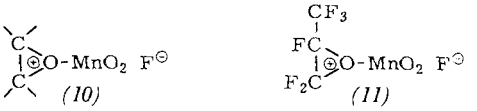
and its acetate are obtained in a total yield of 30% from vinyl chloride. 1,1-Difluoroethylene can be hypofluorinated with freshly prepared peroxyacetic acid in the presence of HF[46].



A solution of potassium permanganate in HF is also an efficient hypofluorinating agent[47]. In this case $FMnO_3$ formed from $KMnO_4$ and HF reacts with the olefin. The reaction probably proceeds *via* the ion

$$\begin{array}{l} CCl_2{=}CH_2 \\ CF_2{=}CH_2 \\ CHCl{=}CH_2 \end{array} \xrightarrow{KMnO_4 + HF} \begin{array}{l} CCl_2F{-}CH_2OH \\ CF_3{-}CH_2OH \\ CHClF{-}CH_2OH \end{array} \qquad (38)$$

[46] *G. G. Belen'ki, L. S. German,* and *I. L. Knunyantz,* Ž. obšč. Chim. *37*, 1687 (1967).

[47] *G. G. Belen'ki, L. S. German,* and *I. L. Knunyantz,* Izvest. Akad. Nauk SSSR, Ser. chim. *1967*, 2780.

(10), which can be stabilized in the reaction with perfluoroolefins ($CF_2{=}CF_2$ and $CF_3{-}CF{=}CF_2$) by cleavage not only of the C–O but also of the O–Mn

bond. The reaction of $KMnO_4$ and HF with perfluoropropene leads to a 30% yield of hexafluoromethyloxirane[47,48].

The presence of such a large number of fluorine atoms in the olefin molecule leads to a decrease in the electron density on the oxygen atom in the complex *(11)*. This explains the ease of cleavage of the oxygen-metal bond.

Other perhalogenoethylenes give only acyl fluorides of the perhalogenoacetic acids on hypofluorination.

$$\begin{array}{l} CF_2{=}CFCl \\ CF_2{=}CCl_2 \\ CFCl{=}CFCl \end{array} \xrightarrow{KMnO_4 + HF} \begin{array}{l} CF_2Cl{-}COF + CF_3{-}COF \\ CFCl_2{-}COF + CF_2Cl{-}COF \\ CF_2Cl{-}COF + CFCl_2{-}COF \end{array}$$

Crystal Structure Analysis by Neutron Diffraction I[**]

By Georg Will[*]

Neutron diffraction is a valuable complement to X-ray diffraction methods for the determination of crystal structures. A description of the principles of the method is followed by specific examples of the additional information obtained from neutron diffraction experiments: in the structural analysis of benzene, oxalic acid dihydrate, vitamin B_{12}, ferrites, metal cyanides and carbides; and in studies of hydrogen bonding, ferroelectric effects, and thermal vibrations in crystals. Anomalous dispersion in neutron diffraction is also discussed.

1. Introduction

Together with X-ray diffraction, neutron diffraction is one of the most important methods for studying the crystal structure and constitution of molecules. However, whereas X-ray structure analyses are now carried out in many laboratories[1], the use of neutron diffraction is at present very limited. The main reasons for this are the great expense involved in neutron diffraction experiments and the small number of suitable nuclear reactors. With the construction of high-flux reactors[2] having neutron fluxes of the order of 10^{15}

[**] Part I: Neutron diffraction at atomic nuclei. – Part II: "Neutron diffraction and magnetic structure" will appear shortly in this journal.

[1] X-ray structure analysis and its application to problems of molecular constitution have been discussed in this journal on a number of occasions: *e.g. W. Hoppe*, Angew. Chem. *69*, 659 (1957); *G. Habermehl, ibid. 75*, 78 (1963); *M. F. Perutz, ibid. 75*, 589 (1963); *I. C. Kendrew, ibid. 75*, 595 (1963); *W. Hoppe, ibid. 77*, 484 (1965); *78*, 289 (1966); Angew. Chem. internat, Edit. *4*, 508 (1965); *5*, 267 (1966).

[2] The HFBR high-flux reactor at Brookhaven National Laboratory (USA) has a flux density of $\approx 6 \times 10^{14}$ neutrons/cm² sec. A similar reactor with a flux density of $\approx 5 \cdot 10^{15}$ neutrons/cm² sec is under construction at Grenoble (France) as a joint Franco-German project. For comparison, the flux density of the FR2 research reactor at the Kernforschungszentrum Karlsruhe is 4×10^{13} neutrons/cm² sec.

neutrons/cm^2 · sec and higher, it can be forseen that neutron diffraction will become increasingly important as an investigational technique. It does not compete with X-ray diffraction but is a valuable complement to it, and a neutron diffraction study is generally an extension of an X-ray investigation to answer specific questions which are difficult to solve from the X-ray data alone.

The neutron is an uncharged elementary particle. Its most important characteristics are as follows: Mass: $m_n = 1.008922$ atomic mass units (Dalton), Spin: $I_n = 1/2$, Magnetic moment: $\mu_n = 1.91319$ nuclear magnetons (μ_N).

According to de Broglie's equation:

$$\lambda = \frac{h}{mv} \qquad (1)$$

a beam of neutrons can be considered to have wave properties in the same way as a beam of electrons. The wave nature of the neutron was demonstrated in 1936 by diffraction experiments on MgO crystals by *Halban* and *Preiswerk* [3] and *Mitchell* and *Powers* [4]. The neutron sources for these experiments were Ra–Be specimens. However, it was not until the development of nuclear reactors in the years following 1942 that there were neutron sources of high enough intensity for the neutron itself to be used as a probe for studying the properties of solids. The first neutron crystal diffractometer was installed at Oak Ridge in the USA in 1946, and neutron diffraction was first used as an experimental tool by *Wollan* and *Shull* in 1948 [5]. Soon after this an antiferromagnetic spin configuration could be detected in MnO [6] using the magnetic moment associated with the neutron as an atomic probe for the first time.

2. Principle of the Method

2.1. Production of a Neutron Beam

At present practically the only sources of thermal neutrons are nuclear reactors in which fast neutrons are produced by fission and are then slowed down by a moderator (hydrogen, deuterium, or graphite). The velocity distribution of the neutron beams in the reactor is therefore Maxwellian with a maximum at about 2.2×10^5 cm/sec, corresponding to 1.8 Å. The equations for converting velocity v (cm/sec) or energy E (eV) into wavelength λ (Å) are

$$\lambda \mathrel{\hat{=}} \frac{3.956 \times 10^5}{v} \mathrel{\hat{=}} \frac{0.286}{\sqrt{E}} \qquad (2)$$

Wavelengths of the order of the interatomic distances are required to achieve resolution of the atoms in the crystals by neutron diffraction experiments. The wavelengths normally used lie within the range of about 1.0 to 1.1 Å, and thus do not originate from the maximum of the Maxwell curve. (The radiation from the Cu–K_α line, which is frequently used in X-ray structure analysis, has a wavelength of 1.54 Å.) The monochromatic neutron beam required for diffraction experiments is generally produced with the aid of a "monochromator crystal", by means of which a narrow wavelength band can be separated from the continuous neutron spectrum by Bragg reflection at the plane (hkl) according to $\lambda = 2d \sin\Theta$. However, the planes of higher order also reflect beams at the same angle 2Θ, particularly the plane of second order (2h, 2k, 2l) which reflects a beam of wavelength $\lambda/2$ [7]. This wavelength contamination is kept small by accepting a loss of intensity and working in the region of the high-energy branch of the Maxwell distribution curve rather than at its maximum. The residual $\lambda/2$ component for 1.05 Å, a frequently used wavelength, is about 1%. This wavelength is often preferred because ^{239}Pu has a resonance absorption line at 0.526 Å, so that it can be used as a $\lambda/2$ filter.

The most common monochromators are single crystals of copper or lead. It is possible to obtain sufficiently large single crystals of these metals which also have a good mosaic spread, the factor which ultimately determines the intensity yield. Single crystals of germanium have also been used in recent times. The structure of these crystals enables a primary beam free from a $\lambda/2$ component to be obtained by the space group extinction. However, the germanium crystals available at present suffer from the disadvantage of small mosaic spread.

2.2. Principles of Neutron Diffractometers

Fig. 1a shows a twin neutron diffractometer [8]. Fig. 1b is a schematic presentation, which is common to all such installations.

A single reactor channel is used to operate two diffractometers. Two primary beams of different wavelengths are separated out from the "white" neutron beam by two differently positioned single crystal monochromators. The two beams reach the two diffractometers from different directions (the figure shows a four-circle single-crystal diffractometer and a two-circle powder diffractometer).

The finite width of the wavelength band produced (half-width ≈ 0.04 Å) raises fundamental difficulties. It causes the width of the reflection peaks to increase very rapidly at large scattering angles 2Θ, and this results in considerably reduced resolution at high scattering angles, particularly in neutron diffraction studies on polycrystalline materials. The practical

Academic Press, London 1965, p. 98.

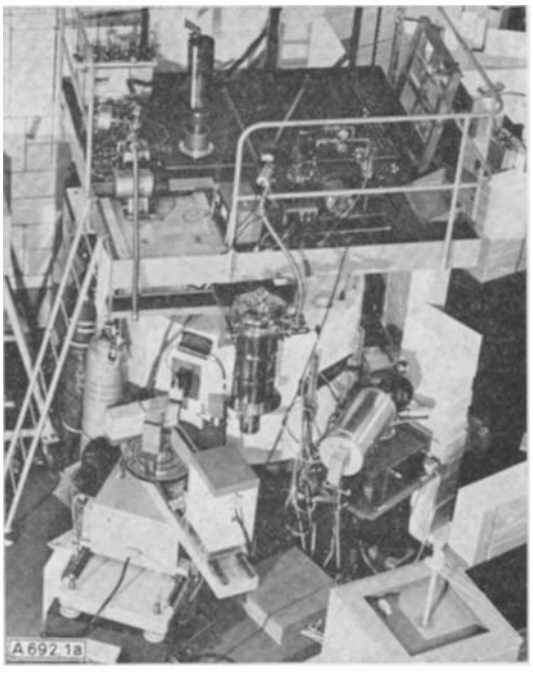

Fig. 1a. Twin neutron diffraction installation of the Technische Hochschule Darmstadt in front of the FR2 research reactor at the Kernforschungszentrum, Karlsruhe (cf. Fig. 1b). A ^{235}U fission chamber as a beam monitor which is used for both diffractometers, can be seen at the channel exit.

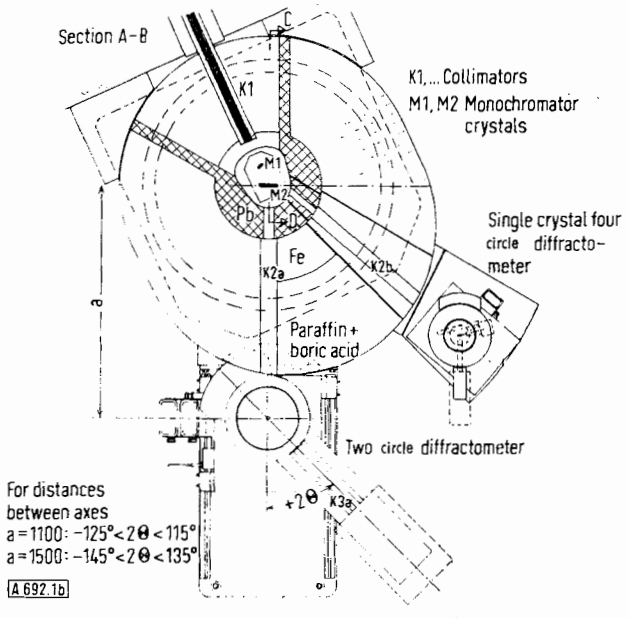

Fig. 1b. Schematic representation of the beam in the twin neutron diffraction installation shown in Fig. 1a. The "white" beam from the reactor is directed by a collimator K_1 to two differently positioned single-crystal monochromators M_1 and M_2, which deflect monoenergetic neutron beams to the two diffractometers [8a].

limit to the range of the measurements with the arrangement shown is therefore reached at a scattering angle of approximately 60–70° (because of the shorter wavelength ($\approx$1.0 Å), this is comparable to a scattering angle of about 100–120° in an X-ray Cu–K_α diagram). The resolution could be improved by having a large angle take-off (up to 90°) between the "white" and monochromatic beams [9], but such an arrangement is seldom possible because of the severely limited space available around reactors.

Neutron diffractometers are very similar to the instruments used for X-ray structure analysis. Depending on their application, we can distinguish single-crystal and powder diffractometers.

The four-circle single-crystal diffractometer shown in Figure 1 differs from an X-ray instrument only in having a heavy neutron counter (the weight resulting from the necessary screening) in place of an X-ray counter [10]. The instrument shown operates on the principle of the Eulerian cradle, which enables the crystal to be rotated about three axes – φ, χ, and ω – to any desired orientation in space. The counter can be rotated about a fourth axis – the 2Θ axis – to satisfy the Bragg reflection condition. The angle settings and data output are program-controlled (in this example with punched tape). The recent tendency is for these instruments to be controlled by small digital computers or by on-line operation with large computers.

Strictly speaking, powder diffractometers are one-circle instruments, since only the 2Θ circle is freely variable, while the Θ circle is coupled in the ratio of 2:1. The construction of these instruments is analogous to that of the Debye-Scherrer powder diffractometers used in the X-ray technique, but they are more robust to enable ancillary equipment such as furnaces and cryostats or magnets (to align the magnetic moments in the sample) to be attached to it.

Because of the high penetration of neutrons the temperature range from about 1.5 K° to about 1100 °C can be covered without difficulty in neutron diffraction experiments.

Figure 2 shows the Debye-Scherrer neutron diffraction diagram for Mg_2Si as an example of the form in which the results are recorded [11]. The neutron flux measured in the neutron counter was transmitted to a linear recorder parallel to the punched tape output. The intensity of the neutron beam is very low compared to the intensities produced by X-ray tubes, and the times required for neutron diffraction measurements are therefore rather long (about one hour per degree).

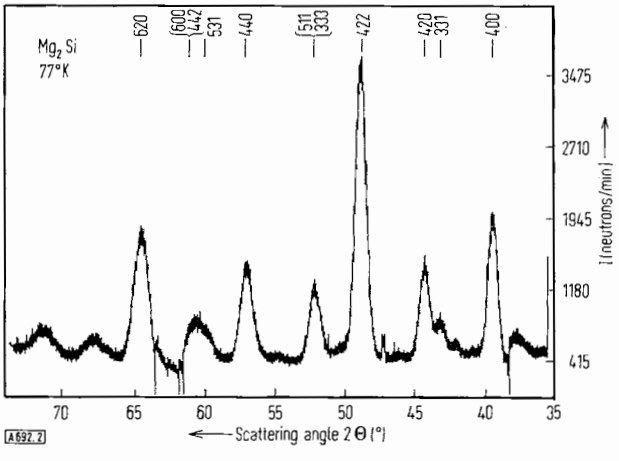

Fig. 2. Debye-Scherrer neutron diagram of Mg_2Si at 77 °K.

2.3. Detection of Neutrons

Since neutrons are uncharged, they can be detected only indirectly by collision processes or nuclear reactions. Until now mainly BF_3 counters have been used

[8a] *U. König*, Dissertation, Technische Hochschule Darmstadt 1967.

[10] For a detailed description of these automatic four-circle diffractometers the reader is referred to the extensive literature on X-ray structure analysis. Cf. *e.g. W. Hoppe*, Angew. Chem. *77*, 484 (1965); Angew. Chem. internat. Edit. *4*, 508 (1965).

[11] *G. Will*, unpublished.

in neutron diffraction experiments, the neutrons being recorded by means of the reaction:

$^{10}B(n, \alpha)^{7}Li$

High-pressure ^{3}He counters[12] operating at about 10 atm are also highly suitable as neutron detectors (their advantage is the very compact construction: 100% absorption with a length of only 3 cm), but have not yet found general acceptance. Uranium fission chambers have a special application as intensity monitors for the primary beam; these counters use the nuclear fission process in ^{235}U and are employed to balance variations in the neutron flux due to fluctuations in the reactor output.

Shull[13] developed a method of neutron photography in which ^{6}LiF and ZnS are used as a fluorescent screen. On neutron capture, ^{6}Li produces α-particles which in turn produce fluorescence in the ZnS, and these flashes are recorded on highly sensitive polaroid film. In principle it is therefore possible to photograph Laue and Debye-Scherrer diffraction patterns but these photographs can be evaluated quantitatively only with the aid of calibration curves. The method is therefore used only for alignment purposes; the exposure required for photographing the direct beam is about 5–10 sec. (A Laue photograph, of a germanium crystal, shown in[13] was exposed for 4 min. Development time is about 1 min. Limit of detection is about 15 neutrons per mm^2).

2.4. Physical Principles of Neutron Diffraction

The interaction of neutrons with matter when a beam of neutrons is incident on a crystal is determined essentially by two processes of approximately the same order of magnitude:

(a) interaction between the neutron and the atomic nuclei through the nuclear forces;

(b) magnetic interaction between the magnetic moment of the neutron and the magnetic moment of the unpaired electrons (in paramagnetic ions or atoms) through a classical dipole interaction. These interactions are of the order of 10^{-12} to 10^{-13} cm.

The nuclear scattering interaction between neutrons and matter is described by the "nuclear scattering length" b (measured in fermis; 1f = 10^{-13} cm). The scattering cross section σ (measured in barns; 1 barn $\equiv$ 10^{-24} cm^2) is related to the nuclear scattering length by the expression $\sigma = 4\pi b^2$. For comparison, the electromagnetic interaction between X-rays and the electric charges on shell electrons is of the order of 10^{-11} cm (1 electron $\triangleq$ 0.282×10^{-12} cm).

Whereas the scattering of X-rays increases in proportion to the atomic number Z, no such simple rule holds for the scattering of neutrons by nuclei, which can be represented by two processes: (1) the scattering of a plane wave at a rigid sphere (hard sphere or potential scattering), which increases with volume and thus with $\sqrt[3]{A}$ (where A is the mass number of the nucleus; cf. Fig. 3). More important than potential scattering is resonance scattering, in which the neutrons are captured and re-emitted by excited nuclei. This results in a random distribution of nuclear scattering amplitudes through the periodic system, depending on the nuclear energy levels (Fig. 3). Because of this resonance scattering different isotopes of the same element may exhibit marked differences in scattering power (isotope-specific scattering amplitudes): *e.g.* ^{58}Ni: b = 14.4 f, ^{60}Ni: b = 3.0 f, ^{62}Ni: b = −8.7 f; or ^{1}H: b = −3.78 f, ^{2}H: b = 6.5 f.

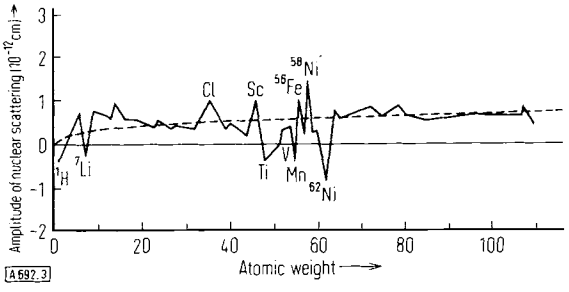

Fig. 3. Nuclear scattering amplitudes as a function of atomic weight. The monotonic curve for "potential scattering" of neutrons by the nuclei is shown by the dotted line.

Under certain conditions, namely when the neutron energy is smaller than the resonance energy of the nucleus, the resonance term in the scattering formula can be negative[14], and if at the same time the contribution of resonance scattering exceeds the potential scattering, the resultant nuclear scattering length b becomes negative. This means that there is no phase difference between the incident and scattered waves (a positive sign of b indicates a phase change of 180°, in analogy to X-ray scattering). The Fourier peaks for such nuclei with negative b values are thus negative in Fourier diagrams. Important nuclei with negative scattering lengths are ^{1}H: −3.78 f, Li (natural mixture): −1.8 f, ^{55}Mn: −3.6 f, ^{51}V: −0.5 f.

The nuclear scattering lengths, which are necessary for evaluation of diagrams must be determined by diffraction experiments on crystals having a simple structure, preferably an NaCl structure, because the energy levels of nuclei are not known with sufficient accuracy for theoretical calculations. The nuclear scattering lengths for natural isotope mixtures are made up of the contributions of the separate isotopes in proportion to their occurrence. The negative scattering length of lithium is thus principally determined by the isotope ^{7}Li with b = −2.1 f.

In contrast to X-ray scattering, which is strongly angle-dependent (atomic diameter $\approx$ 10^{-8} cm), the scattering

[12] *W. R. Mills, R. L. Caldwell,* and *I. L. Moragn,* Rev. sci. Instruments *33*, 126 (1962).

[13] *S. P. Wang, C. G. Shull,* and *W. C. Phillips,* Rev. sci. Instruments *33*, 126 (1962); *S. P. Wang* and *C. G. Shull,* J. physic. Soc. Japan *17*, Suppl. B-II, 340 (1962); *H. G. Smith,* Rev. sci. Instruments *33*, 128 (1962).

[14] The scattering of a neutron at an atomic nucleus was first treated by *G. Breit* and *L. E. Wigner,* Physic. Rev. *49*, 519 (1936), and is described by the Breit-Wigner formula – cf. *G. E. Bacon*: Neutron Diffraction. Clarendon Press, Oxford (1962).

of neutrons by nuclei does not depend on the angle of scattering (nuclear diameter $\approx 10^{-13}$ cm). The atomic form factor used in X-ray structure analysis is therefore unknown in neutron nuclear scattering, although magnetic scattering of neutrons is angle-dependent and is described by a magnetic form factor.

3. Evaluation of the Data

Crystal structure analysis with neutrons is very similar to an X-ray structure analysis. The intensity of a neutron wave scattered at a lattice plane (hkl) is proportional to the square of the crystallographic structure factor F_{hkl} for this plane, for which the following relation holds:

$$F_{hkl} = \sum_i b_i \, e^{2\pi i(hx_i + ky_i + lz_i)} \tag{3}$$

(the summation is carried out over all atoms i). This expression differs from the structure factor in X-ray diffraction only in the substitution of the nuclear scattering lengths b_i, which do not depend on the angle of scattering, for the angle-dependent atomic form factors f_i. The values of the structure factor F can therefore be determined from the measured reflection intensities by the same methods as in X-ray diffraction and Fourier series can be calculated.

$$\rho(xyz) = \frac{1}{V} \sum_{h=-\infty}^{+\infty} \sum_{k=-\infty}^{+\infty} \sum_{l=-\infty}^{+\infty} F_{hkl} \, e^{2\pi i(hx+ky+lz)} \tag{4}$$

Fourier inversion of the experimental structure factors with the correct signs or phases yields Fourier diagrams completely analogous to the electron density diagrams in X-ray structure analysis. The peaks in these diagrams naturally do not represent electron densities, but nuclear scattering densities; they indicate the positions of atomic nuclei in the unit cell. Since the nuclei have a diameter of the order of $10^{-13} - 10^{-12}$ cm and are thus about 10,000 times smaller than the diameter of the electron shells measured with X-rays, the observed diameter of the peaks (≈ 1 Å) is surprising. There are two reasons for this: (i) the thermal vibrations of the nuclei with a mean amplitude of about 0.1 Å and (ii) series-termination effects due to summation of the Fourier series over a finite number of terms. The size of the peaks in the Fourier diagrams is the resultant of these two effects.

Series-termination, which is much more pronounced in neutron diffraction diagrams than in X-ray diagrams, is known to result, in general, in small secondary peaks. In the X-ray diagram, each point in the electron cloud forms its own secondary peaks and these largely cancel out in the regions of low electron density between the atoms. In the neutron diagram on the other hand, the point nucleus is the only scattering center, and the only smearing is caused by thermal vibration. The region between the atoms in Fourier neutron diagrams is therefore very "disturbed" (cf. for example Fig. 8). The series-termination effects could be corrected by calculation, but the method is laborious [15], and this source of error is more easily eliminated by difference-Fourier synthesis, which is therefore more important in neutron diffraction than in X-ray diffraction. In a difference-Fourier calculation with only hydrogen left in the structure the only interference would then be from secondary peaks from the hydrogen atoms. It has been shown that the main effect of series termination lies not in secondary peaks but in the spread of these peaks. Thus, only difference-Fourier synthesis gives a reliable picture of structural details. In the ideal case, the Fourier space between the atoms should be zero between the peaks in neutron diffraction diagrams, and the peaks themselves should have circular symmetry. Deviations from spherical symmetry are thus interpreted as a direct indication of anisotropic thermal vibrations of the nuclei.

Since neutron diffraction analyses are generally a continuation of X-ray diffraction studies, the phases of the structure factors for calculating the Fourier series can be found from the models determined by X-ray methods. The problem of the phase determination is therefore less crucial than in X-ray structure analysis. Although there have been attempts to determine the phases directly from neutron diffraction data [16], these suggestions have not yet been applied in structure analysis. However, as in X-ray structure analysis, the neutron diffraction data are ultimately refined by least-squares methods to obtain the exact atomic thermal parameters.

4. Applications of Neutron Diffraction

The heavy expense involved in neutron diffraction experiments means that their use is justified only when other methods, particularly X-ray diffraction, fail to give satisfactory results. Neutron diffraction is important in:

1. Determination of the coordinates of light elements in the presence of heavy elements, particularly in locating hydrogen atoms: $Z_1 \gg Z_2$; $b_1 \approx b_2$.

2. Diffraction between isotopes or elements of neighboring atomic numbers: $Z_1 \approx Z_2$; $b_1 \neq b_2$.

3. Determination of the structure of crystals which absorb X-rays very strongly, for example lead and mercury compounds, or crystals which contain lanthanides or uranium:

$$\mu_{neutrons} \ll \mu_{X\text{-}rays}$$

4. Determination of the magnetic configuration, the moment distribution in the crystal, spin orientation, sublattice magnetization, and transition temperatures of crystals with magnetic ions.

5. Study of the thermal vibrations of atoms (nuclei).

[16] *J. Karle*, Acta crystallogr. *20*, 881 (1966).

A number of examples will now be presented to give a brief review of some of the problems in which neutron diffraction has been used with particular success in recent years. Studies on glasses, liquids, and gases and the extensive field of inelastic neutron scattering will not be discussed in this review.

4.1. Location of Hydrogen Atoms, Studies on Hydrogen Bonds

By far the greatest number of neutron studies on crystals (more than 50 papers) have been concerned with the location of hydrogen atoms, an application for which neutron diffraction is much superior to X-ray diffraction. The X-ray scattering power of hydrogen is so small that the detection of hydrogen in X-ray diagrams presents considerable difficulties and the results are subject to relatively large errors. However, the neutron-scattering power of hydrogen (b = −3.78 f) is comparable to that of other elements, so that the atoms can be detected more easily and the parameters determined more accurately. Nearly all of these studies are on single crystals, but the crystals to

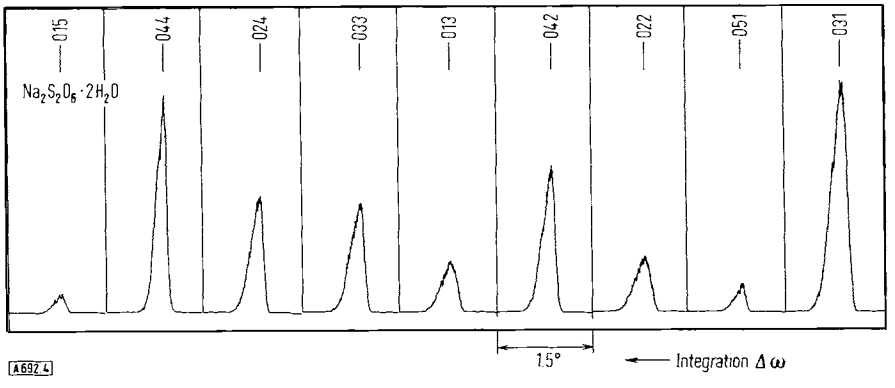

Fig. 4. Example of measurements on a single crystal of $Na_2S_2O_6 \cdot 2H_2O$. The time required for measurement is about 20 min per reflection, with an additional 5 min each for two measurements of the background intensity to the left and right of the reflection. (The crystal used weighed 0.58 g.)

be examined must be relatively large (several mm^3) because neutron fluxes are very low compared to the fluxes produced by X-ray tubes, and about 20–30 min is required to measure a single reflection, about ten times as long as in X-ray diffraction (see Fig. 4).

In the case of organic compounds with discrete molecules in the crystal, features of special interest are the molecular structure and the thermal behavior of the molecules or of molecular groups. Since the H atoms generally lie at the periphery of a molecule and are very light, their behavior provides information about the molecule as a whole. For example, in the oscillatory motion of a molecule the linear amplitudes of the H atoms are especially large because of the large distance of these atoms from the axis. Under certain circumstances, the relatively large thermal vibrations of the H atoms at room temperature can give rise to considerable errors in the apparent bond lengths; for instance, when the H atoms execute oscillations[17] or are to some extent coupled to the thermal vibrations of neighboring heavy atoms ("ride-on" motion[17]). A reliable knowledge of the temperature factors is required to allow for these effects in calculating the bond lengths, but since the effect of thermal vibrations is to reduce the intensity, at higher scattering angles, and in the case of X-ray diffraction this reduction is superimposed on the already rapidly decreasing form factor ($f(H) = 0.1$ when $\sin\Theta/\lambda = 0.45$ Å^{-1}), neutron studies are particularly valuable for detecting hydrogen atoms, and reliable studies on the thermal behavior of these atoms are possible only with the aid of neutrons. Moreover, it is relatively easy to make a fundamental change in the physical conditions under which the molecular vibrations are executed by replacing the hydrogen with deuterium (scattering length $b = 6.5f$), which is twice as heavy. Thermal vibrations can be further reduced by cooling. Because of the high penetration of neutrons, neutron measurements at low temperatures – *e.g.* 77 °K (liquid nitrogen) or 4.2 °K (liquid helium) – present no fundamental difficulties, although there is as yet no satisfactory means of programming the rotation of the crystal in three-dimensional space to the required angle settings φ and χ in a cryostat to satisfy the Bragg condition. Low-temperature studies are therefore at present mainly confined to projections on special crystallographic planes.

4.1.1. Benzene

Solid benzene was studied at −55 and −135 °C[18] (complementary to an X-ray structure determination at −3 °C[19]). It was found that benzene molecules execute angular oscillations in the ring plane about the sixfold axis which diminish rapidly with decreasing temperature; the RMS oscillations were 7.9, 4.9, and 2.5° at temperatures of −3, −55, and −135 °C. The C–H distance was found to be 1.077 Å at −55 °C and 1.09 Å at −135 °C. The mean C–C distance, corrected for thermal vibration, is 1.398 Å at both temperatures (Fig. 5).

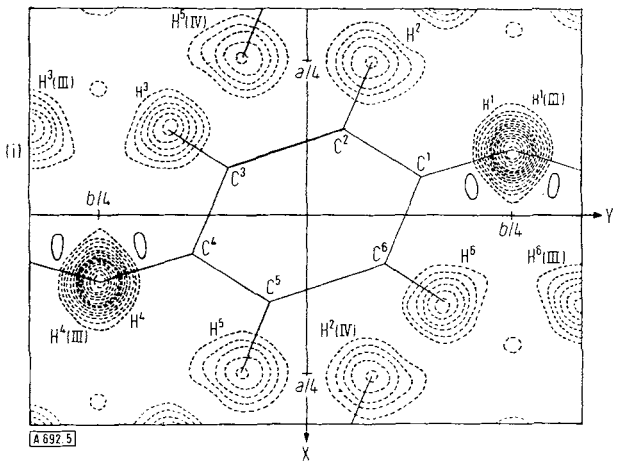

Fig. 5. Difference Fourier projection ($F_{obs}-F_{C_6}$) for benzene on the (001) plane at −135 °C. After subtraction of the C_6 skeleton, the diagram contains only the H atoms. These are indicated by dotted contours (negative regions) because of the negative nuclear scattering length of hydrogen.

4.1.2. Oxalic Acid Dihydrate

Although deuteration of a compound generally has no effect on the crystal structure, there are exceptions in the phenomenon described as the isotope effect. The best-known examples are potassium dihydrogen phosphate [20], resorcinol [21], and oxalic acid dihydrate [22]. Oxalic acid dihydrate was studied both by X-rays and neutrons in the form of $(COOH)_2 \cdot 2\ H_2O$ and $(COOD)_2 \cdot 2\ D_2O$, and thus provides a very good example for comparison. The crystal data for the two forms are given in Table 1.

Table 1. Crystallographic properties of oxalic acid dihydrate and [D_6]-oxalic acid dihydrate.

