.3.2. *Application of the Series $C_2B_nH_{n+2}$ to Carboranes*

The calculation of the electron systems of the carboranes $C_2B_3H_5$ (trigonal bipyramid), $C_2B_4H_6$ (octahedron), $C_2B_5H_7$ (pentagonal bipyramid), and $C_2B_{10}H_{12}$ (icosahedron) gives a closed electronic structure in every case, all the bonding orbitals just being filled [28]. This explains the extraordinary stability of these compounds. Comparative calculations for polyhydropolyborates(2-) $B_nH_n^{2\ominus}$, which are isoelectronic with the carboranes, showed [39] that the order of the molecular orbitals with respect to energy is not affected when the 1s atomic orbitals of hydrogen and the hybrid orbitals directed outward from the B and C atoms toward the hydrogens are omitted from the linear combination. The only differences resulting from this omission are in the calculated electronic transition energies. Thus the BH and CH bonds may be treated as normal covalent bonds. Other simplifications, excluding the factorization associated with the symmetry properties of the bond systems, have been found to be either inadmissible or admissible to a limited extent only [39].

Experimental data for comparison are at present available for the dicarbaclovododecaboranes(12) only *(7)*, and in particular for "*ortho*-carborane" *(7a)*. In this case good agreement is found between experiment and theory [43–47a].

2.2.4. Aromaticity of the Carboranes

The nature of the bonding in the carboranes and their surprising stability suggest a comparison with aromatic systems. If we take the degree of delocalization of the bonding electrons as a measure of the aromaticity, and so regard the metallic phase as a "superaromatic" system, then at least some carboranes, *e.g.* the dicarbaclovododecaboranes(12) possess aromatic character. However, few data are available at present for comparison. Above all, checks should be carried out to see whether the predicted directing influence of sub-

stituents in reactions on the carborane nucleus does in fact occur. In all these comparisons, however, it should be remembered that the carboranes have "electron-deficient" bond systems, whereas an "excess of electrons" in aromatic systems leads to the formation of an additional stabilizing π-bond system.

2.3. Structural Analysis of Carboranes

2.3.1. Characteristics of the Structure Determination

The elucidation of the spatial structure of carboranes has so far been based mainly on the interpretation of ^1H and ^{11}B nuclear magnetic resonance spectra and of IR and Raman spectra. X-ray analysis could be carried out in only a few cases, since the necessary crystalline material is not available. Where such measurements have been possible, as in the cases of 2,3-dicarbahexaborane(8) *(3)* [48,49] and "*o*-carborane" *(7a)* [50–52] the results confirmed the structural formulae postulated on the basis of the NMR spectra. Fragments of the structures have also been characterized by chemical degradation [53–56] and synthesis [21].

2.3.2. Carboranes with Two Carbon Atoms in the Skeleton

2.3.2.1. *The Clovo Type $C_2B_nH_{n+2}$ ($n = 3$ to 10)*

In the fully condensed carboranes $C_2B_nH_{n+2}$, the boron and carbon atoms occupy the apices of generally highly symmetrical polyhedra, the faces of which in most cases are equilateral or almost equilateral triangles. All the structures can be traced back to trigonal, tetragonal, and pentagonal pyramids as the basic shapes. According to an empirical rule [57], compounds in which the carbon atoms have a coordination number of 5 (apex of a tetragonal pyramid) and in which the boron atoms have a coordination number of 6 (apex of a pentagonal pyramid) are particularly stable.

The formal first member of the series $C_2B_nH_{n+2}$ would be boracyclopropene C_2BH_3, which has not yet been definitely detected [58]. However, because of its planar structure and the 2 π-electron system corresponding to the Hückel rule (Fig. 6), this compound would resemble the aromatic hydrocarbons rather than the carboranes.

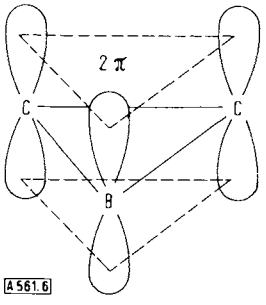

Fig. 6. π-Electron system of the unknown boracyclopropene.

The smallest known molecule of the series $C_2B_nH_{n+2}$ contains three boron atoms. According to NMR [59–61], IR [60,61], and Raman spectra [62], the two dicarbaclovopentaboranes(5) $C_2B_3H_5$ have the trigonal-bipyramidal structure predicted for the isoelectronic, hypothetical $B_5H_5^{2-}$ ion [41]. Of the three possible isomers of this structure, the 1,5- and the 1,2-isomers have been described [see Fig. 2, formula *(6)*].

In the more stable of these two isomers [1,5-dicarbaclovopentaborane(5)], the carbon atoms form the apices of the bipyramid. A quartet and a singlet can be distinguished in the ^1H-NMR spectrum of *(6)*, while the ^{11}B-NMR spectrum shows only a single sharp doublet ($^{11}B/^1H$ coupling) [60]. The ^{11}B-NMR spectra of the fully alkylated derivatives known at present [21,62] accordingly contain only a singlet. The ^1H-NMR spectrum of the 1,5-dimethyl-2,3,4-triethyl derivative [62] consists of two sharp signals having an intensity ratio of 6:15; these are assigned to the six protons of the *C*-methyl groups and to the 15-protons of the *B*-ethyl groups (Fig. 7). It is interesting to note that the methyl and methylene protons of the ethyl groups give only one signal, even at a measuring frequency of 100 MHz. The Raman spectra of the compounds give the symmetry D_{3h} [62].

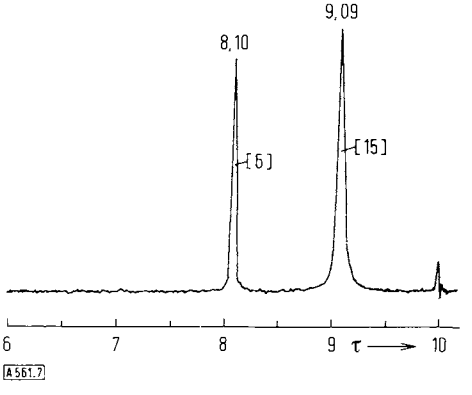

Fig. 7. ^1H-NMR spectrum of 1,5-dimethyl-2,3,4-triethyl-1,5-dicarbaclovopentaborane(5) [62,64].

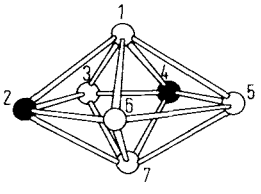
The second isomeric $C_2B_3H_5$ [1,2-dicarbaclovopentaborane(5), cf. *(6)*] is at present known only as a dimethyl derivative [61,63]. One of the methyl groups is attached to B-3 and the other to one of the C atoms. The ^{11}B-NMR spectrum of the compound shows two clearly separated doublets ($^{11}B/^1H$ coupling) and a singlet having an intensity ratio 1:1:1. In the ^1H-NMR spectrum, the intensity ratio of the signals due to the methyl protons and to the hydrogen atom attached to the carborane carbon is 6:1. The two methyl groups give a broad signal, with only weak splitting.

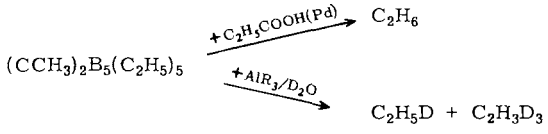


Conclusive evidence of the structures of the two known isomers of the next higher BH homologue $C_2B_4H_6$ is also lacking. However, the data available at present indicate that the predicted octahedral or tetragonal bipyramidal structure *(9)* [7] (with the C atoms in the 1,2 or 1,6 position) is fairly certain.

(9)
a:1,2-; *b*:1,6-

Mass-spectrometric analysis of the partially deuterated isomers have shown that they must be clovo compounds, in which each boron atom is associated with one hydrogen atom [25]. The IR spectra do not contain the characteristic absorption bands for the BH_bB grouping [25]. The ^1H- and ^{11}B-NMR spectra of the 1,6-isomer *(9b)* show four equivalent boron atoms and two equivalent carbon atoms [25,65]; on the other hand, the ^{11}B-NMR spectrum of the asymmetric form *(9a)* with the carbon atoms in the 1,2 position, clearly points to two non-equivalent pairs of boron atoms [25].

2,4-Dicarbaclovoheptaborane(7) $C_2B_5H_7$ *(10)* has a pentagonal-bipyramidal structure [65–66].



(10)

According to LCAO–MO calculations [28], *(10)* has a lower energy than any of the other three isomers having pentagonal bipyramidal structures.

The structure proposed on the basis of the IR and NMR spectra [65] was verified by analysis of the microwave spectrum [66]. The values found for the distances between the boron and carbon atoms in the base (atoms 2 to 6) are as follows:

$r_{B(5)-B(6)} = 1.650 \pm 0.005$ Å, $r_{B(3)-C(4)} = 1.606 \pm 0.1$ Å, $r_{B(5)-C(4)} = 1.502 \pm 0.1$ Å. Thus they roughly correspond to the lengths of BB and CB single bonds. The values for the BH and CH bonds of the base atoms are: $r_{B-H} = 1.250 \quad 0.06$ Å and $r_{C-H} = 1.09 \quad 0.05$ Å.

A fully alkylated and a partly alkylated dicarbaclovoheptaborane(7) could also be identified as 2,4-isomers by the ^1H- and ^{11}B-NMR spectra (cf. Figs. 8 and 9) in conjunction with chemical methods (cf. Section 3.2.2.1.) [55].

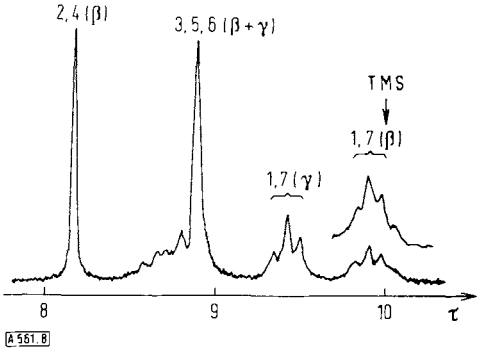


Fig. 8. ^1H-NMR spectrum of 2,4-dimethyl-1,3,5,6,7-pentaethyl-2,4-dicarbaclovoheptaborane(7) [55]. Numbering of the skeletal atoms as in *(10)*; H-atoms of the ligands: $\overset{\alpha}{-H}$, $\overset{\beta}{-CH_3}$, $\overset{\beta}{-CH_2}-\overset{\gamma}{CH_3}$.

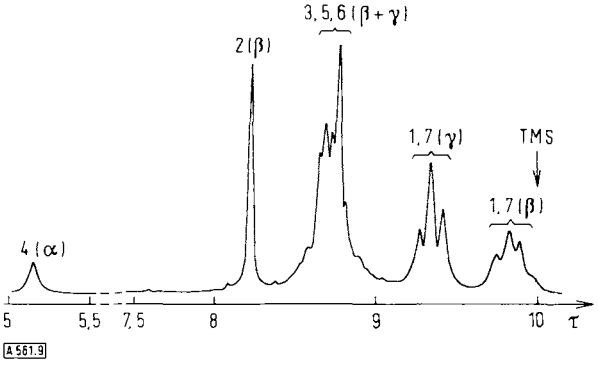

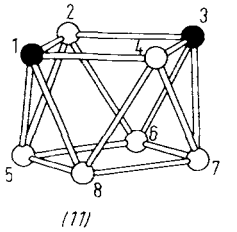

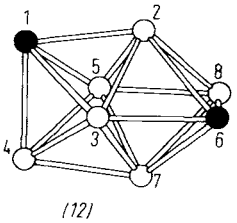

Fig. 9. ^1H-NMR spectrum of 2-methyl-1,3,5,6,7-pentaethyl-2,4-dicarbaclovoheptaborane(7) [55]. Numbering of the skeletal atoms as in *(10)*; H-atoms of the ligands: $\overset{\alpha}{-H}$, $\overset{\beta}{-CH_3}$, $\overset{\beta}{-CH_2}-\overset{\gamma}{CH_3}$.

Two structures are proposed for dicarbaclovooctaborane(8) $C_2B_6H_8$. The latest results [67] favor the Archimedian antiprism *(11)* rather than the bis-disphenoid *(12)* suggested earlier [57].

The one singlet in the ^1H-NMR spectrum of the C,C'-dimethylated compound indicates that the two carbon atoms

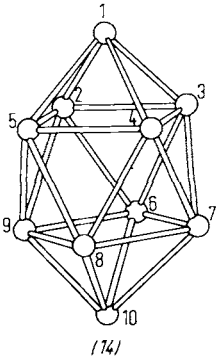
[67] *F. N. Tebbe, P. M. Garret, D. C. Young,* and *M. F. Hawthorne,* J. Amer. chem. Soc. *88*, 609 (1966).

occupy geometrically equivalent positions[57]. Only two doublets having an intensity ratio of 4:2 can be distinguished in the ^{11}B-NMR spectrum at 19.3 MHz[67]. Thus the structure is probably an Archimedian antiprism with the carbon atoms in the 1,3-position. Dicarbaclovooctaborane(8) would therefore be the only exception to the rule[57] that carboranes of the type $C_2B_nH_{n+2}$ have polyhedral structures built up entirely from triangles. If, in agreement with the earlier proposal, the boron and carbon atoms were arranged to form a bis-disphenoid, with the carbon atoms in the 1,6-position, the three pairs of equivalent boron atoms should give three doublets having an intensity ratio of 2:2:2 in the ^{11}B-NMR spectrum. However, the ratio of 4:2 observed at a measuring frequency of 19.3 MHz could be explained if two of the signals coincided. Another possibility that has recently been proposed[68] is that there are two isomeric bis-disphenoid structures with fast interconversion between the two.

For a final decision on the structure, it will be necessary to record a high-resolution ^{11}B-NMR spectrum or to carry out an X-ray analysis.



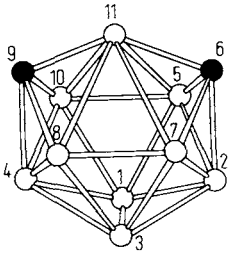
Dicarbaclovononaborane(9) $C_2B_7H_9$ *(13)*, which was reported only recently[67], probably has the structure of a tricapped trigonal prism.

The ^{11}B-NMR spectrum of the *C,C'*-dimethyl derivative indicates the presence of three types of boron atoms in the ratio 1:2:4. As is shown by the sharp signal in the ^{1}H-NMR spectrum, the two C-methyl groups are equivalent. Thus the two C atoms occupy the apices of two of the three pyramids, and have a coordination number of five.

(13)

Two *C,C'*-dimethylated skeletal isomers of the next higher BH homologue $C_2B_8H_{10}$ *(14)*[67] are known. On the basis of the ^{1}H-NMR spectra and by analogy with the isoelectronic $B_{10}H_{10}^{2\ominus}$ ion[69], these are assumed to have the structure of a bicapped Archimedean antiprism[67]. The C atoms in the more stable isomer are situated in the 1,10 positions. The less stable isomer is assigned the skeleton having the carbon atoms in positions 1 and 6.

(14)



[68] *W. N. Lipscomb*, Science (Washington) *153*, 373 (1966).

[69] *R. D. Dobrott* and *W. N. Lipscomb*, J. chem. Physics *37*, 1779 (1962).

The protons of the *C*–CH_3 groups in the 1,10-isomer give one sharp signal in the ^{1}H-NMR spectrum; the boron atoms give only one doublet in the ^{11}B-NMR spectrum. Since the most favorable coordination numbers are 5 for carbon and 6 for boron, this compound should be the most stable of the condensed carboranes.

The ^{1}H-NMR spectrum of the 1,6-isomer consists of two separate sharp lines of equal intensity for the two CH_3 groups, clearly showing that the carbon atoms are not equivalent. The ^{11}B-NMR spectrum contains a single doublet for the apex boron atom, together with three overlapping doublets having an intensity ratio of 1:7. However, these data do not entirely rule out a structure with the C atoms in positions 1 and 2.

X-ray analysis of the *C,C'*-dimethyl derivative of dicarbaclovoundecaborane(11) $C_2B_9H_{11}$ *(15)*[53] confirmed the structure proposed earlier[54,54a], *i.e.* a C_2B_{10} icosahedron in which one edge has been replaced by a single boron atom.

(15)

The distance between atoms 6 and 9[*] (3.09 Å) is much shorter than *e.g.* in bis(acetonitrile)decaborane(12) (3.32 Å) or in decaborane(14) (3.55 Å). Other distances between adjacent atoms are $r_{B(11)-B(5)}$ = 2.05 Å and $r_{B(11)-C(6)}$ = 1.68 Å.

After the structure of the isoelectronic $B_{12}H_{12}^{2\ominus}$ ion, which had previously been deduced from theoretical considerations[12,14], had been confirmed[70], it was to be expected that dicarbaclovododecaborane(12) $C_2B_{10}H_{12}$ *(7)* would also prove to have the icosahedral structure. Contrary to earlier reports[72], three-dimensional X-ray studies on the derivatives $C_2H_2B_{10}Cl_8H_2$[50,51] and $C_2(CH_2Br)_2B_{10}H_{10}$[52] of *o*-carborane (C atoms in positions 1 and 2) and of bis-(*o*-carboranyl)[71] showed that the carbon and boron atoms are arranged in the form of an almost regular icosahedron. There is a slight asymmetry due to the difference in the covalent radii of the boron and carbon atoms.

The mean BC distances are between 1.71 and 1.72 Å, while the mean BB distances are 1.77 to 1.78 Å. The CC distance [1.67 Å in $C_2H_2B_{10}Cl_8H_2$ and 1.64 Å in $C_2(CH_2Br)_2B_{10}H_{10}$] is relatively large, indicating that the two carbon atoms are also joined by multicenter bonds. The dipole moment of unsubstituted *o*-carborane is 4.53 D[73]. The ^{11}B-NMR spectrum of *o*-carborane *(7a)* recorded at a frequency of 64.2

[*] The numbering of the atoms here is based on that used for decaborane(14).

[70] *J. A. Wunderlich* and *W. N. Lipscomb*, J. Amer. chem. Soc. *82*, 4427 (1960).

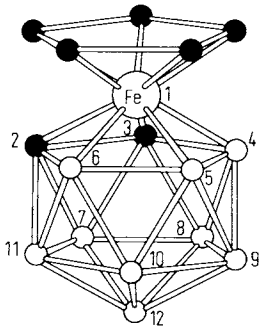
[73] *A. W. Laubengayer* and *W. R. Rysz*, Inorg. Chem. *4*, 1513 (1965).

MHz[74] consists of four doublets in an intensity ratio of 2:2:4:2, corresponding to the four groups of geometrically equivalent boron atoms (positions 3 and 6; 8 and 10; 4, 5, 7, and 11; 9 and 12).



The ^{11}B-NMR spectrum of *m*-carborane (C atoms in positions 1 and 7) shows the presence of four types of equivalent boron atoms in the ratio 2:2:4:2, the signals being split into four doublets at 64.2 MHz[75]. The dipole moment of the compound is only 2.85 D[73].

The ^{11}B-NMR spectrum of *p*-carborane (C atoms in positions 1 and 12), which contains ten equivalent boron atoms, consists of only a single doublet[76]. Because of its molecular symmetry, the compound has no dipole moment[73].

2.3.2.2. *Compounds with π Bonds between Carborane and Metal*

The dicarbollide ion $C_2B_9H_{11}^{2\ominus}$ *(8)* forms a series of compounds with transition metals, which in their composition and structure correspond to the π-cyclopentadienylmetal compounds[32,77–79].

X-ray analysis shows that π-cyclopentadienyliron – π-(1)-2,3-dicarbollide has a ferrocene-like "sandwich" structure *(16)*[80]; in contrast to the ferrocene crystal[80a], however, the two five-membered rings are eclipsed.

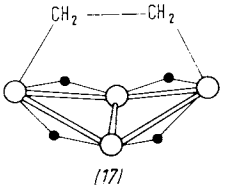
(16)

The distances from the iron atom to the cyclopentadienyl ring (r_{FeC} = 2.07 Å) and to the C_2B_3 ring of the carborane residue (r_{FeB} = 2.09 Å and r_{FeC} = 2.04 Å) are surprisingly similar. The CC distance in the carbollide is 1.58 Å; the mean values for the BC and BB distances have been determined as 1.68 Å and 1.75 Å respectively[80].

2.3.2.3. *The Carboranes $C_2B_nH_{n+4}$*

Dicarbahexaborane(8) $C_2B_4H_8$ *(3)* ("dihydrocarborane") is one of the few carboranes for which an X-ray study has been carried out[48,49]. The apex of the pentagonal pyramid is occupied by a boron atom, while the base is formed by three boron atoms joined together by H bridges and two adjacent carbon atoms.

The following values have been found for the BB and BC distances[49]



B(1)–B(5) = 1.779 Å, B(1)–B(6) = 1.779 Å, B(1)–B(4) = 1.765 Å, B(5)–B(6) = 1.783 Å, B(4)–B(5) = 1.798 Å, B(1)–C(2) = 1.784 Å, B(1)–C(3) = 1.751 Å, B(6)–C(2) = 1.509 Å, B(4)–C(3) = 1.489 Å. The C(2)–C(3) distance is 1.418 Å.

The C–C–C bond angle of 121 ° in the *C,C'*-dimethyl derivative[49] and the coupling constant $J_{^{13}CH}$ of 160 Hz in the ^{13}C-labeled carborane *(3)*[81] indicate substantial sp^2 hybridization of the carbon atoms in the carborane skeleton. The short CC distance also suggests that the CC bond has considerable double-bond character[82].

Dicarbaundecaborane(13) $C_2B_9H_{13}$ has not, as yet, been extensively studied[83]. A weak band at 1960 cm^{-1} in the IR spectrum points to a BH_bB grouping. Like the dicarbollide ion, this is presumably an icosahedral fragment, with the two carbon atoms adjacent to each other (*ortho*) or separated by a boron atom (*meta*) on an "open" pentagonal face.

2.3.2.4. *Compounds Having Special Structural Elements*

"Dimethylenetetraborane" $C_2B_4H_{12}$ *(17)* and dicarbanonaborane(13) *(17a)* occupy a position intermediate between the organoboranes and the carboranes. In contrast to the carboranes, each carbon atom in "dimethylenetetraborane"[84,85] is directly joined to only one boron atom; moreover, since the carbon atoms also carry two H atoms, they cannot contribute orbitals for the formation of multicenter bonds. Consequently, this compound does not exhibit the stabilization that characterizes the carboranes[84].

(17)

The structure of dicarbanonaborane(13) $C_2B_7H_{13}$[86] has been shown, by X-ray analysis[86a] of its C–C-derivative, to be an icosahedral fragment with two methylene groups separated from each other in the borane skeleton *(17a)*[*].

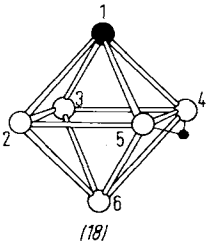
[*] On account of the peculiar structure of *(17a)* the numbering of the atoms [86a] corresponds only partly to the rules given in Section 2.1.2.1.



The structure *(17a)* had previously been suggested on the basis of the ^{1}H-NMR spectrum (two isolated CH_2 groups), the ^{11}B-NMR spectrum (five doublets having an intensity ratio 1:2:2:1:1), and the IR spectrum (ν_{BH_bB} = 2020 cm^{-1}) [86].

(17a)

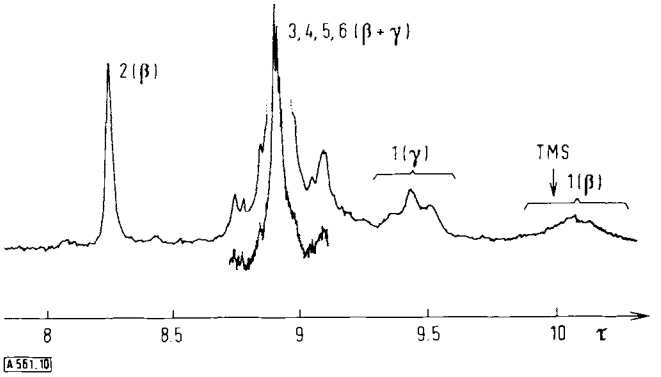
2.3.3. Monocarbaboranes $C_1B_xH_y$

Carbahexaborane(7) CB_5H_7 *(18)* [87] is formally (C/BH exchange), and probably also structurally, derived from dicarbaclovohexaborane(6) *(9)*. The five boron atoms give three doublets having an intensity ratio of 2:2:1 in the ^{11}B-NMR spectrum; the ^{1}H-NMR and IR spectra indicate a CH and a BH_bB grouping.

(18)

Several *B*- and *C*-alkylated derivatives of carbahexaborane(9) CB_5H_9 *(2)* have been described [20,88] and their ^{11}B-NMR, ^{1}H-NMR, and IR spectra indicate a pentagonal-pyramidal structure having a B atom at the apex.

The ^{11}B-NMR spectrum of the *C*-methylpentaethyl derivative [20] consists of three signals in the intensity ratio 2:2:1. The ^{1}H-NMR spectrum (cf. Fig. 10) contains the $C-CH_3$ singlet together with the signals of two different types of B-ethyl groups (ratio 4:1). The protons of the ethyl group on B-1 are split into a "methylene quartet" and a "methyl triplet", while the ethyl groups on the four boron atoms in the base give the same signal for the methyl and methylene protons.



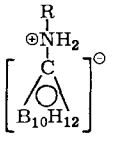


Fig. 10. ^{1}H-NMR spectrum of 2-methyl-1,3,4,5,6-pentaethyl-2-carbahexaborane(9) [64]. For definition of symbols see fig. 8 and 9.

The three BH_bB bridges can be detected from the IR spectrum, and probably link up the boron atoms in the base of the pyramid. In the ^{11}B-NMR spectrum of the 3-methyl derivative [88] of CB_5H_9 *(2)*, the asymmetric substitution leads, not only to splitting due to B–H coupling, but also to further complication. The spectrum contains four signals having an intensity ratio of 1(doublet):2(doublet):1(singlet):1(doublet). The positions of the signals due to the CH and the BCH_3 protons in the ^{1}H-NMR spectrum of the 3-methyl and 4-methyl derivatives differ only slightly.

The compound $RNH_2CB_{10}H_{12}$ (R = alkyl) contains only one carbon atom in the carborane skeleton and is assumed to be a zwitterionic derivative of the $CB_{10}H_{13}^{\ominus}$ ion, which is isoelectronic with dicarbanonaborane(13) [88a].

The ^{11}B-NMR spectrum contains six doublets in the intensity ratio 1:2:2:2:1:2. A BH_bB grouping is indicated by a weak broad band at 1975 cm^{-1} in the IR spectrum.

2.3.4. Carboranes with More Than Two Carbon Atoms in the Skeleton

2.3.4.1. *Carboranes with Three Carbon Atoms in the Skeleton*

One *C*-methyl and two *C,C'*-dimethyl derivatives of 2,3,4-tricarbahexaborane(7) *(5)* have been isolated (cf. Section 3.1.4.) [88b]. A pentagonal-pyramidal structure with three vicinal carbon atoms and one BH_bB grouping in the base of the pyramid [formula *(5)*] is deduced from the ^{1}H- and ^{11}B-NMR spectra and from the IR spectra (ν_{BH_bB} = 1500, 1900 cm^{-1}).

The ^{11}B-NMR spectra of the 2,3-dimethyl derivative *(5b)* and of the 2,4-dimethyl derivative *(5c)* are almost identical, and consist of two doublets having an intensity ratio of 2:1. In the spectrum of the 2-methyl derivative *(5a)*, the signal for the boron atom at the apex is slightly displaced. In addition to broad B–H multiplets, the ^{1}H-NMR spectra contain three singlets in the ratio 3:1:1 for *(5a)*, three singlets in the ratio 3:3:1 for *(5b)*, and two singlets in the ratio 6:1 for *(5c)*.

2.3.4.2. *Carboranes with Four Carbon Atoms in the Skeleton*

According to ^{11}B-NMR, ^{1}H-NMR, and IR spectra, the skeleton of tetracarbahexaborane(6) [diborahexacarbane(6)] $C_4B_2H_6$, several alkyl derivatives of which are known [6], has the pentagonal-pyramidal structure *(4)* predicted from theory [39]. One boron atom occupies the apex of the pyramid, while the other is situated in the base.

The ^{11}B-NMR spectrum of the hexamethyl derivative shows two boron atoms with different shielding (cf. Fig. 11). In agreement with this, the ^{1}H-NMR spectrum indicates two

[87] *T. P. Onak, R. Drake,* and *G. Dunks,* J. Amer. chem. Soc. *87,* 2505 (1965).

[88] *T. P. Onak, G. B. Dunks,* and *J. R. Spielman,* J. Amer. chem. Soc. *88,* 2061 (1966).

[88b] *C. L. Bramlett* and *R. N. Grimes,* J. Amer. chem. Soc. *88,* 4269 (1966).

types of *B*-methyl groups as well as two pairs of equivalent *C*-methyl groups (Fig. 12). The protons of the *B*-methyl group at the base of the pyramid evidently give a sharp signal, whereas the remarkably broad signal at higher field strengths must be assigned to the protons of the *B*-methyl group at the apex [*].

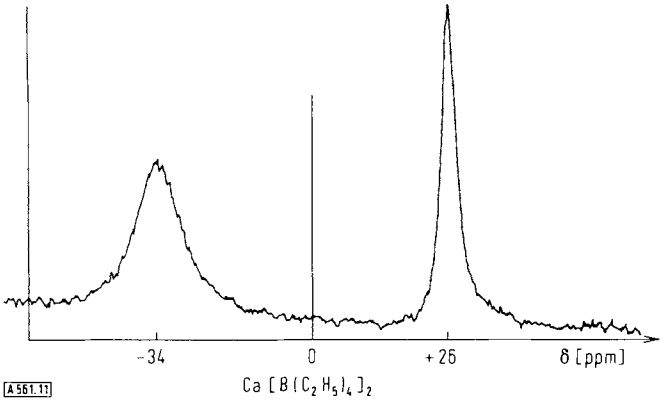

Fig. 11. ^{11}B-NMR spectrum of hexamethyl-2,3,4,5-tetracarbahexaborane(6). Line width (W_H) at −34 ppm; 234 Hz, at +26 ppm: 69 Hz [64].

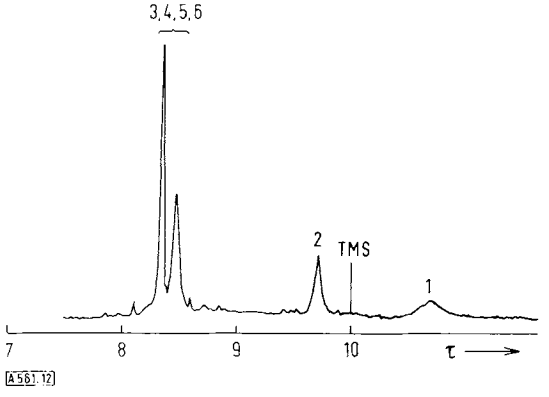

Fig. 12. ^{1}H-NMR spectrum of hexamethyl-2,3,4,5-tetracarbahexaborane(6) [64].

3. Preparation of Carboranes

No method based on readily obtainable derivatives of monoborane, corresponding *e.g.* to the preparation of the polyhedral $B_{12}H_{12}^{2\ominus}$ ion from sodium boranate and diborane [89],

$$2\ NaBH_4 + 5\ B_2H_6 \xrightarrow[100-180\,^\circ C]{N(C_2H_5)_3} Na_2B_{12}H_{12} + 13\ H_2$$

has so far been found for the unsubstituted carboranes. Acetylene and diborane react to give carboranes in small quantities only, and generally in the form of mixtures that are difficult to resolve [8, 11, 25, 59–61, 63].

Carboranes are generally prepared by the reaction of polyboranes [*e.g.* pentaborane(9), decaborane(14)] with an organic component (acetylene, other alkynes). Nearly all carboranes with no substituents on the boron have been prepared in this way, either directly or by degradation or transformation of the primary products (see Scheme 1).

Carboranes with alkyl groups attached to boron (organocarboranes), on the other hand, can also be prepared directly by condensation of simple organoboranes. For example, fully alkylated derivatives of 1,5-dicarbaclovopentaborane(5) *(6)* can be obtained, sometimes in very good yields, by several entirely different routes from alkylhalogenoboranes, alkyldiboranes, and alkynylboranes (cf. Section 3.2.2.) [21, 62].

3.1. Carboranes from Polyboranes

3.1.1. Carboranes from Decaborane(14)

3.1.1.1. *With Alkynes*

The preparation of 1,2-dicarbaclovododecaborane(12) [*o*-carborane *(7a)*] and its *C*-organo derivatives from decaborane(14) and acetylene or alkynes proceeds particularly smoothly in the presence of Lewis bases [9, 10, 30, 90–92].

$$B_{10}H_{14} + RC{\equiv}CR' \xrightarrow{L} RC\underset{\backslash O /}{-}CR' + 2\ H_2$$
$$B_{10}H_{10}$$

The reaction proceeds *via* disubstitution products $B_{10}H_{12}L_2$ (L = Lewis base) formed by elimination of 1 mole of hydrogen:

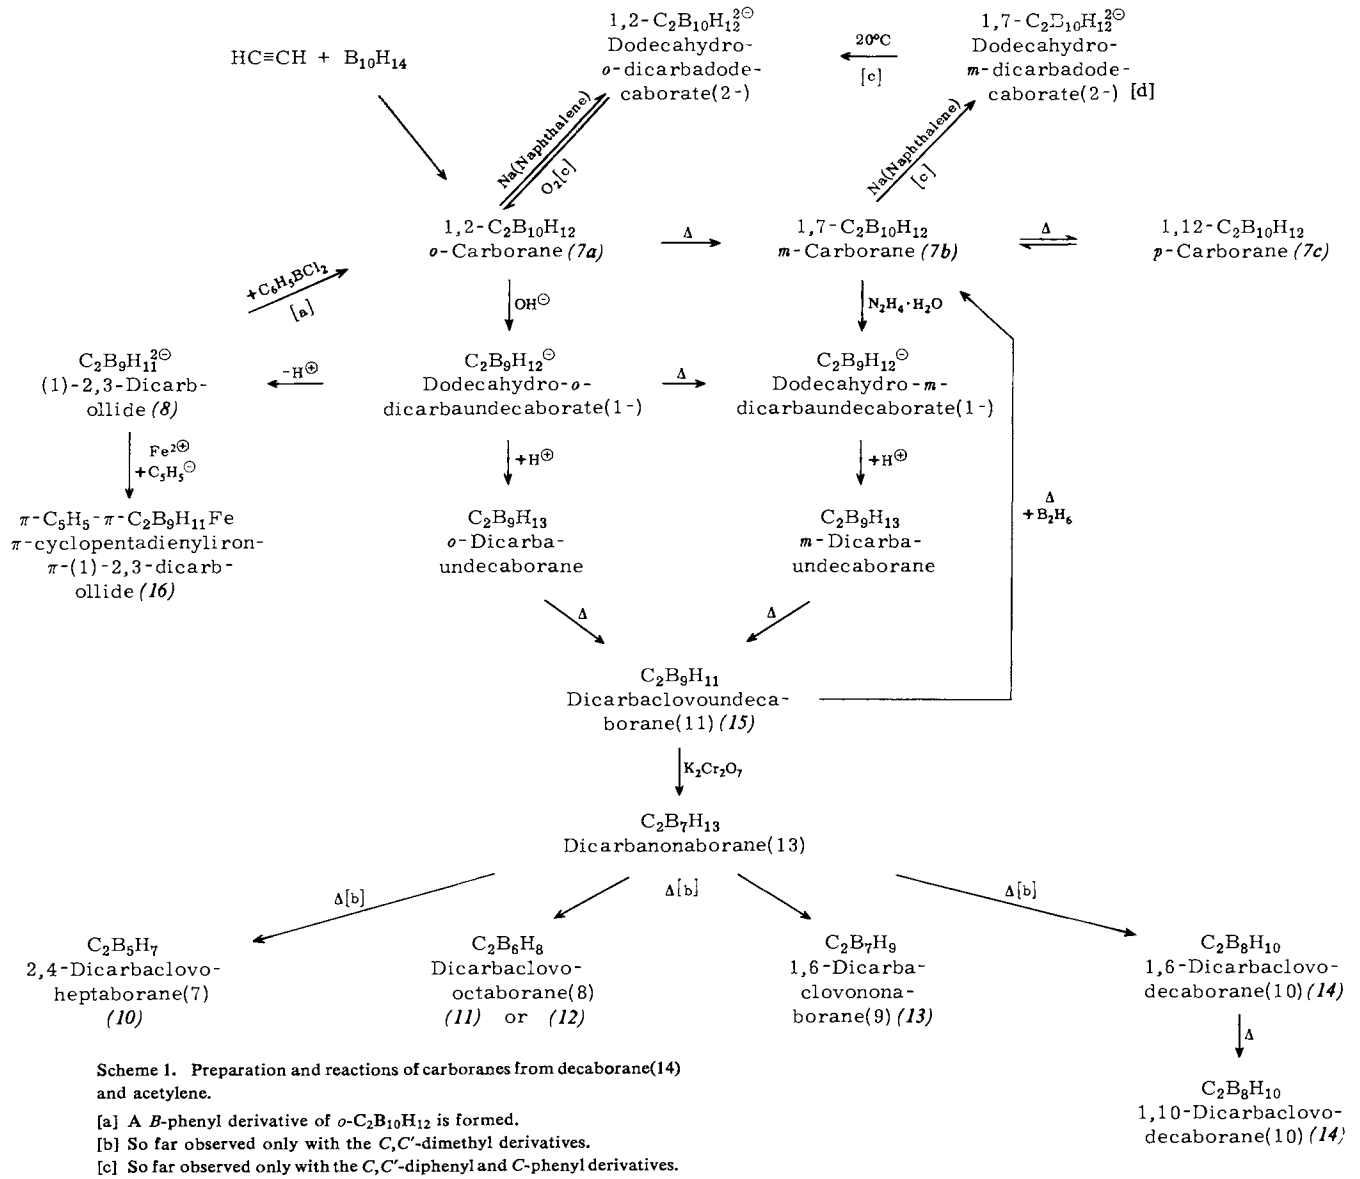
$$B_{10}H_{14} + 2\ L \rightarrow B_{10}H_{12}\cdot L_2 + H_2$$

These intermediates then react with the CC triple bond of the acetylene or alkyne, with elimination of a second mole of hydrogen and simultaneous regeneration of the free base.

The formation of *o*-carborane from acetylene and decaborane(14) in benzene takes place in the presence of only 0.1 mole of acetonitrile per mole of decaborane [9]; however, the optimum ratio of base to polyborane is 0.9:1.

Apart from acetonitrile, a number of other Lewis bases have also been used successfully, *e.g.* trialkylarsines [30, 92] and cyclic ethers such as dioxane and tetrahydrofuran [9]. However, the most suitable compounds are dialkyl sulfides and Lewis bases containing nitrogen, such as alkyl cyanides, trialkylamines, and dialkylamines [9, 10].

1-substituted or 1,2-disubstituted acetylenes give *C*-substituted or *C,C'*-disubstituted 1,2-dicarbaclovododecaboranes(12) [9, 10, 30, 91, 92]. However, unsubstituted 1,2-dialkylacetylenes react very poorly. For example, whereas 1-pentyne and even 1,4-dichloro-2-butyne react smoothy in benzene with decaborane(14) in the presence of acetonitrile to give the corresponding di-



[*] The breadth of the signal has not yet been satisfactorily explained.

Scheme 1. Preparation and reactions of carboranes from decaborane(14) and acetylene.

[a] A *B*-phenyl derivative of $o\text{-}C_2B_{10}H_{12}$ is formed.
[b] So far observed only with the *C,C'*-dimethyl derivatives.
[c] So far observed only with the *C,C'*-diphenyl and *C*-phenyl derivatives.
[d] Not definitely detected [113a].

carbaclovododecaboranes(12) (> 50 and 74% yield respectively), 2-butyne and 2-pentyne give only traces of carboranes [9,91].

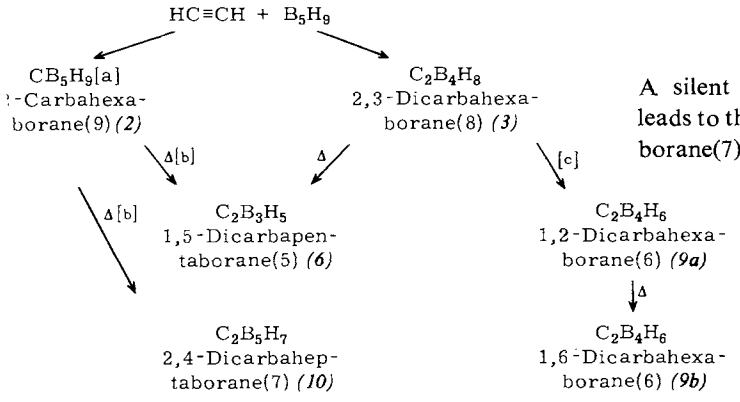
3.1.1.2. *With Alkyl Isocyanides*

Whereas the reaction of decaborane(14) with alkyl cyanides leads to elimination of hydrogen and formation of bis(alkylnitrile)decaboranes(12), the reaction with alkyl isocyanides leads to compounds having the composition $RNH_2CB_{10}H_{12}$ (R = alkyl), in which one carbon atom is joined to the $B_{10}H_{12}$ residue to give a carborane skeleton [88a] (cf. Section 2.3.3.).

3.1.2. Carboranes from Hexaborane(10)

When hexaborane(10) and acetylene are heated to 200 °C, traces of dicarbaclovooctaborane(8) [formula *(11)* or *(12)*] and dicarbahexaborane(8) *(3)* [57] are formed. 2-Butyne may also be used as the alkyne component in this reaction; *C,C'*-dimethyldicarbaclovooctaborane(8) is then formed in < 2% yield.

The formation of the carborane in this case is evidently not catalysed by Lewis bases. Thus no carborane can be detected even after prolonged heating of the adduct $B_6H_{10}\cdot P(C_6H_5)_3$ with an excess of 2-butyne at 100 °C. On the other hand, photochemical activation of the reaction mixture at 35 to 60 °C [57] gave up to 12% of *C,C'*-dimethyldicarbaclovooctaborane(8):



$$B_6H_{10} + CH_3\text{–}C{\equiv}C\text{–}CH_3 \xrightarrow{h\nu} (CH_3)_2C_2B_6H_6$$

An isomeric dicarbaclovooctaborane was also formed in trace amounts.

3.1.3. Carboranes from Pentaborane(9)

The reaction of pentaborane(9) with acetylene or alkynes always yields a mixture of carboranes, the composition of which depends on the reaction conditions. In contrast to the synthesis of *o*-carborane *(7a)* the manner in which these products are formed is not very clear. The mixture generally contains compounds having less boron than the polyborane used.

When a mixture of pentaborane(9) and acetylene is heated at reduced pressure [11,25] or exposed to a silent discharge [25,59,60], extremely small quantities of condensed carboranes $C_2B_nH_{n+2}$ (n = 3–5) can subsequently be detected.

Scheme 2. Preparation and reactions of carboranes from pentaborane(9) and acetylene.

[a] Three isomeric monomethyl derivatives are formed.
[b] So far observed only with fully alkylated derivatives.
[c] Silent discharge.

The pyrolysis of acetylene and pentaborane(9) in closed vessels, on the other hand, leads to the formation of 2,3-dicarbahexaborane(8) *(3)* in 30 to 40% yield [81,93] (see Scheme 2).

$$B_5H_9 + HC{\equiv}CH \xrightarrow{215\,^\circ C} \underset{(3)}{C_2B_4H_8}(30\text{–}40\%) + \underset{(1\text{–}2\%)}{CH_3{-}CB_5H_8}$$

Small quantities of isomeric methylcarbapentaboranes(9) $CH_3{-}CB_5H_8$ are also formed, as well as benzene and toluene [88].

Even better yields are obtained in some cases in the formation of *C*-substituted carboranes from alkynes. For example, 2-butyne and pentaborane(9) at 165 °C give the *C,C'*dimethyl derivative of 2,3-dicarbahexaborane in a yield of more than 50% [81].

These reactions are accelerated by many Lewis bases. Alkylated acetylenes and pentaborane(9) react even at room temperature in the presence of lutidine [81], the yields of carborane being strongly influenced by the alkyl substituents on the acetylene. Whereas acetylene gives only small quantities of the unsubstituted compound *(3)*, the *C,C'*-dimethyl compound is obtained in yields of up to 40% from 2-butyne under the same conditions [65]. The first step in the reaction could be a nucleophilic attack on the pentaborane(9) by the alkyne. However, 2-methylbut-1-en-3-yne, which reacts smoothly with decaborane(14) under similar conditions to give the 1-isopropenyl derivative of *o*-carborane [10], reacts only slowly with pentaborane(9), even in the presence of lutidine. No carborane is formed in the absence of bases [81].

3.1.4. Carboranes from Tetraborane(10)

The reaction of tetraborane(10) and acetylene in the gas phase at room temperature yields solid products together with small quantities (10^{-2} to 10^{-3} mmole per mmole of B_4H_{10} consumed [*]) of methylated 2,3,4-tricarbahexaboranes(7) *(5)* [88b]. The 2-methyl, 2,3-dimethyl, and 2,4-dimethyl derivatives of *(5)* were identified. A small quantity of pentaborane(9) is also formed.

3.1.5. Carboranes from Alkylated Polyboranes

A silent discharge in 1-methylpentaborane(9) vapor leads to the formation of small quantities of carbahexaborane(7) $CB_5{-}H_7$ *(18)* [87], the methyl carbon atom of the 1-methylpentaborane(9) being incorporated into the carborane skeleton. The mechanism of this reaction has not yet been explained; the reaction may become a general method for the synthesis of carboranes.

3.2. Carboranes from Mono- and Diboranes and Their Organo Derivatives

3.2.1. Carboranes from Diborane and Acetylene

The reactions of gaseous mixtures of acetylene and diborane in electric discharges have been extensively studied [63]. When diborane is present in excess, 10 to 15% of the acetylene can react to form volatile carboranes of the clovo type containing three to five boron atoms and methyl derivatives of these carboranes. 1,5-Dicarbaclovopentaborane(5) *(6)*, 1,6-dicarbaclovohexaborane(6) *(9b)*, and their 2-methyl derivatives, 2,4-dicarbaclovoheptaborane(7) *(10)* and its 1,3-dimethyl and 5-methyl derivatives, and a *C*,3-dimethyl-1,2-dicarbaclovopentaborane(5) have been detected. The reaction products also include pentaborane(9) and tetraborane(10), which may be intermediates in this carborane synthesis.

3.2.2. Carboranes from Organo Derivatives of Monoborane

3.2.2.1. *Dehalogenation of Alkylhalogenoboranes*

B- and *C*-alkylated carboranes containing 3 to 7 B atoms have been detected on dehalogenation of alkylhalogenoboranes with alkali metals [94]. Satisfactory

[*] In a reaction mixture containing 3.1 mmole of B_4H_{10} and 3.3 mmole of C_2H_2, nearly all the acetylene and 1.4 mmole of B_4H_{10} had reacted in 7 days.

[93] *I. Shapiro* and *H. G. Weiss*, US-Pat. 3086996 (1956), Olin Mathieson Chem. Corp.; Chem. Abstr. *60*, 548b (1964).

yields of carboranes are obtained in particular by the use of lithium in tetrahydrofuran; diethyl ether and dimethoxyethane may also be used as solvents. However, not all dehalogenations of this type lead to the formation of carboranes; for example, when sodium-potassium alloy, in non-polar solvents such as hexane or toluene at room temperature, is used as the dehalogenating agent, alkali metal halide and diborylated alkanes are formed, but carboranes can be detected only in traces.

Suitable alkylhalogenoboranes for dehalogenation with lithium are dialkylchloroboranes, dialkylfluoroboranes, and alkyldifluoroboranes [20,94]. When alkyldichloroboranes are used, on the other hand, cleavage of the tetrahydrofuran, even at −30 °C, leads to quantitative formation of compounds containing BO bonds, *e.g.* *B*-alkylperhydrooxaborines [95].

The dehalogenation of organohalogenoboranes gives optimum yields of carboranes only within a relatively narrow range of temperatures. Below this range, the dehalogenation proceeds mainly on the ratio R:X in the alkylhalogenoborane $R_nX_{3-n}B$ (n = 1,2; X = halogen). For example, the reaction of diethylchloroborane and lithium at 0 °C in tetrahydrofuran yields *C*-methyl-*B*-ethyl derivatives of 2-carbahexaborane(9) *(2)* and of 2,4-dicarbaclovoheptaborane(7) *(10)*, together with triethylborane, which contains more than 50% of the *B*-ethyl groups used [55]. Thermally unstable and readily oxidizable organocarboranes, the structures of which are not yet known, are also formed. Small quantities of alkyl derivatives of other carboranes (up to 7 B atoms) forming homologous series can also be detected.

A total of 7 to 9% of the boron from the organohaloborane is used in the formation of stable, distillable organocarboranes, which are resistant to hydrogen peroxide in acidic solution. Approximately a further 5% of the boron is used for the formation of a compound $C_{12}H_{30}B_4$, the principal component of the distillable organoboranes that are unstable towards heat and oxidation (cf. Table 1). A substantial proportion of

[a] Determined by mass spectrometry [97]; [b] Separated by gas chromatography [96]; [c] Thermally unstable and autoxidizable; [d] Percentage of boron and of all the carbon bound in the organocarborane, based on the boron and carbon in the organohalogenoborane.

smoothly, but leads mainly to polyorganoboranes, and not to carboranes. For example, carboranes are formed only in traces in the reaction of dialkylchloroboranes with lithium in tetrahydrofuran at −20 to −30 °C. This is shown by the decomposition, by D_2O, of the products formed on reaction with trialkylaluminum (cf. Section 2.3.2.1.), which yields monodeuterated and dideuterated alkane, while the 1,1,1-trideuteroalkane characteristic of carboranes is scarcely detectable. Interference by cleavage of tetrahydrofuran becomes noticeable above +10 °C in the reaction of dialkylmonochloroboranes. The preparation of carboranes from dialkylchloroboranes with lithium in tetrahydrofuran is therefore best carried out at about 0 °C. The most favorable temperature range for the alkyldifluoroboranes is between −10 and −5 °C, since the cleavage of the ether again becomes important at temperatures slightly above this range.

Provided that the reaction is conducted at a suitable temperature, the composition of the resulting mixture of organoboranes and organocarboranes depends

the boron is found in the compounds of the undistillable residue. These are evidently also carborane-like substances. When the distillation residue is heated with triethylborane in a closed vessel, the main products are alkyl derivatives of 1,5-dicarbaclovopentaborane(5) *(6)* and 2,4-dicarbaclovoheptaborane(7) *(10)*.

The carboranes that are unstable to heat and oxidation are partly converted into condensed carboranes at 150 to 200 °C. The total yield of stable carboranes can therefore be increased considerably by subsequent heating of the reaction mixture. The products consist mainly of alkyl derivatives of 1,5-dicarbaclovopentaborane(5). However, members of a new homologous series of carboranes having relatively high molecular weights are also formed (cf. Table 2).

The dehalogenation of ethyldifluoroborane rather than diethylchloroborane leads to much better yields of organocarboranes [20]; cf. Table 1. The directly formed distillable fraction contains alkyl derivatives of 2-carbahexaborane(9) *(2)* and of 2,4-dicarbaclovoheptaborane(7) *(10)*. The yield of derivatives of *(2)* is particularly high in relation to that obtained by the

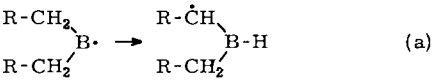
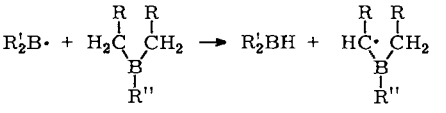
[d] After heating at about 200 °C.



dehalogenation of dialkylchloroboranes. Practically no unstable compounds containing three to five boron atoms are formed. Up to 20% of the boron from the alkyldifluoroborane is utilised in the formation of distillable organocarboranes that are stable to oxygen. About half of the *B*-ethyl groups can be recovered as triethylborane.

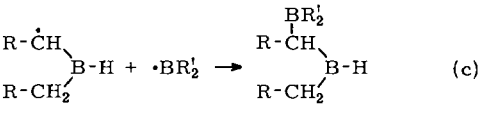
Organocarboranes containing 3 to 7 B atoms are also formed in the reaction of diethylether-trifluoroborane with lithium at about −5 °C in the presence of triethylborane in tetrahydrofuran. As in the dehalogenation of alkylhalogenoboranes, the composition of the carborane mixture depends on the ratio R:X (R = C_2H_5, X = F). When R:X = 2:1 or 1:1, the thermally unstable carboranes predominate. At a ratio R:X = 1:2, the proportion of organocarboranes of the clovo type increases at the expense of the unstable compounds. At the same time, larger quantities of high-boiling organocarboranes and undistillable products are obtained.



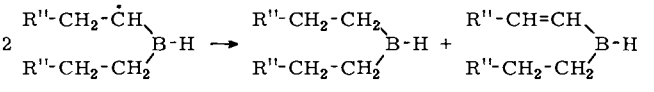
The process involved in the dehalogenation of alkylhalogenoboranes has not yet been fully explained. However, an essential part is probably played, not only by the formation and reaction of free radicals, but also by the catalysed exchange of substituents on boron by BH bonds [98]. Thus the dehalogenation of dialkylhalogenoboranes with lithium in the presence of alkenes yields only small quantities of carboranes, since the BH components required for ligand exchange are evidently taken up by the CC double bond [94]. This is also the case in dehalogenations below −15 °C, since the BH-catalysed exchange is then almost frozen.

[98] *R. Köster*, Angew. Chem. *73*, 66 (1961); *R. Köster* and *G. Schomburg*, Angew. Chem. *72*, 567 (1960).

The first step in the reaction presumably leads to the formation of short-lived *C*-radicals from the free alkylboron radicals [*] by migration of a hydrogen atom from an α-carbon atom to the boron [eq. (a)]. However, an intermolecular hydrogen transfer [eq. (b)] is not impossible. Thus when diethylchloroborane reacts with lithium at −30 °C in the



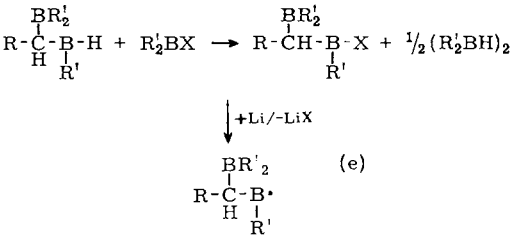
(a)



(b)

presence of tripropylborane, di-and-triborylated C_3 residues are found as well as di- and triborylated C_2 units. The C_3 units can be qualitatively detected *via* the corresponding deuterated hydrocarbons. The organoboranes are made to react with a suitable trialkylaluminum, *e.g.* trioctylaluminum [98a], and the resulting mixtures of organoaluminum and organoboron compounds are decomposed by D_2O.

The combination of a *C*-radical with a *B*-radical leads to the formation of a new BC bond [eq. (c)].



(c)

(d)

Disproportionation of the *C*-radical in accordance with equation (d) can be largely ruled out since alkenyl groups attached to boron have never been detected after dehalogenations in the presence of an excess of olefin.

New dialkylboryl radicals may also be formed, *e.g.* in accordance with eq. (e).

(e)

Contrary to an earlier assumption [94], intermediates of the type $R\text{–}C(BR_2)_3$ probably play no part, or at least no important part, in the formation of carboranes by dehalogenation. Investigations on the hydroboration of dialkyl-(1-alkynyl)boranes with alkyldiboranes (cf. Section 3.2.2.4.2.) have now shown [21] that compounds of this type form trialkylboranes and alkylated 1,5-dicarbaclovopentaboranes(5) *(6)* at room temperature or on gentle heating. However, no derivatives of *(6)* have been detected as primary products in the dehalogenation of alkylhalogenoboranes (c. f. Table 2).

A variant of the dehalogenation that also leads to stable BC compounds has been found for arylated boranes [99]. Di-

[*] In some cases it was possible to intercept these free radicals as stable free BN radicals [98b] by the addition of pyridine [95].

bromophenylborane and diphenylacetylene react in the presence of metallic potassium to form a compound that, because of its stability to oxygen and the absence of C=C stretching vibrations, was assigned the structure, not of hexaphenyl-1,4-diboracyclohexa-2,5-diene, but of an octahedral C_4B_2 skeleton.

However, by analogy with the results obtained in the aliphatic series (cf. Section 2.3.4.2.), this product could be a hexaphenylated C_4B_2 carborane having a pentagonal-pyramidal structure with a boron atom at the apex, as in *(4)*.

3.2.2.2. *Carboranes from Alkyldiboranes and Alkali Metals*

Alkylated carboranes containing three to five boron atoms are also formed in the preparation of alkali metal boranates from alkyldiboranes and alkali metals [100]. For example, the reaction of 2.3 g of sodium with 28 g of tetraethyldiborane at 100–110 °C gives sodium boranate and triethylborane as the principal products [100a], together with 1.5 g of a mixture of carboranes, about 15 % of which consists of compounds that are stable to hydrogen peroxide at room temperature. These are mainly alkyl derivatives of 2-carbahexaborane(9) *(2)* and of 2,4-dicarbaclovoheptaborane(7) *(10)* (c.f. Table 3). The small quantities of 1,5-dimethyl-2,3,4-triethyl-1,5-dicarbaclovopentaborane(5) that can also be detected are presumably formed during distillation by the thermal degradation of unstable carboranes. The higher-boiling fraction consists mainly (about 60 %) of compounds that are unstable to heat and to hydrogen peroxide and oxygen. The proportion of these compounds increases in relation to the proportion of stable organocarboranes as the ratio C_2H_5: H in the ethyldiborane used is increased, and ultimately reaches a value of about 75 % in the reaction of ethyldiborane having 0.6 % of hydride hydrogen. If lithium is used instead of sodium, the same carboranes are obtained from the alkyldiboranes in lower yields and at much lower reaction rates. With sodium-potassium alloy (K_2Na), the reaction is fairly fast at 50 °C, but the result is essentially the same as when sodium is used.

Table 3. Mass-spectrometrically detected organocarboranes [a] from ethyldiboranes and alkali metals.

266	$C_{14}H_{32}B_6$	

[a] The compounds are not attacked by 30 % aqueous hydrogen peroxide in acidic solution at room temperature, and can be distilled under reduced pressure.

[b] Determined by high-resolution mass spectrometry [97] with a CEC 21-110 instrument.

The formation of carboranes from alkyldiboranes and alkali metals is probably initiated by the formation of an $R_2B\cdot$ radical:

$$^1/_2(R_2BH)_2 + M \rightarrow R_2B\cdot + MH \qquad (f)$$

The further course of the reaction is probably substantially the same as in the dehalogenation of alkylhalogenoboranes (cf. Section 3.2.2.1.). However, the BH-catalysed ligand exchange is facilitated by the relatively high concentration of BH groups. The synthesis of 2,4-dimethyl-1,3,5,6,7-pentaethyl-2,4-dicarbaclovoheptaborane(7) from triethyldiborane and sodium can be represented by the overall equation (g):

$$22[(C_2H_5)_2BH]_2 + 12\ Na \rightarrow 12\ NaBH_4 + 27\ B(C_2H_5)_3 + C_{14}H_{31}B_5 \qquad (g)$$

Salt-like compounds containing several boron atoms have not, as yet, been detected.

3.2.2.3. *Carboranes by Pyrolysis of Alkyldiboranes*

The pyrolysates of alkyldiboranes contain up to 5 % of organocarboranes having three to eight, and possibly even more boron atoms [101]. When ethyldiboranes are heated to about 170 °C, the products consist mainly of alkyl derivatives of 2,4-dicarbaclovoheptaborane(7), together with 1,5-dimethyl-2,3,4-triethyl-1,5-dicarbaclovopentaborane(5) (cf. Table 4). The

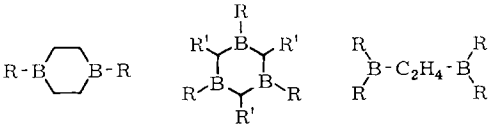
presence of an alkylated carborane $C_{14}H_{32}B_6$ has also been detected by high-resolution mass spectrometry [97].

The formation of carboranes from simple alkylated monoboranes probably proceeds *via* CB_2 and CB_3 groupings resulting from intermolecular elimination of hydrogen or of alkane [102].

However, C–C bonds are also broken during the pyrolysis, with the result that *B*-methyl groups are formed from the *B*-ethyl groups [103].



Consequently, the molecular weights of the homologous carboranes formed by the pyrolysis of ethyldiboranes differ only be the mass of one CH_2 group (cf. Table 4).

3.2.2.4. *Carboranes by Hydroboration of Dialkyl-1-alkynylboranes*

3.2.2.4.1. *From Acetylene and Ethyldiboranes*

Whereas an electric discharge in a mixture of diborane and acetylene yields only small quantities of carboranes (cf. Sections 3.1.3. and 3.1.4.) [63], *B*-alkylcarboranes can be obtained in preparative quantities by the rapid introduction of acetylene into tetraethyldiborane at room temperature followed by heating under pressure [19,62]. In addition to simple cyclic [*(19)*, *(20)*] and acyclic hydroboration products *(21)*, the reaction

R = C_2H_5 *(19)* *(20)* *(21)*

R′ = CH_3

leads in particular to 1,5-dimethyl-2,3,4-triethyl-1,5-dicarbaclovopentaborane(5) in yields of 10 to 15%, depending on the conditions [62]. Very small quantities of homologues of this carborane can also be detected.

In agreement with the results described in the following Section, this synthesis probably proceeds *via* diethylethynylborane, which must be formed from acetylene and the tetraethyldiborane with elimination of hydrogen:

$$^1/_2[(C_2H_5)_2BH]_2 + HC{\equiv}CH \rightarrow (C_2H_5)_2BC{\equiv}CH + H_2 \quad (h)$$

The hydroboration of the diethylethynylborane with tetraethyldiborane then presumably leads to the formation of 1,1,1-tris(diethylboryl)ethane, which is finally disproportionated to form triethylborane and the 1,5-dicarbaclovopentaborane(5) derivative [eq. (i)].

$$(C_2H_5)_2BC{\equiv}CH + [(C_2H_5)_2BH]_2 \rightarrow [(C_2H_5)_2B]_3C{-}CH_3$$
$$2[(C_2H_5)_2B]_3C{-}CH_3 \rightarrow (CH_3C)_2B_3(C_2H_5)_3 + 3(C_2H_5)_3B \quad (i)$$

Acetylene and ethyldiborane also react to form higher carboranes, and particularly derivatives of 2-carbahexaborane(9) *(2)* and of 2,4-dicarbaclovoheptaborane(7) *(10)* (cf. Table 5).

Table 5. Mass-spectrometrically detected organocarboranes [a] from the hydroboration of acetylene with ethyldiborane.

[a] The compounds are not attacked by 30% aqueous hydrogen peroxide in acidic solution at room temperature, and can be distilled under reduced pressure.

[b] Determined by high-resolution mass spectrometry [97] with a CEC 21-110 instrument.

Carboranes containing more than five boron atoms can also be detected. One of the compounds isolated has the formula $C_{14}H_{32}B_6$; from its ^{1}H-NMR spectrum, this compound is probably the *C,C′*-dimethylpentaethyl derivative of a dicarbaclovooctaborane(8) [*(11)* or *(12)*].

3.2.2.4.2. *From Alkyldiboranes and Dialkyl-1-alkynylboranes*

The formation of carboranes by the action of acetylene on ethyldiboranes, for which the above reaction path was postulated, led to the development of a synthesis of carboranes by hydroboration of alkynylboranes with alkyldiboranes. It was found that the alkyl derivatives of 1,5-dicarbaclovopentaborane(5) can be obtained in relatively high yields by this method [21]

An essential requirement for this synthesis was the development of a method for the preparation of uncomplexed dialkyl-1-alkynylboranes, which were unknown until recently [104]. The trimethylamine adducts of these compounds can

[102] It had been observed earlier, in the hydrogenation of trialkylboranes with hydrogen under pressure to obtain alkyldiboranes and/or diborane, that condensations take place particularly readily when the boron hydride content is too high and the reaction mixture is heated to 180 °C or higher (*R. Köster*, *G. Bruno*, and *P. Binger*, Liebigs Ann. Chem. *644*, 1 (1962).

[103] *R. Köster* and *W. Larbig*, Angew. Chem. *73*, 620 (1961).

[104] *H.-J. Horstschäfer*, Diploma Thesis, Technische Hochschule Aachen, 1966.

be obtained in high yields from alkynyl-lithium and the trimethylamine-dialkylfluoroborane adduct, and can be converted into the free dialkyl-1-alkynylboranes *e.g.* by treatment with the boron trifluoride-diethyl ether adduct:

$$LiC{\equiv}C{-}CH_3 + FBR_2{-}N(CH_3)_3 \rightarrow LiF + CH_3C{\equiv}C{-}BR_2{-}N(CH_3)_3 \quad (j)$$

$$\xrightarrow{+F_3B-OR_2} F_3B{-}N(CH_3)_3 + OR_2 + R_2BC{\equiv}CCH_3$$

$R = C_2H_5$

The hydroboration of these dialkyl-1-alkynylboranes with alkyldiboranes leads to the formation of alkyl derivatives of 1,5-dicarbaclovopentaborane(5) in yields of more than 50%. If the hydroborating agent contains alkyl groups different from those in the dialkyl-1-alkynylboranes, the reaction leads to 1,5-dicarbaclovopentaboranes having different alkyl groups on the boron atoms[21]. Reactions studied so far include the hydroborations of diethyl-1-propynylborane and of diethyl-1-octynylborane with ethyl- and methyldiboranes.

In the case of the methyl and ethyl compounds, the distribution of the alkyl groups on the boron atoms of the carborane and of the trialkylborane does not correspond entirely to the expected statistical distribution[105].

The formation of C_2B_3 carboranes evidently involves intermediates containing CB_3 groupings, which disproportionate to form the more stable C_2B_3 carboranes [eq. (k)].

$$R_2BC{\equiv}C{-}CH_3 + (R_2BH)_2 \rightarrow R_2B{-}\underset{R_2B}{\overset{R_2B}{C}}{-}CH_2{-}CH_3 \quad (k)$$

$$2\,(R_2B)_3C{-}C_2H_5 \rightarrow (C_2H_5C)_2B_3R_3 + 3\,BR_3$$

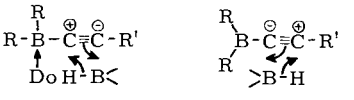
$R = C_2H_5, C_3H_7$

In addition to the derivatives of 1,5-dicarbaclovopentaborane(5) *(6)*, small quantities of high-boiling organocarboranes with up to five boron atoms in the skeleton are also formed. The undistillable fractions also contain compounds having carborane-like structures.

Further carboranes are obtained by subsequent heating of the reaction mixtures, probably as a result of isomerization of 1,1,2-triborylated alkanes[21] [eq. (1)].

$$R_2BC{\equiv}C{-}CH_3 + (R_2BH)_2 \rightarrow (R_2B)_2CH{-}CH(BR_2)CH_3$$

$$(R_2B)_2CH{-}CH(BR_2)CH_3 \xrightarrow{\Delta} (R_2B)_3C{-}CH_2{-}CH_3 \quad (1)$$



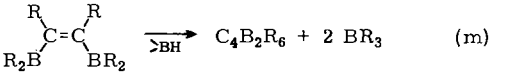
$$\downarrow$$

$$^1/_2\,(C{-}C_2H_5)_2R_3B_3 + {}^3/_2\,BR_3$$

$R = C_2H_5, C_3H_7$

The yields of 1,5-dicarbaclovopentaborane(5) derivatives are highest when the reactions are carried out in dilute solutions of the tetraalkyldiboranes in trialkylborane. The hydroborating agents is then almost free from RBH_2- and BH_3-components, and consists of dialkylboron hydrides R_2BH[106]. This permits a highly selective addition of BH, which, with the 1-alkynylboranes, leads to the formation of 1,1,1-triborylated alkanes.

It is also very important that uncomplexed dialkyl-1-alkynylboranes should be used in the synthesis of the C_2B_3 carboranes and that addition compounds with amines should be absent since they, like the alkali metal trialkyl-1-alkynylboranates $M[R_3BC{\equiv}CR']$ *(24)*, react with alkyldiboranes to give mainly 1,2-diborylated alkenes *(23)*. The polarization of the C≡C bond is then opposite [*(22a)*] to that in the free 1-alkynylboranes *(22b)*.

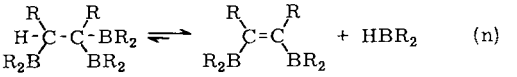


(22a) *(22b)*

Do = electrondonator

If 1,2-diborylated alkenes *(23)* are formed, they disproportionate very readily in the presence of boron hydrides to form stabilized C_4B_2 compounds (cf. Section 3.2.2.5.). Thus in the presence of Lewis bases, C_2B_3 organocarboranes can no longer be prepared by hydroboration of dialkyl-1-alkynylboranes.

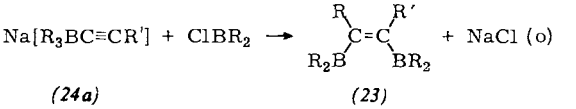
3.2.2.5. *Carboranes ("Boracarbanes") from 1,2-Diborylated Alkenes*



The disproportionation of 1,2-bis(dialkylboryl)alkenes *(23)* leads to fully alkylated derivatives of tetracarbahexaborane(6) *(4a)* [6].

$$\xrightarrow{>BH} C_4B_2R_6 + 2\,BR_3 \quad (m)$$

(23) *(4a)*



The ligand exchange in accordance with equation (m) takes place at temperatures above 40 °C in the presence of alkyldiboranes and proceeds almost quantitatively, since the triborylated alkanes formed by hydroboration readily decompose into their components [eq. (n)].

$$+ HBR_2 \quad (n)$$

(23)

The compounds *(23)* can be obtained *e.g.* from sodium trialkyl-1-alkynylboranates *(24a)* and dialkylchloroboranes in yields of up to 80% [eq. (o)] [107].

$$+ NaCl \quad (o)$$

(24a) *(23)*

The reaction (o) leads exclusively to *cis-(23)*, and takes place with many dialkylchloroboranes R_2BCl (R = CH_3, C_2H_5, C_3H_7) and sodium trialkyl-1-alkynylboranates $Na[R_3BC{\equiv}CR']$ (R = CH_3, C_2H_5; R′ = CH_3, C_2H_5). 2,3-Bis(diethylboryl)-2-pentene, for example, reacts in five to six hours to give isomeric tetraethyl-C,C′-dimethyl-2,3,4,5-tetracarbahexaboranes(6) *(4a)* as well as triethylborane.

However, the compounds *(4a)* can also be obtained from sodium 1-alkynyls and tetraalkyldiboranes in the presence of trialkylboranes, in accordance with equation (p), without isolation of *(23)*.

$$2\,NaC{\equiv}CR' + 2\,BR_3 + 4\,(R_2BH)_2 \rightarrow 2\,NaBH_4 + 6\,BR_3 + R'_2R_2C_4B_2R_2 \quad (p)$$

e.g. R = C_2H_5; R′ = C_3H_7 *(4a)*

[105] *R. Köster* and *H.-J. Horstschäfer*, unpublished.

[106] *R. Köster*, *G. Griasnov*, *W. P. Larbig*, and *P. Binger*, Liebigs Ann. Chem. *672*, 1 (1964).

[107] *P. Binger* and *R. Köster*, Tetrahedron Letters *1965*, 1901.

(4a) is obtained in yields of more than 50%, together with sodium boranate and trialkylborane. When the reaction is carried out in the absence of trialkylborane, the products consist mainly of high molecular weight compounds, together with small quantities of alkyl derivatives of 1,5-dicarbaclovopentaborane(5) *(6)* [eq. (q)].

$$2\,NaC{\equiv}CC_3H_7 + 6\,((C_2H_5)_2BH)_2 \rightarrow 2\,NaBH_4 + 7\,B(C_2H_5)_3 + (C_4H_9)_2C_2B_3(C_2H_5)_3 \quad (q)$$

(6a)

The organo derivatives having the C_4B_2 skeleton *(4a)* are closer in many respects to the organocarboranes than to the organoboranes. The BC bonds of the compounds *(4a)* are practically unaffected by heating for several hours with 6N sulfuric acid. They are also stable to methanol and ethanol up to a temperature of 150 °C. However, the compounds react with boiling propionic acid to give tetrapropionylpyroboric acid $(C_3H_7OCO)_2BOB(OCOC_3H_7)_2$, *cis*-pentene, and a mixture of isomeric decenes.

Trimethylamine *N*-oxide, which smoothly oxidizes all the BC bonds in organoboranes at temperatures slightly above room temperature[107a], does not attack the C_4B_2 compounds even in boiling benzene. Slow oxidation takes place even at room temperature with molecular oxygen and hydrogen peroxide[6]. This illustrates the difference between the organo-substituted tetracarbahexaboranes (diborahexacarbanes) and the condensed organocarboranes of the series $C_2B_xR_{x+2}$ (cf. Section 3.2.2.1.).

When the 1,2-diborylated alkenes are heated above 80 °C in the presence of BH compounds, C–C cleavage and other irreversible reactions (*e.g.* cyclization) take place[108]. The *B*-ethylated compounds yield mainly diboracyclopentenes and similar products, whereas *(23)* with methyl groups on the boron can be converted predominantly into the C_4B_2 compounds even at 150 °C.

The disproportionation of the *cis*-1,2-diborylated alkenes in accordance with equation (o) can also take place at room temperature in the presence of UV radiation[6], but side reactions then become more important.

3.3. Interconversions of Carboranes

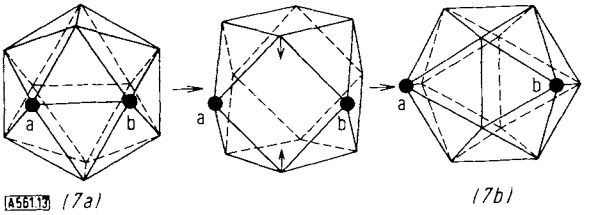
3.3.1. Thermal Isomerizations

At present there are only a few cases in which all the theoretical skeletal isomers of a particular carborane are known. The isomers can sometimes be interconverted by heating, but activation energies may be high.

3.3.1.1. *Isomerization of the Dicarbaclovodecaboranes(12)*

The best-known example of the isomerization of a carborane is the formation of 1,7-dicarbaclovododecaborane(12) [*m*-carborane *(7b)*] at 450–500 °C from *o*-carborane *(7a)*[31,109], which is less stable according to LCAO calculations[28].

The experimental data give an activation energy of 62 kcal/mole[110]. The boron and carbon atoms could conceivably be arranged in the form of a cuboctahedron in the transition state[68,111]; cf. Figure 13.



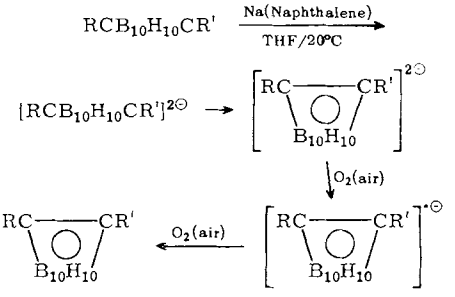


Fig. 13. Skeletal isomerization of dicarbaclovododecaboranes(12) *(7)*. [*o*-carborane *(7a)* → *m*-carborane *(7b)*].

Some of the *C*-substituted *o*-carboranes can also be converted into the more stable *m*-compounds by heating[31,109,110,112,113]. Steric as well as electronic effects often play a part in this isomerization, *e.g.* 1,2-bis (methyldiphenylsilyl) - 1,2 - dicarbaclovododecaborane(12) rearranges at 260 °C to form the *m*-isomer; the activation energy, as found experimentally, is only 45 kcal/mole[110].

Conversely, derivatives of *m*-carborane can be converted into *o*-carboranes *via* the dianion of dicarbadodecaboranes(14)[113a].

R = Phenyl, R' = H, Phenyl

This is in agreement with *Lipscomb*'s predictions[4].

Finally, when *m*-carborane is heated almost to its decomposition point (about 630 °C), it is partly converted into 1,12-dicarbaclovododecaborane(12) *(7c)* (*p*-carborane)[76]. The composition of the resulting mixture of *m*- and *p*-carboranes is in good qualitative agreement with LCAO–MO calculations, which give the same energy content for both isomers[28].

3.3.1.2. *Isomerization of Dodecahydrodicarbaundecaborates(1-)*

Dodecahydro-*o*-dicarbaundecaborate(1-) $C_2B_9H_{12}^{\ominus}$ can be converted into the *m*-isomer by heating at 300 °C[114]; this product is identical with that obtained

by degradation of *m*-carborane with bases (cf. Section 3.3.3.1.).

3.3.1.3. *Isomerization of Dicarbaclovodecaborane(10)*

According to LCAO–MO calculations [111], the stability of the seven possible isomeric dicarbaclovodecaboranes(10) *(14)* decreases in the order (a,b = indices of the C atoms): 1,10 > 1,6 > 1,2 > 2,4 > 2,8 > 2,3 > 2,7.

Dimethyl-1,6-dicarbaclovodecaborane, which can be obtained by pyrolysis of *C,C'*-dimethyldicarbanonaborane(13) (cf. Section 3.3.3.2.), rearranges almost quantitatively into the more stable 1,10-isomer at 350 °C [67]; cf. Figure 14.

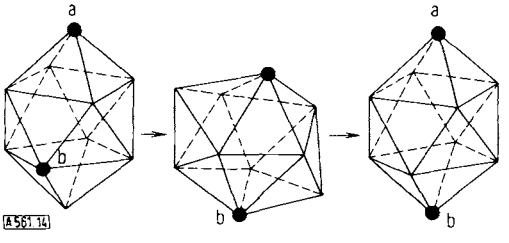

Fig. 14. Skeletal isomerization of dicarbaclovodecaboranes(10) *(14)*; conversion of the 1,6-into the 1,10-isomer.

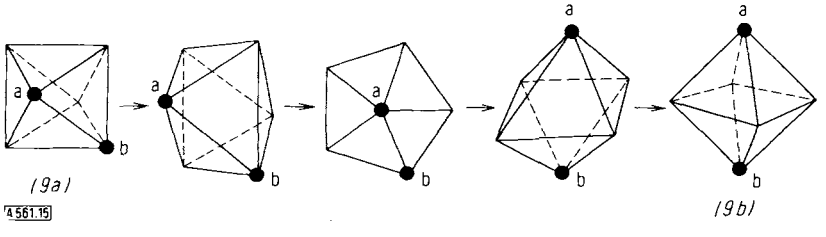
3.3.1.4. *Isomerization of Dicarbaclovohexaborane(6)*

The octahedral 1,2-dicarbaclovohexaborane(6) *(9a)* can be almost quantitatively converted into the more stable symmetrical 1,6-isomer *(9b)* by heating at 250 °C [81]. The rearrangement could proceed *via* a pentagonal pyramid [68, 111]; cf. Figure 15. However, a trigonal prism having symmetry D_{3h} cannot be entirely ruled out as an intermediate [68, 111].



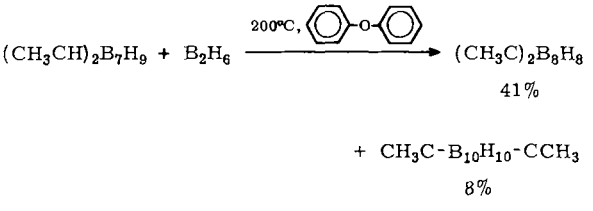


Fig. 15. Skeletal isomerization of dicarbaclovohexaboranes(6); conversion of *(9a)* into *(9b)*.

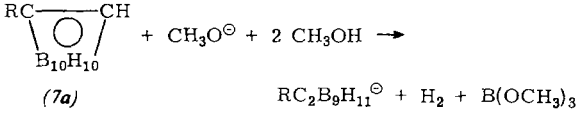
3.3.2. Carboranes by Synthesis from Lower Carboranes

Only a very small number of new carboranes have so far been obtained by synthesis from lower carboranes. The insertion of a B_1 unit into the $C_2B_9H_{11}^{2\ominus}$ ion *(8)* to form the neutral *B*-phenyl-*o*-carborane occurs in the reaction of the disodium salt of the (1)-2,3-dicarbollide ion *(8)* with phenyldichloroborane (−40 °C, THF) [115]; the 3-phenyl derivative of *(7a)* is thought to be formed (cf. also Scheme 1).



The results of the pyrolysis of dicarbanonaborane(13) (cf. Section 2.3.2.3.) in the presence of diborane [67] also indicate the general feasibility of the stepwise synthesis of higher condensed carboranes from lower, incompletely condensed compounds. *C,C'*-Dimethyl-1,6-dicarbaclovodecaborane(10) *(14)* is formed in a relatively high yield (41 %), together with small quantities (8 %) of the *C,C'*-dimethyl derivative of *m*-carborane *(7b)* in the reaction of *C,C'*-dimethyldicarbanonaborane(13) with diborane at about 200 °C in the presence of diphenyl ether.

3.3.3. Carboranes by the Degradation of Higher Carboranes

3.3.3.1. *Degradation with Bases*

o-Carborane *(7a)* and its *C*-substituted derivatives are rapidly degraded by strong bases, such as ethanolic potassium hydroxide solution, amines, alkali metal amides, or hydrazine, with elimination of a boron atom and formation of dodecahydrodicarbaundecaborates [56, 83, 116–118].

Kinetic measurements with 1-phenyl-*o*-carborane in 50 % ethanolic potassium hydroxide solution [83] show that the reaction is first order with respect to the car-

[116] *D. Grafstein, J. Bobinski, J. Dvorak, H. Smith, N. N. Schwartz, M. S. Cohen*, and *M. M. Fein*, Inorg. Chem. *2*, 1120 (1963).

[117] *L. I. Zakharkin* and *V. N. Kalinin*, Tetrahedron Letters *1965*, 407; Izvest. Akad. Nauk SSSR, Ser. chim. *1965*, 579; Bull. Acad. Sci. USSR Div. Chem. Sci. *1965*, 567; Chem. Abstr. *63*, 622f (1965).

[118] *M. F. Hawthorne, P. A. Wegner*, and *R. C. Stafford*, Inorg. Chem. *4*, 1675 (1965).

borane and the hydroxide ion. Experiments with deuterated carborane [83] have shown that the boron atom is removed from position 3 or 6. *m*-Carborane is more resistant to nucleophilic attack than the *o*-isomer.

It is not attacked by boiling methanolic potassium hydroxide solution, but is slowly (R = H, CH_3) or relatively quickly (R = C_6H_5, *p*-Cl–C_6H_4) degraded by boiling hydrazine hydrate to *m*-undecaborate [31, 119].

$$RCB_{10}H_{10}CH + N_2H_4 \cdot H_2O + 2\,H_2O \rightarrow N_2H_5^{\oplus}RC_2B_9H_{11}^{\ominus} + H_2 + B(OH)_3$$

(7b)

R = H, CH_3 [31] R = C_6H_5, *p*-Cl–C_6H_4, *p*-Br–C_6H_4 [119]

Acidification of the *m*- and *o*-$C_2B_9H_{12}^{\ominus}$ anions *e.g.* with phosphoric acid [53,83] yields the neutral dicarbaundecaboranes(13) $C_2B_9H_{13}$.

On the other hand, when the $C_2B_9H_{12}^{\ominus}$ ion is treated with sodium or sodium hydride [77], further proton abstraction leads to the "potlike" dianion $C_2B_9H_{11}^{2\ominus}$ (dicarbollide ion) *(8)*.

By analogy with the reactions of the cyclopentadienyl anion, the reaction of the dicarbollide ion with salts of the transition metals yields compounds in which the transition metal and the carborane nucleus are linked by π bonds, *e.g.* π-cyclopentadienyliron(III)-π-2,3-dicarbollide *(16)* [32, 77–79].

$$[C_5H_5]^{\ominus} + [C_2B_9H_{11}]^{2\ominus} + Fe^{2\oplus} \xrightarrow[-e\ominus]{} \pi\text{-}C_5H_5\text{–}Fe\text{–}\pi\text{-}C_2B_9H_{11}$$

(16)

3.3.3.2. *Oxidative Degradation*

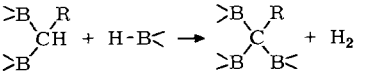
Whereas 1,2-$C_2B_{10}H_{12}$ *(7a)* in acidic media is not attacked by hydrogen peroxide, peroxy acids, or chromic acid [10,92,116], the dicarbaundecaborane(11) $C_2B_9H_{11}$ *(15)* can be smoothly degraded to the dicarbanonaborane(13) $C_2B_7H_{13}$ even by dichromate ions in acetic acid solution [86] (76% yield).

The *C*-methyl and *C*-phenyl derivatives react in the same manner to form the substituted dicarbanonaboranes(13).

3.3.3.3. *Pyrolytic Degradation*

The polyhedral BC compounds with higher hydrogen contents are much less stable than the condensed carboranes $C_2B_nH_{n+2}$. Consequently, compounds such as 2,3-dicarbahexaborane(8) *(3)* or *o*-dicarbaundecaborane(13) cannot be converted by heat into isomers in which the carbon atoms are separated by B atoms; on heating they lose hydrogen to form stable condensed carboranes, and in some cases the reaction proceeds smoothly to give homogeneous products in high yield. *o*- and *m*-dicarbaundecaborane(13) $C_2B_9H_{13}$ both give the same dicarbaundecaborane(11) $C_2B_9H_{11}$ *(15)* with non-adjacent carbon atoms when heated [53, 54, 114].

The removal of hydrogen from the *m* compound is easier than from the *o*-isomer [54]. The pyrolysis of *o*-dicarbaundecaborane(13) probably leads first to isomerization into *m*-dicarbaundecaborane(13); the C-substituted dicarbaundecaboranes(13) behave similarly. On the other hand, the *B*-iodo derivative $C_2B_9H_{12}I$ forms high molecular weight products when heated [120].



Dicarbanonaborane(13) disproportionates at 200 °C with loss of hydrogen, the main products being dicarbaclovooctaborane(8) [structure *(11)* or *(12)*] and 1,6-dicarbaclovodecaborane(10) [cf. *(14)*] [67, 86].

Small quantities of dicarbaclovononaborane(9) *(13)* are also formed.

$$R_2C_2B_7H_{11} \xrightarrow{200\,^{\circ}C} \underset{28\%}{R_2C_2B_8H_8} + \underset{30\%}{R_2C_2B_6H_6} + \underset{7\%}{R_2C_2B_7H_7}$$

R = H, CH_3 (R = CH_3) (R = CH_3) (R = CH_3)

The pyrolysis must (cf. Section 3.2.2.3.) involve the formation of new BC bonds, since investigations carried out so far indicate that dicarbanonaborane(13), unlike the condensed carboranes, contains only methylene groups [86] and no methine groups.

(p)

The pyrolysis of 2,3-dicarbahexaborane(8) *(3)* (dihydrocarborane) at 295 °C leads mainly to 2,4-dicarbaclovoheptaborane(7) *(10)*, together with 1,5-dicarbaclovopentaborane(5) *(6)* and 1,6-dicarbaclovohexaborane(6) *(9b)* [81].

$$2,3\text{-}R_2C_2B_4H_6 \xrightarrow{295\,^{\circ}C} 2,4\text{-}R_2C_2B_5H_5 + 1,5\text{-}R_2C_2B_3H_3 + 1,6\text{-}R_2C_2B_4H_4$$

R = H	28%	2%	1%
R = CH_3	25%	5%	–

C-alkylated 1,6-dicarbaclovohexaboranes(6) and 2,4-dicarbaclovoheptaboranes(7) can be obtained in the same way as the unsubstituted compounds from the *C*-alkyl-2,3-dicarbahexaboranes(8) [65, 81]. The *C,C'*-dimethyl compound gives mainly 2,4-dimethyl-2,4-dicarbaclovopentaborane(7), together with a little 1,6-dimethyl-1,6-dicarbaclovohexaborane(6). Much more of the C_2B_4 carborane is formed in the presence of an amine, even at lower temperatures [65].

$$2.3\text{–}R_2C_2B_4H_6 \xrightarrow{260\,^{\circ}C;\ N(CH_3)_3} 2.4\text{–}R_2C_2B_5H_5 + 1.6\text{–}R_2C_2B_4H_4$$

R = CH_3 15% 25%

The following reaction course has therefore been proposed for the formation of 1,6-dicarbaclovohexaborane(6) and of 2,4-dicarbaclovoheptaborane(7) [65]:

$$2.3\text{–}C_2B_4H_8 \rightarrow 1.2\text{–}C_2B_4H_6 + H_2 \text{ (slow)}$$

(13) *(9a)*

$$1.2\text{–}C_2B_4H_6 \rightarrow 1.6\text{–}C_2B_4H_6$$

(9a) *(9b)*

} catalysed by NR_3

$$1.2\text{–}C_2B_4H_6 + 2.3\text{–}C_2B_4H_8 \rightarrow 2.4\text{–}C_2B_5H_7 + \text{tarry products}$$

(9a) *(3)* *(10)*

[119] *L. I. Zakharkin* and *V. N. Kalinin*, Ž. obšč. Chim. *35*, 1691 (1965); Chem. Abstr. *63*, 18135f (1965).

[120] *F. P. Olsen* and *M. F. Hawthorne*, Inorg. Chem. *4*, 1839 (1965).

The *B*- and *C*-alkylated 2-carbahexaboranes(9) are also converted into condensed carboranes by heat. The *C*-methylpentaethyl derivative of CB_5H_9 reacts at 200–250 °C to give hydrogen, ethane, and unidentified high molecular weight products, together with 1,5-dimethyl-2,3,4-triethyl-1,5-dicarbaclovopentaborane(5) and a mixture of three isomeric *C*,*C'*-dimethyltetraethyl derivatives of 2,4-dicarbaclovoheptaborane(7) [20].

3.3.3.4. *Photolytic Degradation*

2,3-Dicarbahexaboranes(8) *(3)* can also be degraded to condensed carboranes by the action of light [121]; however, this method, unlike pyrolysis, leads mainly to carboranes in which the number of boron atoms is smaller than or equal to that in the starting compound. Hydrogen, diborane, and pentaborane(9) are formed as by-products.

$$\underset{(3)}{2.3\text{-}C_2B_4H_8} \xrightarrow[2\ h]{h\nu/60\,^\circ C} \underset{(9a),\,14\%}{1.2\text{-}C_2B_4H_6} + \underset{(9b),\,22\%}{1.6\text{-}C_2B_4H_6} + \underset{(6),\,17\%}{1.5\text{-}C_2B_3H_5}$$

The maximum total yield of new carboranes, based on the consumed 2,3-dicarbahexaborane(8), is 60%. The yield decreases when the irradiation time is increased, and only a trace of the less stable 1,2-dicarbaclovohexaborane(6) *(9a)* is formed.

4. Outlook

Though a large volume of data on the carboranes and carborane-like compounds has already been accumulated in a relatively short time, research in this new branch of boron chemistry is still in its infancy. Suggestions have already been made for the industrial utilization of the new BC compounds; for example, numerous polymers have been synthesized from derivatives of 1,2-dicarbaclovododecaborane(12) and their properties been tested [122]. Production costs are, however, very high.

The discovery of new BC systems, and refinement of the syntheses of the carboranes already known, will undoubtedly give fresh impetus to the discussion of possible applications of these compounds.

Reactions of Halogen Azides

BY K. DEHNICKE [*]

Until recently, the explosive nature of halogen azides made these compounds unsuitable for preparative uses and greatly impeded investigation of their physical properties. Reactions of ClN_3 and BrN_3 with metal halides, metal carbonyls, and organometallic compounds to form metal azide halides, nitride halides, carbonyl azide halides, and alkylmetal azides were reported only very recently. The stability relationships of the halogen azides are discussed.

A. Preparation of Halogen Azides

The first halogen azide, iodine azide, was prepared by *Hantzsch* and *Schümann* [1] in 1900 from silver azide and iodine in ether at 0 °C:

$$AgN_3 + I_2 \rightarrow AgI + IN_3 \qquad (a)$$

These authors obtained the explosive substance in the crystalline form by careful evaporation of the ether. Soon afterward, *Raschig* [2] synthesized the gaseous chlorine azide by acidification of solutions of sodium azide and sodium hypochlorite with boric or acetic acid:

$$N_3^- + ClO^- + 2\,H^+ \rightarrow ClN_3 + H_2O \qquad (b)$$

The formation of chlorine azide is betrayed by the yellow solution obtained when it dissolves in water. In 1943, *Frierson, Konrad*, and *Browne* [3] obtained

ethereal solutions of chlorine azide by method (a) when Cl_2 was passed into a suspension of AgN_3 in ether. These methods prove unsuitable when the halogen azides are required for preparative purposes. In 1965 a preparation of chlorine azide in large quantities was described, in which a stream of chlorine diluted with nitrogen is passed into an aqueous solution of sodium azide at 0 °C:

$$N_3^- + Cl_2 \rightarrow ClN_3 + Cl^- \quad (c)$$

Under these conditions, the chlorine reacts quantitatively in the exothermic reaction (c); after drying over P_4O_{10}, the resulting chlorine azide can be used directly for syntheses [4].

Almost 20 years after the discovery of chlorine azide, *Spencer* [5] obtained bromine azide as a mobile orange liquid which is very sensitive to hydrolysis. This compound is prepared by passing a stream of bromine diluted with nitrogen over dry sodium azide:

$$NaN_3 + Br_2 \rightarrow BrN_3 + NaBr \quad (d)$$

Fluorine azide was first prepared in 1942. It is a very unstable yellowish-green gas which is formed on reaction of fluorine with hydrazoic acid [6,7]:

$$4\,HN_3 + 2\,F_2 \rightarrow 3\,FN_3 + N_2 + NH_4F \quad (e)$$

Fluorine azide has so far been characterized only by qualitative analysis, by its molecular weight, and with the aid of the decomposition reaction (j) [6]. FN_3 is also formed as a by-product in the synthesis of N_2F_2 from fluorine and solid sodium azide moistened with a trace of water [8]; the sodium azide may be diluted with CaF_2 to avoid local overheating [9].

B. Chemical Properties of the Halogen Azides

The halogen azides are hydrolysed in aqueous media, particularly in the presence of OH^- ions:

$$XN_3 + 2\,OH^- \rightarrow N_3^- + XO^- + H_2O \quad (f)$$
$$X = Cl, Br, I$$

This reaction led at an early stage to the conclusion that the halogens X are electropositive in these compounds [1,2]. The formation of hypochlorite is utilized for analytical determination; arsenite is oxidized smoothly to arsenate [10]:

$$AsO_3^{3-} + XN_3 + 2\,OH^- \rightarrow AsO_4^{3-} + N_3^- + X^- + H_2O \quad (g)$$

Only ClN_3 and IN_3 dissolve in water without decomposing [1,2], whereas BrN_3 decomposes in water to form HN_3 and HOBr; when heated, the reaction products undergo a redox reaction:

$$2\,BrN_3 \quad H_2O \xrightarrow{H_2O} 3\,N_2 + Br_2 \quad (h)$$

ClN_3 BrN_3, and IN_3 dissolve readily in solvents such as ether, benzene, carbon tetrachloride, carbon disulfide, and pentane. Although solutions of ClN_3 in these solvents can be stored for a few days at 20 °C [2], the BrN_3 solutions, which can be kept for only a few hours, must be stored in the dark [5]; IN_3 solutions decompose slowly at 0 °C [1]. Reaction occasionally takes place with the solvent, as in the slow reaction of ClN_3 with pentane according to equation (i) [3]:

$$C_5H_{12} + ClN_3 \rightarrow C_5H_{11}Cl + HN_3 \quad (i)$$

ClN_3 undergoes a complex reaction with an excess of ammonia in the gas phase, which yields N_2, NH_4Cl, and NH_4N_3 [3]. Violent explosions occur when ClN_3, BrN_3, and IN_3 are brought into contact with Na, Mg, Zn, or white phosphorus. When the reaction mixture is diluted with solvents, the reaction products are found to be mixtures of the chloride and azide of the element in question [1,3,5].

All the halogen azides are extremely explosive. The stability appears to increase slightly in the order

$$FN_3 < IN_3 < BrN_3 < ClN_3$$

The halogen azides explode particularly readily in the solid state; however, the utmost caution is advised, even in reactions in the gas phase. Fluorine azide explodes "regularly" on vaporization of the condensate [6]; the reasons for this are largely unknown. It is known that in the presence of nitrogen, even very small pressure variations (Δp = 0.05 mm Hg) can cause chlorine azide and bromide azide to explode [11]. In our experience, explosions are avoided completely if pressure variations are kept within this Δp limit.

The slow decomposition of ClN_3, BrN_3, and IN_3 affords the elements, whereas fluorine azide yields difluorodiazene [6,8,9]:

$$2\,FN_3 \rightarrow N_2F_2 + 2\,N_2 \quad (j)$$

FN_3 reacts slowly with an excess of fluorine in the gas phase to form nitrogen trifluoride [6]:

$$FN_3 + F_2 \rightarrow NF_3 + N_2 \quad (k)$$

An interesting reaction takes place between chlorine azide and silver azide in diethyl ether at −78 °C; a deep blue to black substance is formed which evidently contains an Ag(II) compound [12]:

$$2\,AgN_3 + 2\,ClN_3 \rightarrow 2\,N_3AgCl + 3\,N_2 \quad (l)$$

Silver(II) azide chloride is very sensitive to shock; decomposition into AgCl and N_2 begins at −30 °C [12].

C. Physical Properties of the Halogen Azides

Owing to the instability and explosive nature of the halogen azides, very few of their physical data are known. Determination of the magnetic susceptibility of chlorine azide dissolved in carbon tetrachloride showed a slight paramagnetism of $\chi_{mole} = 16.5 \times 10^{-6}$ [12a].

Table 1. Melting points and boiling points of the halogen azides.

	M.p (°C)	B.p. (°C/mm)	Ref.
FN_3	−154	−82/760 [*]	[6]
ClN_3	−100	15/760	[3]
BrN_3	−45	?	[5]
IN_3	(solid)	?	[1]

[*] The boiling point of FN_3 could be determined only as the condensation point.

Gaseous chlorine azide can be exploded even at low pressures (< 0.1 mm Hg) by the action of an electric discharge [13a]; light is emitted in the wavelength range of 5000 to 5500 Å. The kinetics of the explosion can be represented by equation (m) [13]:

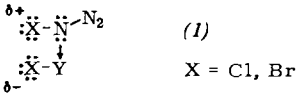
$$ClN_3 \rightarrow Cl + 3\,N \qquad (m)$$

Milligan and *Jacox* studied the UV-induced reactions of FN_3, ClN_3 and BrN_3; when fixed in an argon matrix at 4 °K, these compounds yielded the radicals NF, NCl, and NBr. The IR spectra of these radicals and of the halogen azides (the fundamental vibrations of which are given, with their assignments, in Table 2) have been recorded [14, 15]. The halogen azide molecules all belong to the symmetry class C_s, the angle at the α-N atom being less than 180° [14].

Table 2. IR spectra of the halogen azides in an Ar matrix, after *Milligan* and *Jacox* [14].

	ν (NX)	ν_{as} (N_3)	ν_s (N_3)	δ (N_3)
FN_3	869	2034	1086	503, 654
ClN_3	721(^{37}Cl)724(^{35}Cl)	2060, 2072	1144	520
BrN_3	687	2053, 2070	1160	530

Comparison with the N-halogen stretching vibrations of other molecules shows that only the N–F stretching vibration occurs at a "normal" [16] frequency; the NCl stretching vibration of ClN_3 occurs at the extremely high frequency of 724 cm^{-1} [16–18]. Though no data for comparison are available for NBr stretching vibrations, the NBr stretching frequency in BrN_3 also appears to be very high from its relationship with the N–Cl frequency of ClN_3. This must be interpreted as resulting from an increase in the strength of the N-halogen bond from fluorine azide to bromine azide, which can only be due to interaction of the π-electrons of the N_3 group with free d orbitals of the chlorine or bromine. Since there are no d orbitals available in fluorine, there is no strengthening of the F–N bond, with the result that the F–N stretching vibration occurs in the normal position.



The situation changes when we turn from the halogen azides to the halogen-nitrogen radicals XN. Bond strengthening can now occur in the FN radical owing to the electron deficiency on the N atom. This should give rise to a considerable increase in frequency, and the N–F frequency is in fact found to increase from 869 to 1115 cm^{-1} [14]. A much smaller increase in frequency, *i.e.* only 98 cm^{-1}, is found for the transition from ClN_3 to ClN; this is in agreement with the view that the Cl–N bond is already considerably strengthened in ClN_3. There is no difference between the NBr frequencies of BrN_3 and BrN, evidently because the d orbitals of bromine and its ease of polarization render a very high bond order possible in BrN_3. This explanation agrees with Goubeau's rule [19], according to which groups of atoms tend to form multiple bonds only when the sum of the electronegativities, owing to electron deficiency and low polarity of the bond, is greater than 5.

This casts considerable doubt on the "electropositive" character of the halogens in the halogen azides, because the above discussion suggests that the halogen is the electronegative partner; the relationships are summarized in Table 3.

Table 3. The probable resonance relationships in the halogen azides.

It can be seen that resonance form (a) cannot occur in fluorine azide, but can occur in ClN_3 and to an even greater extent in BrN_3; nevertheless, the halogen azides react as if the halogen atoms were electropositive, *e.g.* in hydrolysis or in substitutions. The explanation of this apparent contradiction must be sought in the kinetics of the first step in the reactions of the halogen azides. In every case studied, this step consists in an attack by an electron acceptor Y (Lewis acid), which is a proton in hydrolysis, on the α-N atom of the halogen azide; this attack leads to the formation of the transition complex *(1)*.

(1)

X = Cl, Br

The attack by the acceptor atom Y, *e.g.* antimony in $SbCl_5$, favors the resonance form (b) (cf. Table 3).

If Y is attached to an electronegative partner X (*e.g.* $Cl^{\ominus}$ in $TiCl_4$; XY = $TiCl_4$), a redox neutralization of

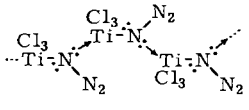
the two oppositely charged halogen species can lead finally to the formation of X_2 [4, 11]. The result is therefore the replacement of halide by azide. This view is substantiated by the fact that ClN_3 and BrN_3 do not react with halides that are not pronounced Lewis acids, *e.g.* $SiCl_4$ or $POCl_3$ [11]. Since the resonance form (a) is more strongly favored in bromine azide, whereas the initial reaction with the acceptor depends on form (b) or (c), reactions with BrN_3 should be inhibited; this agrees with observations [20]. Thus it may be concluded the halogen azides are not *a priori* electropositive, but become so only as a result of reversal of polarization during reactions. The halogen azides might therefore be better described as "azidium halides".



D. Reactions of Halogen Azides Used in Preparative Work

1. Reactions with Metal Halides

When gaseous chlorine azide, diluted with nitrogen, is passed into metal halides such as $TiCl_4$, $VOCl_3$, or $SnCl_4$ at room temperature, an exothermic reaction takes place in accord with equation (n) (cf. also Section C) and metal monoazide halides are precipitated [4].

$$TiCl_4 + ClN_3 \rightarrow TiCl_3N_3 + Cl_2 \qquad (n)$$

This reaction can be used for the synthesis of Cl_3SnN_3, $VOCl_2N_3$ [4], and CrO_2ClN_3 [21]. These metal azide chlorides are crystalline, generally explosive solids; in solution in $POCl_3$ they are monomeric, but in the solid state they tend to associate [4] and are thus stabilized (cf. Section 5):

Not all metal halides containing the metal in its highest valence state are known. However, metal halides of lower valence states, *e.g.* VCl_4 or $MoCl_5$, can be oxidized with ClN_3 [18, 21]:

$$VCl_4 + ClN_3 \rightarrow VCl_4N_3 + {}^1/_2\, Cl_2 \qquad (o)$$

Metal halides that are solid at room temperature and are only slightly soluble in CCl_4 will react, as a slurry, with ClN_3. This method has been used for the conversion of $MoCl_5$ into $MoCl_5N_3$, WCl_6 into WCl_5N_3 [21], and UCl_5 into UCl_5N_3 [22]. The monoazide chlorides of molybdenum and tungsten dissolve readily in CCl_4 to give deep red solutions, in which the compounds are probably present in the monomeric form. $MoCl_5N_3$ and WCl_5N_3 are extremely explosive; in these compounds the stability is considerably decreased by the coordinative saturation of the central atoms Mo and W, which prevents association of the α-N atom of the azide group with a neighboring metal atom [21].

The reactions of chlorine azide with metal chlorides can, in principle, also be applied to bromine azide and metal bromides; this reaction is illustrated by equation (p).

$$WBr_5 + BrN_3 \rightarrow WBr_5N_3 + {}^1/_2\, Br_2 \qquad (p)$$

The properties of WBr_5N_3 [22] are similar to those of WCl_5N_3.

Sometimes, a second azide group can also be introduced with the aid of chlorine azide. Thus $MoCl_5N_3$, which is readily soluble in CCl_4, reacts to form the diamagnetic, highly explosive $MoCl_4(N_3)_2$ as shiny black crystals [21]:

$$MoCl_5N_3 + ClN_3 \rightarrow MoCl_4(N_3)_2 + Cl_2 \qquad (q)$$

In the metal azide halides discussed so far, the bonding of the azide group to the metal is essentially homopolar. This conclusion is based on the characteristic IR vibrations of the N_3 group, which are typical of homopolar bonding of the azide group, and on the metal-nitrogen stretching vibration, which cannot occur in an azide ion. The metal-azide group in every case forms an angle other than 180° at the α-N atom [4, 18, 21, 22]:

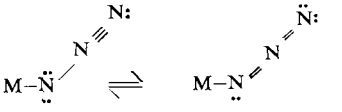


Table 4. Characteristic IR vibrations of azide groups in some metal azide chlorides.

	ν_{as} (N_3)	ν_s (N_3)	δ (N_3)	ν (M–N)	Ref.
$TiCl_3N_3$	2135	1230	659	565	[4]
$VOCl_2N_3$	2130, 2095	1249	698	560	[4]
CrO_2ClN_3	2145	1223	637	495	[21]
VCl_4N_3	2105	1190	703	556	[18]
$MoCl_4(N_3)_2$	2120, 2050	1260, 1230, 1215	683, 614	552	[21]
$SnCl_3N_3$	2158, 2137	1238, 1227	696	556	[4]

Whereas the metal azide halides discussed above associate only in the crystalline state, if at all, the reaction of chlorine azide with $SbCl_5$, which is analogous to the reaction (n), affords dimeric antimony azide tetrachloride [23, 25] $[SbCl_4N_3]_2$, which is soluble even in nonpolar solvents. In agreement with a suggestion of *Wiberg* and *Schmid* [24], this compound forms a four-membered Sb–N ring *(2)* using the α-N atoms of the azide groups. The vibration spectra (IR and Raman) indicate that this four-membered ring is planar (symmetry D_{2h}) both in the solid phase and in solution [25]. The ring can be cleaved with pyridine to form the adduct $[SbCl_4N_3 \cdot C_5H_5N]$, in which the

(2)

α-N atom of the azide group and the nitrogen atom of the pyridine occupy the *trans* positions on the octahedrally coordinated antimony [25].

The reaction of BCl_3 or BBr_3 with chlorine azide or bromine azide yields interesting products, namely the boron azide dihalides $[BX_2N_3]_3$ [26], which dissolve as the trimers in CCl_4 and benzene; the chlorine compound has also been prepared by another route [27]. The vibration spectra indicate that these compounds contain six-membered B–N rings *(3)*, which are characterized in particular by their planarity (symmetry D_{3h}) and a diazonium structure [26]:

(3)

Finally, it should be mentioned that ClN_3 and BrN_3 also take part in addition reactions. Thus ClN_3 reacts with PCl_3 to form the very unstable PCl_4N_3, which reacts further with PCl_3 to give the known compound $[Cl_3P{=}N{-}PCl_3]^{\oplus}Cl^{\ominus}$ [20] [25a] .Antimony azide tetrabromide can be obtained from $SbBr_3$ and BrN_3 in CCl_4 [20]:

$$SbBr_3 + BrN_3 \rightarrow SbBr_4N_3 \qquad (r)$$

2. Reactions of the Metal Azide Halides

Some metal azide halides decompose gently and in a definite manner under the influence of solvents, and are therefore of interest for the synthesis of nitride compounds.

It is possible to distinguish several types of decomposition:

1. In one case, nitrogen and chlorine are split off simultaneously, *e.g.*:

$$TiCl_3N_3 \rightarrow TiNCl + N_2 + Cl_2 \qquad (s)$$

$$VOCl_2N_3 \rightarrow VON + N_2 + Cl_2 \qquad (t)$$

The polymeric nitride compounds $(TiNCl)_x$ and $(VON)x$ are formed quantitatively in a very pure state when carbon tetrachloride solutions of the azide chlorides are heated [4].The decomposition of $MoCl_5N_3$ or WCl_5N_3 in CCl_4 under the same mild conditions leads, again quantitatively, to precipitates having the composition $MoNCl_3$ or $WNCl_3$:

$$MoCl_5N_3 \rightarrow MoNCl_3 + N_2 + Cl_2 \qquad (u)$$

The IR spectra of these substances indicate that the metal atoms have deformed tetrahedral coordination (site symmetries C_s or C_i) in the lattice, and Mo≡N and W≡N triple bonds are detected [21]. Mass-spectrometric examination shows that, in agreement with these findings, $MoNCl_3$ vaporizes as the monomer [28]. $MoNCl_3$ and $WNCl_3$ form adducts with pyridine in the molar ratio of 1:3 [21].

2. In another case, the metal azide halides decompose in a definite manner with elimination of nitrogen only, the initially formed radical being stabilized by migration of Cl from the metal to the nitrogen. Hexachloroborazole has been prepared in this way from $[BCl_2N_3]_3$ [27]. Another example is the decomposition of VCl_4N_3, which proceeds at room temperature and yields *N*-chlorovanadium imide trichloride:

$$Cl_4V{-}N_3 \xrightarrow{-N_2} [Cl_4V{=}N{:}] \rightarrow Cl_3V{=}N{-}Cl \qquad (v)$$

This type of reaction (v) is reminiscent of the Curtius acid degradation. IR-spectroscopic studies indicate that the intermediate radical probably contains a V=N double bond [18]. $VNCl_4$ sublimes readily, is soluble as the monomer in benzene, and, according to the IR spectrum, has a molecular symmetry C_s with an angular V=N–Cl grouping [18]. $VNCl_4$ forms adducts *via* the Cl atom attached to the nitrogen both with Lewis acids and with Lewis bases. Thus it forms a 1:1 adduct *(4)* with $SbCl_5$, and a 1:2 adduct *(5)* with pyridine.

$[Cl_3V{=}N]^{\oplus}\ [SbCl_6]^{\ominus}$ *(4)* $[Cl_3V{\equiv}N]^{\ominus}\ [Cl(C_5H_5N)_2]^{\oplus}$ *(5)*

Both compounds may be regarded as ionic [18], because they crystallize well, are insoluble in nonpolar solvents, and have no definite melting point. The IR spectra do not contain the characteristic N–Cl vibrations of $VNCl_4$. On the other hand, the spectrum of *(4)* contains the two IR-active vibrations (class F_{1u}) of the $SbCl_6^-$ octahedron, as well as the characteristic vibrations of the cation. The IR spectrum of the anion $VNCl_3^-$ in *(5)* agrees with that of the isoelectronic $VOCl_3$ [18].

3. Finally the metal azide halide may also react with the solvent. Owing to the high energy of the azide, reactions of this type can take place even under mild conditions. For example, antimony azide tetrachloride reacts with boiling CCl_4 to form triazidocarbonium hexachloroantimonate [28a]:

$$3\ SbCl_4N_3 + CCl_4 \rightarrow [C(N_3)_3^{\oplus}\ [SbCl_6]^{\ominus} + 2\ SbCl_5 \qquad (w)$$

According to its IR spectrum, the triazidocarbonium cation consists of a planar CN_3 skeleton with azido groups bent out of the plane (symmetry C_{3v}). The CN stretching frequencies agree with those of the guanidinium ion [28a].

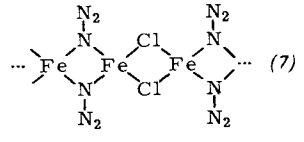
3. Reactions of the Halogen Azides with Metal Carbonyls

Chlorine azide and bromine azide react with the metal carbonyls $Fe(CO)_5$, $Mo(CO)_6$, and $W(CO)_6$ to form carbonylmetal azide halides $M(CO)_2N_3Cl$ [29]:

$$Fe(CO)_5 + ClN_3 \rightarrow Fe(CO)_2N_3Cl + 3\ CO \qquad (x)$$

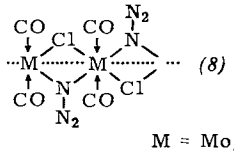
According to the IR spectra and magnetic behavior, the iron compound $Fe(CO)_2N_3X$ consists of substantially planar four-membered Fe–N rings *(6)*, the halogen being ionically bonded (pseudosymmetry D_{2h}) [29]:



(6), X = Cl, Br

These compounds exhibit the paramagnetism of the unperturbed Fe(II) ion (μ = 5.29 B.M.) and obey the Curie law (θ = 0 °C); they are the first paramagnetic carbonyliron derivatives [29]. The Fe–C bonds appear to be pure σ bonds without any back-donation. Thermal degradation under vacuum at 80 °C yields the CO-free azide halides of Fe^{II}, $FeClN_3$ and $FeBrN_3$, which are also paramagnetic:

$$Fe(CO)_2N_3Cl \rightarrow FeClN_3 + 2\ CO \qquad (y)$$



The IR spectra of the iron(II) azide halides indicate that they are polymeric *(7)*, the azide groups retaining their bridge function [29]:

(7)

The genetic relationship with the carbonylmetal azide is obvious. Neither the carbonylmetal azide halides nor the CO-free azide halides of Fe^{II} are explosive; utilization of the lone pair of electrons on the α-N atom offers an explanation of these facts.

The carbonylmetal azide halides of Mo and W are also polymeric *(8)*, but in this case both Cl and N_3 assume bridge functions [29].

(8)

M = Mo, W

This leads to strong metal-metal interactions, as can be seen from the magnetic behavior: $[Mo(CO)_2ClN_3]_\infty$: μ = 0.81 B.M., θ = −20 °C; $[W(CO)_2ClN_3]_\infty$: $\chi_{mole} = -74.9\times10^{-6}$. The carbon monoxide cannot be removed completely from these compounds without risk of explosion [29].

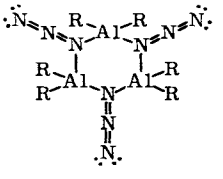
4. Reactions of the Halogen Azides with Organometallic Compounds

Chlorine azide can react with organometallic compounds according to equation (z). These reactions can be carried out in solvents (*e.g.* benzene, pentane, CCl_4) or in the absence of solvents, and lead to excellent yields of metal monoazide derivatives [30]:

$$MR_x + ClN_3 \rightarrow MR_{x-1}N_3 + RCl \qquad (z)$$

For example, dimethylcadmium gives the hygroscopic, white, crystalline methylcadmium azide $[H_3C\text{-}Cd]^{\oplus}N_3^{\ominus}$, which appears from its IR spectrum to be ionic (symmetry of the cation C_{3v}) [30].



On the other hand, the alkylmercury and arylmercury azides obtained by reaction (z) form white, readily sublimable, non-hygroscopic crystals, which are soluble in benzene (monomeric), and whose vibration spectra (IR and Raman) indicate the presence of linear C–HgNNN groups [30,31]:

R = CH_3, C_2H_5, n-C_3H_7, i-C_3H_7 n-C_4H_9, C_6H_5

Ethylzinc azide and phenylzinc azide can also be prepared as in equation (z) from carefully purified chlorine azide. These compounds form white, hygroscopic, explosive crystals, whose physical and chemical properties are intermediate between those of the corresponding cadmium and mercury compounds [31a].

Trialkylaluminums also react readily with chlorine azide to form dialkylaluminum azides [30,32]. The ethyl compound (m.p. −130 °C) dissolves in benzene as the trimer, can be distilled (10^{-3}mm Hg) at 63 °C without decomposition, and is not exploded either by shock or by heat. According to the vibration spectrum, the aluminum atoms are linked with the α-N atoms to form a planar, six-membered Al–N ring *(9)* (symmetry D_{3h}) [30,32]. The indicated electron distribution on the N_3 groups is deduced from thermal and spectroscopic behavior.

(9)

The same structure, with a six-membered Ga–N ring, is found in diethylgallium azide $[(C_2H_5)_2GaN_3]_3$, which is obtained from $Ga(C_2H_5)_3$ and chlorine azide; this compound is again trimeric, and is a colorless, distillable liquid [32a]. In contrast with the diethylalu-

minum azide, the gallium compound does not react with water [32a].

On the other hand, diethylindium azide, which is prepared from triethylindium and chlorine azide, forms crystals that are insoluble in benzene, the α-N atom of the azide group giving rise to polymerisation [32b] in accordance with formula *(10)*.

(10)

5. The Stability Relationships of the Azides

Relatively little is known at present of the thermodynamics of azides; a review has been published by *Gray* [33]. However, chemists are also interested in kinetic aspects, since *e.g.* a prerequisite for handling of an azide is that the activation energy for its decomposition must be sufficiently high. In the case of the diorganylborazides, the kinetics of the decomposition depend on both the bulk and the inductive effect of the organic ligands [33a].

The above discussions show that the classification into stable "azide ions" and "unstable homopolar azides" will have to be extended. Thus it has been seen that stabilization of covalently bonded azide groups is also possible. From experience gained so far, such groups are always stabilized when the α-N atom of the N_3 group forms an additional bond. It is possible to distinguish two cases.

1. The formation of the additional bond by the α-N atom may lead to a multiple bond (dπ–pπ interaction) between the metal and the N_3 group. This requires a sufficiently large d-orbital contribution of the metal, and leads to widening of the bond angle at the α-N atom. Stable conditions of this nature are observed in the monomeric alkylmercury azides $R-Hg=N=N=\dot{N}:$, which contain linear structural groups [30]. The electron requirements of the mercury appear to be satisfied in this way. A second azide group cannot lead to further stabilization; $Hg(N_3)_2$ is explosive.

This case also includes the very stable alkyl and aryl azides of elements of group IV [34,35], though this appears to contradict the calculated force constants for the Si–N bond in trimethylsilyl azide [36].

If the electron requirements of the central atom are satisfied by other ligand atoms, the N_3 group cannot be stabilized in this way, and the resulting azide derivatives are explosive. This situation is found in metal azide halides such as $MoCl_5N_3$, $MoCl_4(N_3)_2$, WCl_5N_3 [21], and WBr_5N_3 [22], in which the electron requirements of the metal are evidently satisfied by the halogen atoms. This concept also explains, in principle, the increase in the stability of the halogen azides from FN_3 to BrN_3 (cf. Section C). FN_3 is the least stable, since no strengthening of the F–N bond is possible; consequently the α-N atom cannot reduce its excess of electrons. HN_3 and CH_3N_3 are also explosive because electrons cannot be transferred into the H–N or C–N bond.

2. Another possibility for the stabilization of covalently bonded N_3 groups is found in the azide derivatives that associate *via* the α-N atom. This always occurs when the central atom is coordinatively unsaturated, so that an additional bond can be formed between this atom, as a Lewis acid, and the α-N atom as a Lewis base. The result is the formation of four-membered or six-membered rings or of polymers *e.g.* the dimeric antimony azide tetrachloride *(2)*, the trimeric diethylaluminum azide *(9)*, and the polymeric diethylindium azide *(10)*. A special case of this mode of stabilization is the protonation of hydrazoic acid $H_2N_3^+$ (as the hexachloroantimonate) [37]. This stabilization results mainly from the possibility of resonance in the N_3 group:

Additional stabilization is to be expected in ring formation (provided that the rings are strainless) as a result of the entropy effect.

Many azidometal complexes are known, *e.g.* $[Pt(N_3)_6]^{2-}$, in which additional stabilization is achieved by the incorporation of bulky cations, *e.g.* $[As(C_6H_5)_4]^+$ [39].

Table 5. Some stabilized azides.

Formation of Amino Acids and their Precursors from Primitive Compounds by High-Temperature Synthesis

By *M. Taube, St. Z. Zdrojewski, K. Samochocka*, and *K. Jezierska*[*]

On high-temperature synthesis of amino acids from methane, ammonia, and water vapor we have found numerous intermediates as well as three amino acids (lysine, tryptophane, and β-alanine) whose formation had not previously been reported[1–3]. We obtained the best yields of amino acids in a streaming apparatus under the following conditions: CH_4 0.5 l/min, NH_3 0.3 l/min, and H_2O 0.2 l/min; the residence time of the gases in the reaction zone was 0.125 sec; warming of the gases from 100 to 800 °C required 0.28 sec, and cooling to 20 °C required 0.4 sec; the optimal temperature in the reaction zone was 1000 °C, 95.4% of the NH_3 in the reaction mixture then undergoing conversion. Yields of amino acids were very low at 900 °C, and at 1150 °C the methane was converted into graphite. At 1050 °C aromatic hydrocarbons and oxygen compounds (mainly acetaldehyde and propionaldehyde) constituted up to 1% of the total product; at this temperature the proportion of nitrogen compounds (methylamine, ethylamine, hydrogen cyanide) amounted to 10 mole-%. The reaction zone was filled with silica gel (particle size 3 to 6 mm).

The products of synthesis were identified by gas chromatography and the individual amino acids by high-voltage paper electrophoresis (50 V/cm).

The compounds identified are listed in the following table.

C, H, N, O compounds identified by gas chromatography (mole-%)

Hydrocarbons		Oxygen compounds	
Benzene	0.16–0.58	Acetaldehyde	0.05–0.29

Pentacyclo[4.3.0.0^{2,4}.0^{3,8}.0^{5,7}]nonane

By *H. Prinzbach* and *D. Hunkler*[*]

The differing rates of the light-induced valence isomerizations *(1)* → *(2)* and *(3)* → *(4)* have been ascribed to the differing overlaps between the π- and the Δ-orbitals[1] in *(1)* and *(3)*[2].

We have now isomerized compounds of type *(5)* photochemically to the corresponding pentacyclic compounds *(6)*. Compound *(6a)* is not formed in isolable amounts under the conditions that are optimal for the change *(1)* → *(2)* (R = CO_2H; yield in water > 90%); further, the yield of *(6b)* is only a few percent when the ester *(5b)* is irradiated in ether. However, isomerization of *(5b)* in glacial acetic acid and of *(5a)* in this solvent, dioxane, or in tetrahydrofuran-ether (5:1 to 7:4)[3] can be achieved, giving (so far) yields of 15 to 30%[4].

(a) R = CO_2H
(b) R = CO_2CH_3 (d) R = CN
(c) R = $CONH_2$ (e) R = $CO_3C(CH_3)_3$

The structure of *(6a)* is proved by the several reactions *(6b)*–*(6e)* as well as by NMR results.

	M.p. (°C)	^{1}H–NMR (τ-values)			
(6a)	246–247	6.69 (4H)	6.98 (2H)	7.82 (2H)	(in CF_3CO_2H)
(6b)	64	6.31 (6H)	7.20 (6H)	8.08 (2H)	(in CCl_4)
(6e)	93–94	7.20 (6H)	8.07 (2H)	8.72 (18H)	(in CCl_4)

On pyrolysis of the di-t-butyl peroxyester *(6e)* in 1,3,5-triisopropylbenzene (N_2 stream; 150–155 °C) we obtained pentacyclo[4.3.0.0^{2,4}.0^{3,8}.0^{5,7}]nonane *(7)*, m.p. 82–84 °C (after repeated sublimation) in 40% yield.

IR: 3067, 2994, 2959, 1302, 1040, 1014, 970, 897, 889, 881, 783, 766, 754 cm^{-1}.

UV: no maximum above 210 μm.

NMR[5]: τ = 7.47 (2H), 7.80–8.20 (8H) in $CDCl_3$ (100 MHz).

Mass spectrum[5]: M^+ = 118 (base peak), and readily assignable peaks *m/e* = 116, 103, 91, 78, 65, 51, 39, and 27, as well as *m/2e* = 57.5.

The pentacycles *(6b)* and *(7)* are very stable thermally. For instance, heating *(6b)* alone or in dimethyl acetylenedicarboxylate (300 °C) does not cause isomerization to *(5b)* or

addition analogous to that of quadricyclene[6] or oxaquadricyclene[7]. Furthermore, heating *(7)* in perchlorobutadiene to 300 °C (50 min) is not sufficient to cause valence isomerization.

Synthesis of *N*-Carboxy-α-amino Acid Anhydrides

By *D. Konopińska* and *I. Z. Siemion*[*]

N-Carboxy-α-amino acid anhydrides *(1)* are starting materials for the synthesis of polypeptides. We have found a new process for the preparation of these anhydrides, namely, treatment of *N*-(benzyloxycarbonyl)amino acids with oxalyl chloride. The acid chloride[1] is first formed, and then cyclizes to form the anhydride.

1 mmole of an *N*-(benzyloxycarbonyl)amino acid is allowed to react with 2 mmoles of oxalyl chloride in 1.5 to 2.5 ml of boiling benzene for 2 to 3 min. The reaction mixture is cooled in a refrigerator and after a short time the amino acid anhydride crystallizes. The leucine derivative is an exception, crystallizing only after addition of petroleum ether.

Parent amino acid	Anhydride		M.p. (°C) lit.
	Yield (%)	M.p. (°C) found	
D,L-Phenylalanine	92	124–125	125–126 [2]
L-*S*-Benzylcysteine	74	102–104	105–106 [3]
D,L-Alanine	69.9	4–46	44–45 [2]
D,L-Valine	71	78–79	77–70 [2]
L-Leucine	65	71–73	76–77 [4]

Prolonged heating of the components leads to formation of polymeric products. If *N*-(benzyloxycarbonyl)glycine is heated with oxalyl chloride for only 2 to 3 min, a product is obtained that does not melt sharply and contains appreciably more nitrogen than is calculated for the anhydride *(1)*.

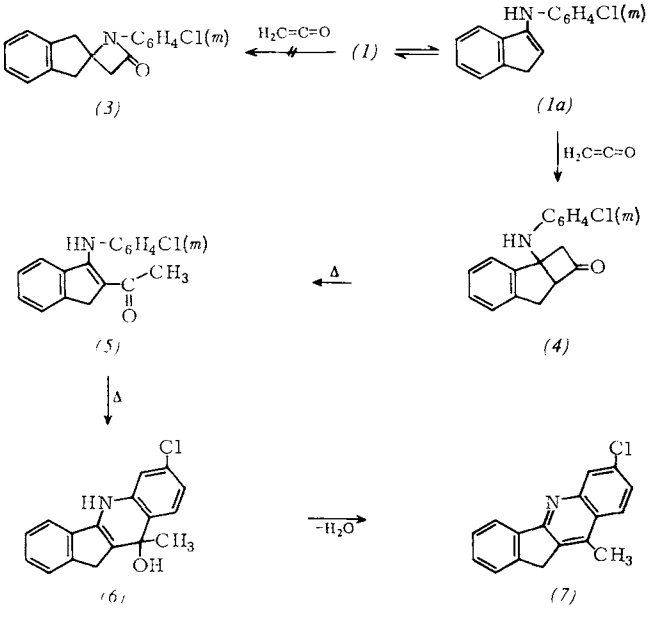
Synthesis and Reactions of *m*-Chloro-*N*-1-indandylideneaniline

By *J. Jaz* and *A. Gerbaux*[*]



We have obtained various derivatives of *N*-1-indanylideneaniline by cycloaddition of substituted phenyl azides to indene[1]. We have now prepared the first *meta*-phenyl-substituted derivative, *m*-chloro-*N*-1-indanylideneaniline *(1)*, by heating an equimolar mixture of *m*-chlorophenyl azide[3] and indene for 20 h, distillation in a high vacuum after gas evolution had ceased, and recrystallization from ether (yield 60%; m.p. 50–52 °C).

If, however, the reaction mixture is left for three weeks at room temperature, substance *(2)* in 40% yield (m.p. 124 to 125 °C; decomp. with gas evolution) is isolated, whose IR spectrum (in CCl_4) shows the bands between 940 and 1000 cm^{-1} that characterize triazolines. The ^1H–NMR spectrum (TMS/$CDCl_3$) shows a methylene doublet at $\tau = 6.45$ (J = 5 Hz), the signals of the angular hydrogen atoms H_a and H_b at $\tau = 4.67$ (J = 9 Hz), and a band system centred at $\tau = 2.75$ to be assigned to the aromatic protons. Compound *(2)* is thus 1-(*m*-chlorophenyl)indano[1,2-*d*]-Δ^2-1,2,3-triazoline. *cis*-Addition has occurred, as proved by the dihedral angle of 20 °C calculated for the protons H_a and H_b by the *Karplus* equation[4].

When heated at 90 °C compound *(2)* undergoes thermal decomposition to *(1)* (yield 82%), with violent evolution of gas. The structure of compound *(1)* was proved by its IR spectrum (CCl_4; imine band at 1600 cm^{-1}), elemental analysis, and chemical reactions: acid hydrolysis affords, as well as *m*-chloroaniline, 1-indanone (yield 20%; m.p. 39–40.5 °C), which was identified by its IR spectrum (CCl_4; carbonyl band at 1720 cm^{-1}), UV spectrum [in C_2H_5OH λ_{max} = 244 nm (ε = 10550), 286 nm (2650), 292 nm (2550)[5]], ^1H–NMR spectrum (TMS/$CDCl_3$; methylene triplet at $\tau = 7.37$ and 6.88; complex band system centered at $\tau = 2.53$, corresponding to four aromatic protons), and its 2,4-dinitrophenylhydrazone (m.p. 259–260 °C).

Passing ketene into the molten compound *(1)* did not give a spirolactam *(3)*[6,7] or a tricyclic cyclobutanone *(4)*, but instead a crystalline product $C_{17}H_{12}NCl$ (yield 75%; m.p. 138–138.5 °C), which, on the basis of its IR, UV, and ^1H–NMR spectra, is 9-chloro-6-methylindeno[3,2-*b*]quinoline *(7)* [IR (CCl_4) methyl bands at 1390 and 2980 cm^{-1};

UV (C_2H_5OH) λ_{max} = 210 nm (ε = 20600), 256 nm (9000), 366 nm (15500); ^1H–NMR (TMS/$CDCl_3$) 7 aromatic protons centered at τ = 2.60, 2-methylene protons at τ = 6.3, methyl protons at τ = 7.8].

The formation of compound *(7)* can be understood if one assumes that the enamine form *(1a)* reacts with ketene to yield *(4)*, which according to *Opitz*[8] is thermolabile and undergoes ring opening and acetylation to give *(5)*. At the reaction temperature, *(5)* (which is molten) undergoes intramolecular addition and cyclization to give *(6)*, which aromatizes to *(7)*. The position of the chlorine atom follows from the ^1H–NMR spectrum and from consideration of molecular models that show cyclization at the 4-position to be sterically hindered.

Thermal decomposition of compound *(2)* yields only *(1)*, whereas the formation of aziridines has been demonstrated for the *para*-substituted analogues of *(1)*[9]. On reaction of *para*-substituted phenyl azides (excepting the *p*-nitro derivative), 2:1 adducts to indene have been isolated and characterized.

Dialkyl(triphenylphosphoniomethyl)sulfonium Bis-salts and their Conversion into Stable Ylide Salts

By *J. Gosselck, H. Schenk*, and *H. Ahlbrecht*[*]

Reaction of α-chloro sulfides[1] with triphenylphosphine in benzene gives (alkyl-, aralkyl-, or aryl-thiomethyl)triphenylphosphonium chlorides *(1a)–(1f)* in 50–80% yields. If these compounds are warmed in acid-free dimethyl sulfate for 1 to 2 h at 90–100 °C, the group R is removed in all cases and dimethyl(triphenylphosphoniomethyl)sulfonium bismethyl sulfate) *(2a)* is formed. It is precipitated by anhydrous ether and isolated from aqueous solution as the bistetrafluoroborate or dipicrate.

Alkylation of the salts *(1b)–(1f)* with triethyloxonium tetrafluoroborate in nitromethane at 50 °C yields the diethyl compound *(2b)*. Treatment of *(1a)* with triethyloxonium tetrafluoroborate gives the ethylmethyl compound *(2c)*. The salts *(2b)* and *(2c)* were isolated by precipitation with anhydrous ether and recrystallized from anhydrous ethanol.

If suspensions of the salts *(2a)–(2c)* in cold anhydrous ethanol are treated with equimolar amounts of sodium ethoxide, ylide salts *(3a)–(3c)* (readily soluble in ethanol) are formed in 70 to 80% yield. These compounds are colorless and stable in air, crystallize well, and are isolated by removal of the solvent and repeated precipitation from methylene chloride/ether (1:5 v/v). Addition of tetrafluoroboric acid to ethanolic solutions of the ylide salts *(3a)–(3c)* regenerates the salts *(2a)–(2c)*.

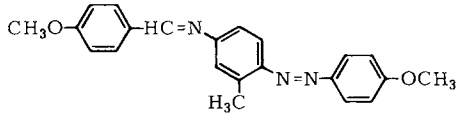
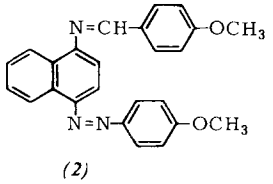
Azo Coupling to Schiff Bases. A New Synthesis of Naphthimidazole Derivatives

By *A. Messmer* and *O. Szimán*[*]



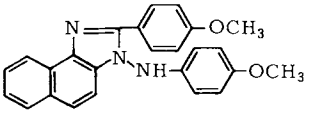
We have found that, in dipolar solvents that cannot take up a proton (nitromethane, nitrobenzene, acetonitrile), arenediazonium fluoroborates react by azo coupling with aromatic amines, and, surprisingly, also with Schiff bases from aromatic amines and aromatic aldehydes, whereas no reaction occurs with phenols. Adding ether to the reaction mixture precipitates the intensely colored fluoroborates of the aminoazo compounds. If the azo group is in the *para*-position to the amino group, the free base is liberated from the salt by pyridine; but if the azo group is in the *ortho*-position to the amino group, salts are formed on addition of pyridine and ring closure takes place to give condensed imidazole derivatives.

R	R′	(5) M.p. (°C)	(5) Yield (%)	(6) M.p. (°C)	(6) Yield (%)
p-CH_3O–C_6H_4	*p*-CH_3O–C_6H_4	168	70	177	80 [b]
C_6H_5	*p*-CH_3O–C_6H_4	165	81	185	88
C_6H_5	C_6H_5	175	72	199	62
p-O_2N–C_6H_4	*p*-Br–C_6H_4	[a]		249	95
p-O_2N–C_6H_4	*p*-O_2N–C_6H_4	[a]		304	99



[a] Not isolated. [b] The same product is obtained from *(7)* and *p*-anisaldehyde [1], whereby the structure of *(6)* is proved.

The reaction of *N*-(*p*-anisylidene)-*m*-toluidine with *p*-methoxybenzenediazonium fluoroborate in nitromethane or acetonitrile, gives the brownish-red, crystalline *N*-(*p*-anisylidene)-4-(*p*-methoxyphenylazo)-3-methylanilinium fluoroborate, m.p. 239 °C (yield 67%), which is quantitatively converted into the red free base *(1)*, m.p. 108 °C, by pyridine. Its structure is established by the fact that the same base can be prepared from 3-amino-4′-methoxy-2-methylazobenzene and *p*-anisaldehyde.



(1)

N-(*p*-Anisylidene)-α-naphthylamine and *p*-methoxybenzenediazonium fluoroborate in nitromethane give a dark blue mixture from which a mixture of red and white crystals is precipitated on addition of pyridine; these can be separated by recrystallization from ethanol. The red crystals are 4-(*p*-aminophenylazo)-*N*-(*p*-anisylidene)-1-naphthylamine *(2)*, m.p. 167 °C (yield 23%); the white crystals are *N*,2-di-(*p*-methoxyphenyl)naphtho[1,2-*d*]imidazol-3-ylamine *(3)*, m.p. 195 °C (yield 30%).

(2)

(3)

N-(*p*-Anisylidene)-β-naphthylamine *(4)*, R = *p*-CH_3O–C_6H_4, has been observed to couple with *p*-methoxybenzenediazonium fluoroborate in the *ortho*-position only. In this case a blue color develops within 30 min of mixing equivalent amounts of the reactants in acetonitrile ar room temperature. On addition of ether *N*-(*p*-anisylidene)-1-(*p*-methoxyphenylazo)-2-naphthylammonium fluoroborate *(5)*, R = R′ = *p*-CH_3O–C_6H_4, is precipitated as deep blue crystals. With pyridine these give white crystalline *N*,2-bis-(*p*-methoxyphenyl)naphtho[1,2-*d*]imidazol-1-ylamine *(6)*, R = R′ = *p*-CH_3O–C_6H_4.

The azo coupling of aromatic amines in nitrobenzene at 20.0 ± 0.1 °C is a reaction of the third order: $v = k$ [Diaz] [Amine]^2 (measurement of unused diazonium salt). The azo coupling of Schiff bases is autocatalytically accelerated after a slow start. Apparently, in coupling with amines, the proton is removed from the σ-complex by the amine, whereas, in coupling with the less basic Schiff bases, the product is necessary for this purpose.

The Schiff bases react only at concentrations above 10^{-2} mole/l. Schiff bases from ketones do not react.

The Structure of the Uridine Dimer Produced by UV Irradiation of Uridine [1]

By *E. Fahr*, *G. Fürst*, *G. Dörhöfer*, and *H. Popp*[*]

UV irradiation of uracil or thymine in an ice matrix affords dimeric pyrimidines that are interesting for interpretation of biological radiation damage. We have been able to isolate the dimeric uridine[2], which is produced on UV irradiation of uridine *(1)*, and have proved its structure to be that of *(2)*.

(1) R = Ribosyl

(2), R = Ribosyl
(3), R = H

Frozen aqueous uridine solutions (*ca.* −5 °C) were irradiated with a low-pressure Hg lamp (Hanau NK 6/20)[3] and the products were separated by column chromatography on

cellulose (liquid phase: butan-1-ol/propan-1-ol/water = 1:1:1 v/v). Dimeric uridine (R_F = 0.13) appeared as third fraction, after uridine and 5,6-dihydro-6-hydroxyuridine, and was obtained analytically pure: colorless crystals, m.p. 178–179 °C (from ethanol); Mol. wt. (cryoscopically and osmometrically in water) 480 (calc. 488).

By degradation of the dimeric uridine *(2)* with concentrated hydrochloric acid [80 mg (0.16 mmole) in 10 ml conc. HCl, 4 h reflux] and thin-layer chromatographic separation we obtained uridine and uracil [fission of the cyclobutane ring of *(2)*], as well as the dimeric uracil *(3)* of known structure[4] (identified by comparison of IR data with data for a sample of *(3)* prepared by UV irradiation of uracil; and by chromatographic data: thin-layer chromatography on silica gel (n-propanol/water, 7:3 v/v) R_F = 0.47, (n-butanol/water (saturated)) R_F = 0.18).

Since *(3)* is unchanged under the conditions used (as proved by boiling a solution of *(3)* in conc. HCl for 4 h) the dimeric uridine has structure *(2)*.

Contrary to expectation, the irradiation of uridine in an ice matrix leads to a dimer[5] in which the sugar residues are oriented next to one another.

Optically Active 2,2'-Dimethylbiphenyl, the Simplest Atropisomeric Hydrocarbon

By *W. Theilacker* and *Horst Böhm*[*]

2,2',3,3'-Tetramethylbenzidine *(1a)* can be obtained relatively easily in optically active form[1], and optically active 2,2',3,3'-tetramethylbiphenyl *(1b)* can be obtained from it by deamination[2]. Both compounds have considerable optical stability although the atropisomerism is caused only by two relatively small *ortho*-substituents in the biphenyl molecule. This stability is caused on the one hand by the support

(1a), X = NH_2
(1b), X = H

(2), X = NH_2
(3), X = H

(buttressing effect) given by the methyl groups in the 3,3'-positions to the 2,2'-substituents and on the other to the fact that these compounds have a relatively large negative racemization entropy. If the buttressing substituents are removed, the optical stability decreases appreciably; earlier unsuccessful attempts to obtain optically active 2,2'-dimethylbenzidine confirmed this.

For the preparation of optically active 2,2'-dimethylbiphenyl we therefore started from optically stable (+)- or (−)-2,2'-dimethylbiphenyl-6,6'-diamine[3] *(2)*. We diazotized this in hydrochloric acid solution at −10 °C and deaminated it with hypophosphorous acid and copper(I) oxide/copper(II) sulfate at approximately −35 °C. The solution was extracted with isobutene at −50 °C, the extract poured through aluminum oxide at −50 °C, and the isobutene evaporated at −78 °C. The optically active 2,2'-dimethylbiphenyl *(3)* obtained in this way was dissolved in dimethylformamide at −55 °C, and the optical rotation of this solution was measured after various times at temperatures between −30 °C and −36 °C.

The following data were obtained for the racemization:

T (°C)	−35.46	−34.42	−33.04	−32.28	−30.94
$k_{rac} \times 10^3$ [s^{-1}]	1.035	1.182	1.426	1.569	1.876

E_A = 15.1 ± 0.4 kcal mole^{-1}; $\Delta H^{\ddagger}$ = 14.6 ± 0.4 kcal mole^{-1}; $\Delta S^{\ddagger}$ = −11.6 ± 1.8 cal mole^{-1} deg^{-1} (calc. for inversion); $\Delta G^{\ddagger}$ = 17.4 kcal mole^{-1} at −35 °C, 18.1 kcal mole^{-1} at + 25 °.

The half-reaction time for racemization at −32 °C is 7 min; that calculated for +25 °C is 1.1 sec.

Since the absolute configuration of *(2)* is known[4] and configuration is not reversed on deamination, the absolute configuration of *(3)* is also established. (+)-*(2)* ($[\alpha]_{546}^{+20}$ = + 53.8°; c = 1.13; ethanol) receives the chirality symbol *(R)*[5]; the (−)-form of *(3)* (maximum value: $[\alpha]_{546}^{-33}$ = −26°; c = 2.7, dimethylformamide) resulting therefrom receives the same chirality symbol.

Anion Radicals from 1-Nitroolefins

By *A. Berndt*[*]

Independently of recent papers[1,2] concerning radicals of unproved[1] or, in the light of our results, incorrectly assigned structure[2], that were formed on reduction of 1-nitroalkenes, we have studied electrolytic one-electron reduction[3] of substituted 1-nitroalkenes *(1)* in acetonitrile. We have thus obtained the first anion radicals from 1-nitroolefins that have been conclusively characterized as radicals of type *(2)* by electron spin resonance (ESR) spectra[4]. The radicals were generated at a platinum cathode in acetonitrile containing 10^{-3} mole/l of *(1)* and 10^{-1} mole/l tetra-n-propylammonium perchlorate as supporting electrolyte, within the ESR spectrometer cavity.

The lifetimes of the new radicals lie between a few minutes and some hours, according to the substituents, the nature of R^1 being of little influence. Substituents R^2 and R^3 that

contribute to delocalization of the unpaired electron, or by their space-filling reduce the chemical reactivity at C^2, are particularly effective in prolonging the life. When R^2 or R^3 = H no anion radical was observed.

Table 1 shows the properties of the new nitroalkenes *(1)*, together with the nitrogen and proton coupling constants a_N and a_H, respectively, of the radicals *(2)* that could be unambiguously assigned. Fig. 1 illustrates a particularly simple ESR spectrum.

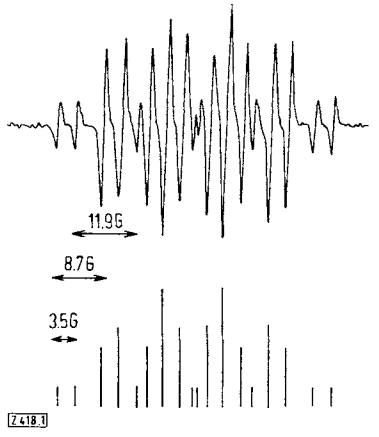

Fig. 1. ESR spectrum of the anion radical from 2-methyl-1-nitro-2-t-butylethylene *(2f)*, and the line spectral diagram.

Table 1. Properties of nitroalkenes *(1)* and radicals *(2)*.

	R^1	R^2	R^3	*(1)* M.p. (°C) or b.p. (°C/mm)	*(2)* a_N	*(2)* $a_H(R^1)$	*(2)* $a_H(R^3 = CH_3)$

(h)	NO_2	C_6H_5	C_6H_5				
	NO_2	C_6D_5	C_6D_5	149	2.8	—	—

[a] Coupling constants (in gauss) of the phenyl protons: a_o and a_p = 1.2; a_m = 0.6.

[b] Stable radicals are also obtained from 9-nitromethylenefluorene (R^1 = H, $R^2 + R^3$ = biphenylylene) and 9-(α-nitrobenzylidene)fluorene ($R^1 = C_6H_5$, $R^2 + R^3$ = biphenylylene), m.p. 123 °C. Their ESR spectra are under study.

The spin density distribution was calculated [7] by *McLachlan*'s method [5] with the parameters for aromatic nitro anion radicals [6]. The nitrogen coupling constants a_N were calculated from the resulting spin densities on nitrogen ρ_N and oxygen ρ_O from equation (a) [6].

$$a_N = (99.0 \pm 10.2)\,\rho_N - (71.6 \pm 11.8)\,\rho_O \qquad \text{(a)}$$

The calculated and the experimental coupling constants are compared in Table 2.

Table 2. Experimental and calculated nitrogen coupling constants a_N (in gauss).

	(2b)	*(2c)*	*(2d)*	*(2e)*	*(2f)*	*(2g)*	*(2h)*
exp.	6.3	7.0	7.9	10.4	11.9	11.6	2.8
calc.	5.4	6.5	9	12	11.8	11.8	2.1

Nitrogen coupling constants of 24.0 and 23.3 gauss have been given for the reduction products of 2-nitropropene [2] and ω-nitrostyrene [2], respectively. According to our calculations 11 gauss and 6–7 gauss, respectively, are to be expected for these anion radicals. a_N values of *ca.* 24 gauss are characteristic of anion radicals from aliphatic nitro compounds [8]. The existence of radicals of this structure is also indicated by the number of proton coupling constants that has been given [2] for the radicals from 2-nitropropene and ω-nitrostyrene.