		$(COOH)_2 \cdot 2\ H_2O$ [23] (α form)	$(COOD)_2 \cdot 2\ D_2O$ [24] (β form)
a	(Å)	11.88	10.021
b	(Å)	3.60	5.052
c	(Å)	6.12	5.148
β	(°)	103.5	99.27
Space group		$P2_1/a$	$P2_1/a$
Z		2	2
V	(Å³)	254	257

The oxalic acid molecules are practically identical in the two structures: they are planar (distance of the D atoms from the plane through the carbon/oxygen atoms 0.02 Å) and have a center of symmetry. The only difference is in the hydroxyl groups, in which the O–D bond length (1.042 Å) is much shorter than the O–H bond length (1.057 Å). In contrast, the bond lengths in the water molecules are equal: O–D = 0.946 Å and 0.960 Å, O–H = 0.945 Å and 0.968 Å, although the angles are different: ∢ DOD = 110.5 °, ∢ HOH = 105.7 ° (∢ DOD in ice = 109.5 °). The hydrogen bonds O–H...O are not of the symmetric type, and in both structures the ^1H or ^2H atom is definitely associated with the carboxyl group. The hydrogen bonding appears to be weaker in the per-deuterated addition compound than in the un-deuterated form (O–H...O = 2.491, 2.518 Å; O–D... O = 2.540 Å). There is no direct relationship between the two structures, and for a long time no α ⇌ β phase change was observed. It is only recently that $(COOH)_2 \cdot 2\ H_2O$ has been prepared in the β form [25], and it remains to be seen whether the bond lengths in the two modifications are identical. The isotope effect in these crystals is possibly due to the considerable shortening of the hydrogen bonds in deuterium, for the major effect of the replacement of H by D is the difference in the zero-point energy, and the higher zero-point energy of the proton results in a reduction of bond length on the substitution O–H → O–D. There is also an effect on the strength of the hydrogen bonding. In the case of oxalic acid dihydrate this energy difference would appear to be so large that it cannot be compensated by merely stretching the hydrogen bond, and thus produces a phase change in the crystal structure.

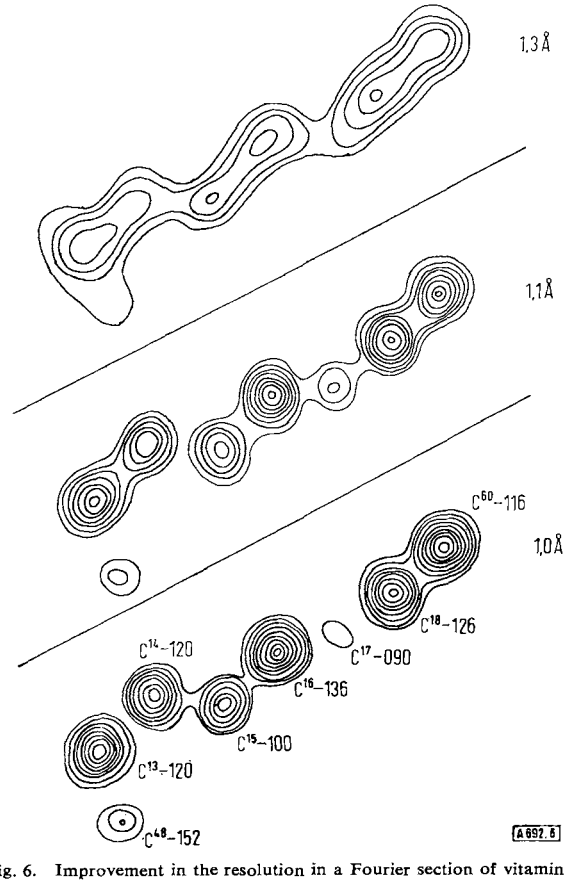

Fig. 6. Improvement in the resolution in a Fourier section of vitamin B_{12} at $y = 0.120b$ (part of diagram). It is not possible to distinguish individual atoms at a resolution of 1.3 Å; complete separation is achieved at 1.0 Å. The numbers next to the assignment of the atoms' identity give the y-coordinates in units of $10^3\ y/b$ [27].

4.1.3. Vitamin B_{12}

The most complicated molecule yet studied by neutron diffraction is a monocarboxylic acid derivative of cyanocobalamin with the empirical formula $C_{63}H_{87}O_{15}N_{13}PCo \cdot 16\ H_2O$ [26]. This compound forms monoclinic crystals with space group $P2_1$; the dimensions of the unit cell are $a = 14.915$ Å, $b = 17.486$ Å, $c = 16.409$ Å and $\beta = 104.11°$. As in X-ray structure analysis of proteins, measurements were first made on this vitamin B_{12} complex at a reduced resolution of 1.3 Å ($d > 1.3$ Å) and the results were subsequently refined at an increased resolution of 1.0 Å. The improvement achieved by the increased resolution is shown in Fig. 6 [27].

This example is also an impressive illustration of the work involved in such studies. For the 1.3 Å resolution 2000 independent reflections had to be measured, of which 1531 (*i.e.* three-quarters) were classed as observable ($I > \sigma(I)$, where $\sigma(I)$ is the standard deviation of the measured intensity I). However, since there are 820 parameters to be determined in the structure, identification of the atoms is difficult with 2000 reflections (Figures 7a and 7b). The resolution was therefore increased to 1.0 Å in the second stage of the experiment; 4400 reflections were measured, and 3000 of them had an intensity $I \geq \sigma(I)$. At approximately 30 min per reflection, the measurements took about 25 weeks. The crystal weighed 11 mg.

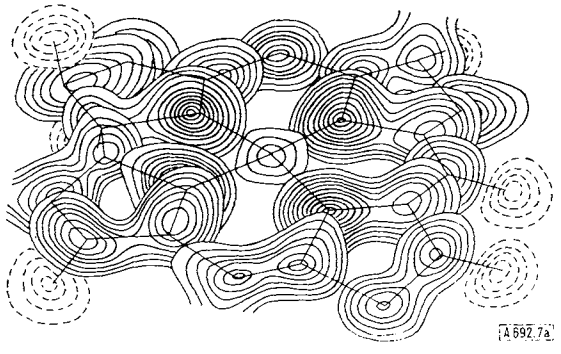

Fig. 7a. Three-dimensional superimposed neutron scattering density of the corrin unit in vitamin B_{12}. The central Co atom appears in the neutron Fourier diagram (resolution 1.3 Å) as a "light" atom because of its relatively low nuclear scattering length. H nuclei are negative (dotted contour lines).

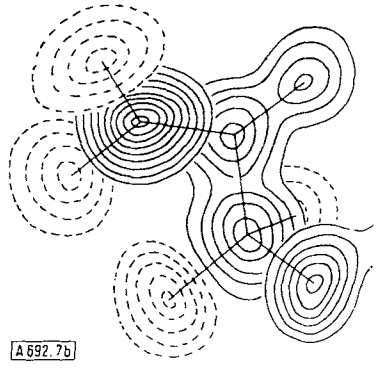

Fig. 7b. Neutron scattering density of the acetamide group at C^7 (cf. [26]). C and N can be distinguished unambiguously because of their different scattering lengths (b(C) = 6.61 f, b(N) = 9.40 f).

An X-ray structure analysis was carried out in parallel with the neutron diffraction measurements [28]. In these studies Bijvoet pairs of reflections [29] from the anomalous dispersions of cobalt were employed to determine the basic features of the crystal structure, and served to provide the preliminary model for analyzing the neutron data. The Patterson diagram of the neutron data was also calculated, but could not be interpreted for obvious reasons: with neutrons, hydrogen cannot be neglected in the vector diagram, and the neutron Patterson diagram for this complex thus contains about 52 000 peaks per formula unit, compared to 11 880 (neglecting H) in the X-ray Patterson diagram. Moreover, in the X-ray diagram the 108 interaction vectors of the Co atom with the C, N, O, and P atoms are about five times the magnitude of the vectors between the C, N, and O atoms, whereas with neutrons all nuclei have scattering powers of comparable orders of magnitude and produce similar Patterson peaks. In contrast, the cobalt nucleus is a "light" atom in the neutron Fourier diagram (Fig. 7a) because of the small scattering length of cobalt ($b = 2.5$ f).

The high incoherent background scattering from hydrogen poses particular difficulties in structure analyses on compounds containing hydrogen. This is essentially due to the nuclear-spin incoherence, resulting from the different possible orientations of the neutron spin ($I_n = 1/2$) to the nuclear spin ($I_{1_H} = 1/2$), and is particularly large in the case of hydrogen (about 34 barns). By comparison, the coherent scattering cross-section of hydrogen is only 1.79 barns. The situation is much more favorable with deuterium ($I_{2_H} = 1$), which has an incoherent scattering cross-section of about 2.2 barns. The signal-to-noise ratio in the measurements on the hydrogen-containing vitamin B_{12} complex thus averaged only 1.3:1, a relatively very low value.

4.1.4. Hydrogen Bonds in Inorganic Compounds

There have been a number of neutron diffraction studies on salts containing water of crystallization aimed at determining the position and nature of the hydrogen bonds in these crystals. Straight and bent O–H...O bonds have been found, as well as bifurcations and hydrogen atoms not involved in any bonding. A strict classification into different types is not, however, possible. A review of the results [30] shows that the position of the H_2O molecules is clearly determined by the electrostatic fields of the surrounding ions, so that there is no point in distinguishing between different types of hydrogen bonds. Other reviews [31, 32] contain correlation diagrams of the observed O–H and O–H...O distances.

The C–H distances determined by neutron diffraction are approximately an order of magnitude more accurate than the values found by X-ray diffraction. It is noteworthy that NMR and neutron diffraction meas-

urements, which record the distances between atomic nuclei, generally give consistent values for C–H distances (1.06–1.10 Å), whereas X-ray diagrams, which define the centers of electron charge distribution, give values that are systematically about 0.2 Å shorter (the calculations already allow for the effects of thermal vibrations). Polarization of the H atoms and displacement of the H electron density toward the neighboring C atom is one possible explanation, although the shorter C–H distances could also be due to systematic errors in evaluating the X-ray data. This latter point has been frequently mentioned [32]. Possible sources of this kind of error include inaccurate form-factor curves for hydrogen or departures of the electron distribution of the C atoms from spherical symmetry.

4.2. Ferroelectricity

The advantages of neutron diffraction measurements are particularly important in structural studies on ferroelectric crystals, and in fact only neutron diffraction studies give meaningful results with such crystals. Ferroelectric crystals are known to exhibit spontaneous polarization below a characteristic temperature (the ferroelectric Curie point). This effect is associated with small displacements of individual atoms in the crystal structure. The ferroelectric transition is therefore always associated with a crystallographic phase transition to a crystal class with pyroelectric symmetry. A knowledge of the structural changes involved in this transition is required to understand ferroelectricity. The displacements are very small, and since the effect is essentially a change in the position of light atoms in the neighborhood of heavy atoms, it is necessary to detect small contributions to the scattered intensities. Since all elements have comparable neutron scattering powers, it is easier and more accurate to detect these small changes in parameters with neutrons than with X-rays. Neutron scattering power does not depend on the scattering angle, and neutron studies therefore have the additional advantage that sufficient intensity is observed at high scattering angles, at which the structure factors, and hence the intensities, are particularly sensitive to small changes in the parameters.

The most important ferroelectric crystals that have been studied with neutrons are $BaTiO_3$, KH_2PO_4, and $NaKC_4H_4O_6 \cdot 4\,H_2O$ (Rochelle salt). $BaTiO_3$ has three ferroelectric phases. Above the Curie point, it forms cubic crystals with the simple perovskite structure (Ti at the center of the cell, Ba at the corners of the cube, and O at the centers of the cube faces). On cooling there is a first transition at 120 °C to a tetragonal modification, with spontaneous polarization along the *c*-axis. At 5 °C a second phase change is observed to an orthorhombic form in which the dipoles are aligned parallel to the (cubic) [110] direction. Finally, at −90 °C there is a third transition to a rhombohedral form.

Highly accurate measurements on the tetragonal form were first made by *Evans* [33], using X-ray methods. These measurements were refined down to an *R* factor of 3.7%. However, in spite of this excellent agreement of the structure factors, the structure itself remained undetermined. It was later recognized that there were fundamental reasons why this should be so, for the thermal vibrations along the ferroelectric *z*-axis are correlated to the coordinate displacements along this axis. (The ions are displaced out of their special sites along the *c*-axis by 0.05 Å.) *Shirane* [34] discussed the reasons for this correlation in detail. It is due partly to the extremely high X-ray scattering power of barium and partly to the basic difficulty in distinguishing small changes in coordinates from the thermal vibration of atoms in a structure with pseudocentral symmetry because of the simultaneous and competing decreases in the scattering power with both the X-ray form factor, *f*, and the temperature factor, $\exp -2B(\sin\Theta/\lambda)^2$. The situation is much more favorable with neutron scattering, which is independent of the angle of scattering, and the structure of the tetragonal phase of $BaTiO_3$ was finally determined with neutrons [35].

The difficulties described can be illustrated by considering, for example, the pair of reflections (h0l) and (l0h). Such reflections are equivalent in the cubic structure: $I(h0l) = I(l0h)$, but not in the tetragonal phase: $I(h0l) \neq I(l0h)$. In X-ray diffraction, only very slight differences in intensity are observed because of the small differences in scattering power of the elements, whereas with neutrons the differences are large and very distinct; for example, for the pair of reflections (104) and (401) the differences are respectively 3 and 70%. A preliminary neutron diffraction study was limited to a projection with 50 reflections (h0l) measured in the zone (010). However, in spite of an excellent *R* factor there was again an initial high correlation between z_{Ti} and β_{33}(Ba), the anisotropic temperature factor for barium, which describes motion along the *z*-axis. The relationship between the parameters was practically linear. The measurements were then extended to the reflections (hhl), and the inclusion of this additional zone eliminated the correlation and led to an unambiguous determination of the structure. The final analysis used 84 reflections in the two zones (h0l) and (hhl). The crystal structure of the orthorhombic modification was then also determined at 1 °C by neutron diffraction [36].

The spontaneous electric polarization in $BaTiO_3$ is the result of a displacement of the Ti^{4+} ions by 0.13 Å along the polar axis inside the oxygen octahedra, which experience only slight distortion themselves. In the orthorhombic lattice the Ti–O distances along the polar axis are 1.90 and 2.11 Å, and perpendicular to the axis 2.00 Å. In the tetragonal phase the Ti–O

[36] *G. Shirane*, *H. Danner*, and *R. Pepinsky*, Physic. Rev. *105*, 856 (1957).

distances along the polar axis are 1.86 and 2.17 Å; perpendicular to this axis there are four oxygen ions at a distance of 2.00 Å (displacement of the Ti^{4+} ions along [001] by 0.05 Å). The essential finding – for the orthorhombic phase as well – is that the oxygen octahedra remain practically undistorted and that the displacement of the Ti^{4+} ions inside the octahedra must be considered responsible for the ferroelectric properties.

Difficulties of an entirely different nature arose during X-ray studies on Rochelle salt when it was found during the measurements that there were changes in structure due to irradiation [37,38]. In this case too, a structure determination was possible only with the aid of neutrons. Above its Curie point (24 °C), Rochelle salt crystallizes to form orthorhombic crystals with the space group $P2_12_12$. On transition to the ferroelectric state, the axis of symmetry 2_1 parallel to the *b*-axis vanishes, and the crystal symmetry therefore becomes monoclinic with the space group $P2_1$. As a result of the change in symmetry, new reflections with the indices (0k0) are allowed, where k is an odd integer. However, these reflections are so weak that they cannot be observed with X-rays. The ferroelectric behavior of Rochelle salt was therefore assumed to be due to a slight displacement of the hydrogen atoms. This assumption was first confirmed by neutron diffraction studies in which the (0k0) reflections with $k = 2n + 1$ were measured at the phase change [39]. However, further neutron diffraction measurements on a deuterated crystal [37] showed that, although

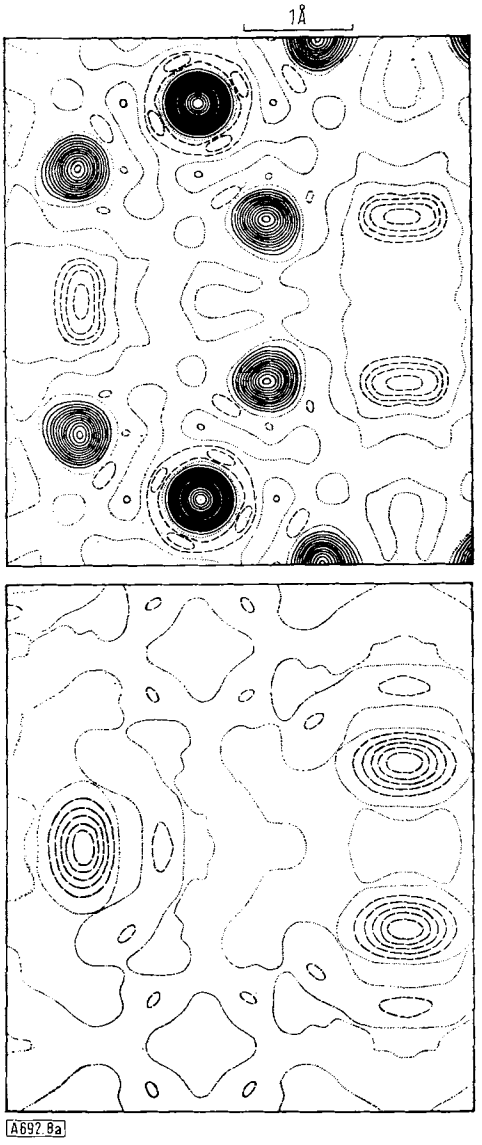

Fig. 8a. Neutron Fourier diagram (F_{obs}, top) and difference Fourier diagram.
($F_{obs}-F_{KPO_4}$, bottom) for KH_2PO_4 above the ferroelectric Curie temperature. Projection on the (001) plane, recorded at 20 °C; tetragonal symmetry. There is a distinct spread of the hydrogen nucleus density in the direction of the oxygen atoms.

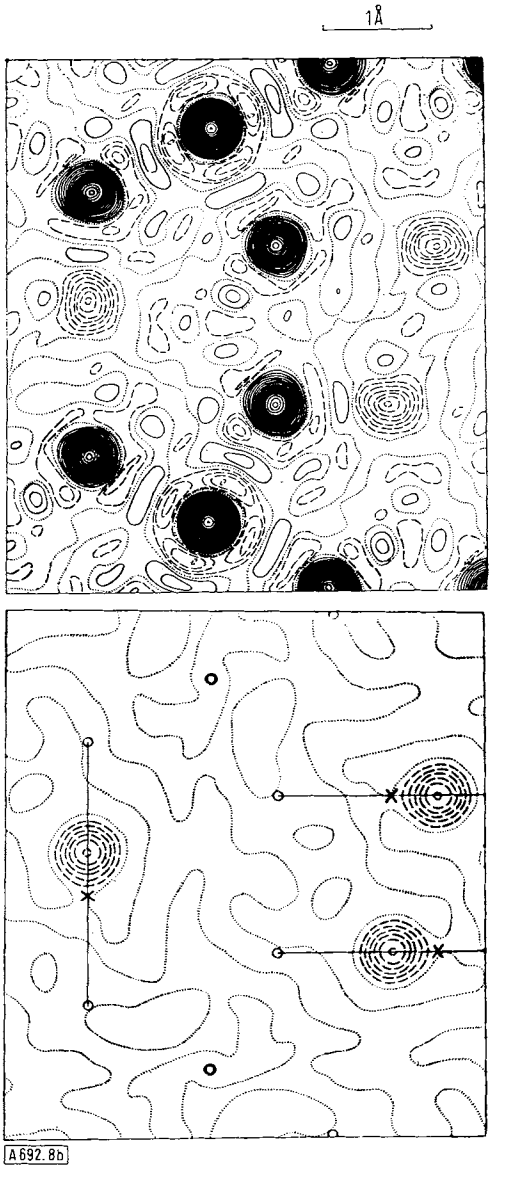

Fig. 8b. Fourier diagram (top) and difference Fourier diagram (bottom) for KH_2PO_4 in the ferroelectric state. Recorded at −180 °C, analogous to Fig. 8a; orthorhombic symmetry. There is a clear displacement of hydrogen nuclei in the direction of the applied external field toward neighboring oxygen ions. Reversal of the field produces displacement in the opposite direction.

[39] *B. C. Frazer*, *M. McKeown*, and *R. Pepinsky*, Physic. Rev. *94*, 1435 (1954).

some hydrogen atoms are displaced, this is not by itself sufficient to explain the symmetry change and hence the ferroelectric properties.

The first compound to be analyzed by Fourier methods was potassium dihydrogen phosphate, KH_2PO_4, which has a ferroelectric Curie point at −123 °C. Neutron diffraction measurements were made on single crystals of KH_2PO_4 above (20 °C)[15] and below (−180 °C)[40] the transition temperature. From the observed changes in the reflections and the Fourier diagrams the ferroelectric properties of this salt can be attributed to the arrangement of the H atoms in the O−H...O hydrogen bonds perpendicular to the *c*-axis between the PO_4 tetrahedra (Fig. 8).

The arrangement of the H atoms depends on the direction of the external electric field. Reversal of the field causes reversal in the hydrogen bonds. This effect can be followed by direct observations of sensitive pairs of reflections. Above the transition temperature both equilibrium positions are occupied on the statistical average, and the hydrogen peaks therefore appear in the Fourier diagram as spread-out ellipsoids (Fig. 9).

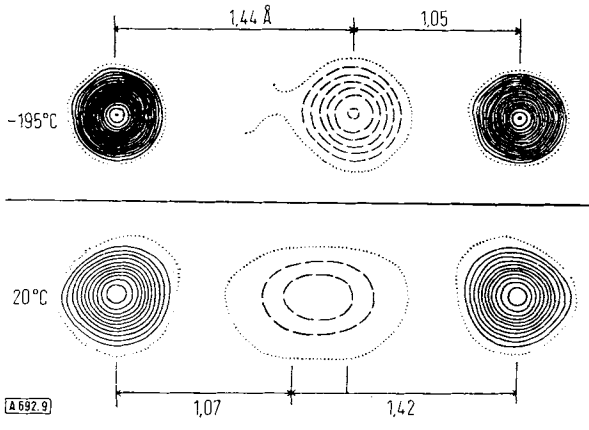

Fig. 9. Comparison of the hydrogen distribution in the hydrogen bonds of KH_2PO_4 above and below the ferroelectric Curie point.

4.3. Differentiation between Elements with Neighboring Atomic Numbers

The X-ray scattering powers of neighboring elements in the periodic table differ very little or not at all (*e.g.* $Mn^{2+} \triangleq Fe^{3+}$, $Mg^{2+} \triangleq Al^{3+}$), so that it is difficult or even impossible to determine their positions in the unit cell reliably from X-ray diffraction diagrams. The situation is quite different with neutron scattering. For example, V, Cr, Mn, Fe, and Co (Z = 23, 24, 25, 26, 27) have nuclear scattering lengths b = −0.5f, 3.5f, −3.6f, 9.6f, and 2.5f respectively. With few exceptions, all elements of similar atomic number can be distinguished without difficulty by neutron diffraction. Nickel (b = 10.3f) differs only slightly from iron (b = 9.6f) when the natural mixtures of isotopes are used. However, in unfavorable cases like this it is possible in principle to use pure or enriched isotopes (*e.g.* ^{57}Fe with b = 2.3f and ^{62}Ni with b = −8.7f); it is then always possible to locate the elements in the structure by appropriate selection. *Walker* and *Keating*[41] took advantage of this isotope specificity of nuclear scattering in studies on the short-range order in β-CuZn (β-brass) by using a crystal enriched with ^{65}Cu, which gave reflection differences seven times greater than with the natural crystal.

4.3.1. Ferrites

Ferrites are of technical interest because of their magnetic properties. They form cubic crystals with a spinel structure, space group Fd 3 m, with eight formula units XY_2O_4 in the unit cell. In the holes between the oxygen ions we distinguish between "A" or tetrahedral sites, which are surrounded by oxygen tetrahedra, and "B" or octahedral sites surrounded by oxygen octahedra. These tetrahedral and octahedral sites can be occupied by either 8 X^{2+} ions on the A sites and 16 Y^{3+} ions on the B sites (normal spinel) or 8 Y^{3+} on the A sites and 8 X^{2+} + 8 Y^{3+} on the B sites (inverted spinel). A continuous transition between these forms is possible. The distribution of the di- and trivalent cations is described by the degree of inversion x, which can be determined most reliably from neutron diffraction measurements. An additional parameter in ferrites is the oxygen coordinate u. The oxygen ions are displaced from their ideal positions u = 3/8, and once

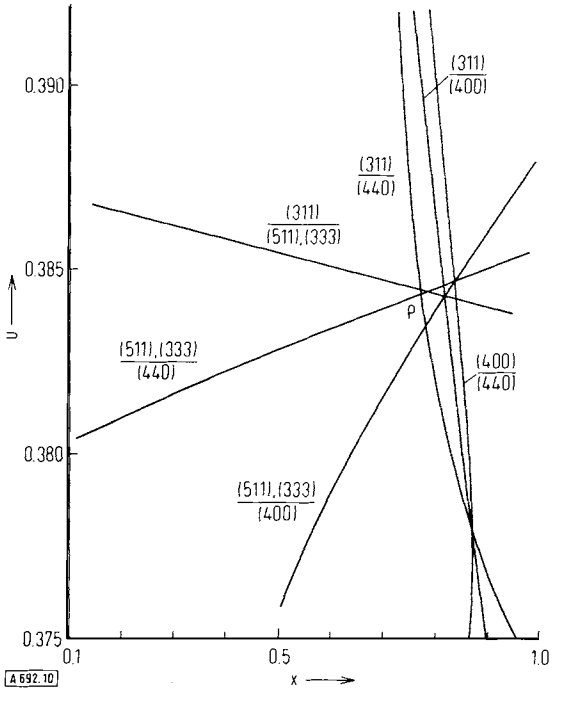

Fig. 10. Intensities of different pairs of reflections from $MnFe_2O_4$ as a function of the degree of inversion x and of the oxygen parameter u, for determining x and u by the method proposed by *Hastings* and *Corliss*[43].

[40] *G. E. Bacon* and *R. S. Pease*, Proc. Roy. Soc. (London), Ser. A *230*, 359 (1955); *S. W. Peterson, H. A. Levy*, and *S. H. Simensen*, J. Physique *21*, 2084 (1953); Physic. Rev. *93*, 1120 (1954).

[41] *C. B. Walker* and *D. T. Keating*, Physic. Rev. *130*, 1726 (1963).

[42] *L. M. Corliss, J. M. Hastings*, and *F. G. Brockman*, Physic. Rev. *90*, 1013 (1953).

[43] *J. M. Hastings* and *L. M. Corliss*, Physic Rev. *104*, 328 (1956).

again the exact oxygen parameters can be determined more accurately from neutron diffraction diagrams than from X-ray diffraction diagrams because of the relatively large scattering length of oxygen. The investigation of ferrites is therefore a two-parameter problem to determine x and u. A graphical method of solution has been proposed by *Hastings* and *Corliss* [42]. As example, Fig. 10 shows the results for $MnFe_2O_4$ [43], with $u = 0.3846 \pm 0.0003$ and $x = 0.81 \pm 0.03$ ($x = 1$ for normal spinel).

In this representation the intensity is calculated as a function of x and u for different pairs of reflections and compared with the observed values. The curves for the separate pairs all cut at or near a particular point which defines the parameters x and u. Other important ferrites studied by this method include $MnCr_2O_4$ [44], with $u = 0.3892 \pm 0.0005$ and $x = 1.00 \pm 0.01$ (normal spinel), Fe_2TiO_4 [45] with $u = 0.386 \pm 0.001$ and $x = 0.91 \pm 0.01$, and $MgFe_2O_4$ [42] with $u = 0.3817$ and $x = 0.87$.

Differentiation between Mg and Al in classical spinel, $MgAl_2O_4$, can also be accomplished only with neutrons, since Mg^{2+} and Al^{3+} (like Mn^{2+} and Fe^{3+} in $MnFe_2O_4$) have equal X-ray scattering powers and therefore cannot be distinguished by X-ray methods. Neutron diffraction studies [46] showed that $MgAl_2O_4$ is essentially a "normal" spinel ($u = 0.387 \pm 0.001$). All these measurements were made on polycrystalline samples.

4.3.2. Cyanides

Neutron diffraction measurements were carried out on cyanides in order to differentiate between the elements C and N and to determine the exact structure parameters in the presence of heavy elements. It was found that in $Hg(CN)_2$ it is the carbon and not the nitrogen atom that links the cyanide group to the metal [47]. The same was obtained for $K_3[Co(CN)_6]$ [48], in which the cobalt ion in the $[Co(CN)_6]^{3-}$ octahedron complex is surrounded by six cyanide ions in the order Co–C–N. An analysis on KCN, which forms cubic crystals with sodium chloride structure, was initially interpreted as indicating that the CN groups in the crystal rotate freely [49]. However, another study [50] showed that the data were more in accord with a model in which the CN groups are statistically oriented in [111] directions. Single-crystal neutron diffraction studies on $K_2[Zn(CN)_4]$, which also forms cubic crystals, conclusively disproved a model with freely rotating CN groups [51]. The sequence of the cyanide ion coordination in this compound is Zn–C–N–K–N–C–Zn. The Zn–C–N groups are linear with a C–N distance of 1.157 ± 0.009 Å.

4.3.3. Carbides

Location of the C atoms in the heavy metal carbides having the formulas MC_2 and M_2C_3 is very imprecise by X-ray diffraction in the presence of the heavy metal atoms. Typical examples are CaC_2, LaC_2 and UC_2 [52], which all form body-centered tetragonal crystals with space group I4/mmm; M = (000; $\frac{1}{2}\frac{1}{2}\frac{1}{2}$), C = (000; $\frac{1}{2}\frac{1}{2}\frac{1}{2}$) ± 00$z$ (C11a-type structure). In this structure (Fig. 11) pairs of C atoms lie parallel to the c-axis in a dumbbell arrangement between pairs of metal atoms. The free position parameter z can be determined very accurately from neutron diffraction diagrams, and from this the C–C distance can be found.

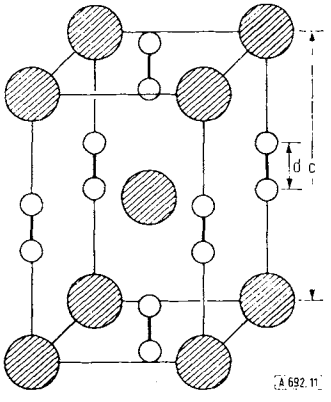

Fig. 11. Tetragonal structure of heavy metal carbides of the general formula MC_2 (with C–C groups along the C – axis between the metal atoms). ◎ = M, O = C.

For CaC_2, a C–C distance of 1.191 ± 0.009 Å was found in this way; this corresponds to the triple bond length in acetylene (the less precise X-ray structural analysis gave a value of 1.4 Å). In UC_2 on the other hand, the C–C distance is 1.340 ± 0.007 Å, corresponding to a C–C double bond. These values fit in well with the view that CaC_2 is an ionic crystal with discrete Ca_2^+ and C_2^{2-} ions, whereas UC_2 has metallic properties and U^{4+} ions in its crystal structure. LaC_2 and many lanthanide carbides such as CeC_2, TbC_2, YbC_2, LuC_2, and YC_2 have a mean C–C distance of 1.278 ± 0.002 Å and therefore occupy an intermediate position between the two extremes of CaC_2 and UC_2. This means that the C–C distance in carbides increases with increasing valence of the metal cation, and that carbides can be descibed generally as $M^{II}C_2$, $M^{III}C_2$, and $M^{IV}C_2$ (corresponding to CaC_2, LaC_2, and UC_2). It can be further shown by analysis of paramagnetic scattering that the metal ions in LaC_2 and the rare earth metal carbides are in the M^{3+} ground state.

[52] *M. Atoji*, J. chem. Physics *35*, 1950 (1961); J. physic. Soc. Japan *17*, Suppl. B-II, 395 (1962); *M. Atoji* and *R. C. Medrud*, J. chem. Physics *31*, 332 (1959); *M. Atoji*, *ibid.* *46*, 1891 (1967).

Therefore, one electron has been transferred to the conduction band (YbC_2, with $Yb^{2,8+}$, is an exception). In general, carbides of this type can therefore be represented as MC_2 with $M = M^{n+}$, $C_2 = C_2^{2-}$ and $n-2$ electrons in the conduction band.

Sesquicarbides form bcc crystals with space group $I\bar{4}3d$ (structure type $D5_c$), with free metal and carbon parameters. The C–C distance in La_2C_3, Pr_2C_3, and Tb_2C_3 [53] was found to be 1.238 Å, and in Ce_2C_3 1.276 Å. Taken with the results of an analysis of paramagnetic scattering, this leads to the conclusion that in Ce_2C_3 only 65% of the cerium ions are in a $^2F_{5/2}$ state as Ce^{3+}, with 35% as Ce^{4+} in the diamagnetic $^1S_0$ state. It follows that in both sesquicarbides and dicarbides the C–C distance increases with increasing valence of the metal.

UC_2 has also been studied with neutrons at 1700 and 1900 °C [54], and the results confirmed a transition from a tetragonal to a cubic phase at 1820 °C [55]. Above 1820 °C, UC_2 crystallizes in a NaCl type structure, with the C–C groups either rotating freely or randomly aligned in the [111] directions between the metal ions.

4.4. Investigation of Thermal Vibrations in Crystals

As with X-ray diffraction, the intensity in neutron diffraction diagrams decreases with increasing scattering angle 2 Θ owing to the thermal vibration of the atoms. This thermal vibration is described by the Debye-Waller factor B, and the observed intensity is given by the equation

$$I = I_0.K.L.A.F^2.e^{-2B\left(\frac{\sin\Theta}{\lambda}\right)^2} \quad (5)$$

where I_0 is the intensity of the incident primary beam, K is an apparatus constant, L the Lorentz factor, A the absorption factor, and F the structure factor from equation (3). It can be shown that the temperature factor B is related to the mean thermal amplitude of the atoms, u:

$$B = \frac{8}{3}\pi^2\langle u^2\rangle \quad (6)$$

so that a knowledge of B provides information about the thermal vibrations of the atoms.

Determination of the temperature factor B from X-ray diffraction diagrams is difficult and unreliable because in this case there is an additional drop in intensity due to the angle-dependent form factor f, so that the reflections in an X-ray diagram always become small at large values of 2Θ. A precise determination of B from X-ray diffraction data requires separation of these two effects, and this means that the electron distribution around an atom in the crystal should be known. (The form factor is the Fourier transform of the electron distribution of an atom.) In neutron diffraction diagrams, on the other hand, apart from the well-known effect of the Lorentz factor (for measurements on single crystals $L = 1/\sin 2\Theta$), the drop in intensity is due entirely to the thermal vibrations of the atoms and ions, and $2B(\sin\Theta/\lambda)^2$ varies linearly with $\ln|I|$.

Detailed studies were carried out on UO_2, ThO_2 [56], and CaF_2 [57], all of which crystallize with a fluorite structure. Between room temperature and 1100 °C the anions in single crystals of UO_2 and ThO_2 execute anisotropic thermal vibrations, preferentially in the [111] direction toward neighboring cations and increasing in amplitude with increasing temperature. This anisotropic thermal vibration in a crystal with cubic symmetry is surprising, for in a cubic system the ellipsoid of vibration, which generally describes the anisotropic temperature factors, reduces to a sphere. However, anisotropic effects are seen very clearly with neutrons when two or more reflections at the same scattering angle 2 Θ are studied, *e.g.* the reflections (755), (771), and (933). Such reflections show clear differences in intensity, increasing with increasing temperature, which can be interpreted only in terms of an anisotropic vibration of the anions along the cube diagonals. This behavior is described by introducing a "tetrahedral smearing function" which displaces the ions from their equilibrium positions by time-averaged small distances δ (about 0.08 Å at 1000 °C). The physical reason for this behavior is considered to be an anharmonic interaction between neighboring ions. (Similar intensity differences are seen with such reflections in X-ray diffraction diagrams, but in this case the differences are of different physical origin due to departures from spherical symmetry in the charge distribution of the electrons, particularly along the direction of the bonds [58]. The effect of the asymmetric charge distribution is much more pronounced than that of anisotropic thermal vibration.)

The measurements on UO_2 were recently repeated at 20 °C with higher accuracy [59]. It was possible to record reflections up to $\sin\Theta/\lambda = 1.08$ Å^{-1}; the resulting structure factors were accurate to 0.5% and the R factor was 0.32%. Neutron measurements of this accuracy are laborious, but they are quite possible and not particularly difficult. The fluorine ions in CaF_2, which was studied between room temperature and 500 °C, must also be assumed to execute anisotropic thermal vibrations in the [111] direction to accord with the experimental data. BaF_2, SrF_2, and Mg_2Si

would be expected to behave analogously; Mg_2Si with a nuclear scattering length ratio (which determines the accuracy) of $b_{Si}:b_{Mg} = 0.693$ would be a particularly suitable experimental material ($b_u:b_0 = 1.440$).

A question of fundamental interest is whether the electron shells vibrate synchronously and with the same amplitude as the atomic nuclei. In a neutron diffraction study on fcc cobalt ($Co_{0.92}Fe_{0.08}$)[60], indications were found that the thermal behavior of the atomic nucleus possibly differs from that of the electron cloud. The measurements were made using polarized neutrons which enable very accurate determination of the ratio of the nuclear scattering amplitude $b.e^{-2W_n}$ to the magnetic scattering amplitude $p.e^{-2W_m}$ [$W = \frac{8}{3}\pi^2.\langle u^2\rangle(\sin\Theta/\lambda)^2$][61]. Differing results obtained at room temperature and 600 °C are due either to a change in the electron distribution (and hence in the form factors) of the 3d electrons at high temperature, or to differences in the behavior of W_n and W_m. Evaluation of the experimental data for the second case show that the mean square amplitude of the 3d electron shell at 600 °C is only 37% of the amplitude of the nucleus: $\langle u^2\rangle_m = 0.37\ \langle u^2\rangle_N$. This would mean that the "magnetic" electrons do not follow the thermal vibrations of the nucleus as if they were rigidly attached to it, but vibrate with a smaller amplitude.

4.5. Anomalous Dispersion

Brief mention should also be made of the phenomenon of anomalous dispersion. In X-ray diffraction this is known to result in violation of Friedel's law, with $I_{hkl} \neq I_{\bar{h}\bar{k}\bar{l}}$. Similar effects can be observed in neutron diffraction when a resonance line of the nucleus lies in the energy range of thermal neutrons. In such cases scattering is accompanied by a discontinuous phase change significantly different from 180° ($+b$) or 0° ($-b$), and the nuclear scattering amplitude assumes the complex form:

$$b = b_0 + \Delta b' + i\Delta b''$$

where $\Delta b'$ and $\Delta b''$ are correction terms for the real and imaginary components. The imaginary term $\Delta b''$ is directly proportional to the total scattering cross section. The effect is therefore particularly large for such elements as ^{113}Cd, ^{149}Sm, and ^{157}Gd. For these elements, $\Delta b''$ at resonance is greater than 47f[62]. Since $\Delta b'$ and $\Delta b''$ are strongly energy-dependent, the nuclear scattering lengths of these elements are generally wavelength-dependent. Anomalous dispersion of neutrons has been demonstrated experimentally in CdS, BP, and $^6Li_2SO_4 \cdot H_2O$[62]. These compounds crystallize with structures having no centers of symmetry, so that pairs of planes hkl and $\bar{h}\bar{k}\bar{l}$ scatter with different intensities.

For example, the nuclear scattering length of Cd at $\lambda = 1.075$Å was found to be $b = (3.8 + 1.2\,i)$f; the effect is even more pronounced at $\lambda = 0.68$ Å, corresponding to the ^{113}Cd resonance line: $b = (7.2 + 6.6\,i)$ f. (The resonance energy of ^{113}Cd is 0.178 eV ≙ 0.68 Å.) In a sample enriched with ^{113}Cd the imaginary part of the scattered amplitude ($\Delta b'' \approx 47$f) finally becomes larger than the real part.

As in X-ray diffraction, the method of anomalous dispersion is of principal importance in determinations of the absolute configuration of polar compounds by measurements of Bijvoet pairs of reflections[29]. However, the resonance lines of most nuclei are well below 1 Å, and practical application of this method will not be possible until neutron beams with wavelengths of the order of 0.1 Å and sufficiently high intensity are available. (The projected high-flux reactor at Grenoble has provision for a beam tube for neutrons of this short wavelength.)

5. Concluding Remarks

In addition to the applications of neutron diffraction selected for this review, there are others of equal importance, for example in studies on alloys, particularly of the transition metals, where again neighboring 3d elements make it difficult to determine the state of order by X-rays, or in studies on ammonium halides and on hydrides, particularly metal hydrides – *e.g.* those of Cu, Hf, Ti, Zr, and Pd, as well as ThH_2, ThD_2, ZrD_2 and UD_3. There is also no space for a detailed discussion of structure determinations on compounds of Pb, Hg, or the lanthanides. X-ray structure analysis on these compounds is difficult because of their strong absorption of X-rays.

Almost all these measurements are done on powder preparations. It has been found that the data obtained from neutron powder diffraction are much more informative than X-ray powder data, because the nuclear scattering lengths of the elements are comparable and the heavy elements which interfere with X-ray measurements are mostly confined to special sites. Powder analyses are naturally restricted to simpler structures with few parameters (up to ten), *e.g.* the perovskite-like structures of orthoferrites[63]. In recent years computer programs have been developed to utilize all the measurable peaks, which in powder diagrams generally result from the superposition of several planes. The programs enable the atomic parameters to be refined by least-squares methods from the observed intensities without it being necessary to resolve the peaks first into their components. This method is similar to the analysis of the structure of single crystals from structure factors. We have used it successfully in studies on $LaFeO_3$, $LaCrO_3$, $MnSO_4$, $MnSeO_4$, $NiSeO_4$, $CoSeO_4$, $ErPO_4$, and $ErVO_4$.

Aryldiimine as an Intermediate during Reduction of Diazonium Salts with Tetrahydridoborate

By *M. Bloch, H. Musso,* and *U. I. Záhorszky*[*]

Dedicated to Professor H. Bredereck on the occasion of his 65th birthday

Aryldiazonium salts may be reduced to the corresponding hydrocarbons by complex hydrides in methanol at 0 °C[1]. The hydrogen introduced can be transferred from various sources as anion, radical, or proton. To discriminate between these possibilities, we treated bimesityl-3,3'-bis(diazonium) bis(tetrafluoroborate) *(1)* in methanol with sodium tetrahydridoborate; in each case the reducing agent or the solvent was deuterated in a different manner (98–99% D). The deuterium content of the resulting bimesityl, which could be isolated in approximately 22% yield by chromatography, was determined by mass spectrometry (± 1%).

(1)

Table 1. Dependence of the deuterium content of the bimesityl on the reaction conditions

	$NaBD_4$ CH_3OH	$NaBD_4$ CD_3OD	$NaBH_4$ CD_3OD	$NaBH_4$ CH_3OD	$4NaOCH_3$ CH_3OD	$4NaOCH_3$ CD_3OD
$[D_0]$-Bimesityl (%)	96	8	7	16	95	63
$[D_1]$-Bimesityl (%)	3	34	36	42	4	33
$[D_2]$-Bimesityl (%)	0	57	57	43	1	4.5
% D	2	74	75	64	3	21

As is evident from Table 1, it is not the hydrido hydrogen that appears in the product but the acidic proton of the methanol to the extent of about 85%.

Since the diazonium tetrafluoroborate *(1)* is stable for two hours in methanol at room temperature, the tetrahydridoborate must first reduce the diazonium salt to the aryldiimine. The latter compound then rapidly exchanges the N–H proton with the solvent and decomposes mainly *via* the diimine anion to give nitrogen and an aryl anion, which abstracts a proton or deuteron from the solvent, thus yielding the hydrocarbon[2,3].

$$Ar{-}N{\equiv}N^{\oplus} + NaBH_4 \rightarrow Ar{-}N{=}NH \overset{\pm H^{\oplus}}{\rightleftharpoons}$$

$$Ar{-}N{=}N^{\ominus} \rightarrow Ar^{\ominus} + N_2 \xrightarrow{+H^{\oplus}} Ar{-}H$$

In acetonitrile, the bimolecular decomposition of phenyldiimine was formulated as a free-radical process and an isotope effect $k_H/k_D = 4$–5 was observed[4]. The difference between the third and fourth columns of Table 1 shows that with hydride in methanol only about 15% of aryl radicals are formed that abstract hydrogen from the C–H bond. In the reaction with 4 mol. equiv. of non-deuterated sodium methoxide the percentage of radicals increases markedly (columns 5 and 6).

We attribute incomplete deuteration (75 and 21%) in $[D_4]$-methanol with $NaBD_4$ and with sodium methoxide, respectively, to the isotope effect[3,4] and to water present in compound *(1)*. If the salt is prepared in D_2O up to 85% deuteration is achieved.

About 10% of 3,3'-difluorobimesityl containing no deuterium and 8% of 3-fluorobimesityl (also deuterated) were obtained as by-products. Decomposition of *(1)* in boiling methanol affords 75% of 3,3'-difluorobimesityl and 13% of 3-fluoro-3'-methoxybimesityl (oil), but no bimesityl.

Experimental:

3,3'-Diaminobimesityl (270 mg) are diazotized in 20% hydrochloric acid (1.1 g) with $NaNO_2$ (138 mg) in water (1 ml) at 0 °C; the filtered solution is treated with $NaBF_4$ (330 mg) in water (0.8 ml) and the resulting precipitate is filtered off after 30 min. The salt (350 mg), which is washed with 5% $NaBF_4$ solution (0.2 ml), cold methanol (0.2 ml), and ether (1 ml) successively and dried over P_2O_5 for 5 h under vacuum, is suspended in methanol (2 ml) and treated at 0 °C, with stirring, with $NaBH_4$ (80 mg); heat is evolved during the reaction. After 2 h the reaction mixture is extracted with *n*-hexane and the residue obtained after evaporation of the solvent is separated by layer chromatography on silica gel (Merck PF 254) with light petroleum (60–70 °C) into three zones. After scraping the compounds off the plate they are eluted and finally sublimed under high vacuum: bimesityl (40 mg, 22% calc. w.r.t. *(1)*, $R_f = 0.57$, m.p. 101 °C); 3,3'-difluorobimesityl (20 mg, 10%, $R_f = 0.67$, m.p. 127 °C); 3-fluorobimesityl (15 mg, 8%, $R_f = 0.61$, m.p. 109 °C).

New Rearrangements during the Reaction of Pyrylium Salts with Nitromethane

By *K. Dimroth* and *G. Laubert*[*]

Dedicated to Professor H. Bredereck on the occasion of his 65th birthday

Whereas 2,4,6-trisubstituted pyrylium salts, and those carrying a greater number of substituents, are converted smoothly into nitrobenzene derivatives by nitromethane and an *excess* of base[1], reaction with only *one mol. equiv.* of base adopts a different course, especially in chlorobenzene, dichloroethane, or ethanol. Thus, 2,4,6-triphenylpyrylium tetrafluoroborate *(1a)* affords 2,4,6-triphenylphenol *(5a)*, 2,3,5-triphenylphenol *(8a)*, and 2,4,6-triphenylnitrobenzene *(6a)*. In a similar manner, 2,3,4,6-tetraphenylpyrylium tetrafluoroborate *(1b)* gives *(5b)*, *(8b)*, and *(6b)*.

If it is assumed that primary attack of the nitromethyl-anion on C-2 or C-6 to give *(2)* is followed by an intramolecular aldol condensation to yield the intermediate *(3)*, then the experimental findings may be interpreted as follows: Formation of the phenols *(5)* proceeds *via* 1,3-nitro-nitroso ester rearrangement to *(4)* and aromatization with subsequent hydrolysis of the phenol nitroso ester. The phenols *(8)* arise by a migration of the aryl group R^1 from C-2 to C-1 with

	R^1	R^2	R^3	R^4	(5) m.p. (°C)	(5) yield (%)	(6) m.p. (°)	(6) yield (%)	(8) m.p. (°C)	(8) yield (%)	(9) m.p. (°)	(9) yield (%)
(a)	C_6H_5	H	C_6H_5	C_6H_5	149–150 [2]	36	142–143 [1]	5	162–163	2	157	14
(b) [a]	C_6H_5	C_6H_5	C_6H_5	C_6H_5	244–245 [3]	7	216–217 [3]	19	272–273 [4]	5	309–310 [5, 6]	60
(c) [a]	$C_6H_4OCH_3$ [4]	C_6H_5	C_6H_5	C_6H_5	195–196	2	200–201	8	193–194	24	192–193	63

[a] Solvent: ethanol; base: triethylamine; 2 hours' reflux.

loss of $NO_2^{\ominus}$ and aromatization, whereas the normal formation of nitrobenzene to yield *(6)*, which proceeds without rearrangement, requires initial loss of the proton on C-1.

The intermediate *(3)* is not isolable. However, we have previously succeeded in isolating a similar, extremely labile intermediate having NO_2 and C_6H_5 attached to C-1 [3]. This compound undergoes not only a 1,3-nitro-nitroso ester rearrangement but also a 1,3-nitro rearrangement, which we were not able to observe in the present case.

The 1,2-aryl shift is favored by the presence of electron-donating substituents in the migrating aryl group. If the pyrylium salt *(1c)* is subjected to this reaction instead of the pyrylium salt *(1b)*, then the phenol *(8c)* is obtained in 24% yield instead of the phenol *(8b)* (5%). In the action of nitromethane on pyrylium salts the new rearrangements lead directly to phenols, which, depending on their substitution, are converted by oxidation into stable phenoxy radicals in the case of *(5)*, and into 1,4-quinones *(9)* in the case of *(8)*. In view of its simplicity and of the high overall yield, the new rearrangement process, which leads from *(1a)* to *(5a)* in *one step*, is certainly competitive with the multi-step process starting from *(6a)* [2].

Procedure

Ethyldiisopropylamine (1.9 g, 15 mmole) is added dropwise to a suspension of *(1a)* (5.9 g, 15 mmole) in chlorobenzene (60 ml) and nitromethane (3.7 g, 60 mmole) and the reaction mixture is refluxed for 15 h, during which nitrous fumes are evolved. The precipitated ammonium salt and unreacted pyrylium salt (2.21 g) are filtered off, and the filtrate is concentrated under vacuum and chromatographed on silica gel (benzene/cyclohexane 3:2). Crystallization from ethanol affords *(6a)* (0.30 g, 5%), *(5a)* (1.76 g, 36%), and *(8a)* (0.097 g, 2%), which is recrystallized from benzene/light petroleum.

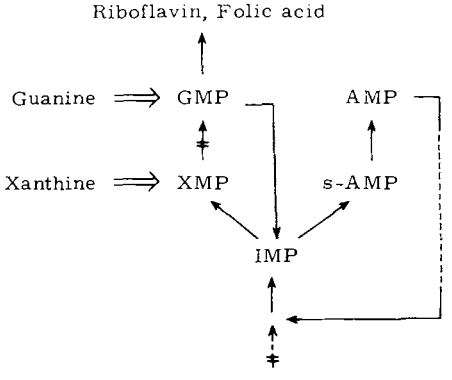
The Structure of the Purine Precursor in Riboflavin Biosynthesis [**]

By *A. Bacher* and *F. Lingens* [*]

Dedicated to Professor H. Bredereck on the occasion of his 65th birthday

Although the involvement of a purine in riboflavin (vitamin B_2) *(2)* biosynthesis has repeatedly been confirmed, the structure of the actual precursor compound has hitherto not been determined [1,2].



Studies on *Eremothecium ashbyii* [3] and riboflavin-less mutants of *Saccharomyces cerevisiae* [4,5] have suggested the

Scheme 1. Intermediates in the biosynthesis of riboflavin.

sequence of intermediates as shown in Fig. 1. The structural similarity of *(1)* and guanine seems to indicate that riboflavin is derived from a guanine compound. This assumption could be proved by experimental work on a purine-deficient mutant.

We started from a polyauxotrophic mutant exhibiting several genetic defects in the biosyntheses of the aromatic amino acids, namely *Aerobacter aerogenes* 62-1 [6]. Following treatment with 1-methyl-3-nitro-1-nitrosoguanidine (MNNG) we obtained a mutant 62-1 A showing a poorly defined genetic block in the common pathway of purine biosynthesis. Further exposure of this mutant to MNNG permitted isolation of a new mutant 62-1 AB exhibiting an additional block between xanthosine monophosphate (XMP) and guanosine monophosphate (GMP) (Fig. 2).

Scheme 2. Biosynthesis of purines in *Aerobacter aerogenes* according to *Magasanik* and *Karibian* [7] and genetic defects (=) of mutant 62-1 AB in purine metabolism. s-AMP = succinyladenosine monophosphate. => conversions of exogenic purines.

Feeding this mutant with purine bases results in the accumulation of riboflavin and xanthosine. After incubation of mutant 62-1 AB with ^{14}C-labeled purines according to Table 1, we found that [2-^{14}C]-xanthine is converted into xanthosine, but not into riboflavin. This means that riboflavin is not derived from a compound at the level of xanthine.

Table 1. Incorporation of radioactively labeled guanine or xanthine into xanthosine and riboflavin.

Added purines (mg/l)		Rel. activity (R. A.) [a] Xanthosine	Riboflavin
[2-^{14}C]-Guanine	5		
Adenine	5		
Hypoxanthine	10	1.6	89
Xanthine	8		
[2-^{14}C]-Xanthine	10·7		
Adenine	5	51	0.3
Guanine	5		

[a] R. A. = $\frac{\text{Sp. activity of isolated compound}}{\text{Sp. activity of proffered compound}} \times 100$

As expected, [2-^{14}C]-guanine is converted into riboflavin without significant dilution. Although adenosine monophosphate (AMP) and inosine monophosphate (IMP) may originate from guanine [7], these compounds can be excluded as precursors of riboflavin since in the presence of unlabeled adenine and hypoxanthine no significant isotope dilution takes place. This leads to the conclusion, confirmed by the results of accumulation studies [5], that riboflavin is derived from a compound at the level of guanine. It remains to be seen whether this substance is free guanine, a riboside, or ribotide.

Tetracarbonyldiphosphanemolybdenum(0)

By *C. G. Barlow*, *E. A. V. Ebsworth*, and *G. C. Holywell* [*]

In view of the recent interest in complexes of transition metals with PH_3 [1,2], and of the preparation of tetracarbonylbisphosphinemolybdenum(0) from phosphine and tetracarbonylnorbornadienemolybdenum(0) [3], we have investigated the reaction between tetracarbonylnorbornadienemolybdenum(0) and P_2H_4 in pentane. At 0 °C a pale yellow microcrystalline solid separated over a period of an hour.

The infrared spectrum of this compound between 4000 and 200 cm^{-1} contains peaks in the regions associated with CO stretching, Mo–C–O bending, and Mo–C stretching; besides these, there were bands near 2200 cm^{-1}, near 1100 cm^{-1}, and at lower frequencies, which shifted to *ca.* 1600 cm^{-1} and 800 cm^{-1} in the spectrum of material prepared from P_2D_4 and which we assign to PH_2 stretching and bending modes. The C, H, and P analyses are in satisfactory agreement with the formulation of the compound as $P_2H_4Mo(CO)_4$. The compound is very slightly soluble in carbon disulfide, but we have been unable to obtain the proton resonance spectrum.

In the mass spectrum the fragments of the greatest mass appear to correspond to ions derived from $Mo(CO)_4(P_2H_4)_2$; there are groups of peaks at lower *m/e* ratios apparently corresponding to successive loss first of all four carbonyl groups and then of the four PH_2 groups. We therefore conclude that the compound should be represented as $[P_2H_4Mo(CO)_4]_x$, where x may be 2 or more.

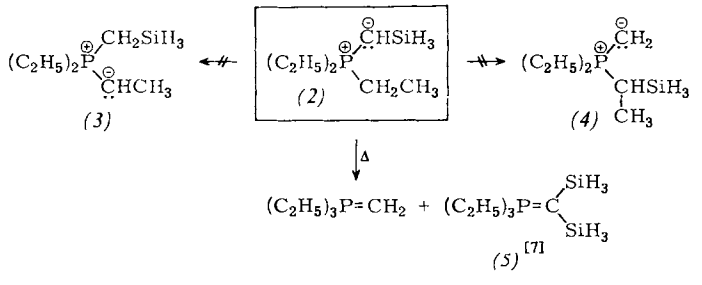
New Evidence for a (p→d)π Effect at Silicon [1]

By *H. Schmidbaur* and *W. Malisch* [*]



Recent investigations on model substances have clearly established that alkylsilyl substituents stabilize the carbanion function of phosphorus ylids to a surprisingly high extent [1–4].

This stabilizing effect is in contrast to the quite obvious destabilizing effect of simple alkyl groups on these anionic groups[5]. Only the *tert*-butyl group exerts an influence akin to that of trialkylsilyl groups. This led *Seyferth et al.*[2] to reject an interpretation that attributes the stabilizing properties of silyl substituents on ylidic carbanions to a ($2p_C \rightarrow 3d_{Si})\pi$ effect, although they and other authors[3,4] had originally preferred this explanation. The objection that the observed phenomena could be attributed solely to steric effects[2] could not initially be discounted.

In order to come to a decision we have now undertaken the synthesis of silyl-substituted ylids containing simple silyl (H_3Si-) instead of the extremely bulky trialkylsilyl groups. The following scheme shows a typical preparative procedure.

The critical last step is to be interpreted as a "transylidation" of triethyl(silylmethyl)phosphonium chloride *(1)* by triethylethylidenephosphorane. This reaction yields tetraethylphosphonium chloride and triethyl(silylmethylene)phosphorane *(2)* almost quantitatively, thus proving the thermodynamic preference of the latter over the possible alternative product diethyl(ethylidene)(silylmethyl)phosphorane *(3)*.

[7]

Earlier experiments with substituted and unsubstituted ylids have shown that the proton migration necessary for the conversion of *(2)* into *(3)* (particularly in the presence of the corresponding salt) is kinetically feasible[4]. Even a silyl migration *(2)* → *(4)* would be conceivable if it were thermodynamically advantageous[1,5]. However, isomerization of *(2)* to *(3)* or to *(4)* could be induced neither thermally nor catalytically.

There is no explanation for the preference of *(2)* over the other isomers on the basis of steric hindrance, nor of a simple inductive effect in the σ skeleton. In this and in many other cases the concept of a $(p \rightarrow d)\pi$ interaction currently represents the most promising theoretical model[6].

Procedure:

$ClCH_2SiH_3$ (2.7 g, 34 mmole) is added over a period of 1 h to $(C_2H_5)_3P$ (4.02 g, 34 mmole) with cooling (methanol/Dry Ice). At −30 °C quantitative formation of quaternary salt takes place spontaneously in an exothermic reaction to yield *(1)* (6.7 g) as a white crystalline powder, m.p. > 340 °C. IR: $\nu_{as}SiH_3$ 2180 cm^{-1}. ^{1}H-NMR ($CDCl_3$, 60 MHz, TMS as external reference[8]): δSiH_3 −240, dt, J(HCSiH) 4, J(PCSiH) 8.2; δCH_2Si −151, dq, J(PCH) 16; δCH_3CH_2 −161, dq, J(PCH) 13, J(HCCH) 7.5; δCH_3 −88, dt, J(PCCH) 18.

$(C_2H_5)_3PCHCH_3$ (3.7 g, 25.4 mmole) is added to a suspension of *(1)* (5 g, 25.4 mmole) in ether (50 ml) and the mixture is stirred for 20 days at room temperature with exclusion of air. The solid reaction product $[(C_2H_5)_4P]Cl$ is filtered off and the ether removed from the filtrate under vacuum, whereupon compound *(2)* remains as a colorless, spontaneously inflammable liquid (78% yield): b.p. 36–38 °C/5 × 10^{-4} torr, mol. wt. (cryoscopic, benzene) 169 (calc. 162.3). IR: $\nu_{as}SiH_3$ 2090 cm^{-1}. ^{1}H-NMR (pure liquid, TMS as external reference[8]): δSiH_3 −239, dd, J(HCSiH) 4, J(PCSiH) 8.5; δCH +89, dq, J(PCH) 7; δCH_2 −92, dq, J(H_2CP), 10.5; δCH_3 −59, dt, J(HCCP) 16.5, J(HCCH) 7.7.

In a similar manner we obtained:

$(CH_3)_3P{=}CH{-}SiH_3$, m.p. −16 °C, mol. wt. 115.2 (calc. 120.2). IR: $\nu_{as}SiH_3$ 2100 cm^{-1}. ^{1}H-NMR (benzene, TMS as external reference): δSiH_3 −2.45, dd, J(HSiCP) 10.4 Hz, J(HSiCH) 3.8 Hz; δCH +77, dq, J(HCP) 6; δCH_3P −26, d, J(HCP) 12.5 Hz.

$(CH_3)_3P{=}C(SiH_3)_2$, m.p. 11–13 °C, b.p. 24–25 °C/4 × 10^{-2} torr, mol. wt. 143.5 (calc. 150.3). IR: $\nu_{as}SiH_3$ 2102. ^{1}H-NMR (see above): δSiH_3 −241.5, d, J(HSiCP) 10.2 Hz; δCH_3 −19.5, d, J(HCP) 12.5; $J(^1H^{13}C)$ 127.5 Hz, $J(^1H^{29}Si)$ 189 Hz.

$FXeOTeF_5$: A Derivative of Xenon Difluoride

By *F. Sladky*[*]

Xenon difluoride reacts with oxyacids such as $HOSO_2F$, $HOClO_3$, and $HOPOF_2$ in the molar ratio 1:1 with elimination of HF.

The xenon-containing intermediate products are thermally unstable and decompose into the corresponding complex peroxides and oxides ($S_2O_6F_2$, Cl_2O_7, $P_2O_3F_4$)[1].

Pentafluoroorthotelluric acid[2], however, quantitatively yields a stable xenon-containing reaction product:

$$XeF_2 + HOTeF_5 \rightarrow FXeOTeF_5 + HF$$

Fluoroxenon pentafluoroorthotellurate is a pale yellow liquid (b.p. 53 °C/0.01 torr; m.p. −24 °C) which can be distilled without decomposition in a glass apparatus under vacuum. IR (liquid film between AgCl plates; 4000–400 cm^{-1}): 768 (s), 704 (vs), 623 (s), 520 (m), and 470 cm^{-1} (m). The ^{19}F-NMR spectrum indicates a value of 37 ppm for δ_{TeF} in the AB_4 part of the $OTeF_5$ grouping and a value of 66.3 ppm for δ_{XeF} (CF_3COOH as external standard).

$FXeOTeF_5$, like XeF_2 [3], can give up a fluoride ion to acceptors such as AsF_5:

$$FXeOTeF_5 + AsF_5 \rightarrow [F_5TeOXe]^+[AsF_6]^-$$

Reaction of $FXeOTeF_5$ with CsF proceeds *via* two routes in almost equal proportions:

$$FXeOTeF_5 + CsF \begin{cases} \nearrow TeF_6 + (FXeO^-Cs^+) \rightarrow CsF + Xe + {}^1/_2O_2 \\ \searrow XeF_2 + Cs[OTeF_5] \end{cases}$$

Experimental:

All reactions were followed gravimetrically and tensimetrically in easily weighable Kel–F reaction vessels fitted with Kel–F taps. Vacuum manipulations were carried out in a Monel system. The XeF_2 used in the experiments was prepared photolytically [4]. Reaction of 2.35 g (13.9 mmole) of XeF_2 with 3.33 g (13.9 mmole) of $HOTeF_5$ yields 5.20 g of $FXeOTeF_5$, yield 96%.

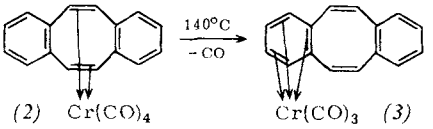
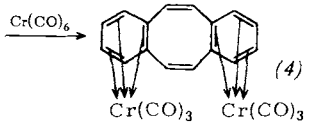
Dibenzo[*a,e*]cyclooctene Complexes of Chromium and Molybdenum

By *J. Müller, P. Göser*, and *M. Elian* [*]

Most of the π-aromatic complexes of chromium are considerably more stable than its π-olefin complexes. For instance, reaction of $Cr(CO)_6$ with 1,4-diphenylbutadiene leads exclusively to tricarbonyl(1,4-diphenylbutadiene)chromium(0) *(1)* [1,2].

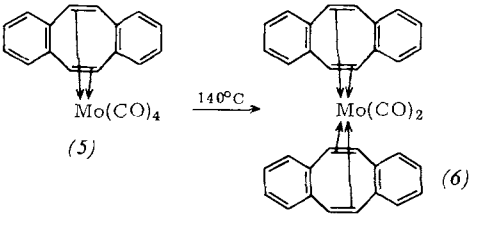


(1)



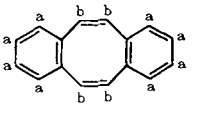
For steric reasons the olefinic π-electron system of dibenzo[*a,e*]cyclooctene [3] (= L) seems to be considerably better able to form complexes with chromium than is that of butadiene, and by its use we have been able to provide the first example of π-aromatic and π-olefin complexes from one ligand.

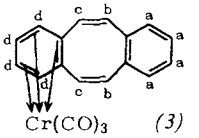
If the compound (L) is treated with tris(acetonitrile)tricarbonylchromium(0) [4] in 5–6-fold excess in di-*n*-butyl ether for 2 hours at 40 °C at water-pump vacuum and the ether is then removed and the residue eluted with warm hexane, the resulting solution affords crystals of the yellow tetracarbonyl(dibenzo[*a,e*]cyclooctene)chromium(0), $LCr(CO)_4$ *(2)*, m.p. 141–143 °C, in 90% yield (calculated on L). This can be sublimed almost without decomposition at 80–100 °C in a high vacuum and is thermally more stable than tetracarbonyl(1,5-cyclooctadiene)chromium(0) [5]. However, when heated in *n*-decane or di-*n*-butyl ether at 140 °C, *(2)* loses CO during 1.5 hours to form yellow tricarbonyl(dibenzo[*a,e*]cyclooctene)chromium(0), $LCr(CO)_3$ *(3)*, m.p. 168–170 °C, that is purified by chromatography on silicagel in benzene and recrystallization from methylene chloride/hexane.



Complex *(3)* is apparently more stable than *(2)*. That the latter is formed first under mild conditions shows that less activation energy is required for complex formation of chromium with the olefinic π-electrons of ligand L (it is not necessary to compensate for the loss of resonance energy).

Heating this product *(3)* for 20 hours with a large excess of $Cr(CO)_6$ in di-*n*-butyl ether enables a further $Cr(CO)_3$ group to be introduced, thereby giving the orange, non-sublimable μ-dibenzo[*a,e*]cyclooctene-bis[tricarbonylchromium(0)], $LCr_2(CO)_6$ *(4)*, which can be purified in the same way as *(3)* (decomp. above 170 °C).





Treating an excess of tris(acetonitrile)tricarbonylmolybdenum(0) [4] with L in dioxane at 35 °C/15 torr for 2 hours gives a 65% yield (calculated on L) of tetracarbonyl(dibenzo[*a,e*]cyclooctene)molybdenum(0), $LMo(CO)_4$ *(5)*, which forms pale greenish-yellow crystals of m.p. 170 °C (decomp.). It has not yet proved possible to convert this into a complex analogous to *(3)*; instead, heating it in di-*n*-butyl ether for 6–8 hours leads to separation of decomposition products and formation of the lime-green *cis*-dicarbonylbis(dibenzo[*a,e*]-cyclooctene)molybdenum(0), *cis*-$L_2Mo(CO)_2$ *(6)*, m.p. 215 °C (decomp.). The contrasting behavior of chromium and molybdenum expresses clearly the differing tendencies of these metals to formation of π-aromatic and π-olefinic complexes.