Imidophosphinatotin Halides [1]

By *A. Schmidpeter* and *K. Stoll* [*]

Diphosphinic imides $(R_2PO)_2NH$ (imidodiphosphinic acids) behave as univalent bidentate ligands toward transition metals [2, 3] and toward main group elements [4] of coordination number 6; in the latter case a larger variety of types of compounds are formed.

$SnCl_4$ or $SnBr_4$ and $((C_6H_5)_2PO)_2NH$ give first adducts *(1)*, which yield bis(imidodiphosphinatotin dihalides *(2)* under the action of a weak base, *e.g.* when boiled with water. This reaction appears to indicate structure *(3)* for the adduct which however is not in accord with the Mössbauer spectrum (only one resonance line with an isomeric shift that is distinctly different from that of SnX_6^{2-}; on the other hand the shifts come close to those of 2,2'-dipyridyltin(IV) halide adducts [5]).

	M.p. (°C)	Sn isomeric shifts (mm/sec) [a]	ν (Sn–X) (cm^{-1})
(1a)	286–292	0.40	342, 330, 304, 170
(1b)	278–280	0.63	244, 226, 209

[a] Relative to SnO_2. – Shifts for $SnCl_6^{2-}$ 0.50 mm/sec, for $SnBr_6^{2-}$ 0.87 mm/sec [5].

In agreement with structure *(1)* the IR spectra contain three to four absorption bands assignable, very probably, to SnX vibrations; the presence of the HN group is shown by a band at 3130 cm^{-1}. The molecular size could not be determined since *(1a)* and *(1b)* are insoluble in non-solvolysing media, *(2a)* and *(2b)* are formed, not only by the solvolytic disproportionation of *(1a)* and *(1b)*, but also by melting *(1a)* or *(1b)* with further $((C_6H_5)_2PO)_2NH$, from SnX_4 and $((C_6H_5)_2PO)_2NNa$, and by addition of Cl_2 or Br_2 to tin(II) bis(tetraphenylimidodiphosphinate) *(5)*.

(5) is formed on melting together tin(II) acetate and $((C_6H_5)_2PO)NH$ in a vacuum. It is soluble and monomolecular in polar organic solvents and aromatic compounds, and according to its ^{31}P–NMR spectrum it contains only equivalent phosphorus atoms, so that it is also a chelate.

(2c) is obtained directly from SnI_4 and $((C_6H_5)_2PO)_2NH$. The complexes *(2)* apparently exist in the *cis*-form; their dipole moments in dioxane amount to 7 to 8 Debyes. *(2c)* in CH_2Cl_2 gives two ^{31}P-resonance signals of comparable intensity.

	(2a)	*(2b)*	*(2c)*	*(5)*
M.p. (°C)	325–327	283–285	yellow, 258–260 (dec.)	215–217
δ (^{31}P) (ppm) [b]	−28.8	−28.4	−28.0; −26.3	−17.9
	(4a)	*(4b)*	*(4c)*	
δ (^{31}P) (ppm) [b]	−45.8	−44.5	−43.3	

[b] Measured in CH_2Cl_2; relative to 85% H_3PO_4; negative values refer to lower field strengths.

Compounds *(2)* are cleaved back to *(1)* and $((C_6H_5)_2PO)_2NH$ by hydrogen halides; anhydrous perchloric acid, however, is added, yielding *(4)*. Structure *(4)* is proved by equivalence of the phosphorus atoms in the ^{31}P–NMR spectrum, the appearance of NH bands at 2925 and 2640 cm^{-1}, and solvolytic removal of $HClO_4$ by acetonitrile or methanol, to give *(6)* or *(2)*, respectively.

The IR spectra of *(4)* do not correspond with those of the adducts from SnX_4 and $((C_6H_5)_2PO)_2NH$. This confirms chemically that the correct formula for the adduct is *(1)*, and not *(3)*.

The Molecules Pd_6Cl_{12} and Pt_6Cl_{12} in the Gaseous State. A Contribution to the Problem of M_6X_{12} Groups

By *H. Schäfer, U. Wiese, K. Rinke*, and *K. Brendel*[*]

Palladium(II) chloride crystallizes in an α-form which, according to *Wells*[1], contains endless chains of coplanar $PdCl_{4/2}$ units ($_\infty[PdCl_{4/2}]$; Fig. 1a). We have found a β-form which, according to Guinier photographs, is isotypic with the modification of platinum(II) chloride described by *Broderson, Thiele*, and *von Schnering*[2]. Thus the Pd_6Cl_{12} molecules assume a space-centered arrangement $I\bar{4}3m$ ($[Pd_6Cl_{12}]$; Fig. 1b). When tempered at 500 °C, this β-form passes into the α-form. The β-modification $[Pd_6Cl_{12}]$ is formed when either form is sublimed in a vacuum.

In the mass spectrometer both modifications yield Pd_6Cl_{12} molecules (mean mol. wt. 1064) with high intensity; $(PdCl_2)_n$ molecules with $n \neq 6$ do not occur. It is therefore improbable that the Pd_6Cl_{12} molecules observed have a chain or ring structure. Pd_6Cl_{12} molecules (as in Fig. 1b) apparently occur in the gas phase, as in the β-modification[3].

Particular interest attaches to the ready transition: chain ⇄ polyhedron. We attribute this to the fact that a Pd_6Cl_{12} polyhedron can be developed from a $[PdCl_{4/2}]$ chain (Fig. 1c). Starting from the end of the chain, one has only to break one of the four bonds attached to each Pd atom, whereby the connection through the chain remains but free rotation becomes possible around each bond. In terms of molecular kinetics this doubtless occurs by opening of alternate bonds and reclosure thereof in their new positions. All the bond angles (Pd–Cl–Pd and Cl–Pd–Cl) remain unchanged. It should be emphasized that this is the first reasonable demonstration of the way in which such M_6X_{12} groups can be formed.

Evaluation of data in the literature[3,4] gives the following bond energies for the Pd–Cl bond: $_\infty[PdCl_{4/2}]$ chain (α-$PdCl_2$) 48 kcal; gaseous Pd_6Cl_{12} 46 kcal; gaseous monomeric $PdCl_2$ 62 kcal. The bond energy for the chain is almost identical with that for the polyhedron. It is significant that the first of the four Pd–C bonds of a $PdCl_{4/2}$ unit is more easily broken than the others and it is for this reason that the chain is not disrupted in forming the polyhedron.

On vaporization of the platinum(II) chloride from a preparation that contains a high proportion of the $[Pt_6Cl_{12}]$ modification, the heaviest particles seen in the mass spectrometer are Pt_6Cl_{12} molecules (mean mol. wt. 1596)[5]. However, ions such as $Pt_4Cl_8^{\oplus}$ and $Pt_5Cl_{10}^{\ominus}$ (of somewhat lower intensity than $Pt_6Cl_{12}^{\oplus}$) are found. This behavior is different from that of Pd_6Cl_{12}.

If the dsp^2-orbitals of the metal atom are used for binding $Cl^{\ominus}$ ions in planar arrangement, the remaining d-orbitals of the palladium or platinum are fully occupied and are not available for metal-metal bonding. The existence of Pd_6Cl_{12}

and Pt_6Cl_{12} in the gas phase expressly confirms the fact that $[M_6Cl_{12}]$ polyhedra are held together by Cl bridges. The importance and the choice of the "inner" atoms X^i [6] that are multiply bound to the M_6 octahedra in such polyhedra (also where M = Nb, Ta, Mo, or W) thus appear in a new light.

Metal atoms in compounds of the type $[Nb_6Cl_{12}]Cl_{4/2}$ or $[Mo_6Cl_8]Cl_2Cl_{4/2}$ have also the same arrangement of chlorine atoms corresponding to the dsp^2-hybridization [7]. However, the atomic distances found show that in these cases there are also metal-metal bonds:

In the $[Nb_6Cl_{12}]^{2\oplus}$ group the available six 4d-orbitals of the niobium atoms combine to give 8 fully occupied three-centre bonds [8] that lie on the faces of the octahedron.

In the $[Mo_6Cl_8]^{4\oplus}$ group the 6×4 d-orbitals of the Mo atoms combine to give 12 fully occupied single bonds that lie along the edges of the M_6 octahedron.

Finally the p_z orbitals of the metal atoms can be occupied. This enables further "outer" [6] atoms X^a to be bound. So groups can be joined by atoms X^a, *e.g.* in $[Nb_6Cl_{12}^i]$-$Cl_{4/2}^a$ [9] and $[Mo_6Cl_8^i]Cl_2^aCl_{4/2}^a$ [6], or there may be complete saturation without further connection, *e.g.* in $K_4[Nb_6Cl_{12}^i]Cl_6^a$ [10] or $\{[Mo_6Cl_8^i]Cl_6^a\}^{2\ominus}$ [11].

Pd_6Cl_{12} and Pt_6Cl_{12} should also have the capacity to bind electron-donors; this should be tested.

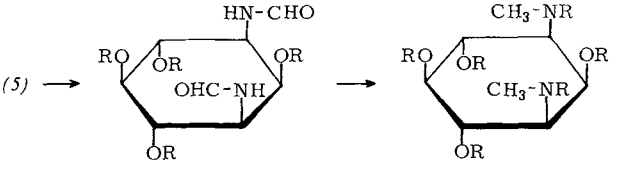
A Simple Synthesis of Streptamine and Actinamine

By *F. W. Lichtenthaler, H. Leinert*, and *T. Suami* [*]

Three syntheses are known [1] for streptamine, a building unit of streptomycin and related antibiotics, and one for actinamine [2], a unit in the antiobiotic actinospectacin. We have devised a simple synthesis of these two units, starting from *myo*-inositol and requiring, respectively, four and six steps.

trans-3,4,5-Trihydroxy-2,6-phenylhydrazonocyclohexanone *(2)*, which can be prepared from *myo*-inositol *(1)* in 10 % yield in three steps [3], is converted on reduction by sodium amalgam in glacial acetic acid into a single isomer that was identified as streptamine *(3)* by paper and thin-layer chromatography.



(5), R = R' = H
(6), R = H, R' = Ac
(7), R = R' = Ac

(3), R = H
(4), R = Ac

It affords a hexaacetate which was isolated in 30 % yield [calculated on *(2)*] and was identical with authentic streptamine hexaacetate in melting behavior (partial melting at 245–250 °C, then resoldification [4]) and IR and NMR data.

Catalytic hydrogenation of the product *(2)* over platinum in 20 % methanolic acetic acid led, however, to *myo*-inosa-1,3-diamine *(5)* [m.p. 230 °C (decomp.)], which was further characterized as the di-*N*-acetate *(6)* (decomp. 310 °C) and the hexaacetate *(7)* (m.p. 270–271 °C; [2] 269 °C).

Di-*N*-formylation with acetic formic anhydride [5] to give *(8)* (m.p. 265 °C) and subsequent reduction of the tetraacetate *(9)* (m.p. 223–224 °C) by $LiAlH_4$ in tetrahydrofuran proved to be the simplest way of converting the diamine *(5)* into its *N,N'*-dimethyl derivative, actinamine *(10)*. Hexaacetylactinamine *(11)*, identical in melting point and IR and NMR spectra with the product prepared from actinospectacin [6], could thus be isolated in 23 % yield [calc. on *(5)*], whereas other methods used for the di-*N*-methylation [2] gave yields of about 8 %.

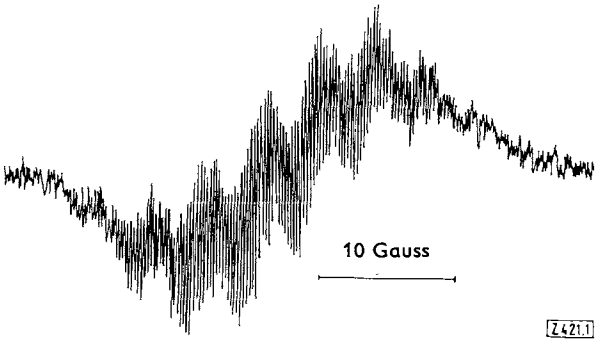
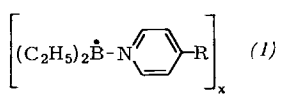
Pyridines as Stabilisers of Free Boron Radicals

By *R. Köster, H. Bellut,* and *E. Ziegler* [*]

Whereas free BN radicals with unresolved ESR signals are formed on dehalogenation of pyridine- and 2-alkylpyridine-dialkylchloroboranes by lithium in tetrahydrofuran [1] at 0 to 5 °C, associated radicals *(1)*, whose ESR spectra show a hyperfine structure of ten lines (distances: 3.83 gauss), are obtained from the adducts of dialkylchloroboranes and 4-alkylpyridines. The resolution can be ascribed to the coupling of the free electron to three boron atoms [2]. In the spectrum of *(1)* in 10^{-2} M solution, an additional hyperfine structure (see Fig. 1) also appears, the resolution of which varies with the linewidth associated with the substituent R in the aromatic ring, in the order
$CH_2C_6H_5 \approx CH_3 \approx C_2H_5 > C_3H_7 > CH(CH_3)_2 > C(CH_3)_3$.
Simultaneously the association (measured cryoscopically in benzene) decreases from $x \approx 3$ to $x \approx 1.5$.





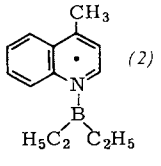


Fig. 1. ESR spectrum of the 4-methylpyridine-diethylboryl radical; *ca.* 0.001 M in diethyl ether.

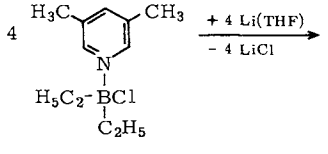
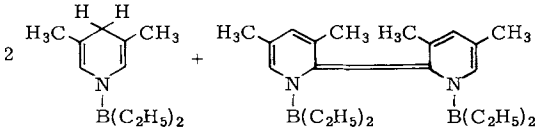


The 4-methylquinoline-diethylboryl radical *(2)* is monomeric in benzene. In agreement with this fact the hyperfine structure of the ESR spectrum shows a clear (1:1) splitting (14 gauss), which can be ascribed to the coupling of the free electron with one proton. *(1)* and *(2)* are highly colored, very viscous liquids, which are decolored by air.



(1)

(2)

R = $CH_2C_6H_5$, CH_3, C_2H_5, C_3H_7, $CH(CH_3)_2$, $C(CH_3)_3$
x = 1,5-3

Dehalogenation of 3-alkylpyridine-dialkylchloroboranes,even at 0 °C, gives either no (3,5-lutidine, 3,4,5-trimethylpyridine) or only a very unstable free radical (3-methylpyridine). From 3,5-lutidine-chlorodiethylborane one obtains a dark red, diamagnetic liquid (b.p. 48 °C/10^{-3} mm) which is composed mostly of *N*-diethylboryl-1,4-dihydro-3,5-dimethylpyridine *(3)* and yellow crystalline *N,N'*-bis(diethylboryl-1,1'-2,2'-tetrahydro-3,3',5,5'-tetramethyl-$\Delta^{2,2'}$-bipyridine *(4)*, m.p. 93 °C; 85 % yield). Structures *(3)* and *(4)* were proved by ^{1}H–NMR.

(3) *(4)*

If pyridine-chlorodiethylborane is dehalogenated in boiling tetrahydrofuran no free radical is formed, but instead a disproportionation product (b.p. 88–89 °C/14 mm) analogous to *(3)*; the dehydrogenated portion corresponding to *(4)* is a dark solid.

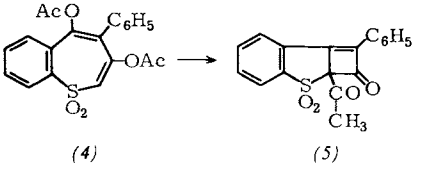
Rearrangements of Derivatives of Benzo[*b*]thiepin and Benzo[*b*]thiepin 1,1-Dioxide [**]

By *H. Hofmann* and *H. Westernacher* [*]



Thiepins contain a cyclic 8π-electron system, so that, as with oxepins, rearrangements to more stable ring systems are to be expected. Indeed, when 3,5-diacetoxy-4-phenylbenzo[*b*]-thiepin *(1)* [1] is heated under reflux with sodium acetate in acetic anhydride for 6 hours, 1,3-diacetoxy-4-acetylthio-2-phenylnaphthalene *(2)*, m.p. 175–176 °C (from methanol), is formed in 53 % yield.

The rearrangement is thus analogous to that observed with benzo[*b*]oxepin derivatives [2]. The structure *(2)* is proved by elemental analysis, the IR spectrum [in KBr; $\nu_{C=O}$ = 1764 cm^{-1} (aromatic acetate), $\nu_{C=O}$ = 1710 cm^{-1} (aromatic thioacetate)], the NMR spectrum [in $CDCl_3$; τ = 8.15 and 8.03 (each 3 H of the two acetate groups), τ = 7.65 (3 H of the thioacetate groups], and by oxidation in an aqueous alkaline (KOH) solution to 2-hydroxy-3-phenyl-1,4-naphthoquinone [3]. However, treatment of the thiepin *(1)* with acetic anhydride in pyridine (15 min at 60 to 70 °C) gives a 66 % yield of a sulfur-free product that was identified by its IR spectrum and mixed m.p. as 1,3-diacetoxy-2-phenylnaphthalene [4].

We assume that in both rearrangements an episulfide *(1a)*, a valence tautomer of *(1)* which has not yet been isolated, is first formed.

(1) *(1a)* *(2)* *(3)*

The same products *(2)* and *(3)* are obtained if 2,3,4,5-tetrahydro-4-phenylbenzo[*b*]thiepin-3,5-dione [1] or 5-acetoxy-2,3-dihydro-4-phenylbenzo[*b*]thiepin-3-one [1] is used in place of *(1)*.

(4) *(5)*

Attempted rearrangement of 3,5-diacetoxy-4-phenylbenz[*b*]-thiepin 1,1-dioxide *(4)* [1] by heating it for 4 hours with sodium acetate in acetic anhydride under reflux gave a completely different result. In this reaction, 2a-acetyl-2,2a-dihydro-4-phenylcyclobutadieno[1,2-*b*]thionaphthen-2-one 3,3-dioxide *(5)*, m.p. 213–215 °C (from methanol; 65 % yield) was formed instead of *(3)*. We suspect that in this case the episulfone corresponding to *(1a)* is not formed but that 1 mol. equivalent of acetic acid is first eliminated followed by ring contraction and subsequent *O*-acyl → *C*-acyl migration to yield compound *(5)*.

Structure *(5)* was proved by elemental analysis, determination of the molecular weight, the IR spectrum (in KBr; $\nu_{C=O}$ = 1733 cm^{-1} for both carbonyl groups; $\nu_{C=C}$ = 1652 cm^{-1}; $\nu_{S=O}$ 1313 and 1160 cm^{-1}), the NMR spectrum (in $CDCl_3$; in addition to the signals of the 9 aromatic H atoms, only one signal for 3 H atoms at τ = 7.3), and by degradation to the known 2,3-dihydrothionaphthen-3-one 1,1-dioxide [5].

Cesium and Rubidium Pentafluoroethoxide

By *F. Seel*, *R. Budenz*, and *W. Gombler* [*]

Trifluoroacetyl fluoride *(1)* reacts with cesium or rubidium fluoride, preferably in acetonitrile, to give the compounds $CsF{\cdot}C_2F_4O$ *(2a)* and $RbF{\cdot}C_2F_4O$ *(2b)*, respectively. Their compositions were determined from the ^{19}F–NMR spectra of the solutions and by wet analysis of the substances that crystallized from the solutions. When the temperature is raised, compounds *(2a)* and *(2b)* decompose reversibly into their components [vapor pressure of *(2a)* = 110 mm at 60 °C, of *(2b)* 48 mm at 25 °C].

On addition of even small amounts of CsF or RbF, or of potassium fluoride, to solution of *(1)* in acetonitrile the multiplet structure of the ^{19}F–NMR signals of *(1)* [$\delta(CF_3)$ = 78.6 ppm and $\delta(CF)$ = −11.3 ppm ($CFCl_3$ as an external standard), J = 6.1 Hz] disappears. This indicates fluoride ion exchange of the type:

$$CF_3COF \rightleftarrows CF_3CO^+ + F^- \quad (A)$$

$$\text{or } CF_3COF + F^- \rightleftarrows CF_3CF_2O^- \quad (B)$$

The fact that alkali-metal fluorides are anion-donors and not anion-acceptors suggests that reaction (B) is favored. The assumption that *(2a)* and *(2b)* are pentafluoroethoxides is supported by the chemical shifts of the CF_3 signal of *(1)* [δ = 85.3 ppm at 0 °C for *(2a)*] to the region of CF_3 groups bound to CF_2 (80 to 93 ppm) and the shift of the CF signal [δ = 36.4 ppm for *(2a)*] towards the signal of the CF_2 group of ethers containing the group $-CF_2OCF_2-$ (70 to 90 ppm) [1]. The ^{19}F–NMR spectrum of a suspension of KF in a solution of *(1)* in acetonitrile shows that *(1)* reacts only partly with KF to give pentafluoroethoxide. $CsF{\cdot}C_2F_4O$ *(2a)* can be included in the series of compounds $CsF{\cdot}SO_2$ [2], $CsF{\cdot}OSF_4$ [3], and in particular in the series $CsF{\cdot}OCF_2$ [4] and $CsF{\cdot}OC(CF_3)_2$ [5].

Pentafluoroethoxides are very sensitive to moisture. It was shown by IR spectroscopy that *(2a)* and water vapor react to give cesium trifluoroacetate:

$$CF_3CF_2OCs + H_2O \longrightarrow CF_3CO_2Cs + 2\ HF$$

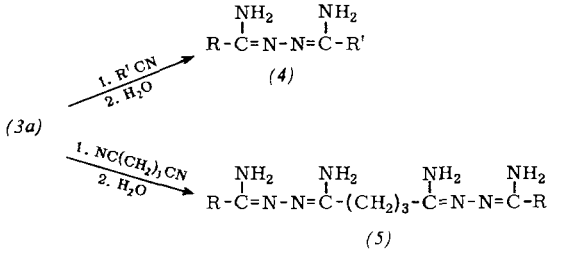
2,3-Diazabuta-1,3-diene-1,4-diamines (1,4-Disubstituted) and N^1-Acylamidrazones from Nitriles and Bis(diethylalumino)-Substituted Amidrazones and Acid Hydrazides



By *Th. Kauffmann*, *L. Bán*, and *D. Kuhlmann* [*]

When 1 molar equivalent of triethylaluminium reacts with amidrazones in benzene under nitrogen at 20 °C, one equivalent of ethane is evolved and mono(diethylalumino)amidrazones *(2a)* are formed [1], which, like the diethylalumino-derivatives *(1a)* [2] of amidines, do not add to nitriles.

(1a), Z = NH, X = H [3]
(2a), Z = NH, X = NH_2 [3]
(3a), Z = NH, X = $NHAl(C_2H_5)_2$ [3]
(1b), Z = O, X = H [3]
(2b), Z = O, X = NH_2 [3]
(3b), Z = O, X = $NHAl(C_2H_5)_2$ [3]

If, however, two molar equivalents of triethylaluminum are used, then two equivalents of ethane are evolved and bis-(diethylalumino)amidrazones *(3a)* [1] are formed, which are readily soluble in benzene and add readily to nitriles and dinitriles in benzene at 70–80 °C (reaction time 20 h), giving the asymmetrically 1,4-disubstituted diazabuta-1,3-diene-1,4-diamines *(4)* [and *(5)*] listed in Table 1. Their structures follow from the fact that, analogously to the symmetrically disubstituted diazabuta-1,3-diene-1,4-diamines [4], they are converted, when heated to *ca.* 250 °C, into 3,5-disubstituted triazoles in 90–95 % yield, with evolution of NH_3.

(4)

(5)

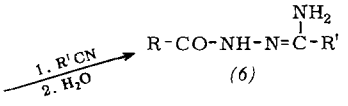


Table 1.

(3a), bis(diethylalumino)-substituted:	R'—CN	*(4)*, *(5)*	Yield (%)	M.p. (°C)
		(4):		
Benzamidrazone	Benzonitrile	R = R' = C_6H_5	95	203
Benzamidrazone	2-Cyanopyridine	R = C_6H_5; R' = 3-pyridyl	88 [a]	186
Benzamidrazone	4-Cyanopyridine	R = C_6H_5; R' = 4-pyridyl	91 [a]	207
Hexanoic acid amidrazone	Benzonitrile	R = n-pentyl; R' = C_6H_5	87 [a]	95
Hexanoic acid amidrazone	Propionitrile	R = n-pentyl; R' = C_3H_7	81 [a]	29
Dodecanoic acid amidrazone	Propionitrile	R = n-undecyl; R' = C_3H_7	80 [a]	82
		(5):		
Benzamidrazone	Glutarodinitrile	R = C_6H_5	53 [a]	205—206

[a] This represents the first preparation of these compounds.

Attempts to add sodio-substituted amidrazones to nitriles were unsuccessful. That bis-2-chloro(diethylalumino)benzamidrazones do not add to nitriles indicates a stabilizing coordinate bond between the chlorine atom and an aluminum atom.

Compounds *(1b)* [2], *(2b)* [1], and *(3b)* [1] are obtained from acid hydrazides in benzene at 20—30 °C analogously to the formation of compounds *(1a)*, *(1b)*, and *(1c)*. Treatment of bis(diethylalumino)-carboxylic acid hydrazides *(3b)* with nitriles for 6—8 h leads to the N^1-acylamidrazones *(6)* and *(7)* listed in Table 2; those products which were not new were identified by comparison with authentic specimins.

[5] From studies to date on the reactivity of diylkylaluminated primary amines [2], hydrazines [6], hydrazones [6], amidines, amidrazones, and acid amides and hydrazides it can be seen that dialkylaluminated nitrogen compounds often react differently from the corresponding alkali-metalated or trimethylsilylated [7] compounds; this can be ascribed to differences in solubility and to the electron deficiency of the triply bonded Al atom.

Preparation of Diammonium Tetraselenomolybdate

By *A. Müller*, *B. Krebs*, and *E. Diemann* [*]

If hydrogen selenide is passed into an ice-cold saturated solution of molybdenum trioxide in concentrated aqueous ammonia, initial yellow and red coloration of the solution is followed by precipitation of black, crystalline $(NH_4)_2MoSe_4$ *(1)*. Substance *(1)* was characterized by elemental analysis and by IR and electron absorption spectra. Solutions of *(1)*, and also the solid substance, decompose very rapidly in the presence of oxygen. Defined selenomolybdates have not been described previously [1].

The IR spectrum (NaCl and KBr region) shows only the vibrations of the NH_4^+ ion for the species F_2 ($\nu_4 \sim 3200$ cm^{-1}; $\nu_4 = 1395$ cm^{-1}). Absence of absorption in the region of the transition-metal-oxygen vibrations (for M—O π bonds $\approx$ 1100 to 800 cm^{-1}) excludes the occurrence of mixed oxoselenomolybdate anions. The fundamental vibrations of $MoSe_4^{2-}$ (IR active vibrations ν_3 (F_2) and ν_3 (F_2) with T_d symmetry) lie below the KBr region.

The electron absorption spectrum of the violet aqueous solution of *(1)* gives strong maxima at 17990 and 26040 cm^{-1} in the region between 10000 and 33000 cm^{-1}. Table 1 lists the absorption maxima of MoO_4^{2-} and MoS_4^{2-} for comparison. The band at 17990 cm^{-1} can be unambiguously assigned to

Table 1. Electron absorption maxima [ν_{max} (cm^{-1})] of MoO_4^{2-}, MoS_4^{2-}, and $MoSe_4^{2-}$ (cf. [2], [3]).

	$t_1 \rightarrow 2e$ ($^1A_1 \rightarrow {}^1T_2$)	$2t_2 \rightarrow 2e$ or $t_1 \rightarrow 3t_2$ ($^1A_1 \rightarrow T_2$)
MoO_4^{2-}	43200	48000
MoS_4^{2-}	21400	31500
$MoSe_4^{2-}$	17990	26040

the transition from the highest occupied molecular orbital of symmetry t_2 to the first unoccupied MO of symmetry 2e [ground state $(1a_1)^2(1t_2)^6(1e)^4(2t_2)^6(t_1)^6$; excited state ... $(2t_2)^6(t_1)^5(2e)^1$; for the MO scheme cf.[2], [3]]. Since the MO t_1 is centered on the ligands and 2e represents mainly a MO that is localized on the central atom, the course of the charge-transfer band $t_1 \rightarrow 2e$ of chalcogenomolybdates can be interpreted as in Table 1 (the ionization energy decreases from oxygen to selenium).

A New, Mild Purine Ring Closure [1]

By *F. E. Kempter, H. Rokos,* and *W. Pfleiderer* [*]

Most purines have been prepared by a modified Traube synthesis[2] involving cyclization of 4,5-diaminopyrimidines. Since it is always the 5-amino group that reacts in the first step, ring closure usually requires drastic conditions for the slightly nucleophilic 4-amino group.

We have now found that this imidazole ring closure can be achieved under much milder conditions from 4-acylamino-5-aminopyrimidines; starting materials are 4-amino-5-nitroso- and 4-amino-5-nitro-pyrimidines. If the acylation is carried out with anhydrides below 120 °C with short reaction times, 4-acylamino-5-nitrosoderivatives *(2)* can be obtained in good yields, and no rearrangement[3] to cyano-*s*-triazines occurs.

Catalytic hydrogenation of 4-acylamino-5-nitrosopyrimidines[2] on Raney nickel or Pt affords first the 5-amino derivatives, which, however, are very unstable and, even at room temperature, are stabilized by nucleophilic attack of the 5-amino group on the 4-acylamino group and formation of the purine derivatives *(3)*. Hydrogenation of compound *(2)* with $R = NH_2$, $R^1 = OCH_2C_6H_5$, $R^2 = CH_3$ on Pd/C leads to 8-methylguanine *(3b)* by simultaneous debenzylation.

	R	R¹	R²	M.p. (°C)	Yield (%)
(3a)	NH_2	OCH_3	H	245–248 (decomp.)	33
(3b)	NH_2	OH	H	> 360	56
(3c)	CH_3S	NH_2	H	285–290	30
(3d)	NH_2	AcNH	H	204	40
(3e)	$(CH_3)_2N$	OCH_3	H	125	62
(3f)	H	$(CH_3)_2N$	CH_3	132	32

(4a)	$(CH_3)_2N$	OCH_3	H	160–161	71
(4b)	$(CH_3)_2N$	OH	H	273–275 (decomp.)	21
(4c)	H	$(CH_3)_2N$	CH_3	100–101	77
(4d)	$(CH_3)_2N$	H	H	168	84
(4e)	OCH_3	NH_2	H	185–190	62

If 4-amino-5-nitropyrimidines are selected as starting materials, the acylation requires much more drastic conditions: good yields are obtained when *(4d)* or *(4e)* is boiled under reflux with acetic anhydride for a short time, but for *(4a)* to *(4c)* several hours' boiling is needed. The catalytic reductions proceed analogously to those of the 5-nitroso derivatives so that the purines *(3e)*, *(3f)*, and *(3g)* are formed at room temperature from *(4a)*, *(4c)*, and *(4d)*.

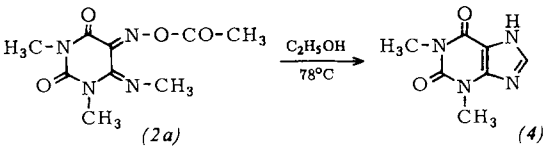
1,3-Disubstituted 5-Acyloxyimino-4-alkylimino-uracils as New "Activated Esters" [1]

By *W. Pfleiderer* and *F. E. Kempter* [*]

When carboxylic acid anhydrides react with 1,3-disubstituted 4-alkylamino-5-nitrosouracils *(1)* at *ca.* 20 to 60 °C (Method A), decoloration and monoacylation occur. This lightening of the color, the absence of a nucleophilic amino group in the



uracil system and the UV spectrum of the products (no uracil chromophore; only end absorption at 220 mμ) indicate clearly that acylation has occurred, not at the amino group[2], but at the nitroso group with formation of 1,3-disubstituted 5-acyloxyimino-4-alkyliminouracils *(2)*.

(1) *(2)*

The same products *(2)* are obtained if the anhydrides are replaced by aliphatic, aromatic, or heterocyclic carboxylic acids in the presence of dicyclohexylcarbodiimide in indifferent solvents such as tetrahydrofuran (method B). After the nitrosouracil color has disappeared, the dicyclohexylurea is filtered off and the reaction products, which are usually soluble, are isolated from the filtrate by evaporation to a small volume.

Moreover, reaction with acid chlorides and triethylamine (method C) leads also to products *(2)*.

(2a) *(4)*

In preliminary attempts to use these new types of "activated ester" *(2)* for peptide syntheses it was found that *N*-substituted amino acids such as *N*-(benzyloxycarbonyl)-DL-phenylalanine and *N*-phthaloyl-DL-phenylalanine can be converted into the activated esters *(2c)* and *(2d)* in high yield by method B. Their use for formation of the peptide link is under study.

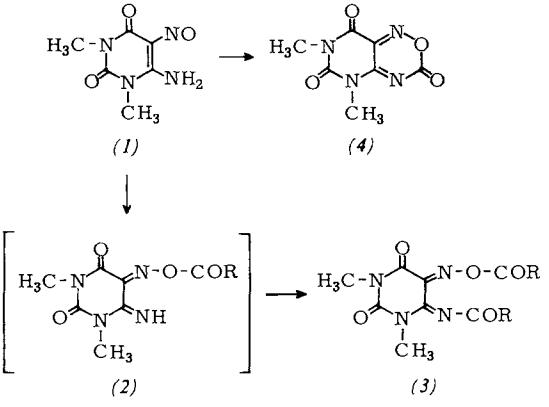
The 5-acyloxyimino compounds are derived from an isonitroso form; the first indication of this is the very high C=O frequency, between 1740 and 1810 cm^{-1} according to the nature of the group R^2.

Nucleophilic compounds are acylated by *(2)* even under the mildest conditions. For instance, *(2b)* reacts with α-methylbenzylamine in tetrahydrofuran at room temperature to give *N*-(α-methylbenzyl)benzamide*(3)* in 71% yield with regeneration of*(1a)*.The weaker nucleophile aniline gives an 80% yield

(2b)

(3)



of benzanilide. The reaction of 5-isonicotinoyloxyimino-1,3-dimethyl-4-methyliminouracil *(2h)* with phenylhydrazine or aniline, to give the *N*-phenylhydrazide or anilide, respectively, of isonicotinic acid, emphasises the general applicability of the "activated esters" *(2)* for acyl transfer. Compounds *(2)* are rapidly hydrolysed by water at room temperature. The reaction with alcohols is very slow and incomplete at *ca.* 20 °C; at higher temperatures a competing reaction takes place, namely the imidazole ring formation that is known from the 4-alkylamino-1,3-dimethyl-5-nitrosouracil series[3]; thus theophylline *(4)* is formed from *(2a)*.

Syntheses and Reactions of 4-Acylimino-5-acyloxyiminopyrimidines [1]

By *W. Pfleiderer* and *F. E. Kempter* [*]

In acylations of 4-amino-5-nitrosopyrimidines the point of entry of the acyl group depends on the nature of the substituents in positions 2 and 6[2]. Acylation of 4-amino-1,3-dimethyl-5-nitrosouracil *(1)* at room temperature by carboxylic acids and dicyclohexylcarbodiimide in indifferent solvents (method A) or by acid chlorides and triethylamine (method B) leads to 4-acylimino-5-acyloxyimino-1,3-dimethyluracils *(3)*.

The stepwise acylation is doubtless initiated by attack on the nitroso group with formation first of the 5-acyloxyimino-4-imino derivative *(2)* (that cannot be isolated), whereby the

(1) *(4)*

(2) *(3)*

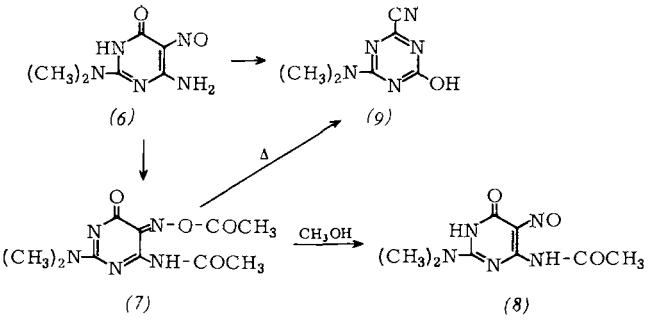
	R	Method	M.p. (°C)	Yield (%)	$\nu_{C=O}$ (cm^{-1})
(3a)	CH_3	A	176–177 (decomp.)	50	1806
(3b)	C_6H_{11}	A	155–156 (decomp.)	73	1790
(3c)	C_6H_5	A; B	191–193 (decomp.)	67	1782
(3d)	2-Furyl	A	188–190 (decomp.)	62	1779
(3e)	$C(CH_3)=CH_2$	A	181–182 (decomp.)	57	1773
(3f)	$CH=CH-C_6H_5$	B	181–182 (decomp.)	57	1757
(4)		B	218–220 (decomp.)	50	1779

relatively inert vinylogous acid amide group is modified and the nucleophilic imine group formed becomes susceptible to a further substitution.

Saturated or unsaturated aliphatic, aromatic, or heterocyclic carboxylic acids react without difficulty. Use of phosgene/triethylamine, or of phosgene alone in tetrahydrofuran, causes intramolecular cyclization with formation of an oxadiazinone ring, as in *(4)*.

4-Acylimino-5-acyloxyimino-1,3-dimethyluracils can be recognized as "activated esters" [2], as is evident from the high IR C=O frequencies. It is remarkable that not only the *O*-acyl group but also the *N*-acyl group is transferred to nucleophilic compounds; compound *(3c)* acylated α-methylbenzylamine (2 equivalents) giving *N*-(α-methylbenzyl)benzamide in 63% yield. It can be assumed that the *O*-benzoyl group acts first as acylating agent, giving 4-benzamido-1,3-dimethyl-5-nitrosouracil *(1)*, with $NHCOC_6H_5$ replacing NH_2, which has not yet been isolated but in turn acts as acetylating agent. Similarly, compound *(3a)* with phenylhydrazine or aniline in tetrahydrofuran at room temperature gives *N*-phenylacethydrazide in 76% yield or acetanilide in 85% yield, respectively.

The diacyl derivatives *(3)* can also be used for synthesis of purines. If *(3)* are hydrogenated catalytically with Raney nickel or Pt at room temperature, 2 equivalents of H_2 are absorbed and 8-substituted theophylline derivatives *(5)* are obtained. The reaction may involve first 1,4-addition, followed by hydrogenolysis of the 5-hydroxyamino derivative and finally nucleophilic attack of the basic 5-amino group on the partially activated 4-acylamino group.



(5)

	R	M.p. (°C)	Yield (%)
(5a)	CH_3	333	74
(5b)	C_6H_{11}	268	57
(5c)	$C(CH_3)_3$	277–278	50

Another interesting diacyl derivative was obtained when 4-amino-2-dimethylamino-5-nitrosopyrimidin-6(1*H*)-one *(6)* was heated with acetic anhydride at 40 to 60 °C until dissolved.

Since there was no end absorption in the UV spectrum of the reaction product we assign to it the structure of a 5-acetamido-4-acetoxyimino-2-dimethylaminopyrimidin-6(4*H*)-one *(7)*. When kept in methanol, compound *(7)* passes into the monoacetyl derivative *(8)* (72% yield) and when heated alone it rearranges, at temperatures above 110 °C, to 4-cyano-6-dimethylamino-*s*-triazin-2-ol *(9)*. Thus compound

(6) *(9)* *(7)* *(8)*

(7) may be an intermediate in the *s*-triazine rearrangement that was first observed by *Taylor* [3] when boiling 4-amino-5-nitrosopyrimidines with acetic anhydride.

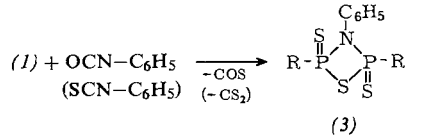
A Simple Preparation of Dithiophosphonic Ester Halides and of the Novel 1-Thia-3-aza-2,4-diphospha^{V}cyclobutane *P,P*-Disulfide System

By *E. Fluck* and *H. Binder* [*]

Dithiophosphonic acid alkyl ester halides *(2)*, which have hitherto been obtained only by multistage processes [1], can be prepared directly by treating 1,3-dithia-2,4-diphospha^V-cyclobutane *P,P'*-disulfides *(1)* (*e.g.* R=C_6H_5, *p*-$CH_3O-C_6H_4$ or *p*-$C_2H_5O-C_6H_4$) with alkyl halides (R'X = CH_3Br, C_2H_5Br, or C_4H_9Cl).



For example, when compound *(1)*, R = C_6H_5 (10 g), is heated with methyl bromide (27.6 g, 10 mol. equiv.) in a sealed tube for 48 h at 80 °C it affords methyl phenyldithiophosphonobromidate (95% yield; b.p. 175 °C/0.01 mm; chemical shift $\delta_P = -71.1$ ppm).

(1) *(2)*

Phenyl isocyanate or isothiocyanate reacts with 1,3-dithia-2,4-diphospha^{V}cyclobutane *P,P'*-disulfides *(1)* with elimination of COS or CS_2, respectively, whereby one sulfur atom of the ring system is replaced by a nitrogen atom and 1-thia-3-aza-2,4-diphospha^{V}cyclobutane disulfides *(3)* containing the hitherto unknown 1-thia-3-aza-2,4-diphospha^{V}cyclobutane ring are formed. Structure *(3)* is assigned because of the molecular weight (cryoscopically in benzene 386) and the NMR-spectroscopic equivalence of the two phosphorus atoms (a single ^{31}P–NMR line at $\delta_P = -61.0 \pm 1.0$ ppm with reference to 85% aqueous orthophosphoric acid).

The second sulfur atom of the ring system *(1)* has not yet been replaceable, even on use of a large excess of phenyl isocyanate or isothiocyanate.

(3)

Preparation of (3), R = C_6H_5: Compound *(1)* (5g) and phenyl isocyanate (2 g) are heated in xylene (50 ml) for 2 h and the xylene and excess of phenyl isocyanate are subsequently distilled off. The colorless substance that crystallizes is filtered off from the distillation residue and recrystallized from a little benzene (yield 4.3 g; m.p. 183 °C; chemical shift δ_P = 61.0 ppm).

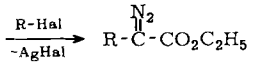
Diazocarboxylic Esters from Ethyl Argentodiazoacetate and Alkyl Halides



By *U. Schöllkopf* and *N. Rieber*[*]

Diazoacetic esters are of considerable importance in preparative organic chemistry[1]. Surprisingly, only a few members of the higher diazocarboxylic esters are known; possibly because the conventional synthetic route *via* α-amino carboxylic acid esters is either inconvenient or gives poor yields.

We have now found that higher ethyl diazocarboxylates *(3)* are relatively easily accessible by treating ethyl argentodiazoacetate *(2)* with S_N1 reactive alkyl bromides and iodides. The argento-ester is obtained from ethyl diazoacetate and silver oxide at 0 °C. This thermolabile compound has not yet been isolated, but its presence is shown by its characteristic IR absorption at 2040 cm^{-1} (N_2 group) and by its being trapped by iodine as ethyl diazoiodoacetate *(1)*[2].

(1) *(2)*

(3)

For example, we obtained ethyl 2-diazo-3-phenylpropionate *(3)* R = $C_6H_5CH_2$ [b.p. 95 C/1 mm (partial decomp. to ethyl cinnamate); IR bands at 2080 cm^{-1} and 1685 cm^{-1}; NMR signals (in CCl_4) at τ = 8.8 (t), 6.4 (s), 5.8 (q), 2.83 (m)] in *ca.* 60% yield when we stirred an ethereal suspension of *(2)* with benzyl bromide for 10 h at 0 to 20 °C. Analogously with crotyl bromide ethyl-2-diazo-4-hexenoate was obtained in about the same yield [b.p. 41 °C/0.1 mm; IR bands at 2080 cm^{-1} and 1680 cm^{-1}; NMR signals (in CCl_4) at τ = 8.75 (t), 8.33 (d), 5.84 (q), 4.5 (m)], accompanied by some ethyl-2-diazo-3-methyl-4-pentenoate.

When heated, ethyl 2-diazo-3-phenylpropionate gives a mixture of ethyl *trans*- and *cis*-cinnamate; this introduces the possibility of a new chain-lengthening synthesis of α,β-unsaturated carboxylic esters.

The existence of the argento derivative *(2)* is also interesting from a theoretical point of view: the role of the catalyst in the Ag_2O-catalysed Wolff rearrangement is still unknown[3]; according to our findings this role is very probably to convert the diazo ketone into its silver derivative, which then undergoes the shift.

Ethyl 2-diazo-4-pentenoate: Silver oxide (5.8 g, 0.025 mole) is added in 2 h in *ca.* 0.5 g portions, with stirring, to ethyl diazoacetate (5.7 g, 0.05 mole) with simultaneous dilution with ether (total 60 ml). After being stirred at 0 °C for 3 h, allyl iodide (12.6 g, 0.075 mole) is added dropwise with ice-cooling and the whole is stirred for a further 3 h at 0 °C. The mixture is then filtered, dried over Na_2SO_4, concentrated in a rotary evaporator (40 °C/13 mm), and fractionated. Yield of ethyl 2-diazo-4-pentenoate 4–5 g; b.p. 39–42 °C/0.5 mm; IR bands at 2080 cm^{-1}, 1685 cm^{-1}; NMR (in CCl_4), τ = 8.75 (t), 7.0 (d, some splitting), 5.8 (q), 4.85 (m), 4.3 (m).

Synthesis of 1,3-Triaryl[1,2,3]triazolo[5,1-*b*]-benzothiazolium and -benzimidazolium Salts, and of 1,3-Diphenyl[1,2,3]triazolo[1,5-*a*]benzimidazole[1]

By *A. Messmer* and *A. Gelléri*[*]

The hitherto recorded triazolium[2,3] and tetrazolium salts[4] have six-membered rings fused to them. We have found that benzothiazol-2-yl phenyl ketone phenylhydrazone *(1a)*, R = R′ = C_6H_5[5], is converted by 4 molar equivalents of *N*-bromosuccinimide in ethyl acetate at room temperature into 1,3-diphenyl[1,2,3]triazolo[5,1-*b*]benzothiazolium bromide *(2a)* with X = Br. A yellow, crystalline 1:1 complex (m.p. 152 °C) that contains *(2a)* X = Br, and *N*-bromosuccinimide is first deposited quantitatively from the solution; the salt *(2a)*, X = Br, is obtained from this complex by dissolution in acetone/methanol (5:1 v/v) and precipitation with ether. It is isolated as white crystals (m.p. 167 °C), which are converted into the excellently crystallizing tetrafluoroborate and perchlorate. The derivatives *(2b)* to *(2d)* are obtained analogously.

(1) *(2)*

	R	R′	$X^{\ominus}=ClO_4^{\ominus}$ *(2)* M.p. (°C)	Yield (%)	$X^{\ominus}=BF_4^{\ominus}$ M.p. (°C)
(a)	C_6H_5	C_6H_5	193	69	185
(b)	C_6H_5	*m*-CH_3O—C_6H_4	204	58	187
(c)	Benzothiazol-2-yl	C_6H_5	230	54	—
(d)	Benzothiazol-2-yl	*p*-CH_3O—C_6H_4	207	54	199

The structure *(2)* is in accord with the elemental analysis and IR spectrum (no NH band). Alkaline $Na_2S_2O_4$ regenerates the hydrazone *(1)* from *(2)*.

In the case of benzoxazol-2-yl phenyl ketone phenylhydrazone, *(1a)* with O in place of S, m.p. 166 °C, cyclodehydrogenation does not occur under the above or under more drastic conditions (40–50 °C); the starting material is recovered in 70% yield.

However, benzimidazol-2-yl phenyl ketone phenylhydrazone[6], *(1a)* with NH in place of S, does undergo cyclode-

hydrogenation. Under the above conditions 1,3-diphenyl-[1,2,3]triazolo[5,1-*b*]benzimidazolium bromide *(3)*, m.p. 195 °C (corresponding $BF_4^{\ominus}$ salt, m.p. 190 °C), is at once precipitated in 72% yield after reaction with one equivalent of *N*-bromosuccinimide. Compound *(3)* can be considered, not only as a triazolium salt analogous to *(2)*, but also as a hydrobromide *(3')*. Thus, with aqueous pyridine it gives the white crystalline free base 1,3-diphenyl[1,2,3]triazolo[1,5-*a*]-benzimidazole *(4)*, m.p. 148 °C, in 88% yield.

(3)

(4)

The structures of compounds *(3)* and *(4)* have been proved by elemental analysis and IR spectra. The starting material, *(1a)* with NH in place of S, gives sharp NH bands at 3400 cm^{-1} and 3300 cm^{-1}, compound *(3)* gives an intense broad band at 2600 cm^{-1} characteristic of the $NH^{\oplus}$ group, but compound *(4)* gives no NH band. A remarkable property of the new ring system *(4)* is the intense blue fluorescence of its solutions.

Carbamoyl Isothiocyanates

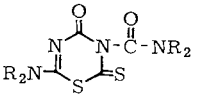
By *J. Goerdeler* and *D. Wobig* [*]

By reaction according to the scheme

$$R_2N{-}COCl + NaSCN \xrightarrow[80\,°C,\ 20min]{CH_3CN} R_2N{-}CO{-}NCS + NaCl$$

we have obtained compounds of type *(1)*, most of them as oils that are difficult to purify (R = CH_3, C_2H_5, allyl, n-C_4H_9, piperidino, or morpholino), but in one case as a crystalline solid (R = cyclohexyl; m.p. 101–102 °C).

The carbamoyl isothiocyanates *(1)* are in equilibrium with the corresponding thiocarbamoyl isocyanates *(2)* [1], as can be seen from the IR spectra and from chemical reactions.



$$R_2N{-}CO{-}NCS \rightleftarrows R_2N{-}CS{-}NCO$$

(1) *(2)*

The isothiocyanate *(1)* predominates strongly in toluene at 20 °C (IR band at 1975–1985 cm^{-1}); the isocyanate component (IR band at 2220 cm^{-1}) is detectable only on use of thick layers (0.1 mm), but increases appreciably in a reversible reaction if the temperature is raised to 40–50 °C.

The chemical reactions are determined by this dualism. Thus rapid action of an excess of H_2O leads to derivatives ($R_2N{-}CO{-}NH_2$) of the isothiocyanate, but slow reaction (exposure to air) leads to derivatives ($R_2N{-}CS{-}NH_2$) of the isocyanate. Schiff bases react with *(2)* only (cycloaddition to give 2-amino-1,3,5-thiadiazin-4-ones). In most of the reactions, the isothiocyanate predominates *e.g.* in addition of benzylamine, aniline, or *p*-nitroaniline to give carbamoylthioureas, or of acetylacetone imine to give derivatives of 3-aminothiocrotonamide; 1,2-cycloaddition of diazomethane to give 1,2,3-thiadiazoles; 1,4-cycloaddition of $\Delta^{2,2'}$-bi(1,3-diphenylimidazolidine) or t-butyl, cyclohexyl, phenyl, or *p*-methoxyphenyl isocyanide to give derivatives of 1,3-oxazole-4-thione.

When kept for some time, some of the undiluted compounds *(1)* ⇄ *(2)* yield colorless, crystalline "dimers" *(3)* [*(3a)*

(3)

R = CH_3, m.p. 198–199 °C (decomp.); *(3b)* R = C_2H_5, m.p. 104 °C (decomp.)], probably by cycloaddition of one molecule each of *(1)* and *(2)*.

Dithioacetylacetonatoiron Complexes [**]

By *K. Knauer*, *P. Hemmerich*, and *J. D. W. van Voorst* [*]

Stable iron mercaptide clusters as found in ESR- and redox-active nonheme iron proteins (*e.g.* ferredoxin [1] and Fe-flavoproteins [2] stimulate the search for model compounds which reflect the structure of FeS-, FeSS- and FeSSFe-groups as a function of the oxidation state and provide a basis for structural assignments of spectral data [3].

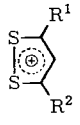
The iron-mercaptide system is defined by equation (a).

$$Fe^{3+} + SR^- \rightleftarrows \frac{1}{n}(Fe^{III}SR \leftrightarrow Fe^{II}\dot{S}R)_n^{2n+} \rightleftarrows Fe^{2+} + {}^1/_2\,(RS)_2 \quad (a)$$

Equilibrium positions, the value of *n*, kinetic stability, structure, and magnetochemistry of intermediates will be widely varying functions of the iron ligand fields and of the steric and electronic requirements inherent to R.

It has been shown earlier, that organic disulfides RSSR and Cu^I may react to give strongly colored CuSSCu-clusters [4]. A similar affinity for RSSR may be associated with low spin d^6-iron. Unfortunately, the two requirements of strong ligand field for preservation of spin state and binding of the relatively weak RSSR-ligand, seem to be mutually exclusive. We have found that a new stable FeSS-system is formed on reaction of dithioacetylacetone [5] *in statu nascendi* with Fe^{3+} according to equation (b).

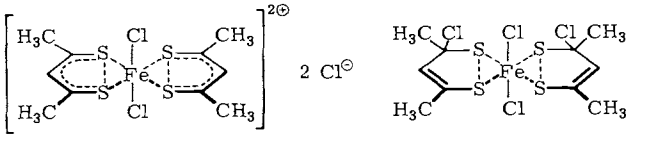
$$2\ CH_3\text{-}CO\text{-}CH_2\text{-}CO\text{-}CH_3 + 4\ H_2S + 4\ Fe^{III}Cl_4^- \xrightarrow{75\%} Fe(C_5H_7S_2)_2Cl_4 + 3\ Fe^{II}Cl_4^{2-} + 2\ H_3O^+ + 2\ H_2O \quad \text{(b)}$$



(1)

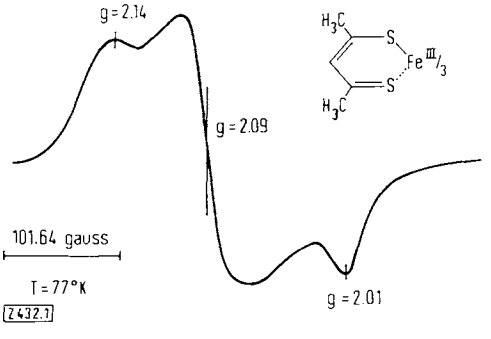
The violet crystals dissolve in water at pH ≤ 3 to give a colorless solution as described by equation (c).

$$Fe(C_5H_7S_2)_2Cl_4 \xrightarrow{H_2O} Fe^{2+} + 4\ Cl^- + 2\ (C_5H_7S_2)^+ \quad \text{(c)}$$



(1)

The Fe^{2+} formed was determined colorimetrically as the bipyridine complex, whereas $(C_5H_7S_2)^+$ was found to have the structure *(2)*, $R^1 = R^2 = CH_3$; the first stable dithiolium cation with only aliphatic substituents. It is stable towards hydrolysis at pH ≤ 4. Structure *(2)* is evidenced by ^1H–NMR-spectroscopy [2 peaks only, 8.4 and 3.1 ppm, of intensity ratio 1:6], by means of UV-spectra ($\lambda_{max} = 280$, 265 nm; $\varepsilon = 9300$, 7200 $mol^{-1}cm^{-1}$ compared to $\lambda_{max} = 356$, 287 nm; $\varepsilon = 19000$, 3800 $mol^{-1}cm^{-1}$ of the known *(2)*, $R^1 = C_6H_5$, $R^2 = H$)[6] and by isolation of the picrate $C_{11}H_9O_7N_3S_2$, m.p. 113 °C.



(2)

The complex *(1)* might have the structure $(C_5H_7S_2)_2[Fe^{II}Cl_4]$ which is in agreement with its elementary composition. Its very intense color, however, suggests Fe–SS-coordination, since $C_5H_7S_2^{\oplus}$ as well as the almost non-polarisable $FeCl_4^{2-}$ are colorless. Therefore, we propose the structures *(1a)* or *(1b)* as the most probable ones.

(1a) *(1b)*

If the colorless aqueous solution of *(1)* (cf. eq. (c)) is reduced by $Na_2S_2O_4$ or $NaBH_4$, red-brown crystalline $Fe^{III}(C_5H_7S_2)_3$ is obtained, which is soluble in $CHCl_3$ and may be further reduced by shaking with aqueous $Na_2S_2O_4$ to give the autoxidable $Fe^{II}(C_5H_7S_2)_2$. The compound $Fe^{III}(C_5H_7S_2)_3$ shows the ESR properties expected for an asymmetrical low spin d^5-octahedron (Fig. 1), while $Fe(C_5H_7S_2)_2$ and *(1)* do not show an ESR absorption at $T \geq 170$ °K.

The formal oxidation state of the iron is increased on reduction of complex *(1)*. This system may be a model for redox-active iron in proteins in which the ESR signals at $g < 2$ appear to belong to an "oxidized" d^5-state, even though they appear only on reduction of the complex. The electron balance of these reductions is thus determined not only by the central atom, but also by the acceptor ligand, a fact which should always be borne in mind when the stoichiometry of electron uptake by iron proteins is discussed.

ESR Studies of Model Complexes for Non-Heme Iron Proteins

By *A. Röder* and *Ernst Bayer* [*]

It is difficult to decide the valence of the iron in redox-active non-heme iron proteins since the ligand, as well as the iron, is redox-active. In the reduced state many of these iron proteins have ESR spectra with g values below that of a free electron [1]. The ESR spectrum of reduced xanthine oxidase contains a broad signal with $g = 1.94$ (−175 °C) [1]; the g values for reduced ferredoxin from *Clostridium pasteurianum* are 1.89, 1.96, and 2.05 (15 °K) [2, 3]. Bonding of the iron to cysteinyl groups appears to be certain for ferredoxin [4]. Thus iron complexes of low molecular weight involving sulfur-containing ligands should also give g values below 2.0 at corresponding redox states, and it should be possible to determine the oxidation state of the active centre in the reduced non-heme iron.

Under the following conditions iron complexes of cysteine, cystine, and cysteamine gave g values at 1.94:

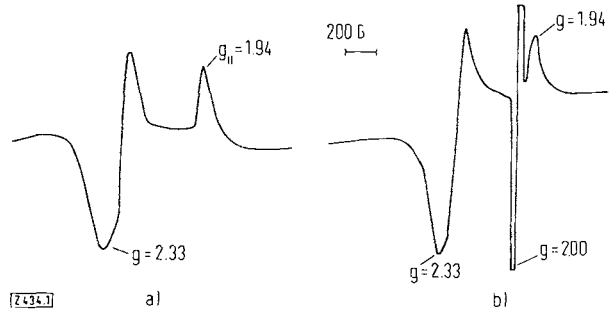
(a) Oxidation of the previously described [4] iron(II) complex of cysteine methyl ester:

1. 392 mg of Mohr's salt is added, under nitrogen, to a solution of 342 mg of cysteine methyl ester hydrochloride in 100 ml of 0.5 M tris-HCl buffer (pH = 7.0). The cysteine methyl ester-iron(II) complex that precipitates immediately is dissolved by the addition of 1 N NaOH (final pH = 9.5). The solution is shaken for 1 min with an equal volume of a 1 % solution of iodine in benzene in an ESR sample tube, then frozen and measured [**].

2. 227 mg of cysteamine and 392 mg of Mohr's salt are dissolved in 50 ml of 1 M tris-HCl buffer (pH = 7.0). The pH is then adjusted to 9.5 by 1 N NaOH, and a solution of 504 mg of the sodium salt of riboflavin monophosphate (FMN) in 25 ml of H_2O is added. After 5 minutes the mixture is transferred to an ESR sample tube, frozen, and measured. In this case absorption by the flavosemiquinone at $g = 2.00$ also occurs (see Fig. 1b).

(b) By oxidation of tricarbonyl(cystine dimethyl ester)-iron(0)[5]:

0.2 ml of a 10^{-2} M ethereal solution of the cystine dimethyl ester-iron(0) complex is treated in an ESR sample tube with 5 mg of solid iodine, frozen after 20-seconds' shaking, and measured.



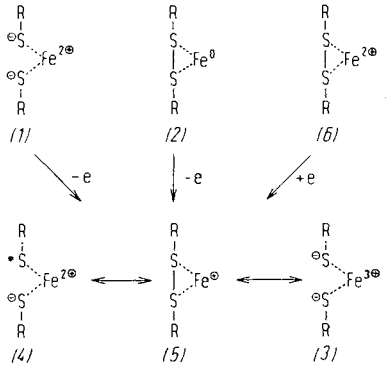


Fig. 1. a) ESR spectrum of the cysteine methyl ester iron(II) complex after oxidation by method (a)1, and of cysteine methyl ester after reaction with iron(III) chloride by method (c) (Mod. 1000, SL 1000, SR 200 gauss/min).

b) ESR spectrum of the radical complex ($g_{\parallel} = 1.94$; $g_{\perp} = 2.3$) obtained by method (a)2, and of the flavosemiquinone radical ($g = 2.00$) (Mod. 1000, Ampl. 1000, SR 250 gauss/min).

The ESR spectrum reproduced in Fig. 1a has the shape that, according to *Kneuenbühl*'s calculations[6], is characteristic of axial symmetry in complexes. A similar symmetry was observed with the reduced non-heme iron protein from *Azotobacter vinelandii*[1].

The oxidation states of the initial complexes used for (a) and (b) are given in the formulae *(1)* and *(2)*. The iron(II) complex *(1)* of cysteine methyl ester is equivalent to the tricarbonyliron(0) complex *(2)* of cystine dimethyl ester with respect to its total oxidation state when the oxidation states of the ligand and the central atom are considered together. Both complexes are converted into ESR-active substances on oxidation. In so far as oxidation involves a one-electron step the same ESR spectrum should result if the iron(III) salt is allowed to react with cysteine methyl ester; one can therefore formulate complex *(3)*.

(c) 80 mg of anhydrous iron(III) chloride is added, under nitrogen, to 100 ml of a 10^{-2} M solution of cysteine methyl ester in 0.5 M tris-HCl buffer (pH = 10.5). The pH value is then adjusted to 9.5 by addition of 1 N NaOH. After 10 min the mixture is transferred to an ESR sample tube, frozen at once, and measured. The same spectrum is obtained as under (a)1 (Fig. 1a).

The total oxidation state of the ESR-active complex is thus proved. The complex can be formulated as iron(III) mercaptide *(3)*, as iron(II) radical complex *(4)*, or as iron(I) complex of the disulfide *(5)*. The unpaired electron is delocalized over the central ion and the ligand. Neither the central ion nor the ligand can be assigned a specific oxidation state.

The similarity between the ESR spectra of reduced non-heme iron proteins and synthetic iron complexes makes it probable that formulations *(3)* to *(5)* can also be applied to reduced non-heme iron. This is supported by ESR-spectroscopic studies of bis(hexamethylbenzene)iron(I) tetrafluoroborate[7], of $Na_3[Fe(CN)_5NO]$[8], and of iron-oxygen-radical complexes[9]. The oxidized form of non-heme iron proteins is therefore described by structure *(6)* of an iron(II) complex of the disulfide; this is in agreement with results obtained by chemical methods.

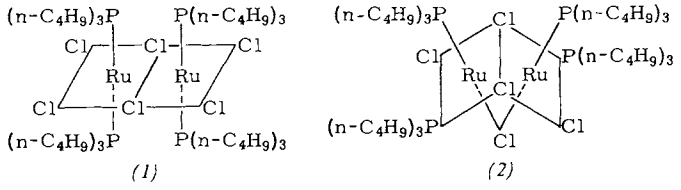
Ruthenium(II, III) Dimeric Complexes

By *J. K. Nicholson*[*][**]



In certain dimeric carboxylate complexes of ruthenium the ruthenium atoms are formally in the oxidation states two and three. Their unexpectedly high magnetic moments have been ascribed to a spin free system[1]. We have now isolated a tri-n-butylphosphine complex of ruthenium, $[Ru_2(II,III)Cl_5\{P(n\text{-}Bu)_3\}_4]$[2] which has the expected magnetic moment for a spin paired dimer containing one unpaired electron per molecule. When a concentrated ethanolic solution of ruthenium trichloride and tri-n-butylphosphine (molar ratio 1:2.2) is allowed to stand at 20 °C under nitrogen for 72 h, a complex $[RuCl_3\{P(n\text{-}Bu)_3\}_2]_2$ *(1')*, dark red crystals, m.p. 132–134 °C, separates. After filtration in air, the mother liquor deposits $[Ru_2Cl_5\{P(n\text{-}Bu)_3\}_4]$ *(2')*, dark red crystals, m.p. 95.5–96 °C, over a period of 24 h.

Complex *(1')* has a magnetic moment of 1.93 B.M./Ru[3], as expected for a spin paired ruthenium(III) complex[4]. Molecular-weight determination (calculated 1224; found 1004; thermoelectric method of *Simon* and *Tomlinson*) suggests that, in dichloromethane solution, the complex *(1')* is largely dimeric. Complex *(2')* has a molecular weight of 1165 ± 24[5] (calc. 1189). The magnetic moment 0.75 B.M./Ru[3] indicates that there is one unpaired electron per molecule. The infrared spectrum exhibits no absorption bands in the region 4.0–6.0 μ (metal-hydride stretching frequency range). Complex *(2')* is formulated therefore with the ruthenium atoms formally in the oxidation states II and III. It is not

yet known whether the ruthenium atoms have similar ligand environments[6], but chemical evidence suggests this is so. Thus reaction of complex *(2')* with carbon monoxide in ethanol at 0 °C yields quantitatively *trans*-$[RuCl_2(CO)_2\{P(n\text{-}Bu)_3\}_2]$[3] *(3)*, and this rearranges in solution to the *cis* form *(4)*[7,8]. Complex *(1)* reacts similarly to give isomers *(3)* and then *(4)* as products.

At temperatures above 0 °C, the isomerization *(3)* → *(4)* is so fast that *(3)* cannot be isolated in a pure state. Complex *(1')* reacts similarly to *(3)* and *(4)*. Of the many possible ligand arrangements for complexes *(1')* and *(2')* the reactions with CO indicate that the following are the most likely.

The complexes $[RuCl_3(P\text{-}n\text{-}Pr_3)_2]_2$, *(1')* type, and $[Ru_2(II,III)Cl_5\{P(n\text{-}Pent)_3\}_4]$, *(2')* type, have also been isolated and shown to undergo the same reactions with carbon monoxide as the tributylphosphine complexes.

CONFERENCE REPORTS

Swiss Chemical Society

The Summer Meeting of the *Schweizerische Chemische Gesellschaft* was held at Solothurn (Switzerland) on October 1st, 1966.

From the lectures:

Enthalpy and Entropy Changes on formation of Complexes

S. Ahrland, Zürich (Switzerland)

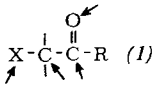
Enthalpy and entropy changes have been compiled for complexes formed between halide (or cyanide) ions and metal ion acceptors, ranging from typically class (a), or hard, to typically class (b), or soft[*]. The ligands have been chosen so that they should vary widely in softness while being as similar as possible in other respects. They become softer in the sequence $F^- < Cl^- < Br^- < I^- < CN^-$.

The stability of complexes between hard acceptors and hard ligands (*e.g.* F^-) is due exclusively to a large gain of entropy, while the enthalpy term as a rule even counteracts the complex formation (endothermic reaction). On the other hand, the stability of complexes between soft acceptors and very soft ligands (*e.g.* CN^-) is exclusively due to a large decrease of enthalpy (exothermic reaction), while the entropy term as a rule counteracts the reaction (which thus involves a loss of entropy). When the acceptor and/or ligand are of intermediate softness, intermediate cases occur where the enthalpy and the entropy terms both contribute to about the same extent towards the formation of the complex (*e.g.* $CdBr^+$, $HgCl^+$).

[*] For the terms "hard" and "soft" cf. *R. G. Pearson*, J. Amer. chem. Soc. *85*, 3533 (1963); *R. F. Hudson*, Chem. Engng. News *43*, No 22, p. 90 (1965).

The large entropy gain found for the fluoride complexes is certainly a combined effect of the breaking of acceptor-to-water and ligand-to-water hydrogen bonds. On the other hand, the softer ligands presumably disorder the solvent in a degree increasing with their softness. On complex formation, only the breakage of the acceptor-to-water bonds will thus involve a gain of entropy, while both the withdrawal of the ligand from its surrounding water molecules and the formation of the acceptor-to-ligand bond will cause entropy losses. For the diatomic cyanide ion, there is in addition a loss of rotational entropy.

Contrary to the electrostatic bonds formed between hard ligands and hard acceptors, the bonds formed between soft ligands and soft acceptors are best described as essentially covalent. The formation of such a covalent bond tends to make the total process of complex formation exothermic. In fact, the enthalpy change seems to be a fairly good measure of the strength of the covalent bonding.



Reactions of Positive Halogen Organic Compounds with Phosphorus(III) Derivatives

P. A. Chopard, Cologny/Geneva (Switzerland)

The characteristic properties of halogeno-organic compounds are related to the "negative" nature of the halogens in comparison to carbon. This is typified by the inductive effect of the halogen which increases the acidity of protons on nearby carbon atoms, and the relatively easy ionization of the C–X bond to halide ions (S_N1 displacement reactions).

With a variety of polarizable nucleophiles, the halogen atom can also act as an electron acceptor, particularly in the cases where the halogeno compounds may form stable anions as leaving groups. Such nucleophiles are often

relatively deficient in non-bonding electrons and also preferably derived from elements of the second or higher periods. Because of their multiple positive centers, α-halogeno keto compounds *(1)* were chosen as model electrophiles and the results of their reactions with tertiary phosphines and phosphites as nucleophiles lead to the following observations:

(1)

a) Phosphines are better nucleophiles than phosphites with regard to displacement reactions and the order of reactivity follows the usual order I > Br > Cl.

b) The selectivity [*] for the reaction at halogen is greater than for the reaction at saturated carbon.

c) Phosphites react preferentially to phosphines at the carbonyl center.

The phosphines, having less non-bonded electrons than the phosphites, are more polarizable and softer than the phosphites. The greater selectivity for the reaction at halogen, with respect to the leaving groups, is interpreted as evidence for a high degree of bond formation in the transition state; this is compatible with a strong contribution of covalent bonding energy and a weak contribution of affinity and solvation energy. The great selectivity with respect to the electrophilic halogen (Br > Cl; $\Delta k \simeq 10^6$) is tentatively compared to the energy difference in the charge-transfer absorptions of complexes of tertiary amines with polyhalogenoalkanes. Support to this interpretation is given by the known light catalysis of some reactions of phosphites with alkyl polyhalides.

Compounds studied: Halogen substituted cyclohexanones, benzophenones, acetones, acetic acid, and esters.

Effect of Solvent Structure on Dissociation

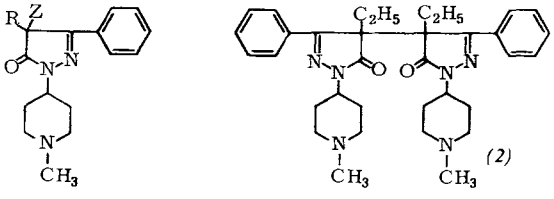
R. Hümberlin, Basel (Switzerland)

When an ion pair dissociates, a void is created between them which remains until it is large enough to be occupied by a solvent molecule, the electrostatic energy required for this separation being about 50 kcal/mole. Interaction between such an intimate ion pair and water molecules is relatively small because the charge centers of the ion pair are close to each other and their effects almost cancel. The farther the two ions separate the stronger is the interaction with the solvent; the effective dissociation energy is thus reduced to about 5 kcal/mole.

An ion pair cannot dissociate spontaneously. There must be a vacant position in the solvent structure next to the departing ion; also a water molecule must be so situated with respect to the ion pair that it can occupy the resulting space as quickly as possible. The ions do not separate linearly – they move from one energetically favored position in the solvent structure to another. The rate and degree of dissociation are thus determined not merely by coulombic forces, but to a much greater extent by permanent and induced dipoles of the solvent molecule.

The potential energy-interionic distance function can be calculated from an electrostatic model, taking into account all the ion-dipole and dipole-dipole interactions. A maximum of about 5 kcal/mole is found when the distance between the electron shells of the ions is 1 Å. The activation energy is comparable with that of a rotation around a C–C-bond in saturated hydrocarbons. The intimate ion pair is thus a real compound but converts easily and reversibly into an ion pair separated by solvent molecules.

For quantitative treatment see: Chimia *18*, 335 (1964); *ibid 19*, 602 (1965).



[*] $\ln k_1/k_2$ where k_1 and k_2 refer to two related reactions.

Transformation of Basically Substituted Pyrazolones

A. Vogel, Basel (Switzerland)

When an aqueous solution of 4-ethyl-1-(1-methyl-4-piperidyl)-3-phenyl-5-pyrazolone hydrogen maleate *(1a)* is kept in the air, the 4,4′-bipyrazolone *(2)* separates as bis(hydrogen maleate) after *ca.* 1 week. This product *(2)* presumably arises by dimerisation of the radical formed as primary product on autoxidation of the protonated molecule from *(1a)*. The structure of *(2)* was proved by elemental analysis and determination of the molecular weight and by comparison of the UV spectrum (ethanol; $\lambda_{max} = 299$ mμ, log ε = 4.26), the IR spectrum (Nujol or CH_2Cl_2; carbonyl bands at 1690 cm^{-1}), and the NMR spectrum with the spectra of compounds of similar structure (*e.g.* compound *(1a)* and the alkylation products 1-(*N*-methyl-4-piperidyl)-3-phenyl-4,4-diethylpyrazolin-5-one, 1-(*N*-methyl-4-piperidyl)-3-phenyl-4-ethyl-5-ethoxypyrazole and 1-(*N*-methyl-4-piperidyl)-2,4-diethyl-3-phenylpyrazolin-5-one.