The constitutions of the new complexes were proved by elemental analyses, mass spectra [6], the number and positions of the ν_{CO} vibrations, and the ^{1}H-NMR spectra (Table).

Compound	τ [a]	I_{rel}	Assignment
	2.73	2	a

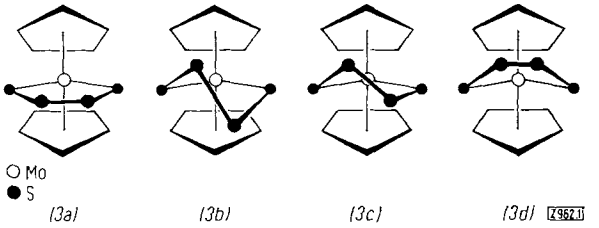
A Tetrasulfide Chelate of Molybdenum[1]

By *H. Köpf*[*]

The few polychalcogenide chelates of platinum[2] and titanium[3] that have become known up to the present time all contain six-membered metal-chalcogen rings ("heterocyclohexachalcogens"). Thus, for example, attempts to prepare the four- and five-membered rings $(C_5H_5)_2TiS_3$ and $(C_5H_5)_2TiS_4$[4] always led to the stable six-membered ring $(C_5H_5)_2TiS_5$ *(1)*[5].

However, when we treated dichlorobis(cyclopentadienyl)-molybdenum(IV) *(2)* with ammonium pentasulfide we obtained, not the expected[6] pentasulfide, but the tetrasulfide chelate *(3)* and thus the first simple hetero derivative[7] of the still unknown cyclopentasulfur.



$$(C_5H_5)_2MoCl_2 + (NH_4)_2S_5 \rightarrow$$
(2)

$$(C_5H_5)_2Mo\begin{matrix}S\!-\!S\\ \|\\ S\!-\!S\end{matrix} + {}^1/_8\,S_8 + 2\,NH_4Cl$$
(3)

The composition $[(C_5H_5)_2MoS_4]_n$ of *(3)* follows from complete elemental analysis; according to ebullioscopic molecular-weight determinations in acetone $n = 1$. Compound *(3)* crystallizes from acetone as dark red, air-stable prisms that decompose slowly above 180 °C and rapidly at 250 °C. It is less soluble than *(1)* in organic solvents and the absorption of its orange to bright red solutions exhibits a hypsochromic shift (absorption shoulder at 400 nm).

The IR spectrum of *(3)* [KBr disk; cm^{-1}: 3100 s (ν_{CH}); 1430 vs, 1410 vs, 1350 w, 1120 vw, (ω_{CC}); 1075 w, 1063 w, 1012 m, 1000 s (δ_{CH}); 954 vw, 926 vw, 872 m, 832 vs, 822 vs (γ_{CH}); 482 w (ω_{SS}?)] shows the vibrations of the intact $(\pi\text{-}C_5H_5)_2Mo^{IV}$ system. The band at 482 cm^{-1} is tentatively assigned to a S_4 skeletal vibration.

Of the four ideal conformations *(3a–d)* that are conceivable for a MoS_4 five-membered ring, *(3a)* and *(3b)* have equivalent cyclopentadienyl rings, whereas in the case of *(3c)* and *(3d)* in the conformationally rigid state two separate ^{1}H-NMR signals for one axial and one equatorial cyclopentadienyl ligand – as have been observed[3], even at room temperature, for *(1)* – are to be expected.

(3a) *(3b)* *(3c)* *(3d)* [Z 962 I]

The ^{1}H-NMR spectrum of *(3)*, which was recorded for saturated solutions in acetone or dimethyl disulfide with TMS as external reference, contains only one sharp signal for the C_5H_5 protons at τ = 5.25 (in acetone) or 4.78 (in dimethyl disulfide) at room temperature, even with scale expansion, and this signal shows no splitting when the sample is cooled down to –95 °C (in acetone)[8].

Since the angle of twist $\sphericalangle$S–S–S–S of 75–100 °[9] necessary for stable sulfur rings can, moreover, only be realized in *(3b)* and *(3c)*, it is probably the conformer *(3b)* that is present in solution at sufficiently low temperatures.

Bis(cyclopentadienyl)tetrasulfidomolybdenum(IV) (3)

Bis(cyclopentadienyl)dihydridomolybdenum(IV) *(4)*[10] (2.3 g, 10 mmole) is refluxed for 3 h with chloroform (150 ml) in the absence of light and with exclusion of air and moisture to yield compound *(2)*[11]. After removal of the excess of chloroform under vacuum, the olive green residue is treated with 150 ml of a saturated solution of freshly prepared ammonium pentasulfide[12] in water/ethanol (1:5 v/v) and refluxed for 1 h with vigorous stirring. The reddish brown precipitate is filtered off, washed with ethanol, and recrystallized from acetone. Yield 3.1 g (88 % calculated with respect to *(4)*).

Bis(sulfinylamido)mercury(II)

By *W. Verbeek* and *W. Sundermeyer* [*]

Not only many organic *N*-sulfinylamines [1] but also *N*-(trimethylsilyl)sulfinylamine [2] are known, the reactions of the latter being very similar to those of silyl pseudohalides.

We have obtained bis(sulfinylamido)mercury(II) *(1)* as the first sulfinylamide of a metal by reaction of mercury(II) fluoride with *N*-(trimethylsilyl)sulfinylamine. The reaction proceeds quantitatively.

$$HgF_2 + 2(CH_3)_3SiNSO \rightarrow Hg(NSO)_2 + 2(CH_3)_3SiF$$
(1)

Tetrahydrofuran is a particularly suitable solvent as *(1)* dissolves readily in it and can be recrystallized from it. 23 g of HgF_2 reacts with 27 g of $(CH_3)_3SiNSO$ in 40–60 ml of boiling, stirred, dry THF within 30 min in a strongly exothermic reaction.

The amide *(1)* crystallizes as colorless needles, m.p. 128 °C (decomp.), but, if heating is too slow, decomposition sets in below the melting point. In contrast to most organic sulfinylamines, it is surprisingly stable to hydrolysis and alcoholysis. Compound *(1)* was identified by analysis and its mass spectrum [3] [with reference to the isotope ^{202}Hg: m/e = 326, $Hg(NSO)_2$; 264, Hg(NSO); 202, Hg; 48, SO; 46, NS; 32, S]. The IR spectrum (Nujol) shows bands at 1250 s, 1217 s, 1078 s, 604 m, 590 m, 561 m, 313 s, and 280 w cm^{-1}.

N-Halosulfinylamines

By *W. Verbeek* and *W. Sundermeyer* [*]

In connection with our studies of the reaction of silyl pseudohalides with the halides of various elements we have treated *N*-(trimethylsilyl)sulfinylamine [1] with halogens. The reaction with chlorine led to an almost quantitative yield of *N*-chlorosulfinylamine *(1)*, in contrast to the reactions of organic *N*-sulfinylamines which afford thionyl chloride and the corresponding amine with scission of the N=S bond [2].

$$(CH_3)_3SiNSO + Cl_2 \rightarrow Cl{-}N{=}S{=}O + (CH_3)_3SiCl$$
(1)

Liquid chlorine (15.8 g) is added dropwise to $(CH_3)_3SiNSO$ (30 g) with stirring at −76 °C, a smooth reaction giving compound *(1)* which, however, can be obtained pure and free from the accompanying chlorotrimethylsilane only by preparative gas chromatography. Alternatively, the reaction mixture may be converted by partial fluorine exchange with HgF_2 into fluorotrimethylsilane and unchanged *(1)*, and the latter then separated by fractional distillation.

(1) is a clear liquid (b.p. 65.5 °C, m.p. −80 °C) with a suffocating odor; it can be distilled under an inert gas at atmospheric pressure without decomposition; the vapor-pressure curve is represented by $\log p = -1784/T + 8.15$. (Trouton constant 24.1 cal/deg). It was identified by analysis and its mass spectrum [3] which contains fragments at m/e = 49 (NCl), 48 (SO), 46 (NS), 35 (Cl), and 32 (S), as well as the molecular ion at m/e = 97 (referred to ^{35}Cl). The IR spectrum (gas) showed the six bands required for a linear tetraatomic molecule (with tentative assignments) at 1248 vs (νS=O), 995 w (νN=S), 676 s (νN−Cl), 532 s (δNSO), 359 s (γ), and 187 s cm^{-1} (δClNS).

Compound *(1)* reacts vigorously with mercury and explosively with water. When heated in air it deflagrates with a bluish-white flame.

The analogous reaction of *N*-(trimethylsilyl)sulfinylamine with bromine gives a difficultly separable mixture that contains *N*-bromosulfinylamine *(2)*. However, *(2)* is formed quantitatively on treatment of stoichiometric amounts of bis(sulfinylamido)mercury [4] with bromine in trichlorofluoromethane at room temperature.

$$Hg(NSO)_2 + 2\,Br_2 \rightarrow 2\,Br{-}N{=}S{=}O + HgBr_2$$
(2)

(2) is a colorless liquid (b.p. 12 °C/12 torr, m.p. −48 °C) which becomes yellow at room temperature owing to loss of bromine. It was identified by its IR spectrum and its mass spectrum [m/e = 141 (BrNSO), 93 (NBr), 79 (Br), 48 (SO), 46 (NS), and 32 (S), referred to ^{79}Br]. There are six IR bands also in this case (with tentative assignments) at 1245 vs (νS=O), 1003 w (νS=N), 621 s (νN−Br), 456 s (δNSO), 335 s (γ), and 161 s cm^{-1} (δBrNS).

Reaction of *N*-(trimethylsilyl)sulfinylamine with fluorine gives a poor yield of *N*-fluorosulfinylamine *(3)*.

$$(CH_3)_3SiNSO + F_2 \rightarrow F{-}N{=}S{=}O + (CH_3)_3SiF$$
(3)

Fluorine, diluted with nitrogen, is passed into a solution of $(CH_3)_3SiNSO$ in trichlorofluoromethane at −80 °C. *(3)* is obtained from the reaction mixture by preparative gas chromatography but tends to explode on crystallization (at −196 °C); it was characterized by its mass spectrum [m/e= 81 (FNSO), 48 (SO), 46 (NS), 33 (NF), and 32 (S)]. IR spectrum: 1246 vs (νS=O), 1007 vs (νN=S), 834 s (νN−F), 606 s (δNSO), 394 s (γ), and 228 s cm^{-1} (δFNS).

The ^{19}F–NMR spectrum [5] at room temperature shows a triplet (NF coupling), δ = −123.3 ppm, referred to $CFCl_3$ as internal standard, with J_{FN} = 112 Hz.

(4c)	121–127	+ 89	*(4f)*	100–101	− 50

In spite of numerous experiments directed toward this aim[3], no simple and productive technique has hitherto been found.

For our investigations we chose the route *(1)*→*(5)* *via* the 5,10β-methylene steroids *(4)*[4]. For the success of this pathway it was essential to reduce 3-oxo-5(10)-estrenes *(1)* (which are readily obtainable by Birch reduction and subsequent enol-ether cleavage of steroids having an aromatic ring A) stereospecifically to 3β-hydroxy-5(10)-estrenes *(2)*. This reduction gives only 15–20% yields when carried out with complex metal hydrides, hydrogen in the presence of a platinum catalyst, or according to the Meerwein-Ponndorf method; the main products are 3α-hydroxy-5(10)-estrenes[4c,5]. A total yield of only about 30% is also obtained in the conversion of *(1)* into *(2)* by epimerization of 3α-hydroxy-5(10)-estrenes[5a] or *via* 5,10β-epoxysteroids[4c].

We have now found that 3-oxo-5(10)-estrenes *(1a)–(1f)* [IR: ν = 1710 cm^{-1} (C=O), NMR[6]: δ = 2.45 (intensity = 4, $W_{1/2}$ = 4 Hz) (H-1 and H-2), 2.75 (intensity = 2, $W_{1/2}$ = 5 Hz) (H-4)][7] can be converted into the corresponding 3β-hydroxy compounds *(2a)–(2f)* [NMR: δ = 3.90–4.20 (H-3); with *(2c)* and *(2f)* this signal partly overlaps with that of the OCH_2 group of the tetrahydropyranyl ether][7] in 65–90% yield by catalytic hydrogenation if highly active Raney nickel is used as catalyst and the reaction is performed under a hydrogen pressure as close to 200 atm as possible.

Compounds *(2b)*, *(2c)*, *(2e)*, and *(2f)* can, according to *Simmons-Smith*[8], be converted into the 5β,19-cycloandrostanes *(3b)*, *(3c)*, *(3e)*, and *(3f)*, respectively [IR: ν = 3050 cm^{-1} (cyclopropane), NMR: δ = 0.40 (cyclopropane)][7] in yields of up to 90% by refluxing with diiodomethane and zinc-copper couple[9] in ether/1,2-dimethoxyethane for 2 h. Jones oxidation[10] of the products with chromic acid in acetone smoothly affords the 3-ketones *(4b)*, *(4c)*, *(4e)*, and *(4f)* [IR: ν = 1705 cm^{-1} (C=O), 3050 cm^{-1} (cyclopropane), NMR: δ = 0.48 (cyclopropane), 2.52 (singlet, intensity = 2) (H-4)][7], which are isomerized on treatment with concentrated hydrochloric acid in glacial acetic acid (2:3) for 10 min at 70 °C[3b,3c,4c]. Mixtures of 17β-hydroxy and 17β-acetoxy steroids may then be isolated which can be hydrolyzed to the testosterones *(5a)* or *(5d)*, or acetylated to the testosterone acetates *(5b)* or *(5e)* [UV: ε_{240} = 16500; IR: ν = 1670 cm^{-1} (C=O), 1615 cm^{-1} (C=C); NMR: δ = 1.20 (CH_3-10), 5.70 (H-4)][7]. The yield of the reaction *(4)*→*(5)* again amounts to up to 90%.

cis-Tricarbonyltris(phosphine)chromium(0)[1]

By *E. O. Fischer, E. Louis*, and *C. G. Kreiter*[*]

Stable mono- and bis-(phosphine) complexes of transition metals have already been reported by various authors[2–5]. We have now, for the first time, incorporated three PH_3 ligands into the molecule of an octahedral complex[**].

Reactions of the reactive tricarbonyl(hexamethylborazine)-chromium(0), $[B_3N_3(CH_3)_6]Cr(CO)_3$ [6] *(1)*, with tertiary phosphines and phosphites in suitable solvents lead rapidly to good yields of *cis*-tricarbonyl complexes, provided that steric factors do not introduce difficulties [7,8].

We have found that the analogous reaction with PH_3, namely:

$$(1) + 3\ PH_3 \xrightarrow{20\,^\circ C} \underset{(2)}{(PH_3)_3Cr(CO)_3} + B_3N_3(CH_3)_6$$

occurs in cyclohexane at room temperature almost quantitatively within a few minutes. Considering the low solubility of PH_3 in C_6H_{12} at atmospheric pressure, this shows once more the great tendency of PH_3 ligands for complex formation. The identity of the tricarbonyltris(phosphine)chromium(0) *(2)* produced was proved by total analysis and mass spectrometry and the IR and ^1H–NMR spectra show that it has exclusively the *cis*-configuration.

Thus the ν_{CO} region of the spectrum shows only two IR active fundamentals (A_1, E), as expected for a molecule of C_{3v} symmetry, and can be assigned on the basis of a series of known *cis*-$L_3Cr(CO)_3$ compounds (Table 1). The position of the A_1 band shows that for complex *(2)*, as in PH_3 complexes studied previously, the π-acceptor contribution to the metal-phosphorus bond is greater than in PR_3 compounds where R is alkyl or aryl.

Table 1. IR spectra (cm^{-1}) of *cis*-$L_3Cr(CO)_3$ complexes (Perkin-Elmer model 21, LiF optics).

Compound	ν_{CO} (A_1)	ν_{CO} (E)	Solvent
$(PH_3)_3Cr(CO)_3$	1972	1892	[a]
	1970	1887	[b]
$[P(n\text{-}C_4H_9)_3]_3Cr(CO)_3$ [7]	1920	1828	[b]
$[P(C_2H_5)_2C_6H_5]_3Cr(CO)_3$ [7]	1925	1835	[b]
$[P(OC_2H_5)_3]_3Cr(CO)_3$ [7]	1967	1874	[b]
$[B_3N_3(CH_3)_6]Cr(CO)_3$ [6, 8]	1963	1876	[b]

[a] *n*-Hexane. [b] Cyclohexane.

The IR spectrum of *(2)* (KBr pellet, NaCl optics) shows a band of moderate intensity at 2309 cm^{-1} in the ν_{PH} region and two strong to very strong bands at 1027 and 1004 cm^{-1} in the δ_{PH} region, and a further strong band at 917 cm^{-1}.

The ^1H-NMR spectrum (in CD_3COCD_3) shows two groups of signals, each containing three broadened bands, symmetrically around $\tau = 6.33$, which agrees with the *cis*-arrangement of the CO and PH_3 ligands [***]. In contrast, the *trans*-isomer would be expected to show two identical PH_3 groups and one unique PH_3 group differently shielded from the other two. The separations of the mutually symmetrical bands are 338, 308, and 282 Hz, and the intensities are in the ratio 1:0.98:0.46, respectively. The bands could not be resolved into single lines.

The rather complex structure of the proton resonance spectrum is caused by the nuclear-magnetic non-equivalence of the three PH_3 groups: We have here a $X_3X_3'X_3''$ partial spectrum of an $AA'A''X_3X_3'X_3''$ spin system. The almost identical chemical shifts of the PH protons in *(2)* and *cis*-$(PH_3)_2Cr(CO)_4$ ($\tau = 6.26$ in $CDCl_3$ [9]) suggest very similar electronic properties for the Cr–P–H_3 bonding. It seems reasonable to assume that the coupling constants between H and P in *(2)* are similar to those in *cis*-$(PH_3)_2Cr(CO)_4$.

Experimental:

Pure *(1)* (100 mg, 0.33 mole), obtained from $(CH_3CN)_3Cr(CO)_3$ according to ref. [6], is suspended in cyclohexane (30 ml) at room temperature and stirred vigorously under pure PH_3 (*ca.* 800 torr). A color change from orange-yellow to pale yellow is complete within 10 min. The product *(2)* is formed as a fine, pale-yellow precipitate. If larger amounts of *(1)* are used, the reaction requires a longer time since the solid *(1)* reacts slowly owing to its poor solubility.

For purification, *(2)* is collected on a G_4 fritted filter, washed several times with cold pentane, and finally dried at 0 °C *in vacuo*. The yield of crude product is 88% (70 mg).

Rapid working is required for complete purification of *(2)*. This is done by preparation of a saturated solution of the crude product in hexane at 25 °C [*ca.* 12 mg of *(2)* per 100 ml of hexane], filtration through filter wool, concentration of the filtrate to one-third of its volume under water-pump vacuum, and cooling to 0 °C. Decantation, washing with cold pentane, and drying *in vacuo* affords analytically pure *(2)*, which decomposes at 133–137 °C. Oxygen and moisture must be excluded during these operations.

Compound *(2)* dissolves only very slightly in aliphatic saturated hydrocarbons, moderately in ether, and readily in ethylene glycol dimethyl ether, tetrahydrofuran, or acetone. However, it decomposes rapidly in solution, especially if warmed or exposed to light. It sublimes slowly at 50–60 °C with slight decomposition. Mass spectrometry gave a molecular weight of 238.

Association of Bis(trimethylsilyl)amidolithium and Methyl(trimethylsilanolato)beryllium in the Solid State

By *D. Mootz, A. Zinnius,* and *B. Böttcher* [*]

Bis(trimethylsilyl)amidolithium, $[(CH_3)_3Si]_2NLi$, known since 1961 [1] and today a versatile reagent in preparative inorganic chemistry [2], is dimeric in solution, but, as we found by X-ray structure analysis, trimeric in the solid state.

Crystals obtained from petroleum ether [3] belong to space group $P2_1/c$ with twelve monomer units in the unit cell. The trimeric unit that is indicated thereby was confirmed by a complete X-ray structure analysis with more than 3000 photographic data: three crystallographically independent monomers are associated with formation of a planar six-membered ring with alternating nitrogen and lithium atoms. The bonding parameters given in Figure 1 are mean values

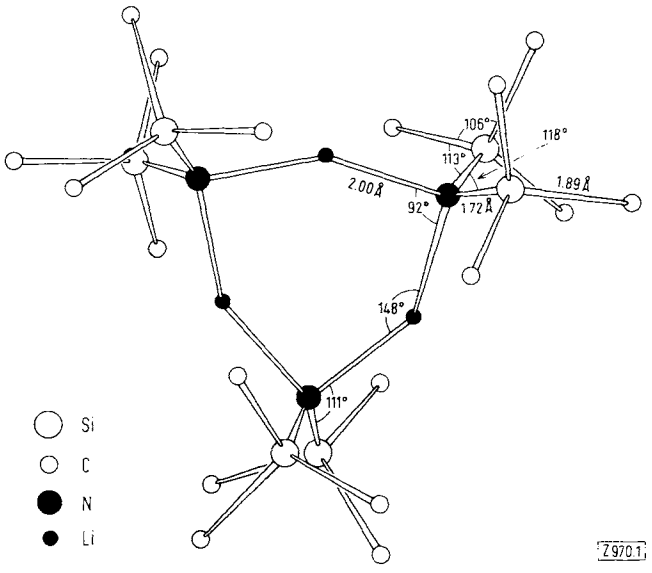

Fig. 1. *cyclo*-Tris[bis(trimethylsilyl)amidolithium] molecule, with bond lengths and bond angles. Estimated standard deviations are 0.02 to 0.05 Å and 1 to 2°.

of chemically equivalent individual distances and angles, deviations from the means being small and usually insignificant.

Comparison with the structures recently established for $\{[(CH_3)_3Si]_2N\}_3Fe$ (X-ray structure analysis[4]) and $[(CH_3)_3Si]_2NH$ (electron diffraction[5]) shows similar values for the Si–N atomic distances and a distinct minimum of the SiNSi bond angle for the structure now determined with the onium configuration of the nitrogen atom:

	$[(Me_3Si)_2NLi]_3$	$[(Me_3Si)_2N]_3Fe$	$(Me_3Si)_2NH$
Si–N	1.72 Å	1.731 Å	1.735 Å
∢ SiNSi	118°	121.2°	125.5°

Me = CH_3

On treatment of trimethylsilanol with dimethylberyllium a compound is formed[6] that crystallizes from petroleum ether in the space group C 2/c. The Patterson function with *ca.* 900 data measured on a single-crystal diffractometer permitted localization of two independent silicon atoms. An electron-density function phased therewith showed a tetrameric molecule of formula $[(CH_3)_3SiOBeCH_3]_4$ with a structure analogous to that of cubane, these facts being confirmed on refinement. The oxygen and beryllium atoms are situated at alternate vertices of an only slightly distorted cube (Figure 2); the O–Si and Be–C bonds lie on outward prolongations of the diagonals of the cube. A symmetry axis of the space group passes through the middle of the molecule, being parallel to the edges of the cube that are shown as approximately vertical in the Figure.

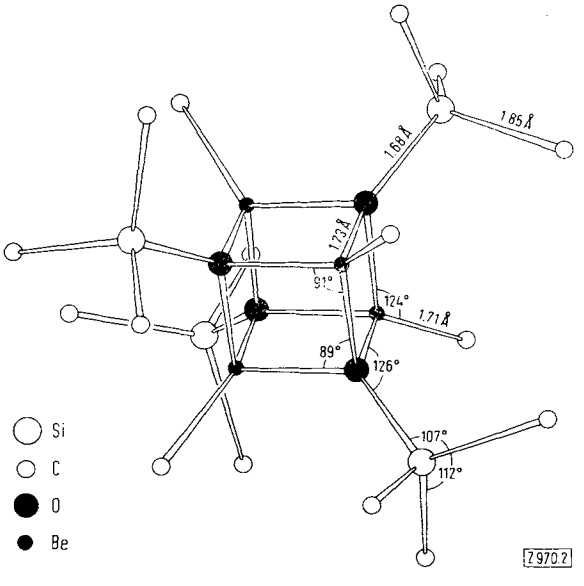

Fig. 2. *closo*-Tetrakis[methyl(trimethylsilanolato)beryllium] molecule, with bond lengths and bond angles. Estimated standard deviations are 0.01 to 0.02 Å and 1°.

None of the crystallographically independent but chemically equivalent bonding parameters differs significantly from the mean values given. The Be–O distance, 1.73 Å, is distinctly longer than in beryllium oxide[7] (1.65 Å). This results from repulsion between the large oxygen atoms, whose distance from one another in the cube is considerably smaller (2.47 Å) any way than in the more open BeO structure (2.70 Å).

The structure determined by us is the first certain oxaberyllia-cubane, although similar structures have been discussed for $[ROBeCH_3]_4$ where R = benzyl or phenyl[8].

A New Synthesis of a Linear Poly(phenylene Oxide)

By *W. Ried* and *W. Merkel*[*]

N-Bromosuccinimide and mercury bis(phenylacetylide) in benzene afford compound *(1)* as well as 1-bromo-2-phenylacetylene *(4)*; and in THF the second phenylacetylene group is also replaced, affording mercury bis(succinimide). However, with 2,4,4,6-tetrabromo-2,5-cyclohexadienone *(2)*[1] we obtained poly(2,6-dibromo-1,4-phenylene oxide) *(8)*, 1-bromo-2-phenylacetylene *(4)*, and phenylethynylmercuric bromide *(6)* even at room temperature. Like *N*-bromosuccinimide, the ketone *(2)* contains a positively activated and thus very mobile bromine atom.

The polymer is a white amorphous powder, softening in the region 230–260 °C and with the formula $(C_6H_2OBr_2)_n$. An osmometric determination[2] in benzene at 36 °C leads to a mean molecular weight of 13000 ± 650, which corresponds to a mean chain length of 49–52 units. The IR spectrum (KBr disk) shows neither a C=O nor an O–H absorption, but there is a strong C–O–C band at about 1190 cm^{-1}.

Since the reaction under nitrogen proceeds in exactly the same way and here too no diphenoquinone can be detected, and in consideration of the by-products *(4)* and *(6)*, the reaction is postulated as occurring by way of *(5)* and *(7)*. Free

radicals are unlikely as intermediates because the pale yellow solution barely changes color during the reaction. If mercury diacetate or dichloride is used there is no formation of polymer. A formal consideration must thus include an acceptor for both bromine cations and bromide ions in order that polymerization may start. Up to the present a branched polymer of this type with a low molecular weight has been prepared only by oxidative coupling of 2,4,6-tribromophenol [3].

Poly(2,6-dibromo-1,4-phenylene oxide) (8):

Equivalent amounts of 2,4,4,6-tetrabromo-2,5-cyclohexadienone *(2)* and mercury bis(phenylacetylide) are dissolved in anhydrous THF and stirred for about 2 hours at room temperature. Addition of ether or methanol precipitates the polymer *(8)* together with *(6)*. The pure polymer is obtained by digestion of the crude product with benzene and subsequent precipitation by methanol. The reaction is quantitative.

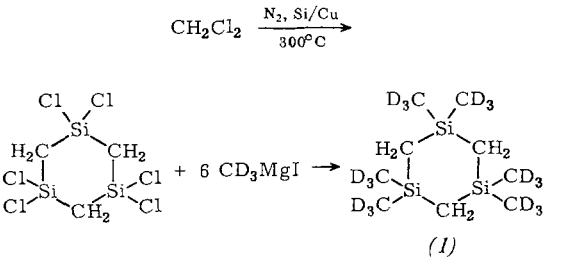
"Cyclosilane-d_{18}", a New ^{1}H–NMR Standard for Measurements up to 200 °C

By *L. Pohl* and *M. Eckle* [*]

During the past ten years numerous organosilicon compounds have been suggested as suitable stable internal standards for use in NMR measurements up to 200 °C – the upper limit of modern high-resolution NMR spectroscopy – in place of tetramethylsilane, which, on account of its low boiling point (27 °C), can be used only at temperatures up to 100 °C, even in sealed tubes. As can be seen from the table, however, not one of these compounds fulfills the requirements of a suitable standard, which should:



1. be chemically inactive and nonpolar,

2. be stable enough for measurements to be carried out at temperatures up to 200 °C,

3. have a chemical shift which permits measurements over the whole range downfield from δ = 0ppm.

Standard	B.p. (°C)	δ(ppm) in $CDCl_3$
Tetramethylsilane (TMS)	27	0.000
Hexamethyldisilane	113	0.037
Hexamethyldisilazane	126	0.042
Hexamethyldisiloxane	100	0.055
Octamethylcyclotetrasiloxane	134	0.085
Tris(trimethylsilyl)amine	m.p. 70	0.229
Tetrakis(trimethylsilyl)methane	m.p.307	0.236
"Cyclosilane-d_{18}" *(1)*	208	−0.327

We have now developed a standard, called "cyclosilane-d_{18}", which does satisfy the above requirements. It is 1,1,3,3,5,5-hexakis(trideuteriomethyl)-1,3,5-trisilacyclohexane *(1)*, which can be prepared according to the following reaction scheme [1]:

(1)

Compound *(1)* is a colorless liquid which boils without decomposition at 208 °C and has a ^{1}H-NMR singlet at δ = −0.327 ppm having a halfwidth of 0.5 Hz, thus permitting the recording of an unperturbed spectrum from δ = 0ppm downfield. It is very soluble in those solvents, such as [D_5]-pyridine (b.p. 116 °C), [D_2]-tetrachloroethane (148 °C), [D_7]-dimethylformamide (153 °C), [D_{12}]-tetramethylurea (176 °C), [D_8]-decalin (195 °C), hexachloroacetone (202 °C), hexachlorobutadiene (212 °C), and [D_{18}]-hexamethylphosphoric triamide (225 °C; HMPT), which come into consideration for measurements at increased temperatures. Compound *(1)* thus permits measurements with a stable internal standard to be carried out at 200 °C in unsealed sample tubes, *e.g.* in HMPT. Furthermore, it can also be used for internal field stabilization from temperatures of −100 °C upwards (with TMS as zero-point signal if necessary). "Cyclosilane-d_{18}" therefore represents a standard of unusual potential [2].

Sodium 3-Trimethylsilyltetradeuteriopropionate, a New Water-Soluble Standard for ^{1}H-NMR

By *L. Pohl* and *M. Eckle* [*]

Sodium 3-trimethylsilylpropanesulfonate $(CH_3)_3SiCH_2CH_2CH_2SO_3Na$, which was suggested by *Tiers* and *Kowalewsky* [1] as a water-soluble ^{1}H-NMR standard, suffers from the disadvantage that it gives rise not only to the desired trimethylsilyl signal at $\delta = 0.015$ ppm (in water), but also to three other absorption regions between $\delta = 0.5$ and 3.0 ppm which can cause interference, especially in the case of dilute solutions of samples, when the standard is used simultaneously as an internal "lock signal" because of the higher concentration required.

The sodium salt of 3-trimethylsilyltetradeuteriopropionic acid $(CH_3)_3SiCD_2CD_2COONa$ [2] *(1)*, m.p. 302–304 °C (uncorrected), which we have now synthesized, shows a single sharp resonance signal of half-width 0.5 Hz at $\delta = 0.00$ ppm exactly (in water, methanol) so that the conversion of observed chemical shifts to values measured against TMS is no longer necessary. The solubility in water and in a series of polar organic solvents, such as methanol, hexafluoroacetone · 3/2 H_2O, or HMPT, is higher than that of *Tiers'* salt *e.g.* by a factor of 10 in water and methanol. Owing to the lower molecular weight (172 instead of 218) and the consequently more favorable ratio trimethylsilyl/total molecule, less of the new standard is required (2 mg instead of 4–5 mg per 0.5 ml of sample solution), which largely obviates the salting out that sometimes occurs during the preparation of sample solutions. Aqueous solutions of *(1)* are weakly alkaline (0.05 N: pH = 7.92), while those of the sulfonate are acid (0.05 N: pH = 4.56). Compound *(1)* is stable toward acids and bases, and does not undergo deuterium/hydrogen exchange under normal conditions, even at elevated temperatures. Unlike *Tiers'* salt, which decomposes in solution above 120 °C, the new standard can be used up to at least 200 °C.

Preparation of (1):

Reaction of $(CH_3)_3SiCl$ with $NaC\equiv CH$ in propylene glycol ether affords $(CH_3)_3SiC\equiv CH$ in 70% yield. This compound is treated with C_2H_5MgBr in ether to yield $(CH_3)_3SiC\equiv CMgBr$, which is subsequently converted into $(CH_3)_3SiC\equiv CCOOD$ (yield 60%) by reaction with CO_2 and D_2O. The acid is deuterated with D_2 at 50 atm over a Pd/C catalyst and then neutralized with NaOH to give the sodium salt *(1)*. The degree of deuteration of the two methyl groups is at least 99%. Yield calculated with respect to $(CH_3)_3SiCl$ is 40%.