The bipyrazolone *(2)* is also formed on oxidation of compound *(1a)* with ferric chloride; also by condensation of 4-bromo-4-ethyl-1-(1-methyl-4-piperidyl)-3-phenyl-5-pyrazolone with the sodium salt of *(1a)*.

(2)

(1a), *(1b)*, R = C_2H_5, CH_2-C_6H_5, Z = H

(3a), *(3b)*, R = C_2H_5, CH_2-C_6H_5, Z = HO_2C-CH-CH_2-CO_2H

Adducts *(3a)* and *(3b)* separated after several months when aqueous solutions of the hydrogen maleates of *(1a)* and *(1b)*, respectively, were allowed to stand under carbon dioxide in sealed ampoules. They are assumed to be formed by an ionic mechanism involving addition of the inner salts of *(1a)* or *(1b)* to maleic acid. The acids *(3a)* and *(3b)* were converted by diazomethane into their esters, which could also be prepared by Michael addition of *(1a)* or *(1b)* to dimethyl maleate. Hydrolysis of the esters with hydrochloric acid gave the hydrochlorides of *(3a)* and *(3b)*.

Matrix Spectroscopy

R. D. Werder, Zürich (Switzerland)

The first paper on matrix spectroscopy appeared in 1955. The principle of this technique is to embed a chemically active substance, preferably finely divided, in an inert solid matrix. Spectra obtained from such samples are similar to gas spectra but have certain advantages and certain disadvantages when compared with these. Advantages: substances of low vapor pressure can also be examined; there is no broadening of the absorption bands such as is caused by excitation to higher rotational energy levels. Disadvantages: the original absorption bands are generally shifted a few cm^{-1} to longer wavelengths.

Matrix spectroscopy is not merely a subsititute for gas spectroscopy, for the substance examined may also be an unstable radical or an easily polymerized monomer. At first, only such substances could be studied [1] as could be mixed in the gaseous state at room temperature with the matrix gas. In 1961 *Linevsky* [2] introduced a decisive innovation. By use of a Knudsen cell it was possible to study substances that had very small vapor pressures at room temperature.

[1] *G. C. Pimentel*, J. chem. Physics *25*, 224 (1956).

[2] *M. Linevsky*, J. chem. Physics *34*, 587 (1961).

The molecular beam issuing from the Knudsen cell was immediately condensed, together with the matrix gas, on the cold surface of a sample-container. Generally, neon, argon, krypton, or nitrogen are used as matrix-gas. The sample-container is placed in a low-temperature Dewar flask such that it can be rotated through 90° and the spectra of the sample directly recorded.

The matrix material must fulfill the following conditions: The matrix must be chemically inert and optically transparent, and have little tendency to scatter or to hinder diffusion. An important datum from matrix spectroscopy is the proportion of matrix molecules M to substances molecules A. The table shows the percentage of completely isolated molecules A with various M:A ratios and for various crystal lattices. (The calculation depends on the assumptions that the molecules A and M are of equal size and that there is no interaction between the molecules.) In our experience a ratio M:A = 100 to 1000 suffices to lead to "well isolated" spectra.

M:A	Simple cubic lattice	Body-centered cubic lattice	Face-centered cubic lattice
10000	99.9 %	99.9 %	99.9 %
1000	99.4 %	99.2 %	98.8 %
100	94.1 %	92.3 %	88.6 %
10	53.1 %	43.0 %	28.2 %

The first matrix spectra were taken in the infrared region; the method can, however, be used for recordings in the ultraviolet and visible regions as well as for electron spin resonance spectroscopy. With the aid of this technique we have examined metal halides which exist mainly as solid dimers or tetramers. It could be shown that $NbCl_5$ is monomeric in the gaseous phase, and is composed of dimeric units in the solid phase and in CCl_4 and cyclohexane solutions. [VB 31 IE]

Semiconductor Chemistry

The "Semiconductor Chemistry" Group of the *Gesellschaft Deutscher Chemiker* held a lecture meeting in Munich on October 18th and 19th, 1966.

From the lectures:

Pyrolytic Preparation of Boron Carbides

By *E. Amberger, M. Druminski,* and *W. Dietze*[*]

Pure boron triiodide is known to give red α-rhombohedral boron on pyrolysis on tantalum wire between 850 and 1100 °C. The great structural similarity between this boron modification and boron carbide, $B_{12}C_3$, prompted us to search for a carbon compound that could be pyrolysed under similar conditions. The preparation of pure boron carbide was then to be attempted by allowing boron and carbon to form simultaneously.

Carbon tetraiodide proved a suitable carbon component. This compound decomposes between 800 and 1050 °C to give pure carbon, particularly in the presence of boron and aluminium iodides.

BI_3 and CI_4 were simultaneously sublimed in a vacuum-tight borosilicate-glass apparatus and decomposed on tantalum wire at 900 to 1050 °C. Between 900 and 950 °C, boron and carbon are deposited together in varying ratios, depending on the ratio of the vapor pressures of the two components; the product is amorphous to X-rays. α- or β-Rhombohedral boron is also formed, depending on the experimental conditions. Above 1000 °C, however, the decomposition yields crystalline boron carbide, which could be unambiguously identified by X-ray analysis.

Pyrolytic Preparation of Silicon Borides

By *W. Dietze* and *E. Amberger*[**]

An apparatus was described for the pyrolytic decomposition of BI_3 and SiI_4, together or successively in any order, at various temperatures on tantalum wire.

The formation of silicon borides between 900 and 1250 °C by successive pyrolysis of BI_3 and SiI_4 was investigated. Below 1000 °C, finely crystalline silicon and amorphous boron, but not α-rhombohedral boron, were deposited; no silicon borides were formed. Above 1000 °C, however, the pyrolysis led to increasing formation of B_3Si at the interface between silicon and boron (which was still deposited only in the β-rhombohedral form).

The pyrolysis of BI_3 at 1200 °C on silicon that had previously been deposited by pyrolysis led to complete formation of B_3Si. An electron probe showed the presence of two boundary layers between the B_3Si and the silicon, one of which is possibly an unknown silicon-boron phase having the composition B_xSi, where $x \leq 1$. It was also found that the phase B_3Si can very widely in composition with no appreciable change in the lattice structure. Silicon diffuses only slowly into an existing deposit of β-rhombohedral boron.

Semiconductor Properties of Hexacyanobenzene

By *N. Karl*[*]

The most thoroughly investigated of the molecular crystals of small organic molecules having semiconductor properties is anthracene. However, this substance has properties which make it not very suitable as a model substance: low mechanical and thermal stability, low symmetry of the molecule and of the lattice, presence of pure σ bonds, presence of hydrogen atoms (possibility of protonic conduction).

Hexacyanobenzene[1] possesses an aromatic π-electron system, and might therefore be expected to exhibit semiconductor properties. The substance crystallizes in the cubic system[2]. It is thermally very stable (sublimation point 494–497 °C/760 mm) and can be obtained in good, relatively inert single crystals; furthermore it contains only nitrogen and carbon, and has at least one π-electron on each atom. Because of these features we decided to investigate it. Single crystals of hexacyanobenzene were prepared from chromatographically purified material in acetonitrile as pale yellow octahedra several millimeters long. In an electric field the crystals are easily polarized. (All measurements were carried out before an appreciable space charge had built up).

With the electrodes short circuited these induced charges can be neutralized with white light.

The dark conductivity at 169 °C and at field strengths of 1 to 300 V/mm (crystal thickness 1 mm) accurately obeys Ohm's law. At 20 °C its value is 1×10^{-18} ohm^{-1} cm^{-1} and this increases on heating according to $\sigma = \sigma_0 e^{-E/2kT}$ (activation energy 2.0 eV from 20 to 169 °C).

The photoconductivity (side irradiation of the crystal carrying silver paint electrodes) is 2×10^{-13} ohm^{-1} cm^{-1} at 20 °C and at a photon flux density of about 8×10^{17} photons/cm^2 sec with a wavelength of between 300 and 582 mμ. A good linear relationship is again found between log σ and $1/T$, with an activation energy of 0.52 eV; the relationship is independent of the field strength (10, 30, 100, and 300 V/mm, measured between 20 and 97 °C). At higher temperatures the photocurrent is less than proportional to the applied voltage.

The photocurrent density j_{el} obeys the relationship $j_{el} \propto j_{hv}{}^{3/4}$ over three powers of ten, where j_{hv} is the photon flux density. The quantum yield of the photocurrent is constant for wavelengths between 314 and 582 mμ, and is equal to 5×10^{-9} electrons in the external circuit per photon falling on the crystal (± 10 %), at a photon flux density of 10^{16} photons/cm^2 sec. Like the optical absorption, it falls off rapidly towards greater wavelengths. Thus the optical absorption limit of the π-electrons, the onset of photoconduction, and the thermal activation energy of the dark conductivity all approximately coincide (≈ 2 eV).

Spectroscopic and Electrical Properties of Polymeric Donor-Acceptor Complexes

W. Klöpffer and *H. Rabenhorst*[*]

The spectroscopic and electrical properties of the complexes of poly-*p*-dimethylaminostyrene with the acceptors chloranil, tetracyanoquinodimethane, tetracyanoethylene, and dichloro dicyano-*p*-benzoquinone, the electron affinities of which are between 1.3 and 2.0 eV, were studied. The concentration of the acceptors was varied between 0.01 and 0.5 mole of acceptor/mole of the basic structural unit of the polymer. The ionization energy of the basic structural unit was found to be 7.2 eV.

Spectroscopic examination of the poly-*p*-dimethylaminostyrene/chloranil complex shows a charge-transfer band [(λ_{max} = 680 cm^{-1}) or: (ν'_{max} = 14700 cm^{-1})], while the stronger acceptors are partly to fully converted into radical-anions. No radical-cation derived from the polymer could be detected. Measurement of the Seebeck coefficient for the system poly-*p*-dimethylaminostyrene/tetracyanoquinodimethane showed that the charge carriers are electrons.

[*] Dr. W. Klöpffer
Dr. H. Rabenhorst
Battelle-Institut e.V.
6 Frankfurt (Germany)

It is shown that acceptors that form radical-anions considerably increase the conductivity of the poly-*p*-dimethylaminostyrene ($\sigma_{60\,°C}$ increases from $< 10^{-15}\,\Omega^{-1}$ cm^{-1} to about $10^{-10}\,\Omega^{-1}$ cm^{-1}). The fact that the conductivity of the samples increases rapidly with the acceptor concentration rules out the possibility of a band model for the explanation of the charge transport. The charge transport in these systems is due to electron jumps between radical-anions and neutral acceptor molecules over a potential barrier, the height of which gives the activation energy. A similar conduction mechanism occurs in the case of low temperature conductivity in doped germanium if the majority centers are partly compensated by minority centers.

Macromolecular Organic Semiconductors with Phthalocyanine Structures

G. Manecke, D. Woehrle, and *G. Kossmehl*[**]

Tetracyanothiophene *(1)*, tetracyanofuran *(2)*, and octacyanotriphenylphospholidine *(3)* were converted into polymers having phthalocyanine structures by reaction with various metal acetylacetonates. The reaction of *(1)*, *(2)*, and *(3)* with copper acetylacetonate in various molar ratios and with the addition of *o*-phthalodinitrile was studied.

The products are dark-colored to black, and are insoluble in organic solvents. They were characterized by elemental analysis, by their IR and ESR spectra, and by X-ray analysis.

The d.c. conductivity at a pressure of 1500 kg cm^{-2} was measured between 20 and 150 °C. The activation energy was determined from

$$\sigma = \sigma_0\, e^{-E/2kT}$$

The maximum conductivities at 300 °K are 5.7×10^{-5} for the copper chelate of *(1)*, 1.5×10^{-8} for that of *(2)*, and 2.2×10^{-9} ohm^{-1} cm^{-1} for that of *(3)*. The activation energies are between 0.36 and 1.29 eV. The conductivity increases with increasing pressure. For various metal chelates of *(1)*, there seems to be a relationship between the conductivity and the ionization potentials or the ionic radii of the metals.

Measurement of the thermal e.m.f. of the copper chelates of *(1)*, *(2)*, and *(3)* showed p conduction. Seebeck coefficients of +83 to +3160 μV/°C were obtained for the range 20 to 70 °C. [VB 34 IE]

Reactor Chemistry

On October 3rd and 4th, 1966, the "Nuclear, Radio-, and Radiation Chemistry" Group of the *Gesellschaft Deutscher Chemiker* and the Kernforschungsanlage Jülich held a symposium on reactor chemistry at Jülich.

From the lectures:

Analytical Studies on Fuels Containing Plutonium

A. von Baeckmann, E. Mainka, and *L. Lindner*[*]

The methods used for the determination of the plutonium content in PuO_2 are as follows (all work with plutonium is carried out in gastight glove boxes, in which a vacuum of 20 mm H_2O is maintained):

1. *Cerimetric determination*[1]: Dissolution in 11 N HNO_3 and 0.05 N NH_4F, oxidation with AgO to PuO^{2+}, addition of NH_2SO_3H and Al^{3+}, reduction with Fe^{2+} to Pu^{4+}, oxidation of the excess Fe^{2+} with Ce^{4+}. (The end-point is determined

[*] Dr. A. von Baeckmann
Dr. E. Mainka
Dr. L. Lindner
Kernforschungszentrum
75 Karlsruhe (Germany)

[1] *J. Corpel* and *F. Regnaud*, Analytica chim. Acta *35*, 508 (1966).

potentiometrically with the Radiometer Titrigraph. The relative standard deviation is 0.2 %).

2. *Coulometric determination*[2]. Reduction to Pu^{3+} at a controlled-potential working electrode at +400 mV (against a saturated calomel electrode) followed by controlled oxidation to Pu^{4+} at +900 mV. (The Numec Electronic Controlled Potential Coulometric Titrator Model 600 is used. The relative standard deviation is 0.25 %).

As a check, the plutonium content is also determined gravimetrically by calcination at 1200 °C to obtain stoichiometric PuO_2. (The relative standard deviation is 0.1 %; on average, the results are 0.1 to 0.2 % higher than those obtained by oxidimetric determinations).

To determine other elements, the solution obtained after separation of the plutonium on ion exchangers (8 N HNO_3) is analysed by emission spectrography[3] for Al, B, Ca, Cr, Cu, Fe, Mg, Mn, Mo, Ni, Pb, and V. To determine traces of carbon, the samples are calcined in a current of oxygen at 1400 °C, and the CO_2 that escapes is determined coulometrically.

The plutonium content in UO_2/PuO_2 fuels is determined cerimetrically and coulometrically; the impurities are determined by emission spectrography. The uranium content is determined either from the sum of the uranium and plutonium[4] as determined by reduction to U^{4+} and Pu^{3+} with $TiCl_3$ and oxidation with Ce^{4+} with potentiometric end-point determination, or, after reduction of the UO_2^{2+} in approximately 60 % phosphoric acid with Fe^{2+} to U^{4+} and oxidation of the residual Fe^{2+} and dilution with 2 N H_2SO_4, by controlled oxidation of the U^{4+} with $Cr_2O_7^{2-}$ to UO_2^{2+}[5]. The end-point is determined with barium diphenylaminesulfonate. (The relative standard deviation for both methods is 0.3 %). For photometric analyses, a spectrophotometer (Zeiss PMQ II) was modified in such a way that the normal sample chamber was firmly attached to a glove box, so that it can be used for the examination of α-emitters. A second sample chamber was introduced between the light source and the monochromator for the analysis of inactive samples. The spectrophotometric determination of traces of boron, fluorine and nitrogen in PuO_2/UO_2 is being investigated.

Separation of Fission Products by Extraction Chromatography

R. Denig, N. Trautmann, and *G. Herrmann*[*]

Alkali metals, alkaline earths, and rare earth metals can be separated by elution chromatography on cation-exchange resins; other fission products as well as fissionable elements can be separated by extraction chromatography of solutions in hydrochloric acid. The extracting agent is adsorbed on a fine-grained support and packed into columns; the mixture is introduced and resolved by elution. Extracting agents tested include di(2-ethylhexyl)orthophosphoric acid (HDEHP), tri-n-butyl phosphate (TBP), tri-n-octylphosphine oxide (TOPO), and tri-n-octylamine (TOA), these agents being adsorbed on polytrifluoromonochloroethylene (Hostaflon C 2).

The partition coefficients of the elements Zn, As(III,IV), Sr, Zr, Nb, Mo, Tc, Ru(III,IV), Rh, Ag, Cd, In, Sn(IV), Sb(III,V), Te(IV), I, Cs, Ba, Ce, Tb, Th, Pa, U, Np(IV,VI) between the stationary phases and 0.1 to 12 N hydrochloric acid were determined. The elements behave towards TBP, TOPO, and TOA as towards anion-exchange resins, *i.e.* anionic complexes are extracted. HDEHP, on the other hand, preferentially extracts highly charged cations at low concentrations of hydrochloric acid, but also extracts anion complexes at high acid concentrations.

The separation scheme for the principal components is as follows:

1. Extraction with TBP from 8 M HNO_3 + $NaClO_3$ (Z_r, U, Np); elution with 8 M HNO_3 + SO_2 (Zr + Np) and water (U).
2. Extraction with HDEHP from 9 M HCl + $NaClO_3$ (Nb, Sb, I); elution with 0.1 M HCl (Sb, I; exchange of I on AgCl) and with 3 M HCl/0.4 M HF (Nb).
3. Extraction with HDEHP from 0.1 M HCl (Mo, rare earth metals); elution with 1.5 M HCl (rare earth metals) and 12 M HCl (Mo).
4. Extraction with TBP from 6 M HCl (Tc, Te); elution of both with 0.4 M HCl.

Sr, Ru, Rh, Cs, and Ba cannot be extracted. Ru is distilled after group 4. from perchloric acid; after the addition of a carrier, Rh is separated by precipitation with ammonia.

Decontamination of Radioactive Waste Water by Salts of Fatty Acids

By *L. von Erichsen*[*]

Many radioactive nuclides (with and without carriers) can be coprecipitated during the precipitation of calcium soaps by potassium salts of higher fatty acids. The decontamination is very nonspecific, calcium soaps being much more effective than Fe or Al salts of fatty acids. Potassium salts of mixtures of fatty acids are more effective than the salt of a single acid. If the calcium hardness of the water is not sufficiently high, Ca may be added in the form of gypsum solution.

The highest decontamination factors (about 12 to $\gg$ 100) are achieved with the alkaline earth and rare earth metals, actinides, and elements from Cr to Zn, while medium decontamination factors (about 10 to 65) are obtained with Y, PO_4, Sb, and Hg. No appreciable decontamination occurs with the alkali metals and halogens (as ions). Where a nuclide exists in several valence states, the decontamination factors for the various states can differ considerably (*e.g.* for Cr, Mn, Tc, I).

With substoichiometric precipitation ($<$ 50 % of the theoretical quantity of soap), the active calcium soaps coagulate well and can be satisfactorily filtered; when dry, they can be briquetted, and the fatty acid can be removed by ashing.

Since the salts of the higher fatty acids with various cations give large lattice constants on X-ray analysis, and since precipitates crystallize only slowly, the simultaneous incorporation of different types of cations (solid solution, adsorption, occlusion) becomes easier to understand. The calcium soaps exhibit lipophilic-polar characteristics and ion-exchanger properties. Moreover, free halogen adds to unsaturated fatty acids.

The process can probably be used for neutral or alkaline radioactive waste waters having wide ranges of activities.

Corrosion of Zirconium and Zirconium Alloys

By *K. H. Lieser*[**]

Radiochemical methods can be used to study the transfer of matter between the surface of a metal and a solution. Autoradiographs are particularly useful in this connection.

When heated in an atmosphere of water vapor, zirconium at first shows a parabolic increase in mass with time. The break in the curve indicates the bursting of the oxide film, and the water vapor can then penetrate freely to the metal. Zirconium and zircaloy-2 are remarkably stable in electrolyte solutions, provided that no fluoride ions are present since these form complexes with the metal. Even in 6 N HCl, the average rate of dissolution at 97 °C is only about 0.2 $\mu g\ cm^{-2}\ h^{-1}$. No exchange is observed between labeled zirconium ions in solution and the metal. The labeled zirconium ions in the solution participate to a very small extent in the corrosion, which takes the form of pitting.

The corrosion becomes very much more pronounced in the presence of iron(III) or copper(II) salts. The experimental results obtained under various conditions are compared and discussed. The pitting can be detected even in the early stages by autoradiography. The alloying metals also appear in solution, the iron being present in relatively large amounts.

The behavior of zirconium in solutions with organic solvents, *e.g.* alcoholic hydrochloric acid, is quite different from its behavior in aqueous electrolyte solutions. If the water content is sufficiently low (less than about 1 %), the protective ZrO_2 film cannot be reformed, and the zirconium dissolves rapidly. In zircaloy-2, the alloying metals have a very unfavorable influence; the zirconium is completely corroded. A black residue containing zirconium hydride remains.

The experiments are significant in connection with the use of zirconium and zirconium alloys in reactors moderated with organic liquids. Here the protective ZrO_2 film is open to attack if there is no water present. The unfavorable influence of the alloying metals is probably due to the fact that the ZrO_2 film is no longer so inert when it contains other ions.

Radiometric Isotope-Frequency Analysis of $^{233}U/^{235}U$ Mixtures

By *E. Merz*[*]

Analysis of the fission products of nuclear fuels is generally carried out radiometrically after preliminary quantitative determination of one fission nuclide, *e.g.* ^{95}Zr, ^{137}Cs, or ^{144}Ce. However, this isotope-abundance analysis fails in cases where the two uranium isotopes ^{233}U and ^{235}U, which can both be fissioned by thermal neutrons, are present together, as can occur in thermal thorium breeder reactors.

However, the analysis can be carried out radiometrically by measurement of the neutron-induced radioactivity ratio of two fission nuclides whose fission yields for ^{233}U and ^{235}U are very different. The contents of ^{233}U and ^{235}U in the unknown sample can then be determined by comparison with pure ^{233}U and ^{235}U standards irradiated under identical conditions. Two pairs of nuclides, $^{103}Ru/^{89}Sr$ and $^{103}Ru/^{131}I$, are particularly suitable. The ^{238}U content can be simultaneously determined for the same sample by measurement of the (n,γ)-induced ^{239}Np γ-activity.

The Use of Boron Compounds in Gas-Cooled High-Temperature Reactors

H. Nickel[**]

Control elements containing boron or boron compounds have been considered for use in gas-cooled high-temperature reactors. This raises the important question of the stability of substances containing boron in a graphite matrix at high temperatures.

Emission-spectrographic measurements have shown that in graphite electrodes containing boron (carbon arc), the boron always diffuses towards the focus, *i.e.* towards the hot zone. The rate of this boron transport depends on the chemical nature of the boron compounds, the degree of graphitization, and the density of the graphite matrix. It is suggested that the diffusion mechanism is a combination of volume diffusion through lattice vacancy movement, and grain boundary diffusion.

Coated particles containing boron are suitable for use in the reactor (> 1000 °C) only if they contain a dense, isotropic high-temperature pyrocarbon layer. However, slight migration of the boron through the pyrocarbon layer into the surrounding graphite matrix cannot be completely avoided, even by prolonged heat treatment.

Radiochemical Determination of the Activities of Fission Products in Irradiated Fuel Elements

By *H. Wertenbach* and *A. von Baeckmann*[*]

In the radiochemical determination of the distribution of the various fission products in a fuel element after irradiation, very simple separation and measuring procedures have been developed for the nuclides Sr, Zr, Mo, Ru, Te, I, Cs, Ba, and Ce[1]. An accurately known quantity of an inactive carrier of the element to be determined is added to the solution of the fission products, care being taken to ensure homogeneous mixing of the carrier and the active component.

Precipitation and extraction operations for the isolation of the element in question in a radiochemically and chemically pure state were formerly followed by final precipitation, determination (generally gravimetric) of the chemical yield, and measurement of the activity. An appreciable simplification can be achieved by the addition of a known substoichiometric quantity of precipitant[2]. An accurately known constant proportion of the quantity of carrier added is now precipitated and it is ascertained whether the precipitation was substoichiometric. A separate determination of the chemical yield thus becomes unnecessary and the reproducibility and standard deviations (1–2.5 %) can be improved. The final precipitation is now carried out at boiling point in the following manner:

Sr is precipitated from ammoniacal solution (10 ml, 0.25 mmole of Sr carrier) with exactly 5 ml of 0.02 M oxalic acid. Zr is precipitated from 0.6 N HF solution (8 ml, 0.25 mmole of Zr carrier) with exactly 5 ml of 0.04 M $BaCl_2$ solution. The ratio Ba:Zr in the precipitate is constant (≈ 2.12). Mo is precipitated from phosphate-free acetic acid solution buffered with ammonium acetate (15 ml, 0.4 mmole of Mo carrier) with exactly 5 ml of 0.03 M of $Pb(CH_3COO)_2$ solution. The solution of tellurium(IV) in 3 N hydrochloric acid (10 ml, 0.3 mmole of Te carrier) is mixed with exactly 5 ml of 0.08 M $TiCl_3$ solution to reduce Te^{4+} to Te^0. I (carrier: 0.3 mmole of I) is precipitated from 25 ml of 0.5 N hydrochloric acid solution with exactly 5 ml of 0.01 M $PdCl_2$ solution. Cs (carrier: 0.5 mmole of Cs) is precipitated from acetic acid solution (40 ml) by the addition of exactly 10 ml of 0.0146 M sodium tetraphenylborate solution[2]. Ba is precipitated from weak hydrochloric acid solution (10 ml, 0.25 mmole of Ba carrier) with exactly 5 ml of 0.02 M H_2SO_4 solution. Ce (carrier: 0.25 mmole of Ce is precipitated from 0.02 N nitric acid solution (6 ml) with exactly 5 ml of a 0.025 M oxalic acid solution. [VB 35 IE]

The Influence of the Solvent on Coordination-Chemical Reactions

V. Gutmann [*]

Solvents can be classified as donor or acceptor solvents. Interaction of a covalent acceptor molecule and a donor solvent molecule (D) can be measured calorimetrically. The values of $-\Delta H$ (not ΔH^0) for the reaction

$$SbCl_5 \text{ (soln.)} + D \text{ (soln.)} \rightleftharpoons D{\cdot}SbCl_5 \text{ (soln.)}$$

are termed donor numbers, $DN(SbCl_5)$. They are proportional to the equilibrium constants K_1 and the $-\Delta H$ values of the corresponding reactions of the solvent with other acceptors, such as $SbCl_3$, $SbBr_3$, $(CH_3)_3SnCl$, I_2, and phenol.

Formation of a chloro complex on addition of chloride ions is considered as a ligand exchange:

$$D{\cdot}SbCl_5 \text{ (soln.)} + Cl^- \rightleftharpoons [SbCl_6]^- + D \text{ (soln.)}$$

The equilibrium constant is inversely proportional to the donor number of the solvent:

$$DN\ (SbCl_5) \cdot \log K_2 \sim \text{const.}$$

The donor number of a solvent determines its ability to dissolve ionic as well as covalent compounds, also the ionization of dissolved substances, the occurrence of autocomplex formation, and the tendency to formation of coordination compounds with other ligands (competing ligands).

The larger $DN(SbCl_5)$ is, the better is the dissolving power and the greater the ionization. Competing ligands give complexes if they are stronger complexing agents than the solvent. The smaller the donor number, the smaller is the dissolving power and the ionization; thus solvents with relatively small $DN(SbCl_5)$ must be used for reactions with weakly competing ligands. Autocomplex formation is to be expected when the coordination-chemical properties of the donor solvent and competing ligands are similar.

The dielectric constant is important only for ionic dissociation and thus for the electrochemical behavior of solutions.

Steric factors have more effect the higher the coordination number, the smaller the central ion, and the more bulky the solvent molecule.

Numerous examples in, particularly, acetonitrile (DN 15), propylene carbonate (DN 15), trimethyl phosphate (DN 23), and dimethyl sulfoxide (DN 30) are used to show that the donor number can be used to explain the varied behavior of one system, *e.g.* $Fe^{3+} + Cl^-$, in different solvents. Whereas in acetonitrile all the Cl^--coordination forms can be obtained, $FeCl_3$ undergoes autocomplex formation in trimethyl phosphate, and ionization occurs in dimethyl sulfoxide even in the presence of large concentrations of Cl^-:

$$FeCl_3 + 6\ DMSO \rightleftharpoons [Fe(DMSO)_6]^{3+} + 3\ Cl^-.$$

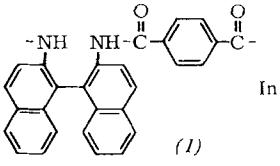
Recent Studies of Optically Active Polymers

R. C. Schulz [*]

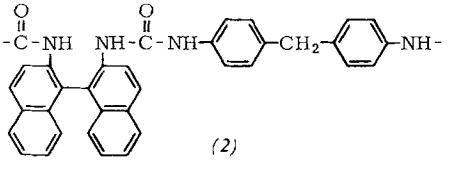
The rotatory dispersion of poly-L-lactide [1] can be described by the Moffit-Yang equation (a) or by the modified two-term Drude equation (b).



$$m' = a_0 \frac{\lambda_0^2}{\lambda^2-\lambda_0^2} + b_0 \frac{\lambda_0^4}{(\lambda^2-\lambda_0^2)^2} \quad \text{(a)}$$

$$m' = A_1 \frac{\lambda_1^2}{\lambda^2-\lambda_1^2} + A_2 \frac{\lambda_2^2}{\lambda^2-\lambda_2^2} \quad \text{(b)}$$

where m' = the reduced monomer unit rotation; the constants were calculated electronically: $\lambda_0 = 201$ mμ, $\lambda_1 = 225$ mμ, $\lambda_2 = 163$ mμ, for $CHCl_3$ $a_0 = -641$; $b_0 = 311$; $A_1 = 212$; $A_2 = -1402$.



Copolymers of L-lactide with DL-lactide, glycollide, 6-hexanolactone, 3,3-bis(chloromethyl)oxetane, 3-propiolactone, epichlorohydrin, and 1,2-epoxy-4-vinylcyclohexane have been prepared and the influence of composition on the rotatory dispersion has been studied.

Racemisation of atropisomeric groups is much slower when they are present in polymer molecules than when they are present in model compounds of lower molecular weight [2]; but the viscosity of the medium has no influence on the rate of racemisation. Optically active polyamides *(1)* and polyureas *(2)* have been prepared from (+)-1,1′-binaphthalene-2,2′-diamine.

In THF, $[\alpha]_{589} = -20.4$
$[\alpha]_{353} = -2330$

(1)

(2)

On the basis of the helix structure assumed by *Freudenberg* [3] the familiar blue iodine-starch complex should show an induced Cotton effect; in fact, a maximum in the ORD curve occurs at 585 mμ; the circular dichroism is positive, with a maximum at 545 mμ. With a molar ratio I_2/glucose unit = 1:6, $[\alpha]_{580}^{25} = +4000$ (calc. per $C_6H_{10}O_5$). In contrast to the extinction ($\lambda_{max} = 565$ mμ), the rotation is approximately doubled in 40 hours. Factors that destroy the helix structure (heating, addition of urea or detergents) decrease the rotatory power. Addition of solvents (methanol, dimethyl sulfoxide, hexafluoroacetone hydrate) also alter the absorption and rotatory dispersion curves.

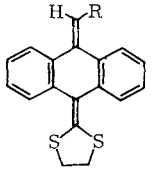
Chemistry of Quinonemethides and Quinodimethanes

By *R. Gompper* [*]

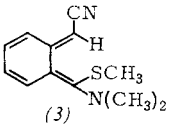
ω,ω-Bis(alkylthio)quinomethides [1] *(1a)* and related compounds *(1b)* are ambifunctional nucleophiles and electrophiles.



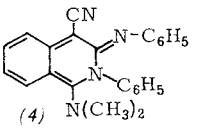
Typical reactions of *(1a)* with electrophiles include those with PCl_5 or $SOCl_2$, whereby, for instance, 4-chloroaryl 1,3-dithiolanium salts are formed. *o*- and *p*-Quinodimethides

(1a), R = R' = SR
(1b), R = R' = NR_2, OR, Hal

differ in their reactions with diphenylketene: whereas the *para*-compounds give diphenylquinodimethanes, dihydrocoumarins are formed from the *ortho*-isomers.



Reaction of *(1a)* with nucleophiles normally leads to removal of RSH, addition of amines gives, for instance, the product *(1b)* with R = R' = NR_2. The CO group is attacked only on interaction of Grignard compounds with compounds of type *(1a)* in the anthracene series; this yields *p*-quinodimethanes *(2)* that are characterized by halochromism (violet coloration). Synthesis of other *p*-quinodimethanes can be achieved (i) by heating phenylmalonodinitrile or related compounds with, *e.g.*, 1-methyl-2-methylthio-1,3-dithiolanium methyl sulfate[2] or (ii) by removal of HX from *N,N*-disubstituted *p*-cyanomethylthiobenzimidic ester salts. The color of quinodimethanes is strongly dependent on the extent of annelation. Some 2-aryl-1,3-dithiolanium salts of related structure were prepared by dehydration of the corresponding aldehyde



(2), R = Alkyl, C_6H_5

mercaptals, to serve as models for study of the relation between color and constitution.

Method (ii) was used in the first synthesis of an *o*-quinodimethane *(3)* that was stable at −40 to −20 °C, and in which valence isomerisation to the substituted bicyclo[4.2]octatetraene is apparently hindered. Compound *(3)* dimerises rapidly at room temperature to give a dibenzocyclooctate-

(3)

(4)

traene and reacts with acetylenedicarboxylic ester to give a naphthalene derivative. Heterocycles of *o*-quinodimethane structure, *e.g.* *(4)*, are obtained on treatment of *(3)* with diphenylcarbodiimide, phenyl isocyanate, phenyl isothiocyanate, or carbon disulfide. Substitution of *(3)* by 1-fluoro-2,4-dinitrobenzene affords an *o*-quinodimethane that is stable even at room temperature. [VB 40 IE]

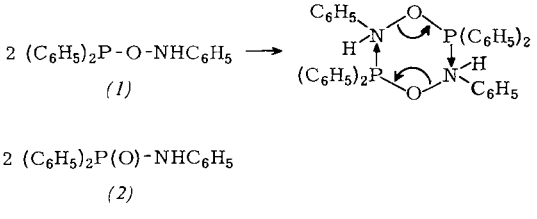
SELECTED ABSTRACTS

Tetrangomycin and tetrangulol, the first benz[*a*]anthraquinone derivatives obtained from natural sources, have been isolated by *M. P. Kunstmann* and *L. A. Mitscher* from *Streptomyces rimosus* cultures. 363 mg of tetrangomycin *(1)*, $[\alpha]_D^{25} = 41.8 \pm 3.5°$ (chloroform), yellow crystals, m.p. 182–184 °C, and

(1)

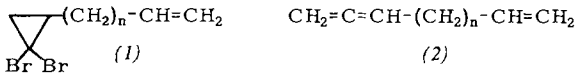


(2)

2.41 g of tetrangulol *(2)*, purple needles having m.p. 189 to 200 °C, were obtained from a 3000 l fermentation. Hydrocarbons with this ring system can act as carcinogens. / J. org. Chemistry *31*, 2920 (1966) / −De. [Rd 605 IE]

1,2-Azaboretidine *(1)* has been synthesized by *S. Åkerfeldt* and *M. Hellström* by the reaction of aziridine with sodium tetrahydridoborate in moist tetrahydrofuran, or in dry tetrahydrofuran with the addition of glacial acetic acid [*(1)*, m.p. 47–48 °C, yield 70 or 73%]. The compound is relatively toxic. Its structure was established from the NMR and IR spectra. / Acta. chem. scand. *20*, 1418 (1966) / −WG. [Rd 606 IE]

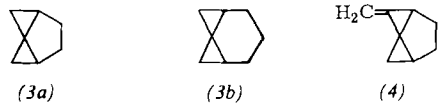
An Arbusov-type rearrangement of a >P−O−N grouping has been postulated for the first time by *B. J. W. F. Hibberd* and *B. L. Tonge.* For example, *N,P,P*-triphenyl-*O*-phosphinohydroxylamine *(1)*, which is prepared from equimolar amounts of chlorodiphenylphosphine and phenylhydroxylamine in benzene in the presence of triethylamine or pyridine at 5 °C, rearranges spontaneously and quantitatively to give *N,P,P*-triphenylphosphinamide *(2)*, probably by a six-center synchronous mechanism.



(1)

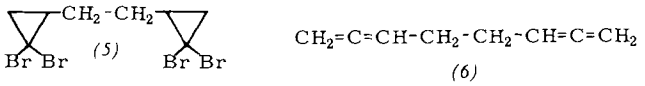
(2)

However, only compounds of the type $(RO)_2P-O-N<$ have so far been isolated, and not compounds of the type *(1)*. / Chem. and Ind. *1966*, 1599 / −Jg. [Rd 607 IE]



The separation of zirconium and hafnium with *o*-phenylenebis(dimethylarsine) in a single operation has been achieved by *R. J. H. Clark, W. Errington, J. Lewis,* and *R. S. Nyholm.* The rates of precipitation of the complexes $[MX_4 \cdot 2o\text{-}C_6H_4(As(CH_3)_2)_2]$ (M = Zr, Hf; X = Cl, Br) differ considerably. These complexes (coordination number 8, symmetry class D_{2d}) are obtained from the anhydrous tetrachlorides in anhydrous THF. Corresponding complexes can also be prepared with $TiCl_4$ and $TiBr_4$; with TiF_4 and TiI_4, however, the coordination number 8 is evidently no longer reached. The first fraction in the fractional precipitation of a mixture of zirconium and hafnium halides contains 35% of the zirconium used, but no hafnium. A disadvantage of the separation process is probably the need for complete exclusion of air and moisture. / J. chem. Soc. (London) A *1966*, 989 / −Bu. [Rd 617 IE]

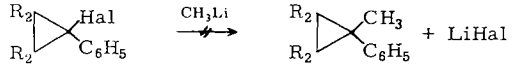
Tricyclo[4.1.0.0.^{4,6}]heptane *(3)* **and tricyclo[5.1.0.0^{5,7}]octane** *(4)* have been synthesized by *L. Skatteböl.*



(1) *(2)*

(a): n = 2; *(b)*: n = 3; *(c)*: n = 1

(3a) *(3b)* *(4)*



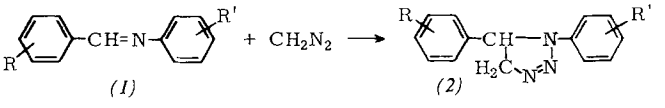
(5) *(6)*

(1a) reacts *e.g.* in ether solution with methyl-lithium to give *(2a)* (b.p. 104 °C, $\nu_{C=C=C}$ = 1950 cm^{-1}) and *(3a)* (b.p. 108 °C) in a total yield of 85%. Similarly, *(1b)* gives *(2b)* (b.p. 64 °C/100 mm, $\nu_{C=C=C}$ = 1950 cm^{-1}) and *(3b)* in 85% total yield, while *(1c)* gives only *(2c)* (b.p. 74 °C, $\nu_{C=C=C}$ = 1945 cm^{-1}) in 46% yield. Compounds such as *(5)* also give tricycloheptanes such as *(4)*, together with diallenes such as *(6)* (b.p. 48–50 °C/25 mm, $\nu_{C=C=C}$ = 1960 cm^{-1}). / J. org. Chemistry *31*, 2789 (1966) / –Bu. [Rd 618 IE]

The stereoselectivity of the addition of olefins to phenylhalocarbenoids (C_6H_5–$CHal_2M$) has been studied by *G. L. Closs* and *J. J. Coyle* and by *R. A. Moss* and *R. Gerstl.* Benzylidene chloride or bromide was allowed to react with strong bases such as potassium t-butoxide (at 25 to 70 °C) or methyl-lithium (at –40 °C) in the presence of olefins having neither a center of symmetry nor a mirror plane parallel to the π-electron cloud. The products are cyclopropanes in which the halogen atom is preferentially attached on the side carrying the largest number of methyl groups ("*anti* form" with regard to the phenyl group; individual phenyl and (to a greater extent) halogen substituents on the carbenoid carbon are *syn*-directing).

Olefin	*anti*/*syn* Ratio	
	(1a)	*(1b)*
2-Methyl-2-butene	1.5	1.28
cis-2-Butene	3.0	1.35
Cyclohexene	2.0	0.33
1-Butene	1.7	—

The *anti*/*syn* ratio does not depend on the base used. This is explained by assuming an interaction to take place between the alkyl groups of the olefin and the substituents on the carbenoid carbon before the formation of the three-membered ring. If methyl-lithium is used in excess, three-membered ring compounds *(2)*, as well as styrene and cumene, are formed in addition to *(1a)*. The ratio of these products depends on whether the methyl-lithium is prepared from CH_3Cl, CH_3Br, or CH_3I; the presence of I^- leads to higher yields.

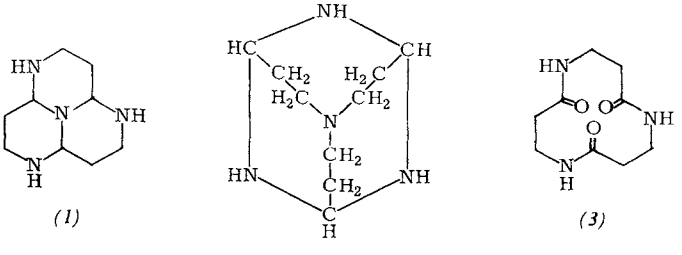


(1a) Hal = Cl *(2)*

(1b) Hal = Br

Reaction of *(1a)* with CH_3Li to give *(2)* could be ruled out. These findings can be explained without the assumption of a carbene intermediate. However, at present, stable carbenoids are known only with Li, and not with K. No stereospecificity is observed when cyclopropane derivatives such as *(2)* are produced from diazo compounds. / J. org. Chemistry *31*, 2759 (1966); Tetrahedron *22*, 2637 (1966) / –Bu. [Rd 619 IE]

The 1,3-dipolar addition of diazomethane to Schiff bases, previous attempts at which having met with little success, has now been achieved in aqueous solvents by *P. K. Kadaba.* This is the more remarkable in that kinetic measurements by the author indicate a one-step synchronous mechanism which is almost independent of the polarity of the solvent. This reaction can be used to obtain good yields of 1,2,3-triazolines *(2)*, which are analytically pure without recrystallization. The new method is far superior to the earlier process, in which *(2)* were prepared by 1,3-dipolar addition of azides to olefins.



(1) *(2)*

(a) R = H; R' = *m*-Cl
(b) R = *o*-Cl; R' = *m*-NO_2

For example *(2a)*, m.p. 73–74.5 °C could be obtained in 59% yield from *(1a)* in aqueous dioxane after 4 days at 20 °C. Particularly high yields were obtained when R and/or R' = NO_2 [*e.g. (2b)*, m.p. 118–120 °C, 92%]. / Tetrahedron *22*, 2453 (1966) / –Bu. [Rd 620 IE]

Dodecahydro-1,4,7,9b-tetraazaphenalene *(1)* was obtained in 87% yield by *J. L. Van Winkle, J. D. McClure,* and *P. H. Williams* from acrolein and ammonia (molar ratio ≈ 1:10) in methanol at 150 °C and 105 atm.

(1) *(2)* *(3)*

Apart from polymers, only the 1:1 and 2:2 condensation products of acrolein and ammonia were hitherto known. The only way in which a decision could be made between *(1)* and *(2)* was by X-ray analysis of the trishydrochloride (by *A. E. Smith*) and by degradation. A C=N double bond could be introduced in the allyl position with respect to the central nitrogen (yield 44%, m.p. 118–120 °C) by oxidation with $Hg(ac)_2$, while oxidation with $KMnO_4$ gave 1,5,9-triazacyclododecane-4,8,12-trione *(3)* yield 11%, m.p. 300 °C). Hydrolysis of *(3)* gave a 90% yield of β-aminopropionic acid. *(3)* was also reduced with $LiAlH_4$ to 1,5,9-triazacyclododecane (b.p. 77–78 °C/3 mm). *(1)* (m.p. 118–120 °C, b.p. 117 °C/0.1 mm) reacts with HNO_2, H_2O_2, *etc.* as a secondary amine. pK_a values of *(1)* in aqueous solution: 7.6; 5.8; 3.3. Methacrolein and crotonaldehyde probably give homologous products. / J. org. Chemistry *31*, 3300 (1966) / –Bu. [Rd 624 IE]

The trimethylsilyl group can be used as a protective group for aromatic amines in organometallic syntheses. To introduce the protective group, the amines are selectively dimetalated at the nitrogen with C_2H_5MgBr and converted into the *N,N*-bistrimethylsilyl derivatives by treatment with trimethyl-

silane. After reaction, the trimethylsilyl groups can be removed from the nitrogen by refluxing with methanol. In this way, *D. R. M. Walton* converted *p*-bromoaniline into *N,N*-bis(trimethylsilyl)-*p*-bromoaniline (b.p. 106 °C/1.2 mm; n_D^{25} 1.5140); the lithium compound was then prepared by halogen/metal exchange with n-butyl-lithium. Reaction with $(CH_3)_3SiCl$, $(C_2H_5)_3GeBr$, or addition to benzophenone, followed by heating with methanol, gave *p*-trimethylsilylaniline (yield = 90%; b.p. 102 °C/6 mm Hg; n_D^{25} = 1.5348), *p*-triethylgermylaniline (yield = 96%; b.p. 94 °C/0.4 mm; n_D^{25} = 1.5487) or *p*-aminophenyldiphenylmethanol (yield = 76%; m.p. 120 to 121 °C). / J. chem. Soc. (London) C *1966*, 1706 / –Bu.

[Rd 627 IE]

Ag_2^+ ions are formed from silver atoms and silver(I) in γ-irradiated (^{60}Co) vitreous solutions of silver(I) salts, as has been shown ESR-spectroscopically by *L. Shields* and *M. C. R. Symons*. At low temperatures (*e.g.* 77 °K), silver atoms are formed during γ-irradiation; the ESR spectrum changes on slow warming; the new lines can be explained only by formation of Ag_2^+ ions. For further confirmation, similar experiments were carried out with silver salts enriched in ^{109}Ag. The formation of a silver-silver bond appears to be exothermic since all the silver atoms are converted into the dimeric species in the presence of an excess of Ag^+. At higher initial Ag^+ concentrations, the electrons for the formation of Ag^0 (and hence Ag_2^+) can be obtained not only from the solvent, but from Ag^+ ions; it is then also possible to detect Ag^{2+} ions. The Ag^+ ion may also play a part in the primary photographic process. / Molecular Physics *11*, 57 (1966) / –Hz.

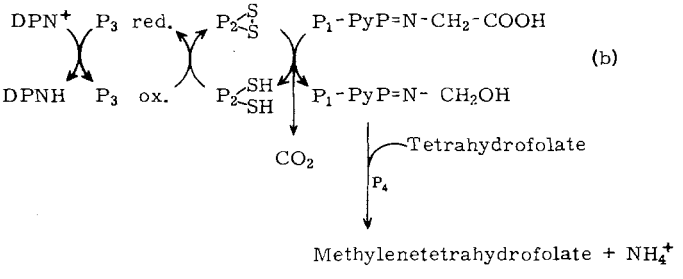
[Rd 631 IE]

The states responsible for the photochemical decomposition of formaldehyde in the region of the $\pi^* \leftarrow n$ ($^1A_2 \leftarrow {}^1A_1$) absorption (2200–3700 Å) are described in MO schemes by *E. W. Abrahamson, J. C. F. Littler*, and *Kim-Phan Vo*. The decomposition takes place on occupation of one of the two CH_2-antibonding orbitals with an electron. One of these orbitals has H–H-bonding character ($^1A''$) and leads to decomposition into $CO + H_2$; the other CH_2-antibonding orbital ($^1A'$) also weakens the H–H "bond", and decomposition in this state yields H + HCO or 2H + CO. These two orbitals become occupied by radiationless transitions from the (n, π*) state, which, unlike the ground state (C_{2v} symmetry), has no planar nuclear skeleton (C_s symmetry; angle between CH_2 plane and CO axis: 20.7 °). The decomposition into $CO + H_2$ predominates in the range 3550 to 3700 Å with maximum quantum yields of 0.3. At shorter wavelengths the second type of decomposition becomes increasingly frequent, until at wavelengths lower than 3130 Å, it completely replaces the first type; the quantum yield of the latter type of decomposition is 0.4 to 0.5. / J. chem. Physics *44*, 4082 (1966) / –Hz.

[Rd 632 IE]

Ribosomes and aminoacyltransferase II interact with each other, according to *R. P. Sutter* and *K. Moldave*. The incorporation of amino acids from aminoacyl-tRNA into peptides requires the presence of the two aminoacyltransferases I and II, guanosine triphosphate (GTP), ammonium ions, and a thiol, as well as mRNA and ribosomes. The action of the thiol is based on the activation of the transferase II; the lag phase often observed in the incorporation of amino acids disappeared when transferase II and the thiol are preincubated together. The initial rate of incorporation is further increased when the ribosomes, transferase II, GTP, and ammonium ions are preincubated. mRNA and aminoacyl-tRNA need not be present during this preincubation, and these are added to start the reaction. The transferase II, which is very sensitive to oxidation *e.g.* by oxidized glutathione, is very much less susceptible to oxidation in the reaction product resulting from the preincubation. / J. biol. Chemistry *241*, 1698 (1966) / –Hö.

[Rd 579 IE]



The regulation of the specificity of an enzyme has been observed by *W. S. Beck* and his co-workers. The cobamide-dependent ribonucleotide reductase from *Lactobacillus leichmannii* catalyses the reduction of ribonucleoside triphosphate, CTP, GTP, ATP, and UTP to the deoxyribonucleoside triphosphates by dihydrolipoic acid or by the system thioredoxin/thioredoxin reductase/TPNH. ATP and dATP stimulate the reduction of CTP, while dTTP stimulates that of GTP, dGTP that of ATP, and dCTP that of UTP. 8×10^{-3} M ATP, which acts catalytically (no degradation), is required in order to reduce the Michaelis constant for CTP by a factor of 6. dATP, dCTP, and dTTP inhibit the reduction of ATP, and dGTP inhibits the reduction of GTP. It is assumed that the regulation processes are based on an allosteric mechanism. / J. biol. Chemistry *241*, 2176 (1966) / –Hö.

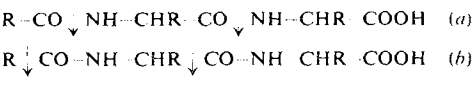
The oxidative decarboxylation of glycine [eq. (a)], according to *M. L. Baginsky* and *F. M. Huennekens*, involves an elec-

$$\text{Glycine} + \text{tetrahydrofolate} + DPN^{\oplus} \rightarrow 5,10\text{-Methylenetetrahydrofolate} + CO_2 + NH_4^{\oplus} + DPNH \quad \text{(a)}$$

tron-transferring protein. Four protein components are required for the reaction: P_1 is a pyridoxal phosphate (PyP) enzyme, P_2 is a small heat-resistant and acid-resistant protein having the properties of the thioredoxin found in *Escherichia coli*, P_3 is a flavoenzyme with the function of a thioredoxin reductase, and P_4 is presumably the catalyst for the formation of the methylenetetrahydrofolate. The roles of P_2 and P_3 are indicated by the following reactions: 1. Chemically reduced P_3 is readily oxidized by DPN. 2. DPN and P_3 can be replaced in the overall reaction by substrate amounts of 5,5'-dithiobis-2-nitrobenzoic acid (*Ellmann's*

reagent). 3. DPNH reduces *Ellmann's* reagent in the presence of P_2 and P_3. Scheme *(b)* is proposed for the decarboxylation of glycine in *Peptococcus glycinophilus*. / Biochem. biophysic. Res. Commun. *23*, 600 (1966) / –Hö.



[Rd 581 IE]

Apoferredoxin has been reactivated by *R. Malkin* and *J. C. Rabinowitz*. The free thiol groups in crystallized ferredoxin from *Clostridium pasteurianum* were protected by blocking with Mersalyl (sodium *o*-[(3-hydroxymercuri-2-methoxypropyl)carbamoyl]phenoxyacetate), whereupon the brown color disappeared. The iron was then removed with the weak cation exchanger Chelex 100. The ferredoxin was regenerated with iron(II) salts and 2-mercaptoethanol. When the apoferredoxin was also filtered through Sephadex G25 to remove sulfide ions, renaturation was possible only in the presence of Na_2S. / Biochem. biophysic. res. Commun. *23*, 822 (1966) / –Hö.

[Rd 582 IE]

Methods for the automatic determination of amino acid sequences are reported by *M. Senn* and *F. W. McLafferty*. The determination is carried out by evaluation of mass spectra of peptides with the aid of computers. The peptide

is labeled at the amino end with a group X, so that *N*-terminal fragments can be easily identified. Suitable groups are the trifluoroacetyl, trideuteroacetyl, and CF_2BrCO derivatives, which permit an unambiguous assignment of the mass numbers, owing to the constant isotope ratio. The structure of a linear molecule is established when the fragments containing the introduced group, the possible mass numbers of which can be programmed, have been identified.

Depending on the peptide in question, the fragmentation proceeds almost exclusively in accordance with (*a*) or (*b*). / Biochem. biophysic. Res. Commun. *23*, 381 (1966) / –Hö.

BOOK REVIEWS

Zahlentafeln zur Elementaranalyse (Tables for elementary analysis). By *G. Ege*. Verlag Chemie GmbH., Weinheim/Bergstr. 1966. 1st Edit., xxviii, 356 pp., plastic cover, DM 30.–.

The conversion of the percentages found in the elementary analysis of organic compounds into the empirical formula involves a relatively lengthy routine calculation. To avoid this, *Hatt et al.* published a reference work more than ten years ago (for nitrogen-free compounds up to C_{50}, atomic weight basis O=16). This work is now supplemented by *Ege*'s tables, which also cover compounds containing nitrogen.

Ege has used a new arrangement for the percentages (compounds up to C_{40}; basis: $^{12}C=12$), which greatly simplifies the work involved in searches; even in his first "emergency", the reviewer was able to find the correct formula immediately. Very well-chosen and well discussed examples in the "explanations" also provide for cases in which the indices of a formula have a common factor; such cases, as in *Hatt*'s book, are not given directly in the tables *i.e.* $C_{12}H_{18}O_3$ is found only under C_4H_6O, so that the molecular weight differs from that found from the mass spectrum or by titration. The use of other information, such as is often available in practice, is also discussed to enable the reader to make the maximum use of the data given.

A new feature is the inclusion of the *Beynon* unsaturation number R, which the computer has calculated from the H deficit and which gives the number of rings (and multiple bonds); this can be very useful in the establishment of possible structures.

Thus the new tables are found to be extremely useful; since the computer has expressed its results directly, the tables can claim to be "infallible". Mistakes of the kind that the reviewer found in another book of tables (*Stout*, Composition tables), namely, that all the values given for C_{84} to C_{120} are wrong since the computer found no position for the thousands digit and simply left it out, do not occur in *Ege*'s book.

F. Kuffner [NB 545 IE]

Anwendungen der kernmagnetischen Resonanz in der Organischen Chemie (Applications of Nuclear Magnetic Resonance in Organic Chemistry). By *H. Suhr*. Organische Chemie in Einzeldarstellungen (Organic Chemistry Monographs). Vol. 8. Springer-Verlag, Berlin-Heidelberg-New York 1965. 1st ed., viii, 424 pp., 123 illustrations, 110 tables, cloth DM 68.– (*ca.* $17.–).

This book starts with a simple introduction to NMR and is intended for those coming into contact with this method for the first time. It is also intended as a primer in the evaluation of spectra of organic compounds and presents comparative data for this purpose. Thus the author makes no attempt at a rigorous derivation of the observed patterns from theory; he touches only lightly on the technique of measurement and on the preparation of the sample, and he writes not so much for the physical chemist or spectroscopist as for the organic chemist who requires NMR for structural determinations, but cannot study it in full detail. For the last-named audience, this is an easy to follow and recommendable book.

The first 73 pages describe the main features of chemical shift and spin coupling. The two sections on the theory of τ and J values (p. 28 and p. 45) are kept qualitative, and fulfil their purpose admirably. The chapter on splittings of higher order should have explained in greater detail the practical procedure in the analysis of spectra. It is repeatedly suggested that theoretical spectra should be constructed with the aid of equations or tables. However, it is much less time-consuming to leave this work to a computer; a short description of the programs available for this purpose appears more to the point than the reproduction of rarely-used tables from the literature (27 pp.).

The special part of the book dealing with proton resonance (172 pp.) is arranged according to classes of compounds.

The considerable amount of experimental data and references collected makes this book an excellent source of quickly accessible reference values. However some of the many useful tables could have been improved with respect to the clarity and unambiguity of the data presented (*e.g.* p. 87, p. 93, and p. 134). A separate chapter (43 pp.) is devoted to nuclei other than the proton which are important in organic chemistry. The book closes with 77 pages describing a number of special application The topics discussed include solvent effects, hydrogen bonds, substituent effects, equilibria of all types, and conformation of cyclohexanes. The many references to methods of simplifying complicated spectra deserve special mention, since the success of structural determinations often depends on such simplifications.

The book contains many useful formulae and illustrations. The literature is covered up to the end of 1964, and in some cases to early 1965.

A. Mannschreck [NB 531 IE]

Fortschritte der Chemie organischer Naturstoffe (Progress in the chemistry of organic natural products). Edited by *L. Zechmeister*. Vol. 23. Springer-Verlag, Vienna-New York 1965. 1st Edit., viii, 397 pp., 58 figures, cloth DM 93.60.

Chemists interested in natural products will welcome the publication of any new volume of "Fortschritte", and Vol. 23 [*] certainly will be of great benefit to the reader.

In a survey of the polysaccharides of marine algae, *S. Peat* and *J. R. Turvey* discuss not only the chemistry of these compounds, but also their relation to the polysaccharides of higher plants. However, their biosynthesis is not mentioned. On the other hand, *H. Schlubach*'s contribution on carbohydrate metabolism in barley, oats, and millet deals not only with the constitution of the polyfructosans, but also with the enzymatic control of polyfructosan formation. It is interesting to note that the grains preferentially cultivated by man are those in which the amount of polyfructosans is greatest. *F. Schleuk* makes a successful attempt to explain the properties and functions of the biological sulfonium compounds on the basis of their reactions. The experiments, which show that, in some cases of transmethylation, only

[*] For a review of Vol. 22 see Angew. Chem. *78*, 554 (1966); Angew. Chem. internat. Edit. *5*, 529 (1966).

two protons of the *S*-methyl group of methionine appear in the methylation product, unfortunately could not be included.

A comprehensive review of chemical aspects and functions of human and animal hemoglobins is contributed by *W. A. Schrödinger* and *R.T. Jones*. A very original feature is the description of the construction of a paper model of the β-chain of hemoglobin A. The structure and metabolism of collagen are exhaustively discussed in a brilliant article by *W. Grassmann et al.* In the final chapter, *L. M. Jackmann* first presents a short but very informative introduction to nuclear magnetic resonance methods, and then with the aid of a number of typical examples, he discusses the application of NMR to the elucidation of the structures of natural products. Special attention is given to spin decoupling and the application of nuclear resonance to questions of stereochemistry. *H. Grisebach* [NB 547 IE]

ABC der Chemie (ABC of Chemistry) (2 volumes). Verlag Harri Deutsch, Frankfurt 1966. 1st Edit., 1590 pp., numerous illustrations, 40 tables, bound, total price DM 89.80 (about $ 23).

Good reference books are always welcome, and the present 2-volume work must be described as good. It contains some 12000 entries and 800 illustrations. For many of the entries one finds not only definitions, but descriptive articles which partly have the character of handbook articles. For example, under the entry "Lösungsmittel" (solvents) is given a 3½-page table listing 75 solvents with their densities, melting points, boiling points, flash points, methods of drying, and solvent powers. Similarly detailed information is given, *e.g.*, under "Nomenclature", "Coal", "Nuclear reactors", *etc.* The article on "Laboratory", which covers over six pages, unfortunately is rather inane, and the space could have been put to better use.

It is unlikely that everything in a reference work will be correct, but the number of serious errors here is small (*e.g.* adamantane is not a tetracyclic but a tricyclic hydrocarbon, and in the list of Nobel Laureates the merits of *Krebs* and *Lipmann* are interchanged). More often one finds information that is not strictly accurate: for example, in the article on enzymes, it is stated that " ... they enable reactions to proceed that would occur only under extreme conditions in the absence of the catalys "

Nevertheless, the work would have merited the grade "very good" were it not for the fact that the editors have adhered with Teutonic thoroughness to a spelling that is now considered archaic for technical literature. For example, they use "Azetyl-Koferment A" instead of "Acetyl-Coferment A" ("Coenzym" should be used rather than "Coferment" in any case), and "Azetonzyanhydrin" instead of "Acetoncyanhydrin"; one wonders why they did not have the courage to extrapolate to "Azetofenon". *H. Grünewald* [NB 543 IE]

Praktikum der makromolekularen organischen Chemie (Laboratory manual of macromolecular organic chemistry). Edited by *D. Braun, H. Cherdron*, and *W. Kern*. Dr. Alfred Hüthig-Verlag, Heidelberg 1966. 1st Edit., 250 pp., 25 figures, DM 26.—.

In view of the great importance of macromolecular organic chemistry, universities are showing a growing tendency to incorporate this important branch of organic chemistry into their curricula in the form of lectures and special courses. A handy primer corresponding to "Gattermann" for practical organic chemistry therefore has become a necessity. The present work is matched to the situation in Germany, and was produced with the support of the "Plastics and Rubber" Group of the *Gesellschaft-Deutscher Chemiker*.

Many companies have made tested laboratory procedures available to the compilers. The book gives not only a series of excellent and carefully selected examples of the preparation of the various types of polymers, but also a general picture of the precautions to be taken in laboratory preparations (choice of reaction conditions, purification and storage of monomers, temperature adjustment, control and termination of polymerizations, *etc.*). The theory of the macromolecular compounds is also clearly presented in the various experiments. The reviewer finds it rather disturbing that the examples begin with number 300 and that the decimal classification is used elsewhere.

As is only to be expected from these authors, the book is an excellent introduction to practical macromolecular chemistry and will certainly be warmly welcomed in all technical colleges. *H. Hopff* [NB 550 IE]

Physikalische Anorganische Chemie (Physical inorganic chemistry), by *M. D. Sienko* and *R. A. Plane*. Translated and enlarged by *F. Steinbach*. S. Hirzel, Stuttgart 1965. 1st Edit., 46 figures, 32 tables, 160 pp., paper DM 18.—.

One must be quite optimistic in order to believe that an understandable discussion of those fields of physical and theoretical chemistry with which inorganic chemists are currently involved can be treated in 169 small-format pages.

The abundance of material presented, the many useful tables, and the easy reading seems to make this book suitable for the beginner, who is less concerned with understanding and noting every detail, but rather with obtaining a general picture. Precision is not the strong point of the book, and one does not always gain the impression that the authors themselves fully understand what they are writing about, particularly in the chapters on atomic and molecular theory. This impression is probably more pronounced in the German translation than in the original. The German text is in fact clumsy in many places. Expressions translated too literally from the English version often do not correspond to German usage. For example, the correct German term for "normalization" should be "Normierung", rather than "Normalisierung", and "orbital quantum number" is not "Orbitalquantenzahl", but "Nebendnantenzahl". "Legendre polynomials" are not "Kugelfunktionen", "valence bond" is not normally rendered by "Valenzbindung", and hybridization and degeneracy are entirely different concepts. There is no "procedure called resonance". "Der Orbital" sounds odd when one is accustomed to "das Orbital". The reader is recommended to use in addition a more thorough treatment if he is interested in the theoretical part.

W. Kutzelnigg [NB 562 IE]

Kleine Quantenmechanik (Quantum mechanics in brief), by *W. Wessel*. Physik-Verlag GmbH., Mosbach/Baden 1966. 1st Edit., 161 pp., 46 figures, cloth DM 16.80.

As the author remarks in the introduction, he would like his book to appeal to that kind of non-physicist who might have been enthused in the 1920's by *Sommerfeld*'s "Atombau und Spektrallinien" (Atomic structure and spectral lines).

The particle-wave dualism and the particular role of probability statements in quantum theory are well presented. The author is wary of philosophical conclusions, despite his tendency towards belletristic insertions. The central theme of the book is guidance, as simply as this is possible, along the path that led *Heisenberg* to the development of matrix mechanics.

The subject matter is made somewhat difficult to follow by the fact that important and also secondary concepts and equations are simply pulled out of thin air without proof, or with the remark that their proof would be too difficult. Anyone who expects an introduction to the current formalism of quantum mechanics to enable him, for example, to obtain a better understanding of its chemical applications will be disappointed. However, for a theoretical chemist it

may be worth the experience to be presented the familiar one-dimensional free-electron model from quite a different point of view under the unusual name of "reflection oscillator".

W. Kutzelnigg [NB 563 IE]

Einführung in die Chromatographie (Introduction to Chromatography). By *H. Hrapia*. Wissenschaftliche Taschenbücher (Scientific Manuals), Vol. 30. Akademie-Verlag, Berlin 1965. 1st ed., 236 pp., 32 illustrations, 12 tables, paper \$ 8.00.

More or less comprehensive monographs on the various types of chromatography, *e.g.* paper, thin layer, and gas chromatography, already exist. However, until now there has been no German-language "Introduction to Chromatography", so that the 236-page book from the WTB series fills a gap. The author has a lucid style, and knows how to present even difficult ideas in a comprehensible manner. The subdivision is almost too rigid, so that the beginner may overlook the common feature of all these processes. However, a clearer separation of the actual types of chromatography from the numerous operating techniques is desirable. An introductory "Classification" is followed by a 44-page discussion of the theories of chromatography, the mathematical treatment of the plate theory being given more space than is necessary. The section on the "Practice of Column Chromatography" (45 pp.) is very successful. The next-largest section (37 pp.) is that on gas chromatography. A striking feature here is that details are given for the construction of detectors. 23 pages are devoted to paper chromatography, and 13 pages to thin-layer chromatography. Electrophoresis is discussed rather too briefly in 7 pages. References to companies are mainly confined to manufacturers in East Germany. For a second edition, the reviewer would like to see a more international character also in this respect.

On the whole, the book fully achieves its purpose, *i.e.* to introduce the beginner to the various and versatile possibilities of chromatography. It presents a good survey of the field. It can only be hoped that it will lead, not only to the use of one of these methods, but to their rational combination.

E. Stahl [NB 533 IE]

Synthetic Methods of Organic Chemistry, Vol. 20, by *W. Theilheimer*. Verlag S. Karger, Basel-New York 1966. 1st Edit., xiv, 740 pp., sFr 246.00.

The present volume of this well-known series [1] continues to report on modern synthetic reactions in the proven manner. 702 well-chosen articles from the period 1963–1965 cover the entire field of organic chemistry. In view of the growing importance of stereospecific reactions and photoreactions, more space is devoted to these topics. Numerous reactions for the synthesis of complicated isocyclic and heterocyclic ring systems are also included. To limit the volume to a reasonable size, synthetic work that has nothing new to offer with regard to method is omitted. However, the articles in earlier volumes are brought up to date by the list of "Supplementary references" (17 pages).

This comprehensive volume concludes the series 16–20, and accordingly contains all the references of volumes 16–19 in the text and in the index. This index (148 pages) will be welcomed by all who cannot become accustomed to the system of arrangement used throughout the series. The value of the collection is increased by the inclusion of new entries such as "prevention" and "retention" of functional groups. The four pages on important developments in organic chemistry in 1965–1966 are particularly useful.

This series, which was launched some time ago, no longer requires special recommendation. However, it occurs to the reviewer that the a supplementary peep-hole index might be a useful aid to the retrieval of the information collected in the 20 volumes of this work.

S. Hünig [NB 549 IE]

[1] Cf. Angew. Chem. *78*, 555 (1966); Angew. Chem. internat. Edit. *5*, 529 (1966).

The Penicillin Group of Drugs. By *G.T. Stewart*. Elsevier Publishing Company, Amsterdam 1965. 1st ed., xii, 212 pp., 11 illustrations, bound Dutch fl. 27.50 (*ca.* \$ 7.50).

Penicillin, originally the name of an active principle rather than of a definite substance, not only formed the starting point for antibiotics research in general, but also became a collective term for a group of drugs long after its first investigation. The author's description of this development in the first three chapters shows a great deal of detailed knowledge. This part of the book presents interesting information about the history of medicine, though it is not exhaustive, particularly in relation to non-British contributions.

The next five chapters deal with the semi-synthetic penicillins, mainly from the point of view of application. Chapter 9 discusses morphological and biochemical aspects of the mode of action, and the chemical aspects are discussed in Chapter 10. It would have been better if, *e.g.*, of the six structural formulae on page 100, at least one had been correct, and if C-2 of the penicillin skeleton had not been trivalent throughout the book. The general conclusions on the mode of action (Chapter 11) are very cautious. They are intended to show how far away we still are from an understanding of the relationships. Though the pharmacology and toxicology of some penicillins have already been considered, these and the problems of resistance and allergy are again discussed in three further chapters. The book closes with the epidemiologic importance of the penicillins and a brief discussion of the cephalosporins.

The book was not written for the organic chemist, but microbiologists, physicians, and pharmacists will find some fundamental information in it. Care has been taken with its presentation, and the index and reference lists are comprehensive.

H. A. Offe [NB 523 IE]

Théories moléculaires de la Résonance Magnétique Nucléaire. Applications à la chimie structurale. (Molecular Theories of Nuclear Magnetic Resonance. Applications to Structural Chemistry). By *G. Mavel*. Dunod, Paris 1966. 1st ed., x, 325 pp., 64 illustrations, 47 tables, paper F 78.– (*ca.* \$17.–).

In only a few years, high-resolution nuclear magnetic resonance gained an important place alongside other spectroscopic methods in chemistry. In the present book, *G. Mavel* reviews recent publications (subsequent to the book published in 1959 by *Pople, Schneider*, and *Bernstein*) dealing with the theoretical aspects of nuclear magnetic resonance with special reference to the electronic structure of organic molecules. The obvious aim of the author was to provide a bridge between theory and experiment in this rapidly developing field for the chemist who uses nuclear resonance as an aid in his work.

The two introductory chapters (20 pp.) on the interpretation of nuclear magnetic resonance on the basis of the Bloch equations and on the introduction of the chemical shift and nuclear spin coupling, consequently, are short. In the section on the chemical shift (60 pp.), the fundamental principles of the perturbation theory and of the variation method are first described, and the semi-empirical theories by means of which the empirical data have so far been interpreted are then discussed. A similar plan is followed in the chapter (34 pp.) on indirect spin coupling. Unfortunately, the recent development of the theory by the molecular orbital method (*Pople, Santry, Bothner-By*) is mentioned only briefly. The analysis of nuclear resonance spectra (72 pp.) is carried out explicitly for the simpler cases. Tables are given for a number of more complicated cases, and the moment method and iterative methods are mentioned. This chapter also contains a discussion (unfortunately very short) of the spectra of oriented molecules, which have recently attracted considerable attention. The book closes with chapters on multi-quantum transitions (10 pp.), the theoretical aspects of double reso-

nance (34 pp.), and the change in the spectra as a result of chemical exchange (8 pp.).

The book leans closely on the original literature, with the result that the mathematically more demanding chapters often make difficult reading for the beginner. However, as a guide to the growing literature (more than 1800 references are given) this book will be useful to anyone who is concerned with nuclear resonance. *H. Dreeskamp* [NB 524 IE]

Advances in Quantum Chemistry, Vol. 2. Edited by *P. O. Löwdin.* Academic Press, Inc.. New York-London 1965. 1st ed., xi, 372 pp., 79 figures, bound $ 14.50.

Like the first volume of the series, the present volume contains a collection of reviews on aspects of quantum chemistry ranging from general theory through *ab-initio* calculations to semiempirical applications. Strictly speaking, not all the articles are really reviews; for example, the contribution by *McWeeny* and *Steiner* on the theory of "pair-correlated wave functions" resembles more an original paper.

S. F. Boys and *P. Rajagopal*, in their article on "Quantum Calculations", deal with special problems in numerical *ab-initio* calculations for small molecules. *Inga Fischer-Hjalmars* reviews earlier work by other authors as well as her own more recent work on the justification for the neglect of differential overlap in the theory of π-electron systems. The theory of the hyperfine structure in atomic spectra (as well as in ions and complexes) is the subject of the article by *S. M. Blinder*, which includes a very extensive bibliography. *McWeeny* and *Steiner* discuss the theory of pair-correlated wave functions, as known from *Sinanoğlu*'s papers, but in a more rigorous manner within the framework of perturbation theory. In a detailed article on "Quantum Chemistry and Crystal Physics *L. Jansen* presents an absorbing illustration of the importance of short range interactions between three atoms or ions in the explanation of the relative stability of various crystal lattices of inert gases and alkali metal halides. *H. Jehlen* discusses the possible mechanisms for the interaction of large molecules under biological conditions.

Finally, more than one third of the book is taken up by an article by the editor, *P. O. Löwdin*, on "Quantum Genetics and the Aperiodic Solid", in which he presents his not undisputed views on the relationship between the tunneling of proteins in nucleic acids and special aspects of heredity.

W. Kutzelnigg [NB 568 IE]

Chemical Kinetics in Homogeneous Systems. *By M. Ritchie,* Vol. 2 of the Series "University Chemical Texts". Edited by *T. L. Cottrell.* Oliver & Boyd. Edinburgh-London 1966. 1st Edit., viii, 115 pp., 9 figures. 21 s (Paper 13s6d).

After a short introductory passage on experimental methods for the determination of reaction orders, simple reactions, and the temperature-dependence of reaction rates, the author discusses numerous examples of complex reactions, radiation and photochemical reactions, and acid and base catalysis in aqueous solutions. The greatest space is devoted to photochemical reactions. Unfortunately the modern methods for the investigation of fast reactions and the results of these investigations are hardly mentioned. The author has attempted to give the mechanisms deduced for the various reactions from the kinetic measurements. It should be remembered, however, that the reaction mechanisms are only an interpretation of the kinetic measurements, and that the mechanisms are by no means proved by these measurements.

The intention of the author is that this book should occupy a position midway between a chapter in a general textbook of physical chemistry and a detailed monograph on kinetics. This aim is achieved, but little more.

U. Schindewolf [NB 552 IE]

Mathematics for Quantum Chemistry. By *J. M. Anderson.* W. A. Benjamin, Inc., New York-Amsterdam 1966. 1st ed., x, 154 pp., several illustrations, $6.00.

A deep understanding of the quantum-mechanical principles underlying the approximation methods of quantum chemistry requires a familiarity with mathematical techniques and concepts that is generally quite difficult to acquire for the chemist who has not specialized in theoretical chemistry. *Anderson*'s "Mathematics for Quantum Chemistry" is a successful attempt to tackle these difficulties. This short introduction to the mathematical apparatus that is essential for the proper application of quantum mechanics to problems of chemistry is based on a course of lectures intended as a preliminary to a course in quantum mechanics. The book deals with "orthogonal functions" including Fourier series and the special functions of physics (*e.g.* spherical harmonics), "linear algebra" including linear operators and their matrix representation, and contains in a chapter on "classical mechanics", the Lagrangian and Hamiltonian formulations with brief examples of their applications to molecular vibrations and rotations.

The presentation is lively and readily comprehensible, and is supplemented by well-chosen exercises. The occasional reference to detailed textbooks is entirely in line with the aim of this book, *i.e.* to make the abstract world of pure mathematics more accessible to the chemist. The book can be strongly recommended as a stimulating introduction to anyone who wishes to use the methods of quantum mechanics beyond the stage of simple Hückel calculations.

M. Klessinger [NB 532 IE]

The Chemistry of Open-Chain Organic Nitrogen Compounds. By *P. A. S. Smith.* W. A. Benjamin, Inc., New York-Amsterdam. 1st Edit., Vol. 1, 1965; xi, 356 pp., $ 21.45; Vol. 2, 1966: xii, 531 pp., $ 37.50.

Organic nitrogen compounds are treated in textbooks partly as functional derivatives of inorganic nitrogen compounds, *e.g.* amines as substitution products of ammonia, and partly as derivatives of alcohols, aldehydes, ketones, and carboxylic acids (*e.g.* hydrazines, hydrazones, acid hydrazides).

In the present work, the former method of classification is followed throughout. The members of the various classes of compounds appear as derivatives of ammonia, hydrazine, hydroxylamine, *etc.*; this is an unusual approach from the structural point of view, and has the advantage that the organic chemist can see familiar classes of compounds in a new light.

The first of the fifteen chapters presents a brief survey of the inorganic nitrogen compounds on which the organic derivatives discussed are based. The next six chapters deal with ammonia derivatives: aliphatic amines, aromatic amines, amides, nitriles and isonitriles, *N*-derivatives of carbonic acid, and ammonia derivatives of aldehydes and ketones.

The second volume begins with hydroxylamine derivatives, including the amine oxides; this is followed by hydrazine derivatives, azides and diazo compounds, diazonium, azo, and azoxy compounds, substances having chains of three or more nitrogen atoms, *C* nitroso compounds, *C*-nitro compounds, and finally in the last chapter, the esters and amides of the oxo acids of nitrogen.

The various chapters are similar in structure. They start with a discussion of nomenclature, followed by a summary of physical properties, and the main part of each chapter is formed by a clear and systematic treatment of the reactions of the functional group in question. The most important syntheses are given at the end of each section.

In scope and structure, this work is a textbook on organic nitrogen compounds; with its extensive bibliography, which covers the literature up to the beginning of 1965 (some 2560 references), it offers all the comprehensiveness of a handbook. It enables one to obtain a very quick and thorough

grounding on a given class of substances. As can be seen from the contents, the work is intended for the advanced reader, so that the discussion of general problems could well have been shortened as *e.g.* in the case of deamination (Vol.1, p. 36) or the nitration mechanism (Vol. 2, p. 436). Instead, the author might profitably have provided an introductory chapter on bond lengths, energy relationships, hybridization, *etc.* in nitrogen compounds.

The printing errors, which are particularly common in the first volume, should be corrected in future editions. With a little effort it should also be possible to present many of the structural formulae in a clearer form.

Apart from these small defects, the author has succeeded in presenting a comprehensive survey of the chemistry of open-chain organic nitrogen compounds that restricts itself to the description of the functional groups containing nitrogen. It is to be hoped that the work will find a wide audience.

F. Effenberger [NB 548 IE]

Transition Metal Chemistry. Edited by *R. L. Carlin.* Vol. 1 Marcel Dekker, Inc., New York 1966. 1st Edit., xi, 307 pp., numerous figures and tables, cloth $ 12.75.

The present volume begins what should become a very useful series of short monographs on current problems in the field of transition metals. As is shown by a preview of the contents of future volumes, recognized experts will report not only on questions concerned purely with coordination chemistry, but also on special physical and biological results in connection with the transition metals.

In the first chapter (*R. L. Carlin*, 32 pp.) of the present work, the electronic configuration and molecular geometry of a wide range of Co(II) complexes are discussed on the basis of the ligand field theory and with the aid of spectroscopic and magnetochemical results. A well written section by *H. B. Gray* (49 pp.) deals with the electronic structure of square-planar metal complexes from a similar point of view. After an introduction on bonding mechanism and electronic spectra in simple complexes of the type $[M^{II}L_4]^{2-}$, the section deals in particular with the recently discovered systems having bidentate ligands containing sulfur and which are stabilized in a rigidly planar conformation.

Another article (*J. E. Earley* and *R. D. Cannon*, 77 pp.) is concerned with the coordination chemistry of the Cr(III) ion in aqueous systems. Finally, special mention should be made of the excellent section on "Hydrido complexes of transition metals" (*A. P. Grinsberg*, 127 pp.), which presents a systematic survey of practically all molecules and ions of the type $H_iM_jL_k$ (L = any ligand, $k \geq 0$) known up to February 1965 that contain a direct M–H bond. In accordance with the definition, for $k = 0$ the section only deals with ions of the general formula $[M_jH_i]$. In addition to preparative techniques, the author presents a particularly critical discussion o the structure of these complex hydrides and the M–H interaction.

The volume is richly provided with references, and has a good author- but a rather poor subject-index. It is not only a progress report, but also can be recommended to anyone who is interested in modern inorganic chemistry, both as an introduction and for further study. *Th. Kruck* [NB 546 IE]

Advances in Chromatography, Vol. 1. Edited by *J. C. Giddings* and *R. A. Keller.* Marcel Dekker, Inc., New York 1965. 1st ed., xiv, 368 pp., numerous illustrations, bound $14.50.

Modern analysis makes wide use of physical methods. The physical effects on which these methods are based are so numerous that there is a considerable need for textbooks, monographs, or reviews. However, textbooks in particular satisfy only in part the readers information requirements. Though they generally describe the theoretical basis of the method and the principle of the apparatus used, too little space is given to applications to the various classes of substances and to the discussion of special techniques. Finally, most textbooks are outdated by the time they are read, and owing to their limited scope, fail to give the reader the answers to the very questions in which he is interested.

The "Advances in Chromatography", the first volume of which contains four contributions on liquid-phase chromatography and six on gas chromatography, do not exhibit these disadvantages to the same extent as conventional textbooks. Specialists were asked to write on narrowly limited topics in the hope that the authors would give a picture, even subjective, of the current state of development. Accordingly, nearly all the chapters in the first volume are interesting and stimulating. The content of new information of practical value is high. The theoretical and practical aspects of the techniques under discussion are well presented by the authors. Thus the reader of the Advances" is spared the complete study of the original literature, and is nevertheless acquainted with the latest position and the trend of the development of the methods in question. The fact that the individual articles bear little relation to one another detracts little from the value of the book. However, the reader of the chapters on gas chromatography will generally not be so interested in those on liquid chromatography, and *vice versa*. The editors are to be congratulated on their project and the authors on the articles in the first volume, and it is to be hoped that future volumes can also do justice to the editors' intentions.

G. Schomburg [NB 528 IE]

Dynamics of Chromatography. Part 1. Principles and Theory. By *J. C. Giddings.* Series of monographs: Chromatographic Science, Vol. 1. Marcel Dekker, Inc., New York 1965. 1st ed., xii, 323 pp., numerous illustrations, bound $11.50.

The first six chapters present a step-by-step build-up of the general dynamic theory of chromatography as applied to the behavior of the zones, and in particular to the changes in the zone profiles in column chromatography. The seventh chapter alone is devoted to the problems of the actual separation. The author never fails to indicate the relationships between theory and experiment.

The formulae are carefully chosen and clearly listed at the end of the book. One defect, which could easily be rectified in a later edition, is the absence of section numbers at the top of each page. A pleasing feature of the book is the extensive list of references at the end of each chapter, though it must be admitted that practically no recent German-language literature is included.

This book, like the other well-known works on the fundamentals of chromatography, is indispensable to anyone who wishes to penetrate more deeply into this field and who seeks a new approach. It is outstanding for its lucidity of expression and its accurate mathematical formulations without making too heavy demands on the reader's mathematical knowledge.

There are so many elementary physical processes underlying the chromatographic procedures that it seems hopeless to build up a theory that offers a quantitative approach to all chromatographic phenomena which can be utilized in practice. Of the various theoretical models. the conventional "discontinuous plate model is not acceptable in the author's view. The author is not entirely consistent, since he nevertheless regards the conventional concept of plate height, which is used to characterize the chromatographic separating power, as indispensable. In the reviewer's opinon, this inconsistency is one shortcoming of this book, but probably the only one.

On the whole, this is a thorough and interesting treatment of general chromatography; we must therefore wait expectantly to find what results will be achieved by its application to gas chromatography (Vol. 2) and to liquid-phase chromatography (Vol. 3). *E. Palm* [NB 535 IE]

New Methods of Preparative Organic Chemistry VI[**]

Syntheses of Thiocarbamates

BY W. WALTER AND K.-D. BODE[*]

The methods suitable for the preparation of thiocarbamates are described and illustrated by examples and procedures. They are grouped under the following headings:

1. Addition of Alcohols and Thiols to Isothiocyanates
2. Thioacylation of Amines
   a) with chlorothioformates
   b) with *O,S*-diesters of dithiocarbonic acid
   c) with trithiocarbonates
3. Thioacylation of Alcohols, Phenols, and Thiols
   a) with thiocarbamoyl chlorides
   b) with *N,N*-dialkylmercaptochloroformimidium chlorides
   c) with *N,N'*-thiocarbonyldiimidazole
4. Reaction of Thiocyanates and Cyanates with Hydrogen Sulfide
5. Alkylation of Metal Dithiocarbamates
6. Additions to Thiocyanic Acid

A. Introduction

Following the discovery that thiocarbamates exert many biological actions, ranging from hypnotic, analgesic, and anesthetic to fungicidal, bactericidal, and tuberculostatic activity, these compounds have been investigated by many research groups [1–12b]. The biocidal properties are particularly pronounced in thiocarbamates which can liberate isothiocyanates, as was shown by *Rieche* [7] and *O.-E. Schultz* [8]. *Kreutzkamp et al.* [11] confirmed this observation, and also studied other compounds that can release isothiocyanates, such as cyanothioformamides, dialkylphosphorylthioformamides, and the alkali metal salts of monosubstituted thioformamidosulfonic acids.

However, the activity of many thiocarbamates is not entirely due to this decomposition, since disubstituted compounds of this class, which cannot release isothiocyanates in an organism, are frequently also biologically active. For example, dithiocarbamates of the

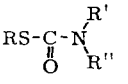
type *(1)* have relatively high fungicidal activities [12]. This is evidently because of the ability of these compounds to react with nucleophiles *(2)* in accordance with equation (a).

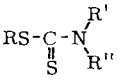
$$R_2N{-}CS{-}SCH_2NR_2 \rightleftharpoons \underset{(1)}{R_2N{-}CS{-}S^{\ominus}} + [\overset{\oplus}{C}H_2{-}NR_2 \leftrightarrow CH_2{=}\overset{\oplus}{N}R_2]$$

$$R_2N{-}CS{-}S^{\ominus} + CH_2{=}\overset{\oplus}{N}R_2 + R'^{\ominus} \quad (2)$$



$$\rightarrow R_2N{-}CS{-}S^{\ominus} + R'{-}CH_2{-}NR_2 \qquad (a)$$

The thiocarbamates can be divided into three classes [*(3a)*, *(3b)*, and *(3c)*]. The names primary, secondary,



(3a)

O-Alkyl thiocarbamates (*O*-Alkylthiourethanes)

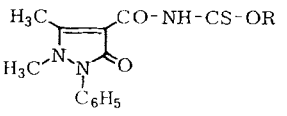
(3b)

S-Alkyl thiocarbamates (*S*-Alkylthiourethanes)

(3c)

Dithiocarbamates (Dithiourethanes)

and tertiary thiocarbamates refer to the substitution of the amino groups. We have investigated only dithiocarbamates and thiocarbamates containing the thioamide group $-C(S)-NR_2$, the oxidation of which was of interest to us [14]. Substances in which the thiocarbamate structure forms part of a ring system or is joined to hetero atoms such as phosphorus and silicon were not considered (see [13, 15, 16]).



B. Methods

1. Addition of Alcohols or Thiols to Isothiocyanates

Aliphatic alcohols add to isothiocyanates to form secondary thiocarbamates [17–19]:

$$ROH + R'N{=}C{=}S \rightarrow R'NH{-}CS{-}OR$$

The isothiocyanate is usually refluxed for 10–20 hours with a large excess of the alcohol [20–27a]. On the other hand, when the more strongly nucleophilic alkoxide anions are used, the reaction is complete in 10 min. *Kaufmann* and *Lüthje* [27b] obtained *N*-(2,3-dimethyl-5-oxo-1-phenyl-3-pyrazolin-4-yl)carbonylthiocarbamates *(4)* in good yields from the acyl isothiocyanates and alcohols in only 15 min.

(4), R = Alkyl

Göckeritz and *Pohloudek-Fabini* [28] recommend a reaction time of 2 h for the reaction of aliphatic alcohols with aromatic isothiocyanates; the thiocarbamates are obtained in yields of between 40 and 80% (for procedure see Section C, Method 1).

Favorable results are obtained by the addition of aliphatic alcohols to aryl isothiocyanates in dimethyl sulfoxide or dimethylformamide. *N*-Alkyl isothiocyanates react under these conditions on the introduction of potassium t-butoxide [28b].

Table 1. Preparation of secondary thiocarbamates and dithiocarbamates according to $R{-}C_6H_4{-}N{=}C{=}S + R'XH \rightarrow R{-}C_6H_4{-}NH{-}CS{-}XR'$ *(5)*.

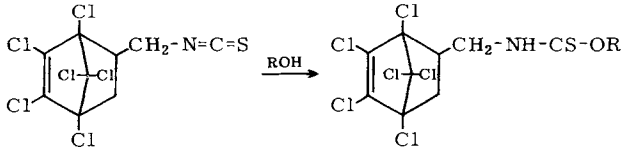
iodopropargyl alcohol [29], pyridols [29a], and quinolinols [29b] may also be used for the preparation of pharmaceutically valuable *O*-alkyl thiocarbamates. On the other hand, various types of isothiocyanates have also been used. Thus *Goerdeler* and *Schenk* obtained *e.g.* the *O*-alkyl thiocarbamate *(6)* from diphenylcarbamoyl isothiocyanate and ethanol [29c]:

$(C_6H_5)_2N-CO-NH-CS-OC_2H_5$

(6)

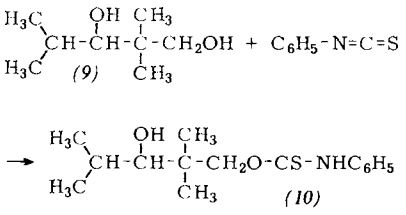


Substituted benzenesulfonyl isothiocyanates react with aliphatic alcohols to give *O*-alkyl thiocarbamates in quantitative yield [29d]. Very reactive members of this class, *e.g. (8)*, which are used as fungicides and herbicides, are obtained by the addition of alcohols to dichlorotriazinyl isothiocyanates *(7)* [30].

Hexachlorobicycloheptenylmethyl isothiocyanate *(7a)* reacts with aliphatic alcohols to form *O*-alkyl thiocarbamates *(8a)*, which are effective fungicides [30a].

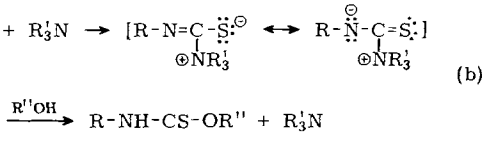
(7) *(8)*

R = CH_3, C_2H_5, C_4H_9, $C_6H_5CH_2$



(7a) *(8a)*

R = CH_3, C_2H_5, C_3H_7, i-C_3H_7, n-C_4H_9, i-C_4H_9, sec-C_4H_9



Cherbuliez et al. [30b] studied the addition of diols to phenyl isothiocyanate, which lead to crystalline *O*-alkylthiocarbamates. In the presence of pyridine at 65 to 140 °C, 1,3- to 1,10-diols always give bis (*O*-alkyl thiocarbamates), occasionally together with low yields of *O*-alkyl monothiocarbamates. On the other hand, the reaction of 2,2,4-trimethyl-1,3-pentanediol *(9)* leads only to the formation of the *O*-alkyl monothiocarbamate *(10)*, the structure of which has been verified by NMR spectra.

Under these conditions ethylene glycol gave *N,N'*-diphenylthiourea and by-products, but no *O*-alkyl thiocarbamate. The bis(*O*-alkyl thiocarbamates) obtained from 1,3-propanediols influence the clotting of blood [30c].

(9) *(10)*

The addition of alcohols to isothiocyanates is a second-order reaction [31]. Since the nucleophilic character of aliphatic alocohols decreases with increasing chain length, their reactivity is low, therefore it is recommended that the more strongly nucleophilic alkoxide ions should be used [2, 27, 32–35]. The reaction can also be accelerated by the addition of catalytic quantities of triethylamine [31, 36], diethylamine, or pyridine [30b, 37], as shown in equation (b).

(b)

The reactivities of *m*- and *p*-substituted phenyl isothiocyanates with hydroxide ions [37a, 37b] obey the Hammett equation. The rate of reaction increases with decreasing π-electron density on the C atom of the NCS group (Table 2). The rate is increased by sub-

stituents having a –I effect, the values for *m*-cyanophenyl and 5-acridinyl isothiocyanates being particularly high. *o*-Substituted aryl isothiocyanates frequently react more slowly than would be expected from the substituent; this is due to the steric influence of the *o*-substituent, which is even more pronounced in the 2,6-disubstituted aryl isothiocyanates [37].

The increased reactivity of halogenated phenyl isothiocyanates has been utilized for the paper-chromatographic separation and identification of aliphatic alcohols [28].

The literature contains contradictory reports on the reaction of isothiocyanates with thiols. Since the resulting secondary dithiocarbamates readily decompose into the starting substances [38,39], this method was regarded as unsuitable for the preparation of dithiocarbamates; on the other hand, aromatic dithiocarbamates prepared in this way have been described [25]. We have found that the method gives dithiocarbamates in good yields, which are analytically pure and are therefore not susceptible to decomposition during purification [28c] (see Table 1). *Asinger* and *Gentz* [39a] recently obtained the compounds *(12)* and *(14)* in very good yields by the reaction of phenyl isothiocyanate with 4,4-dimethyl-3-mercapto-2-pentanone *(11)* and 4,4-dimethyl-1-mercapto-2-pentanone *(13)* respectively; it must be assumed that the sterically hindered mercapto group in *(11)* is activated by the adjacent acyl group.

$$\underset{(11)}{CH_3\text{-}CO\text{-}CHSH\text{-}C(CH_3)_3} + C_6H_5NCS \rightarrow \underset{(12)}{CH_3\text{-}CO\text{-}\overset{\displaystyle S\text{-}CS\text{-}NHC_6H_5}{\overset{|}{C}}H\text{-}C(CH_3)_3}$$

$$\underset{(13)}{(CH_3)_3C\text{-}CH_2\text{-}CO\text{-}CH_2SH} + C_6H_5NCS \rightarrow \underset{(14)}{(CH_3)_3C\text{-}CH_2\text{-}CO\text{-}CH_2\text{-}S\text{-}CS\text{-}NHC_6H_5}$$

Triphenylmethyl isothiocyanate *(15)* differs appreciably from the other isothiocyanates in its chemical behavior. With nucleophilic reagents for example, it can undergo not only addition [eq. (c)], but also substitution [eq. (d)] [39b,39c].

$$(C_6H_5)_3C\text{–}N{=}C{=}S + ROH \rightarrow (C_6H_5)_3C\text{–}NH\text{–}CS\text{–}OR \quad (c)$$

$$(C_6H_5)_3C^{\oplus} + NCS^{\ominus} + ROH \rightarrow (C_6H_5)_3COR + NCS^{\ominus} + H^{\oplus} \quad (d)$$

The reactions with methanol and ethanol lead to ether formation, whereas 2-propanol, cyclohexanol, and cyclopentanol give ketones [39d].

$$\underset{(15)}{(C_6H_5)_3C\text{–}N{=}C{=}S} + RR'CHOH \rightarrow (C_6H_5)_3CH + NCS^{\ominus} + RR'CO + H^{\oplus}.$$

The addition of alcohols to *(15)* as indicated in equation (c) can be achieved by the use of the alkoxides in a suspension in xylene at room temperature [39c]. The reactivity of the alcohols in this addition reaction decreases in the following order:

$$C_2H_5 > i\text{-}C_3H_7 \approx C_6H_{11} > CH_3.$$

The addition of alcohols or thiols to isothiocyanates (Method 1) is best suited for the preparation of *N*-aryl-*O*-alkyl thiocarbamates. Phenols give unsatisfactory results [40], and *O*-aryl thiocarbamates are better prepared by the following method (Method 2a).

2. Thioacylation of Amines

a) With Chlorothioformates

Alkali metal salts of alcohols [21], phenols [14,41–43], and thiols [3,44,45] react with thiophosgene under mild conditions to form the easily handled chlorothioformates or chlordithioformates:

$$RX^{\ominus}Na^{\oplus} + CSCl_2 \rightarrow RX\text{–}CS\text{–}Cl + NaCl$$

X = O, S

R = Alkyl, aryl

The reaction with enols, on the other hand, has so far been unsatisfactory [11], presumably because *C*-thioacylation occurs as well as the desired *O*-thioacylation.

The chlorothioformates and chlorodithioformates, which are often obtained in yields of more than 90%, are very suitable agents for the thioacylation of ammonia, primary and secondary aliphatic amines, and aromatic amines, as well as for hydroxylamines [1,3,4,14,21,42,45a,46–52d].

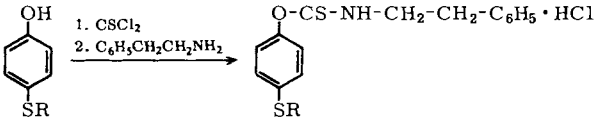
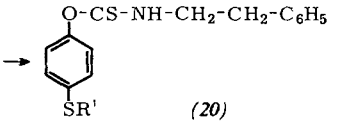
$$R{-}X{-}CS{-}Cl + 2\ R'_2NH \rightarrow R{-}X{-}CS{-}NR'_2 + R'_2NH{\cdot}HCl$$

X = O, S
R′ = H, alkyl, aryl

Triethylamine, sodium hydrogen carbonate, or alkali metal hydroxides may also be used as acid acceptors instead of the amine undergoing thioacylation. It is interesting to note, however, that the reaction of 2-biphenylyl chlorothioformate with 2,6-dialkylanilines in the presence of triethylamine leads not to the expected thiocarbamate, but to *O,O′*-di-2-biphenylyl thiocarbonate *(16)* [53]:



(16)



Similarly, the reaction of aryl chlorodithioformates with aromatic amines yields trithiocarbamates as well as the corresponding thioureas [53a].

However, this method normally gives good results, which cannot be achieved by any other method in the case of secondary and tertiary thiocarbamates (for procedure see Section C, Method 2a).

The versatility of the method is illustrated by the synthesis of the water-soluble thiocarbamate *(20)*: *Rieche et al.* [1] treated the thioglucoside *(18)* with thiophosgene to form the chlorothioformate, which was converted into the thiocarbamate *(19)* by reaction with phenylethylamine without prior isolation. Deacetylation of *(19)* yields the water-soluble compound *(20)*.

(18) *(19)*

(20)

R = Tetraacetyl-β-D-glucosyl R′ = β-D-Glucosyl

b) Thioacylation with *O,S*-Diesters of Dithiocarbonic Acid (Xanthates)

Alcohols react with carbon disulfide and bases to form salts of xanthic acid, which can be *S*-alkylated to form esters [53b].

$$ROH + CS_2 + NaOH \rightarrow RO{-}CS{-}S^{\ominus}Na^{\oplus}$$
$$RO{-}CS{-}S^{\ominus}Na^{\oplus} + R'I \rightarrow RO{-}CS{-}SR' \quad (21)$$

These esters react with ammonia to give moderate yields of thiocarbamates [54–67]. Better results can be

obtained with aliphatic amines, alkyl dithiocarbonates [*(21)*, R = R′ = alkyl] having proved particularly suitable as the xanthate component [68–71].

$$RO{-}CS{-}SR' + R''NH_2 \rightarrow RO{-}CS{-}NHR'' + R'SH$$
(21)

(Alkoxythiocarbonylthio)acetic acids *(21a)*, which are obtained by reaction of alkali metal xanthates with sodium chloroacetate, react with primary and secondary amines to form thiocarbamates in good yield, with liberation of thioglycolic acid *(22)* [35,55,57,72].

$$RO{-}CS{-}SCH_2CO_2H + R'NH_2 \rightarrow RO{-}CS{-}NHR' + HSCH_2CO_2H$$
(21a) *(22)*

This method is particularly suitable for the preparation of primary aliphatic thiocarbamates, which are difficult to obtain by other methods. The reaction of the dithiocarbonates *(21a)* with glycine leads to good yields of thiocarbamate derivatives. An example of this interesting group of compounds is *N*-ethoxythiocarbonylglycine, the synthesis of which is described in Section C, Method 2b.

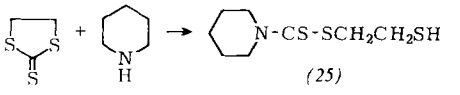
Replacement of the alkoxy group in compounds of the type *(21a)* by an alkylthio group leads to the trithiocarbonates, which react with amines to form dithiocarbamates.

c) Thioacylation of Amines with Trithiocarbonates

Diesters *(23)* of trithiocarbonic acid can be prepared from thiols and thiophosgene (for procedure see Section C).

$$2\,ArSH + Cl{-}CS{-}Cl \xrightarrow{NaOH} ArS{-}CS{-}SAr + NaCl$$
(23)

These compounds (also with heterocycles as "Ar") may be used for the thioacylation of amines, particularly piperidine [70,74,74a]. *N*-Ethylaniline and diphenylamine do not react. Primary amines are also unsuitable, since the monosubstituted dithiocarbamates *(24)* decompose under the conditions of the reaction to form thiols and isothiocyanates, which can then react further to give thioureas [75]:



$$ArS{-}CS{-}SAr + RNH_2 \rightarrow ArS{-}CS{-}NHR$$
(23) *(24)*

$$ArS{-}CS{-}NHR \rightleftharpoons ArSH + RNCS$$
(24)

$$RNCS + RNH_2 \rightarrow RNH{-}CS{-}NHR$$

As can be seen from Table 4, tertiary dithiocarbamates can be obtained in very good yields by this method, provided that the above limitations are borne in mind. However, this method is of no great preparative importance, since the alkylation of metal dithiocarbamates (see Sections B.5 and C, Method 5) using more readily obtainable starting materials is preferable.

An interesting example of the use of the reaction is the synthesis of the very sensitive *S*-(β-mercaptoethyl)dithiocarbamate *(25)* [74a,76]:

(25)

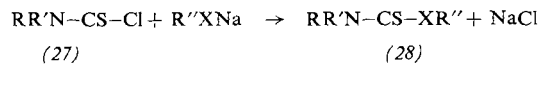
Table 4. Dithiocarbamates by thioacylation of amines with trithiocarbonates [75] [solvent ethanol; ether for *(26g)*].

Compound	ArS–CS–NR$_2$ *(26)* Ar	R_2	M.p. (°C)	Yield (%)
a	*p*-CH_3–C_6H_4	$(CH_2)_5$	121–121.5	95
b	*p*-CH_3O–C_6H_4	$(CH_2)_5$	107.5–108.5	93
c	2,4-Cl_2–C_6H_3	$(CH_2)_5$	94.5–95.5	90
d	4-Cl-α-Naphthyl	$(CH_2)_5$	128.5–129.5	91
e	*p*-Br–C_6H_4	$(CH_2)_5$	120.5–121.5	96
f	2,5-Br_2–C_6H_3	$(CH_2)_5$	117.5–118.5	98
g	2-Benzo[1,3]thiazolyl	$(C_2H_5)_2$	80	97
h	4-Phenyl[1,3]thiazolyl	$(C_2H_5)_2$	94–95	90

Tertiary thiocarbamates have been obtained by the reaction of diaryl thiocarbonates with secondary aliphatic amines [76a].

3. Thioacylation of Alcohols, Phenols, and Thiols

a) With Thiocarbamoyl Chlorides



Thiocarbamoyl chlorides (chlorothioformamides) *(27)* are obtained by chlorolysis of thiuram disulfides [78] or better, by reaction of amines with thiophosgene [79].

$$R_2N{-}CS{-}S{-}S{-}CS{-}NR_2 + Cl_2 \rightarrow 2\,R_2N{-}CS{-}Cl + 2\,S$$
(27)

$$2\,R_2NH + Cl{-}CS{-}Cl \rightarrow (27) + R_2NH{\cdot}HCl$$

Alcohols, phenols, and thiols (frequently used as the alkali metal salts) react with the compounds *(27)* to form thiocarbamates or dithiocarbamates in good yields.

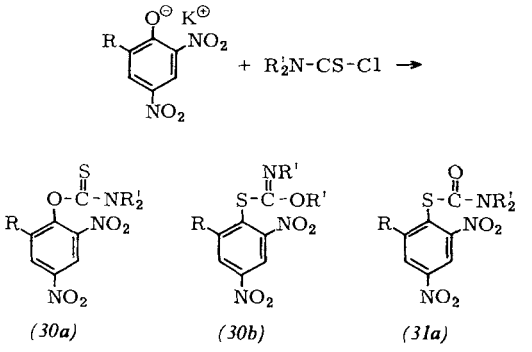
(27) (28)

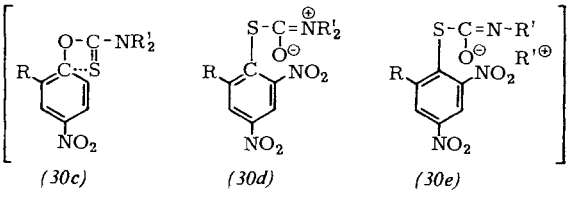
X = O, S

Since the primary and particularly the secondary thiocarbamoyl chlorides *(27)* are not very stable, this reaction is used almost exclusively for the synthesis of tertiary thiocarbamates[14,21,48,80,81] and dithiocarbamates[41,82–85c] (see Table 5 and procedure for *(28a)* in Section C). *Battegay* and *Hégazi*[86] have used this method for the preparation of primary thiocarbamates, though these are better prepared by other methods. Primary and secondary thiocarbamoyl chlorides *(27)* are of little interest in this connection because of their low stability and sensitivity to moisture[87]; a number of disubstituted thiocarbamoyl chlorides also decompose readily. Thus *N*-t-butyl-*N*-ethylthiocarbamoyl chloride decomposes even during distillation, with formation of ethyl isothiocyanate and probably isobutylene[88].



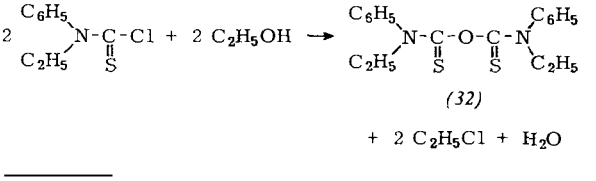
It should also be noted that in these syntheses, rearrangement to form *S*-alkyl thiocarbamates *(31)* frequently occurs[89]. For example, the reaction of diphenylthiocarbamoyl chloride *(27a)* with the sodium salt of *N,N*-diethylaminoethanol *(29)* yields not the expected *O*-substituted thiocarbamate *(30)*, but the *S*-substituted compound *(31)*.

(27a) (29) (30) (31)



This rearrangement depends on the substitution of the thiocarbamoyl chloride; *N*-phenyl-*N*-ethylthiocarbamoyl chloride gives the expected *O*-substituted thiocarbamate. The nucleophilic component also plays a part, since this abnormal reaction behavior is observed particularly with amino alcohols of the type *(29)*.

Edwards and *Pianka*[89a] recently reported similar observations in the reaction of *o*-substituted 2,4-dinitrophenoxides with aliphatic thiocarbamoyl chlorides. Depending on the substituent R and on the reaction conditions, these authors obtained an *O*-aryl thiocarbamate *(30a)*, an *O*-alkyl alkylimidothiocarbonate *(30b)*, or an *S*-aryl thiocarbamate *(31a)*.



(30a) (30b) (31a)

The *O*-aryl thiocarbamates *(30a)* are formed at high temperatures when R = t-butyl; *O*-alkyl alkylimidothiocarbonates *(30b)* are formed as by-products, whereas *(30b)* are the only products at room temperature. When R = s-butyl, on the other hand, the *O*-aryl thiocarbamates and the *O*-alkyl alkylimidothiocarbonates *(30b)* rearrange to form the *S*-aryl thiocarbamates *(31a)*. The authors explain this difference as resulting from the weaker +I effect of the s-butyl group and its smaller bulk. They propose the transition states *(30c)* and *(30e)*, the most important step being assumed to be an attack of the nucleophilic sulfur on the phenolic carbon atom.

(30c) (30d) (30e)

Kwart and *Evans*[89b] and *Newman* and *Karnes*[89c] have developed the thermal rearrangement of thiocarbamates into a preparatively useful method for the conversion of phenols into thiophenols that are otherwise difficult to obtain. In the reaction of free alcohols with thiocarbamoyl chlorides, the alcohols are not thioacylated, but halogenated, a thiocarbamic anhydride *(32)* being formed also[90].

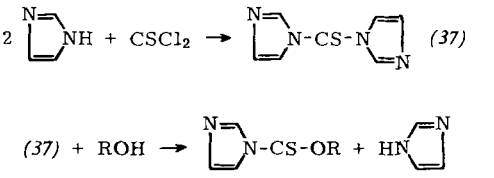
A new type of disubstituted dithiocarbamate *(35)* was obtained by *Davidson* and *Peak* [91] by the thioacylation of cyanamide *(33)*.



Some examples of tertiary thiocarbamates and dithiocarbamates are shown in Table 5.

c) Thioacylation with *N,N'*-Thiocarbonyldiimidazole

Thioacylation with *N,N'*-thiocarbonyldiimidazole *(37)* [93] is of little general interest, since it leads only to the thiocarbamate derivatives of imidazole.

Thiophosgene reacts with imidazole to form the compound *(37)*, which transfers its thioacyl group to alcohols and phenols.

(38a), R = C_2H_5, yield 76%
(38b), R = C_6H_5, yield 78%
(38c), R = β-naphthyl, yield 74%

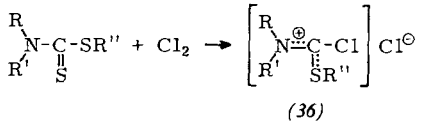


Table 5. Thiocarbamates and dithiocarbamates by thioacylation of nucleophilic compounds with thiocarbamoyl chlorides RR'N–CS–XR'' *(28)*.

[a] Not given in the literature.

b) Thioacylation with *N,N*-Dialkylmercaptochloroformimidium Chlorides

Very little investigation has been carried out as yet on the reaction with *N,N*-dialkylmercaptochloroformimidium chlorides *(36)*, which can be obtained by chlorination or phosgenation of disubstituted dithiocarbamates [92].

(36)

Though this synthesis has so far been studied for only two examples (β-naphthol and 2-hydroxyanthraquinone), it is expected to become very important for the preparation of tertiary thiocarbamates, since the dithiocarbamates required are very readily obtainable from cheap starting materials, as described in Section C, Method 5.

The thioacylation of thiols by this method apparently has not been studied; the reaction with enols and oximes is also unknown at present.

4. Reaction of Thiocyanates and Cyanates with Hydrogen Sulfide

Nitriles add on hydrogen sulfide to form thioamides. This reaction [94] has also been applied to the preparation of thiocarbamates (from thiocyanates and hydrogen sulfide) [95–98]; the addition of H_2S under increased pressure has proved particularly favorable [99]. The thiocyanates may also be prepared from ammonium thiocyanate and alkyl halide, and can then be treated with hydrogen sulfide without first being isolated [100]. *Wheeler* and *Johnson* [100a] obtained acyldithiocarba-

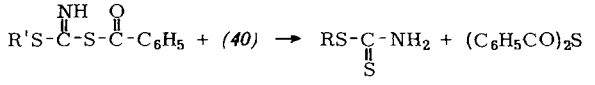
mates by the addition of thiocarboxylic acids to thiocyanates. This reaction is assumed to proceed *via (39)* [100b].

v. Braun and *Lemke* [100c] later obtained unsubstituted dithiocarbamates with thiobenzoic acid; the dibenzoyl sulfide expected as a by-product could not be detected.



(39)

(40)

On the other hand, the synthesis of thiocarbamates from thio acids and cyanates had not previously been known, since the required cyanates have only recently become available [101–104]. For the preparation of primary thiocarbamates, it is of interest to observe that cyanates can be obtained from phenoxides and cyanogen halides [101, 102, 105, 106], whereas the synthesis of the cyanates *via* the chlorothioformates [103, 104] is of no interest since thiocarbamates can be prepared directly from chlorothioformates (see Method 2a, Sections B 2a and C).

The addition of hydrogen sulfide to cyanates proceeds in good yield in the presence of triethylamine (see *e.g.* synthesis of 2,6-di-t-butyl-4-alkylphenyl thiocarbamate in Section C) [14, 107]. *Jensen* and *Holm* [103] used this synthesis to prove the structure of the alkyl cyanates, which they had prepared for the first time. *Grigat* and *Pütter* have shown that thioureas (see *e.g.* procedure for *p*-tolyl thiocarbamate in Section C) [108], thiocarboxylic acids [108a, 109], and thioamides [109] may be used as sources of H_2S, the products in every case being very pure primary thiocarbamates (see *e.g.* procedure for 2,4-dimethylphenyl thiocarbamate in Section C).

A particularly convenient method is the reaction with sodium thiosulfate in acidic solution, which also gives very good yields [109a]. Thus this synthesis was found to be the best method for the preparation of primary thiocarbamates (see Table 6). Method 5 (see Section B 5 and C) is generally more suitable for the preparation of dithiocarbamates.

Table 6. Preparation of primary thiocarbamates from cyanates and hydrogen sulfide, RO–CS–NH_2 *(41)*.

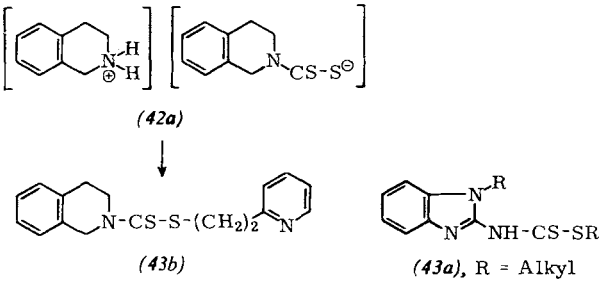
5. Alkylation of Metal Dithiocarbamates

Amines react with carbon disulfide and alkali metal hydroxides to form salts *(42)* of dithiocarbamic acids, which are strongly nucleophilic and react with many electrophiles to give dithiocarbamates *(43)* [111, 112, 96].



(42)

(43)

This method can be used for the preparation of 2-benzimidazolyl-dithiocarbamates *(43a)*, which are used as anthelmintics [112a].

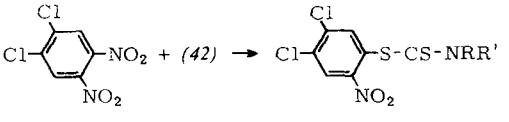
The compound *(42a)*, which can be obtained by the reaction of 1,2,3,4-tetrahydroisoquinoline with carbon disulfide, reacts with 2-vinylpyridine to form the dithiocarbamate *(43b)*; 1-aminoisoquinoline does not react in this way [112b].

A survey of the possible applications of this very versatile method is given in Table 7.

An interesting reaction is that of metal dithiocarbamates *(42)* with diazonium salts *(44)*, since *S*-aryl compounds can also be obtained in this way [3] (see also Section C).



$$\underset{(42)}{RR'N-CS-S^{\ominus}Na^{\oplus}} + [C_6H_5N{\equiv}N]^{\oplus}Cl^{\ominus} \rightarrow \underset{(44)}{RR'N-CS-SC_6H_5} + N_2 + NaCl$$

Table 7. Dithiocarbamates by addition of dithiocarbamate ions to electrophiles RR'N–CS–SR'' *(43)*; R = R' = Alkyl or aryl.

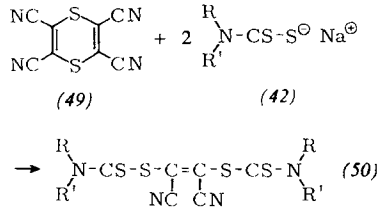
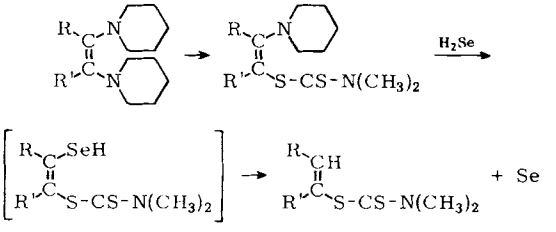
acid result in yields of 72–92% [134c]. The strongly fungicidal compounds *(46)* have been obtained from halogenated carbamates of the type *(45)* [134d].



Another synthesis of dithiocarbamates is based on the reaction of acyl chlorides *(47)* with paraformaldehyde and salts of dithiocarbamic acid *(42)* [134e].

$$RR'\text{–}CS\text{–}S^{\ominus}Na^{\oplus} + R''COCl \xrightarrow{CH_2O} RR'N\text{–}CS\text{–}SCH_2OCOR''$$



(42) *(47)* *(48)*

R,R′ = Alkyl, aryl; R″ = Alkyl, aralkyl, aryl

Dithiocarbamates containing sulfo groups are prepared by the reaction of alkali metal dithiocarbamates with sultones [134f]. Whereas the compounds described here are "true" dithiocarbamates, those described below can only be formally regarded as such. For example, *Vest* [134g] has described the cleavage of tetracyanodithiin *(49)* by sodium dithiocarbamate to form a bis-dithiocarbamate *(50)*.

Alkenyldithiocarbamates are obtained by the reaction of enamines with tetramethylthiuram disulfide followed by treatment with hydrogen selenide [134h]

On the basis of their chemical behavior, the *S*-acyl dithiocarbamates *(51)* [135, 136] must be regarded as mixed anhydrides.

$$Ar\text{–}CO\text{–}S\text{–}CS\text{–}NRR'$$

(51)

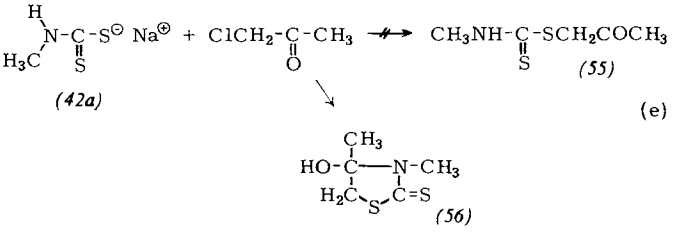
Finally, mention should also be made of the *S*-aminoalkyl dithiocarbamates *(53)*, which behave as aminoalkylating agents. *Kreutzkamp et al.* have synthesized these compounds from alkali metal dithiocarbamates, formaldehyde, and amines [11, 135a].

$$R_2N\text{–}CS\text{–}S^{\ominus}Na^{\oplus} + CH_2O \xrightarrow{H^{\oplus}} R_2N\text{–}CS\text{–}SCH_2OH$$

(42) *(52)*

$$(52) + R_2'NH \rightarrow R_2N\text{–}CS\text{–}SCH_2NR_2'$$

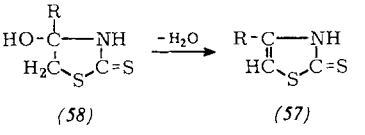
(53)



Another possibility is the reaction of aminals *(54)* or Mannich bases, *e.g.* gramine, with carbon disulfide [135a, 135b].

$$R_2N\text{–}CH_2\text{–}NR_2' + CS_2 \rightarrow R_2N\text{–}CS\text{–}SCH_2NR_2'$$

(54) *(53)*



This reaction, which may be regarded as an insertion of carbon disulfide, finds a parallel in the reaction of olefins with amines and carbon disulfide, leading to the formation of true dithiocarbamates (see Table 7).

The alkylation of metal dithiocarbamates has sometimes been misinterpreted in the past. As early as 1955, *Hirano* [136a] reported, that the reaction of sodium *N*-methyldithiocarbamate *(42a)* with chloroacetone leads, not to the expected dithiocarbamate *(55)*, but to the thiazolidinethione *(56)* [*].

(e)

This was confirmed by *Humphlett* and *Lamon* [137] in analogous investigations on the reactions of ammonium dithiocarbamate with chloroacetaldehyde, chloroacetone, ethyl chloroacetate, and phenacyl bromide. These reactions again lead, not to the primary dithiocarbamates, as had previously been assumed [138–140], but to the 4-hydroxythiazolidinethiones *(58)*, which lose water within a few days to form thiazoline-2-thiones *(57)*.

These results, which are based on IR investigations, were confirmed by *Humphlett* and *Lamon* by the preparation of stable 4-hydroxythiazolidine-2-thiones of the type *(58a)*, R = CH_2–SO_2–C_2H_5 [141].

In a variant of this synthesis[142], sulfonamides *(59)* are treated with carbon disulfide and sodium hydroxide solution. Subsequent alkylation yields *N*-sulfonyldithiocarbamates *(61)*.

$$\underset{(59)}{RSO_2NH_2} + CS_2 + 2\,NaOH \rightarrow \underset{(60)}{RSO_2N{=}C(S^{\ominus}Na^{\oplus})_2}$$

$$(60) \xrightarrow[2.\ HCl]{1.\ R'X} \underset{(61)}{RSO_2NH{-}CS{-}SR'}$$

The analogous reaction with α-halogensulfonamides *(62)* leads to the sodium salt of Δ^2-3-mercapto[1,2,4]dithiazoline 1,1-dioxide *(63)* [142a].

$$\underset{(62)}{ClCH_2SO_2NH_2} + NaOH + CS_2 \rightarrow \underset{(63)}{\text{sodium salt of } \Delta^2\text{-3-mercapto[1,2,4]dithiazoline 1,1-dioxide}}$$

6. Addition to Thiocyanic Acid

The reactions of thiocyanic acid described in this section are not very important. However, they should be mentioned, since the starting materials are readily available and the low yields are consequently not significant. *Blankenhorn* [143] and *Rathke* [144] observed the formation of *O*-ethyl thiocarbamate *(41b)* in the reaction of ammonium thiocyanate with concentrated hydrochloric acid in ethanolic suspension. It must be assumed that the alcohol adds to the free thiocyanic acid *(64)*.

$$\underset{(64)}{[H{-}N{=}C{=}S]} + C_2H_5OH \rightarrow \underset{(41b)}{C_2H_5O{-}CS{-}NH_2}$$

The analogous reaction with ethyl chloroformate *(65)* [145–148] proceeds in very good yields with formation of *O*-alkyl thiocarbamates of the type *(67)*. This reaction evidently proceeds by initial formation of ethyl isothiocyanoformate *(66)*.

$$KSCN + Cl{-}CO{-}OC_2H_5 \rightarrow \underset{(66)}{[C_2H_5O{-}CO{-}NCS]}$$

$$(66) + C_2H_5OH \rightarrow \underset{(67)}{C_2H_5O{-}CO{-}NH{-}CS{-}OC_2H_5}$$

This synthesis was used by *Skinner* and *Vogt* [149] for the preparation of *O*-ethyl-*N*-benzoyl-thiocarbamate *(68)* from benzoyl chloride *(69)*, potassium thiocyanate, and ethanol, but the yield obtained is low.

$$\underset{(69)}{C_6H_5COCl} + KSCN \rightarrow \underset{(70)}{[C_6H_5{-}CO{-}NCS]}$$

$$(70) + C_2H_5OH \rightarrow \underset{(68)}{C_6H_5CONH{-}CS{-}OC_2H_5}$$

7. Concluding Remarks

The present survey has been deliberately confined to reactions having some preparative importance. However, mention should also be made of the conversion of thioureas into thiocarbamates by the action of an excess of alcohol in the presence of acidic catalysts, as described in the literature (see *e.g.* [150]). This synthesis could become industrially important, since the starting materials are relatively easily obtainable. The comparison of the various methods in each section is intended as an aid to the choice of the best method. Finally, the choice of method should also be facilitated by the following procedures, nearly all of which have been checked in our laboratory.

C. Procedures

Method 1 [28]

0.01 mole of the isothiocyanate is refluxed with 0.1 mole of the alcohol for 2 hours. The thiocarbamate precipitates when the reaction mixture is cooled in an ice/salt bath. To remove any isothiocyanate that may be present, the product is recrystallized either from the alcohol used in the reaction and water, or from petroleum ether (Yield 40–80%; see also Table 1).

Method 2a

0.2 mole of the primary or secondary amine is dissolved in carbon tetrachloride and cooled to 0 °C. A solution of 0.1 mole of the chlorothioformate in carbon tetrachloride is added slowly to the above solution. After 24–48 hours, the amine hydrochloride that has precipitated is filtered off and the filtrate is evaporated to dryness under vacuum. The residue crystallizes immediately or within a few days (see Table 3).

Preparation of Chlorothioformates and Chlorodithioformates

0.1 mole of thiophosgene and 0.1 mole of the phenol or thiophenol are dissolved in dichloromethane and cooled to about 0 °C. A solution of 5.6 g of KOH in 100 ml of water is added dropwise with stirring, the temperature not being allowed to rise above 10 °C. When the addition is complete, stirring is continued for 1 hour, and the reaction mixture is then poured into ice/water. The organic phase is separated and washed with water. The solution is dried over sodium sulfate and then evaporated to dryness. The resulting orange oil is distilled under vacuum.

[150] *J. Nishimura*, Sci. Pap. Inst. physic. chem. Res. (Tokyo) *40*, 181 (1942); Chem. Abstr. *41*, 6214 (1947).

Method 2b: N-Ethoxythiocarbonylglycine [73]

1 mole of ethanol is shaken with 250 ml of carbon disulfide and 1 mole of potassium hydroxide until the hydroxide dissolves and a crystalline substance separates. The mixture is cooled in ice to complete the precipitation, and is then filtered. The crude potassium ethyl xanthate is introduced into 200 ml of methanol and refluxed for 30 min with 1 mole of ethyl bromide. The solution is diluted with 200 ml of water and extracted twice with ether. Evaporation of the ether leaves a yellow oil, which is heated for 24 hours on a boiling water bath with a solution of 1 mole of glycine and 1 mole of potassium hydroxide in 200 ml of 50% ethanol. The solution is condensed under vacuum to about 100 ml, dissolved in an equal volume of water, and slowly acidified with concentrated hydrochloric acid, whereupon the desired product is precipitated. Recrystallization from water gives 77% of *N*-ethoxythiocarbonylglycine (*N*-carboxymethyl-*O*-ethylthiocarbamate), m.p. 186 °C.

Method 2c [77]

A large excess of pyridine or diethylaniline (about 1 mole) is added to 0.1 mole of a diester of trithiocarbonic acid in the absence of solvent. The reaction begins immediately with strong evolution of heat, and the ester dissolves. The clear solution is heated for a further 15 min on a boiling water-bath, and is then diluted with a large quantity of water. When the solution is cooled, the dithiocarbamate often separates as an oil, but this soon crystallizes (for examples see Table 4).

Preparation of Diester of Trithiocarbonic Acid [77]

1 mole of a heterocyclic thiol is dissolved in 10% sodium hydroxide solution under nitrogen, and 0.5 mole of thiophosgene is added slowly with vigorous stirring. After the addition, stirring is continued until the solution is clear and the ester separates as an oil. (This can be best seen if stirring is interrupted for a short time). Water is added dropwise to complete the separation of the ester. The oil solidifies after a short time and is recrystallized from benzene/methanol (yields: 60–98%).

Method 3a:
N,N-Dimethyl-O-(2-nitrophenyl)thiocarbamate (28a)

8.7 g of sodium 2-nitrophenoxide is dissolved in 80 ml of water, and 10.0 g (approx. 50% excess) of *N,N*-dimethylthiocarbamoyl chloride in 50 ml of chloroform is added. The mixture is shaken vigorously until the dark red color disappears and a light yellow organic phase is obtained. The organic phase is separated, washed with $NaHSO_3$ solution and water, and dried with sodium sulfate. On evaporation to dryness under vacuum, a yellow crystalline product is obtained. M.p. 126.5–128 °C (from benzene/petroleum ether), yield 6.9 g (57%).

Method 4:
2,6-Di-t-butyl-4-allylphenylthiocarbamate [14]

5 g of 2,6-di-t-butyl-4-allylphenyl cyanate [101] is dissolved in 80 ml of dry benzene. After the addition of 0.1 ml of triethylamine, a vigorous current of H_2S is passed through the solution for 50 min, and the reaction mixture is allowed to stand overnight in the closed vessel at room temperature. The solvent is evaporated under vacuum, and the residue is recrystallized from benzene. Yield 4.4 g (78%), m.p. 190 to 190.5 °C.

2,4-Dimethylphenylthiocarbamate [109]

7.35 g (50 mmole) of 2,4-dimethylphenyl cyanate is added dropwise at room temperature to a suspension of 6.85 g (50 mmole) of thiobenzamide in 100 ml of petroleum ether. The solution becomes slightly warm. After 24 hours, the pure thiocarbamate is filtered off. Yield 8.8 g (97%), m.p. 138 to 139 °C.

p-Tolylthiocarbamate [108]

5.2 g (0.05 mole) of *N,N*-dimethylthiourea and 6.7 g (0.05 mole) of *p*-tolyl cyanate in 20 ml of acetone are refluxed for one hour. The solvent is distilled off under vacuum, and the dimethylcyanamide is filtered off from the thiocarbamate, which is recrystallized from toluene. Yield 7.5 g (90%), m.p. 153 °C.

Thiourea, *N*-methylthiourea, and *N*-phenylthiourea have also been used as thiourea components.

Method 5:
Arylation of Metal Dithiocarbamates with Diazonium Salts [3, 121]

0.1 mole of sodium dithiocarbamate is dissolved in 250 ml of water, and a diazonium salt solution, freshly prepared from 0.1 mole of amine, is added at 25–35 °C (the temperature must not be allowed to rise higher) with vigorous stirring. An orange oil separates out within an hour and nitrogen is liberated. The oil crystallizes after a short time. Yields 25 to 90%.

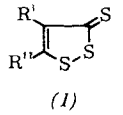
The Action of Carbon Disulfide and Sulfur on Enamines, Ketimines, and CH Acids [1]

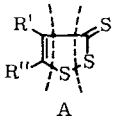
BY ROLAND MAYER AND K. GEWALD [*]

The reaction of sulfur, carbon disulfide, and enamines at room temperature leads mainly or exclusively to 3H-1,2-dithiole-3-thiones; these are occasionally accompanied by 2H-1,3-dithiole-2-thiones, which can also be prepared by a modified procedure. Many enamines react with sulfur at room temperature to form thioamides. At about 50 °C, enamines of acetophenone give 2-benzylidene-4-phenyl-2H-1,3-dithiol. The action of isothiocyanates and sulfur on enamines leads to the formation of thiazolidine-2-thiones. 2H-Thiopyran-2-thiones can be prepared from enamines or dienamines with carbon disulfide at room temperature. The reaction of ketimines (Schiff bases) with carbon disulfide and sulfur yields 3H-1,2-dithiole-3-thiones or isothiazoline-5-thiones. The reaction of alkynes with sulfur and carbon disulfide leads to 2H-1,3-dithiole-2-thiones. Nitriles containing active methylene groups react with carbon disulfide and sulfur to form 5-amino-3H-1,2-dithiole-3-thiones. When isothiocyanates are used instead of CS_2, the reaction leads to Δ^4-4-amino-thiazoline-2-thiones.



I. Introduction

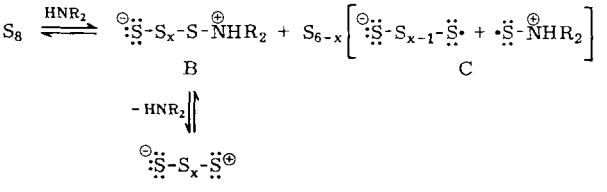
In our investigations on organic sulfur compounds [1] and CH-acid nitriles [2], we tried to find a generally applicable and efficient synthesis of 3*H*-1,2-dithiole-3-thiones *(1)*, preferably proceeding at atmospheric pressure and at room temperature.



This class of compounds, which was already well known [3], had attracted renewed interest on theoretical and practical grounds. In the course of this work we found simple routes to other, new sulfur heterocycles, as well as new and efficient methods for the preparation of known classes of compounds.

The present paper deals particularly with preparatively useful syntheses of 3*H*-1,2-dithiole-3-thiones, 2*H*-1,3-dithiole-2-thiones, Δ^3-isothiazoline-5-thiones, 2*H*-thiopyran-2-thiones, thioamides, and thiophene derivatives.

In order to synthesise the dithiolthiones *(1)*, we decided to adopt the approach indicated in A. A sufficiently active two-carbon system was therefore required



(1)

A

that would react directly with elementary sulfur and carbon disulfide under the required conditions to give *(1)*.

Elementary sulfur (S_8) is activated on nucleophilic attack by a base (*e.g.* an amine). (Investigations are being carried out at present to determine whether the activated complex B exists (*e.g.* in the form C at room temperature.)

In addition to amines [4], which activate sulfur at about 10 °C, the S_8 ring can also be attacked by other bases of corresponding nucleophilic strength, including bases formed during sulfurization, such as sulfide, polysulfides, and sulfite [5–7].

Little is known [5–11] about the mechanism of thiolation reactions [9], particularly the action of sulfur on compounds containing nucleophilic C atoms. Thus, it is not even always clear whether the sulfur is attacked directly by the C base and transferred to the substrate as "activated" sulfur. However,

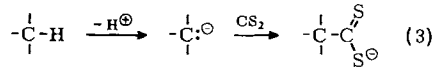
it should be possible to thiolate not only a CH compound [eq. (1)], but also an SH grouping [eq. (2)] at low temperatures, if necessary in the presence of an auxiliary base. This has already been achieved, in principle, in the formation of trithiolanes[9,12] tetrathianes[9,13], pentathiepanes[13], and hexathiocanes[14]. The *McMillan-King* reaction[9,15] may also be regarded as involving an intermediate thiolation.

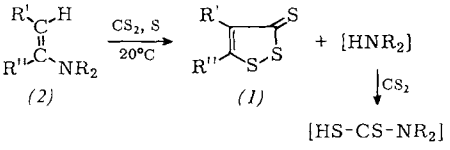


(1)

(2)

Whereas only heat-resistant products may be isolated after the reaction of sulfur on organic compounds at high temperatures, the base catalysed reaction of sulfur with suitable reactants at room temperature permits the interception of thermally labile intermediates existing in the equilibrium, in which *e.g.* S_8 may be wholly or partly incorporated.

As far as we know, the simultaneous action of carbon disulfide in thiolation reactions has not been studied. Carbon disulfide is known to add to nucleophiles at ambient temperatures. However, in the reaction of CH acids with CS_2, an auxiliary base must generally be present to act as a proton acceptor in the formation of the actual C base [eq. (3)].



(3)

Possible reaction of the auxiliary base, *e.g.* alkoxide, with carbon disulfide presents a problem. We therefore had to use systems which contained two carbon atoms and which were already sufficiently nucleophilic to react with carbon disulfide. Such systems had to permit the cyclization step in the formation of *(1)*. Enamines, dienamines, Schiff bases, alkynes, and CH-acid nitriles were found to be particularly suitable reactants.

II. The Reaction of Enamines with Carbon Disulfide and Sulfur

The above requirements for the C_2 system are satisfied by the enamines *(2)*, which are readily available nowadays[16–18]. They are sufficiently basic and nucleophilic to activate elementary sulfur without an additional catalyst, and sufficiently reactive for the reaction with carbon disulfide; moreover, they permit the cyclization step with formation of 3*H*-1,2-dithiole-3-thiones *(1)*.

Thus the action of carbon disulfide and elementary sulfur on enamines *(2)* at room temperature, preferably in the presence of a polar solvent, leads to the formation of 3*H*-1,2-dithiole-3-thiones *(1)* with evolution of heat[19,20].

(2) *(1)*

The yields of *(1)* can sometimes be increased considerably by catalytic quantities of vulcanization accelerators such as tetramethylthiuram disulfide or 2-mercaptobenzothiazole[18]; this variation is being investigated at present. The yields in Table 1 relate to the reaction without catalysts.

It can be seen from Table 1 that the process is very flexible concerning the substituents R′ and R″.

In the preparation of cyclic enamines [*(2)*, $R'R'' = (CH_2)_n$] from ketone and amine, it should be noted that cyclohexanone tends to undergo addition to the carbonyl group, since this leads to a decrease in ring strain; this adduct is readily dehydrated to form the enamine *(2)*. On the other hand, owing to its lower ring strain, cyclopentanone is much more stable than the addition compound; moreover, dehydration of the latter to form a cyclopentene derivative is difficult. The ketone structure is also favored in the case of cycloheptanone, though the effect is not so strong as in cyclopentanone. The same order is found in the benzo series[27], the enamines of α- and β-tetralone being most readily obtainable (yield: 75–86%), followed by those of benzocycloheptanone (yield: about 60%), and finally those of α- and β-indanone (yield: 50–55%).

The yields of 1,2-dithiolethiones obtained from unsubstituted cyclic enamines with 5-, 6-, and 7-membered rings are as expected. Tetramethylene-1,2-dithiolethione [*(1)*, $R'R'' = (CH_2)_4$] is not dehydro-

[20] *R. Mayer*, *P. Wittig*, *J. Fabian*, and *R. Heitmüller*, Chem. Ber. *97*, 654 (1964). General procedure: The enamine (0.2 mole) is added dropwise to a vigorously stirred mixture of powdered sulfur (6.4 g, 0.2 g-atoms), CS_2 (0.6 mole), and dimethylformamide (40 ml), the temperature being maintained below 15 °C. The reaction mixture is stirred for a further 2–4 h at room temperature and is then added, with stirring, to 400 ml of water. Precipitated crude products are warmed with 50% sulfuric acid to decompose any dithiocarbamate, and diluted further with water. Liquid products are extracted into chloroform and distilled.

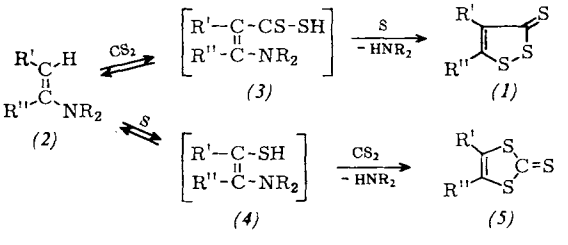
[c] Liquid; methyl iodide adduct melts at 90 °C.

[d] 32% of 4,5-dihydro-2*H*-naphtho[2,1-*d*]-1,3-dithiole-2-thione, m.p. = 115—116 °C, is also formed.



genated to the benzo derivative under the mild conditions used; similarly, the dihydronaphtho-1,2-dithiolethione obtained from enamines of α-tetralone is not converted into the naphtho compound during the reaction. However, the dehydrogenation can be subsequently carried out almost quantitatively, *e.g.* with sulfur at 220 °C, and in this way benzo- and naphtho-1,2-dithiolethiones can also be obtained from enamines [27, 28].

Alkyl aryl ketones give lower yields of enamine with increasing chain length of the aliphatic group, despite the use of longer reaction times. The yield of 1,2-dithiolethione *(1)* also decreases. This is evidently connected with electronic and steric factors, which become particularly noticeable in the branched types.

Mixtures of enamines having the double bond in different positions generally also give mixtures of 1,2-dithiolethiones. The only exception known so far is observed with a mixture of the enamines from methyl ethyl ketone, which gives only 4,5-dimethyldithiolethione [*(1)*, R′ = R″ = CH_3] [25]. (For the tautomerism of enamines, cf. [29].)

The above synthesis of 4- or 5-substituted or 4, 5-disubstituted 3*H*-1,2-dithiole-3-thiones *(1)* is adoptable and simply executed. For maximum yields, the "General Procedure" [20] should be adhered to fairly closely; changes in the conditions promote side reactions. A close study of the reaction ultimately led to other simple syntheses of organic sulfur compounds.

The combined action of carbon disulfide and sulfur on enamines should present at least two general possibilities, (i) primary reaction with carbon disulfide to form *(3)* followed by the incorporation of sulfur, and (ii) initial attack by sulfur.

It was therefore to be expected that the action of CS_2 and sulfur on enamines would lead not only to 3*H*-1,2-dithiole-3-thiones *(1)*, but also to 2*H*-1,3-dithiole-2-thiones *(5)*.

The experimental data show clearly that under the conditions used in the present work, all the alkyl-substituted enamines *(2)* studied so far gave only 1,2-dithiol-3-thiones *(1)*. Enamines of α-indanone and 1-benzocycloheptanone behave similarly [27].

With a few aryl-substituted enamines, *(5)* is formed as well as *(1)*; thus the enamines of acetophenone, propiophenone, butyrophenone, and valerophenone

[28] *P. Wittig*, Diploma Thesis, Technische Universität Dresden, 1963.

[29] *G. Bianchetti, D. Pocar, P. D. Croce*, and *A. Vigevani*, Chem. Ber. *98*, 2715 (1965); *W. D. Gurowitz* and *M. A. Joseph*, Tetrahedron Letters *1965*, 4433.

yield small amounts of *(5)* [24, 27, 30] and larger amounts (up to 50% of the mixture) are formed from enamines of α-tetralone [27], and of deoxybenzoin [31]. Enamines of isovalerophenone and of caprophenone give *(5)* only [27]. Neither *(1)* nor *(5)* has so far been isolated in the case of β-tetralone. Within the limits prescribed for the reaction conditions, the ratio of *(1)* to *(5)* cannot be appreciably altered by varying the reaction conditions and solvent, or by variation of the order of addition of the reactants. The only known exceptions are observed with enamines of ring-substituted acetophenones, where the formation of the 2*H*-1,3-dithiole-2-thione system is favored by an increase in the reaction temperature to 50 °C. (For the side reactions occuring in this case, cf. Sections III and IV).

Steric factors undoubtedly play an important part in the above reactions. Thus the 1,3 system *(5)* is evidently favored when the bulky thiocarbonyl group would not have sufficient room in a 1,2 system *(1)*. However, this is no longer the case in the enamines of α-tetralone and of acetophenone. The 1,2-dithiolethione *(1)* is also always formed in the aliphatic series, in spite of any bulky groups. Thus the question of whether *(5)* or *(1)* is formed probably also depends on electronic factors; owing to the electron-attracting action of the aryl groups, aryl-substituted enamines have a lower electron density on the enamine double bond than alkyl-substituted enamines.

Consequently, the electrophilic carbon disulfide preferentially adds to the much more reactive aliphatic compounds, which, according to experimental observations, is equivalent to the formation of the 1,2 system *(1)*. In the aromatic series, the attack of carbon disulfide is inhibited by the lower electron density on the β-C atom, so that the equilibrium reaction discussed below leads to the thiolation product *(4)* as well as to *(3)* (since the position of the equilibrium depends *inter alia* on the nucleophilic strength of the double bond in the enamine), and hence to a mixture of *(1)* and *(5)*, or occasionally even exclusively to *(5)*. It must be assumed that the enamine initially undergoes a reversible attack by the sulfur as well as by the carbon disulfide. The stabilization of the intermediates, which are formulated as *(3)* and *(4)*, undoubtedly depends on factors that cannot be determined quantitatively at present, such as the electrophilicity of the reactants and the tendency of the product to be formed, *i.e.* the rate of the irreversible stabilization reaction.

The fact that complex equilibrium reactions are involved in the reaction of enamines with CS_2 and sulfur is clear from the following observations. Though there is no longer any doubt that the reaction of an enamine of cyclohexanone with elementary sulfur leads to the thiolation product *(6)*, the subsequent introduction of carbon disulfide results in the formation of the compound *(1a)*. However, the expected 1,3-compound *(5)*, with R'R'' = $(CH_2)_4$, cannot be detected. We have shown, *e.g.* by interception with isothiocyanate, that the intermediate *(6)* is formed, *i.e.* the primary thiolation product of an enamine of cyclohexanone or cyclopentanone. The introduction of isothiocyanate leads smoothly to the adducts *(7)* (*N*-substituted 4-dialkylaminothiazolidine-2-thiones), which react readily with acid to form the stable Δ⁴-thiazoline-2-thiones *(8)*. This led to a new and efficient synthesis of these substances by the action of sulfur and isothiocyanates on enamines [32] (see Table 2). (For the formation of thiazolinethiones *(8)* from α-mercaptoketones and isothiocyanates, cf. [33].)

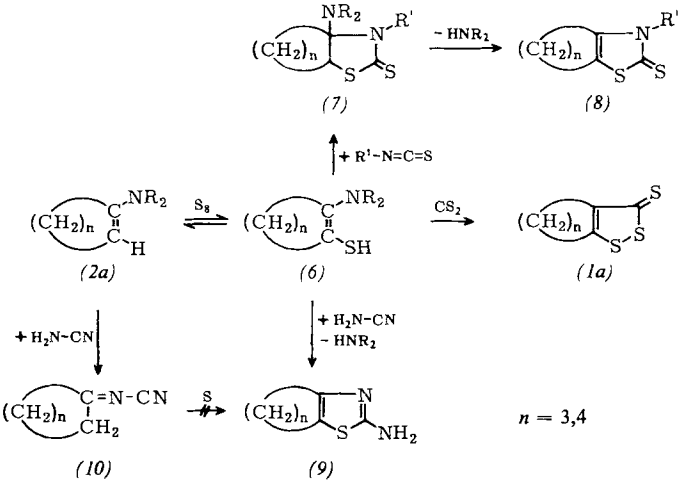


Table 2. Thiazolidine-2-thiones *(7)* and Δ⁴-thiazoline-2-thiones *(8)* from enamines, isothiocyanates, and sulfur [32].

1-Morpholinocyclopentene	Phenyl-	150–152	66	116	95
1-Morpholinocyclopentene	Methyl-	[a]	40	104–105	50

[a] Colorless oil, not distillable.

The analogous reaction with isocyanates, which leads to the formation of 2-thiazolidones *(11)*, has now also been described [34].

Finally, the thiolation product *(6)* can also be detected indirectly by the reaction of the enamine *(2a)* with sulfur and cyanamide in alcohol or in dimethylformamide, which yields 2-aminothiazoles *(9)* [35, 36]. A similar reaction takes place with other enamines. *(9)* is formed only when the enamine *(2a)* is first treated with sulfur and then with cyanamide; if the enamine is allowed to react first with cyanamide, it forms the known condensation product *(10)* [37], which does not react further with sulfur.

To summarize, therefore, we can say that the reaction of enamines *(2)* with sulfur and carbon disulfide leads, in the aliphatic series exclusively, and in the aromatic

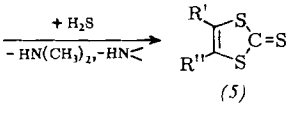
series mainly, to 3*H*-1,2-dithiole-3-thiones *(1)*, and that the formation of 2*H*-1,3-dithiole-2-thiones *(5)* is observed only with a few types of enamines. The occasional formation of *(5)* in our synthesis of *(1)* represents a new discovery. However, since the ratio of *(1)* to *(5)* is largely independent of the reaction conditions discussed here, it is not yet clear why the yield of *(1)* is so strongly dependent on the reaction conditions.