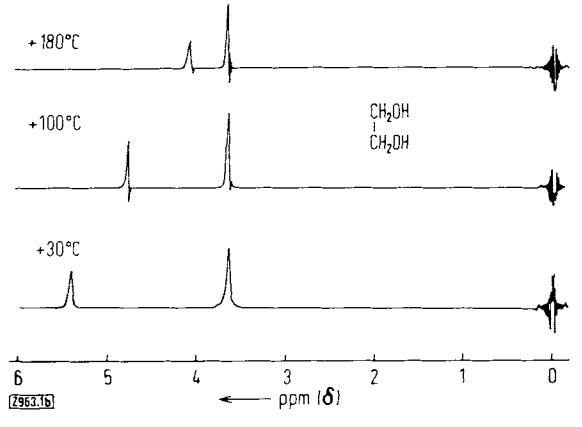

Fig. 1. Sodium 3-trimethylsilyltetradeuteriopropionate as lock and zero signal in ethylene glycol at various temperatures (Varian HA-100 D).

Technetium(VII) Oxide: A Transition Metal Oxide with a Molecular Structure in the Solid State

By *B. Krebs* [*]

As previously reported, solid rhenium(VII) oxide forms a polymeric layer structure which contains a mixture of tetrahedrally and octahedrally coordinated rhenium and in which the molecular structure $O_3Re-O-ReO_3$ of the oxide in the gaseous phase is already latent [1]. The structure, bonding, and coordination in the corresponding (not isotypic) technetium oxide were hitherto unknown [2]. Comparison of its physical properties with those of the neighboring d^0 metal oxides indicates that the structure of Tc_2O_7 is more similar to that of the lower molecular oxides RuO_4 and OsO_4 than to the highly polymeric oxides MoO_3 and WO_3 [3].

Single crystals of Tc_2O_7 could be obtained as thin, pale-yellow, very hygroscopic plates (plate face (100)) by combustion of ^{99}Tc in a stream of oxygen at 400 °C [2] followed by slow sublimation of the oxide in a closed system.

Ditechnetium heptoxide crystallizes in the orthorhombic space group D_{2h}^{15}–Pbca with $a = 13.756 \pm 0.007$, $b = 7.439 \pm 0.004$, $c = 5.617 \pm 0.003$ Å, $V = 574.8$ Å^3. $Z = 4$; $d_{x\text{-ray}} = 3.582$, $d_{exp} = 3.5$ g/cm^3. The intensities of 625 independent reflections were recorded on a Hilger-Watts four circle diffractometer using Mo–K_α radiation. The structure was determined from the three-dimensional Patterson synthesis. The least squares refinement with anisotropic temperature factors converged to an R_1 factor of 4.9 %. As in Fig. 1 the structure consists of an arrangement of isolated Tc_2O_7 molecules with tetrahedral coordination of the technetium. Therefore, in addition to OsO_4 [8] and RuO_4 (and very probably Mn_2O_7), Tc_2O_7 is one of the few known transition metal oxides having a molecular structure in the solid state.

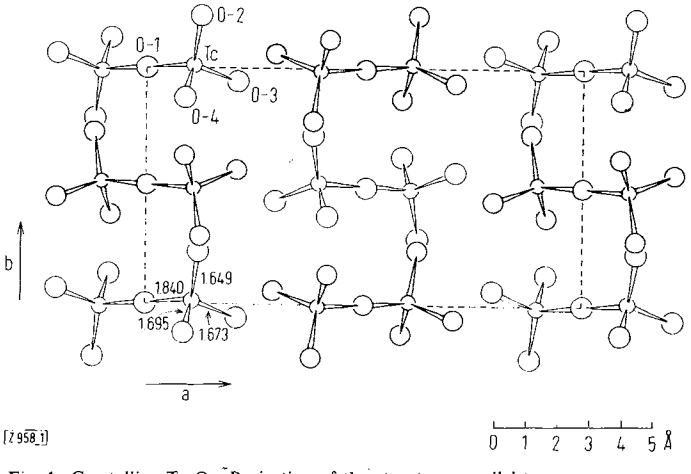

Fig. 1. Crystalline Tc_2O_7: Projection of the structure parallel to *c* (bond lengths in Å; uncorrected).

Tc_2O_7 differs from all previously investigated oxides and oxoanions having isolated $A_2O_7^{(n-)}$ structural units (*e.g.* Cl_2O_7, $S_2O_7^{2-}$, $P_2O_7^{4-}$, $Cr_2O_7^{2-}$) in that the configuration about the central O-atom is exactly linear as a result of the C_i symmetry of the molecule. The M_2O_7 units in the thortveitite type structure cannot be regarded as isolated anions. A statistical disorder of the bridge O-atom (potential maximum at 0,0,0, *etc.*), which would simulate a linear configuration, is most improbable. The experimentally determined principal vibration amplitudes of O-1 (with 0.25, 0.23, and 0.18 Å) are only slightly greater than those of O-2, O-3, and O-4.

Corresponding to the difference in the covalent radii, the bond lengths are about 0.02 – 0.03 Å shorter than those in similarly bonded rhenium compounds: the Tc–O bridge bonds (1.840 ± 0.001 Å) are comparable to the Re^{IV}–O and Ru^{IV}–O bonds in the symmetrical linear bridges of $[Cl_5Re-O-ReCl_5]^{4-}$ (1.86 Å)[4] and $[Cl_5Ru-O-RuCl_5]^{4-}$ (1.80 Å)[5]. The average value for the lengths of the terminal Tc–O bonds (1.673 Å; σ for a single value 0.006 Å) corresponds to the Re–O distances in the tetrahedra of ReO_3Cl (1.702 Å)[6], Re_2O_7 (1.70 Å)[1], and $Re_2O_7(OH_2)_2$ (1.73 Å)[7]. Angular distortion of the O–TcO_3 tetrahedra is only slight; the bond angles vary between 107.8 and 110.9°. It has not yet been possible to elucidate completely the nature of the crystalline red phase of probable composition $Tc_2O_7 \cdot H_2O$ in the system ditechnetium heptoxide–water.

Preparation of Pure 2nd and 3rd Phase Graphite-Iron(III) Chloride Inclusion Compounds and of Graphite-Iron(III) Bromide Inclusion Compounds

By *D. Hohlwein, F. D. Grigutsch,* and *A. Knappwost*[*]

From the results of sorption measurements carried out by *Hooley* and *Bartlett*[1] we have developed a process for the preparation of graphite-$FeCl_3$ inclusion compounds in definite phases. Anhydrous $FeCl_3$ and graphite (in the ratio 5:1 by weight) are placed without mixing in opposite ends of a bomb tube. The tube is evacuated and, by using two ovens, each end is heated to a different but definite temperature. The graphite is heated to a higher temperature than that of the pure $FeCl_3$, so that a thermodynamic equilibrium can be set up between included and pure $FeCl_3$. On completion of reaction the equilibrium composition of the product is "frozen in" by quenching.

The disadvantage mentioned by us[2] regarding the methods of preparation previously adopted, *i.e.* formation of higher (metal-halide deficient) phases by subliming off metal halide without reaching thermodynamic equilibrium between inclusion compound and sublimate, does not occur in this process.

In accord with the 350 °C isotherm[1], a pure second phase with 48–51 wt-% $FeCl_3$ (after washing with 2 N HCl) occurs at T_1 (temperature of graphite) = 350 °C and T_2 (temperature of $FeCl_3$) = 300 °C. The Debyeogram shows the basal reflections of the second phase with $d = (9.38 + 3.35) = 12.73$ Å 002, 003, 004, 007, and 008 and, with lesser intensity, the graphite reflections 002 and 004. Because of the pronounced texture further reflections are not observable.

The third phase, with 34–40 % $FeCl_3$, is formed at T_1 = 410–420 °C, T_2 = 300 °C. In the Debyeogram the weak reflections 002 and 004 of the graphite occur in addition to the basal reflections 002, 003, 004, 005, 006, 007, 009, 0010, 0011 with $d = (9.38 + 2 \times 3.35) = 16.08$ Å.

Iron(II) bromide, bromine, and graphite undergo reaction in a bomb tube to give graphite-$FeBr_3$ inclusion compounds. At a reaction temperature of 100 °C the included $FeBr_3$ can amount to 55 wt-% (after washing). If the lattice dimensions of the $FeBr_3$ in the layer planes, like those of the $FeCl_3$, do not alter during the inclusion reaction this $FeBr_3$ content corresponds analytically to a compound of the second phase. The observed X-ray reflections, however, have not as yet been interpreted.

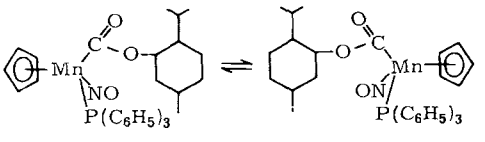
Optical Activity at an Asymmetrical Manganese Atom



By *H. Brunner*[*]

The compounds $[C_5H_5Mn(CO)(NO)P(C_6H_5)_3]^+[PF_6]^-$[1] *(1)* and $[C_5H_5Mn(COOCH_3)(NO)P(C_6H_5)_3]$[1], which is prepared from *(1)* by methoxide addition, contain four different substituents attached to a central manganese atom. Since these complexes have pseudotetrahedral structures enantiomeric pairs must exist. The diastereomers occurring on introduction of an optically active agent into the molecule ought to be separable from each other, provided that the configurations are sufficiently stable.

Addition of the optically active L-mentholate anion *(2)* to the carbonyl group of the D,L mixture *(1a,b)* leads to the formation of the D, L-L derivative *(3a,b)*. The IR spectrum (KBr) of the red crystalline product contains, in addition to the bands of cyclopentadienyl-, triphenylphosphine-, and menthyl residues, the NO stretching vibration at 1724 cm^{-1} and the absorption of the CO double bond at 1616 cm^{-1}.

The difference in solubility between the two diastereomers *(3a)* and *(3b)* is so great that they can easily be separated from each other; the dextrorotatory isomer *(3a)* dissolves in pentane, whereas the levorotatory isomer *(3b)* is sparingly soluble in aliphatic hydrocarbons.

The high specific rotations of both forms slowly decrease in benzene solution and reach an equilibrium value of $[\alpha]_{578}^{25} = +105°$ which is to be ascribed to the remaining optical activity of the menthyl group after racemization at the manganese atom. The diastereomers *(3a)* and *(3b)* are configurationally stable in the solid state. On prolonged heating in pentane *(3a)* is converted into the difficultly soluble *(3b)*; conversion of *(3b)* into the more easily soluble diastereomer *(3a)* is possible by extraction from the equilibrium mixture with pentane.

Experimental:

To 3.75 g (6.4 mmoles) of compound *(1)* [1] at 0 °C is added a solution of Na-mentholate *(2)* [prepared from lg (6.4 mmoles) (−)-menthol and excess of sodium] in 30 ml of tetrahydrofuran saturated with N_2. The deep-red reaction mixture is evaporated and the residue is dissolved in 50 ml of benzene. The red benzene solution is filtered over anhydrous Na_2SO_4 and concentrated. Pentane is added to the concentrated benzene solution and the precipitate thus obtained is isolated and extracted with pentane until the eluate is colorless. The extract contains 1.5 g (40 %) of the dextrorotatory diastereomer *(3a)* which separates out partially racemized. The residue from the extraction contains 1.3 g (35 %) of the levorotatory diastereomer *(3b)*, $[\alpha]_{578}^{25} = -450°$ (c = 0.1 g/100 ml; benzene). If pentane is added to the extracted product – which, depending on the conditions, is more or less dextrorotatory – and the mixture is filtered so that the filtrate drops into a receiver cooled to −50 °C, pure *(3a)*, $[\alpha]_{578}^{25} = +460°$ C (c = 0.1 g/100 ml benzene) separates out.

Stable Salts Containing the Unusual Anions $[Fe(CN)_5NO]^{3-}$ and $[Fe(CN)_5NOH]^{2-}$

By *R. Nast* and *J. Schmidt* [*]

The previously postulated anions $[Fe(CN)_5NO]^{3-}$ and $[Fe(CN)_5NOH]^{2-}$ [1] can be prepared by reduction of $Na_2[Fe(CN)_5NO]$ *(1)* with sodium in liquid ammonia. We have succeeded in preparing for the first time the ocher-yellow compound trisodium pentacyanonitrosylferrate-2-ammonia, $Na_3[Fe(CN)_5NO] \cdot 2NH_3$ *(2)*, which is sparingly soluble at −70 °C and is sensitive to air. At temperatures above −30 °C, compound *(2)* disproportionates – as can be followed IR spectroscopically – according to the following scheme:

$$2\,[Fe(CN)_5NO]^{3-} \rightarrow [Fe(CN)_5NO]^{2-} + [Fe(CN)_4NO]^{3-} + CN^-$$

On addition of $[Et_4N]Cl$ (Et = C_2H_5) to the brown solution of this compound in liquid ammonia at − 40 °C, gold-brown crystals of $[Et_4N]_3[Fe(CN)_5NO]$ *(3)* precipitate which are stable at room temperature. With $[Ph_4X]Cl$ (Ph = C_6H_5), however, we obtained blue stable compounds of the composition $[Ph_4X]_2[Fe(CN)_5NOH]$ (*(5)*: X = P; *(6)*: X = As). In proton active organic solvents such as acetonitrile, *(3)* is also present in the temperature-dependent equilibrium.

$$[Et_4N]_3[Fe(CN)_5NO] + H^+ \rightleftharpoons [Et_4N]_2[Fe(CN)_5NOH] + [Et_4N]^+$$
$$(3) \qquad\qquad (4)$$

After addition of acetic acid, the blue stable salt *(4)* can be precipitated with ether.

All the stable complexes are paramagnetic with $\mu \approx 1.75$ BM. The UV-absorptions of *ca.* 4000 and 6050 Å for the brown anions and the blue anions agree with the values given in the literature [1].

Table 1. Stretching vibrations (cm^{-1}) of the complexes *(1)*–*(6)*.

[a] F_{NO} (mdynes/Å): VFF force constants in −NOH without consideration of the proton.

[b] N_{NO}: bond order according to *H. Siebert*.

The decrease of about 0.6 in the NO bond order on going from $[Fe(CN)_5NO]^{2-}$ to $[Fe(CN)_5NO]^{3-}$ supports the concept of *Manoharan* and *Gray* [2], according to which an e* orbital having predominant π^*_{NO} character is occupied in the reduction. It seems to us that the increase in bond order of *ca.* 0.2 on protonation is understandable only if a strong contribution of the H1s orbital to the unpaired e* (π^*_{NO}) electron of the complex is assumed. This view is further supported by the difference (observed by us and by *van Voorst* and *Hemmerich* [1]) between the ESR spectra of the blue and the brown anions. Accordingly, the proton must be bound to the NO group with participation of the unpaired electron in a type of bonding which has yet to be elucidated. The existence of a FeCNH grouping can be excluded on the basis of the IR spectra and chemical reactions.

To regard $[Fe(CN)_5NOH]^{2-}$ as a Brønsted acid having a pK_a value of 6.5 [1] appears to us to be unjustified since the precipitation of $[Ph_4X]_2[Fe(CN)_5NOH]$ from liquid ammonia at the high basicity of the solvent cannot then be explained. Participation of the unpaired electron in the protonation is plausible since no protonation at the NO has hitherto been observed in any NO^+ complex.

Further reduction of $[Fe(CN)_5NO]^{3-}$ yields $[Fe(CN)_4NO]^{3-}$ and $[Fe(CN)_3NO]^{4-}$ [3].

Synthesis of Pyrimido[4,5-*d*]pyrimidine

By *H. Bredereck*, *G. Simchen*, and *M. Krämer* [*]

Pyrimido[4,5-*d*]pyrimidine *(2)* is a theoretically interesting compound because of the anellation of two π-electron deficient systems; however, attempts to prepare it or its derivatives bearing substituents in position 2 from 4-aminopyrimidine-5-carbaldehyde [1,2] by condensation with formamidine, acetamidine [3], and benzamidine [3], and with formamidinium acetate, have failed since the water formed during

(1) *(2)*

the reaction leads to ring opening. We have succeeded in preparing *(2)* by direct reaction of 4-amino-5-dimethoxymethylpyrimidine *(1)* [2] with *s*-triazine.

Compound *(2)* is very sensitive toward water. Its structure has been proved by elemental analysis and by IR and NMR spectroscopy. The NMR signals [δ = 9.91 (H^2 and H^7), δ = 9.76 (H^4 and H^7)] are shifted to lower field strengths than those of pyrimidine.

Pyrimido[4,5,-d]pyrimidine (2)

2.5 g (15 mmoles) of 3-amino-5-dimethoxymethylpyrimidine and 1.2 g (15 mmoles) of *s*-triazine are intimately mixed by grinding in a dish-shaped mortar in the absence of moisture. The mixture is then heated to 130 °C (oil bath temperature) in an atmosphere of highly pure nitrogen over a period of 90 minutes. The product is immediately sublimed from the reaction mixture at 110 °C (oil bath temperature) and 0.05 torr. 0.8 g of crude product, m.p. 90–135 °C (decomp.), is obtained, which, after recrystallization from anhydrous benzene or anhydrous tetrahydrofuran, affords 0.3 g of pure *(2)* [m.p. 193 °C (decomp.); yield 15 %].

CONFERENCE REPORTS

Macromolecular Colloquium

The Macromolecular Colloquium was held at Freiburg/Br. (Germany) from February 27 to March 1, 1969.

From the lectures:

Determination of the Compatibility of Polymers in Solution

By *D. Berek* [*]

The compatibility of two chemically different polymers in solution can be determined by investigation of the viscosities and the phase relations (phase equilibria, critical concentrations, and limiting miscible concentrations) of the mixtures. These parameters were determined for three binary polymer combinations of polystyrene, polypropylene, and polymethyl methacrylate in toluene and for the system polystyrene + polypropylene in various solvents. It was found that the critical concentration of the ternary system can be readily found by measurement of the limiting concentration of the mixture at a given, calculated (theoretical) relative concentration of the polymers in the system. The critical concentration c_c depends on the molecular weight of the polymer as follows:

$$c_c = A\overline{M}^{-2/3} + c_\infty \qquad (1)$$

where $\overline{M}$ is the weighted average of the molecular weights of the two polymers in the system and A and c_∞ are constants for the given system.

Eq. (1) can be used for the approximate determination of the molecular weight of one of the polymers if the molecular weight of the other is known. This method also allows the estimation of the molecular weights of polymers that would have been blended without solvents.

The observed dependence of the critical concentrations on the chemical nature of the solvent can be eliminated by the introduction of the Staudinger indices of both polymers in the solvent used.

The polymer-polymer interaction parameters b_{23} obtained from the viscosity measurements permit the quantitative characterization of the compatibility of the given polymer pair in solution. There is a simple relation between the b_{23} values and the corresponding Flory-Huggins polymer-polymer interaction parameters χ_{23} calculated from the critical concentrations.

Structure of Cellulose Fibrils

By *R. Muggli, K. Mühlethaler,* and *H.-G. Elias* (Lecturer) [*]

The smallest structural elements in cellulose fibers are the elementary fibrils having a diameter of about 35 Å. To establish whether the chain molecules are present in the extended or the folded state, molecular weight determinations were carried out on thin transverse sections of ramie fibers and the results were compared with those obtained for whole fibers. Gel permeation chromatograms of the carbanilates of the uncut and the cut cellulose samples showed that the molecular weights of the fractions having the highest molecular weights decrease very appreciably on cutting. Theoretical calculations showed that the degree of breakdown for molecules in the extended state agrees closely with the experimental findings [1].

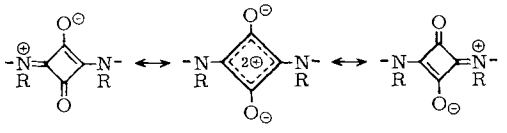
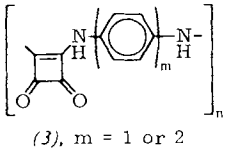
Polar Superpolyamides

By *J. Gauger* (Lecturer) and *G. Manecke* [*]

1,3-Polyamides of squaric acid [*(1)* and *(2)*] have been synthesized by polycondensation of 1,2-dihydroxycyclobutenedione (squaric acid) with bifunctional primary or secondary

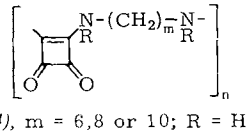


(1), m = 1 or 2



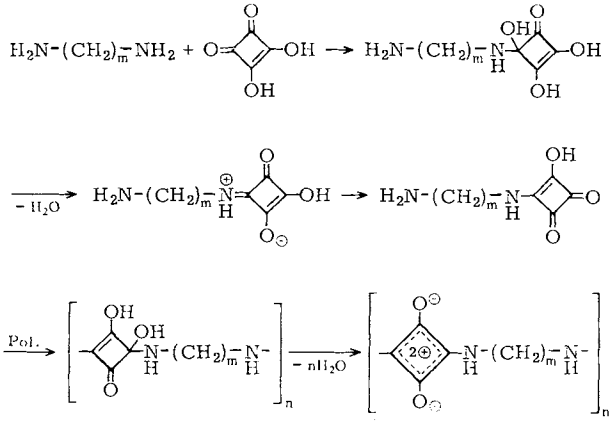
(2), m = 6,8 or 10; R = H, alkyl or aryl

amines. These products are the first members of a new group of polyamides containing the mesomeric cyclobutenediyliumdiolate system.



This system contains strongly polar CO groups, which could explain the high mechanical stability of the polycondensates. The polyamides with R=H are thermally very stable and do not melt below 350 °C (hydrogen bonds and dipole-dipole interactions), whereas those with R = alkyl or aryl are fusible thermoplastics. Copolyamides have been prepared by co-polycondensation of salts of squaric acid with diamines (squarates) and nylon salts.

If esters of squaric acid are used as the starting materials, the 1,2-polyamide isomers [*(3)* and *(4)*] of *(1)* and *(2)* are obtained.



(3), m = 1 or 2

(4), m = 6,8 or 10; R = H, alkyl or aryl

The properties of both groups of polyamides have been characterized by thermogravimetric measurements and determination of the Staudinger indices.

The formation of *(2)*, R = H, was followed by IR spectroscopy and by isolation of intermediates. The reaction scheme

indicated has been confirmed by investigations on the mode of formation of monomeric model compounds and by isolation of the monomeric intermediates.

Preparation of Block and Craft Copolymers by an Anionic Method

By *G. Greber* (Lecturer) and *W. Behr* [*]

Using an anionic method, we synthesized a series of pure block and graft copolymers in which stereospecific poly-1,4-*cis*-isoprene blocks or side chains are combined with corresponding blocks or chains of atactic vinyl polymers.

We also tested the ability of terminal or lateral vinylsilyl and α-substituted *p*-vinylphenyl groups in the polymer molecule to form radical-anions and their suitability for use in graft and block reactions.

A simple method was also developed for the preparation of interesting block and graft copolymers in which organic polymer molecules (possibly having a stereospecific structure) are covalently linked to methylpolysiloxane blocks or side chains by hydrolysis-resistant Si–C bonds. Organic polymer molecules with terminal or lateral sodium or potassium silanolate groups were used as macromolecular initiators for the polymerization of hexamethylcyclotrisiloxane. Organic polymer molecules with lateral silanol groups were obtained by copolymerization of *p*-vinylphenyldimethylsilanol with vinyl monomers. Polystyrene or poly-1,4-*cis*-isoprene molecules were obtained by termination of the corresponding "living" polymers with *n*-butoxydimethylchlorosilane followed by hydrolysis to remove the protective *n*-butoxy groups.

In the synthesis of graft copolymers by the method described here, it can be decided in advance, by choice of the backbone copolymer, whether the arrangement of the grafting sites in the product will be random or regular.

Temperature Dependence of the Thermal Conductivity of Amorphous High Polymers

By *G. Hirsch* (Lecturer) and *G. Rehage* [*]

The thermal conductivities of high polymers above and below their glass transition temperatures were determined in a continuous series of measurements with an apparatus operating on the stationary measuring principle. The investigations on polymers differing in the intensity of their polar character led to conclusions regarding the heat conduction mechanism in high polymers and its temperature dependence. Further investigations on the corresponding metal-containing or cross-linked products yielded information on the extent to which these modifications affect the thermal conductivity.

The measurements showed that heat transport in amorphous high polymers is strongly influenced not only by the increase in mobility of the polymer chains (glass transition temperature) but also by the increase in mobility of the side groups which occurs at lower temperature. These results lead to a heat conduction model in which the heat is transported by intermolecular interactions. In addition to the thermal expansion, the possibility of exchange of position of the side groups must also be considered. The intensity of the heat flow is determined by the number and intensity of the intermolecular interactions. These are increasingly intensified when exchange of position occurs as a result of increase in mobility of the side groups. The increase in mobility of the main chains allows further interactions, but this does not lead to increased intensification of the heat transport, since the competing effect of thermal expansion, which weakens the interactions and hence also the effects of exchange of position, becomes more pronounced. The intensity of the heat transport is also influenced by the difference in the polar character of the various polymers because there are differences in the distance laws for the interaction forces. By combination of

all these effects it is possible to deduce a temperature dependence for the thermal conductivity of amorphous polymers that is in good agreement with the experimental results.

Stimulation of Crystallization of Polymers by Nucleating Agents of High Molecular Weight

By *M. Hoffmann* [*]

Some polymers which do not crystallize easily can be induced to do so more rapidly and extensively by intimately mixing them with a low percentage of a chemically almost identical yet readily crystallizing polymer. Hence the dilatometrically measured crystallization rate of the slow-crystallizing polychloroprene Neoprene W is increased 20 times and the maximum degree of crystallization increased 4.5 times by the addition of 6% of the fast-crystallizing polychloroprene Neoprene HC at 20 °C. Experiments at various temperatures show, moreover, that the melting point of the mixture is 13 °C higher than that of the slow-crystallizing polychloroprene, and that the dependence of the rate of crystallization on temperature is lower than in non-mixed polychloroprenes. The crystallization rate at 22 °C is proportional to the square of the concentration of the added nucleating agent, whereas the increase in the degree of crystallization is proportional to the root of this concentration. It follows from these observations and the rise in the melting point that mixed crystals are formed. Similar stimulation of crystallization is found with polyvinyl chloride and similar polymers and with *cis*-polyisoprene and *cis*-polybutadiene. Such findings are contrary, however, to those made with mixtures of polyethylene and ethylene copolymers and with some other polymers and copolymers. Here there is no stimulation of crystallization, apparently because chain-folding prevents mixed crystallization.

Formation of Macro-Zwitterions in Ionic Polymerizations

By *K. Boehlke, M. J. Han, V. Jaacks* (Lecturer), *N. Mathes*, and *K. Zimmerschied* [*]

Several ionic polymerizations involve the formation of macro-zwitterions (polymer chains having a positive charge at one end and a negative charge at the other). Lewis acids such as SO_3 or BF_3 and bases such as R_3N or R_3P are suitable initiators and heterocyclic or carbonyl compounds are the preferred monomers. The charge separation during initiation and during the first propagation steps does not present an insuperable energy barrier. The formation of macro-zwitterions has been proven by investigation of the end groups and, in the case of dissolved polymers, by measurement of their (very high) dipole moment. In many cases the zwitterion structure is at least partly destroyed by transfer reactions in the further course of the polymerization. The following systems have been studied:

1. Anionic polymerization of β-propiolactone and of pivalolactone with tertiary amines or with preformed low molecular weight betaines. Since these polymerizations (and only these) proceeded homogeneously, the dielectric constants of the solutions could be measured. From the results a value of 40 Debye was calculated for the dipole moment of an oligomeric macro-zwitterion

$$(CH_3)_3N^{\oplus}-CH_2-CO-(OCH_2CH_2CO)_n-O^{\ominus}$$

with $n \approx 7$ in chloroform at 0 °C. Model calculations show that the chain ends are at about the same distance as in random coils of non-ionic polymer.

2. Anionic polymerization of anhydrous formaldehyde with tertiary amines and phosphines. Triphenylphosphine is incorporated into the polyoxymethylene, indicating zwitterion initiation with formation of

$$(C_6H_5)_3\overset{\oplus}{P}-(CH_2O)_n-CH_2-O^{\ominus}$$

With triethylamine, on the other hand, water or methylene glycol appears to act as a cocatalyst with formation of the low molecular weight cation $Et_3\overset{\oplus}{N}H$.

3. Anionic and simultaneous cationic polymerization of anhydrous formaldehyde initiated by diazomethane. The primary reaction product $^{\oplus}CH_2-CH_2-O^{\ominus}$ grows at both ends by addition of formaldehyde. Termination by combination of the ions is largely prevented by the heterogeneity of the polymerization medium.

4. Polymerization of crystalline trioxane on sublimation or on irradiation with γ rays. As in case 3, both anionic and cationic chain ends have been detected in the polyoxymethylene.

5. Cationic polymerization of dissolved trioxane with $TiCl_4$. In this case chain propagation *via* zwitterions of the structure $Cl_4\overset{\ominus}{Ti}-(OCH_2)_n-\overset{\oplus}{O}CH_2$ seems to be prevented by side reactions.

ORD and CD Measurements on Substituted Polysaccharides

By *H. Bittiger* and *G. Keilich* (Lecturer) [*]

Optical rotatory dispersion (ORD) and circular dichroism (CD) have been measured in substituted polysaccharides between 600 and 215 nm, in oder to investigate the influence of the substituents on the behavior of these polymers and to find relations between configuration and conformation on the one hand and these spectra on the other.

1. 2,3,6-Tris(*O*-trimethylsilyl)cellulose and -amylose in *n*-hexane (600–215 nm) and 2,3,6-tri-*O*-methylcellulose and -amylose and 2,3,6-tri-*O*-acetylcellulose and -amylose in chloroform (600–235 nm) exhibit no Cotton effects in the spectral ranges indicated, but give normal ORD curves that can be described by one-term Drude equations (λ_0 between

$$[M] = K/(\lambda^2 - \lambda_0^2)$$

200 and 130 nm). The direction of rotation corresponds to that of the unsubstituted polysaccharides (cellulose in cuprammonium [1] and amylose in water or dimethyl sulfoxide).

2. Tribenzoylpolyglycans (2,3,6-tribenzoylcellulose, -amylose, and -mannan, 2,3,4-tribenzoyldextran, and tribenzoylpullulan) exhibit Cotton effects in dioxane between 280 and 220 nm. The CD spectra of the tribenzoylpolysaccharides differ in the number, position, and sign of the extrema; they

can be interpreted on the basis of the positions of the substituents and the configuration of the monosaccharide units.

3. Carbanilyl derivatives behave quite differently. All trisubstituted and disubstituted β-polyglycans have only a single negative Cotton effect at 238–240 nm. The CD spectra of the corresponding α-polyglycans have a minimum at 240–242 nm and a maximum at 223–225 nm; the ORD curves are asymmetric and cross the abscissa in two places, at 241–243 nm and 220–222 nm. The derivatives of disaccharides with β- and α-glycosidic linkages behave similarly, whereas pentacarbanilylglucose has a single positive Cotton effect. The striking difference between the CD and ORD curves of tricarbanilyl-β-polyglycans and tricarbanilyl-α-polyglycans can be explained with the aid of the excition theory, which has been applied to helical polymers by *Moffit et al.*[2]. The effects suggest a planar arrangement of the chains in the case of β-polyglycans and a helical arrangement in α-polyglycans.

Synthesis of Coding Polynucleotides with Repeating Base Sequences

By *H. Kössel* (Lecturer), *H. Büchi, T. M. Jacob, A. R. Morgan, S. A. Narang, E. Ohtsuka, R. D. Wells*, and *H. G. Khorana*[*]

The following types of reactions are used for the chemical synthesis of deoxypolynucleotides with repeating base sequences.

(A) polycondensation of mononucleotides,

(B) polycondensation of preformed dinucleotide or trinucleotide blocks,

(C) stepwise condensation of mononucleotides with preformed oligonucleotide blocks,

(D) condensation of preformed oligonucleotide blocks.

Type A leads to a mixture of homopolymers of various chain lengths. Type B gives mixtures of polydeoxydinucleotides or polydeoxytrinucleotides of various chain lengths. The strictly repeating base sequences of the polycondensation products are dictated by the base sequences of the preformed di- or trinucleotide blocks. Reaction types C and D lead to polydeoxynucleotides of any (*i.e.* repeating or non-repeating) base sequence.

Dicyclohexylcarbodiimide or aromatic sulfonyl chlorides are used as condensing agents. Specific protective groups are necessary for the nucleotide components to ensure that the condensations lead to 3′ → 5′-phosphoric acid diester linkages. Chains of up to 20 nucleotide units are obtained (molecular weight ≈ 7000).

To obtain high molecular weight, DNA-like polynucleotides, pairs of deoxypolynucleotides with complementary base sequences and containing at least 8–12 nucleotide units must be elongated with DNA polymerase in the presence of the four deoxynucleoside triphosphates. The resulting products consist of 1.5×10^2 to 6×10^3 nucleotide units per single strand. The strictly repeating base sequences are retained in this reaction.

The individual strands of the DNA-like polynucleotides are selectively transcribed with DNA-dependent RNA polymerase in the presence of the corresponding ribonucleoside triphosphates to give messenger-RNA-like ribopolynucleotides with repeating base sequences. When used as a messenger in the cell-free protein biosynthesis system of *E. coli*, these products stimulate the formation of polypeptides with defined repeating amino-acid sequences, and so allow the assignment of trinucleotide sequences to individual amino acids.

Polymerization of Ethylene with Methyltitanium Trichloride and Methyltitanium Dichloride

By *K. Kühlein* (Lecturer) and *K. Clauss*[*]

Polymerization experiments were carried out with CH_3TiCl_3 and CH_3TiCl_2 to clarify the question whether the active species in the polymerization of olefins with Ziegler catalysts is a two-component system or a one-component system.