Mention should first be made of another point. 2*H*-1,3-dithiole-2-thiones *(5)* should also be formed from enamines and carbon disulfide in accordance with principle D, by primary attack of the carbon disulfide on the enamine with formation of a CS bond. However, since carbon disulfide alone reacts with the enamine to give only a C–C bond, the incorporation of the CS_2 grouping in the desired direction can be achieved only with the aid of a CS_2 derivative in which the S atom is more electrophilic than the carbon of the thiocarbonyl group. This requirement has been shown to be satisfied by thiuram disulfides *(12)*, enamines being sufficiently nucleophilic to cleave the disulfide bridge in such compounds. In the presence of hydrogen sulfide, the intermediate is stabilized by formation of the 1,3-dithiolethione *(5)* [38,39].



The yields are between 50 and 70%. 1,2-Dithiolethiones *(1)* are not formed in this reaction.

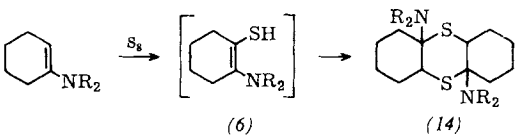
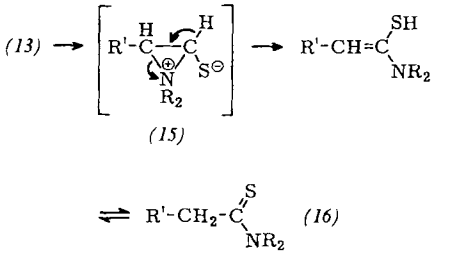
(c) R' = C_6H_5, R'' = CH_3



III. The Reaction of Enamines with Sulfur

Let us now return to the thiolation of enamines:

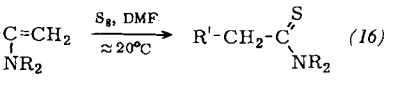


(13)

The intermediate *(13)* is undoubtedly extremely reactive, and should undergo stabilization, even when no other component (such as carbon disulfide or isothiocyanate) is available. In the case of morpholinocyclohexene, it was already known [40] that a hydrogenated thianthrene *(14)* is formed in benzene at 90 °C.

(6) *(14)*

However, thiolated enamines of the type *(13)*, unlike those of the type *(6)*, should become stable by formation of the thioamide *(16)*.



(15)

(16)

Aziridinium ions have often been postulated as intermediates in rearrangements [41], which, however, are not directly comparable with the rearrangement of aziridines into enamines, cf. [42]. The rearrangement of *(13)* into *(16)* is simply a nucleophilic attack of an amine on a thiocarbonyl group or on an enthiol. Reactions of this type always result in addition to the C atom [43]. Thioamides *(16)* therefore occur as by-products in our synthesis of 1,2-dithiolethiones, and should be the main product when the amines react in the presence of sulfur but in the absence of carbon disulfide.

Though the formulation of the rearrangement *(13)* → *(16)* is speculative, it has been fully corroborated in preparative work [18,30]. Thus elementary sulfur reacts with suitable enamines at room temperature (preferably in dimethylformamide) with direct formation of thioamides, sometimes in very high yields [44].

(16)

During the initial thirty minutes of the reaction, the temperature of the reaction mixture rises by 4–5 °C; no resinification occurs, but a brown to red color develops with simultaneous more or less rapid dissolution of the sulfur. Hydrogen sulfide is not formed under these conditions [30]. (Concerning the reaction of amines with sulfur, which is sometimes exothermic, and the resulting activation of the sulfur, cf. [4,8]). In general, the yield of thioamide can be increased by the use of longer reaction times, by stirring the reaction mixture, or by increasing the quantity of dimethylformamide. The yields of thioamide also depend on the nature of the amine component in the enamine. This dependence has been studied for enamines of acetophenone [30]. 1-Morpholino-1-phenylethylene reacts very well (yield up to 95%), whereas the pyrrolidino compound and 1-diisobutylamino-1-phenylethylene give only small quantities of thioamide *(16)*. Under the same conditions, the enamines of acetophenone with diisopropylamine and *N*-methylaniline give no thioamide. (Concerning the problems of the synthesis of thioamides, cf. [44a].)

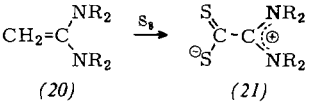
The similarity to the Willgerodt-Kindler reaction (cf. [9,44a] and the literature cited there), *i.e.* the action of sulfur on the enamine components (ketone and amine) at about 130 °C, is obvious, particularly since we have shown that catalysts that favor the enamine formation give increased yields of thioamide *(16)* in the Willgerodt-Kindler reaction. Since the enamine reacts with sulfur at room temperature to form the thioamide *(16)*, the high temperature in the Willgerodt-Kindler reaction is evidently necessary for the enamine formation [18, 30, 43].

This observation, which was also made by *F. Asinger et al.* [9, 45,46], has been confirmed by other workers [47] who found that enamines were formed in the reaction of sulfur with methyl ketones in the presence of secondary amines, and that these enamines themselves reacted with sulfur to form thioamides, though a reaction time of 4 hours at 125 °C was required. An apparently important point is the fact that enamines of the types *(17)* and *(18)* also give thioamides with sulfur at room temperature [30,44]. However, enamines with longer chains give much lower yields and enamines of isobutyrophenone and isovalerophenone do not give thioamides at room temperature [30].

(17), n = 1
(18), n = 2

The fact that enamines of propiophenone *(17a)* react with sulfur at room temperature to give thioamides has led to an interesting observation [18, 30, 48]. This reaction proceeds analogously to that of the enamines of methyl ketones, but the enamine *(17a)* first isomerizes to give *(19)* [48a].



The terminal double bond in *(19)* reacts with sulfur to give the thioamide. The isomerization of the enamine *(17a)* is "catalysed" by sulfur. However, a relatively long time is required for establishment of the equilibrium, so that when one mole of sulfur is used per mole of *(17a)*, the unrearranged compound is also consumed in side reactions. This leads to a decrease in the yield of thioamide from longer-chain enamines.

We also interpret the "migration" of the carbonyl group of aryl ketones to the end of the chain in the Willgerodt-Kindler reaction as an isomerization of the initially formed enamine, at least for the types of compounds discussed here (cf. [49]). As soon as an enamine with a terminal double bond [type *(19)*] is present, the equilibrium is disturbed with irreversible formation of a thioamide. It should also be mentioned that the sulfur-"catalysed" conversion of *(17a)* into *(19)* can also be utilized for a planned synthesis of 1,2-dithiolethiones by the combined action of carbon disulfide and sulfur on enamines [48]. Whereas the normal procedure leads to 4-methyl-5-phenyl-3*H*-1,2-dithiole-3-thione, a modified procedure gives considerable quantities of the 5-benzyl-3*H*-1,2-dithiole-3-thione derived from *(19)*. 1 mole of sulfur and 1 mole of *(17a)* are first allowed to react for a relatively short time in dimethylformamide (this leads mainly to *(19)* and very little thioamide), and the carbon disulfide is then added.

In the normal operation, some thioamide is naturally always formed as a by-product in the synthesis of *(1)*. However, if the operations are carried out quickly and if the sulfur is not allowed to act on the enamine for too long, the thioamide formation is largely suppressed in favor of the 1,2-dithiolthione. Otherwise, suitable structural types lead mainly to thioamides.

In contrast to the action of sulfur on enamines, which yields thioamides, the reaction of endiamines *(20)* with sulfur under similar conditions leads, not to analogues of thioamides, but to high-melting colored salts having the structure *(21)* [50]. These salts are also obtained by the reaction of tetraaminoethylenes with carbon disulfide [51].

(20) *(21)*

The reaction of 1-morpholino, 1-diisobutylamino-, 1-di-n-butylamino, or 1-di-n-propylamino-1-phenylethylene with sulfur in dimethylformamide at room temperature (see Table 3) yields a yellow by-product having m.p. 207 °C. This compound becomes the main product at 50–80 °C, and can be isolated in a yield of approximately 50% together with the thioamide [30]. The compound, which can also be obtained from the

Table 3. *N*-substituted phenylthioacetamides and 2-benzylidene-4-phenyl-2*H*-1,3-dithiole *(22)* from enamines of acetophenone and sulfur in dimethylformamide at 20 °C [30].

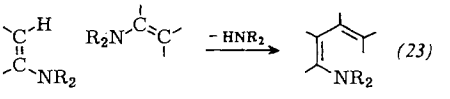
Schiff base[54] or in 60% yield from phenylacetylene (see below), and the formation of which is evidently strongly favored, was characterized as 2-benzylidene-4-phenyl-2*H*-1,3-dithiole *(22)* by comparison with authentic material[52] and by an independent synthesis[53].



(22) was observed in 1958 as a photolysis product of 4-phenyl-1,2,3-thiadiazole[55]. The tendency of *(22)* to be formed is also observed in the normal synthesis of 1,2-dithiolethiones from 1-morpholine-1-phenylethylene, carbon disulfide, and sulfur[24] when the reaction is carried out above about 30 °C. At room temperature, *(22)* can be detected only in traces by thin-layer chromatography. Thus to synthesize definite compounds *(1)* in high yields from enamines, sulfur, and CS_2, the reaction temperature should be kept below 30 °C, and the CS_2 should be added initially to ensure that the sulfur is not allowed to act on the enamine alone.

These observations undoubtedly explain why the yields of *(1)* depend on the reaction conditions for certain enamines. However, they do not explain why this is also found with enamines that, for structural reasons, cannot form 1,3-dithiolethiones *(5)*, thioamides *(16)*, or dithioles of the type *(22)*. Other competing reactions are evidently also possible, and these will be discussed below.

IV. Reaction of Dienamines with Carbon Disulfide and Sulfur

In general, enamines are not particularly stable, and undergo polycondensation even at low temperatures. As is known, enamines obtained from aldehydes[56] give dienamines of the type *(23)*, as well as polyenamines. 1-Amino-1,3-butadienes of the type *(23)* are also formed during the thermal decomposition of enamines[56] and by the action of amines on α,β-unsaturated aldehydes followed by thermal deamination[57, 58]. (The reaction of ketals with secondary amines, on the other hand, leads to 2-amino-1,3-butadienes[59].) A pyrrolidine residue can be eliminated much more easily than *e.g.* a morpholino or a piperidino grouping; consequently, the pyrrolidinoethylenes have a particularly strong tendency to undergo self-condensation[60].

The formation of dienamines would be expected to be favored by an amine interceptor such as CS_2. Thus the action of carbon disulfide and sulfur on enamines should lead to the formation of dienamines. Like

Table 4. 2*H*-Thiopyran-2-thiones *(24)* from enamines and carbon disulfide [63a].

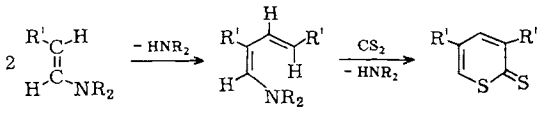
simple enamines, these should react again with CS_2, the resulting product being stabilized by deamination to form a 2*H*-thiopyran-2-thione (α-dithiopyrone) *(24)*.

This conclusion was confirmed experimentally. α-Dithiopyrones *(24)* occur as by-products in most of our syntheses of 1,2-dithiolethiones, particularly when carbon disulfide is used in excess, when the carbon disulfide is allowed to act on the enamine *(2)* for too long in the absence of sulfur, when the reaction temperature is too high, or when relatively non-polar solvents are used instead of the required strongly polar solvents.

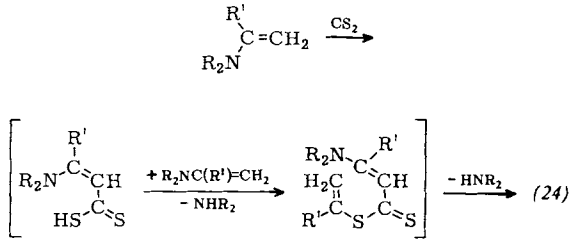
Only a few α-dithiopyrones *(24)* have been described so far (cf. [61,62]). It is therefore interesting to note that they can also be obtained in fairly good yield by the reaction of enamines *(2)* with carbon disulfide at room temperature in the absence of sulfur (Table 4) [63, 63a].



Enamines of aldehydes give 3,5-disubstituted α-dithiopyrones *(24)*, while enamines of ketones give 4,6-disubstituted derivatives. Closer investigation showed that the above considerations concerning the reaction sequence enamine → *(23)* → dithiopyrone *(24)* are also valid for the enamines of aldehydes. In this case the dienamine *(23)* can be detected as an intermediate if the addition of carbon disulfide is stopped prematurely. As expected, the separately prepared dienamines *(23)* can react with carbon disulfide at room temperature to give dithiopyrones *(24)* (see Table 5).

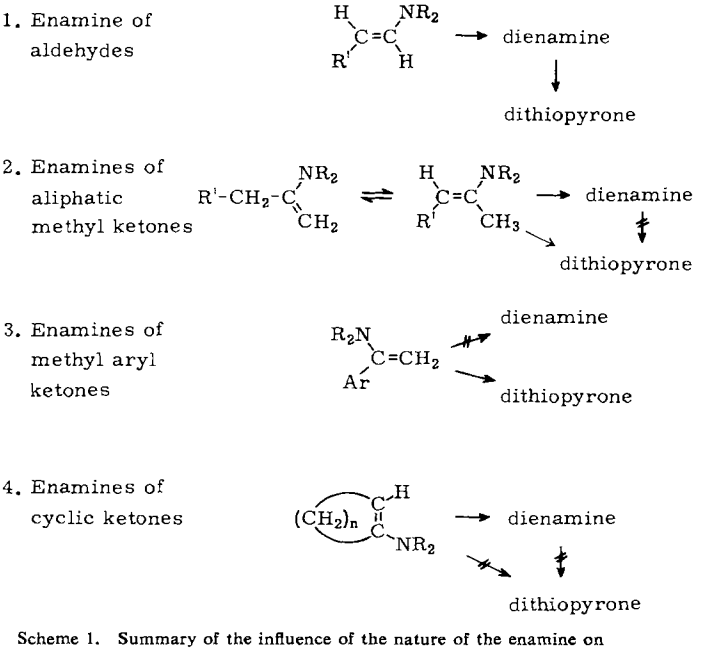
Table 5. 2*H*-Thiopyran-2-thiones *(24)* from dienamines and carbon disulfide [63a].

Dienamine	*(24)*	M. p. (°C) (b. p. (°C/mm)	Yield (%)	Ref.
1-Diethylamino-1,3-butadiene	*(24)*	64	16	[31]
1-Pyrrolidino-2-methyl-1,3-pentadiene	3,5-Dimethyl-	100	58	[31]
1-Piperidino-2-methyl-1,3-pentadiene	3,5-Dimethyl-	100	30	[21]
1-Piperidino-2-ethyl-1,3-hexadiene	3,5-Diethyl-	(132–134/0.1)	68 [a]	[31]
1-Piperidino-2-n-pentyl-1,3-nonadiene	3,5-Di-n-pentyl-	(160/0.5)	51 [a]	[31]



[a] Crude product.

It is also possible to prepare in this way the unsubstituted 2*H*-thiopyran-2-thione [63a], the formation of which had been previously detected in the reaction of thiacyclohexane and sulfur at high temperature [64].



The situation is more complex in the case of enamines derived from ketones. Enamines of aliphatic methyl ketones react with carbon disulfide to form *(24)*; however, when the enamines are converted into dienamines[64a] followed by treatment with carbon disulfide, dithiopyrones *(24)* can be detected in only a few cases, and then only in traces by thin-layer chromatography. Instead of *(24)*, considerable quantities of an inner ammonium salt are obtained (for the structure of this salt, cf. [63a]).

Enamines of methyl aryl ketones cannot be converted into dienamines, but they still give dithiopyrones on treatment with carbon disulfide. Since dienamines can be ruled out as intermediates in this case, it must be assumed that dithiopyrones *(24)* can be formed from enamines of methyl ketones by some other route; for example, carbon disulfide may be added first, the intermediate dithio acid then undergoing cyclization with a second molecule of enamine.

Though enamines of cyclic ketones can be converted into dienamines, neither the enamine nor the dienamine reacts with carbon disulfide to form dithiopyrone *(24)*. Finally, neither dienamines nor dithiopyrones have so far been obtained from the enamines of higher dialkyl or aralkyl ketones.

The various types of enamine are again compared in Scheme 1. Steric factors again have an important effect

Scheme 1. Summary of the influence of the nature of the enamine on the formation of dithiopyrone.

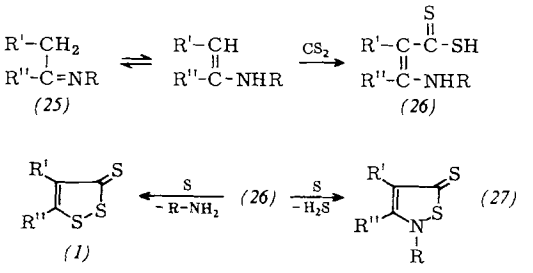
on the reactions described here. Though the nature of the amine component can influence the yields (cf. Table 4), the formation of thiopyranthione depends mainly on the bulk of the substituents in the enamine.

Dienamines should also undergo thiolation with elementary sulfur, particularly since the product can be stabilized by cyclization to form the thiophene ring.

The action of sulfur on enamines should also lead occasionally to thiophenes.



However, it has been found that much higher temperatures are required for the preparation of thiophenes from both enamines and dienamines than for the synthesis of 1,2-dithiolethiones or thioamides. Consequently, thiophenes have so far been detected only in traces (if at all) as by-products of the synthesis of 1,2-dithiolethiones at room temperature. Thiophene is also detected only in traces in the reaction of 1-diethylamino-1,3-butadiene with sulfur. Enamines that condense rapidly have a stronger tendency toward thiophene formation. Thus in the reaction of the labile 1-pyrrolidine-1-phenylethylene with sulfur in dimethylformamide at 20 °C, about 2% of 2,4-diphenylthiophene is obtained as a by-product of the thioamide synthesis described in Section III. Large quantities of diphenylthiophene (about 20%, and 30% in the presence of *p*-toluenesulfonic acid) are also formed from acetophenone and pyrrolidine at 130 °C under the conditions of the Willgerodt-Kindler reaction; this does not necessarily mean that thiophenes cannot be formed by other routes in this reaction [65]. (Concerning thiophenes as by-products of the Willgerodt reaction, cf. also [66], and concerning the thiophene derivatives observed in the reaction of enamines with sulfur at 125 °C, see [47].)

V. Reaction of Ketimines with Carbon Disulfide and Sulfur

In some cases Schiff bases exist in equilibrium with enamines [67]; it was therefore to be expected that Schiff bases react with carbon disulfide and sulfur in the same way as enamines [67a]. (Concerning the treatment of Schiff bases with sulfur, cf. also [9].)

However, it was found that ketimines first react with carbon disulfide to form isolable dithio acids *(26)* [68], which have not so far been detected in the reactions of enamines.

The further stabilization of *(26)* in the presence of sulfur can take place in two ways, both of which can be achieved in practice [12,69]. On the one hand, *(26)* may be *S*-thiolated and converted into 3*H*-1,2-dithiole-3-thiones *(1)* with elimination of amine. This is a special case of the synthesis of *(1)* from enamines as described above. Unlike the enamines, Schiff bases *(25)* in the enamine-like equilibrium form have a *N*-hydrogen atom that can be split off. Secondly, in the presence of sulfur, *(26)* can be dehydrogenated with elimination of H_2S, with formation of novel Δ^3-isothiazoline-5-thiones *(27)*. The dehydrogenation *(26)* → *(27)* can also be brought about by other oxidizing agents, such as iodine.

Table 6. Δ^3-1,2-Thiazoline-5-thiones *(27)* from ketimines, carbon disulfide, and sulfur [69, 70].

Ketimine	*(27)*	M.p. (°C)	Yield (%)
N-Cyclohexylidene-cyclohexylamine	2-Cyclohexyl-3,4-tetramethylene-	195—196	50
N-Cyclohexylidene-isopropylamine	2-Isopropyl-3,4-tetramethylene-	167—168	35
N-Cyclohexylidene-n-propylamine	2-n-Propyl-3,4-tetramethylene-	125—126	30
N-Cyclohexylidene-n-butylamine	2-n-Butyl-3,4-tetramethylene-	74	25
N-Cyclohexylidene-allylamine	2-Allyl-3,4-tetramethylene-	105—106	27
N-Cyclohexylideneaniline	2-Phenyl-3,4-tetramethylene-	134	12
N-Cyclohexylidene-benzylamine	2-Benzyl-3,4-tetramethylene-	170—172	14
N-Cyclohexylidene-α-phenylethylamine	2-(α-Phenylethyl)-3,4-tetramethylene-	100—101	25
N-Cyclohexylidene-β-phenylethylamine	2-(β-Phenylethyl)-3,4-tetramethylene-	187—188	20
N-Cyclohexylidene-β-hydroxyethylamine [a]	2-(β-Hydroxyethyl)-3,4-tetramethylene-	165—166	25
N-Cyclopentylidene-cyclohexylamine	2-Cyclohexyl-3,4-pentamethylene-	168—172	15
N-(1-Phenylethylidene)-cyclohexylamine	2-Cyclohexyl-3-phenyl-4-methyl-	143—144	32
N-(3-Pentylidene)-cyclohexylamine	2-Cyclohexyl-3-ethyl-4-methyl-	149—150	10

[a] In equilibrium with 1-oxo-4-azaspiro[4,5]decane (2,2-pentamethylene-1,3-oxazolidine).

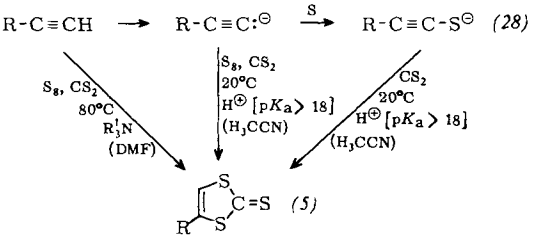
[70] *R. Mayer*, *H.-J. Hartmann*, and *J. Jentzsch*, J. prakt. Chem. [4], *31*, 312 (1966).

The question of whether the intermediate *(26)* reacts to form *(1)* or *(27)* is determined mainly by the temperature. The reaction takes place in only a few cases below 10 °C; between 15 and 20 °C, the principal (but not the only) products are isothiazolinethiones *(27)* (see Table 6), whereas the main product at about 50 °C are 1,2-dithiolethiones *(1)* (see Table 7)[12,69]. The reaction is best carried out in dimethylformamide[70, 71].

Table 7. 3*H*-1,2-Dithiole-3-thiones *(1)* from Schiff bases, carbon disulfide, and sulfur.



Schiff base	*(1)*	M.p. (°C) (b.p. (°C/mm))	Yield (%)	Ref.
N-Cyclohexylidene cyclohexylamine	4,5-Tetramethylene-	102	47	[69,70]
N-Cyclopentylidene-cyclohexylamine	4,5-Pentamethylene-	98	48	[70]
N-(3-Pentyliden)-β-hydroxyethylamine [a]	4-Methyl-5-ethyl-	(160–165/3)	42	[70,71]

[a] In equilibrium with 2,2-diethyl-1,3-oxazolidine.

The structure of the Schiff base *(25)* generally appears to have no appreciable effect on the direction of the reaction. However, it is interesting to note that derivatives of cyclohexanone [*(25)*, R′R″ = $(CH_2)_4$] give good yields of isothiazolinethiones *(27)*, whereas the readily obtainable, very stable dithioacid *(26)* [R′R″ = $(CH_2)_3$, R = *e.g.* cyclohexyl] derived from cyclopentanone cannot be converted into derivatives of either *(1)* or *(27)*[68,69,70]. The 5-membered ring evidently forms a compound having an exocyclic double bond rather than a cyclopentane ring, a tendency that has already been observed in another connection[72]. A preference for the formation of 1,2-dithiolethiones has so far been observed only in the Schiff bases of β-aminoethanol, which exist predominantly as oxazolidines[73].

VI. The Action of Sulfur and Carbon Disulfide on Alkynes

It is well known that acetylene and monosubstituted acetylenes react as CH acids with electrophiles in the presence of an auxiliary base. It should therefore be possible to use these compounds instead of enamines as C_2 components in the synthetic principle (A) mentioned in the Introduction. This has been confirmed by preparations using acetylene and phenylacetylene[53,74,75]. In contrast to the reactions of enamines, the formation of an intermediate dithio acid is not favored in the case of the alkynes[76], whereas the primary thiolation is favored. The products are therefore of the 1,3-dithiole-2-thione type *(5)*. If sodium acetylide is used as the starting material, no auxiliary base is required and the action of sulfur and carbon disulfide in the presence of a protonic solvent leads, even at room temperature, to good yields of 1,3-dithiol-2-thiones (*e.g.* 60% of *(5)*, R = C_6H_5, and 25% of the unsubstituted compound)[53,74,77,78].

The reaction is generally applicable. For example, if selenium is used instead of sulfur, the reaction with phenylacetylene leads smoothly (yield about 50%) to 5-phenyl-1,3-thiaselenole-2-thione[79]. This reaction evidently proceeds *via* the thiolation product *(28)*, which can be prepared from sodium phenylacetylide and sulfur[80]. Thus the thiolate *(28)* may be used directly as the starting material.

We found[53,81] that sodium phenylethynylthiolate dimerizes very rapidly in the presence of acids or other H-active compounds having a pK_a value < 18, with formation of 2-benzylidene-4-phenyl-1,3-dithiole *(22)*, which can be obtained in better yields (about 60%) in this way than from enamines and sulfur.

Similarly, the very stable selenium analogues of *(22)*[53] are obtained from sodium phenylacetylide and selenium[82] *via* sodium phenylethynylselenolate.

The synthesis of 1,3-dithiolethiones *(5)* from CS_2, sulfur, and sodium phenylacetylide requires the presence of a proton-transfer agent, which may be identical with the polar solvent. However, this solvent should have a pK_a value > 18 (*e.g.* acetonitrile), since the yield of 1,3-dithiolethione is otherwise reduced as a result of the very fast dimerization of the intermediate *(28)* to form the compound *(22)*. Even in methanol ($pK_a = 16$), the main product is *(22)*[53].

Some interesting results were obtained in attempts to catalyse the synthesis of 1,3-dithiolethiones from alkynes, CS_2, and sulfur by means of amines. Whereas phenylacetylene, CS_2, and sulfur react in the presence of tertiary amines (though a temperature of about 80 °C is required in this case) to form phenyl-1,3-dithiolethiones, the tertiary amine acting as an auxiliary base, the reaction in the presence of secondary amines leads, not to 1,3-dithiolethiones, but to phenylthioacetamides. This is interesting, since the thiolate *(28)* adds on *e.g.* morpholine or diethylamine, even in the cold, to form thioamides[53].

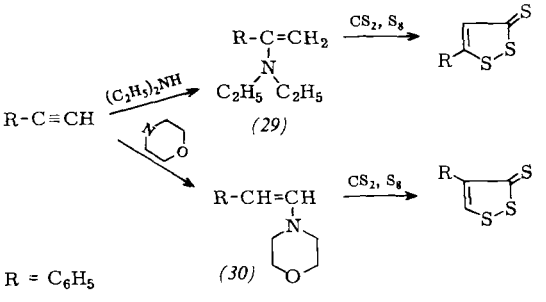
$$\xrightarrow{HNR'_2} R\text{-}CH_2\text{-}C(=S)\text{-}NR'_2$$



The analogous addition of mercaptans to alkynethiolates *(28)*, which leads to dithio esters, has now also been described [82a]. The thioketene *(28a)* is proposed as an intermediate (cf. [53]).

The similarity to the Willgerodt-Kindler reaction is again obvious, particularly since it is known that the reaction of phenylacetylene, sulfur, and morpholine at about 150 °C leads to phenylthioacetomorpholide [83,84].

Since the reactions of sulfur at room temperature with enamines of acetophenone (see Section III) and with sodium phenylacetylide in the presence of secondary amines lead to the same thioamide, an equilibrium could exist between the enamine and the alkyne + amine [49,84].

The conversion of the enamine into phenylacetylene has not so far been achieved under such mild conditions. However, we have been able to show indirectly [85] that phenylacetylene and a secondary amine react to form the enamine. Thus when sodium phenylacetylide in dimethylformamide at about 130 °C is treated with morpholine or diethylamine followed by the addition of sulfur and carbon disulfide in the cold, the products contain 4-phenyl-1,3-dithiolethione and the corresponding 1,2-dithiolethione, the 5-phenyl derivative of the latter being obtained in the presence of diethylamine and the 4-phenyl derivative in the presence of morpholine. The addition of the amines to phenylacetylene, evidently on steric grounds, leads to the enamines *(29)* and *(30)* respectively, which necessarily give the two isomeric 1,3-dithiolethiones.

VII. The Reaction of Nitriles Containing Active Methylene Groups with Carbon Disulfide and Sulfur

Nitriles *(31)* having an active methylene group in the α-position (*e.g.* malonodinitrile and ethyl cyanoacetate) very readily add to carbon disulfide in the presence of auxiliary bases to form salts of the dithiocarboxylic acids *(32)*, which are unstable in the free state [86]. The action of sulfur and carbon disulfide on the nitrile at room temperature in a polar solvent and in the presence of triethylamine leads to the formation of 5-amino-3*H*-1,2-dithiole-3-thiones *(33)* [87] (see Table 8).

Table 8. 5-Amino-3*H*-1,2-dithiole-3-thiones *(33)* and isothiazoles from nitriles having active methylene groups, carbon disulfide, and sulfur [87].

Nitrile	X	*(33)* M.p.	*(33)* Yield (%)	3,5-Bis(methylmercapto)isothiazole M.p. (°C)	3,5-Bis(methylmercapto)isothiazole Yield (%)
Malonodinitrile	4-Cyano-	> 230 dec.	86	133	60
Methyl cyanoacetate	4-Methoxycarbonyl-	197–199	30	130–132	40
Cyanoacetamide	4-Carbamoyl-	260–264	26	—	—

X = CN, CO_2R, $CONH_2$

Whereas the very weakly basic 1,2-dithiolethione derivatives *(32)*, which are similar in their behavior to 3-amino-Δ^3-[1,2,4]dithiazoline-5-thione [88,89], are extremely stable to acids, the action of strong bases leads to a reversal of their formation, with decomposition into sulfur and the salt of the dithio acid *(32)*; the latter gradually takes up sulfur again to form the salt of the dimercaptoisothiazole *(34)*.

The reaction of nitriles with carbon disulfide in the presence of strong bases (*e.g.* sodium alkoxide) leads immediately to *(34)* as the only product; it can be isolated as the *S*-methyl derivative. The free thiol very rapidly rearranges to form *(33)*.

Independently of our work, *Söderbäck* [90] and *Hatchard* [91] reported the conversion of *(32)* (X = CN) into the isothiazole *(34)* [90,91] and the rearrangement *(34)* → *(33)* (X = CN); however, *(33)* is formulated as the imine [90].

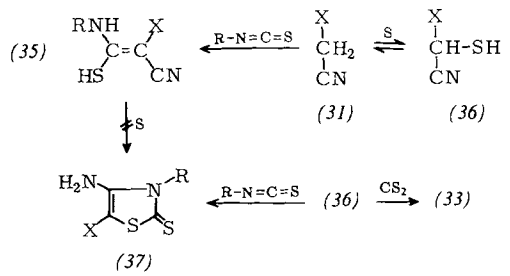
[89] *E. Söderbäck,* Acta chem. scand. *1*, 529 (1947).

[90] *E. Söderbäck,* Acta chem. scand. *17*, 362 (1963).

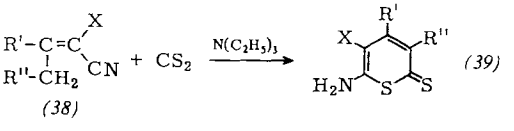


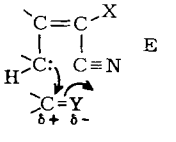
[91] *W. R. Hatchard,* J. org. Chemistry *28*, 2163 (1963); *29*, 660, 665 (1964).

The 1,2-dithiolethione *(33)* (X = CN) is also formed by the reaction of carbon disulfide with cyanothioacetamide in the presence of sulfur or iodine as oxidizing agents [87].

It should also be mentioned that *(33)* (X = CO_2R, $CONH_2$) can be obtained directly from *(32)*. Thus when acetic acid is added to the disodium salt of *(32)*, *(33)* is formed as a stabilization product *via* a desulfurization reaction that has not yet been explained [96]. The formation of *(33)* from nitriles, CS_2, and sulfur is analogous to the synthesis of 1,2-dithiolethiones from enamines (Section II). In this case the C base must be produced by the action of an auxiliary base; the cyclization step is a nucleophilic addition to the C=N group, while the enamine is stabilized by addition and elimination. This reaction again leads exclusively to the 1,2-dithiole system, irrespective of the order of addition of the reactants. Though *(31)* is evendently easily thiolated (thus elementary sulfur dissolves rapidly *e.g.* in ethyl cyanoacetate in the presence of triethylamine), the sulfur is displaced gain by the subsequent action of electrophiles such as carbon disulfide.

The interception of the α-thiolated nitrile *(36)* has so far been accomplished only with isothiocyanates. Whereas the action of CS_2 following the treatment of the nitrile with sulfur in the presence of triethylamine leads to the 1,2-dithiolethione system *(33)*, a strongly exothermic reaction takes place with isothiocyanates, and Δ^4-4-aminothiazoline-2-thiones *(37)* are formed in good yields [2,92] (see Table 9). *(37)* is also formed by the combined action of isothiocyanate and sulfur on nitriles having active methylene groups in dimethylformamide at room temperature, but not when the isothiocyanate and the nitrile are allowed to react first. The addition product *(35)*, which is already known [93], does not take up further sulfur, even on heating. *(37)* is also formed when the primary amine and CS_2 are used instead of the isothiocyanate. Triethylamine is added to the mixture of CS_2, amine (*e.g.* aniline or allylamine), sulfur, and nitrile in dimethylformamide. However, the yields obtained are lower than when the isothiocyanates are used.





We were also interested in the behavior of the nitriles *(38)*, which are readily obtainable from nitriles having active α-methylene groups and carbonyl compounds by the Knoevenagel-Cope reaction, toward carbon disulfide and sulfur.

(38) should react with 1,2-bifunctional compounds such as CS_2 to form 6-membered heterocycles. In fact, some nitriles *(38)* add on carbon disulfide in dimethyl formamide at room temperature, with triethylamine as the auxiliary base, to form 6-amino-2*H*-thiopyran-2-thiones *(39)* [2,94] (see Table 10).

Table 10. 6-Amino-2*H*-thiopyran-2-thiones *(39)* from nitriles *(38)* and carbon disulfide [94].

Nitrile *(38)*	*(39)*	M.p. (°C)	Yield (%)
2-Cyano-3-ethyl-2-penteno-nitrile	3-Methyl-4-ethyl-5-cyano-	171—172	70
Cyclohexylidenemalono-dinitrile	3,4-Tetramethylen-5-cyano-	270—272	85
Cyclopentylidenemalono-dinitrile	3,4-Trimethylen-5-cyano-	253	57
2-Cyano-3-methylcinnamonitrile	4-Phenyl-5-cyano-	266—268	66
Ethyl-2-cyano-3-methyl-cinnamate	4-Phenyl-5-ethoxycarbonyl-	201—203	67
Ethyl-2-cyano-3-benzyl-crotonate	3-Phenyl-4-methyl-5-ethoxycarbonyl-	164—165	40

The reaction is analogous to the reaction of dienamines with carbon disulfide (Section IV). *(39)* with R′R″ = $(CH_2)_4$, X = CN can also be obtained directly in 60% yield by a single-vessel reaction from cyclohexanone,

Table 9. Δ^4-4-Aminothiazoline-2-thiones *(37)* from nitriles having active methylene groups, isothiocyanates, and sulfur [92].

Nitrile	Isothiocyanate	*(37)*	M.p. (°C)	Yield (%)
Malonodinitrile	Phenyl	3-Phenyl-5-cyano-	283—285	80
Ethyl cyanoacetate	Phenyl-	3-Phenyl-5-ethoxy-carbonyl-	221—223	70
Ethyl cyanoacetate	Methyl-	3-Methyl-5-ethoxy-carbonyl-	173	35
Cyanoacetamide	Allyl-	3-Allyl-5-carbamoyl-	172—173	88
Cyanoacetamide	Phenyl-	3-Phenyl-5-carbamoyl-	248—250	56

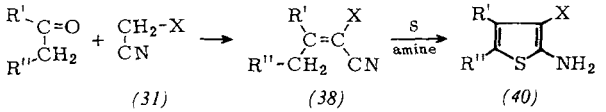
CS_2, and malonodinitrile in alcohol and in the presence of triethylamine or sodium hydroxide.

However, the generalization of the reaction is subject to limitations. It appears that only strong CH-acid alkylidene compounds can add on CS_2; derivatives of cyanoacetic ester ($X = CO_2R$) react only when R′ or R″ is an aryl group. The competing process in the reaction of alkylidenemalonodinitriles *(38)* ($X = CN$) is their base-catalysed dimerization [95], which can be largely suppressed in dimethylformamide. If the dimerization is not sterically hindered (as in *(38)*, $R' = R'' = CH_3$; $R' = CH_3$, $R'' = C_2H_5$; $R' = H$, R'' = alkyl; $X = CN$ for all compounds), this becomes the only reaction, and the addition of CS_2 does not take place. Addition of CS_2 to *(38)* and dimerization of *(38)* may be regarded as a special case of a general addition principle E, but one in which the dimerization plays the dominant role. However, according to observations made so far, isothiocyanates [2,96] also add to *(38)*.



It should be possible to thiolate nitriles of the type *(38)* on the methylene group in the presence of auxiliary bases, cyclization to form the thiophene system being a possibility for the stabilization of the thiol. The reaction of sulfur with *(38)* proceeded surprisingly smoothly and uniformly. In the presence of secondary amines, and preferably in alcohol as the solvent, 2-aminothiophenes *(40)* [97] are formed even at room temperature, sometimes in very good yields (see Table 11, variant b).

Table 11. 2-Aminothiophenes *(40)* from carbonyl compounds R′—CO—CH_2—R″, nitriles having active methylene groups X—CH_2—CN *(31)*, and sulfur [97].

R′	R″	X	Yield (%) [a]	Yield (%) [b]	M.p. (°C) (b.p. (°C/mm))
H	CH_3	C_2H_5OCO	42	—	46 (159–161/19)

CH_3	C_2H_5OCO	C_2H_5OCO	32	—	108–109

[a] From the components indicated.

[b] The carbonyl compound and the nitrile are first condensed; the yield is based on the alkylidene or arylalkylidene compound used.

(31) *(38)* *(40)*

Two possibilities must be considered for the incorporation of sulfur into *(38)*. *(38)* may be thiolated directly, or it may be cleaved by the secondary amine in an initial equilibrium, the sulfur then being taken up by the resulting enamine. The latter possibility is opposed by the fact that the reaction also proceeds in the presence of triethylamine, although much more slowly [98].

It is unnecessary in most cases to isolate *(38)*; the carbonyl compound and the nitrile may be allowed to react with sulfur in a single-vessel reaction in the presence of diethylamine or piperidine (see Table 11, variant a). In this way, aliphatic ketones and aldehydes having a free α-methylene group (with the exception of acetone [99] and acetaldehyde) and β-dicarbonyl compounds [98] can be converted into 2-aminothiophene derivatives *(40)*. The most important nitrile components are malonodinitrile, cyanoacetic ester, cyanoacetamide, and ω-cyanoacetophenone. The reaction of ketones and sulfur with cyanamide instead of with nitriles having active methylene groups leads to 4,5-disubstituted-2-aminothiazoles [36,100]. In this case, however, the first step cannot be a condensation (cf. Section II: for the α-thiolation of carbonyl compounds, cf. [9,10]).

Carbonyl compounds with less reactive carbonyl groups, such as alkyl aryl ketones, can be converted into thiophenes by thiolation only in the form of their alkylidene derivatives *(38)*. Finally, the enamine may be used instead of the free carbonyl compound [97,100a]. The condensation step [enamine + nitrile → *(38)*] is then facilitated; this variant is therefore particularly suitable for the reaction of inert carbonyl compounds. However, it offers few preparative advantages over the thiolation of *(38)*. Thiophenes of the type *(40)* are also formed in the reaction of α-mercaptoketones with nitriles having active methylene groups [101]. The 4,5-tetramethylenethiophenes *(40)* derived from cyclohexanone can be smoothly dehydrogenated as acyl derivatives with sulfur at high temperatures, so offering a new route to 2-aminobenzo[*b*]thiophene derivatives [99,102].

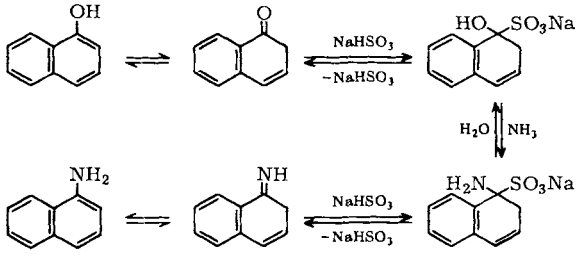
The Bucherer Reaction and the Preparative Use of its Intermediate Products

BY H. SEEBOTH [*]

Dedicated to Professor A. Rieche on the occasion of his 65th birthday

The study of purified intermediate products of the Bucherer reaction has shown that this reaction proceeds, not via bisulfite addition compounds of the keto form of the naphthols and the ketimine form of the naphthylamines, but via tetralonesulfonic acids and tetraloniminesulfonic acids. The intermediates lead to compounds that are otherwise difficult or impossible to obtain, and some of which are new. The mechanism of the Bucherer reaction is discussed in detail.

1. Introduction



The Bucherer reaction provides a relatively simple method for the conversion of aromatic amines into hydroxy compounds or of hydroxyaromatic compounds into primary, secondary, and tertiary aromatic amines. It proceeds in the aqueous phase in the presence of sulfurous acid or its salts, and is used *e.g.* for the preparation of many naphthalene derivatives, which are particularly important as dye intermediates. Although only a few benzene derivatives react, the Bucherer reaction has been successfully used in many cases with anthracene and phenanthrene derivatives, as well as with heterocyclic compounds.

Several reports have been published on the preparative importance of the Bucherer reaction [1]; some recent examples of its application are:

The natural products cupreine and (+)-equilenin have been converted into 6-aminocinchonidine [2] and (+)-3-aminodeoxyequilenin [3], respectively, in good yield by the action of NH_4HSO_3. Many aminoquinoline and aminoisoquinoline derivatives have been obtained with the aid of the Bucherer reaction [1b]. Other successful applications of the sulfite reaction to heterocyclic compounds are the conversion of 2-aminobenzo-1,3-thiazoles into hydroxy compounds [4] and the conversion of 8-hydroxycinnoline into 8-aminocinnoline [5].

A modified process developed by *MacDonald* and *Chechak* [6], in which the organic compound is made to react in a sealed tube at 100 °C in a water/dioxane mixture (1:1 v/v) which is previously saturated with SO_2 at 0 °C, has also proved useful for the preparation of hydroxyphenanthrenes [7]; this method is recommended when the starting compound is completely insoluble in water. Taking the conversion of α-naphthol into *N,N*-dimethyl-*N'*-1-naphthylpropylenediamine as an example, *Werbel* [8] showed that the reaction is advantageously carried out in aqueous $Na_2S_2O_4$ solution instead of in aqueous $NaHSO_3$ solution.

Until recently the views of *Woroshzow* [9], *Friedländer* [10], *Raschig* [11], and *Fuchs* [12–14] were considered to apply, *i.e.* that the reaction proceeded *via* bisulfite adducts of the tautomeric keto or ketimine forms of the naphthols or naphthylamines, in accordance with Scheme 1, and that it should be regarded as a series of equilibrium reactions.

The pure bisulfite adducts of 2-hydroxy-, 4-hydroxy-, and 5-hydroxynaphthalene-1-sulfonic acid were first prepared by *Ufimtsev*[15,16], who confirmed the proposed course of the reaction on the basis of his experiments[17].

The kinetics of the Bucherer reaction were first studied by *Cowdrey* and *Hinshelwood*[18] for the conversion of 4- and 5-amino- and 5-dimethylaminonaphthalene-1-sulfonic acids into the corresponding hydroxynaphthalenesulfonic acids. The rate-determining step is first order with respect to the aminonaphthalenesulfonic acid and the bisulfite. The rate constants k_2 [g mole^{-1} l h^{-1}] of the bimolecular reaction *e.g.* in the case of 4-aminonaphthalene-1-sulfonic acid are 8.52×10^{-2} at 80.5 °C and 19.1×10^{-2} at 99.8 °C; the activation energy of the reaction is 11.8 kcal/mole.

The kinetics of the conversion of naphthols into naphthylamines were studied for 4-hydroxy- and 5-hydroxynaphthalene-1-sulfonic acids[19]. The activation energy of the formation of the bisulfite adduct of 4-hydroxynaphthalene-1-sulfonic acid was found to be 16.8 kcal/mole, and that of its decomposition reaction to be 24.2 kcal/mole. The rate of conversion of the naphthols into naphthylamines by heating with ammonia and ammonium sulfite is directly dependent on the concentrations of the naphthol, the ammonium ions, and the sulfite ions, and is independent of the concentration of excess free ammonia. The reaction is reversible, and the position of the equilibrium depends on the concentration of free ammonia, but not on the presence of ammonia or sulfite ions. *Cowdrey* and *Hinshelwood* regard Scheme 1 as basically correct. However, since the addition of $NaHSO_3$ to the ketimine form of 5-dimethylaminonaphthalene-1-sulfonic acid during the conversion of the latter into 5-hydroxynaphthalene-1-sulfonic acid is not feasible, these authors believe that $NaHSO_3$ may add on to the C=C double bond adjacent to the OH or NH_2 group. *Kozlov* and *Veselovskaya*[20] reached similar conclusions in a kinetic study of the formation of α- and β-naphthylamines by amination of α- and β-naphthols.

A different view is held by *Bogdanov*[21]. Since the bisulfite adduct of α-nitroso-β-naphthol can be converted into 1-amino-2-hydroxynaphthalene-4-sulfonic acid *(3)* by reduction, this author believes that the sulfo group is attached to C-4, even in the bisulfite adduct, *i.e.* that the $NaHSO_3$ adds to the C=C double bond between C-3 and C-4 to form *(2)*, contrary to the usual formulation *(1)*.

Bogdanov has also applied this assumption to the Bucherer reaction, and has proposed the (unverified) course shown in Scheme 2. This scheme has been severely criticized[22,23].

Scheme 2.

2. Preparation and Constitution of the Intermediate Products

a) Bisulfite Adducts of Naphthols

Rieche and *Seeboth* started their study of the course of the Bucherer reaction in 1955. In the preparation of a number of pure bisulfite adducts, they were able to correct a number of earlier ideas[24].

It has long been known that naphthol-bisulfite adducts are stable in aqueous and acidic solution at 20 °C, and that they decompose into $NaHSO_3$ and naphthol under the action of alkalis or when continuously heated in aqueous mineral acids. These naphthol-bisulfite adducts do not couple with diazonium salts, and, unlike the bisulfite adducts of aldehydes and ketones, they are not reduced to the corresponding sulfinic acids by zinc and hydrochloric acid[15,25]. The bisulfite adducts of β-naphthols are less stable than those of α-naphthols.

The isolated bisulfite adducts of the naphthols do not behave as $NaHSO_3$ adducts of the keto form of naphthols[24]. These ketone adducts would be expected to readily lose water with reformation of the aromatic system, so offering a convenient synthesis of sulfonic acids; however, this reaction does not take place. Moreover, no hydroxy groups capable of being esterified could be detected in the $NaHSO_3$ adduct by the action of acetic anhydride, acetyl chloride, or benzoyl chloride; in every case, the bisulfite adduct was recovered unchanged. *Ufimtsev* and *Chernyak*[26] tried unsuccessfully to make the bisulfite adducts of 5-hydroxynaphthalene-1-sulfonic acid, resorcinol, and 2-methyl-1,4-naphthoquinone react in aqueous solution with acetic anhydride. These authors assumed that their failure was due to the fact that tertiary alcohols are difficult to esterify; however, the OH groups

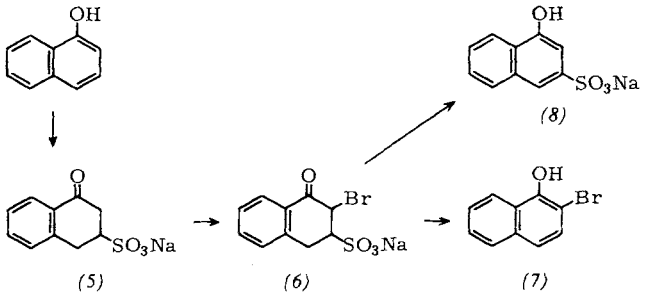
[26] *V. N. Ufimtsev* and *M. I. Chernyak*, Ž. obšč. Chim. *21*, 1883 (1951).

of the bisulfite adducts of aldehydes and ketones can in principle be esterified [27].

The bisulfite adducts of naphthols also fail to undergo replacement of the sulfo group by a cyano group, which is another characteristic reaction of bisulfite adducts of aldehydes and ketones. "Pressureless" hydrogenation to form tetralin derivatives in the presence of high-activity catalysts (*e.g.* Rh on $BaSO_4$) was also found to be impossible. On the other hand, the $NaHSO_3$ adducts of the naphthols react smoothly with ketone reagents such as phenylhydrazine, semicarbazide, and hydroxylamine, the reaction being accompanied by the elimination of water [24]. The condensation products are resistant to alkalis, and are broken down into the starting compounds (bisulfite adduct and the nitrogen compound) when heated in mineral acids. The reaction of the bisulfite adducts with phenylhydrazine had already been observed by *Ufimtsev* [28], who assumed that water was eliminated between the phenylhydrazine and the hydroxy group, and that the condensation products were α-(2-phenylhydrazino)sulfonic acids *(4)*; however, no analogue of this reaction appears to be known.

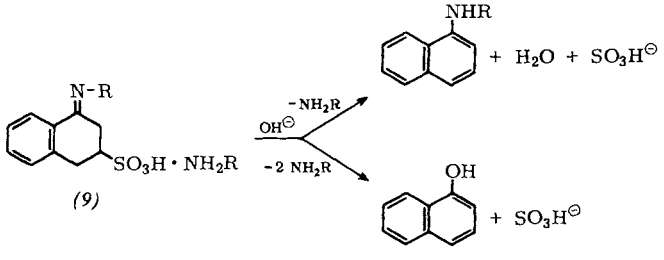


(4)

The IR spectra provided final proof that the intermediates of the Bucherer reaction are not bisulfite adducts of ketones, but are in fact ketones. Like α-tetralone, the adducts of α-naphthols give pronounced keto bands at 1695 and 1610 cm^{-1} [24]. $NaHSO_3$ adducts of β-naphthols, like β-tetralone, give a strong carbonyl band at 1720 cm^{-1} [29]. The spectra of the products of condensation with carbonyl reagents clearly show the presence of a C=N double bond, (*e.g.* a band at 1625 cm^{-1} for the 11-semicarbazone, and bands at 1610 and 1650 cm^{-1} for the 5-oxime).

Thus the intermediates of the Bucherer reaction must be formulated as α- or β-tetralonesulfonic acids, depending on whether they are formed from α- or β-hydroxynaphthalene derivatives. The reactions with carbonyl reagents yield oximes, semicarbazones, and phenylhydrazones. Several indications, and in particular the observation that, on addition of bisulfite to α,β-unsaturated carbonyl compounds, the sulfo group becomes attached to the β-C atom [30], suggest that the sulfo group is in position 3 with respect to the keto group.

The constitution of the bisulfite adduct of α-naphthol has been proved as follows [31]:



Bromination of *(5)*, analogous to that of α-tetralone [32], yields 2-bromo-1-tetralone-3-sulfonic acid *(6)*, which loses $NaHSO_3$ under the action of alkalis to form 2-bromo-1-naphthol *(7)*. *Krollpfeiffer* and *Müller* [33] have prepared *(7)* by the elimination of HBr from β,β-dibromo-α-tetralone. The structure of the 2-bromo-1-naphthol is proved by the formation of 2,4-dibromo-1-naphthol on bromination. When 2-bromo-1-tetralone-3-sulfonic acid *(6)* in acetate buffer solution is treated with small quantities of an organic base, HBr is eliminated and 1-hydroxynaphthalene-3-sulfonic acid *(8)* is formed. *(8)* was identified by paper chromatography (coupling with *p*-nitraniline to form a dye), as the *p*-toluidine and as the *S*-benzylthiouronium salt.

Conversion of the brominated bisulfite adduct of α-naphthol into 2-bromo-1-naphthol and 1-hydroxynaphthalene-3-sulfonic acid proves that the adduct is 2-bromo-1-tetralone-3-sulfonic acid *(6)*. The bisulfite adducts of the α-naphthols must therefore be 1-tetralone-3-sulfonic acids.

b) Bisulfite Adducts of Naphthylamines

Despite numerous attempts, no bisulfite adducts of naphthylamines have been obtained by reactions in aqueous $NaHSO_3$ solution. This is understandable, since the ketimines corresponding to the tetralonesulfonic acids are very readily hydrolysed.

However, reaction of the ammonium salts of the tetrasulfonic acids with an amine, which also acts as the solvent, yields the ketimines *(9)* (IR bands at 1620 to 1640 cm^{-1}) of the ammonium tetralonesulfonates [34, 35]; the water formed during the reaction is distilled off with the solvent.

[35] *H. Seeboth* and *A. Rieche*, Liebigs Ann. Chem. *671*, 77 (1964).

The ketimines are hydrolysed by dilute acids to give the tetralonesulfonic acid and the amine; treatment with hot 2N NaOH yields a mixture of *N*-alkyl-naphthylamine and naphthol.

c) General Methods for the Preparation of Tetralonesulfonic Acids

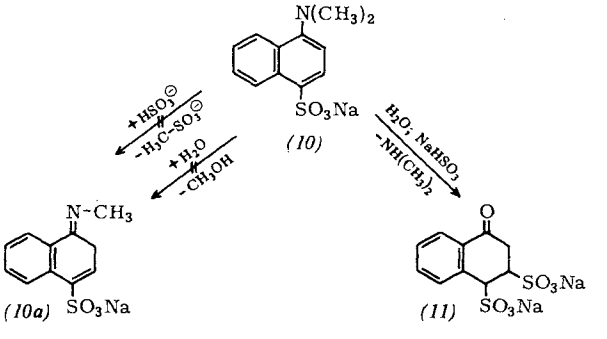
The tetralonesulfonic acids (see Table 1) are generally prepared by heating a naphthol or naphthylamine for 6 to 30 hours in $NaHSO_3$ solution with a 3- to 10-fold excess of $NaHSO_3$; the reaction is usually carried out in a 35 to 40% $NaHSO_3$ solution. The reaction temperature should initially be about 80 °C, and subsequently raised to 90 °C.

Table 1. Tetralonesulfonic acids obtained in the pure state.

Starting material	Tetralonesulfonic acid	Ref.	Remarks [a]; decomp. temp. (°C)
2,7-Dihydroxynaphthalene	6-Hydroxy-3-tetralone-1-sulfonic acid	[12, 24]	
1,5-Dihydroxynaphthalene	5-Hydroxy-1-tetralone-3-sulfonic acid	[12, 24]	Strongly colored and unstable
1,4-Dihydroxynaphthalene	1-Hydroxy-4-tetralone-2-sulfonic acid	[13, 24]	
1,8-Diaminonaphthalene	8-Benzoylamino-1-tetralone-3-sulfonic acid	[24]	T, 225–228
1,8-Diaminonaphthalene	8-Amino-1-tetralone-sulfonic acid	[24]	
α-Naphthol, α-Naphthylamine	1-Tetralone-3-sulfonic acid	[36, 24]	S–B, 142
4-Aminonaphthalene-1-sulfonic	4-Tetralone-1,2-disulfonic acid	[15, 19, 24]	Bis-S–B, 224–227
5-Aminonaphthalene-1-sulfonic	1-Tetralone-3,5-disulfonic acid	[15, 37, 38]	Bis-S–B, 182–185
1-Aminonaphthalene-6-sulfonic	1-Tetralone-3,6-disulfonic acid	[38]	Bis-T, 135
1-Aminonaphthalene-7-sulfonic	1-Tetralone-3,7-disulfonic acid	[38]	Bis-T, 222–224
3-Hydroxynaphthalene-2-carboxylic acid	3-Tetralone-1-sulfonic acid	[29]	S–B, 178–179
2-Aminonaphthalene-1-sulfonic acid	2-Tetralone-1,4-disulfonic acid	[16]	Bis-S–B, 154–155
2-Hydroxy-1-sulfonaphthalene-3-carboxylic acid	2-Tetralone-1,4-disulfonic acid	[39c]	Bis-S–B, 154–155

[a] S–B = *S*-benzylthiouronium salt, T = *p*-toluidine salt.

Where the reaction time is relatively long, SO_2 is passed in at intervals for 20 to 30 min, the reaction mixture being vigorously stirred. With naphthols or naphthylamines that are substantially insoluble in water, the reaction mixture is clear at the end of the reaction. The reaction is complete when no coupling takes place on addition of a diazonium salt to a sample of the solution.



The isolation and purification of the tetralonesulfonic acids is often difficult and laborious. The excess $NaHSO_3$, which interferes with product recovery from the reaction solution, is removed by addition of HCl and passage of a current of air through the solution until no more SO_2 escapes. The solution is then evaporated down under vacuum. The inorganic salts (mainly NaCl) precipitate out first. The subsequent precipitates are tested for tetralonesulfonic acid by checking whether the action of alkalis leads to the elimination of $NaHSO_3$ and formation of a naphthol. In many cases the tetralonesulfonic acids can be separated from inorganic salts by precipitation from methanol, ethanol, or acetone; repeated recrystallization (from C_2H_5OH/H_2O) or reprecipitation (from aqueous solution by the addition of ethanol or acetone) is generally required for purification. The pure tetralonesulfonates crystallize well. They are readily soluble in water and insoluble in organic solvents. The toluidine and *S*-benzylthiouronium salts, which are sparingly soluble in water, may be used for identification. Thin layer and paper chromatography are suitable methods for testing purity and uniformity of the product [24].

3. Mechanism of the Bucherer Reaction

The conversion of α-naphthols into naphthylamines, and *vice versa*, under the catalytic action of bisulfite is seen to proceed *via* 1-tetralone- and 1-tetralonimine-3-sulfonic acids. Similarly, the reaction of β-naphthols and β-naphthylamines with $NaHSO_3$ yields the sodium 3-tetralone- or sodium 3-tetralonimine-1-sulfonates.

Addition of $NaHSO_3$ to the C=C double bond of the keto form of the naphthols or of the ketimine form of the naphthylamines is incompatible with the fact that *N,N*-dialkylated naphthylamines, which cannot normally give a ketimine form, can also be converted into naphthols by means of $NaHSO_3$. A more detailed insight was obtained by the study of the reaction of sodium 4-dimethylaminonaphthalene-1-sulfonate *(10)* with $NaHSO_3$ [34].

(10) reacts with $NaHSO_3$ in the same way as 4-amino- and 4-hydroxynaphthalene-1-sulfonic acids, with formation of disodium 4-tetralone-1,2-disulfonate *(11)*. If one adduct were formed *via* a reactive ketimine

form *(10a)*, a methyl group would have to be removed. If this occurred by hydrolysis, methanol should be formed. A second, but less likely possibility, would be methylation of the bisulfite anion to form methane-

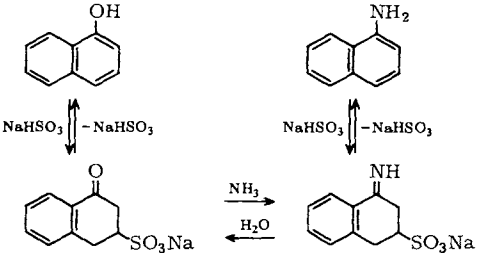
sulfonic acid. However, in the reaction *(10)* → *(11)*, neither methanol nor methanesulfonic acid was found, nor was the methylamine that would be expected as a hydrolysis product of any ketimine form that might occur. On the other hand, 80% of the theoretically expected amount of dimethylamine was isolated. The starting compound *(10)* shows no tendency to lose the dimethylamino group by hydrolysis, even on prolonged heating in 0.1 N to 1 N sulfuric acid. It must therefore be concluded that bisulfite can add directly to naphthol or naphthylamine in the Bucherer reaction.

The first step may be assumed to be the electrophilic addition of a proton to a C atom having a high electron density, *i.e.* C-2 or C-4 in α-naphthols or α-naphthylamines. (An energy of about 25 kcal/mole is required for the dearomatization of the first ring in the naphthalene system). α-Naphthol, for example, gives the resonance-stabilized proton adducts *(12)* and *(13)*. A bisulfite anion can then add to C-3 *via (13b)* to form the compound *(14)*, which tautomerizes to give the lower-energy form *(14a)*.

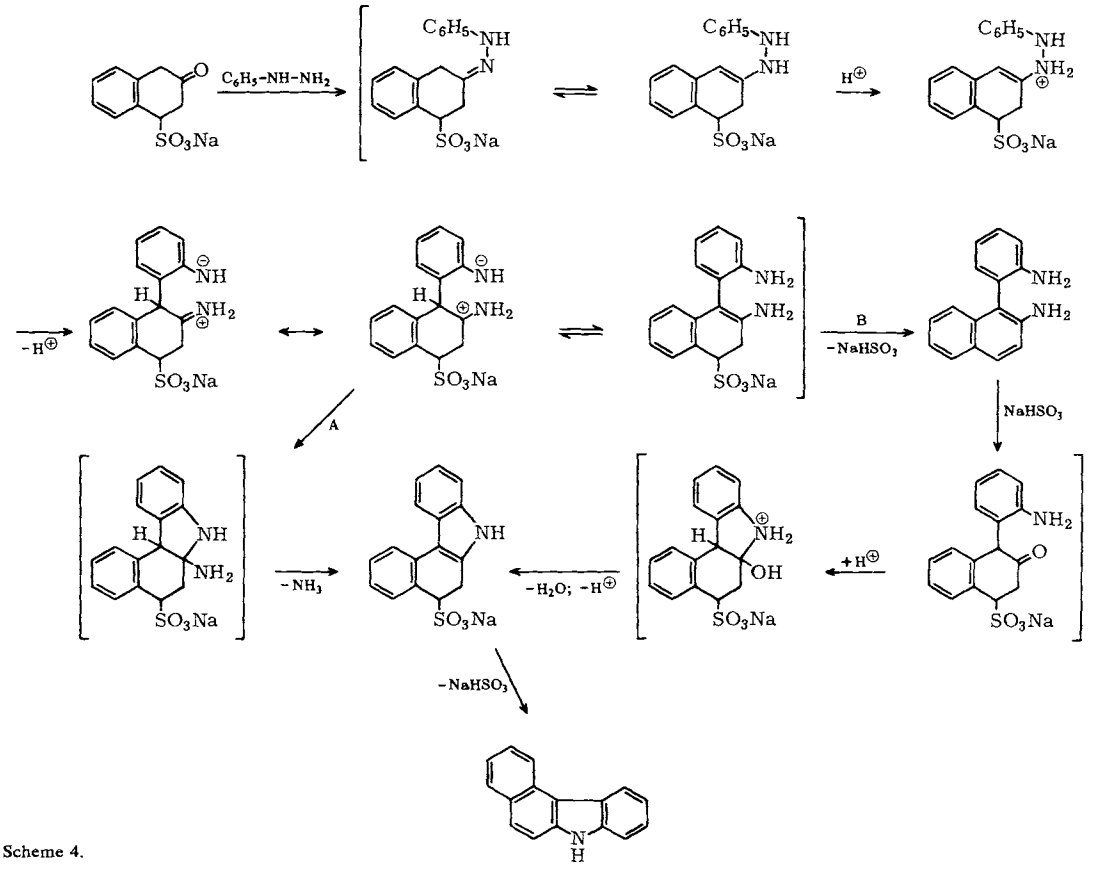
Whereas the first step in additions of nucleophiles to olefines, *i.e.* the addition of a proton, is accelerated by an increase in the $H^{\oplus}$ concentration, this is not the case in the Bucherer reaction, since protonation eliminates the +M effect of the amino or hydroxy group. It is possible that naphthalene derivatives having substituents with a +M effect can add $NaHSO_3$. Attempts to add $NaHSO_3$ *e.g.* to 4-chloronaphthalene-1-sulfonic acid were unsuccessful. It may be concluded, therefore, that the rate of formation of 4-chloro-1,2-dihydronaphthalene-1,2-disulfonic acid is lower than its rate of decomposition; stabilization as in the case *(14)* → *(14a)* is not possible in this instance. The formation of 4-hydroxynaphthalene-1-sulfonic acid or its bisulfite adduct, which might have been expected in the reaction of chloronaphthalenesulfonic acid, was not observed.



The amination of the tetralonesulfonic acids, *e.g. (14a)*, starts with a nucleophilic attack by the amine. The protonated species *(15)* loses water from its tautomeric form *(15a)* to give the resonance-stabilized cation *(16)*, which can lose $H^{\oplus}$ in two ways to give stable molecules. Ketimines[34,35] which can be converted into naphthylamines[34] have been isolated from tetralonesulfonic acids and amines. Under the conditions of the Bucherer reaction, the intermediate formation of *(9)* is unnecessary. It is possible that owing to the strong inductive effect of the sulfo group, a proton is lost from C-2 of the compound *(16)* to give the sulfonic acid *(9a)*, which contains an enamine grouping; *(9a)* is unstable and rapidly loses sulfite to form a naphthylamine.

Thus in the conversion of naphthols into naphthylamines, the primary products from naphthols and $NaHSO_3$, *i.e.* tetralonesulfonic acids, form tetraloniminesulfonic acids in the presence of an excess of amine. The tetraloniminesulfonic acid (or rather its enamine form) is stabilized by loss of $NaHSO_3$ and formation of the naphthylamine. The "enaminesulfonic acids", which in the case of primary and secondary amines exist in equilibrium with the more stable ketimine form, are unstable.

In the conversion of naphthylamines into naphthols, the "enamine-" or tetraloniminesulfonic acid formed from the naphthylamine and $NaHSO_3$ is hydrolysed to the tetralonesulfonic acid, which is stable in acidic media and decomposes into naphthol and sulfite only under the action of alkalis.



Thus the course of the Bucherer reaction may be summarized as in Scheme 3; all the reaction steps are equilibria.

Scheme 3.

4. Mechanism of the Bucherer Carbazole Synthesis

Knowledge of the intermediates of the Bucherer reaction made it possible to elucidate fully the reactions involved in the Bucherer synthesis of carbazoles from naphthols or naphthylamines and phenylhydrazine in the presence of $NaHSO_3$[39]. The reaction of α-naphthols or α-naphthylamines with phenylhydrazine and

Scheme 4.

$NaHSO_3$ leads to stable 1-tetralonephenylhydrazone-3-sulfonic acids, which form 1,2-benzocarbazoles, among other products, on treatment with acids. In the β-naphthalene series, the reaction does not generally stop at the 2-tetralonephenylhydrazonesulfonic acid stage, but gives 1,2-dihydro-3,4-benzocarbazole-2-sulfonic acid (which readily loses $NaHSO_3$ under the action of acids or bases) or 3,4-benzocarbazole, depending on the conditions (see Scheme 4).

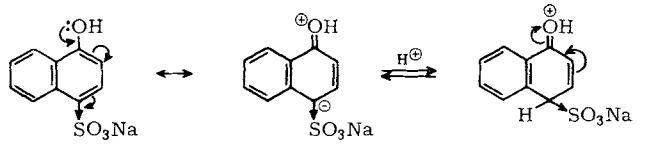
Scheme 4 shows the formation of 3,4-benzocarbazoles. The reaction of sodium 3-tetralone-1-sulfonate with phenylhydrazine in 40% acetic acid at room temperature leads smoothly to phenylhydrazinium 1,2-dihydro-3,4-benzocarbazole-2-sulfonate [39a]. No 2-amino-1-(2-aminophenyl)naphthalene is formed. It may be concluded, therefore, that the reaction proceeds exclusively by route A.

The formation of 3,4-benzocarbazole from β-naphthol [14] or 2-hydroxynaphthalene-3-carboxylic acid [40a] and phenylhydrazine in aqueous $NaHSO_3$ solution in a single-vessel process (30 and 18 hours respectively; 100 °C) yields considerable quantities of 2-amino-1-(2-aminophenyl)naphthalene as a by-product. The observation that this diamine gives 3,4-benzocarbazole in 15% yield when heated for $2^1/_2$ hours in 2 N HCl, but in 89% yield when heated for $2^1/_2$ hours in aqueous SO_2 solution [14, 39a] suggests that the formation of carbazoles from naphthols and phenylhydrazine in the presence of $NaHSO_3$ also proceeds by route B. The conversion of the diamine into benzocarbazole by treatment with $NaHSO_3$ is a normal Bucherer reaction.

In principle, the Bucherer carbazole synthesis, the Fischer indole synthesis [40b], and the Borsche-Drechsel carbazole synthesis from phenylhydrazones and cyclanones [40c] all proceed in a similar manner. The analogy between the formation of carbazoles from naphthols, phenylhydrazine, and $NaHSO_3$ and the Fischer indole synthesis has already been pointed out by *Bucherer* and *Seyde* [40a].

5. Selectivity and Limited Scope of the Bucherer Reaction

The course proposed by *Rieche* and *Seeboth* for the Bucherer reaction provides an explanation for the fact that the reactions proceed readily in some cases, and with difficulty or not at all in others. This is illustrated by the following examples.



4-Hydroxy- and 4-aminonaphthalene-1-sulfonic acids react more readily than α-naphthol or α-naphthylamine with $NaHSO_3$. This is due to the −I effect of the sulfo group, which strongly favors the addition of a proton to C-4 and the nucleophilic attack of $NaSO_3^{\ominus}$ on C-3.

In 1-hydroxynaphthalene-2-sulfonic acid *(18)*, the −I effect of the sulfo group and the weakening of the +M effect of the hydroxy group by hydrogen bonding with the sulfo group

(17)

(18) (18a) (18b)

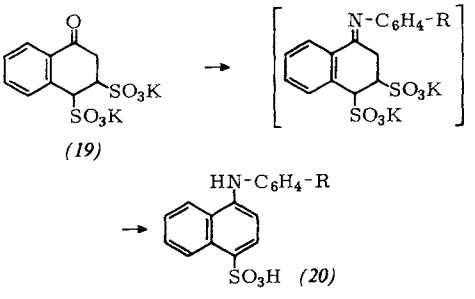
(18c) (18d)

lead to a lower electron density on C-4. The importance of the limiting form *(18b)* is less than that of *(18a)*, and the strong −I effect of the SO_3H group, which favors the nucleophilic addition of $NaSO_3^\ominus$ in 4-hydroxynaphthalene-1-sulfonic acid *(17)*, is considerably reduced by interaction [cf. *(18c)*] with the OH group. Consequently, protonation at C-4 and nucleophilic attack of $NaSO_3^\ominus$ on C-3 are hindered. In 1-hydroxynaphthalene-3-sulfonic acid, the addition of a proton to C-4 and the addition of $NaSO_3^\ominus$ to C-3 are again inhibited by the negative charge on C-3. The last two acids do not undergo the Bucherer reaction. It is thus clear why OH and NH_2 groups in *m*-hydroxy- and *m*-aminonaphthalenesulfonic acids cannot be interchanged by the sulfite reaction.

The selectivity frequently exhibited by the reaction is now also understandable. In 4,5-diaminonaphthalene-1-sulfonic acid, for example, only the amino group in the *p*-position with respect to the sulfo group reacts, and the product is 5-amino-4-hydroxynaphthalene-1-sulfonic acid[41], the reasons being the same as those given for the formation of *(17)*.

The preparation of 7-amino-1-hydroxynaphthalene-3-sulfonic acid ("γ-acid") from 1,7-dihydroxynaphthalene-3-sulfonic acid[42] is selective because a *m*-tetralonesulfonic acid intermediate can be formed only by the ring containing the β-hydroxy group, so that only the β-hydroxy group can be replaced by the amino group.

It is now also possible to explain why only one substituent can be exchanged in diamino- and dihydroxynaphthalenes and in aminonaphthols. Thus if the two functional groups are attached to different rings, the replacement of the second would require the dearomatization of the benzene ring in the tetralonesulfonic acid. If both substituents are attached to the same ring, a second addition of $NaHSO_3$ is no longer opssible.