In the polymerization of ethylene with CH_3TiCl_3 under the conditions of Ziegler polymerization (20–100 °C)[1], partial decomposition of the CH_3TiCl_3 yields the two-component system $TiCl_3/CH_3TiCl_3$, which, like a Ti^{III}/Al system, gives a high molecular weight polyethylene with little branching. In order to suppress the conversion of the CH_3TiCl_3 into the two-component system and so determine its specific activity, the reaction with ethylene was investigated below −50 °C. Depending on the solvent, a slow growth reaction on the Ti–C bond was observed, and this was accompanied by displacement by the monomer.

Under the same conditions, CH_3TiCl_2, which was obtained without complexing agents for the first time, exhibited a very high polymerization activity for ethylene. High molecular weight polyethylene having a reduced viscosity of 4 to 6 is obtained rapidly even at −70 °C. The experiments appear to confirm the views developed by *Cossee*[2].

Cation Radicals in Vinyl Polymerization

By *A. Ledwith*[*]

One-electron oxidation of olefins leads to cation radicals which may dimerize to give propagating di-cationic species. Olefins that react readily with one-electron oxidants have powerful electron releasing substituents, *e.g. N*-vinylcarbazole, *p*-methoxystyrene. Polymerization of these monomers is readily effected using stable cation radicals as initiators *e.g.* $(BrC_6H_4)_3N^+ClO_4^-$. Cation radicals also play a vital role in the catalytic cyclodimerization of electron rich olefins.

Optical Activity and Conformation in Solution of Copolymers of Optically Active α-Olefins with Styrene and 4-Methyl-1-pentene

By *P. Pino* (Lecturer), *F. Ciardelli*, and *C. Carlini*[*]

Optically active poly-α-olefins derived from *(1)* and *(2)* were investigated[1] in order to obtain a better insight into the relationships between stereoregularity and conformation of

isotactic polymers in solution. On the basis of the data obtained it was proposed that the macromolecular main chains of poly-*(1)* and poly-*(2)* in solution were in a helical conformation, both screw senses being present. However, when the asymmetric carbon atom is in the α or β position with respect to the main chain (as in poly-*(1a)*, poly-*(1b)*, or poly-*(2)*) one of the screw senses is largely favored, the prevailing one being determined by the chirality of the monomer.

(1a), n = 0
(1b), n = 1
(1c), n = 2

(2)

(3)

(4)

To confirm this hypothesis, optically active stereoregular copolymers of styrene *(3)* with *(R)*-3,7-dimethyl-1-octene *(2)*[2], *(S)*-4-methyl-1-hexene *(1b)*, and *(S)*-5-methyl-1-heptene *(1c)* as well as of 4-methyl-1-pentene *(4)* with *(1b)*[3] were prepared with Ziegler-Natta type catalysts. In these cases, the units derived from *(3)* and *(4)* do not contain asymmetric carbon atoms in the side chain and any contributions they may make to the optical rotation of the copolymer should be attributed to a displacement of the conformational equilibrium of the above units towards dissymmetric conformations of one predominant chirality. In fact also in "isotactic" copolymers of vinyl monomers the optical activity connected with the tertiary carbon atoms in the main chain should be vanishingly small.

ORD and CD measurements of the styrene copolymers in chloroform solution showed a Cotton effect between 275 and 245 nm connected with a $\pi \rightarrow \pi^*$ transition of the aromatic chromophore[2]. The sign of the above Cotton effect is positive or negative when the chirality of the optically active comonomer is *(S)* or *(R)*, respectively. These results show that the units derived from styrene, which *per se* should be optically inactive, contribute to the optical rotation of the copolymer, and that the sign of this contribution depends on the chirality of the optically active comonomer and hence on the prevailing screw sense of the helical conformation of the copolymer macromolecules.

In the case of the copolymer from *(4)* and *(1b)* the optical rotation at 589 nm in hydrocarbon solution is higher, at each composition, than that of the corresponding homopolymer mixtures and increases with increasing stereoregularity. The optical rotation per mole of *(4)* in the copolymer, $[\Phi]_{(4)}$, was found to increase with increasing the content of *(1b)* reaching a limiting value at 50% of *(1b)*.

Taking in account the value calculated according to *Brewster*[4] for the molar optical rotation of units from *(4)* included in right- or left-handed helical sections, the highest value found for $[\Phi]_{(4)} = +160°$ is in excellent agreement with our model, according to which most of the units derived from *(4)* should be included in left-handed helical sections, which largely prevail when the optically active comonomer has *(S)* chirality[1].

Semisynthetic and Synthetic Macromolecules in Immunochemical Research

By *E. Rüde* (Lecturer), *K. Himmelspach,* and *C. Sorg*[*]

The investigation of the chemical principles of immunological processes has been greatly aided by the use of semisynthetic antigens ("artificial antigens") prepared by the attachment of low molecular weight compounds to natural antigens, which are mostly proteins. *K. Landsteiner* showed that immunization of test animals with antigens of this type leads *inter alia* to the formation of antibodies that react specifically with the groups introduced. Thus antibodies are directed not against the macromolecular antigen as a whole, but against definite structural subunits, the determinant groups.

The first artificial antigen capable of producing protective antibodies was synthesized in 1939 by coupling cellobiuronic acid to protein. This antigen contained a determinant group of a bacterial surface antigen, and when used for the immunization of test animals, it protected them against infection by the corresponding bacterial strain. Methods have now been developed that allow the conversion of higher oligosaccharides of bacterial origin into full antigens by coupling with proteins without loss of their serological specificity.

In addition to semisynthetic antigens of this type, fully synthetic polypeptide antigens are finding increasing use in the clarification of immunological problems. These synthetic antigens, which are mostly prepared by polymerization of *N*-carboxy-α-amino acid anhydrides, have well defined structures. Because of their great variability, they allow a systematic study of the chemical and physical parameters that are important to immunogenicity, *i.e.* to the ability of a substance to initiate the formation of antibodies in higher organisms. By incorporation of monosaccharides and disaccharides into a very weakly immunogenic synthetic polypeptide, for example, the effects of sugars on the immunogenicity of this model antigen were studied. It has recently been shown that branched polymers in which peptide side chains are bound to a polyvinyl alcohol backbone initiate antibody formation upon injection, and even pure vinyl polymers have been found to be immunogenic under certain conditions.

Synthetic polymers and chemically modified natural antigens play an important part in the detection and isolation of antibodies. Thus it has been shown that macromolecules esterified with fatty acids are readily fixed to the surface of erythrocytes by adsorption. This considerably widened the scope of the important passive hemagglutination method for the detection of antibodies. Methods that permit the labeling of polysaccharides with radioactive iodine are also important, since the binding to antibodies can be measured directly and very sensitively with the aid of these labeled derivatives.

Investigations on the Structure of Fibroin

By *W. Schade*[*]

Whereas the amino-acid sequences of many globular proteins and even the complete three-dimensional structures of some are known, even the molecular weights of the fibrous proteins wool and silk are not known accurately. The difficulties in the determination of the structures of fibrous proteins are due to the fact that they are probably built up from several different protein chains, which cannot be directly separated from one another because of their poor solubility.

A considerable advance in the investigation of silk has resulted from the realization that the crystalline and amorphous components of fibroin, which were detected some time ago

by X-ray analysis, have different chemical compositions and can be separated by enzymatic degradation. The amino-acid sequences of the degradation products obtained in this way have been largely established.

To establish the arrangement of the peptide fragments of the crystalline and amorphous regions in the fibroin molecules, it would be necessary to determine the sequences of larger peptides or of the fibroin molecules themselves.

Larger peptide fragments can be obtained by mild acid or alkaline partial hydrolysis followed by chromatographic separation of the fragments on a column. This method has the advantage that the original fiber structure is partly retained and can be examined microscopically. Intact fibroin has also been resolved into several components by disk electrophoresis.

This confirms the hypothesis frequently advanced in the literature that fibroin consists of several different protein chains. The results of the investigations also indicate that the crystalline and amorphous regions do not alternate in the same chain but are contained in separate chains.

Recent Results on the Kinetics of Anionic Polymerizations

By *L. L. Böhm, B. J. Schmitt,* and *G. V. Schulz* (Lecturer) [*]

The active end group of polystyrylsodium exists in three forms in polar solvents (*e.g.* tetrahydrofuran and tetrahydropyran): the free anion, the solvent-separated ion pair, and the contact ion pair. The equilibria between the three forms are shifted by temperature changes; addition of a sodium salt (*e.g.* sodium tetraphenylborate) changes the degree of dissociation. The following parameters can be determined for any solvent by measurement of the conductivity of the living ends and the polymerization rate as functions of the temperature, the concentration of the living ends, and the sodium ion concentration:

1. enthalpy and entropy differences between the two types of ion pairs;
2. enthalpy and entropy of the electrolytic dissociation;
3. activation energy and activation entropy of the monomer addition for all three forms of the active end group.

The extremely strong dependence of the polymerization rate on the solvent and its anomalous temperature dependence can be easily and quantitatively explained with the aid of these parameters.

Microseparation of Phases in Swollen Gels and its Investigation by Light Scattering

By *K. Dušek* and *B. Sedláček* (Lecturer) [*]

The interaction of *n*-butanol and poly(ethylene glycol monomethacrylate) crosslinked with ethylene glycol dimethacrylate has been studied by light-scattering measurements. The swollen and homogeneous gels contain small concentrations of heterogeneous zones having diameters $> 3\,\mu m$. Phase separation (microsyneresis) occurs in the interior of the swollen gel with falling temperature, and droplets having a diameter of about $0.15\,\mu m$ are formed.

This order of magnitude confirms the view that the size of the particles formed is determined by the retractive force of the deformed network and by the interfacial energy between the swollen gel and the *n*-butanol.

The Combination Reaction During the Thermal Decomposition of Aliphatic Azo Compounds in the Presence of Oxygen. Cage Reaction and Cross-Termination

By *W. Vogt* [*]

On thermal decomposition of azoisobutyronitrile (AIBN), a certain amount of tetramethylsuccinonitrile is always formed by combination of the initially formed 2-cyanoisopropyl radicals. Depending on whether the two combining radicals come from the same molecule or from two different molecules of AIBN, we speak of primary combination or cross-combination (or termination). The theory of the cage effect enables us to predict that the primary combination will be much less influenced than the cross-combination by the presence of a free-radical scavenger.

We were interested in whether any cross-combination occurs at all in the presence of oxygen, which is a particularly effective free-radical scavenger.

To clarify this question, we decomposed a mixture of tetramethylazoacetonitrile (=AIBN) and tetraethylazoacetonitrile in the presence of oxygen and determined the resulting 2,2-dimethyl-3,3-diethylsuccinonitrile (which can only be formed by cross-combination) by quantitative gas chromatography. 2,2-Dimethyl-2′-2′-diethylazoacetonitrile was treated in the same way and the products were examined for tetramethyl- and tetraethylsuccinonitriles.

The experiments were carried out at 90 °C and an oxygen pressure of about 1 atm with a total concentration of azo compounds of about 0.1 mole/l. The figures given for the following solvents are the maximum values found for the cross-combination in mole-%, based on the total quantity of azo compound decomposed: benzene (<1 %); toluene (<0.6 %); *n*-propyl acetate (<0.5 %), dioxane (<0.3 %); cyclohexane (<0.1 %); methyl methacrylate (<0.1 %).

Interpretation of Coils and Structure in the Aggregated Polymer State

By *B. Vollmert* (Lecturer) and *H. Stutz* [*]

Polymers (A) containing free OH groups were prepared by copolymerization of butyl acrylate with small quantities of hydroxybutyl acrylate, and polymers (B) containing free NCO groups were prepared by copolymerization of butyl acrylate with small quantities of isocyanatoethyl acrylate. When the polymers were mixed in solution (at various polymer concentrations and with various concentrations of OH and NCO groups along the chains) in ratios such that the functional groups were present in the stoichiometric ratio of 1:1, they gave conversions of up to 16%. It was therefore concluded that the polymer coils in concentrated solutions and gels interpenetrate only in relatively thin zones on their surfaces.

The application of these results makes it necessary to revise our views on the rubbery-elastic state and the glass state.

It is concluded from the classical theory *(P. Flory)* that intramolecular cross-linkages ("loops") have no influence on the degree of swelling and the mechanical modulus of gels,

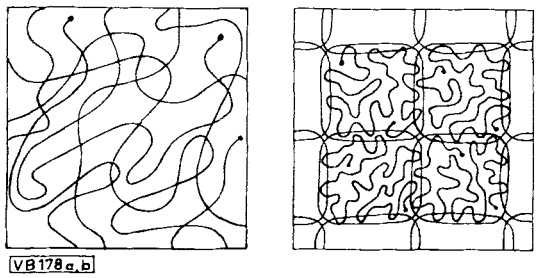

Fig. 1. Left: Classical model of aggregated polymer state. Right: Individual coil-structure model of aggregated polymer state.

whereas our *Individual coil structure* model of cross-linked polymer systems suggests that the degree of swelling (= swelling ratio) decreases and the modulus increases by additional intramolecular crosslinking.

Experiments with our A-B-polymer system, however, showed that intramolecular cross-linkages have a strong influence on the mechanical properties of gels. The modulus of intermolecular crosslinking gels without any intramolecular crosslinking is lower and the modulus of the same gels with additional intramolecular crosslinkages is higher than is predicted by the classical theory.

According to the ICS-model, the proportion of intramolecular crosslinkages in ordinarily mixed crosslinked system is much higher than assumed until now (70–80%).

Contrary to the classical theory, chain entanglements (physical crosslinkages) are not to be expected in the aggregated polymer state.

Investigations on the Epitactic and Topotactic Polymerization of Trioxane and Tetroxane[**]

By *A. Munoz-Escalona, E. W. Fischer,* and *G. Wegner* (Lecturer)[*]

Though the formation of polyoxymethylene [POM] from crystalline trioxane was one of the first examples of polymerization in the solid state, the mechanism of the polymerization and the morphology of the resulting polymers are still largely unknown. The same is true of the polymerization of tetroxane, which can also be converted into polyoxymethylene in the solid state.

We have polymerized single crystals of both monomers by the action of γ radiation, by the addition of boron trifluoride-ether, and by slow sublimation of monomer. The resulting polymers were investigated by large-angle and small-angle-X-ray scattering and by electron microscopy.

Large-angle X-ray photographs of the polymers from trioxane always exhibit well oriented fiber diagrams with pronounced twinning, irrespective of the polymerization method. The small-angle scattering for these samples shows no long period, indicating a texture with extended polymer chains parallel to the fiber axis. Examination in the electron microscope shows well-ordered fibrils, but the twinning structure cannot be observed. A different morphological structure is obtained on polymerization of crystalline tetroxane. Large-angle X-ray diagrams of samples polymerized by γ radiation between 60 and 100 °C showed that very few twins are formed at 60 °C, and none between 80 and 100 °C. Small-angle diagrams reveal a long period which increases with the reaction temperature. It is found on examination in the electron microscope that the fibrils of POM formed by this method show ripples perpendicular to the fiber axis. It follows from this and from the results of molecular weight measurements that the structure in this case involves folded chains.

When tetroxane is polymerized by the action of boron trifluoride-ether or by slow sublimation, regularly shaped hexagonal lamellae with distinct growth spirals are formed. Some signs indicate that epitactic polymerization occurs in this case. The reasons for the differences in structure and morphology of POM from trioxane and from tetroxane are probably mainly concerned with the different lattice structures of the two monomers.

Solution Properties of Random Copolymers of Methyl Methacrylate and *n*-Butyl Acrylate

By *W. Wunderlich*[*]

Viscosity measurements and light-scattering measurements have been carried out on chemically homogeneous random copolymers of methyl methacrylate (MMA) and *n*-butyl acrylate (BA). In the good solvent chloroform, the copolymers in the composition range $79.5 \geqslant [\text{MMA}] \geqslant 20.5$ wt-% show a uniform relation between the viscosity $[\eta]$ and the molecular weight *(M)*, which lies between that of PMMA and that of PBA: $[\eta] = 4.2 \times 10^{-3} M^{0.8}$ ($\text{cm}^3\,\text{g}^{-1}$), $T = 20\,^\circ\text{C}$. In the fair solvent acetone the $[\eta]$ $-M$ function for MMA/BA = 56/44 wt-% is above those of PMMA and PBA. The values of the second osmotic virial coefficient A_2 behave in the same way. Using equations given by *Stockmayer-Fixman, Burchard,* and *Kurata et al.*, the effects of the short-range and the long-range interactions on the composition dependence of $[\eta]$ and A_2 were estimated from the molecular weight dependence of A_2 and $[\eta]$. It was found that the short-range interactions correspond to the mean of the values for the two comonomers, while the long-range interactions are considerably greater than those of the corresponding homopolymers. The increase in the viscosity and in A_2 in the random copolymers can be explained as a result of intramolecular incompatibility.

Structural Investigations on Semicrystalline Polyethylene and Ethylene-Propylene Copolymers

By *P. Zugenmaier* (Lecturer) and *H.-J. Cantow*[*]

The crystal structures of polyethylene crystallized from the melt and from solution, as well as of ethylene-propylene copolymers, were investigated by X-ray diffraction. With linear polyethylene that had been crystallized extremely slowly from the melt, reflections were observed over the entire range of angles. The previously unknown reflections were indexed by a new procedure, which also permits the extremely accurate determination of the lattice parameters.

The reflection intensities were calculated for a simple polyethylene model. Comparison of the calculated and measured intensities for various samples of homopolymer and copolymer that had been crystallized and treated with fuming nitric acid gave the following results.

1. The angle between the plane containing the carbon backbone of the polymer chain and the lattice vector α is $\delta = 45 \pm 1\,^\circ$ for highly annealed linear polyethylene. The angle δ is smaller near the folds, *i.e.* at the crystallite surface, than in the interior of the crystalline zone. This decrease is due to the strain where the chain is folded.

2. No methyl side groups were found inside the crystalline zones in homopolymers or copolymers.

3. The disorder function, which describes the deviations of the atoms from their ideal position, is anisotropic. The magnitude of the anisotropy depends on the crystallization conditions. The influence of strain on the disorder function could be detected in the case of copolymers.

X-Ray Spectroscopic Studies of the Chemical Bond in Oxides

By *H.-U. Chun* [*]

The contribution of the valence electrons of an atom toward the screening of the nuclear charge is so low in the case of elements having large nuclear charges and for electron transitions between the innermost shells that no measurable shift of an X-ray line occurs when the valence electrons take part in chemical bonding. In the case of the lighter elements, however, the bonding is observed to exert a definite effect on the energy and form of X-ray spectral lines, as has been demonstrated in particular by *Faessler* [1] for the K lines of Si, P, and S compounds, and by *Meisel* [2] for the K_α lines of Ti, V, Cr, Mn, Fe, Co, and Ni in their compounds. The effect is greatest in the X-ray K spectra of compounds of the elements Li to F since the L shell involved in the K → L transition ($K_{\alpha 1,2}$ line) actually contains the valence electrons. The X-ray spectra of the series Li to F can provide a great deal of information about changes in the bonding of one of these elements in various compounds, *e.g.* about the nature of the metal-oxygen bond in oxides.

The O–K spectra of BeO, MgO, CaO, SrO, BaO, Sc_2O_3, Y_2O_3, La_2O_3, Sm_2O_3, Yb_2O_3, NiO, ZnO [4], α-Al_2O_3, and γ-Al_2O_3 [5] were recorded at high resolution by means of a spectrograph constructed for X-ray spectroscopic investigation of light elements [3]. The spectra were produced by direct electronic excitation (2–4 kV, 1–10 mA) of a thin layer of powdered sample applied to the anode of an X-ray tube. Evaluation of the spectra showed that characteristic relationships exist between the type of spectrum (number and intensity ratios of the lines) and the energy of the individual lines in the O–K spectrum on the one hand, and the nature of the metal-oxygen bond in these oxides on the other.

Of the alkaline earth oxides, only CaO, SrO, and BaO give the O–K spectrum typical of the O^{2-} ion, while the O–K spectrum of MgO and also of the oxides of the lanthanides evidence a transition state between ionic and covalent bonding. For NiO, ZnO, BeO, α-Al_2O_3, and γ-Al_2O_3 the metal-oxygen bond is deduced to be largely covalent from the spectra. As the metal-oxygen distance and the ionic character increase within a series of oxides having the same crystal structure, all the lines of the O–K spectrum are seen to shift toward shorter wavelengths (Table 1).

Table 1. Wavelengths (Å) of the O–K lines $\alpha_{1,2}$, α_3, and α_4 of metal oxides.

Oxide	Crystal structure	M–O-distance (Å)	$\alpha_{1,2}$ [a]	α_3 [a]	α_4 [a]
NiO	[c]	2.097	23.622	—	—
MgO	[c]	2.104	23.599	23.560	23.521
CaO	[c]	2.401	23.609	23.525	23.481
SrO	[c]	2.573	23.605	23.519	23.475
BaO	[c]	2.762	23.595	23.501	23.460
BeO	[d]	1.64	23.596	—	—
ZnO	[d]	1.98	23.564	—	—
Sc_2O_3	[e]	2.11 [b]	23.597	—	23.515
Yb_2O_3	[e]	2.25 [b]	23.585	32.538	23.501
Y_2O_3	[e]	2.28 [b]	23.578	23.535	23.478

[a] Standard deviation ± 0.008 Å. [b] Mean M–O distance.
[c] NaCl type. [d] Wurtzite type. [e] C type of the lanthanide oxides.

The O–K band of γ-Al_2O_3 (maximum: 23.591 Å) is shifted to lower energies compared to that of α-Al_2O_3 (maximum: 23.562 Å) and the bands of both oxides exhibit a fine structure that is due to the short-range order in their lattices.

The results of these investigations show that conclusions concerning the relative ionic character of the metal-oxygen bond in oxides and concerning the structure of regions of short-range order can be reached with the aid of the X-ray spectroscopic technique. Moreover, the use of this method can contribute to our knowledge of the structure of oxidic surface layers.

The Boundary between Fluid Phases as a Barrier for the Passage of Molecules

By *W. Nitsch* [*]

The phase change of molecules at the boundary between fluid phases is to be regarded as a kinetic consequence of transport processes and boundary layer reactions; during the reaction step, solvations of the exchanging molecules can occur, the rates of which determine the barriers for the passage through the boundary layer. Since this process is generally transport-controlled, or is regarded as such, little is known about this type of heterogeneous reaction, which can be of significance for mass transfer. It may be deduced from the laws of diffusion that the boundary reactions in stationary phases or under conditions of laminar flow can only be found for very short phase contact times. Owing to the inadequate knowledge of the hydrodynamics applying to turbulent motion of phases the corresponding transport processes under such conditions are not known. A description of the boundary layer processes on turbulent flow depends on the realization of a flow state in which the mass transfer is independent of the flow, *i.e.* proceeds at a maximum rate and is thus reaction-controlled.

A number of examples of the description of reactions in stationary phases and in phases in turbulent flow, as carried out in our laboratory, will now be considered. The boundary layer reactions occurring on physical absorption of a gas could first be delineated for the transport of oxygen and nitrogen in a film of water that was continuously being reformed on a horizontal roller that was partly immersed in an absorption bath [1]. As a result of the contact times that could be realized by means of this method (down to 10^{-4} s), the relevant boundary layer reactions could be investigated. The collision yield factors for the reaction of nitrogen and oxygen with water are of the order of $\alpha = 10^{-4}$. The boundary layer reaction between carbon dioxide and water, on the other hand, is too fast to be investigated by the above technique.

The realization of mass transfer independent of the flow state, and therefore reaction-controlled, could be accom-

plished with the system propionic acid/water/carbon tetrachloride in a flow apparatus specially developed for this purpose[2]. The resulting kinetic data are plausible if the boundary layer reaction occurring on transfer of a caroxylic acid is formulated as a series of three individual reaction steps[3]. For the passage through the boundary layer from water to carbon tetrachloride, these steps are:

1) Adsorption of the carboxylic acid molecule, which exists as the monomer in water;

2) dimerization of the adsorbed molecules; and

3) desorption of the dimer into the CCl_4 phase.

The same processes occur in the reverse order on passage in the opposite direction. The dependence of the rate constants on the length of the fatty acid residues lends support to the above interpretation. This dependence corresponds quantitatively to established adsorption phenomena.

Cyclization of Unsaturated Fatty Acids

By *V. Wolf*[*]

The cyclization of 9,12,15-*c,c,c*- (linolenic acid), of 9,12,15-*t,t,t*- (linolenelaidic acid), of 9,11,13-*c,t,t*- (α-eleostearic acid), and of 9,11,13-*t,t,t*-octadecatrienecarboxylic acid (β-eleostearic acid) has been studied in alkaline diethylene glycol solutions at 180–220 °C. An alkali-induced ionic reaction occurs in which the non-conjugated acids undergo allylic rearrangement, whereas *cis-trans* rearrangement and double-bond shifts are observed in systems already containing two or three conjugated double bonds or in cases in which such conjugated systems are formed.

The α,γ,ε-*t,c,t*-triene formed in this manner is cyclized in a thermal multi-center process to give 5,6-disubstituted 1,3-cyclohexadiene. Compounds of this kind occur in equilibrium with all conceivable cyclohexadienes and cyclohexenes having conjugated semi-cyclic double bonds. About 10% of the cyclic dienes form *o*-substituted aromatic carboxylic acids. The aromatization proceeds by loss of either two hydrogen atoms, or one hydrogen atom and one side chain, or two side chains. Interpretation of the mechanism is greatly facilitated by the diverse but highly characteristic distribution of the lengths of the alkyl and ester side chains for each of the acids investigated.

New Investigations of the Biosynthesis of Flavonoids

By *H. Grisebach*[*]

trans-Cinnamic acid which is formed from L-phenylalanine by the enzyme phenylalanine-ammoniumlyase is an important precursor for the formation of flavonoids. Its hydroxylation to 4-hydroxycinnamic acid (*p*-coumaric acid) is catalyzed by a microsome fraction from peas[1]. This enzyme belongs to the mixed-function hydroxylyases; it could be shown that the H atom originally in the *para*-position migrates into the *ortho*-position to the hydroxyl group ("NIH shift"). A similar reaction occurs in the biosynthesis of several flavonoids.

Further hydroxylation of *p*-coumaric acid, giving caffeic acid, can be catalyzed by an enzyme (or several enzymes) of phenolase type[2]. This enzyme, purified from spinach beet, can also hydroxylate several flavonoids at the 3′-position of the B-ring.

According to our results, chalcones are the central intermediates in the biosynthesis of flavonoids. The enzyme chalcone-flavanone-isomerase, first enriched by *E. Wong*, has been found to be present in all plants so far studied. The substrate specificity of several isoenzymes, which are found in plants, were investigated. It remains unsolved whether the further changes start from the chalcone or the flavanone precursors. Kinetic experiments with the pair [^{14}C]chalcone-[^{3}H]flavanone have been carried out in this connection.

Coumestanes and related natural products are biogenetically to be counted among the isoflavones since, like isoflavanones, the latter can be converted into coumestanes. Coumestrol and a new coumestane have been isolated from Mung bean *(Phaseolus aureus)*.

Dihydrodaidzein can be converted into daidzein in seedlings of the Mung bean. Dihydroisoflavones are, however, probably not intermediates in the biosynthesis of isoflavones. The fate of the hydrogen was studied in the conversion of 7,4′-dihydroxy[2-^{14}C-3-$^{3}H_2$]flavanone and 5,7,4′-trihydroxy-[2-^{14}C-2-^{3}H]flavanone; the H atom on C-2 is retained but a H atom is lost from C-3.

Work by *W. Barz* in our Institute indicates that some isoflavones and coumestrols in *Cicer arietinum* and *Phaseolus aureus* undergo a turnover whose biological half-life is of the order of 50 hours. Thus synthetic and degradative reactions will have to be considered in future studies of the metabolism of these compounds.

Investigation of Binding of Inhibitors to Ribonuclease by NMR Spectroscopy

By *H. Rüterjans*[*]

Hitherto, high-resolution nuclear resonance spectra have been little used for the structural analysis of such macromolecules. The signals are broad and overlap because of the small mobility of the individual molecular groups. Only a limited number of the signals in the NMR spectra can be unequivocally assigned to particular protons of the protein. As example can be cited the signals of the C-2 protons of the histidine-imidazole rings, which are shifted beyond the spectral region of the remaining protons to lower field. Furthermore, the signals of these protons shift about 1.0 ppm to higher field during the deprotonation to the uncharged imidazole ring; if the chemical shift of the imidazole C-2 protons is plotted against the pH value, "titration curves" and p*K* values of the histidines are obtained.

In the case of bovine pancreatic ribonuclease A, different p*K* values are obtained for the four histidines present in the enzyme. From NMR investigations on carboxyalkyl derivatives of RNase A and on the subtilisin-cleaved enzyme (RNase S), these p*K* values can be assigned to the histidines 12, 48, 105, and 119 of the polypeptide chain[1]. The p*K* values of the histidines 12 and 119 of the active site are unusually low; they increase by about 1.0 and 0.7 respectively if the NaCl concen-

tration is increased from 0.1 M to 0.4 M, whereas the pK value of His 105 increases by only 0.2 on changing the ionic strength by this amount. This finding indicates that a positively charged group, probably the ε-amino group of the lysine 41, is immediately adjacent to the two imidazole rings of His 12 and His 119. Furthermore, from an accurate analysis of the titration curves of His 12 and His 119 it can be shown that the imidazole rings of these two histidines are coupled by a hydrogen bond in a specific conformation of the enzyme. There are many indications that this specific conformation of the RNase A is the catalytic form of the enzyme.

If competitive inhibitors, such as cytosine 3′-monophosphate or cytosine 2′-monophosphate, are added to a solution of RNase A, the C-2 NMR-signals of His 12 and His 119 shift to lower field, indicating protonation of the imidazole rings. On addition of inhibitors both histidines remain protonated until decomposition of the RNase-inhibitor complex at pH values of about 7–9. The chemical shift and line width of the two signals are different. The fact that this shift of the C-2 NMR-signals to lower field is also observed on addition of sodium phosphate and sodium pyrophosphate, lends further support to the conclusion that the ε-amino groups of Lys 41 and of the positively charged imidazole rings of His 119 probably fix the doubly negatively charged phosphate group of the inhibitor [2].

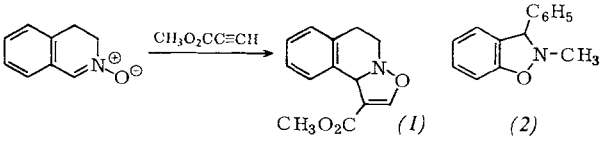
Molecular Structure from Rotational Spectra

By *H. D. Rudolph* [*]

Rotation spectroscopy, in addition to electron-, X-ray-, and neutron diffraction, furnishes data concerning the geometry of a molecule. For known atomic masses, the bond lengths and angles determine the three principal moments of inertia, upon which the rotational energy terms of the freely rotating molecule (gas phase) alone depend. Once the spectrum has been assigned then the principal moments of inertia are known.

Molecules containing isotopes have different moments of inertia because of the different masses; consequently, they have different spectra despite the fact that they have the same geometry. If the spectra of a large enough number of isotopically substituted molecules have been analyzed a sufficiently large set of principal moments of inertia can be accumulated to derive from it the structural parameters.

Rotation-vibration interactions give rise to difficulties. Whenever possible one attempts the determination of an "r_s-structure" (s = substitution): For the location of an atom only the *differences* of the principal moments of inertia before and after the isotopic substitution of that particular atom are used. Thus the greater part of the vibration-rotation interaction which is independent of isotopic substitution is eliminated. Only one atom at a time may be substituted. At least partial r_s-structures have been given for some 500 smaller or moderately sized molecules. The accuracy of the bond lengths lies between 0.001 and 0.01 Å. For the determination of the physically defined "equilibrium structure" (minimum of the potential surface), explicit consideration of vibration-rotation interaction is necessary, *i.e.* the analysis of the rotational spectra also in the excited states of each vibration of all molecular isotopes is required. The effort for such an investigation to be carried out is justified only in the case of the smallest molecules. It is believed, however, that the above r_s-structure comes very near the equilibrium structure.



In addition to providing data about geometry, rotation spectroscopy also furnishes a great deal of further data concerning structure: definite dipole moment components, internal mobility, *etc.* The instrumentation is characterized by high resolution but low intensity of the spectra recorded, and by the use of waveguide techniques, as well as monochromatic, tunable radiation sources.

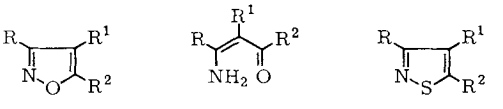
SELECTED ABSTRACTS

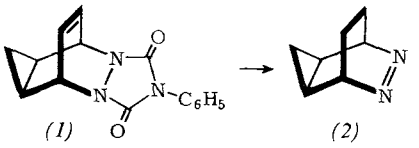


Isoxazol-4-ine derivatives such as *(1)* have been prepared for the first time by *M. Seidl, R. Huisgen,* and *R. Knorr* by 1,3-dipolar cycloaddition of nitrones to alkynecarboxylic esters, *e.g.* methyl propiolate, ethyl phenylpropiolate, and dimethyl acetylenedicarboxylate. The five-membered heterocycle produced can be stabilized in different ways. Thus the thermolabile compound *(1)*, m.p. 53–55 °C, is converted into a betaine by cleavage of the five-membered ring in boiling glacial acetic acid. On the assumption that the isoxazol-4-ine ring could be stabilized by incorporation of the double bond

(1) *(2)*

of a benzene ring, the previously unknown benz[*d*]isoxazolines were synthesized from nitrones and arynes *e.g.* dehydrobenzene. Compound *(2)*, yield 100%, melts at 59–59.5 °C. / Chem. Ber. *102*, 904 (1969) / –Ma. [Rd 999 IE]

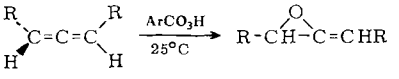
The synthesis of substituted isothiazoles from isoxazoles has been reported by *D. N. McGregor, U. Corbin, J. E. Swigor,* and *L. C. Cheney*. The isoxazole ring *(1)* is first opened up by reduction with Raney Ni–H_2 (in CH_3OH, C_2H_5OH; at *ca.*



(1) *(2)* *(3)*

3 atm) and the enamine ketone *(2)* thus formed is converted into the isothiazole *(3)* by treatment with P_2S_5 followed by oxidation with *e.g.* chloranil. The yields are between 38 and 90%. / Tetrahedron *25*, 389 (1969) / –Ma. [Rd 1000 IE]

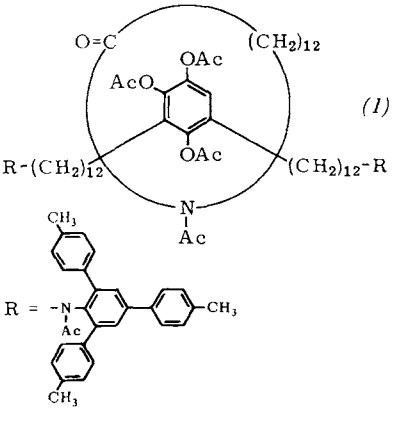
The synthesis and pyrolysis of 6,7-diazatricyclo[3.2.2.0^{2,4}]-non-6-ene *(2)* has been investigated by *M. Martin* and *W. R. Roth*. The synthesis is accomplished by Diels-Alder addition of 1,3,5-cycloheptatriene and 4-phenyl-1,2,4-triazoline-



3,5-dione to form the adduct *(1)* which after catalytic hydrogenation, alkaline hydrolysis, decarboxylation, and oxidation with $CuCl_2$ affords a stable Cu complex from which the compound *(2)* can be isolated by treatment with aqueous NH_3 at 0 °C (yield 45%). Solutions of *(2)* gradually decompose at room temperature into 1,4-cycloheptadiene and N_2;

(1) *(2)*

similar decomposition takes place on photochemical excitation in ether at −60 °C. / Chem. Ber. *102*, 811 (1969) / −Ma.
[Rd 1 IE]

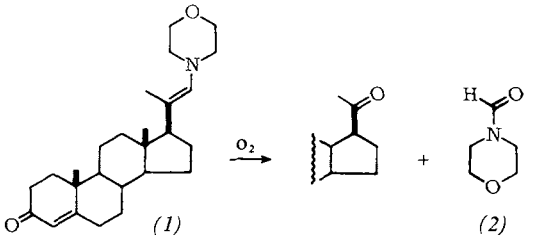


An allene oxide, 2-*tert*-butyl-3-(2,2-dimethylpropylidene)-oxirane *(2)* has been synthesized by *R. L. Camp* and *F. D. Greene*; it is the first representative of a molecular species that has been assumed to occur as an intermediate but has never been isolated. Reaction of an excess of 2,2,4,4-tetramethyl-2,3-pentadiene *(1)* with *m*-chloroperbenzoic acid in hexane followed by distillation and gas-chromatographic separation affords, as main fraction, a liquid which on the

(1) R = $C(CH_3)_3$ *(2)*

basis of its mass- and NMR-spectra proves to have the structure *(2)*. On heating to 100 °C isomerization to 2,3-di-*tert*-butylcyclopropanone takes place. / J. Amer. chem. Soc. *90*, 7349 (1969) / −Ma.
[Rd 2 IE]

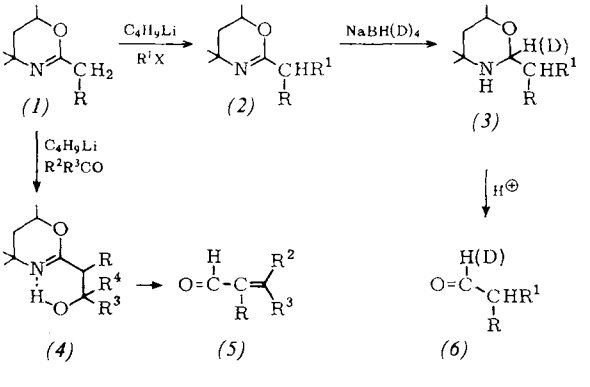
Rotaxanes, novel aggregates of a macrocycle and an elongated molecule with bulky end groups, have been obtained by *G. Schill* and *H. Zollenkopf* by specific synthesis from a diansa compound containing two paraffin chains with reactive end groups. One bulky residue is attached to each chain and the precursor, in which the "ring" is still joined to the "dumb-bell" by a bond on the nitrogen, is split to give the rotaxane. Compound *(1)*, the rotaxane from 1,2,4-triacetoxy-



(1)

3,5-bis[12-(*N*-acetyl-2,4,6-tri-*p*-tolylanilino)dodecyl]benzene and 1-acetyl-1-aza-14-cyclohexacosanone, melts at 65–67 °C. Its IR spectrum contains one weak band more than an equimolar mixture of the components; *(1)* is uniform in the thin layer chromatogram, and its R_f value is different from those of its components. / Liebigs Ann. Chem. *721*, 53 (1969) / −Kr.
[Rd 3 IE]

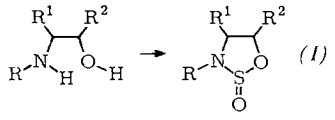
The catalytic reduction of nitrous oxide by dinitridohydrido-tris(triphenylphosphine)cobalt has been studied by *L. S. Pu, A. Yamamoto*, and *S. Ikeda*. N_2O, which acts as a competitive inhibitor of the fixation of nitrogen in biological systems, was allowed to react with $H(N_2)Co[P(C_6H_5)_3]_3$ in benzene. The red solution effervesced and turned first yellowish green and then pale blue. Free $P(C_6H_5)_3$ present during the reaction was oxidized to $OP(C_6H_5)_3$. When $H_3Co[P(C_6H_5)_3]_3$, $P(C_6H_5)_3$, and N_2O were allowed to react, the $\nu(N_2)$ band at 2088 cm^{-1} and the ν(PO) band at 1200 cm^{-1} were observed after a short time. The escaping gas consisted of H_2 and N_2. / Chem. Commun. *1969*, 189 / −Kr.
[Rd 4 IE]



The Cu-catalyzed oxidation of enamines, according to *V. Van Rheenen*, leads under mild conditions to good yields of ketone and amide. The enamine *(1)*, for example, is quantitatively split into progesterone and *N*-formylmorpholine *(2)* by O_2 in the presence of CuCl in $CHCl_3$ at 0 °C. *N*-(2-Methylethylidene)morpholine (the morpholine enamine of isobutyraldehyde) gives acetone and *(2)*. Suitable catalysts are CuCN

(1) *(2)*

and the chlorides and bromides of Cu^{I} and Cu^{II}. Pyridine and trimethyl phosphite completely inhibit the reaction. / Chem. Commun. *1969*, 314 / −Ma.
[Rd 7 IE]

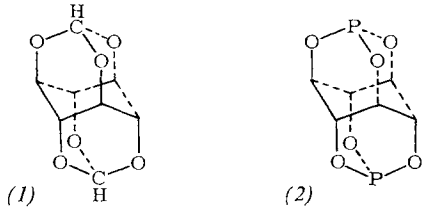


A new aldehyde synthesis from dihydro-1,3-oxazines *(1)* has been described by *A. I. Meyers et al.* Compounds *(1)* react with phenyllithium, *n*-butyllithium, or *tert*-butyllithium in THF at −78 °C to form the lithium salts, and then with alkyl halides to give compounds *(2)* in high yields. Reduction of *(2)* with $NaBH_4$ (or $NaBD_4$) gives tetrahydro-1,3-oxazines *(3)*, hydrolysis of which with dilute oxalic acid

(1) *(2)* *(3)* *(4)* *(5)* *(6)*

leads to aldehydes *(6)* (overall yield 47–70%). Addition of an aldehyde or ketone to the Li salt formed from *(1)* gives an oxazinyl alcohol *(4)*, from which an α,β-unsaturated aldehyde *(5)* is obtained (48–69%) by reduction and hydrolysis. Alicyclic and α,α-disubstituted aldehydes can be prepared with the aid of α,ω-dibromoalkanes. / J. Amer. chem. Soc. *91*, 763, 764, 765 (1969) / −Ma.
[Rd 8 IE]

1,2,3-Oxathiazolidines, members of a new heterocyclic system, have been synthesized by *J. A. Deyrup* and *C. L. Moyer.* 1,2,3-Oxathiazolidine *S*-oxides *(1)* are obtained by reaction of β-amino alcohols with $SOCl_2$ in the presence of bases such as triethylamine or pyridine as proton acceptors in hexane or benzene. The yields were between 15 and 99%. *cis-trans*



(1)

Isomers were observed in several cases, and these are ascribed to asymmetry at the S atom. The cyclization can also be applied to larger rings, as is shown by the conversion of 3-*tert*-butylamino-1-propanol into 3-*tert*-butyltetrahydro-1,2,3-oxathiazine *S*-oxide. / J. org. Chemistry *34*, 175 (1969) / –Ma.

[Rd 9 IE]

Hexaoxadiamantanes have been synthesized by *O. Vogl, B. C. Anderson,* and *D. M. Simons.* The reaction of scyllite (all-*trans*-hexahydroxycyclohexane) with triethyl orthoformate in DMSO, succinodinitrile, tetramethylene sulfone, acetic anhydride, *etc.* at 150–200 °C gives a polymeric product, which forms hexaoxadiamantane *(1)*, m.p. 302–304 °C, on

(1) *(2)*

pyrolysis at 250–350 °C. The rather low yield of about 15% is due to many side reactions. Reaction of scyllite with trimethyl phosphite in DMSO similarly gave hexaoxadiphosphadiamantane *(2)*, m.p. 276–280 °C. / J. org. Chemistry *34*, 204 (1969) / –Ma.

[Rd 10 IE]

The dissociation constants of some phosphoric acid derivatives have been determined by *C. J. Peacock* and *G. Nickless* by potentiometric titration, theoretical titration curves with the dissociation constants as parameters being matched to the experimental curves by means of a computer. Reliable values were obtained for ortho-, monothio-, monoamido-, and diamidophosphoric acids, whereas the values found for diamidothio- and tetrathiophosphoric acids are less certain.

The results were used as the basis for a discussion of the position at which the ions are protonated. The most acid proton

Anion	pK_1	pK_2	pK_3
PO_4^{3-}	1.85	6.69	12.3
PO_3S^{3-}	1.67	5.40	10.14
PS_4^{3-}	1.8	3.5	6.6
$PO_3NH_2^{2-}$	2.74	8.17	
$PO_2(NH_2)_2^-$	1.18	5.00	
$POS(NH_2)_2^-$	2.0	4.3	

in monothiophosphoric acid is that bound to the sulfur; the dianion of monoamidophosphoric acid is evidently protonated first on the nitrogen. It is interesting to note that the monoanions of diamidophosphoric and diamidothiophosphoric acids take up two protons each, *i.e.* first one on the nitrogen and then one on the oxygen. The cationic two-proton adducts could not be isolated. / Z. Naturforsch. *24a*, 245 (1969) / –Hz.

[Rd 11 IE]

The spectroscopic and photochemical properties of benzene-chloroform mixtures at low temperatures ($T \geqslant 77$ °K) in saturated hydrocarbons have been studied by *N. C. Perrins* and *J. P. Simons.* Displacements of the benzene band at 250 nm indicate hydrogen bonding of the proton of chloroform (and other incompletely halogenated alkanes and alkenes) with the aromatic ring. The C–H axis of $CHCl_3$ in the associates should be perpendicular to the plane of the benzene ring. It is possible to distinguish two association steps, in which one and then two molecules of the halogen compound associate with benzene. The thermodynamic data for the first association step at 77 °K are $\Delta G = -(354 \pm 70)$ cal/mole; $\Delta H = -(1170 \pm 120)$ cal/mole; $\Delta S = -(9.3 \pm 2.5)$ cal deg^{-1} $mole^{-1}$. On irradiation of the benzene-chloroform solutions, instead of the usual addition of solvent, only chloroform adds on to the benzene. / Trans. Faraday Soc. *65*, 390 (1969) / –Hz.

[Rd 12 IE]

The increase in the catalytic activity of magnesium oxide powder for hydrogen-deuterium exchange in the presence of 3–7 eV (180–400 nm) UV radiation has been studied by *C. G. Harkins, W. W. Shang,* and *T. W. Leland.* The relative increase in the first order rate constant, when plotted against the energy of the light used, shows distinct maxima at 5.7, 4.9, and 4.0 eV. To interpret these photocatalytic maxima, the band structure of MgO is discussed, taking into account internal impurities and adsorbed water. The authors conclude that a catalytically active surface state is reached from various initial states. The catalytic activity is thought to be due to hydroxide groups on the surface with localized defect electrons, *i.e.* to OH radicals bound to the surface. "Reaction rate spectroscopy" should also be of use in the investigation of other catalytic effects on the surfaces of semiconductors or insulators. / J. physic. Chem. *73*, 130 (1969) / –Hz.

BOOK REVIEWS

Hochauflösende ESR-Spektroskopie, dargestellt anhand aromatischer Radikal-Ionen (High-Resolution ESR Spectroscopy, with Special Reference to Aromatic Radical Ions). By *F. Gerson.* Vol. 1 of "Chemische Taschenbücher", edited by *W. Foerst* and *H. Grünewald.* Verlag Chemie GmbH., Weinheim/Bergstrasse 1967. 1st Edit., 210 pp., 42 illustrations, 14 tables, DM 16.–.

This volume is the first of a new series of monographs being published by Verlag Chemie under the title "Chemische Taschenbücher". These pocket books are aimed at providing both advanced students and qualified chemists with a reasonably priced introduction to specialist fields of chemistry. The choice of High Resolution Electron Spin Resonance as the subject of the opening volume is particularly fortunate, since this is an important physical method by which surprisingly accurate predictions can be made about the residence time of an unpaired electron on the individual atoms.

The author uses a general section to introduce the reader to the fundamentals of ESR spectroscopy, starting with the quantum nature of the electron and the interaction of its spin with a magnetic field. He then shows how, in organic radicals, the interaction of the unpaired electron with atoms that have

nuclear spin leads to the hyperfine structure of ESR spectra. The chemical production of radicals and their measurement in the ESR spectrometer are described only briefly, and the main emphasis is laid on understanding the theoretical interpretation of spectra with hyperfine structure and of their relation to concepts of the electronic structure of organic radicals that can be derived from HMO theory and its refinements.

For this purpose the author confines his attention almost wholly to radicals anions and cations of aromatic hydrocarbons and their aza derivatives, ions that have been particularly thoroughly studied. The book thus gains much in clarity and immediacy, especially as the author himself is a recognized master of the field. Several of the inherent problems are given a first, very clear interpretation without making too great mathematical demands; examples are the formation, by π-σ spin polarization, of a finite spin density at the H atoms of benzene situated at the nodal plane of the unpaired π-electron; the formation of negative spin densities by π-π spin polarization; and the occurrence of relatively large coupling constants on β-hydrogen atoms owing to hyperconjugation.

A relatively short Appendix 1 follows, describing methods of quantitative calculation used in estimating π-σ and π-π spin polarization; here, however, considerable knowledge of the techniques of quantum-mechanical calculation is assumed, and this the ordinary chemist may often not possess.

In that section devoted to nitrogen-free and nitrogen-containing aromatic radical ions, it is shown how far predictions from ESR spectroscopy can be extended, and to what extent the results of quantum-mechanical calculations agree with experimental results. The examples are excellently chosen to demonstrate, by concrete cases, the extraordinary power of prediction inherent in ESR spectroscopy.

The writing is concise and there is no unecessary repetition The book requires concentrated reading, but it makes no demand beyond the capacity of a student who is reasonably familiar with HMO theory. This is an excellent book and it is also an aesthetic pleasure owing to the splendid illustrations of typical ESR spectra (most of them from the author's Zürich school), very clear schematic drawings, and the clean and pleasant photomechanical reproduction of typescript. References covering the literature up to the end of 1965 are an aid to deeper study.

It is to be hoped that the book has a wide circulation and that the later volumes in the series will be equally successful.

K. Dimroth [NB 809 IE]

Theorie der Molekülspektren (Theory of Molecular Spectra). By *W. A. Bingel.* From the series "Chemische Taschenbücher", Vol. 2, edited by *W. Först* and *H. Grünewald.* Verlag Chemie GmbH, Weinheim/Bergstr. 1967. 1st Edit., 206 pp., 62 figures, 21 tables, bound DM 16.—.

This volume of the series "Chemische Taschenbücher" fills a gap among German-language monographs on molecular spectroscopy, since apart from a few specialized works with very narrowly limited subject matter, recent German literature has nothing to offer as an introduction to the theory of spectra. The author of the present book has therefore concentrated on the fundamental theoretical relations. A short introduction is followed by a discussion of rotation and rotation-vibration spectra; the vibrational and rotational structure of electronic transitions is then also discussed. Special attention is given to intensities and selection rules, which are hardly mentioned in other, more experimentally oriented books. The relation between the theory of the chemical bond and UV spectroscopy is presented in a clear manner. The author's own special interests are reflected in a very comprehensive discussion of the classification of the electronic states of diatomic and triatomic molecules.

Since the book is intended primarily as an introduction for beginners, the treatment of infrared and Raman spectra has had to be kept relatively brief. The author has tried to explain the essential relations with the minimum use of formal mathematics. The success of the treatment will depend on the reader's background knowledge. The book is well worth the price, and it is to be hoped that it will be widely read, particularly by the younger chemistry students.

Th. Ackermann [NB 792 IE]

Gruppentheorie für Chemiker, Physiko-Chemiker, Mineralogen ab 5. Semester (Group Theory for Chemists, Physical Chemists, and Mineralogists in their 5th Semester and Beyond). By *K. Mathiak* and *P. Stingl.* From the Series: Hochschul-Studienbuch. Friedr. Vieweg und Sohn, Braunschweig, Akademische Verlagsgesellschaft, Frankfurt/M. 1968, paperback DM 9.80.

The modern chemist is making ever-increasing use of numerical methods (particularly quantum mechanical approximation methods) and sooner or later he is bound to have to come to terms with the mathematical fundamentals of these techniques. The present book by *Mathiak* and *Stingl* provides an opportunity for him to get acquainted with the important subject of group theory. Since the inclusion of numerous examples and problems imparts the necessary "substance" to the highly abstract subject matter, the reader can profit considerably from a study of the sections entitled "Abstract Group Theory", "Symmetry Groups of Molecules", and "Representation Theory". An additional section on "Vector Spaces" has been included to furnish the necessary background. However, the section on the application of group theory to Hückel theory and molecular vibrations will do little to stimulate the faith of the reader in this book, since it not only contains many obscurities, inaccuracies, and mistakes, but unfortunately also makes no mention of the most important applications of group theory: Selection rules and polarization of electronic transitions, band forms and polarization for IR bands, degree of depolarization of Raman bands, as well as considerations of the symmetry types of overtones and combination frequencies in vibration spectra.

The apparently unavoidable mistakes in the character tables are found in this book, *e.g.*, in the groups C_4, C_{4h}, C_{6v}, and D_{4h}.

K. Wilhelm [NB 787 IE]

Grundzüge der Radio- und Reaktorchemie (Fundamentals of Radiochemistry and Reactor Chemistry). By *F. Hecht.* Akademische Verlagsgesellschaft, Frankfurt/M. 1958. 1st Edit., x, 426 pp., 130 figures, 39 tables, paperback DM 25.-.

Though radiochemistry or nuclear chemistry forms part of the curriculum of a number of universities where German is spoken, there has until now been no satisfactory German-language textbook in this field, and the standard work for radiochemists is therefore the excellent "Nuclear and Radiochemistry" (2nd Edit., 1966) by *Friedländer, Kennedy,* and *Miller.* Because of its strong physical orientation, however, this cannot really be recommended as an introduction. The book by *Hecht* is intended to fill this gap, and can be said to have succeeded in this object.

The book is divided into the following sections:

1. Nuclear-physical data, 2. Nuclear reactions, 3. Radiation measurements, 4. Radiochemical procedures, 5. Artificial radioactivity, 6. Nuclear reactors, 7. The effects of radiation and radiation loading, 8. Use of radionuclides in industry and medicine, and 9. Chemistry of hot atoms. The chapter size ranges from 6 pages (Chapter 9) to more than 100 (Chapter 4). This very lucidly written book is of particular value for students choosing radiochemistry as a subsidiary subject as well as for practical chemists seeking an introduction to experimental radiochemical techniques. However, these are not the only readers to whom the extensive Chapters 3 and 4, which are outstanding for the expert knowledge shown by the author, will appeal. Special mention should be

made of the numerous figures and graphs. The various types of reactors are discussed in Chapter 6, though the reviewer would have expected a more detailed discussion of nuclear-physical principles (*e.g.* four-factor formula); however, this is a shortcoming of all (even English-language) books on radiochemistry and nuclear chemistry. Even physical principles are sometimes unfortunately not discussed at length; there was no need to avoid mathematical formulations almost completely. What the Friedländer-Kennedy-Miller book lacks in chemistry, the Hecht book lacks in physics. One would also have expected that in 1968 (the year of publication), the new position regarding the No isotope (dating from 1963–1965) could have been presented; moreover, the symbol Mv for element 101 (p. 241) was changed by the IUPAC into Md almost ten years ago. These and other minor points can, however, be corrected in a later edition.

The presentation and print are well below average, even if allowance is made for the relatively low price. At least two types of paper had been used in the reviewer's copy, several pages showed variation in print thickness or unsharp print, and the paper binding delaminated after use for a short time, so that the life of the book will probably be limited.

C. Keller [NB 799 IE]

Synthesen mit Kohlenmonoxid (Syntheses with Carbon Monoxide). By *J. Falbe*. Vol. 10 in the Series "Organische Chemie in Einzeldarstellungen". Springer Verlag, Berlin, Heidelberg, New York, 1967. 1st Edit., vii + 212 pp., 20 tables, DM 48.–.

Except for a few omissions, the author has succeeded in writing a comprehensive monograph on syntheses involving CO, and even experts in this field can find something new in it. Hydroformylation, carbonylation, the Gattermann-Koch synthesis, and carbonylation with Pd catalysts are described in detail, irrespective of their technical importance. It is obviously impossible in such a comprehensive book to consider singly the entire literature quoted and to specify in each case the importance of the individual works.

It is mentioned in the Preface that, prior to their detailed investigation, Reppe syntheses and Roelen reactions were described after World War II in FIAT, BIOS, and CIOS Reports. Despite this, workers engaged in the subsequent intensive research in this field outside Germany hardly took into account the previous investigations, with the result that many aspects have been discovered twice. This could have been brought to light still better by modifying the structure of the book.

In connection with the reaction mechanisms, mention is made again of the three-membered ring and ketene theory, which was rejected years ago. On the other hand, only footnotes are devoted to the important hypotheses proposed a long time ago about the intermediates of hydroformylation and carbonylation (FIAT, Houben-Weyl). At the same time, a detailed account is found on the mechanisms which were proposed much later, and which closely resemble these hypotheses.

This does not alter the fact that this is a very good book, which can be recommended to those who work in this field.

H. Kröper [NB 791 IE]

Comprehensive Biochemistry, Vol. 20: Metabolism of Cyclic Compounds. By *M. Florkin* and *E. H. Stotz*. Elsevier Publishing Co., Amsterdam, London, New York, 1968. 1st Edit., xiii + 533 pp., 135 figs., 34 tables; Dfl. 75.–.

This volume[1] deals with the biosynthesis and the degradation of complicated organic molecules arising in the metabolism of carbohydrates and amino acids. It bears witness to the great progress made in the last 15 years in the elucidation of structural relationships by new methods and improved techniques. Not only is the literature well documented up to 1967, but also a great number of quotations are included in some cases. As a result, this book often makes it unnecessary to consult the original articles for details. It also gives surveys which enable the reader to familiarize himself with the relevant material.

Discussing the isoprene derivatives, *H. J. Nicholas* describes the synthesis, degradation, occurrence, and function of vitamin A, α-tocopherols, vitamin K, ubiquinones, plastoquinone, carotinoids, squalene, and other terpenes, as well as rubber. He also discusses ecdysone and the giberellins, together with their function and the regulation of the biosynthetic cycles between organelles. The metabolism of steroid hormones and bile acids is discussed by *D. B. Gorer*, whose account includes the formation and the conversion of C_{18}, C_{19}, and C_{21} sterols, the action of ACTH and other hormones, the enzymatic hydroxylation and dehydrogenation of the steroid skeleton, and processes of conjugation and elimination. The author examines the reaction mechanisms in great detail and also discusses the secondary conversion of bile acids by intestinal microflora, though the products of this conversion are only indirectly connected with biogenetic cycles.

The phenolic substances are divided into flavonoids (*F. de Eds*), tannins (*D. G. Roux*), and lignin (*W. J. Schubert*), which is biogenetically connected with tannins in carbohydrate metabolism. The glycosides and the aglycons of flavones and flavonones are of pharmacologic interest, and their toxicology and therapeutic use therefore receive critical treatment. One finds a similarly good account of the influence of intestinal bacteria, nutritional factors, and dosage on the products of metabolism and elimination. The hydrolyzable and condensed polyphenols of the tannins are examined in a relatively short but informative section. Here and in the chapter on lignin, one encounters isocyclic polyhydroxy compounds, which occupy a central position in the metabolism of aromatic systems, and which are aromatized and – in the case of lignin – condensed into large, complex polymeric molecules. Their chemical structure is mainly hypothetical, and it is therefore too soon to discuss the general features of these molecules. By contrast, the general outlines of the biogenesis based on CO_2, carbohydrates, shikimic acid, and C_3 fragments are known. The same applies to the origin of methoxy groups and to the polymerization of monomeric phenylacrylic acid precursors by enzymatic oxidoreductase and peroxidase (laccase). The degradation by fungi that decompose wood is first hydrolytic (even ether bridges are cleaved here by etherases), and then oxidative, leading to vanillin derivatives.

A monographic study of the biosynthesis of alkaloids and other secondary nitrogen metabolites by *J. B. Spenser* represents the main part of the book. This subject is treated in biogenetic terms, and, despite the great variety of the substances, the study shows the relations between the synthetic pathways, which had been earlier proposed speculatively by organic chemists, mostly exhibiting an extraordinary insight. The syntheses involved are relatively simple (Mannich condensations and oxidative coupling of phenols), but give rise to a remarkable group of compounds, which are difficult to systematize.

One of the most fascinating chapters of the chemistry of natural products is that of secondary fungal metabolism, although the underlying principles are not clear since we do not know whether we are dealing here with elimination processes or with accumulation processes; nevertheless, about 1000 compounds have so far been isolated. *R. Bentley* and *J. M. Campbell* examine some routes for the aromatic syntheses based on glycolysis intermediates, acetate, mevalonate, and polyoxomethylene compounds, together with the formation of terpenes, sterols, and anthraquinones. The enzymatic halogenation and the regulation of these processes have also been described.

[1] Cf. Angew. Chem. *80*, 974 (1968); Angew. Chem. internat. Edit. *7*, 901 (1968).

When such a variety of fields is covered, it is understandable that the chapters cannot always be perfectly dovetailed into one another, and in fact they overlap at several places. However, the Editors have minimized this, and so ensured readability and maintained the monographic nature of the sections. The book is carefully edited, easy to use, and has a comprehensive subject index. This excellent work, "Comprehensive Biochemistry", is thus enriched by a further volume, which retains the high standard we have grown accustomed to throughout the series.

L. Jaenicke [NB 790 IE]

Carbocyclic Ring Expansion Reactions. By *C. D. Gutsche* and *D. Redmore*. Supplement 1 to Advances in Alicyclic Chemistry. Edited by *H. Hart* and *G. J. Karabatsos*. Academic Press, New York-London 1968. 1st Edit., viii, 243 pp., stitched $ 13.50.

Do you know what MLOC is? The explanation can be found in the preface to this book. It is the "*M*agnificent *L*and of *O*rganic *C*hemistry", of which carbocyclic ring expansion reactions form a part. At one time a "hamlet" in the great land of OC, the CRER (*C*arbocyclic *R*ing *E*xpansion *R*eactions) has now grown into a sprawling town, the study of which has won the interest of many chemists, and will continue to do so in the future. The present book is intended as a chemical "Guide Michelin" to the region of CRER.

The book is divided into nine sections: 1. Wagner-Meerwein rearrangements of cycloalkanecarbinyl systems; 2. Pinacol-type rearrangements of cycloalkanecarbinyl systems; 3. Diazoalkane ring expansions of cycloalkanes; 4. Ring expansions *via* anionic intermediates; 5. Ring expansion *via* carbenes as free-radical intermediates; 6. Photochemically induced ring expansions; 7. Ring expansion reactions with bicyclo[*n*.1.0]alkanes as intermediates; 8. Ring expansion by two carbon atoms; 9. Ring expansion by three or more carbon atoms.

The authors have succeeded in presenting a concise, easily readable discussion of all that is important about the course, mechanisms, substituent effects, and steric factors of these reactions without historical trimmings. Practical applications are also dealt with. The authors incorporate the discussion of their own research field fully into this framework, and lose nothing in the way of detail as a result. Clear reaction schemes are given for many of the reactions, which are of widely differing nature in some cases.

When used in conjunction with the text, the detailed and particularly up-to-date reference list (up to 1967) enables anyone interested to acquire within a short time a good knowledge of the reaction types discussed. A few printer's errors (*e.g.* 2-methyl-4- instead of 2-methyl-5-isopropylcyclohexanone and 2-methyl-6- instead of 3-methyl-5-isopropylcycloheptanone) do not detract from the value of the book, which can be wholeheartedly recommended to all organic chemists.

E. Müller [NB 797 IE]

Contact and Frictional Electrification. By *W. R. Harper*. From the series: Monographs on the Physics and Chemistry of Materials. Oxford at the Clarendon Press (Oxford Univ. Press), London 1967, 1st Edit., xii, 369 pp., numerous figures, 70 s.

This book deals with the build-up of electrostatic charges on substances as a result of mutual contact or friction. It appears in the series "Monographs on the Physics and Chemistry of Materials", which presents recent results concerning solids and in the related field of materials research.

An attempt is made in the present book to set out the numerous experimental findings relating to contact or frictional electrification in an orderly manner and to explain them with the aid of models. Terms such as surface charges, contact, and frictional electricity are introduced and explained in the first of the three parts of the book. The second part deals with physical principles, particularly from solid physics, that appear necessary for an understanding of frictional electricity. The lack of reference to physicochemical or thermodynamic aspects is regrettable. Experimental results and special systems are discussed in the third part.

The book is of particular interest to physicists and fundamental research workers who are concerned with problems of frictional electricity; however, it should also provide some stimulus to chemists and engineers, who are more interested in the practical aspects of frictional electricity.

H. Rickert [NB 795 IE]

Reagents for Organic Synthesis. By *L. F. Fieser* and *M. Fieser*. John Wiley and Sons Inc., New York-London-Sydney 1967. 1st Edit., ix, 1457 pp., $ 210

A chapter in the book "Experiments in Organic Chemistry" by the same authors was the forerunner of the present, comprehensive work, which considers 1120 reagents, arranged in alphabetical order, that are of importance to the experimental organic chemist.

The various reagents are described according to the following pattern: Structural formula, molecular weight, physical constants, most important methods for synthesis and purification, commercial sources, as well as characteristic examples for the application of the reagent, containing in most cases information regarding optimum weight ratios, reaction conditions, and yields each supplemented by copious references. The examples illustrating the application of the reagents are generally chosen to have a maximum information content. 17% of the literature references cite procedures in "Organic Syntheses".

The authors have consciously refrained from treating the common solvents and their purification in the same manner, since they contend that adequately useful literature is available on this subject. This book contains no more than commercial sources for solvents.

As an illustration of the makeup and utility of the present work let us consider the keyword "Phosgene": Here one finds the structural formula, molecular weight, boiling point, melting point, information concerning toxicity, and commercial sources. There follow data on purification and particularly on the detection and removal of chlorine. Under the heading "Use of Phosgene" the reader finds methods for the preparation of carbonic half-ester chlorides. The method of *Barton* – conversion of primary alcohols *via* carbonic half-ester chlorides and their reaction with dimethyl sulfoxide – comes next. There follows an account of the use of phosgene in the preparation of isocyanates from primary amines, which also gives the most important experimental data as well as the preparation of isocyanides from alkylformamides with phosgene and triethylamine.

The dehydration of amides with phosgene and pyridine, the preparation of cyclic carbonates and of mixed anhydrides of carbonic acids, and finally the preparation of benzyl esters of α-amino acids *via* the oxazolidines, which are obtained from the α-amino acids and phosgene, represent further examples of the application of phosgene. In total, 18 literature references and numerous structural formulas illustrating the reactions are to be found under this keyword.

Lists of the manufacturers and of the pieces of apparatus included in the text are also to be found alongside the subject and author indexes at the end of the book. An alphabetical list of the reactions and reaction types giving details of reagents required proves to be an extremely valuable feature. The book is one of the most important recent publications for organic chemists working in research establishments and in industry. It certainly closes a gap in the existing literature and will undoubtedly soon be numbered among the standard works of organic chemistry.