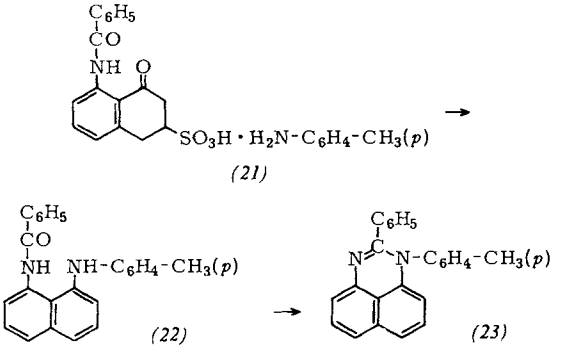


6. The Preparative Use of Tetralonesulfonic Acids

The intermediates of the Bucherer reaction have provided access to many compounds that are difficult or impossible to prepare by other methods. The use of salts of tetralonesulfonic acids is limited mainly by their instability in alkaline media and by their insolubility in organic solvents; however, it is often possible to use salts of organic bases, which are soluble in methanol, ethanol, and other water-miscible solvents.

a) Preparation of *N*-Arylated α-Naphthylamines and Naphthyl Sulfides

β-Naphthalene derivatives are generally smoothly aminated by alkyl- and arylamines under the conditions of the Bucherer reaction. Arylaminations of α-naphthalene derivatives, on the other hand, take place only in exceptional cases[1,43]. This is due to the lower nucleophilic strength of the arylamines as compared with the alkylamines, and to the lower electron density on the carbonyl carbon atom of 3-tetralone-1-sulfonic acids as compared with 1-tetralone-3-sulfonic acids.



The reaction of 1-tetralone-3-sulfonic acids in anhydrous media with aromatic amines in the presence of strong acids yields 1-arylaminonaphthalenes, owing to the increase in the polarity of the carbonyl group[44]. *N*-Substituted naphthionic acids *(20)* are obtained in good yield from dipotassium 4-tetralone-1,2-disulfonate *(19)* *e.g.* in acetic acid or diglycol in the presence of small quantities of concentrated H_2SO_4.

(19) (20)

R = $CH_3(p)$; $OCH_3(p)$; $NO_2(p)$; $Cl(o, m, p)$

N-Arylated α-naphthylamines are formed when sodium 1-tetralone-3-sulfonate is heated for about 7 min at 180–200 °C with amine hydrochlorides. However, the action of one equivalent of $(NH_4)_2SO_4$ or NH_4Cl on sodium 1-tetralone-3-sulfonate at 210–230 °C yields α,α'-dinaphthylamine (probably *via* α-naphthylamine). In the pyrolysis of the *p*-toluidine salt of 8-benzoylamino-1-tetralone-3-sulfonic acid *(21)*, reaction again

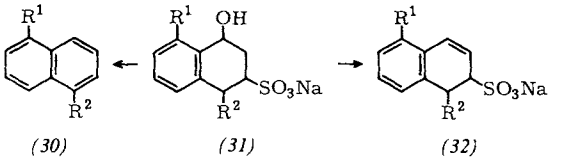
does not stop at the 8-benzoylamino-1-(*p*-tolylamino)-naphthalene stage *(22)*, but proceeds further to give 2-phenyl-1-(*p*-tolyl)perimidine *(23)* with elimination of water.

The ammonium salts of 4-tetralone-1,2-disulfonic acid do not form an *N*-substituted naphthionic acid when heated to 205–215 °C, but give *N*-substituted α-naphthylamines, with hydrolysis of the sulfo group on C-4.

In the study of the reaction of tetralonesulfonic acids with other nucleophiles that undergo acid-catalysed reactions with carbonyl compounds, it was found that thiols react smoothly with formation of naphthyl sulfides [45]. Sodium 3-tetralone-1-sulfonate *(24)* reacts in glacial acetic acid in the presence of small quantities of hydrochloric acid to give excellent yields of β-naphthyl sulfides *(28)*. Dithioacetals *(26)* are not formed; the assumed intermediate *(25)* appears to be very rapidly stabilized by loss of a proton and $NaHSO_3$, since the sodium 3-alkylthio-1,2-dihydronaphthalene-1-sulfonate *(27)* was not detected. 1-Tetralone-3-sulfonates

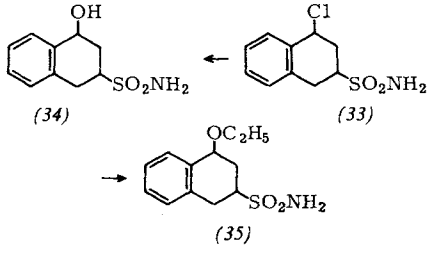
also react with thiols in glacial acetic acid at 20 °C when dry HCl gas is passed through the solution. This process is particularly suitable for the synthesis of 1-alkylthio- and 1-arylthionaphthalenesulfonic acids such as *(29)*, which are practically impossible to prepare in the usual manner (*via* naphthalenesulfonyl chlorides) [46].



R = C_2H_5, C_6H_5, CH_2-C_6H_5, H_2C-$(CH_2)_n$-CH_3, H_2C-CO_2H

b) Reduction of Intermediates of the Bucherer Reaction

Reduction of tetralonesulfonic acids can be used for the preparation of ac-hydroxytetralinsulfonic acids, which had not previously been described in the literature [47].



Sodium 1-tetralone-3-sulfonate can be converted into 1-hydroxytetralin-3-sulfonic acid *(31)*, $R^1 = R^2 = H$, by three methods: with sodium amalgam at pH = 6–7, with amalgamated aluminum [48], and by hydrogenation under pressure (40 atm, 80 °C, Raney nickel). The sodium salt of 8-amino-1-hydroxytetralin-3-sulfonic acid *(31)*, $R^1 = NH_2$; $R^2 = H$, and the dipotassium

salt of 4-hydroxytetralin-1,2-disulfonic acid *(31)*, $R^1 = H$; $R^2 = SO_3H$, were prepared in the pure state only by reduction of the corresponding tetralonesulfonic acid with activated aluminum.

The salts of the ac-hydroxytetralinsulfonic acids are stable toward dilute acid and alkali in aqueous solution at room temperature. They are decomposed by hot concentrated alkalis or hot 40% H_2SO_4 into water, SO_2, and naphthalene [or naphthalene derivatives *(30)*]. This reaction could be used for the elimination of hydroxy groups from naphthols *via* their bisulfite adducts. Attempts to dehydrogenate ac-hydroxytetralinsulfonic acids with sulfur or selenium lead to naphthalenes, but not to naphthols. The action of hot dilute mineral acids leads to elimination of water and formation of 1,2-dihydronaphthalenesulfonic acids *(32)*.

The sodium or *p*-toluidine salt of 1-hydroxytetralin-3-sulfonic acid reacts with thionyl chloride in dimethylformamide [49] to form 1-chlorotetralin-3-sulfonyl chloride, which gives 1-chlorotetralin-3-sulfonamide *(33)* on treatment with NH_3 gas in benzene. *(33)* is hydrolysed to 1-hydroxytetralin-3-sulfonamide *(34)* when heated in 2N Na_2CO_3 solution, and is alcoholysed to 1-ethoxytetralin-3-sulfonamide *(35)* in hot absolute alcohol.

The tetraloniminesulfonic acids *(36)*, which can be obtained from 1-tetralone-3-sulfonic acids and amines [34, 35], give *N*-substituted 1-aminotetralin-3-sulfonic acids *(37)* in yields of between 50 and 70% on reduction with $NaBH_4$ [50]. The compounds are very stable toward hot acids and bases.

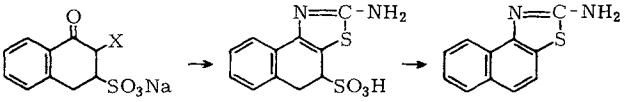
[50] Cf. *E. Schenker*, Angew. Chem. *73*, 99 (1961).

(36) *(37)*

1-Aminotetralin-3-sulfonic acid *(39)* can be obtained in good yield by reduction of the Na salt of 1-hydroxyiminotetralin-3-sulfonic acid *(38)* with sodium amalgam at pH = 7–8 or with activated aluminum [35]. A process reported by *Bogdanov* [51], namely, reduction of *(38)* with zinc in the presence of copper acetate, yields only unchanged starting material and a little 1-tetralone-3-sulfonic acid [35].

(38) *(39)* *(40)*

(39) is very stable toward acids and bases, and cannot be dehydrogenated to 1-aminonaphthalene-3-sulfonic acid with sulfur. Treatment with HNO_2 yields 1-hydroxytetralin-3-sulfonic acid *(40)* (the amino and sulfo groups are *cis* and equatorial).



c) Preparation and Use of Halogenated Tetralonesulfonic Acids

1-Tetralone-3-sulfonic acids can be halogenated in position 2 [31, 38]. Bromination or chlorination takes place *e.g.* in aqueous solution in the presence of carbon tetrachloride as a solubilizing agent for the halogen. 2-Halogeno-1-tetralone-3-sulfonic acids *(41)* lose sulfite under the action of alkalis, with formation of bromonaphthols. It is possible in this way to prepare 2-bromo-1-hydroxynaphthalene-5-, -6-, and -7-sulfonic acids and 2-bromo- and 2-chloro-1-naphthol, which are otherwise obtainable only with difficulty, if at all [38].

The dehydrohalogenation of *(41)*, *i.e.* conversion into 1-hydroxynaphthalene-3-sulfonic acid, can be accomplished with catalytic quantities of carbonyl reagents (phenylhydrazine, hydrazine, or hydroxylamine) in alcohol in the presence of sodium acetate [52] or in acetate buffer solution with small quantities of organic bases or hydrazine. This method has been used for the preparation of 1-hydroxynaphthalene-3-sulfonic acid, and also of the 1-hydroxynaphthalene-3,5--3,6-, and -3,7-disulfonic acids. There is no need to isolate the halogenotetralonesulfonic acids; the acidic aqueous solution obtained on halogenation is simply neutralized with sodium acetate, a little hydrazine hydrate is added, and the solution is heated for about 10 min.

3-Bromo-4-tetralone-1,2-disulfonic acid could be only incompletely dehydrobrominated. On heating in benzylamine, 4-hydroxynaphthalene-1,2-disulfonic acid is isolated only in small yields as the bis-(*S*-benzylthiouronium) salt, together with 2-bromo-1-hydroxynaphthalene-4-sulfonic acid.

Hantzsch's classic thiazole synthesis [53], in this case the reaction of sodium 2-bromo-1-tetralone-3-sulfonate *(41)*, X = Br, and thiourea, leads to the formation of 2-amino-4,5-dihydrothiazolo[4,5-*a*]naphthalene-4-sulfonic acid *(42)* [54]. In acetate-buffered aqueous solution, the yield of *(42)* is 50%, whereas the

(41), X = Cl, Br *(42)* *(43)*

yield obtained in methanol is only 25% [55]; 1-hydroxynaphthalene-3-sulfonic acid is also formed. When *(42)* is heated in 2N NaOH, it loses bisulfite to form 2-aminothiazolo[4,5-*a*]naphthalene *(43)*, which can also be obtained from 1-(α-naphthyl)thiosemicarbazide [56] and from α-naphthylthiourea [57]. The synthesis *via (41)* is simpler, since *(42)* can be conveniently obtained in a single-vessel process from 1-tetralone-3-sulfonic acid [58].

d) Aminomethylation of 1-Tetralone-3-sulfonic Acid

Sodium 1-tetralone-3-sulfonate, like α-tetralone [59], reacts with formaldehyde and amines (*e.g.* morpholine, diethylamine, piperidine, and benzylamine) at 20 °C to form derivatives of 2-aminomethyl-1-tetralone-3-sulfonic acid *(44)* [60]. Although the keto group of *(44)* does not react with carbonyl reagents, its presence is demonstrated by bands at 1605 and 1680 cm^{-1} in the IR spectrum.

When heated in dilute alkalis, the compounds *(44)* lose sulfite and form Mannich bases *(45)* of α-naphthol [61]. Attempted reduction of 2-morpholinomethyl-1-tetralone-3-sulfonic acid led to 1-hydroxy-2-morpholinomethyltetralin-3-sulfonic acid *(46)*, $R^1 + R^2 = CH_2-CH_2-O-CH_2-CH_2$, which loses H_2SO_3 and H_2O in hot 65% sulfuric acid to form 2-morpholinomethylnaphthalene *(47)*, $R^1 + R^2 =$ $CH_2-CH_2-O-CH_2-CH_2$.

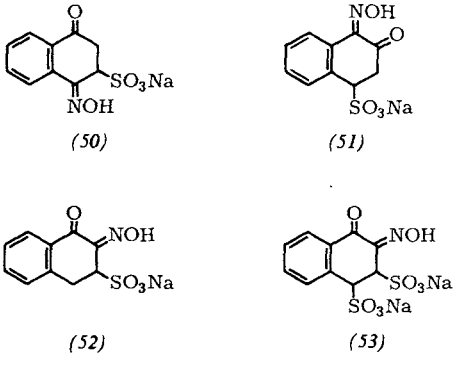
Wagner*, J. org. Chemistry *7*, 31 (1942); *J. W. Cornforth*, *R. H. Cornforth*, and *R. Robinson*, J. chem. Soc. (London) *1943*, 168.



(46) (47) (44) (45) (48) (49)

$R^1 + R^2 = -CH_2-CH_2-O-CH_2-CH_2-$; $-(CH_2)_5-$;
$R^1, R^2 = C_2H_5$; $R^1 = H$, $R^2 = CH_2C_6H_5$

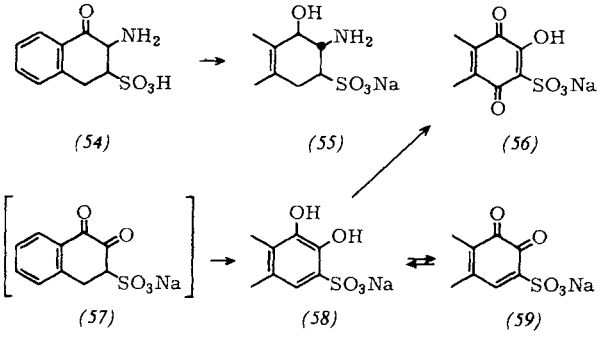
When the compounds *(44)* are heated in alcohol in the presence of an equivalent amount of $KHCO_3$, amine is eliminated and the potassium salt of 1-hydroxy-2-methylnaphthalene-3-sulfonic acid *(49)* is formed *via* the unstable methylene ketone *(48)* [62].

e) Bisulfite Adducts of Nitrosonaphthols

The hydroxyiminotetralonesulfonic acids *(50)* to *(53)* may be regarded as adducts of $NaHSO_3$ with 4-nitroso-1-, 1-nitroso-2-, and 2-nitroso-1-naphthol and with 1-hydroxy-2-nitrosonaphthalene-4-sulfonic acid. These substances are more stable than the bisulfite adducts discussed so far; for example, they do not decompose

(50) (51) (52) (53)

in alkaline solution at 20 °C. The adducts *(50)* and *(51)* are formed from $NaHSO_3$ and the corresponding nitrosonaphthol [21,63,64], whereas the compounds *(52)* and *(53)* cannot be obtained in this way. A well-known method for the separation of 2- and 4-nitroso-1-naphthols is based on the fact that 4-nitroso-1-naphthol forms a bisulfite adduct, while 2-nitroso-1-naphthol does not [63]. 2-Nitroso-1-naphthols, like 1-hydroxynaphthalene-2-sulfonic acids, evidently do not add $NaHSO_3$.



[62] Cf. *M. Mühlstädt* and *O. Scholz*, Chem. Ber. *97*, 1 (1964).

[63] *N. N. Woroshzow* and *S. W. Bogdanow*, Ber. dtsch. chem. Ges. *62*, 68 (1929).

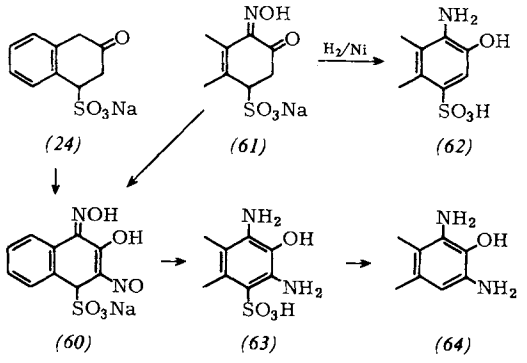
[64] *S. V. Bogdanov*, Ž. obšč. Chim. *2*, (64) 770 (1932).

Seeboth and *Becker* [65] found that 1-tetralone-3-sulfonic acids react with HNO_2 to form 2-hydroxyimino-1-tetralone-3-sulfonic acids. Thus *(53)* was prepared from dipotassium 4-tetralone-1,2-disulfonate [31] and *(52)* from sodium 1-tetralone-3-sulfonate and isoamyl nitrite [65]. The IR spectrum of *(52)*, like that of α-tetralone, contains strong carbonyl bands at 1680 and 1600 cm^{-1}; there is no evidence of the existence of the tautomeric nitrosonaphthol form [66].

2-Hydroxyimino-1-tetralone-3-sulfonic acids undergo a number of interesting reactions. Hydrogenation (Raney nickel in water/methanol) of *(52)* yields the inner salt of 2-amino-1-tetralone-3-sulfonic acid *(54)*, which can be converted into *trans*-2-amino-1-hydroxytetralin-3-sulfonic acid *(55)* by the action of $NaBH_4$ as a suspension in methanol. When *(54)* is heated for a short time in 20% hydrochloric acid, it forms 2-amino-1-naphthol hydrochloride and 1-hydroxynaphthalene-3-sulfonic acid.

(54) (55) (56) (57) (58) (59)

When the sodium salt *(52)* is heated in 30% hydrochloric acid, it is hydrolysed to 1,2-dioxotetralin-3-sulfonic acid *(57)*, which rearranges to give the more stable tautomer, sodium 1,2-dihydroxynaphthalene-3-sulfonate *(58)*. *(58)* is stable in acidic media, but in alkaline solution it is oxidized by air to 3-hydroxy-1,4-naphthoquinone-2-sulfonic acid *(56)*. The action of nitrous acid on *(58)* in acidic solution leads to oxidation, with formation of the orange Na salt of 1,2-naphthoquinone-3-sulfonic acid *(59)*, which has a relatively low solubility. However, *(59)* is more easily obtained by the action of HNO_2 or isoamyl nitrite on *(52)* in acidic aqueous solution, or directly from the Na salt of 1-tetralone-3-sulfonic acid with an excess of isoamyl nitrite at 20 °C [67]. *(59)* can be reduced to 1,2-dihydroxynaphthalene-3-sulfonic acid *(58)* with phenylhydrazine [68], $NaBH_4$, or sulfurous acid.

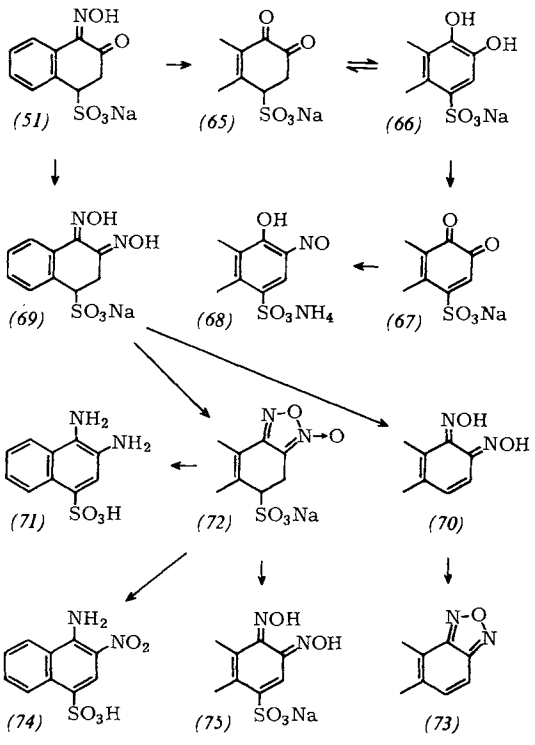


The sodium salt of 3-tetralone-1-sulfonic acid *(24)* reacts with 2 moles of nitrous acid to form 4-hydroxyimino-3-hydroxy-2-nitroso-1,4-dihydronaphthalene-1-sulfonic acid *(60)*. The same product is obtained from 1-hydroxyimino-2-tetralone-4-sulfonic acid *(61)* and isoamyl nitrite in concentrated hydrochloric acid [65].

[65] *H. Seeboth* and *B. Becker*, Liebigs Ann. Chem. *693*, 201 (1966).

[66] Cf. *D. Hadži*, J. chem. Soc. (London) *1956*, 2725.

[67] Concerning the oxidation of 3-methyl-1-tetralone and α-tetralone with SeO_2, see *F. Weygand* and *K. Schröder*, Ber. dtsch. chem. Ges. *74*, 1844 (1941); *F. Weygand* and *I. Frank*, Chem. Ber. *84*, 591 (1951).



[68] Cf. *H. Teichner*, Ber. dtsch. chem. Ges. *38*, 3377 (1905).

Hydrogenation of *(60)* in methanol/water in the presence of Raney nickel yields 2,4-diamino-3-hydroxynaphthalene-1-sulfonic acid *(63)*; this reaction is similar to the conversion of *(61)* into 1-amino-2-hydroxynaphthalene-4-sulfonic acid *(62)* by reducing agents [21,69]. A remarkable feature in both cases is the aromatization under hydrogenating conditions. The sulfo group in *(63)* is removed hydrolytically when the compound is heated in 40% sulfuric acid. 1,3-Diamino-2-naphthol *(64)* is stable as the hydrochloride [70] or sulfate; the free base is extremely readily oxidized.

Bogdanov [71] observed a number of interesting reactions of 1-hydroxyimino-2-tetralone-4-sulfonic acid *(51)*. In hydrochloric acid solution, the action of hydroxylamine hydrochloride leads to the formation of the ammonium salt of 1-hydroxy-2-nitrosonaphthalene-4-sulfonic acid *(68)*. Contrary to *Bogdanov*'s assumption [71], the reaction probably proceeds analogously to the formation of 1,2-naphthoquinone-3-sulfonic acid from 2-hydroxyimino-1-tetralone-3-sulfonic acid, as follows: *(51)* is hydrolysed to the unstable 1,2-dioxotetralin-4-sulfonic acid *(65)*, which tautomerizes to form 1,2-dihydronaphthalene-4-sulfonic acid *(66)*; *(66)* is then oxidized to 1,2-naphtho-quinone-4-sulfonic acid, which condenses with hydroxylamine.

The reaction of *(51)* with hydroxylamine hydrochloride in the presence of sodium acetate yields 1,2-bis-(hydroxyimino)tetralin-4-sulfonic acid *(69)*, which loses sulfite at low temperatures to form 1,2-naphthoquinone dioxime *(70)*, and at high temperatures forms [2,1,3]oxadiazolo[4,5-*a*]naphthalene *(73)* *via* *(70)*. Oxidation of *(69)* with HNO_3, HNO_2, or H_2O_2 leads to the bisulfite adduct of [2,1,3]oxadiazolo[5,4-*a*]naphthalene 3-oxide *(72)* [72]. This can be reduced to 1,2-diaminonaphthalene-4-sulfonic acid *(71)* with zinc in alkaline media. When *(72)* is heated for 10 min in soda solution, 1-amino-2-nitronaphthalene-4-sulfonic acid *(74)* is obtained together with products such as naphtho[1,2-*d*]furazan 3-oxide; *(74)* is hydrolysed to 1-hydroxy-2-nitronaphthalene-4-sulfonic acid on prolonged heating [73]. Treatment of *(72)* with sodium

hydroxide solution leads to isomerization to the dioxime of 1,2-naphthoquinone-4-sulfonic acid *(75)*.

Similar reactions have been carried out *e.g.* with the bisulfite adducts of 2-hydroxy-1-nitrosonaphthalene-6- and -7-sulfonic acids [71,74] and of 1-nitroso-2-anthrol [75].

6. Conclusion

This review provides an example of the many revelations and the many preparative and industrial applications that lie hidden in "classical" chemistry. Owing to lack of space, no mention has been made of the application of the Schmidt reaction [76] to tetralonesulfonic acids [54], the formation of substituted naphthylhydrazines in the "single-vessel process" from 2-hydroxynaphthalene-3-carboxylic acid, acid hydrazide, and bisulfite [39b], or the synthesis of new carbazole derivatives [39b,39c]. The bisulfite adducts of azo compounds of naphthols and naphthylamines [39a,77] have also been omitted from the discussion.

The results described should provide an incentive for further experiments, *e.g.* on the stereochemistry of actetralinsulfonic acid derivatives. The principal outcome of this report is the elucidation of the mechanism of the Bucherer reaction, which has been used in industry for almost 70 years.

The Solvent Dimethyl Sulfoxide

BY D. MARTIN, A. WEISE, AND H.-J. NICLAS [*]

Dedicated to Professor Alfred Rieche on the occasion of his 65th birthday.

The dipolar aprotic solvent dimethyl sulfoxide is liquid over a wide range of temperatures, is a strong electron donor, and has a high polarity. It is therefore an excellent and selective solvent for many organic and even polymeric compounds, and can enter into H-bonding and dipole-dipole association. The structure of dimethyl sulfoxide, with a "hard" oxygen atom and a "soft" sulfur atom, leads to good solvation of cations and poor solvation of anions. Mixtures of alkoxides with dimethyl sulfoxide are therefore among the most strongly basic systems in organic chemistry, and are excellently suited for the deprotonation of weakly acidic OH, NH, and CH bonds, for eliminations, and for the initiation of polymerizations.

I. Introduction

The classic principle "like dissolves like" is valid only as a rule of thumb. A deeper understanding of solvent properties has been gained by classification into protonic and dipolar aprotic solvents. According to *Parker* [1], protonic solvents are proton donors such as water, alcohols, carboxylic acids, and formamide. Dipolar aprotic solvents such as dimethylformamide, dimethylacetamide, tetramethylurea, dimethyl sulfoxide, acetonitrile, and nitrobenzene are characterized by dielectric constants $\varepsilon > 15$ and dipole moments $\mu > 3$ D. Since the hydrogen in these compounds is firmly bound, they cannot act as proton donors. The solvating powers of the two groups of solvents can be estimated from these properties:

1. Protonic solvents solvate anions by ion-dipole interactions and by strong hydrogen bonding, the ease of solvation increasing with decreasing size and increasing electronegativity of the anion: $SCN^- < I^- < N_3^- < Br^- < Cl^- \ll F^- \approx OH^-$ [2,3].

2. Anions are much less strongly solvated by dipolar aprotic solvents, owing to the absence of hydrogen bonding; in this case the large polarizable anions are more easily solvated than the small, more electronegative anions, so that the solvation series given under 1 is reversed [2,3].

3. Cations are generally less strongly solvated in protonic solvents than anions [3,4]. The reverse is true for dipolar aprotic solvents [1].

Thus the ability of a solvent to act as a proton or electron donor characterizes the solvent better than its polarity.

Among the dipolar aprotic solvents, dimethyl sulfoxide (DMSO) has become increasingly important in recent years. This importance is due not only to its high solvent power for many inorganic and organic compounds and its compatibility with many container materials [5], but also to its ease of production [5] and its pharmacological harmlessness [6–10,15]. *Schläfer* and *Schaffernicht* [14] have described the physical properties of DMSO and its use as a solvent in inorganic chemistry. (Other reviews: [5,11–13].)

The present article deals mainly with the use of DMSO in organic reactions and as a solvent for organic compounds. Special emphasis is placed on examples that show DMSO to possess special properties within the series of dipolar aprotic solvents. Apart from the formation of the methylsulfinyl carbanion in reactions with bases, we shall not discuss the cases in which DMSO enters into reaction and does not act merely as a solvent.

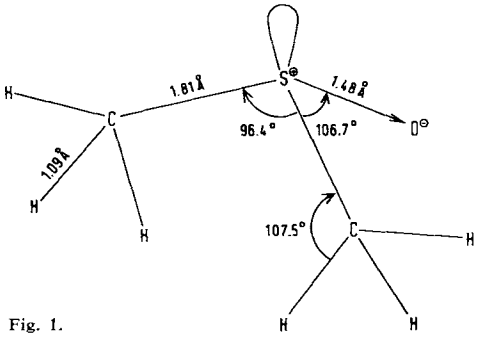
II. Physical Properties

Dimethyl sulfoxide is a colorless, odorless, and hygroscopic liquid with a slightly bitter taste. At 20 °C it has an equilibrium moisture content of 10% water [16]. Some of its physical properties [17] are listed in Table 1, and the bond lengths and valence angles [18–21] are shown in Figure 1.



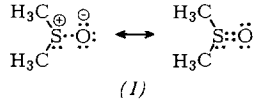


Fig. 1.

DMSO is best formulated as a resonance hybrid *(1)* [14, 39] of the canonical structure having a polarized S–O bond and that having a (p → d)$_\pi$ SO double bond [31, 40]. This representation agrees best with the physical properties and the reactivity of the compound.

vestigations in benzene [26] show that liquid DMSO is strongly associated. The associates, which could be formed by O–H *(2)* [14] as well as by S–H *(3)* [14] and S–O *(4)* [1] bridges, are broken down between 40 and 60 °C, as can be seen from the temperature-dependence of several physical properties (density, refractive index, increase in the limiting conductivity, and decrease in the Walden product, $\lambda_0 \cdot \eta_0 = \text{const.}$) [1,14]. The associates can rearrange in the presence of proton donors (cf. Section III).

(2) *(3)* *(4)*

The partial decomposition observed during boiling at normal pressure is strongly dependent on the impurities present, and decreases with increasing purity. The thermal decomposition is catalysed by acids [5,41] and inhibited by sodium formate, oxalate, and chloride, by borax, and by barium hydroxide [42]. When DMSO is refluxed for three days, 3.7% of volatile products are formed: dimethyl sulfide, dimethyl sulfone, dimethyl disulfide, bis(methylthio)methane, water, and paraformaldehyde [43].

As a solvent for spectroscopic studies, DMSO frequently offers decisive advantages in addition to its excellent solvent properties (cf. Section IV). Owing to the strong association of the OH and NH protons with DMSO (Section III) their rates of exchange are reduced. Thus the spin-spin splitting of the OH protons can be observed in the NMR spectrum, and also sharp NH resonance lines are recorded (example: sugar osazones [44]). Hydrogen bonding shifts the OH resonance lines to lower fields ($\tau \leqslant 6.0$); below 25 mole-%, the position of the OH lines is independent of concentration [45]. The methanol OH proton gives a quartet, and primary, secondary, and tertiary alcohols give clearly resolved triplets, doublets, and singlets [45] (examples: study of the conformation of epimeric cyclohexanols [46] and anomeric sugars [47,48]). [D_6]-DMSO (cf. Section VI) can be used for the study of tautomerism in pyrimidines and nucleosides [49], and unlike deuterochloroform it can be used, because of its greater solvent power, for the NMR spectroscopy of steroids [50].

DMSO is highly transparent between 350 and 2200 μ (see Table 1), whereas water absorbs at 1300 μ. DMSO can therefore be advantageously used instead of water for spectroscopic studies in the near IR region [51].

Owing to its good solvent properties and its favorable melting point, DMSO can also be used as a solvent in cryoscopic molecular-weight determinations by the *Beckmann* method [24,52].

III. Association and Solvation in Dimethyl Sulfoxide

Electron donor(D)–acceptor(A) molecular complexes exist in equilibrium with ion pairs, which are partly dissociated into free, solvated ions. The position of the equilibrium [eq. (a)] is determined by the nature of the solvent and of the donor-acceptor system. In most of the cases studied so far, $k_1 \gg k_2$, k_3 [53].

$$D + A \underset{}{\overset{k_1}{\rightleftharpoons}} (D \ldots A \longleftrightarrow D^{\delta\oplus} \ldots A^{\delta\ominus}) \overset{k_2}{\rightleftharpoons} (D^{\oplus}A^{\ominus})\ \text{solv.}$$

$$\overset{k_3}{\rightleftharpoons} D^{\oplus}_{\text{solv.}} + A^{\ominus}_{\text{solv.}} \qquad \text{(a)}$$

The equilibrium constants and the enthalpy change (ΔH) for equation (a) can be easily determined, and can be used for the comparison of the strengths of electron donors [54]. For example, the donor strength toward $SbCl_5$ was found to decrease in the order pyridine > DMSO > dimethylacetamide > dimethylformamide > diethyl ether > acetone > acetonitrile [54]. A study of dimethyl sulfoxide with various acceptors gave the order $SbCl_5$ > phenol > I_2, the ΔH values being −29.8, −6.5±0.2, and −4.4±0.3 kcal/mole respectively [54,55].

Similar considerations apply to proton donor and acceptor equilibria [eq. (b)] [56].

$$\underset{}{AH} + B \rightleftharpoons \underset{\text{(5)}}{AH \ldots B} \rightleftharpoons \underset{\text{(6)}}{A^{\ominus} \ldots HB^{\oplus}} \rightleftharpoons \underset{\text{(7)}}{A^{\ominus}_{\text{solv.}} + HB^{\oplus}_{\text{solv.}}} \qquad \text{(b)}$$

H-bridge; H-bridged ion-pair

DMSO contains two acceptor sites: the oxygen atom, which is the position of highest electron density, and the sulfur atom, which, in spite of its partially positive character, still possesses nucleophilic properties because of the lone pair of electrons [see formula *(1)*] [57].

This view is supported by the complexes with palladium and platinum, in which the S atom forms a coordinate

bond [58], and by the methylation with methyl iodide to form $[(CH_3)_3S^{\oplus}O]I^{\ominus}$ [59]. All other electron acceptors (Lewis acids), which have been studied so far, attack at the oxygen atom.

The only possible point of association for the proton is the O atom of dimethyl sulfoxide. An explanation for this is offered by the theory of "hard" and "soft" bases and acids [60,61], according to which the "hard" proton can coordinate strongly only with the "hard" oxygen atom, whereas the "soft" atoms Pd and Pt and the "soft" methyl cation can attack the "soft" S atom. For these reasons the postulated dimethyl sulfoxide-S...H association *(3)* cannot be significant. Owing to the low CH acidity of DMSO (see Table 1), however, O...H association *(2)* is also unlikely.

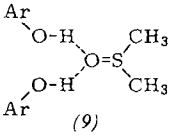
1. Proton Donors

Thermodynamic, dielectric, and viscometric data show the existence of a strong interaction between DMSO and water [1,62–64]. One molecule of DMSO preferentially associates with two molecules of water [1,63,65]; *Tommila* [66] has suggested the structure *(8)*.

$$(CH_3)_2\overset{\displaystyle OH_2}{\overset{|}{S}}{=}O...H\text{-}O\text{-}H \quad (8)$$

However, definite complex formation could not be detected by cryoscopic investigations [67]. It was deduced from IR- [38] and Raman-spectroscopic findings [68] that the water molecules in DMSO are subject to strong dipole-dipole interactions, and may cause a partial ionic character in *(6)*. These interpretations are supported by kinetic data [69], which also show that the DMSO–H_2O interactions are stronger than the intermolecular association of H_2O [66,70,71].

Alcohols are weaker proton donors toward DMSO, and form only H-bonded complexes *(5)*. Calorimetric determination of the partial molar enthalpy of mixing ΔH_S gave an exothermic value only for methanol (−0.34±0.03 kcal/mole, H_2O: −1.28±0.03 kcal/mole), in contrast to the higher alcohols (ethanol 0.28±0.02 kcal/mole, n-propanol 0.61±0.04 kcal/mole, and n-butanol 0.99±0.03 kcal/mole) [3].



The proton association on the oxygen atom is clearly evidenced by the displacement of the SO stretching vibration to lower wave numbers as a result of the decrease in the (p → d)π-bond component [72,73]. Complexing on the S atom should lead to an increase in the frequency of the SO stretching vibration [73]. The association of DMSO with compounds containing OH groups is summarized in Table 2.

Table 2. Association of compounds containing hydroxy groups with dimethyl sulfoxide $[(CH_3)_2SO\cdots HOR]$.

Carboxylic acids and phenols give 1:2 as well as 1:1 associates. In the case of phenols, the structure *(9)* probably predominates over *(10)* [37].

(9)

(10)

The acidity of phenols and carboxylic acids changes significantly with the transition from protonic to dipolar aprotic solvents (see Table 3) [1,29,81]. This is

due to the difference in the solvation of the anions and cations formed in accordance with equation (b), which displaces the equilibrium more or less towards *(7)*. If the anions are small, they are strongly solvated *via* H-bonds by protonic solvents, and HA is a relatively strong acid in water. On the other hand, DMSO solvates anions only weakly, and so decreases the acidity. Large anions (*e.g.* the picrate anion, see Table 3) are more strongly solvated by DMSO, so that the system is more strongly acidic than the aqueous system. At the same time, the strong electron-donating action of DMSO leads to strong solvation of protons, which are thus withdrawn from the reverse reaction (formation of HA).

Sulfuric and hydrochloric acids are strong acids in DMSO[29]. The *i* factor [*] for the protonation with concentrated sulfuric acid is about 2[57,82]. Nitric acid forms a 1:1 adduct with DMSO[14]. The acidity of very weak acids in DMSO mixtures has also been studied[83–85].

Table 3. pK_a values of some phenols and carboxylic acids in dimethyl sulfoxide and in water.

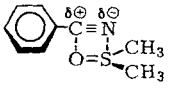
Acid (Ion)	pK_a (DMSO)	pK_a (H_2O)	Ref.
Picric acid	−1.9	0.71	[81]
2,4-Dinitrophenol	5.2	4.10	[81]
Salicylic acid	6.9	2.98	[29]
4-Nitrophenol	9.9	7.15	[81]
Benzoic acid	10.0	4.20	[29]
(Di-n-butylammonium)	10.3	11.31	[29]
Acetic acid	11.4	4.76	[29]

The association of OH-proton donors in DMSO shows a gradation: alcohols form H-bonds *(5)*, water and phenols form H-bonded ion pairs *(6)*, and strong acids are present as free (solvated) ions *(7)*.

In contrast to OH association, very few investigations have been carried out on NH complex formation in DMSO (see Table 4). The shifts of the NH signal to lower fields in the ^{1}H–NMR spectrum show the following sequence of electron donor strengths[86]:

DMSO > pyridine > acetone > RNO_2 > $CHCl_3$.

Table 4. Association of compounds containing NH groups with dimethyl sulfoxide.



Amine	Amine:DMSO	Proof of association	Ref.
$C_6H_5NH_2$	1:1	[a, b, c]	[87]
$C_6H_5NH-CH_3$	1:1, 2:1, 3:1	[a, b, c]	[87]
$C_6H_5NH-C_6H_5$	1:1, 2:1	[a, b]	[87]
$4\text{-}H_3CC_6H_4-NH_2$	1:1	[b]	[87]
$4\text{-}BrC_6H_4-NH_2$	1:2	[d]	[88]
$(C_2H_5)_3Si-NH_2$	1:1	[d]	[89]
Sugar osazones	1:1	[e]	[44]

[a] Cryoscopic measurements, [b] refractometric measurements, [c] UV spectra, [d] IR spectra, [e] NMR spectra.

The proton donor strength of CH bonds depends on the hybridization of the C atom and on the substitution. The formation of H bonds is favored by increasing s-character $C_{(sp^3)}-H < C_{(sp^2)}-H < C_{(sp)}-H$ and by electron-attracting substituents. $C_{(sp^3)}-H$ bonds have a detectable donor action only in combination with two electron-attracting substituents[90,91], the influence of which can be expressed by "spectral displacement increments"[91]. For example, chloroform forms 1:1[71,92] ($\Delta H_S = -1.32 \pm 0.09$ kcal/mole[31]) and 2:1 complexes[92] with dimethyl sulfoxide. In compounds of the type RR'C=CHX, clearly detectable H-bonding occurs only when X and at least R or R' are electronegative; benzene requires three electron-attracting substituents, whereas alkynes having terminal triple bonds act as proton donors, even in the absence of electronegative substituents[90].

2. Dipole Associates

Nitriles and ketones form dipole-dipole complexes with DMSO, as is shown by the changes in the position and intensity of the carbonyl and nitrile absorption in the IR spectrum[93–95]. It can be seen from the arrangement *(11)* that the dipole-dipole complexes are much more sensitive to steric effects than the H-bonded complexes. The association affects the reactivity of the nitrile group, so that electrophilic attack on the N atom is facilitated[96].

(11)

As is shown by the dissociation constant, the dipole-dipole complexes are much weaker than the H-bond complexes: $K_{\text{acetone·DMSO}} = 2.7$ mole l^{-1}[95], $K_{C_6H_5CN\cdot DMSO} = 1.1$ mole l^{-1} (also $p\text{-}ClC_6H_4CN$, $p\text{-}O_2NC_6H_4CN$, and $m\text{-}O_2NC_6H_4CN$)[95], $K_{C_6H_5OH\cdot DMSO} = 5.5 \times 10^{-3}$ mole l^{-1}[55].

3. Charge-Transfer Complexes

Iodine chloride, iodine, and iodine cyanide form 1:1 complexes with DMSO (the bond strengths decreasing in the above order)[55,73,97], as can be seen from the

[*] The *i* factor is the number of particles formed on dissolution of one "molecule" of the substance.

lower intensities and lower frequencies (1011–1036 cm^{-1}) of the SO stretching vibrations. The reason is the same as in the H-bonded complexes, *i.e.* lowering of the (p → d)π-bond order [73]. The charge-transfer band for the iodine cyanide-DMSO complex in heptane occurs at 223 μ, and that for the iodine-DMSO complex [97] in carbon tetrachloride is at 272 μ.

IV. Solvent Power

The high and selective solvent power of DMSO is due to three important properties, *i.e.* its relatively high polarity, its ability to form hydrogen bonds, and the fact that it is liquid over a wide range of temperatures.

1. Solvent Power for Gases and Water

The gases HCl, SO_2, SO_3, and NO_2 dissolve very readily in DMSO at room temperature. At NO_2 contents higher than 25%, as with HNO_3, addition compounds having explosive properties are formed. CO_2 and NH_3 are moderately soluble, NO, CO, N_2, H_2, and O_2 are insoluble, and H_2S is oxidized to sulfur.

Ethylene oxide and unsaturated hydrocarbons such as acetylene [98,99], ethylene, and propylene are very readily soluble in DMSO, whereas the solubility of saturated hydrocarbons is low.

About 30% more acetylene dissolves in DMSO than in acetone at normal pressure; however, DMSO cannot be used as a storage liquid for acetylene, since the solubility of acetylene decreases with increasing pressure – this is in contrast with the solubility of acetylene in acetone [100]. The solubilities of some gases in dimethyl sulfoxide are given in Table 5.

Table 5. Solubilities of gases in dimethyl sulfoxide at 20.3 °C and atmospheric pressure [25].

Gas	Wt.-%	Vol. gas per vol. DMSO
SO_2		500
NH_3	2.6	40
CO	0.0	—
CO_2	0.6	4
Methane	0.0	—
Propane	—	1.8
Ethylene	0.1	1.1
Propylene	—	3.2
Isobutylene	2.5	—
Butadiene	—	30
Acetylene	2.8	30
Dimethylether	3.9	—
Ethylene oxide	—	48.2
Methanethiol	35	—

DMSO is perfectly miscible with water. Owing to the high specific heat of DMSO (see Table 1), these solutions have lower freezing points and lower viscosities than mixtures of water with glycol, glycerol, methanol, *etc.* Aqueous solutions of DMSO are therefore very suitable for use as cooling brines [25,101].

2. Solvent Power for Organic Compounds

Apart from the saturated paraffins, nearly all the common organic solvents (alcohols, glycols, ethers, aldehydes, ketones, carboxylic acids, nitriles, amines, thioethers, chloroform, and aromatic solvents) are completely soluble in DMSO. DMSO is a good solvent for fats, carbohydrates, camphor, heterocycles, dyes, and drugs. The solubilities of some organic compounds in DMSO are given in Table 6.

Table 6. Solubilities of some organic compounds in dimethyl sulfoxide [25] at 20.3 °C.

Compound	Wt.-%	Compound	Wt.-%
n-Hexane	2.6	Glycine	0
n-Decane	0.6	Methionine	0.1
n-Dodecane	0.3	Saccharose	30–50 (warm) [a]
Napthalene	27	Urea	25–55
Triethylamine	8.3	Thiourea	25–40
Di-n-butylamine	10.0	Phenol	completely miscible
Methyl laurate	6.0	Picric acid	completely miscible
Oxalic acid	26	Terephthalic acid	15–25 (warm) [a]
Citric acid	40	CS_2	45

[a] No details in original paper.

DMSO is well suited for use as a solubilizing agent in the dyeing and printing of textiles. It can be used for the preparation of pastes of naphthol-AS components, which are not obtainable by the cold dissolution method with alcohol, furthermore, it may be used for the preparation of solutions of certain naphthols, from which the naphthol is not precipitated in the aqueous-alkaline dye bath [5]. Thus cellulose fibers can be uniformly dyed in aqueous media by dispersion of the water-insoluble dye in DMSO [102]. Synthetic polymers such as Dacron, Nylon, polyvinyl chloride, and polystyrene can also be dyed with a soluble dye or with a pigment in admixture with DMSO [103]. DMSO can be used as a carrier for dyes, pigments and chemicals for rubber processing, or in pesticides. These solutions are characterized by a long storage life and a remarkable compatibility with a large number of substrates [104].

In recent years, the outstanding power of DMSO to penetrate the skin has attracted special interest as a result of the discovery that it greatly improves the percutaneous resorption of a large number of drugs [105].

Quaternary oximes such as 1-methyl-2-hydroxyiminomethylpyridinium methanesulfonate are continuously carried

through the skin of guineapigs and rats [106]. This penetration takes place only to a small extent or not at all by water. The penetration of glucocorticosteroids and hydrocortisone through human skin *in vitro* is 5 to 20 times as fast in DMSO as in 95% ethanolic solution [107]. Similar improvements in penetration have been observed in *in-vivo* studies *e.g.* with dyes, vitamins, insulin, glucocorticosteroids, and griseofulvin [107a, 108]. The stratum corneum reservoir [*] was saturated 5 min after application. This retention persists for up to 16 days, and is not affected by washing of the skin with soap, water, and ethanol [109].

3. Solvent Power for Macromolecular Compounds

DMSO has found wide use as a solvent for natural and synthetic polymers (cf. Table 7). It is an excellent solvent for polymeric carbohydrates and their derivatives, polyamides, polyvinyl compounds, resins, and paints.

Table 7. Examples of polymers soluble in dimethyl sulfoxide.

Soluble polymers	Polymers that dissolve on heating and precipitate out on cooling:
Cellit T 900 and T 1000	Polyurethanes
Cellulose acetates	Polymethacrylates
Collodion cottons	Coumarone resin
Cellulose ethers	Copal
Urea resins	Phenolic resin (Super Beck. 2000)
Epoxy resins	
Polyvinyl alcohol	Swellable polymers
Polyacrylonitrile	Plexigum M 265
Mowital B 60H	Vinoflex MP 400
Mowilith 50	
Plastopal EBS	
Shellac	
Rosin	
Chlorinated rubber	

Granulated starch [110, 111] dissolves in anhydrous DMSO without swelling. The solubility is decreased by chemical cross-links. Nonionic cellulose ethers such as methyl cellulose and methyl hydroxyethyl cellulose dissolve readily in DMSO. It is the only known organic solvent for the water-soluble ethyl hydroxyethyl cellulose [112], and is also good solvent for acetylcelluloses and nitrocelluloses. DMSO can be used in the manufacture of uniformly drying noninflammable paints with improved frost resistance and high adhesion [5]. However, since DMSO is hygroscopic, concentrations of more than 10% should not be used in air-drying paints [113]. In combination with 3 parts by volume of methylene chloride, DMSO provides an excellent, incombustible paint remover [113].

DMSO is particularly useful for the removal of polyisocyanate paints (DD paints and epoxide stoving paints), which are resistant to all the usual paint removers because of their strong internal crosslinking [5]. DMSO is a suitable solvent for polyurethanes [114] and polycaprolactam [115] at 160 °C. These solutions can be used for the production of films, sheets, and coating compositions having high strength and flexibility. The solubility of polyamides, polyureas, and polyurethanes in DMSO can in some cases be increased by a factor of four by the addition of 10% of alkali metal or alkaline-earth metal chlorides or bromides [116].

DMSO is very important as a solvent for polyvinyl compounds for the production of spinnable solutions. The disadvantages of the solvents used previously (lack of stability, large losses during processing, high toxicity, poor quality of the fibers) can in many cases be eliminated by the use of DMSO. Thus polyacrylonitrile fibers having excellent textile properties are obtained by the use of polyacrylonitrile-DMSO spinning solutions [117–119]. Acrylonitrile-methacrylate copolymers (having an average methacrylate content of 5 mole-%), which have a higher viscosity in concentrated solutions than in dimethylformamide [120] can also be converted into fibers by the wet [121] and dry spinning processes [122]. A comparison of the solubilities of several vinyl polymers showed that DMSO is a better solvent than dimethylformamide for polymers having high cohesive energies, such as polyacrylonitrile and polyvinyl alcohol [123, 124].

However, polyvinyl cyanoethyl ether, which is also readily soluble, is cleaved above 50 °C [125]. A solvent mixture of DMSO and aromatic compounds in a ratio of 25:75 to 40:60 has proved suitable for vinyl chloride-vinyl acetate copolymers [126]. DMSO is also a

good solvent for polyvinyl fluoride[127,128] and polyacrolein[129].

One of the most surprising results in connection with the plastics industry was the excellent solubility of polyethylene terephthalate, which permits spinning from DMSO/water[5].

4. Utilization of the Selective Solvent Power for Separations

The selective solvent power of DMSO presents excellent possibilities for separations. *A. Waksmundzki et al.* have determined the phase equilibria and partition coefficients of liquid ternary systems of DMSO, aromatic hydrocarbons, and hexane[130], heptane[131], and octane[132]: DMSO was found to be a good selective solvent for aromatic compounds over a wide range of concentrations.

The extraction is favored by increasing molecular weight of the aliphatic and aromatic hydrocarbons *e.g.* in petroleum fractions. A mixture of DMSO with 10% of water is a particularly selective solvent[133,134]; thus, benzene (having m.p. 5.5–5.6 °C), toluene, and xylene containing less than 1% of aliphatic hydrocarbons can be extracted at 25 °C. Further, up to 96.2% of the aromatic components can be removed from a reformate (b.p. 65–180 °C) containing 40–64% of aromatics, the content of aliphatic components in the extract being less than 3%[135]. This selectivity is not affected by the presence of dienes[136].

Naphthalene hydrocarbons are also smoothly removed from non-naphthalene hydrocarbons (tetralin, alkylbenzenes)[137] and sulfur compounds from petroleum fractions[138]. In anthracene oil, the readily soluble phenanthrene and carbazole can be separated from the sparingly soluble anthracene (95% purity after two extraction stages) with DMSO[5]. Pure terephthalic acid is precipitated by water from solutions of terephthalic and isophthalic acids in DMSO[5]. The dimethyl esters of these acids can also be readily separated[139].

Other industrially important separations include: (i) the extraction of high molecular weight alkaline-earth metal sulfonates, such as are formed in the sulfonation of lubricating oils with fuming sulfuric acid followed by treatment with $Ba(OH)_2$ or $Ca(OH)_2$[140], (ii) the quantitative separation of mono- and dicarboxylic acids from montan waxes with DMSO/heptane at 90 °C[141], (iii) the extraction of water-insoluble alcohols from the hydrocarbon mixture of the Fischer-Tropsch synthesis[142], and (iv) the separation of acetylene from the pyrolysis products of hydrocarbons[143]. The ability of DMSO to absorb acetylene can be increased by the addition of dioxane, benzene, or nitrobenzene[144].

Monomeric formaldehyde having a water content of 3–5% can be dried by treatment with DMSO at 70–100 °C[145]. 1 g of DMSO can take up 0.05 g of water, and the water content of the formaldehyde can be reduced to 0.1–0.01%.

A very important application of DMSO is the extraction of plant components. At an average DMSO: wood ratio of 10:1, DMSO extracts lignin (90%) at 25 °C, and extracts lignin (93%) and pentosans (87%) at 140 °C[146–148]; 0.2% of hydrochloric or sulfuric acid must be added in order to obtain the maximum possible removal of the lignin[149]. Sodium sulfide is also claimed to have catalytic properties[150]. The lignin can be precipitated in a coarse and easily filterable form by the addition of water, and the DMSO can be recovered by fractional distillation. The hemicellulose extract contains a high percentage of the acetyl and formyl groups originally present in the wood[16].

DMSO can also be used as a selective precipitant for the partial separation of hemicelluloses. DMSO in neutral solution precipitates mainly the polysaccharides containing mannose from an extract of delignified fir wood with 18% sodium hydroxide solution[16]. Extraction experiments with wood flour have also yielded information on the structure of the carbohydrate-lignin complex bonding state[151].

The mild extracting action of DMSO permits the isolation of glycogen from rat liver in a form closer to that of native glycogen than in any other extraction known so far[152].

DMSO has also occasionally been used as the stationary phase in paper-chromatographic separations. Tropolones can be satisfactorily and reproducibly separated on paper impregnated with ethylenediaminetetraacetic acid/DMSO, with petroleum ether, cyclohexane, or isopropanol as the mobile phase[153]. Paper impregnated with DMSO can be

used for the separation of sugar acetates, alcohols, cyclitols, and glycosides, with petroleum ether, diethyl ether, or diisopropyl ether as the mobile phase [154]. This method offers special advantages over conventional paper chromatography:

The rate of migration is strongly dependent on the structure, while the molecular weight has little influence; in the D series, the α anomers migrate more rapidly than the β-anomers, and the 2,3,6-tri-*O*-methyl derivatives of D-glucose and D-mannose, which could formerly be distinguished only with difficulty by paper chromatography, can be separated as the acetates. Investigations by *Soczewinski* have shown that DMSO can be used as the polar phase for the paper-chromatographic separation of naphthols [155] and dihydroxydibenzofurans [156]. DMSO is a highly selective solvent for gas-liquid chromatography. C_1–C_6 hydrocarbons, including olefins, show significant differences in retention volume on a firebrick-powder column with 30% of DMSO. Thus a mixture of 13 hydrocarbons from CH_4 to n-hexane could be completely separated in 35 min [157].

V. Reactions in Dimethyl Sulfoxide

The distinction between protonic and aprotic dipolar solvents has proved particularly noticeable in the kinetic study of solvent effects in S_N2 reactions [1,2]. Thus the reactivity of small anions with high charge densities increases by a factor of 10^4 to 10^{10} on changing from protonic to dipolar aprotic solvents [1]. The small anions are less reactive in protonic solvents, because of solvation (*via* H-bonds), whereas in dipolar aprotic solvents they are "bare", and are therefore very reactive. The situation is reversed for large anions having low charge densities.

The poor solvation of the attacking anions and the strong solvation of the transition states with wide charge distributions lead to a marked decrease in the activation energy of bimolecular reactions, which fall from $\geq$ 20 kcal/mole in protonic solvents to between 15 and 17 kcal/mole (and in some cases to 13 kcal/mole) in dipolar aprotic solvents [158]. The differences in the entropy of activation are smaller, but $\Delta S^{\neq}$ is always slightly lower in dipolar aprotic solvents.

The two groups of solvents do not differ so greatly in the solvation of cations, since the solvation of a given cation is determined mainly by the electron-donor strength of the solvent. However, small metal cations are more strongly solvated in dipolar aprotic solvents than in protonic solvents [3], since the solvation is promoted by prior association [1,3].

The postulate by *Hughes* and *Ingold* (cf. [159]) that bimolecular reactions with strongly polarized transition states are accelerated in proportion to the polarity of the solvent is valid only within each of the two groups of solvents [66,160]. In general the effect of changing from a protonic to a dipolar aprotic solvent is greater (*e.g.* higher reaction rates in DMSO (D.C. = 48.9) than in methanol (D.C. = 33.6)) or even reversed (higher reaction rates in DMSO than in water (D.C. = 80.4)).

The solvation effects also influence the character of the reaction. S_N1 reactions are suppressed or displaced into the S_N2 range by dipolar aprotic solvents [1].

DMSO occupies a special place among the dipolar aprotic solvents. Consideration of the polarized bonds *e.g.* of dimethylformamide, acetone, or acetonitrile shows that the partially negative *and* positive atom is "hard" in the sense of the theory of "hard" (unpolarizable) and "soft" (polarizable) acids and bases [60,61], whereas DMSO contains a partially positive "soft" sulfur atom. *R. G. Pearson* [60] has shown that, as a general rule, "hard" (*i.e.* difficulty polarizable) acids combine particularly firmly with "hard" bases, and "soft" (*i.e.* readily polarizable) acids form particularly firm bonds with "soft" bases (see also Section III). Thus the "soft" character of the electrophilic S atom and the weak CH acidity permit little interaction between DMSO and "hard" nucleophiles. The "hard" oxygen atom of DMSO limits its use as a solvent, since it reacts with "hard" electrophiles (reactive alkyl halides and alkyl sulfonates, as well as acylating agents and mineral acids). Thus the range of application of DMSO as a solvent extends from weakly electrophilic reagents to strong bases and nucleophiles.

1. The Activation of OH, NH, and CH Bonds

The usual pK_a values for alcohols (16–18) are valid only in solvents containing hydroxyl groups. With increasing DMSO content, the pK_a values of n- and t-butanol increase to a limiting value of about 30 [83, 161]. This means that alkoxides are 10^{12} to 10^{14} times as basic in pure DMSO as in alcohols. (However, this is true only of potassium and cesium alkoxides; sodium and lithium alkoxides are less basic, owing to ion-pair formation.) The quantity of methylsulfinyl carbanion existing in equilibrium with potassium t-butoxide [eq. (c)] is sufficient for quantitative interception as the benzophenone adduct *(12)* [161].

$$\begin{array}{l} CH_3\text{-}SO\text{-}CH_3 \rightleftharpoons K^{\oplus}\overset{\ominus}{C}H_2\text{-}SO\text{-}CH_3 + t\text{-}BuOH \\ \quad + \\ t\text{-}BuO^{\ominus}K^{\oplus} \end{array} \qquad (c)$$

$$\xrightarrow[2.\ H_3O^{\oplus}]{1.\ (C_6H_5)_2CO} (C_6H_5)_2C(OH)\text{-}CH_2\text{-}SO\text{-}CH_3 \quad (12)$$

Solutions of potassium t-butoxide in DMSO are among the most strongly basic systems of organic chemistry. Their basicity is equivalent to that of the sodium salt of the methylsulfinyl carbanion ($Na^{\oplus\ominus}CH_2$–SO–CH_3) [162], and is surpassed only by that of $K^{\oplus\ominus}CH_2$–$SOCH_3$. An important use of these base systems in DMSO is therefore in the deprotonation of weakly CH-acidic compounds such as triphenylmethane [83], phosphonium salts (Wittig reaction) [163], sulfoxonium and sulfonium salts [164], and sulfones [162].

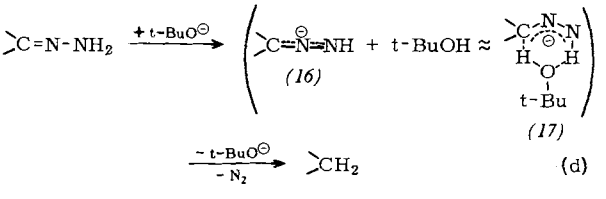
[164] *E. J. Corey* and *M. Chaykovsky*, J. Amer. chem. Soc. *87*, 1353 (1965).



The methylsulfinyl carbanion acts as a specific deprotonating agent in the Sommelet rearrangement of benzyltrimethylammonium salts *(13)* to (2-methylbenzyl)dimethylamine *(14)* (85%, without isomers). Other bases, with the exception of alkali metal amides in liquid ammonia, are less selective. Thus butyllithium gives 35–45% of *(14)* together with 21–30% of *(15)* (Stevens shift), phenyl-lithium leads mainly to *(15)*, and sodium hydride has no effect [164a].

(13) *(14)* *(15)*

In the presence of $Na^{\oplus}$, the basicity of the alkoxide ion is weakened by ion-pair formation with the sodium ion. It thus becomes possible to titrate alcohols against $Na^{\oplus\ominus}CH_2-SO-CH_3$, using triphenylmethane as the indicator [165]. The titration of amine salts with potassium methoxide or tetrabutylammonium hydroxide gives particularly sharp end-points in DMSO [166].

The Wolff-Kishner reaction of hydrazones of aldehydes and ketones with the potassium t-butoxide/DMSO system proceeds much more rapidly (0.5–1 h at room temperature) than under the usual conditions (heating for several hours at about 200 °C) [167]. To suppress the formation of azine, which competes up to the extent of about 25%, it is recommended that the reaction time should be increased to about 8 h. The yields of hydrocarbon are then 60–90%. It can be seen from the kinetics of the reaction [168] that a hydrazone anion *(16)* is first formed from alkoxide

(16) *(17)*

(d)

and hydrazone, and that the isomerization of *(16)* to form a dense complex [probably *(17)*] solvated by DMSO is the rate-determining step [eq. (d)].

2. t-Butoxide-Catalysed Isomerization of Olefins, Stereoisomerizations, and H-D-T Exchange Reactions

A solution of potassium t-butoxide in DMSO is an excellent medium for the anionic activation of α-CH bonds in ethers [169], thioethers [170], olefins [171], and alkylaromatic compounds [172]. In these cases, the high basicity and the high solvent power act in the same direction. The mixtures are always homogeneous and easy to handle and to reproduce, and in this respect they are superior to sodium alkyls or alkali metal amides in liquid ammonia [173].

The catalytic rearrangement of allyl ethers into enol ethers in the presence of potassium t-butoxide [eq. (e)] is 10^5 times as fast in DMSO as in 1,2-dimethoxyethane/t-BuOH [169].

$$CH_2{=}CH{-}CH_2{-}O{-}R \xrightarrow[DMSO]{t\text{-}BuOK} \underset{99\%\ cis}{CH_3{-}CH{=}CH{-}O{-}R} \qquad (e)$$

According to *Schriesheim et al.* [171,173,174], simple olefins (butenes, pentenes, hexenes) can also be isomerized at a measurable rate with potassium t-butoxide in DMSO [eq. (f)–(h)] [171,173–176].

(18)

The rates and activation parameters of the isomerizations are very strongly dependent on the nature of the group R: phenyl ≈ vinyl ⋙ methyl > isopropyl > t-butyl [175]. Methylenecyclobutane isomerizes faster than methylenecyclohexane [176]. It can be seen from this and from the distinct isotope effect (k_H/k_D = 4.4 at 55 °C) in the isomerization of 1-pentene and perdeutero-1-pentene [174] that the rate-determining step is the deproponation and formation of a planar mesomeric allyl anion *(18)* in the transition state. The high

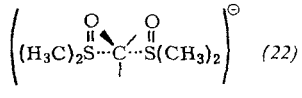
negative entropy of activation ($\Delta S^{\neq} < -20$ cal deg^{-1} mole^{-1}) and the observation that the isomerization is 16 times as fast as the H–D exchange [174] indicate an intramolecular cyclic transition state *(19)*.

(19)

The catalytic effect of lithium, sodium, and potassium alkoxides on the H–D exchange in optically active CH bonds activated by nitrile, amide, and ester groups was measured for several solvents by *Cram et al.* [177]. The rates of exchange and racemization in DMSO are higher by factors of 10^4 to 10^9 than in methanol, t-butanol, and ethylene glycol. Li, Na, and K methoxides (90% DMSO, 10% CH_3OH) are equally active at lower concentrations ($< 0.01-0.02$ M). The decrease in catalytic activity at higher concentrations owing to ion-pair formation first becomes noticeable with lithium methoxide.



The catalytic H–D exchange in optically active compounds containing substituted benzyl groups (2-phenylbutane and 1-phenyl-1-methoxyethane) in the presence of t-butoxide [172] is approximately 10^5 times as fast in DMSO as in t-butanol or ethylene glycol. Potassium t-butoxide is 100 times as reactive as sodium t-butoxide. In the absence of substituents (CN, CO_2R) that stabilize carbanions, the steric course of the reaction is strongly dependent on the solvent (retention in t-butanol, predominantly inversion in ethylene glycol, complete racemization in DMSO). The stereospecificity in cases of retention *(20)* and inversion *(21)* is attributed to "asymmetric solvation" of the substituted benzyl carbanion. In DMSO, symmetrical solvation *(22)* of the benzyl carbanion leads to racemization. The relatively low isotope effect ($k_H/k_D = 1.7-3.0$) indicates that the exchange reaction is preceded by an equilibrium stage.

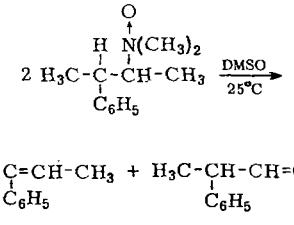
(20)

(21)

(22)

According to *Schriesheim* [178], the absence of a significant primary D–T and H–D isotope effect for the exchange between [D_3]-(and [T_3]-)toluene and DMSO in the presence of equimolar quantities of potassium t-butoxide can be explained by assuming that the ionization of the CH bond is not the rate-determining step, and that the complete ionization is instead preceded by a compact complex of the resulting anion and the resulting alcohol [eq. (i)], which must decompose before interaction with other molecules of alcohol or with the solvent can take place, and whose concentration and stability determine the rate of the reaction.

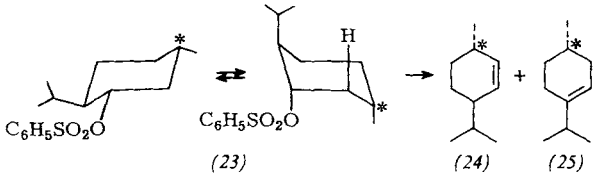
$$R\text{–}H + KOR' \rightleftharpoons (R^{\ominus}K^{\oplus}/HOR')_{solv.} \qquad \text{(i)}$$



The catalytic H–D exchange on thiophene in the presence of potassium t-butoxide, in which the α-H atom is exchanged much more rapidly than the β-H atom, also proceeds at a measurable rate [179]. The α-H atoms in diethyl sulfide can be replaced with D by the deuterated sodium methylsulfinyl carbanion [170].

3. Eliminations and Dehydrations

a) In the Absence of Bases



Owing to its high polarity, low nucleophilic strength, and relatively high basicity, DMSO is particularly suitable for use as a solvent in elimination reactions. t-Alkyl halides, which tend to form intermediate carbonium ions, decompose very readily in DMSO to form olefins [180]. Nucleophilic substitutions on the t-butyl residue cannot take place in DMSO [1].

Cope eliminations [eq. (j)] of tertiary amine oxides proceed 10^4 times as rapidly at 25 °C as in water [167], which deactivates the oxygen of the amine oxide by solvation.

(j)

Arylsulfonates of secondary alcohols give olefins in yields of up to 80% when heated for six hours at 100 °C in a 4- to 8-molar excess of DMSO [181]. The fact that (–)-menthyl benzenesulfonate *(23)* gives a mixture of alkenes containing 60 to 70% of (+)-Δ^3-menthene *(25)* rules out the possibility of an E_2 elimination, which would lead exclusively to (+)-Δ^2-menthene *(24)*.

(23) *(24)* *(25)*

Even pure alcohols (benzyl alcohols, secondary and tertiary alcohols, aldols, 1,2- and 1,3-diols) can be dehydrated by heating for 8 to 16 hours in DMSO at 160–185 °C [182, 183]. The yield of alkene can be

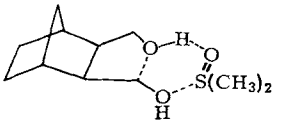
[183] *V. J. Traynelis, W. L. Hergenrother, H. T. Hanson,* and *J. A. Valicenti,* J. org. Chemistry *29,* 123 (1964).

increased to 90% by the addition of small quantities of sulfuric acid. Under these conditions, 1,2-diols undergo partial pinacolic rearrangement while 1,4-diketones are dehydrated to form furan derivatives *(26)*.

R = CH_3, C_6H_5 *(26)*, 60-70%



The structure of the alcohols, the catalytic effect of sulfuric acid, the pinacolic rearrangement, and the non-stereospecific course of the dehydration of *erythro*- and *threo*-1,2-diphenyl-1-propanol (50% of *cis*- and 50% of *trans*-methylstilbene in each case) [182] point to a mechanism in which carbonium ions play an important part.

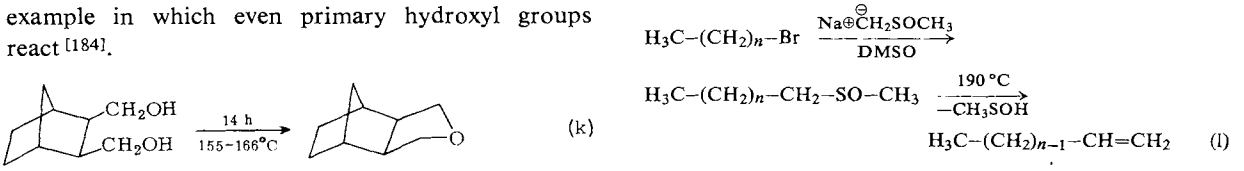
If the ratio of DMSO to alcohol is reduced from 4 to 8:1 to 1:3, the yield of alkenes falls to 30%, while ether is formed to an extent of more than 50% [183]. However, ether formation can be observed even with a 12-fold excess of DMSO (8–16 h, 160 °C, 75–98%) in the case of 1,4-diols, which are converted into stable tetrahydrofuran derivatives. Equation (k) shows an example in which even primary hydroxyl groups react [184].

(k)

98%

This method is superior to all others for the preparation of tetrahydrofuran derivatives. The transition state *(27)* is postulated to explain the smooth course of the reaction.

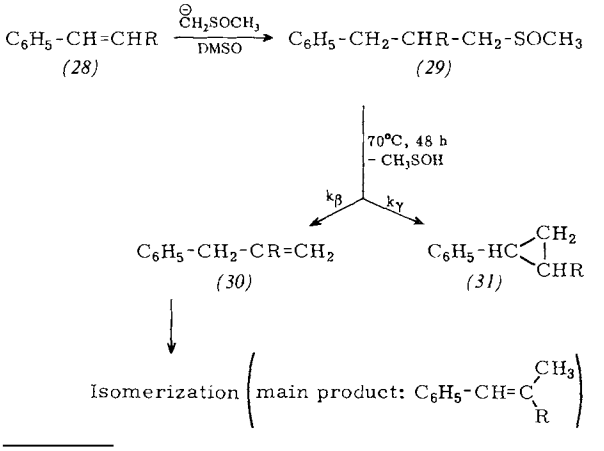
(27)



b) Eliminations and Dehydrations in the Presence of Bases

When DMSO is used as the solvent instead of alcohols, the increase in the ease of elimination of sulfonate and halide is of approximately the same magnitude as the acceleration of S_N2 reactions with nucleophiles. Alkoxide-catalysed eliminations from benzenesulfonates of primary and secondary alcohols, which require several days at 80–140 °C in alcohol or diglyme [1,2-bis(methoxy)ethane], proceed to completion within 30 min at room temperature in DMSO [185, 186], though ether formation then competes with the elimination. In the presence of potassium t-butoxide, the sulfonates of secondary alcohols give up to 80% of alkene and a little ether, while the sulfonates of primary alcohols give 20–25% of alkene and 60–70% of t-butyl ether [186]. The nature of the sulfonate residue has practically no influence on the yields or on the product distribution; however, chlorides exhibit a stronger tendency toward elimination [185]. Fluoride is such a strong base in DMSO that primary alkyl halides form olefins in the presence of fluoride [1].

It is interesting to note that even compounds containing groups which are eliminated usually only with difficulty undergo eliminations with the system potassium t-butoxide/DMSO [187, 188]. The ease of elimination from isopropyl derivatives decreases in the following order, the yields from the nitro compound onward being less than 10%: $Br^{\ominus} \approx RSO_2^{\ominus} \approx RSO^{\ominus} > NO_3^{\ominus} > SCN^{\ominus} > RS^{\ominus} > NO_2^{\ominus} > S^{2\ominus} > CN^{\ominus}$.



The reactivity of the t-butoxide ion decreases with increasing tendency of the cation to form ion pairs, *i.e.* in the order Cs > Rb > K ≫ Na ≫ Li.

The elimination of $RSO^{\ominus}$ from sulfoxides offers the possibility of preparing olefins with terminal double bonds from primary alkyl bromides in accordance with [eq. (l)] [189].

(l)

3-Phenyl-2-alkylpropyl sulfoxides *(29)*, which are formed by the addition of the methylsulfinyl carbanion to β-alkylstyrenes *(28)*, undergo γ-eliminations to form cyclopropane derivatives *(31)* as well as β-eliminations to form olefins *(30)* [189a]. The β-elimination proceeds mainly by the E2 mechanism [188] and the γ-elimination by the E1cB mechanism. The yield of cyclopropane derivatives increases with the size of R [R = H: 0% of *(31)*, R = t-C_4H_9: 97% of *(31)*], since it becomes increasingly difficult for the molecule to assume the conformation that favors β-elimination. The potassium salt of the methylsulfinyl carbanion is

less selective in the formation of *(30)* and *(31)* than the less strongly basic sodium compound.

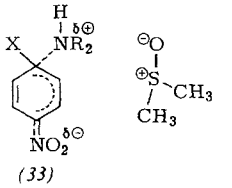
The system potassium t-butoxide/DMSO is more suitable for dehydrohalogenations than the sodium salt of the methylsulfinyl carbanion [190], which only dehalogenates vicinal dibromides [see *e.g.* eq. (m)].

An example showing the high basicity of the system potassium t-butoxide/DMSO is the formation of 1,2-cyclohexadiene from 1-bromocyclohexene [eq. (n)] [191, 192], the diene being detected by interception with 1,3-diphenylbenzofuran and by dimerization.

The direction of elimination from 2-butyl and 2-pentyl *p*-toluenesulfonates is increasingly displaced from the Saytzeff to the Hofmann orientation in the order $C_2H_5OH/C_2H_5OK <$ $DMSO/C_2H_5OK <$ DMSO/t-BuOK [193]. Such a change in the product ratio (2-alkene:1-alkene) simply as a result of variation of the solvent and of the base strength had not been observed previously. In the opinion of *Froemsdorf* and *McCain* [193], this points to a transition state that tends toward the carbanion elimination mechanism E1cB [194], *i.e.* in which the CH bond exhibits a higher degree of heterolysis than the CX bond. However, the facts that no H–T exchange takes place in the β position with respect to the departing group and that deprotonation of a secondary CH bond takes place in preference to that of a primary CH bond suggest that elimination of $R-SO^{\ominus}$ from sulfoxides by the potassium t-butoxide/DMSO system [188] proceeds by a synchronous E 2 mechanism.

4. Nucleophilic Substitutions, Condensations, and Additions

All reactions between electrophiles, which do not react with DMSO, and nucleophiles, which are more strongly solvated in protonic solvents than in DMSO, are accelerated when DMSO is used as the solvent. It is not uncommon for the rate of reaction to be faster by a factor of 10^6 than in protonic solvents. The reactions are strictly bimolecular. Lithium or sodium ions again reduce the rate of reaction by ion-pair formation. The nucleophilic strengths of the hydroxide ion and of the alkoxides increases with the increase in their basicity (see also Section V 1), so that *e.g.* esters with strong steric hindrance [195] and epoxides [196] can be readily hydrolysed with alkali metal hydroxide/DMSO. Even non-enolizable ketones [*e.g. (32)*] can be cleaved [197].



(32)

The ambidentate phenoxide ions are alkylated only on the oxygen atom in DMSO, whereas the "selective solvation" of the O atom of the phenoxide in polar solvents allows partial *C*-alkylation, the extent of which increases with proton-donor strength in the order $C_2H_5OH < CH_3OH < H_2O < F_3C-CH_2OH$ [198, 199].

Alkylcyanates ($R-O-C\equiv N$) which may act as ambidentate electrophiles, can be attacked either at the alkyl carbon atom or at the nitrile carbon atom. The point of attack is dependent on the type of nucleophile and, furthermore, is strongly influenced by the type of solvent [198a]. In DMSO, alkylation reactions are favored (see Table 8). The reason might be that attack at the nitrile carbon atom according to *(11)* is hindered by association with DMSO.

Nucleophilic substitutions in aromatic compounds are also accelerated in DMSO. The reaction of 4-nitrofluorobenzene with piperidine is 5×10^3 times as fast in DMSO as in benzene. Even the addition of 11% of DMSO increases the reaction rate by a factor of 400 [213]. The acceleration is again due to specific solvation of the transition state *(33)* by DMSO [199a]; however, polarization of the substrate as suggested by *Kingsbury* [160] may also play a role.

(33)

Table 8 shows the types of nucleophilic substitutions and condensations studied so far.

[a] R = primary or secondary alkyl residue, X = F, Cl, Br, I, sulfonate, cyanate; [b] attack of HB not rate-determining; a cyclic four-membered ring transition state is postulated; [c] in the presence of t-BuOK; [d] in the presence of C_2H_5ONa; [e] 1,5-diazabicyclo[4.3.0]non-5-ene; [f] catalysed by benzyltrimethylammonium hydroxide; [g] *N*-bromosuccinimide.

The use of DMSO as the solvent offers the following advantages: homogeneous reaction medium, high yields ($\geqslant 80\%$), relatively low temperatures (generally room temperature), and shorter reaction times (1/2 to 6 h).

5. Base-Catalysed Oxidations

DMSO is oxidized by oxygen in the presence of alkoxides to form dimethyl sulfone and methanesulfonic acid. A mixture of 80 vol-% of DMSO and 20 vol-% of t-butanol is stable towards oxygen in the presence of potassium t-butoxide (or tetramethylammonium t-butoxide) at room temperature, and in comparison with other solvent combinations, this mixture is excellently suited for base-catalysed oxidations with oxygen and for electron-transfer reactions in general [224].

Under these conditions, the rate of oxidation of triphenylmethane is the same as the rate of the H–D exchange α-deuterotriphenylmethane [216a]. It follows that the ionization of the CH bond [eq. (o)] is the rate-determining step. The carbanion intermediate reacts preferentially with the oxygen atom to form a free

radical [eq. (p)], which then undergoes various free-radical steps, depending on the substrate, to form the final oxidation product [224]

$$R{-}H + B^{\ominus} \rightleftarrows R^{\ominus} + BH \qquad (o)$$

$$R^{\ominus} + O_2 \rightarrow R\cdot + O\cdot_2^{\ominus} \qquad (p)$$

The method is very effective, can be carried out at room temperature, and is characterized by relatively high reaction rates. Many compounds, except alkanes, simple alkenes (cyclohexene), and simple alkylaromatic compounds (toluene), undergo this oxidation. For example diarylmethanes can be converted into ketones, triarylmethanes into alcohols, ketones into carboxylic acids, nitroalkanes into ketones, and anilines into azobenzenes.

6. Polymerizations

The significance of DMSO in the production of polyacrylonitrile fibers [225] was increased by the observations that polyacrylonitrile can be spun not only from a solution in DMSO but furthermore that DMSO can also be used as the solvent for the polymerization of acrylonitrile. Solution polymerization in DMSO is technically easier to control than emulsion polymerization; furthermore, the chain termination observed in dimethylformamide does not occur.

Thus acrylonitrile can also be polymerized in admixture with copolymerizable monomers in DMSO and in the presence of suitable catalysts and regulators; even below 80 °C the polymerization time is short. The yield of polymer is higher than 70%, and can be adjusted in such a way as to give solutions having a polymer content of about 20% (molecular weight 42000–64000), which can be used directly for spinning.

The polymerization of acrylonitrile is industrially important, and its kinetics and mechnism have been thoroughly investigated [226, 227]. In the free-radical polymerization initiated by ammonium peroxidisulfate, the chain initiation proceeds in accordance with equation (q).

$$S_2O_8^{2\ominus} + 2\ CH_3{-}\overset{\overset{O}{\|}}{S}{-}CH_3 \rightarrow 2\ SO_4^{2\ominus} + 2\ (CH_3{-}\overset{\overset{O}{\|}}{S}{-}CH_3)^{\oplus} \qquad (q)$$

The constants for chain transfer to the solvent and to the monomer at 30 °C are 4.7×10^{-5} and 1.5×10^{-4} respectively [228]. These values are lower than those for other solvents. The activation energy was found to be approximately 18.5 (16.5 [229]) kcal/mole [228]. The reactivity of the radicals formed in the azodiisobutyronitrile-initiated polymerization is again relatively low, so that the chain transfer constant is of the same order of magnitude (2.9×10^{-5}) [4].

The polymerization of acrylonitrile and methacrylonitrile in DMSO with anionic initiation by methylsulfinyl carbanions ($CH_3{-}SO{-}CH_2^{\ominus}Na^{\oplus}$ or $Li^{\oplus}$) leads quantitatively to a high molecular weight polymer, in contrast to the reaction in dimethylformamide [230]. The methylsulfinyl carbanion catalysts are of medium activity, and allow the polymerization to proceed rapidly and exothermally. The electrolytically initiated polymerization of methacrylate in DMSO also yields polymers having a higher molecular weight than in other solvents [231].

DMSO is also a very suitable solvent for the free-radical polymerization of vinyl acetate [232, 233]. Polyvinyl acetate having a degree of polymerization of 2960 is obtained in 95% yield, and the hydrolysis by bases proceeds more completely and more uniformly in DMSO than in methanol to give a polyvinyl alcohol (degree of polymerization 1700) that is stable in aqueous solution.

DMSO has proved to be better than any other solvent examined for the γ radiation-induced graft polymerization of styrene on amylose. The grafting process is accelerated by water in quantities of less than 1% [234].

The polymerization of β-propiolactams in DMSO with butyl-lithium, sodium methoxide, KOH [235], or pyrrolidone [236] as catalysts proceeds more rapidly, even at room temperature, than in the solid state, and gives polyamides in yields of up to 97%. Polyethers have been obtained from carbohydrates and epoxides in DMSO with alkaline catalysts [237]. Dioximes can also be copolymerized with diisocyanates in DMSO in the presence of triethylamine [238].

Price and *Carmelite* have studied the kinetics of the t-butoxide-catalysed polymerization of epoxides in DMSO [239]. Epoxyethane polymerizes readily and in high yields to give a high molecular weight polymer (molecular weight up to 43000). Under the same conditions, epoxypropane *(34)* gives a polymer having a maximum molecular weight of 1200; in comparison with the polymerization without chain transfer, this corresponds to a ratio $k_p:k_{tr} = 20$ [eq. (r)]. In less reactive solvents such as ethers and alcohols, $k_p:k_{tr} \approx 50$. This means that in DMSO, the deprotonation of *(34)* by bases is favored by a factor of about 2.5, and so causes more frequent chain transfer.

(r)

(34)

Since its deprotonation is slower than that of epoxyethane by a factor of 10^4 and slower than that of epoxypropane by a factor of 10^3, DMSO itself does not hinder the chain growth. Consequently, no sulfoxide end groups can ever be detected in the polymers. 2-Methyl- and 2,3-dimethyl-2,3-epoxybutane are not polymerized by t-butoxide, but are converted into the corresponding allyl alcohols.

7. Reactivities in Dimethyl Sulfoxide Mixtures

The reactivities of nucleophiles in bimolecular reactions in protonic and nonpolar solvents can be increased by the addition of DMSO even in relatively small quantities. In general, the effect of DMSO is greater than that of any other additive with the exception of hexamethylphosphorotriamide. However, log k_2 does not vary linearly with the composition or dielectric constant of the mixture. Between a concentration of about 10% and a DMSO/HOH(R) ratio of approximately 1:2, k_2 shows a moderate increase, which is often approximately inversely proportional to the dielectric constant [66]. At concentrations above a molar ratio of 1:2, which is characterized by a special "structure" *(8)*, the accelerating effect increases more rapidly and is greatest at concentrations above 80 mole-%.

As in pure DMSO, the accelerating effect on anions in mixtures is greater than that on neutral nucleophiles [160, 206]. Thus the participation of the neighboring carboxyl group in the solvolysis of α-bromoacetic acid in 80% aqueous DMSO is five times as strong for the anion as for the free acid [240]. On the other hand, acid-catalysed hydrolyses (hydrolysis of acetals [241] and esters [71]) are mainly inhibited by the addition of DMSO.

Though several investigations on the mechanism of the accelerating effect of DMSO in dilute solution have been reported [66, 70, 160, 240, 242–245], no uniform picture has been established so far. The formation of a highly reactive sulfonium intermediate $RO-S^{\oplus}(CH_3)_2X^{\ominus}$ can be ruled out, since a doubly bimolecular reaction cannot be detected either stereochemically or kinetically [70].

The increase in the ρ value of the alkaline hydrolysis of *p*- and *m*-substituted ethyl benzoates [242, 243] and the decrease in the value of $\Delta H^{\neq}$ with increasing DMSO concentration indicate that DMSO has a marked influence on the solvation of the transition state. However, since no equilibrium relationships can be detected between ROH, $RO^{\ominus}$, DMSO, the dimethylsulfoxonium ion $(CH_3)_2S^{\oplus}OH$, and the course of the reaction [160], and since the catalytic effect of DMSO in mixtures with alcohols is practically the same for all anions and electrophiles within a given reaction type (independence of substrate) [160], the interaction between DMSO and the transition states must be regarded as nonspecific. In agreement with this, the view [1, 245] that the DMSO "liberates", and so activates the solvated anions simply by association with the protonic solvents, must be limited:

a) Dilute solutions (< 30 mole-% of DMSO) exhibit considerable acceleration of the reaction, though a sufficiently large number of proton-donor molecules are still present.

b) In concentrated solutions, DMSO strengthens the association between the anion (when it is "hard") and the proton donor.

c) Up to high concentrations, DMSO has no influence on the ρ values of the reaction between phenoxides and 2,4-dinitrochlorobenzene in $DMSO/CH_3OH$, as must be the case if there is effective breakdown of the H-bonds to the phenoxide ion.

Thus the effect of DMSO in dilute solutions is due only to breakdown of the outermost parts of the protonic solvation shell surrounding the anion (or to destruction of the "hard, pseudopolymeric structure" of the protonic solvent) [160].

However, reactions have also been reported in which even very small quantities of DMSO have a catalytic or inhibiting effect. *Cooper* and *Elliott* [246] found that the KOH-catalysed conversion of octamethylcyclotetrasiloxane *(35)* into the high molecular weight polymer *(36)* at 95 °C is accelerated by factors of 100 to 1000 by small quantities of DMSO (0.5%).

$$\frac{x}{4}[(CH_3)_2SiO]_4 \xrightarrow[0{,}01\text{–}0{,}1\%\ DMSO]{12\text{–}100\ ppm\ KOH} [(CH_3)_2SiO]_x$$

(35) *(36)*

Rapid equilibration also occurs in a mixture of *(35)* with hexamethyldisiloxane at 80 °C with 0.01% of KOH and 1% of DMSO. The first step in these base-catalysed reactions is the formation of metal siloxides and their dissociation to form free siloxide ions [eq. (s)]. The catalytic effect of DMSO is due to specific solvation of the cation, leading to promotion of the solvation of the metal siloxide which can then react preferentially with the Si–O dipoles that are present in high concentration.

(s)

A high dipole moment ($\mu \geqslant 3.7$ D) and solubility in water are essential properties of an organic solvent if it is to catalyse the formation of polyurethane foams [247]. Among the sulfoxides, the catalytic action increases with decreasing size of the groups attached to the sulfur atom: $Ar_2SO < (i\text{-}C_4H_9)_2SO < (n\text{-}C_4H_9)_2SO < (CH_3)_2SO$. Sulfoxides inhibit the autoxidation of squalene by suppression of the homolytic decomposition of the primary hydroperoxides, the effect increasing with increasing α-branching (di-t-butyl sulfoxide is 144 times as effective as DMSO) [248]. The sulfoxides are not effective in the presence of alkyl, alkoxy, alkylperoxy, or acyloxy radicals. Their specific inhibiting action on the primary hydroperoxides consists in the formation of strong H-bonds, which are destroyed by the addition of carboxylic acids.

The polymerization of vinyl compounds can also be suppressed by DMSO (in concentrations of from 0.05 to 5%) [249]. However, the polymerization can then be started by the addition of suitable initiators.

An interesting observation is the inhibiting action of DMSO on free-radical biological redox depolymerizations. Thus DMSO inhibits the decomposition of hyaluronic acid, the principal polysaccharide of the ventricular fluid, by reducing agents such as ascorbic acid, hydroquinone, or tetracycline in the presence of oxygen, the inhibiting effect increasing with the DMSO concentration [250].

The stabilization of trichloroethylene and perchloroethylene by the addition of 0.5 to 5% of DMSO is of practical interest [251].

VI. Purification of Dimethyl Sulfoxide

Commercial DMSO generally contains about 0.5% of water, small quantities of dimethyl sulfide, and dimethyl sulfone. Purification presents no difficulties, and can be achieved by fractional vacuum distillation, fractional extraction [252], treatment with activated charcoal [253] or molecular sieves [31, 176, 246], or column chromatography [254]. Very pure DMSO is obtained by fractional vacuum distillation under carefully dried nitrogen [14, 24]. The process is preferably carried out in such a way that subsequent slight recontamination in the vapor phase is impossible. To obtain anhydrous DMSO, vacuum distillation at 18 mm Hg over calcium hydride has proved suitable for most purposes [218, 239].

The purity can be established by conductivity measurements [14], and titration with Karl Fischer solution is used for the determination of water [14]. Traces of water can escape detection in gas-chromatographic purity checks; IR and mass spectrometry are more suiable methods [176]. Dimethyl sulfoxide (and sulfoxides in general) can be quantitatively determined by iodometric titration of acyloxysulfonium salts in accordance with equation (t) [255]:

(t)

[D_6]-Dimethyl sulfoxide, which is an important solvent in NMR spectroscopy, can be obtained by base-catalysed exchange with D_2O [256] or by thermolysis of [D^9]-trimethylsulfoxonium iodide [257] (yield 80%, with 99–99.2% deuteration).

The Formation of C–C Bonds with the Aid of α-Halogeno Ethers, Sulfides, and Amines[1]

BY H. GROSS AND E. HÖFT [*]

Dedicated to Professor Alfred Rieche on the occasion of his 65th birthday

α-Halogeno ethers, sulfides, and amines are reactive compounds which can be used for the formation of new C–C bonds, either as nucleophilic or as electrophilic reagents, or by α-elimination. The use of these compounds in the synthesis of many classes of organic compounds is reviewed.

α-Halogeno ethers, sulfides, and amines can be formally derived from, and are generally prepared from, carbonyl compounds. Whereas α-halogeno ethers and sulfides may be regarded as homopolar compounds as indicated in formula *(1a)*, the α-halogeno amines, according to *Böhme*[2], exist largely as resonance-stabilized carbenium-immonium salts corresponding to formula *(2b)*.

$$\underset{(1)}{R\text{-}Z\text{-}\overset{Hal}{\overset{|}{C}}H\text{-}R^1} \rightleftharpoons [R\text{-}Z\text{-}\overset{\oplus}{C}H\text{-}R^1 \longleftrightarrow \underset{(2)}{R\text{-}\overset{\oplus}{Z}=CH\text{-}R^1}]\,Hal^{\ominus}$$

(a), Z = O, S
(b), Z = N-R^2

All compounds of the types *(1)* and *(2)* are much more reactive than simple alkyl halides. α-Halogeno ethers have been widely used in preparative chemistry[3–7]. The *N*- and *S*-analogues have recently also been studied by several research groups, and particularly by *Böhme* and his co-workers.

The present review deals with methods for the formation of C–C bonds with the aid of α-halogeno ethers and sulfides derived from oxo compounds, carboxylic acids, or carbonic acid, whereas the only *N*-analogues considered are those derived from oxo compounds. Reviews on α-halogenated amino compounds in higher oxidation states (carbonamide chlorides, carbamide chlorides, *etc.*) have already been published[8,9].

For earlier work and for the preparation of α-halogeno ethers and sulfides, the reader is referred to the articles mentioned in[3–7]. Information about the preparation of the *N*-derivatives may be obtained from the original publications[9,10].

A. α-Halogeno Ethers, Sulfides, and Amines as Electrophiles

The earliest known reactions of the halogen derivatives *(1a)* and *(2b)* leading to the formation of new C–C bonds were those involving the addition of a nucleophile to the carbenium-onium ion. This leads, formally, in accordance with equation (a), to a product

$$R\text{-}Z\text{-}\underset{R^1}{\overset{|}{C}}H\text{-}Hal + \overset{\ominus}{\overset{|}{C}}\text{-} \rightarrow R\text{-}Z\text{-}\underset{R^1}{\overset{|}{C}}H\text{-}\overset{|}{C}\text{-} + Hal^{\ominus} \quad (a)$$

in which the group R–Z–CHR¹ remains intact. Sometimes, *e.g.*, on reaction with aromatic nucleophiles, products with other structures can be formed.

1. Reactions with Cyanides

The active halogen compounds react with cyanides according to Scheme (b) to form nitriles.

$$R\text{–}Z\text{–}CH_2Cl \xrightarrow[-Cl^{\ominus}]{CN^{\ominus}} R\text{–}Z\text{–}CH_2\text{–}CN \quad (b)$$

The reaction of alkali-metal cyanides with chloromethyl aryl ethers in aqueous acetone gives good

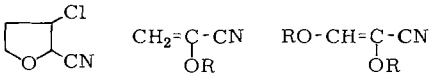
yields of aryloxyacetonitriles *(3)*, R = aryl[11]; benzene[12] and dimethylformamide[13] have been recommended as solvents for the reaction with chloroalkyl alkyl ethers. Chloromethyl alkyl ethers react with heavy-metal cyanides such as AgCN[14], $Hg_2(CN)_2$[15] or $Cu_2(CN)_2$[16], even in nonpolar solvents, to form α-alkoxynitriles *(3)* in yields of up to 80 %.

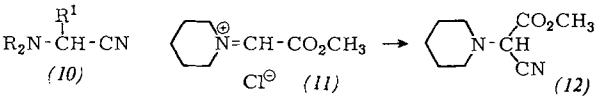


$RO-CHR^1-CN$ *(3)* $\qquad$ $C_2H_5O-CH(CN)-CO_2C_2H_5$ *(4)*

R = Aryl, alkyl
R^1 = H, alkyl

Ethyl ethoxychloroacetate reacts similarly in xylene to give ethyl ethoxycyanoacetate *(4)*[17]. 2-Cyano-1,4-dioxane[18] and 2-cyanotetrahydropyran[19] can be prepared in an analogous manner. Bis(cyanomethyl) ether *(5)*[13] can be obtained from bis(chloromethyl) ether, but in α,β'-dihalogeno ethers only the α-halogen atom undergoes substitution, with formation of *(6)*[20,21]. Thus 3-chloro-2-cyanotetrahydrofuran *(7)* is obtained from 2,3-dichlorotetrahydrofuran[22,23],

$NC-CH_2-O-CH_2-CN$ *(5)* $\qquad$ $Hal-CH_2-CH_2-O-CHR-CN$ *(6)*, R = H, CH_3

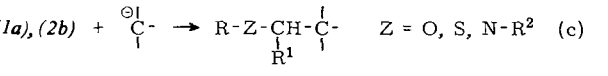


while the reaction of α,β-dibromodiethyl ether or 1,2-diethoxy-1,2-dichloroethane with $Cu_2(CN)_2$ and subsequent dehydrohalogenation leads to the unsaturated

(7) $\qquad$ *(8)* $\qquad$ *(9)*

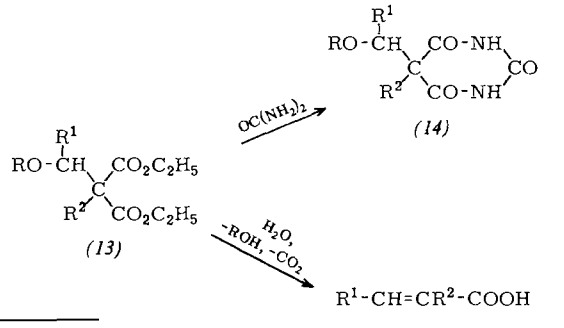
α-alkoxynitriles *(8)*[24] and *(9)*[25]. *S*-Cyanomethyl thioacetate can be obtained from *S*-chloromethyl thioacetate[26].

According to *Böhme*[2,27,28], α-aminonitriles *(10)* can be prepared in very good yields by the reaction of α-halogeno amines with anhydrous hydrogen cyanide. *N*-(Methoxycarbonylmethylene)piperidinium chloride *(11)* reacts in a similar manner to give the piperidinocyanoacetate *(12)*[29].



(10) $\qquad$ $Cl^{\ominus}$ *(11)* $\qquad$ *(12)*

R, R^1 = Alkyl



2. Reactions with Compounds Containing Active Methylene Groups

Alkoxymethyl, alkylthiomethyl, and dialkylaminomethyl groups can be introduced into compounds containing active methylene groups by reaction of their alkali metal salts with compounds of the type *(1a)* or *(2b)*.

(1a), (2b) $\qquad$ Z = O, S, $N-R^2$ (c)

Reaction (c) has been known for some time, *e.g.* in the reaction of α-halogeno ethers with sodiomalonic esters[3,30,31], and has recently been extensively used[12,32–37] *e.g.* for the preparation of alkoxyalkylmalonates *(13)* (R, R^1, R^2 = alkyl, or R^1, R^2 = H;

(13) $\qquad$ *(14)*

$R^1-CH=CR^2-COOH$

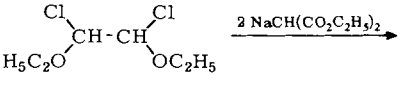
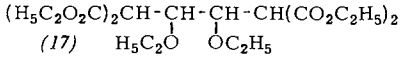
Diethyl phthalimidomalonate reacts with chloromethyl methyl ether to give diethyl methoxymethylphthalimidomalonate *(15)* [40].

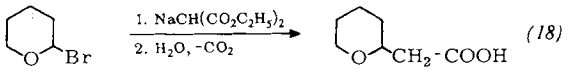


(15)

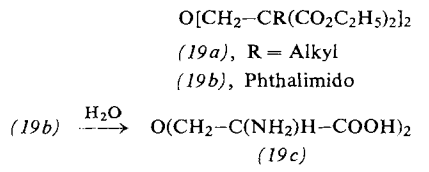


Methyl chloromethoxyacetate *(16)* reacts similarly to form esters of tricarboxylic acids [41].

(16)



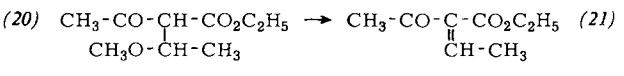
1,2-Diethoxy-1,2-dichloroethane and diethyl sodiomalonate react to form tetraethyl 2,3-diethoxybutane-1,1,4,4-tetracarboxylate *(17)*, and hence, *e.g.* by elimination of alcohol, give tetraethyl buta-1,3-diene-1,1,4,4-tetracarboxylate [4, 42].



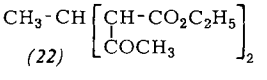
(17)

2-Tetrahydropyranylacetic acid *(18)* has been prepared from 2-bromotetrahydropyran by reaction with diethyl sodiomalonate, hydrolysis, and partial decarboxylation [43].

(18)



The reaction of bis(halogenomethyl) ether with diethyl alkylmalonates leads to tetraethyl 3-oxapentane-1,1,5,5-tetracarboxylate *(19a)* [44]; diethyl phthalimidosodiomalonate gives the bisphthalimido compound *(19b)*, which yields 2,4-diamino-3-oxapentane-1,1,5,5-tetracarboxylic acid *(19c)* on hydrolysis [45].

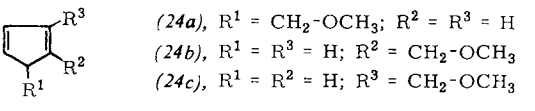


(19a), R = Alkyl
(19b), Phthalimido

(19c)

Other CH acids, such as β-keto esters, react analogously to the malonates. With acetoacetic ester, competition occurs between *O*- and *C*-alkylation [3]. According to more recent investigations [46], the reaction of α-chloroethyl methyl ether and lithioacetoacetic ester leads only to the *C*-alkylation product *(20)*, which loses methanol to form α-ethylideneacetoacetic ester *(21)*. Diethyl 1,3-diacetyl-2-methylglutarate *(22)* was also isolated; this product was presumably formed by Michael addition of acetoacetic ester to *(21)*.

(20) *(21)*



(22)

In the case of benzoylacetates or esters of higher α-acetylcarboxylic acids, the product corresponding to *(20)* is stable [46]; this is also true of cyclic β-keto esters, from which the alkoxymethyl and acetoxymethyl derivatives *(23)* have been obtained [47].

(23)

Cyclopentadienylsodium reacts with chloromethyl methyl ether to form the isomeric methoxymethylcyclopentadienes *(24a)* to *(24c)* [48], the main product, particularly at low temperatures, being *(24a)*.

(24a), R^1 = CH_2-OCH_3; R^2 = R^3 = H
(24b), R^1 = R^3 = H; R^2 = CH_2-OCH_3
(24c), R^1 = R^2 = H; R^3 = CH_2-OCH_3

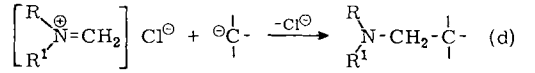
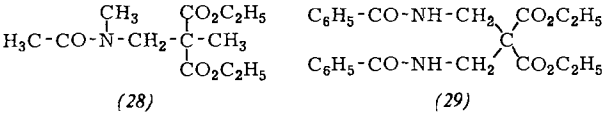
Trimethyl alkoxymethyl- or acetoxymethylmethane tricarboxylates *(25a)* and *(25b)* can be obtained from trimethyl sodiomethanetricarboxylate and chloromethyl methyl ether or chloromethyl acetate, respectively [49].



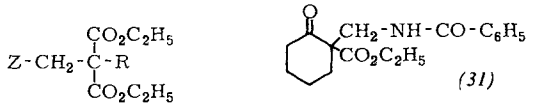
(25a), Z = O, R = CH_3
(25b), Z = O, R = CH_3CO
(25c), Z = S, R = C_6H_5

(26)

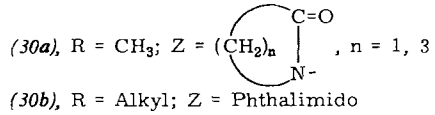


Chloromethyl thioethers and compounds having active methylene groups also react according to equation (c). Thus trimethyl sodiomethanetricarboxylate gives the methylthio compound *(25c)* [49], while acetoacetic esters give the *S*-analogue of *(20)* [50]. Diethyl acetylthiomethylmethylmalonate *(26)* can be obtained from *S*-chloromethyl thioacetate and methyl malonate [47].

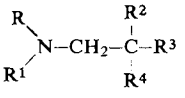
Böhme found that compounds containing active methylene groups are aminomethylated by α-halogeno amines *(27)*, R, R^1 = alkyl, in accordance with equation (c) or (d) [51]. This provides a route to dialkyl-



spondingly substituted amides or diacylamides ("amidomethylation"). Thus the compounds *(28)* to *(31)* can be obtained in this way. These reactions are particularly useful for the amidomethylation of β-diketones, which cannot be accomplished by the usual methods.



(27), R,R^1 = H, Alkyl, Acyl



(28) *(29)*

(31)

aminomethyl compounds, which can be obtained only with difficulty, or not at all, by the usual aminomethylation reactions. Similarly, *N*-halogenomethylamides, *(27)* with R = H, alkyl; R^1 = acyl [52,53], halogenomethyldiacylimides, *(27)* with R = R^1 = acyl [54], or *N*-chloromethyllactams [57] give corre-

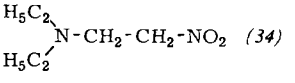

Table 2 shows a selection of possible preparations. *(30a)* and *(30b)* can be converted into barbituric acid derivatives by reaction with urea.

Diethyl piperidinomethylmalonate *(32a)* was obtained *e.g.* from *N*-chloromethylpiperidine and diethyl sodioethylmalonate [51]. *(32b)* to *(34)* have been prepared in a similar manner from compounds containing active methylene groups [51].

(33)

(32a), R_2 = -$(CH_2)_5$-; R^1 = $CO_2C_2H_5$; R^2 = C_2H_5
(32b), R = C_2H_5; R^1 = $COCH_3$; R^2 = CH_3

(34)

This principle can also be used for the synthesis of α-substituted α-amino acids. The halogeno amine compounds, *e.g.* *(35)*, which can be readily prepared

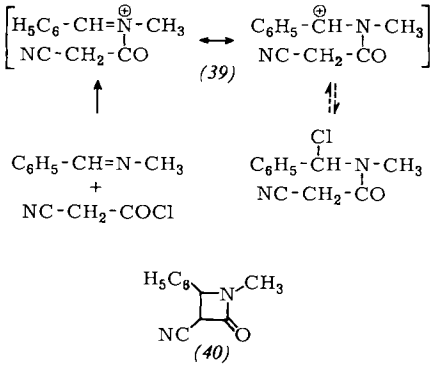
from dichloroacetic acid[55], react with active methylene groups in accordance with equation (d), to give α-substituted α-amino acid derivatives; for example, reaction with *(35)* leads to *(36)*[55,56].

(35) $Cl^{\ominus}$ Z = OCH_3, Piperidino



(36), R = *p*-C_3H_7O-C_6H_4-CO-CH_2-, C_6H_5-CH=CH-CO-CH_2-, *N*-(*p*-CH_3-C_6H_4)-pyrrolyl

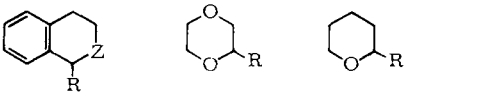
N-(9-Fluorenylidene)piperidinium iodide *(37)*, which may be regarded as an α-halogeno amine, reacts with malonodinitrile to give 9-fluorenylidenemalonodinitrile *(38)* in 62 % yield[58].

(37) *(38)*

The formation of the azetidinone *(40)* can also be formulated as proceeding *via* an intermediate "α-halogeno amine"[59]: methylphenylmethyleneamine reacts with cyanoacetyl chloride to form an adduct *(39)*, which cyclizes in the presence of triethylamine to give 3-cyano-1-methyl-4-phenylazetidin-2-one *(40)*.

(39)

(40)

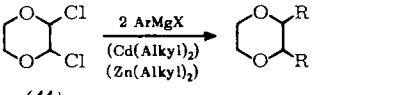


3. Reactions with Grignard Compounds

Substituted ethers, thioethers, and amines can be obtained by reaction with Grignard compounds in accordance with equation (e) (cf.[3,60]). Of the many possible preparative uses, only a few will be mentioned here; for further examples, the reader is referred to the original literature[12,61–63].

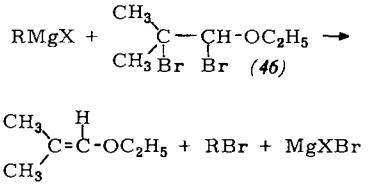
(1a), *(2b)* $\xrightarrow{R^2MgX}$ R–Z–CHR^1–R^2 (e)

Z = O, S, NR^3



The halogen atom in 1-halogenoisochromans[64], 1-halogenoisothiochromans[65], 2-chloro-1,4-dioxane[66,67], or 2-chlorotetrahydropyran[68–71] can be replaced smoothly by alkyl or aryl groups, with formation of *(41)*, *(42)*, or *(43)*.

(41) *(42)* *(43)*



Z = O, S R = Alkyl, Aryl, C≡CH

2,3-Diaryl-1,4-dioxanes *(45)* have been obtained in very good yields from 2,3-dichloro-1,4-dioxane[67,72,73].

(44) *(45)*, R = Aryl, Alkyl

In the reaction of α,β-dihalogeno ethers, *e.g. (46)*, or 2,3-dichlorodioxane *(44)*, particularly with alkylmagnesium halides or organolithium compounds, the nucleophilic substitution is occasionally accompanied by dehalogenation to form the vinyl ethers[67,73,74];

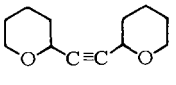
this reaction can be utilized *e.g.* for the preparation of *p*-dioxene [67]. Phenyl-lithium reacts with 2,3-dichloro-1,4-dioxane to give the unstable 2-phenyldioxene. Unsaturated ethers can be obtained by the use of alk-1-enylmagnesium halide [75–77]. The reaction of α,β-dibromodiethyl ether with vinylmagnesium chloride yields 4-bromo-3-ethoxybut-1-ene *(47)* [78, 79].

$$CH_2{=}CH{-}\underset{\displaystyle OC_2H_5}{\underset{|}{CH}}{-}CH_2Br \quad (47)$$



The reaction of α,β′-dihalogeno ethers, for instance *(48)*, with *e.g.* propenylmagnesium halide leads to crotyl β-halogenoethyl ether *(49)*; the crotyl vinyl ether formed on dehydrohalogenation of *(49)* can then rearrange to give the unsaturated aldehyde *(50)*. This very flexible synthesis has been used for the preparation of a series of γ,δ-unsaturated aldehydes [80].

$$CH_3{-}CH{=}CH{-}MgHal + ClCH_2{-}O{-}CH_2{-}CH_2Br \longrightarrow$$
(48)

$$CH_3{-}CH{=}CH{-}CH_2{-}O{-}CH_2{-}CH_2Hal \longrightarrow$$
(49)

$$CH_3{-}CH{=}CH{-}CH_2{-}O{-}CH{=}CH_2 \longrightarrow CH_2{=}CH{-}C(CH_3)H{-}CH_2{-}CHO$$
(50)

Alk-1-ynylmagnesium halides also react with α-halogeno ethers [3]. The reaction of ethynylmagnesium bromide with 2-chlorotetrahydropyran yields 2-tetrahydropyranylacetylene *(43)*, R = C≡CH [69, 70], while ethynylenebis(magnesium bromide) gives bis-(2-tetrahydropyranyl)acetylene *(51)* [70].

(51)

$$HC{\equiv}C{-}(CH_2)_4{-}C{\equiv}C{-}CH_2{-}OCH_3$$
(52a)

$$CH_3O{-}CH_2{-}C{\equiv}C{-}(CH_2)_4{-}C{\equiv}C{-}CH_2{-}OCH_3$$
(52b)

Alkali-metal acetylides react in a similar manner. For example, the mono- and diethers *(52a)* and *(52b)* have been obtained from the α-mono- and α,ω-disodium compounds of 1,7-octadiyne [81]. Hex-1-ynyl-lithium reacts with chloromethyl methyl ether to give hept-2-ynyl methyl ether [82]. Compounds of this type (see Table 3), including the acetylene ethers *(53)* obtained from alk-1-ynyl- or arylethynylmagnesium halides [77, 83] or from lithium derivatives of alkylacetylenes [84] and α-chloro ethers, have been used for further syntheses. For example, *(53)* can rearrange to allenes *(54)* [83, 84], which give unsaturated carbonyl compounds *(55)* on hydrolysis [83].

$$R{-}C{\equiv}CR^1H{-}OR^2 \longrightarrow R{-}CH{=}C{=}CR^1{-}OR^2 \longrightarrow R{-}CH{=}CH{-}CO{-}R^1$$
(53) *(54)* *(55)*

C_6H_5	C_6H_5	55			[83]

Ethyl 1-(bromomethyl)pent-4-en-2-ynyl ether *(56)* has been prepared from but-3-en-1-ynylmagnesium halide and α,β-dibromodiethyl ether.

$$CH_2{=}CH{-}C{\equiv}C{-}\underset{\displaystyle OC_2H_5}{\underset{|}{CH}}{-}CH_2Br \quad (56)$$

Further reactions of α-halogeno ethers with alkenyl- and alkynylmagnesium halides are to be found in the original literature [86–90].

In contrast to the behavior of α,β-dichloroethers, both halogen atoms can be substituted in 1,2-diethoxy-1,2-dichloroethane or in 2,5-dichlorotetrahydrofuran, as well as in *(44)*. It is possible in this way to prepare ethers such as *(57a)* [91] or *(57b)* [4, 92] and 2,5-dialkyl- and 2,5-diaryltetrahydrofurans [93]. Bis(chloromethyl) methylene diether *(58a)* reacts with Grignard compounds to give methylene diethers *(58b)* [94].

$$R{-}C{\equiv}C{-}\underset{\displaystyle OR^1}{\underset{|}{CH}}{-}\underset{\displaystyle OR^1}{\underset{|}{CH}}{-}C{\equiv}C{-}R \qquad R{-}CH_2{-}O{-}CH_2{-}O{-}CH_2R$$

(57a), R = H — *(58a)*, R = Cl

(57b), R = $CH_3O{-}CH{=}CH$ — *(58b)*, R = Alkyl, Aryl

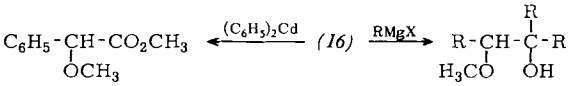
Both halogen atoms can also be substituted in α,α-dihalogenated ethers; 2,2-disubstituted benzodioxoles *(59a)* have been prepared in this way from pyrocatechol dichloromethylene ether. Benzodioxoles such as *(59c)* are obtained from 2-chloro-2-phenylbenzodioxole *(59b)* [95]. Dichloromethyl alkyl ethers react with Grignard compounds to form ethers of secondary alcohols *(60)* [96–98].



(59a), R = R^1 = Alkyl, Aryl
(59b), R = Cl, R^1 = C_6H_5
(59c), R = CH_3, R^1 = C_6H_5

Aldehydes can be obtained in low yields as by-products, probably as a result of the elimination of R–Cl from *(61)* [98].

The reaction of Grignard compounds with methyl chloromethoxyacetate *(16)* leads not only to substitution of the halogen, but also to addition to the methoxy carbonyl group with formation of glycol monomethyl ethers *(62)*; with diphenylcadmium, on the other hand, the only reaction is replacement of the halogen and formation of methyl *O*-methylmandelate [41].

(62)

An interesting variant of the reaction of α,β-dihalogeno ethers with Grignard compounds is *Boord*'s synthesis of unsaturated compounds (see Table 4 and [116–118]).

The initially formed β-bromo ether *(63)* can be converted either into the olefin *(64a)* by treatment with

Table 4. Olefins, vinyl ethers, and unsaturated alcohols having the general formula *(64c)* synthesized by *Boord*'s method from α,β-dihalogenated ethers.

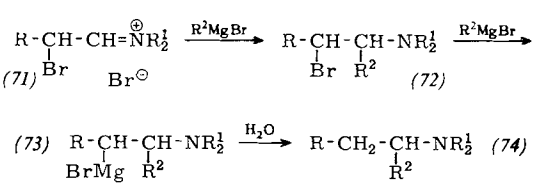
Mg or Zn, or into the vinyl ether *(64b)* by reaction with KOH. *(64b)* reacts with bromine to form the dibromo ether *(65)*, which can be converted by a similar reaction sequence into the olefin *(64c)*. This method has been used for the preparation of monoolefins containing up to 20 C-atoms [99–106] and (using unsaturated Grignard compounds) of diolefins [107] and vinyl ethers *(64b)* [108–110].

A similar reaction with cyclic α,β-dihalogeno ethers yields unsaturated alcohols, *e.g. (66)*.

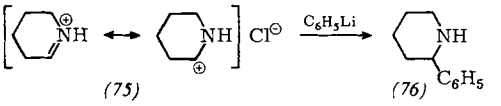
$$NaO\text{-}(CH_2)_{n+1}\text{-}CH{=}CH\text{-}R \longrightarrow HO\text{-}(CH_2)_{n+1}\text{-}CH{=}CH\text{-}R \quad (66)$$

The cleavage of the β-halogeno ether, which has been carried out for a number of examples with $n = 1$ [111,112] and $n = 2$ [113,114] proceeds more readily with sodium, and is not stereospecific; *(66)* is generally obtained as a *cis-trans* mixture.



Chloromethyl sulfides react with Grignard compounds, in accordance with equation (e), to form thioethers *(67)* [119], while α-halogeno amines give trialkylamines *(68)* (for R, R^1, R^2, R^3 = alkyl, aryl, or R^3 = H, see [2,27,28,120]).

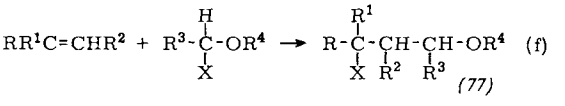
$RS{-}CHR^1{-}R^2$ *(67)* $\qquad$ $RR^1N{-}CHR^3R^2$ *(68)*



The reaction of allylmagnesium halides with chloromethyldialkylamines leads to almost quantitative yields of γ,δ-unsaturated amines *(69)*, which add HCl to form γ-chloro-*N*-alkylamines *(70)* [121].

$$R_2N{-}CH_2{-}CH_2{-}CH{=}CH_2 \xrightarrow{HCl} R_2N{-}CH_2{-}CH_2{-}CHCl{-}CH_3$$
(69) $\qquad$ *(70)*

α-Dibromoalkylamines *(71)*, which can be obtained by the addition of bromine to enamines, react with Grignard compounds to form α-branched β-bromoalkylamines *(72)*; reaction with a further molecule of alkylmagnesium bromide followed by the elimination of alkyl bromide gives *(73)*, which affords the amine *(74)* on hydrolysis [122].



Piperidine hydrochloride *(75)* reacts with phenyllithium to form 2-phenylpiperidine *(76)* in approximately 50 % yield [28].

4. Reactions with Unsaturated Compounds

a) Reactions with Olefins

The addition of α-halogeno ethers to unsaturated compounds has frequently been used to establish new C–C bonds [7,123,124]. This addition is catalysed by $HgCl_2$, $ZnCl_2$, $BiCl_3$, or $AlCl_3$, and proceeds as shown in equation (f), in agreement with the Markovnikov rule.

Some γ-halogeno ethers *(77)* obtained in this way are listed in Table 5; for further examples, see [125,140–150].

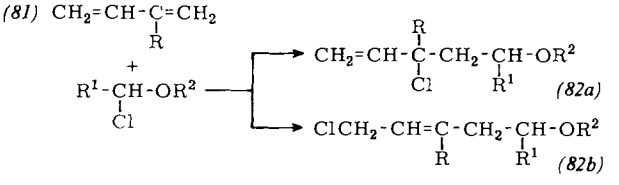
α,α'-Dihalogeno ethers, *e.g.* bis(chloromethyl) ether, may be added to propylene and isobutylene in the presence of $ZnCl_2$ to form *(78a)* and *(78b)* [151].

$(Cl-CRR^1-CH_2-CH_2)_2O$ $(XCH_2-CXH-CH_2-CH_2)_2O$

(78a), $R = CH_3$; $R^1 = H$ *(79a)*, X = Cl



(78b), $R = R^1 = CH_3$ *(79b)*, X = Br

The reaction with chlorinated ethylenes [131,142] or with allyl chloride [133] to form *(79a)* takes place only in the presence of $AlCl_3$, whereas bis(bromomethyl) ether reacts with allyl bromide/$ZnBr_2$ to give *(79b)* [152]. Bis(chloromethyl) ethers of glycol, of 2,3-butanediol, and of 1,2-cyclohexanediol also give good yields of the expected addition products with 2 moles of propylene or butylene [151,153]. α,β-Dihalogeno ethers add to monoolefins to form dihalogeno ethers having the structure *(80)* [96,136]; for example, 2,3-dichlorotetrahydrofuran gives *(80a)* [147,154,155].

(80) *(80a)*

Reaction with conjugated diolefins *(81)* proceeds particularly readily [124] as 1,2- or 1,4-addition. A mixture of the two products is obtained in most cases.

(82a) *(82b)*

Pudovik [156] found that butadiene initially gives mainly 1,2-adducts. However, since these readily isomerize under the conditions of the reaction to form the 1,4-adducts, the proportion of the latter present toward the end of the reaction is always higher. Similar results were obtained in the reaction of various α-chloro ethers with butadiene, isoprene, and chloro-

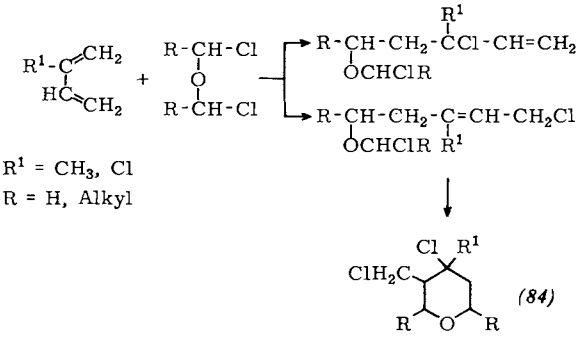
CH_3	C_6H_5	C_2H_5		70	[159]

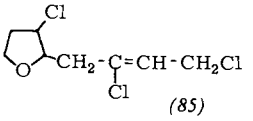


prene (see Table 6 and [141, 160–165]); cyclic dienes give analogous products [124, 166]. 2-Chlorotetrahydropyran reacts with isoprene or 2,3-dimethylbutadiene to give good yields of the 1,4-adducts *(83a)* and *(83b)* [167].

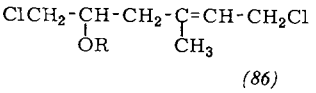
(83a), R = H

(83b), R = CH_3

Tetrahydropyran derivatives *(84)* are obtained from bis(α-chloroalkyl) ethers and chloroprene or isoprene [168] in good yields. α,β-Dichlorodiethyl ether and butadiene [165] or chloroprene [162] also give mainly



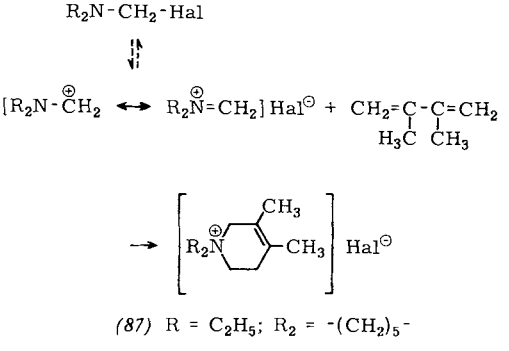
R^1 = CH_3, Cl



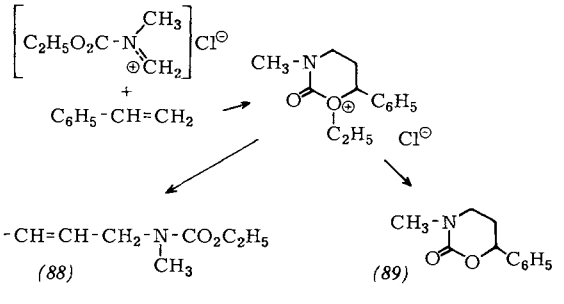
R = H, Alkyl

(84)

the 1,4-adducts, together with small quantities of 1,2-products, whereas the addition of 2,3-dichlorotetrahydrofuran to chloroprene leads exclusively to the 1,4-adduct *(85)* (yield 80 %) [155, 169]. Part of the side chain of vitamin A was synthesized by the addition of α,β-dichloroethyl alkyl ether to isoprene in the presence of $TiCl_4$ to form *(86)* [170].



(85)



(86)

α-Halogenated amines, such as halogenomethyldiethylamine or *N*-bromomethylpiperidine, react with 2,3-dimethylbutadiene (at room temperature or when heated in methylene chloride) to give a Δ^3-piperidinium halide *(87)* by a reaction resembling the Diels-Alder synthesis [171].

(87) R = C_2H_5; R_2 = $-(CH_2)_5-$

Another reaction of this type is the addition of ethyl *N*-chloromethyl-*N*-methylcarbamate to styrene in the presence of boron trifluoride; this reaction probably leads first to an oxonium salt, which decomposes into *(88)* (65 %) and *(89)* (8–10 %). When the benzyl ester of the same carbamic acid is used, the 1,3-oxazine is formed in 65 % yield [172].

(88)

(89)

b) Reactions with Acetylene and Vinylacetylene

α-Halogenomethyl alkyl ethers add to acetylene in the presence of $AlCl_3$ to give the 3-chloroallyl alkyl ether *(90)*.

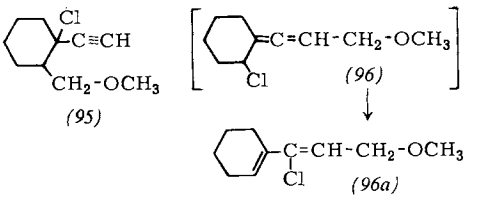
$$HC\equiv CH + ROCH_2Cl \xrightarrow{AlCl_3} RO-CH_2-CH=CHCl + ClCH_2-CH=CHCl$$
(90)

With chlorodimethyl ether, 1,3-dichloroprene is obtained as well as *(90)*, R = CH_3 [173]. The addition of chloromethyl alkyl ethers to tetramethylbutynediol leads to 3-chloro-2,5-dihydroxy-4-methoxymethyl-2,5-dimethylhex-3-ene *(91)*, which gives the furanone derivative *(92)* on treatment with sulfuric acid [174].

$$(CH_3)_2C(OH)-C\equiv C-C(OH)(CH_3)_2 \xrightarrow{CH_3OCH_2Cl} (CH_3)_2C(OH)-C(Cl)=C(CH_2-OCH_3)-C(OH)(CH_3)_2$$
(91)



(92)

Dykstra [175] and *Vartanyan* [7] have found that in the presence of $BiCl_3$ [175,176] or $ZnCl_2$ [177], α-chloro ethers add to vinylacetylene in the 1,4-position to give *(93a)*, which then undergoes partial isomerization into *(93b)*. The latter compound can add another mole of chloro ether to form *(94)* [177].

(93a) *(93b)* *(94)*

Similar reactions have been carried out with propyl- [177], 1-chloro-1-methylethyl- [178], and allylvinylacetylene [179] and similar compounds [180]. In most cases these reactions also proceed *via* 1,4-addition. The products can isomerize in various ways.

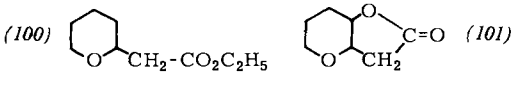
The addition of monochlorodimethyl ether to Δ^1-cyclohexenylacetylene yields a mixture of the cyclohexane derivatives *(95)* and *(96a)* (molar ratio 62:38). The compound *(96a)* is probably also formed by isomerization of the 1,4-addition product *(96)* [181].

(95) *(96)* *(96a)*

α-Chloromethyl alkyl ethers add to divinylacetylene in the 1,2-positions to give *(97a)* [182]. The addition to isopropenylvinylacetylene takes place selectively at the double bond having the highest electron density;

$$RO-CH_2-CH_2-CR^1Cl-C\equiv C-CH=CH_2$$
(97a), $R^1 = H$ *(97b)*, $R^1 = CH_3$

the product is *(97b)* [183]. 2,3-Dichlorotetrahydrofuran and isopropenylvinylacetylene give a product analogous to *(97b)* [155].



c) Reactions with Ketenes

The reaction of α-chloro ethers with ketenes leads to β-alkoxycarbonyl chlorides *(98)*. Monochlorodimethyl ether gives low yields [184].

$$RO-CHR^1-Cl + CH_2=C=O \longrightarrow RO-CHR^1-CH_2-COCl$$
(98)

Better results are obtained with α-chloro-β,β-diphenyldiethyl ether and 2-chlorotetrahydropyrans [186,187]; the resulting acyl chlorides were converted directly into β-ethoxy-γ,γ-diphenylbutanoic acid *(99)* and ethyl 2-tetrahydropyranylacetate *(100)*. The reaction of ketene with 3-acetoxy-2-chlorotetrahydropyran gives a product that yields perhydrofuro[3,2-*b*]pyran-2-one

$$(C_6H_5)_2CH-CH(OC_2H_5)-CH_2-COOH$$
(99)

(100) *(101)*

(101) directly on distillation [185]. Addition of α,β-dichlorodiethyl ether [187] and 2,3-dichlorotetrahydrofuran [188] to ketene and subsequent alcoholysis yields the esters *(102)* and *(103)*, respectively, while 2,5-di-

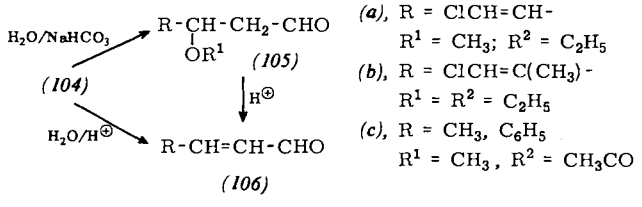
chlorotetrahydrofuran gives the corresponding bifunctional acyl chloride [189].

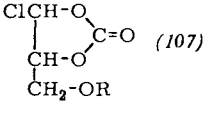


(102) *(103)*

d) Reactions with Vinyl Ethers, Enamines, Ketene Acetals

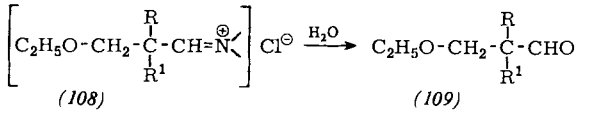
Olefins with *O* and *N* groups on the double bond react with α-halogeno ethers [cf. eq. (f)] to give very reactive addition products, which, in many cases, react further without being isolated. The addition of α-chloro ethers to vinyl ethers proceeds, even in the absence of catalysts, to give *e.g. (104a)* and *(104b)*.

(104)



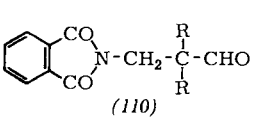
(105) *(106)*

(a), R = ClCH=CH-, $R^1 = CH_3$; $R^2 = C_2H_5$
(b), R = ClCH=C(CH_3)-, $R^1 = R^2 = C_2H_5$
(c), R = CH_3, C_6H_5, $R^1 = CH_3$, $R^2 = CH_3CO$



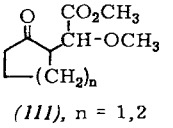
The primary products *(104a)* and *(104b)*, which are obtained in 80–92 % yield, give *(105a)* and *(105b)* on hydrolysis with aqueous $NaHCO_3$ [190], while hydrolysis in acidic solution is accompanied by elimination of methanol and formation of *(106a)* and *(106b)* [191].

Vinyl acetate reacts similarly in the presence of $HgCl_2$ [133] or $ZnCl_2$ [192]. Hydrolysis of the primary product *(104c)*, which is obtained in good yields, again leads to the elimination of an alkoxy group and formation of the unsaturated aldehyde. 2-Oxo-1,3-dioxole and α-chloromethyl alkyl ethers react to form the glyceraldehyde derivative *(107)* [133].



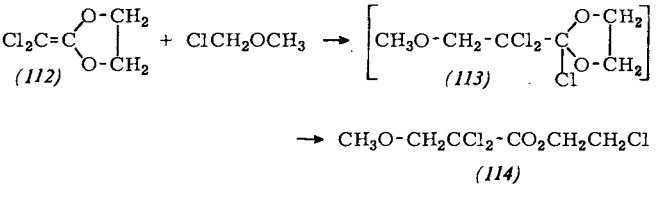
(107)

The reaction of chloromethyl ethyl ether with enamines in acetonitrile leads initially to immonium salts *(108)*, which give β-ethoxyaldehydes *(109)* on hydrolysis [193].



(108) *(109)*

Enamines derived from indanones have been alkylated in a similar manner [194]. *N*-(Bromomethyl)phthalimide and enamines give good yields of β-phthalimidoaldehydes *(110)* [193], while methyl chloromethoxyacetate *(16)* reacts in a similar manner with *N*-cyclopent-1-enyl- or *N*-cyclohex-1-enylmorpholine to form methyl methoxy-(2-oxocycloalkyl)acetates *(111)* [41].



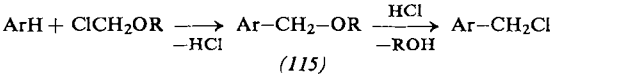
(110)

(111), n = 1,2

The addition of chlorodimethyl ether to 2-(dichloromethylene)-1,3-dioxolane derivative *(112)* probably leads first to the unstable dioxolane derivative *(113)*, which, however, rearranges to give the ester *(114)* [195].

(112) *(113)* *(114)*

5. Reactions with Aromatic and Heterocyclic Compounds



In the presence of Friedel-Crafts catalysts, compounds of the type *(1a)* and *(2b)* react with simple and condensed aromatic compounds, phenols, phenol ethers, and heteroaromatic compounds, sometimes in excellent yields.

a) Formation of Benzyl Compounds

α-Halogeno ethers, sulfides, and amines react with aromatic compounds, primarily in accordance with equation (g).

$$ArH + Cl{-}CHR^1{-}X{-}R \rightarrow Ar{-}CHR^1{-}X{-}R \qquad (g)$$
$$X = O, S, NR^2$$

Chloromethyl alkyl ethers give benzyl ethers *(115)* (Ar = C_6H_5; R = CH_3, C_4H_9) under mild conditions (−40 to −20 °C in $CS_2/AlCl_3$) in yields of up to 37 %, together with benzyl chloride [196].

[196] *M. Sommelet*, C. R. hebd. Séances Acad. Sci. *157*, 1443 (1913).

Above 0 °C, the benzyl ethers are evidently unstable under the conditions of the reaction; consequently, the reaction with chloromethyl alkyl ethers always proceeds as a chloromethylation [197, 198].

The symmetrical dichloro- or dibromodimethyl ethers can be used in the same way for halogenomethylation [197, 199–202]. CS_2 has been used as solvent, and the

$$2\,ArH + (XCH_2)_2O \xrightarrow[-H_2O]{} 2\,Ar{-}CH_2X$$

catalyst in this case was $SnCl_4$ [203]. No catalyst is required in acetic [198] or sulfuric acid [200, 201]; zinc chloride was added for the reaction in concentrated hydrochloric acid [202].

Halogenoalkylation with α-halogeno ethers often presents certain advantages over earlier methods with respect to both yields and procedures; some examples are given in Table 7.

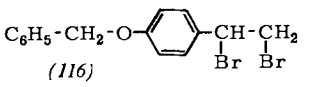

Table 7. Chloromethylated aromatic compounds prepared by halogenoalkylation with CH_3OCH_2Cl (I) or $ClCH_2O{-}CH_2Cl$ (II).

Benzyl chlorides prepared	Yield (%)	Chloro ether	Ref.
2,4-Dimethyl-	50–60	I	[198]
2,4,6-Trimethyl-	80–85	I	[198]
2,4,6-Triisopropyl-	90	I	[203]
2-Methyl-5-nitro-	100	II	[204]
4-Ethyl-3-nitro-	57	I	[205]
2-(β-Chloroethyl)-5-nitro-	65	II	[200]
3-Formyl-2-hydroxy-5-nitro-	90	I	[206]
2-Methoxy-5-nitro-	74, 90	II	[207, 202]
4-Methoxy-3-nitro-		II	[202]
3-Chlormethyl-2-methyl-5-nitro-	43	II	[204]
3-Formyl-4-hydroxy-5-methoxy-	28	II	[208]
4-Acetamido-		II	[201]

The reaction with monochlorodimethyl ether has recently been more widely used for the chloromethylation of styrene-divinylbenzene polymers; depending on the reaction conditions, it is possible to obtain polymers of various degrees of chloromethylation [209–221], which react with amines to give strongly basic ion-exchange resins. Polymers with lower degrees of chloromethylation are specially used for automatic peptide synthesis by *Merrifield*'s method [222]. Investigations have also been carried out on the chloromethylation of benzanthrones [223–225] and triaryltriazines [226].

The reaction of aromatic compounds with α,β-dibromodiethyl ethers proceeds as a dibromoethylation. Phenyl benzyl ether gave a 55 % yield of *p*-(α,β-dibromoethyl)phenyl benzyl ether *(116)* [227].

$$C_6H_5{-}CH_2{-}O{-}C_6H_5 \xrightarrow[-C_2H_5OH]{C_2H_5O{-}CHBr{-}CH_2Br}$$

(116)

Friedel-Crafts reactions of α-halogeno ethers with benzene derivatives can give benzyl ethers as the principal products if the ether grouping is sterically or electronically stabilized. For example, chloromethyl β-phenylethyl ether *(117)*, $n = 2$, undergoes intramolecular reaction in the absence of catalysts to form isochroman *(118)*, $n = 2$, in a yield of more

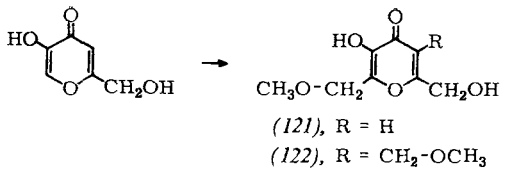
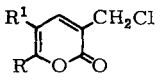
than 90 %[228]. Isochromans having substituents in the benzene nucleus or in the heterocycle have been prepared in a similar manner[229,230]; in the presence of $AlCl_3$, chloromethyl γ-phenylpropyl ether *(117)*, $n = 3$, gives homoisochroman *(118)*, $n = 3$[231].

(117) *(118)*



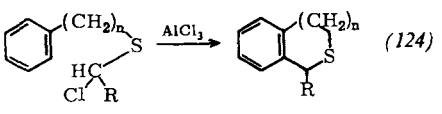
In the reaction of methyl chloromethoxyacetate *(16)* with benzene derivatives, the corresponding methyl *O*-methylmandelates *(119)* can be isolated in yields of up to 86 %[41]. With an excess of the aromatic component, the methyl diarylacetate *(120)* can be obtained



(119) *(120)*

in one step after prolonged reaction. Bromination of *(119)* leads smoothly to methyl arylglyoxylate[232].

α- and γ-Pyrones react with monochlorodimethyl ethers to form the methoxymethyl derivatives. Thus kojic acid gives the 6-methoxymethyl *(121)* or the 3,6-bis(methoxymethyl) compound *(122)*, depending on the amount of chloro ether used, whereas chroman-2-one gives 3-methoxymethylchromanone[233]. The reaction of α-pyrones with a mixture of monochloro- and symmetrical dichlorodimethyl ethers yields 3-chloromethyl-α-pyrones *(123)*[234].



(121), R = H
(122), R = CH_2-OCH_3

(123), R = CH_3
R^1 = CH_3, C_3H_7

thioisochromans *(124)*, *e.g.* with R = H, CH_3, C_6H_5; $n = 2$, can be obtained from α-chloroalkyl β'-phenylethyl sulfides/$AlCl_3$ in good yield[65]. Homoisothiochromans *(124)*, $n = 3$, are obtained in the same way from α-chloroalkyl γ-phenylpropyl sulfides[236].

(124)

α-Halogeno amines or α-halogeno amides can react with aromatic compounds, in some cases in the absence of a catalyst, also in accordance with equation (g). *N*-Chloromethyldialkylamines react both with sodium phenoxides or *N,N*-dialkylaniline hydrochlorides[237] and with furans[238] to form dialkylaminomethylated aromatic compounds *(125)*. α-Halogeno amines such as *(35)* can be used in accordance with equation (g) for the synthesis of *N*-alkylated amino-acid derivatives (see Table 8).

Table 8. Dialkylaminomethylated aromatic compounds synthesized. Ar–CH(R)–N(R^1)(R^2) *(125)*

Ar	R	R^1	R^2	Yield (%)	Ref.

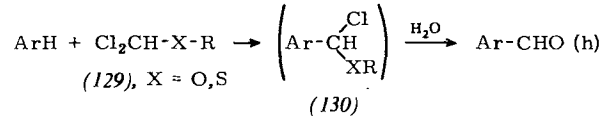
The reaction of dimethyl-*p*-dimethylaminobenzylamine *(126)* and benzoylchloride leads to *p*-dimethylaminobenzyl chloride, which cannot be isolated, but reacts as a phenylogous α-halogeno amine with *N,N*-dimethylaniline to give bis(*p*-dimethylaminophenyl)-methane *(127)* [239].

(126) $(CH_3)_2N-C_6H_4-CH_2-N(CH_3)_2$ $\xrightarrow{C_6H_5COCl}$ $[(CH_3)_2N-C_6H_4-CH_2Cl]$ $\xrightarrow{(CH_3)_2N-C_6H_5}$ $[(CH_3)_2N-C_6H_4]_2CH_2$ *(127)*

$AlCl_3$ is recommended as the catalyst for the reaction of α-halogeno amides with aromatic compounds to form α-arylalkylamides *(125)*, R = alkyl, R^1 = acyl, R^2 = H [240]. *N*-Bromomethylphthalimide reacts with benzene in boiling benzene/$ZnCl_2$ to give *N*-benzylphthalimide in 94 % yield [241], while the reaction of *N*-chloromethylphthalimide with benzene, xylene, biphenyl, or naphthalene in nitromethane/Zn Cl_2 leads to the introduction of two phthalimidomethyl groups and formation of *e.g. (128)* in yields of up to 95 % [242, 243].



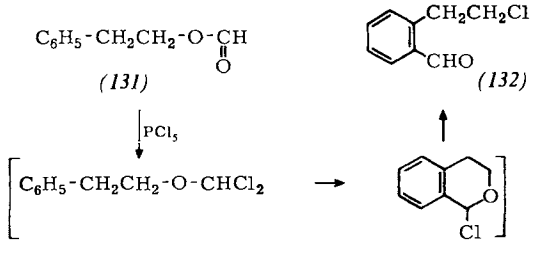
$ZCH_2-C_6H_4-CH_2Z$ *(128)*, Z = Phthalimido

For further reactions of *N*-chloromethylphthalimide with aromatic compounds [244, 245] and of 1,4-bis (chloromethyl)piperazine-2,5-dione [246] with benzene to form 1,4-dibenzylpiperazine-2,5-dione, see the original literature. Some of the amines and amides prepared are listed in Table 8.

b) Synthesis of Aldehydes

When dichloromethyl alkyl ether *(129)*, X = O, react with aromatic compounds in the presence of Friedel-Crafts catalysts ($AlCl_3$, $SnCl_4$, $TiCl_4$), only one chlorine atom is replaced by the aromatic group, as indicated in equation (h). Hydrolysis of the primary product

ArH + $Cl_2CH-X-R$ → $[Ar-CH(Cl)-XR]$ $\xrightarrow{H_2O}$ Ar-CHO (h)



(129), X = O,S — *(130)*

(130), which cannot be isolated, leads to good yields of the corresponding aldehyde [247]. Similarly, dichloromethyl methyl sulfide *(129)*, X = S, can be used for the formylation of aromatic compounds [248]. Table 9 lists a number of the aldehydes prepared by this method.

Table 9. Aldehydes obtained from aromatic compounds by formylation with α,α-dichloro ethers or α,α-dichloro thioethers RX—$CHCl_2$.

Aldehyde	RX	Yield (%)	Ref.
Cuminaldehyde	CH_3O	69	[247]
2,4,6-Trimethylbenzaldehyde	CH_3O	85	[247]
Biphenyl-4-carbaldehyde	C_4H_9O	64	[247]
4-Phenylmethylbenzaldehyde	CH_3O	64	[98]
α-Naphthaldehyde	CH_3O	80	[247]
Fluorene-2-carbaldehyde	C_4H_9O	62	[247]
Anthracene-9-carbaldehyde	CH_3O	92	[247]
Pyrenecarbaldehyde	C_4H_9O	88	[247]
4-Methoxybenzaldehyde	CH_3S	94	[235]
2-Methoxy-5-nitrobenzaldehyde	CH_3O	62	[247]
2-Methoxy-1-naphthaldehyde	CH_3S	94	[235]
Veratraldehyde	CH_3S	87	[235]
4-Hydroxybenzaldehyde	CH_3S	83	[235]
4-Hydroxy-3-methoxybenzaldehyde	CH_3S	91	[235]
2,4-Dihydroxybenzaldehyde	CH_3O	68	[248]
Orcylaldehyde	CH_3S	84	[235]
2,4,6-Trihydroxybenzaldehyde	CH_3S	73	[235]
Ferrocenecarbaldehyde	C_2H_5O	72	[249]
Coronenecarbaldehyde	C_4H_9O	77	[250]
Thiophene-2-carbaldehyde	CH_3O	90	[247]
1-Formylcolchicine	CH_3O	80	[251]

The final product of the reaction of β-phenylethyl formate *(131)* with PCl_5 is *o*-(β-chloroethyl)benzaldehyde *(132)* [252]. The reaction probably proceeds *via* dichloromethyl β-phenylethyl ether, which first undergoes an intramolecular Friedel-Crafts reaction to give 1-chloroisochroman; the latter subsequently rearranges to *(132)* [228, 253].

$C_6H_5-CH_2CH_2-O-CH(=O)$ *(131)* → PCl_5 → $[C_6H_5-CH_2CH_2-O-CHCl_2]$ → 1-Chloroisochroman → *(132)* o-$(CH_2CH_2Cl)C_6H_4CHO$

α-Halogeno amines such as *N,N*-dimethylformamide dichloride can be used for the formylation of aromatic compounds. These reactions proceed as Vilsmeier formylations.

c) Synthesis of Carboxylic Acids

In the reactions of trichloromethyl methyl ether *(133)*, X = O, with aromatic compounds in the presence of Friedel-Crafts catalysts, again only one chlorine atom is replaced by the aryl residue. Hydrolysis of the intermediate, which again cannot be isolated, yields an aromatic carboxylic acid [254, 255]. However, the yields

[255] *H. Gross*, *J. Rusche*, and *M. Mirsch*, Chem. Ber. *96*, 1382 (1963).

$$ArH + Cl_3C\text{-}X\text{-}CH_3 \longrightarrow$$

(133), X = O,S

$$(Ar\text{-}CCl_2\text{-}X\text{-}CH_3) \xrightarrow{H_2O} Ar\text{-}CO_2H \qquad (i)$$

$$Ar\text{-}C(=O)SCH_3$$

(134)

are very low, owing to a competing reaction of trichloromethyl methyl ether with traces of $AlCl_3$, which results in decomposition into phosgene and methyl chloride [254].

$$Cl_3C\text{–}O\text{–}CH_3 \xrightarrow{AlCl_3} COCl_2 + CH_3Cl$$

Nevertheless, carboxylic acids can be obtained in good yields if trichloromethyl methyl sulfide *(133)*, X = S, is used instead of the ether. Hydrolysis in this case leads first to the thiolester *(134)* of the aromatic carboxylic acid, which can readily be hydrolysed by alkali to obtain the carboxylic acid [235].

Carboxylations of aromatic compounds can be readily accomplished *e.g.* with pyrocatechol dichloromethylene ether *(135)*. Hydrolysis of the ortho acid diester monochloride *(136)* formed in the presence of $AlCl_3$ or $SnCl_4$ affords first the pyrocatechol monoester of the aromatic carboxylic acid, which can be readily hydrolysed with alkali [255]. Alternatively, orthoesters of the type *(138)* can be obtained by treatment of the reaction mixture containing *(136)* with alcohol/pyridine [95].

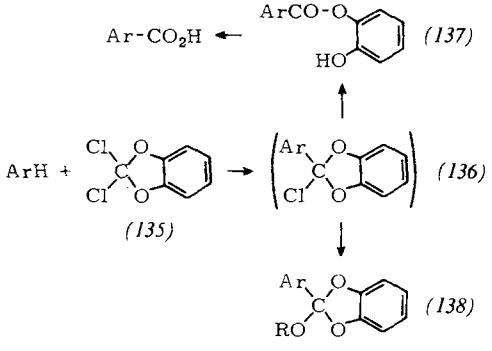

Table 10. Carboxylic acids and carboxylic acid derivatives prepared by reaction of trichloromethyl methyl sulfide *(133)*, X = S, or pyrocatechol dichloromethylene ether *(135)* with aromatic compounds.