A number of minor defects do little to detract from the virtues of the book. For instance, the Non-American is at a certain disadvantage because only American firms are given in the list of sources. Further, the selected literature references too often concern highly specialized examples. In some cases, the examples that are given lack any general significance. This applies, *e.g.*, to the reaction of hydrazine with 1,3-cyclohexanedione mentioned on p. 449. On the other hand, no reference is made to the one-step acid cleavage and reduction of alkylated 1,3-cyclohexanediones to the reduced carboxylic acids. A critical reappraisal of the literature citations with regard to their general interest might well be appropriate in future editions. *H. Stetter* [NB 784a IE]

Physical Methods in Advanced Inorganic Chemistry. Edited by *H. A. O. Hill* and *P. Day*. Interscience Publishers, London-New York-Sydney 1968. 1st Edit. xii, 627 pp., numerous Figs. and Tables, bound, *ca.* DM 74.—.

This book contains descriptions of physical methods that are of immense value to the practical inorganic chemist. It contains eleven sections covering the following topics: 1. Diffraction methods (*C. K. Prout*), 2. X-ray spectroscopy (*C. Bonelle*), 3. Molecular photoelectron spectroscopy (*D. W. Turner*), 4. Electronic absorption spectroscopy (*H. Schmidtke*), 5. Rotatory dispersion and circular dichroism (*R. D. Gillard*), 6. Vibrational spectroscopy (*M. J. Ware*), 7. Electron spin resonance (ESR) (*E. König*), 8. Mössbauer spectroscopy (*J. Danon*), 9. Nuclear quadrupole resonance (NQR) (*H. Sillescu*), 10. Nuclear magnetic resonance (NMR) (*D. R. Eaton*), and 11. Thermochemistry in inorganic solutions (*J. J. Christensen* and *R. M. Izatt*).

To provide such a wealth of information within the confines of little more than 600 pages requires careful and clever planning of each of the sections. The authors do not give accounts of all theories, apparatus, and results but explain the application of their methods on the basis of theoretical fundamentals using numerous practical examples; and plenty of references are given for those readers who wish to gain further detailed information about the subject matter of the book. In section 12 (General conclusions), the editors show with the aid of several examples how a critical evaluation of the results obtained by each of the methods mentioned can lead to a uniform picture of the structure of a molecule even, if the results appear to be contradictory.

A general index of about 750 entries at the end of the book is very useful, even though some of the authors have made little contribution (*e.g.* for Section 2 there are only 10 entries). All the methods described excepting method 11 can be used for the elucidation of atomic or electronic structure. A different title for the book in which the word "structure" occurs would have made the reader understand why a number of elemental-analytical and kinetic methods (relaxation effects) have not been considered and why the electric and dielectric properties of solutions and gases have not been treated. Mass- and rotation spectrometry of inorganic substances, further solid-state methods, as well as electron diffraction in gases could easily have been included and the scope and usefulness of the book thus increased. However, it is a handy book containing a compact account of methods used in (molecular) structural research. It can be recommended to all inorganic chemists who wish to judge the merits of these methods and to all students of chemistry who are embarking on research work in structural chemistry.

The Synthesis of Rare Sugars

By J. S. Brimacombe[*]

The use of new oxidation reagents, such as the Pfitzner-Moffatt reagent, dimethyl sulfoxide-acid anhydrides, and ruthenium tetroxide, has significantly improved the yields obtained on oxidation of a secondary hydroxyl group to a carbonyl group in suitably protected sugars. The application of these new oxidants in the carbohydrate field is briefly surveyed. The product ketones are convenient intermediates for syntheses of amino, branched-chain, deoxy, and other rare sugars. Some representative syntheses are illustrated.

1. Introduction

In recent years there has been a dramatic increase in the number of rare sugars isolated from natural sources and these have provided the carbohydrate chemist with new and challenging problems of structural determination and synthesis. A potentially valuable approach to the synthesis of amino, branched-chain, deoxy, and other rare sugars is based upon a class of carbohydrates systematically named as osuloses but which are better known, perhaps, by the trivial names of "keto" or "oxo" sugars. From the viewpoint of synthesis, the most important members of this group have the aldehyde group substituted either by glycosidation or by ketalation and they are normally prepared by the direct oxidation of a secondary hydroxyl group to a keto group in partially protected sugars [1–4].

One of the drawbacks to early synthetic work was the low yields of keto sugars obtained in the oxidation reaction [1,2]. Fortunately, the situation has been improved enormously by the discovery of new oxidative procedures that have given high yields of keto sugars on oxidation of "isolated" hydroxyl groups in sugar derivatives.

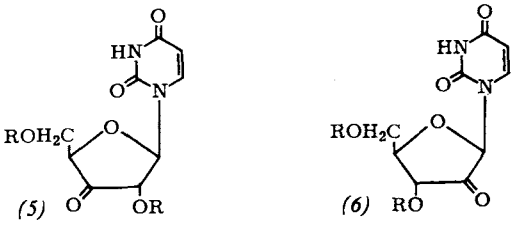
2. Oxidation

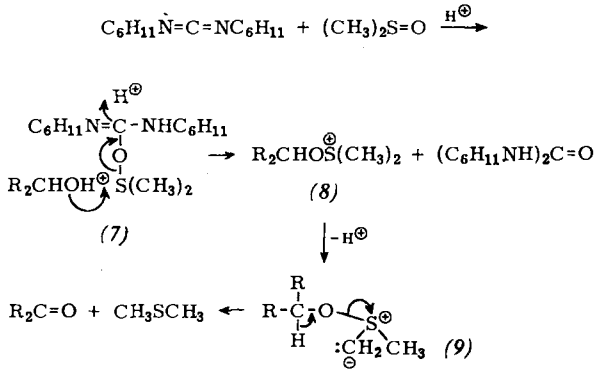
2.1. Oxidation with Dimethyl Sulfoxide-Carbodiimide



Pfitzner and *Moffatt* [5] found that attempts to polymerize thymidine 5′-phosphate *(1)* with dicyclohexylcarbodiimide in dimethyl sulfoxide led to cleavage of the *N*-glycoside and phosphate ester groups. Treatment of thymidine with *N,N*-dicyclohexylcarbodiimide-dimethyl sulfoxide in the presence of anhydrous phosphoric acid or, less effectively, trifluoroacetic acid also resulted in release of the base and this behavior was exhibited on similar treatment of other nucleotides

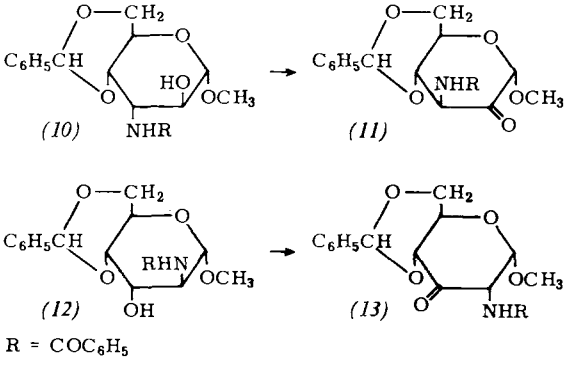
containing an unsubstituted hydroxyl group on C-3′. 3′-*O*-Acetylthymidine *(3)*, on the other hand, was converted into a carbonyl-containing compound formulated as the 5′-aldehydo derivative *(4)*. The

[5] *K. E. Pfitzner* and *J. G. Moffatt*, J. Amer. chem. Soc. *85*, 3027 (1963); *87*, 5661 (1965).



cleavage of the bonds in thymidine and its 5′-phosphate was attributed to oxidation of the 3′-hydroxyl group to a keto group, *e.g. (2)*, which was responsible for β-elimination of the base and 5′-phosphate group, if one was present. This proposal is supported by the isolation [6] of the ketones *(5)* and *(6)* from the oxidations of 2′,5′- and 3′,5′-di-*O*-trityluridine, respectively, with dimethyl sulfoxide-carbodiimide. The Pfitzner-Moffatt reagent proved to be an efficient oxidant of

(5) R = $(C_6H_5)_3C$ *(6)*



steroid and alkaloid alcohols [7] and of particular relevance to carbohydrate chemistry was the observation that oxidation could be achieved at room temperature under essentially neutral conditions (*i.e.*, by using pyridinium trifluoroacetate as a proton source). Another distinct advantage of the procedure lies in the oxidation of primary alcohols exclusively to the aldehyde stage.

The mechanism of the oxidation was elucidated [8] through isotope experiments. The oxidation proceeds with the initial formation of a sulfoxide-carbodiimide adduct *(7)* that is attacked by the alcohol to give an alkoxysulfonium ion *(8)*. This then undergoes proton abstraction and a concerted collapse of the resulting ylid *(9)* to give the carbonyl compound and dimethyl sulfide.

(7) *(8)* *(9)*

The Pfitzner-Moffatt reagent was first used in the carbohydrate field by *Dyer, McGonigal,* and *Rice* [9] to oxidize 5-deoxy-1,2-*O*-isopropylidene-β-L-arabinose *(50)* into 5-deoxy-1,2-*O*-isopropylidene-β-L-*threo*-pentofuranos-3-ulose *(51)*, which was ultimately transformed into L-streptose *(53)* (Section 3.6). The reagent was more extensively applied to carbohydrates by *Baker* and *Buss* [10] who obtained smooth oxidations of the "isolated" hydroxyl groups of 1,2:5,6-di-*O*-isopropylidene-3-*O*-methylsulfonyl-D-mannitol, methyl 4,6-*O*-benzylidene-2-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside, methyl 3-benzamido-4,6-*O*-benzylidene-3-deoxy-α-D-glucopyranoside, and methyl 2-benzamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside. It was noted [10] that oxidation of methyl 3-benzamido-4,6-*O*-benzylidene-3-deoxy-α-D-altropyranoside *(10)* and the isomeric altroside *(12)* gave the ketones *(11)* and *(13)*, respectively, with epimerization of the benzamido groups to the more stable equatorial positions. This presumably occurs through an acid-catalyzed enolization [11]. A number of sugar alcohols, including 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose *(14)*, methyl 3,5-*O*-isopropylidene-α-D-xylofuranoside, and

(10) *(11)* *(12)* *(13)* R = COC_6H_5

methyl 3,4-*O*-isopropylidene-β-L-arabinopyranoside, resisted oxidation [10] and these results imply that the Pfitzner-Moffatt reagent is fairly demanding in its steric requirements.

The reagent has been applied, in one instance, to the oxidation of a carbohydrate primary hydroxyl group. Thus, 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose was transformed [12] into 1,2:3,4-di-*O*-isopropylidene-6-*aldehydo*-α-D-*galacto*-hexodialdo-1,5-pyranose, an intermediate required for chain-extension reactions leading to sugar derivatives related to lincomycin.

2.2. Oxidation with Dimethyl Sulfoxide-Acid Anhydride

Mixtures of dimethyl sulfoxide and certain acid anhydrides (for example, acetic anhydride, benzoic anhydride, and phosphorus pentoxide) were found by *Albright* and *Goldman* [13] to be efficient oxidants of hindered alkaloid and steroid alcohols. The oxidation with dimethyl sulfoxide-acetic anhydride was visualized [13] as proceeding *via* the alkoxysulfonium salt *(18)*, so that the mechanism is related to that of the Pfitzner-Moffatt procedure [8]. This general mechanism is supported by the isolation of (methylthio)methyl ethers *(17)* from some oxidations, and these compounds are thought to be formed from a competitive reaction of the acyloxysulfonium intermediate *(16)*. The use of dimethyl sulfoxide containing phosphorus pentoxide as an oxidant for partially protected sugars was communicated independently by *Onodera, Hirano,*

and *Kashimura* [14]. Oxidations using these procedures give good yields and can be conducted at room temperature; the reagents are inexpensive. The dimethyl sulfoxide-acetic anhydride method is particularly suited to the carbohydrate field because the excess of reagents and by-products can be removed simply by evaporation at low temperature [15] or by straightforward extraction procedures.

A number of the keto sugars that have been prepared by these procedures are listed in Table 1. Studies by *Onodera*, *Hirano*, and *Kashimura* [21] have shown that oxidations with dimethyl sulfoxide-phosphorus pentoxide are not markedly influenced by the orientation of the hydroxyl group in pyranoid and furanoid ring systems. The same applies to oxidations using dimethyl sulfoxide-acetic anhydride.

Oxidation of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose *(14)*, for example, is achieved only with great difficulty with most other reagents [2], but it was readily converted into 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose

(15) by using either acetic anhydride[22,25] or phosphorus pentoxide[14,21,22] in dimethyl sulfoxide. It is pertinent to note that methyl 2-azido-4,6-*O*-benzylidene-2-deoxy-α-D-altropyranoside was oxidized with methyl sulfoxide-acetic anhydride to methyl 2-azido-4,6-*O*-benzylidene-2-deoxy-α-D-*ribo*-hexopyranosid-3-ulose[11].

(14) *(15)*

Oxidation with dimethyl sulfoxide-acetic anhydride has been of value[23,24] in the synthesis of unsubstituted glycopyranosiduloses which, hitherto, have been obtained from glycopyranosides, either by non-specific oxidation[2] or by selective catalytic oxidation of axial hydroxyl groups[1,26]. The method takes advantage of the stability of phenylboronate esters[27] under the conditions of oxidation and of their ready removal in hydroxylic solvents. The methyl D-*erythro*-pentopyranosid-3-uloses were prepared[24], in high yield, following oxidation of the anomeric methyl D-xylopyranoside 2,4-phenylboronates with dimethyl sulfoxide-acetic anhydride.

Attempts to oxidize the primary hydroxyl group of 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose with acetic anhydride-dimethyl sulfoxide gave[28] a mixture of 1,2:3,4-di-*O*-isopropylidene-6-*O*(methylthio) methyl-α-D-galactopyranose and 6-*O*-acetyl-1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose, but the anticipated 6-aldehydo compound was not formed. (Methylthio)methyl ethers have been isolated[19] as by-products from similar oxidation of other carbohydrates.

(For reviews of oxidations employing dimethyl sulfoxide see Ref.[29].)

2.3. Oxidation with Ruthenium Tetroxide

Oxidation of partially protected sugars with ruthenium tetroxide[30] was reported by *Overend et al.*[31,32] to give better yields than those generally obtained with the chromium trioxide-pyridine complex[2].

Oxidations are conducted in carbon tetrachloride at room temperature by using a slight excess of ruthenium tetroxide, prepared by oxidation of the dioxide with sodium metaperiodate, or, with a catalytic quantity of the tetroxide in the presence of sodium metaperiodate[32,33]. It is important that the dihydrate $RuO_2 \cdot 2H_2O$ is used for oxidation to the tetroxide since other modifications are not oxidized under the mild conditions employed[34].

A number of keto sugars that have been prepared by these procedures are listed in Table 1. Axial and equatorial hydroxyl groups on an otherwise protected pyranoid ring appear to be oxidized with equal ease[34].

2.4. Other Methods

Lead tetraacetate is a good oxidant[41] of certain simple alcohols in pyridine solution but low yields of glycopyranosiduloses were afforded on oxidation of glycosides, such as methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*arabino*-hexopyranoside[32], and the procedure has been unsatisfactory with other partially protected sugars[15,42].

Rearrangement of certain methyl 4,6-*O*-benzylidene-3-deoxy-3-phenylazo-aldohexopyranosides with sodium methoxide yield the 3-phenylhydrazones[43], which are converted into the hexopyranosid-3-ulose on reaction with benzaldehyde in acetic acid solution.

3. Keto Sugars as Intermediates

A number of rare sugars have become available through syntheses which use the new oxidative procedures described above. It should be remembered that nucleophilic additions to keto sugars can lead to two diastereoisomeric products and this is clearly disadvantageous from a synthetic viewpoint. In many cases, however, the addition is markedly stereoselective and, with certain fused-ring systems, a stereospecific addition is often achieved. In any event, the successful application of the method requires a definitive establishment of the stereochemistry of the product(s). Similar considerations apply to the reduction of keto-sugar oximes and hydrazones.

3.1. D-Allose and its Derivatives

Both 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose *(15)*[44] and 1,2:5,6-di-*O*-cyclohexyl-

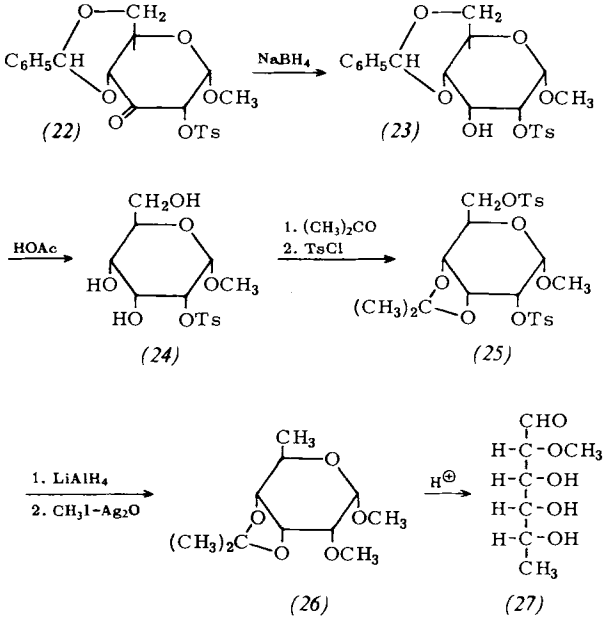
idene-α-D-*ribo*-hexofuranos-3-ulose *(19)* [19] are reduced stereospecifically, with $NaBH_4$, to the allose diacetals *(20)* and *(21)*, respectively, which afford D-allose on removal of the acetal groups with acid. $LiAlH_4$ reduction of ketone *(19)* is also stereospecific [19] but similar reduction of ketone *(15)* produced [45]

(19)

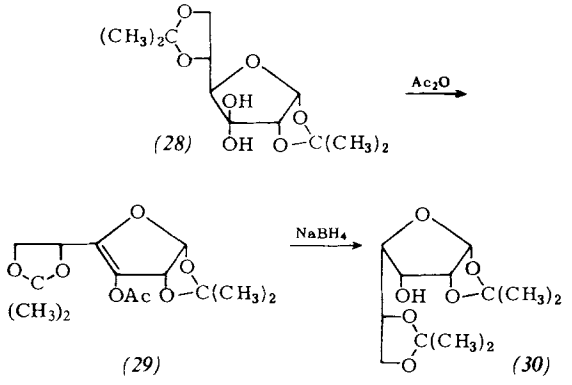


(20), R = CH_3
(21), R-R = $-(CH_2)_5-$

a mixture containing the allose and glucose diacetals in a ratio of 7:3.

Reduction of methyl 4,6-*O*-benzylidene-2-*O*-*p*-tolylsulfonyl-α-D-*ribo*-hexopyranosid-3-ulose *(22)*, with $NaBH_4$, yielded [10] exclusively methyl 4,6-*O*-benzylidene-2-*O*-*p*-tolylsulfonyl-α-D-allopyranoside *(23)*. Methyl-α-D-allopyranoside is formed [46] on successive treatments of compound *(23)* with dilute acid and sodium methoxide, while methanolysis of the α-alloside afforded a mixture of glycosides from which methyl β-D-allopyranoside was crystallized. Thus, D-allose and the anomeric allopyranosides are available from straightforward procedures.

Alloside *(23)* is a key intermediate in syntheses of 6-deoxy-3-*O*-methyl-D-allose [47], a component of the sarcostin glycosides of *Ascelepias lilacina* Weimarck [48] and *A. swynnertonii* S. Moore [49], and 6-deoxy-2-*O*-

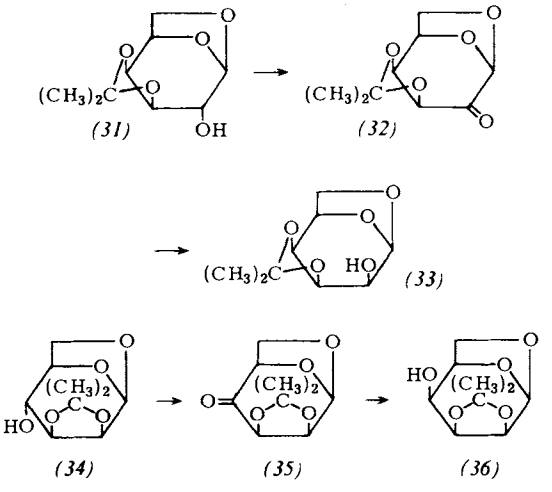


(22) *(23)* *(24)* *(25)* *(26)* *(27)*

methyl-D-allose (D-javose) [50], a constituent of two cardenolide glycosides found in the seeds of *Antiaris toxicaria* Lesch [51]. One synthesis of D-javose *(27)*, for example, used the route illustrated *(22)* → *(27)*.

3.2. D-Gulose

The crystalline hydrate *(28)* derived from compound *(15)* is converted [52] into the enol-acetate *(29)* on treatment with acetic anhydride in pyridine at 60 °C.



(28) *(29)* *(30)*

Reduction of *(29)* with $NaBH_4$ in methanol afforded 1,2:5,6-di-*O*-isopropylidene-α-D-gulofuranose *(30)*, in approximately 30% yield [53], which was then converted into D-gulose by acid hydrolysis.

3.3. D- and L-Talose and their Derivatives

Oxidation of 1,6-anhydro-3,4-*O*-isopropylidene-β-D-galactopyranose *(31)* and 1,6-anhydro-2,3-*O*-isopropylidene-β-D-mannopyranose *(34)* is readily accomplished with either dimethyl sulfoxide-acetic anhydride [15,16] or ruthenium tetroxide [15,16,35] to give the ketones *(32)* and *(35)*, respectively.

(31) *(32)* *(33)* *(34)* *(35)* *(36)*

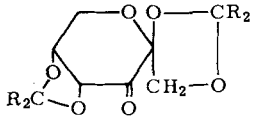
[52] *W. Meyer zu Reckendorf*, Angew. Chem. *79*, 151 (1967); Angew. Chem. internat. Edit. *6*, 177 (1967).

[53] *W. Meyer zu Reckendorf*, private communication.

These ketones can be reduced quantitatively and stereospecifically with metal hydrides to yield 1,6-anhydro-3,4-*O*-isopropylidene-β-D-talopyranose *(33)* and the 2,3-isopropylidene derivative *(36)*, respectively. Both compounds afforded the previously unknown 1,6-anhydro-β-D-talopyranose [16,35] on mild acid treatment while more vigorous treatment gave a mixture of products from which D-talose was crystallized [16].



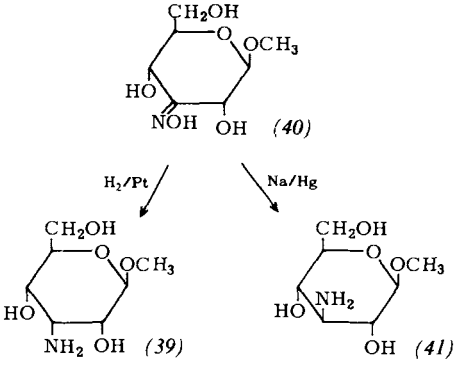
Reduction of methyl 6-deoxy-3,4-*O*-isopropylidene-α-L-*lyxo*-hexopyranosid-2-ulose and methyl 2,3-*O*-isopropylidene-α-L-*lyxo*-hexopyranosid-4-ulose, either catalytically or with $LiAlH_4$, yields [39] predominantly products having the L-*talo* configuration. Deacetonation and acetylation of the product mixtures permits the isolation of methyl 2,3,4-tri-*O*-acetyl-6-deoxy-α-L-taloside which gives crystalline 6-deoxy-L-talose on deacetylation and acid hydrolysis.

The stereochemical outcome of reduction of the foregoing keto sugars has been rationalized [16,39] on the basis of the reagent's approach from the less hindered side of the carbonyl function.

1,2:5,6-Di-*O*-isopropylidene-α-D-allofuranose *(20)* has been transformed [54] into L-acovenose (6-deoxy-3-*O*-methyl-L-talose) by a sequence involving methylation, graded acidic hydrolysis, periodate oxidation, and addition of methylmagnesium bromide.

3.4. D-Psicose (D-*ribo*-hexulose)

Two groups [19,20] have shown that D-psicose can be readily prepared by a route involving stereoselective reduction of 1,2:4,5-di-*O*-isopropylidene-β-D-*erythro*-2,3-hexodiulo-2,6-pyranose *(37)* or the dicyclohexylidene ketone *(38)* to the related psicopyranose diacetals. Ketones *(37)* and *(38)* are obtained by oxidation of 1,2:4,5-di-*O*-isopropylidene-β-D-fructopyranose



(37), R = CH_3
(38), R-R = $-(CH_2)_5-$

and 1,2:4,5-di-*O*-cyclohexylidene-β-D-fructopyranose, respectively, with dimethyl sulfoxide-acetic anhydride.

3.5. Amino Sugar Derivatives

Keto sugars have been utilized in syntheses of amino sugar derivatives in three ways. Firstly, the reduction of oximes or hydrazones derived from keto sugars provides a now well-established route [3] to amino sugars and a parallelism has been noted [55] between the steric course of metal hydride reduction of ketones and their oximes. This is particularly true of metal hydride reductions of ketones and oximes attached to fused-ring systems (for example, ketones *(32)* and *(35)* and their oximes) where the geometry of the molecule favors attack of the reagent from one direction only. In less substituted systems, the choice of reducing agent can often lead to a preponderance of one epimer over the other. Catalytic reduction of methyl β-D-*ribo*-hexopyranosid-3-ulose oxime *(40)* gave [56] exclusively methyl 3-amino-3-deoxy-β-D-allopyranoside *(39)*, while reduction with sodium amalgam yielded predominantly methyl 3-amino-3-deoxy-β-D-glucopyranoside *(41)*.

A number of amino sugars and their derivatives including 2-amino-2-deoxy-L-ribose [3], 2-amino-2,6-dideoxy-L-talose [57,58] (pneumosamine) *(43)*, 2-amino-2,6-dideoxy-L-galactose [58] (L-fucosamine) *(44)*, 2-amino-2,6-dideoxy-L-mannose [59] (L-rhamnosamine), 2-amino-2,6-dideoxy-L-glucose [59], 3-amino-3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose [14,21], methyl 4-acetamido-4,6-dideoxy-α-L-talopyranoside [60], 4-amino-1,6-anhydro-4-deoxy-β-D-talopyranose [61], and 3-amino-1,6-anhydro-3-deoxy-β-D-galactopyranose [62] have been prepared by the oxime route.

The method offers some advantages for the synthesis of 2-amino-2-deoxy sugars since bimolecular nucleophilic displacement of sulfonic esters at C-2 with azide ion and hydrazine is extremely difficult to effect. For example, the absolute configuration of pneumosamine was established [63] by a synthesis of the D-enantiomer which involved the reaction of anhydrous hydrazine on methyl 6-deoxy-3,4-*O*-isopropylidene-2-*O*-*p*-tolylsulfonyl-α-D-galactopyranoside. An improved procedure [57] for the naturally occurring L-sugar *(43)* utilized the catalytic reduction of methyl 6-deoxy-3,4-*O*-isopropylidene-α-L-*lyxo*-hexopyranosid-2-ulose oxime *(42)* even though chromatographic separation of the epimeric amino sugars *(43)* and *(44)* was necessary at the final stage of the synthesis.

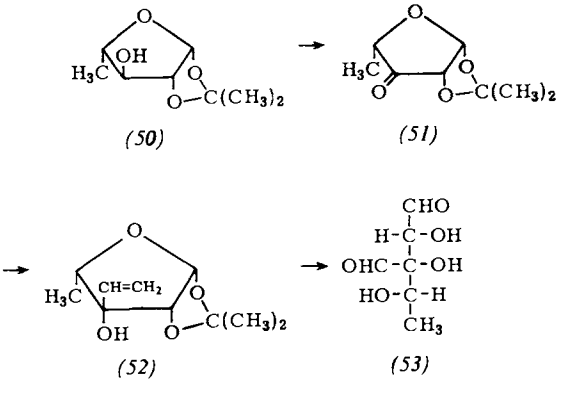
(42) (43) (44)

Secondly, configurational inversions can be effected by oxidation of partially protected acetamido sugars and reduction of the resulting ketone. Oxidation of methyl 2-benzamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside, with the Pfitzner-Moffatt reagent, afforded the ketone *(13)* which is reduced stereospecifically to methyl 2-benzamido-4,6-*O*-benzylidene-2-deoxy-α-D-allopyranoside *(45)* with $NaBH_4$[10]. Since ketone *(13)* is also the product of similar oxidation[10] of methyl 2-benzamido-4,6-*O*-benzylidene-2-deoxy-α-D-altropyranoside *(12)*, the altroside *(12)* can be converted into the alloside *(45)* *via* the ketone *(13)*.

(45)

Finally, a route to certain 3-acetamido-3-deoxy sugars is based upon the ready displacement of *endo*-sulfonyloxy groups attached to trioxabicyclo[3.3.0]octane ring-systems such as occur in 1,2:5,6-di-*O*-isopropylidene-3-*O*-*p*-tolylsulfonyl-α-D-allofuranose *(46)* and 1,2:5,6-di-*O*-isopropylidene-3-*O*-*p*-tolylsulfonyl-α-D-gulofuranose *(48)*. Sulfonates *(46)* and *(48)* were prepared from the parent alcohols *(20)* and *(30)*.

(46) (47) (48) (49)



Whereas the *exo*-sulfonyloxy group of 1,2:5,6-di-*O*-isopropylidene-3-*O*-*p*-tolylsulfonyl-α-D-glucofuranose is generally unreactive[64] towards bimolecular nucleophilic displacement, the epimeric D-allose sulfonate *(46)* (*endo*-substituent) undergoes ready displacement with a variety of nucleophiles[22,65] due to the more favorable approach of the nucleophile from the *exo*-direction. The sulfonyloxy groups of compounds *(46)*[22,65] and *(48)*[66] are smoothly displaced with azide ion in dimethylformamide to give, after reduction and *N*-acetylation, 3-acetamido-3-deoxy diacetals possessing the D-*gluco* *(47)* and D-*galacto* *(49)* configurations, respectively. The free acetamido sugars were afforded on mild acid hydrolysis of these compounds. 3-Amino-3-deoxy-D-xylose can be synthesized[22] from 3-acetamido-3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose *(47)* by selective removal of the 5,6-*O*-isopropylidene group, followed by a conventional chain-shortening sequence and acid hydrolysis.

Other nucleophiles have been used in displacement reactions of sulfonate *(46)*. With tetrabutylammonium fluoride, for example, the method has led[67] to excellent syntheses of 3-deoxy-3-fluoro-D-glucose and 3-deoxy-3-fluoro-D-xylose.

3.6. Branched-Chain Sugars

Branched-chain sugars of the type R–$\overset{|}{\underset{|}{C}}$OH and R–$\overset{|}{\underset{|}{C}}$H are found in Nature[3]. Treatment of glycopyranosiduloses with Grignard reagents[3,40], organolithium reagents[68], diazomethane[69,70], or dimethylsulfoxonium methylide[71] provides access to the former type of branched-chain sugar. The two latter reagents yield epoxides which can be opened either with lithium aluminum hydride to give a glycoside having a *C*-methyl substituent, or, with alkali to give a *C*-hydroxymethyl substituent.

A constitutional synthesis of streptose (5-deoxy-3-formyl-L-lyxose) *(53)* was achieved[9] by way of the reaction of 5-deoxy-1,2-*O*-isopropylidene-β-L-*threo*-

(50) (51) (52) (53)

pentofuranos-3-ulose *(51)* with vinylmagnesium bromide. The addition appeared to be stereospecific and afforded 5-deoxy-1,2-*O*-isopropylidene-3-*C*-vinyl-β-L-lyxofuranose *(52)*, which was converted into L-streptose *(53)* following ozonolysis and deacetonation. Methyl 3,4-*O*-isopropylidene-β-L-*erythro*-pentopyr-

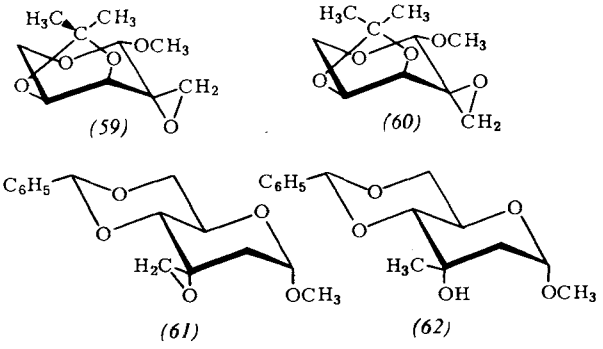
[68] *A. A. J. Feast, W. G. Overend,* and *N. R. Williams,* J. chem. Soc. (London) *(C) 1966,* 303.

[69] *W. G. Overend* and *N. R. Williams,* J. chem. Soc. (London) *1965,* 3446.

[70] *R. J. Ferrier, W. G. Overend, G. A. Rafferty, H. M. Ware,* and *N. R. Williams,* J. chem. Soc. (London) *(C) 1968,* 1091.

[71] *R. D. King, W. G. Overend, J. Wells,* and *N. R. Williams,* Chem. Commun. *1967,* 726.

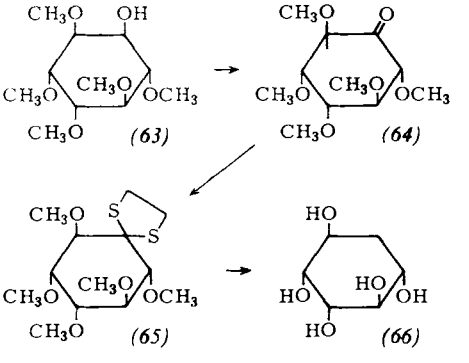


anosid-2-ulose *(54)* has been reacted[40] with a range of Grignard reagents (RMgHal, where R = CH_3, C_6H_5, $C\equiv C-C_6H_5$, $CH_2=CH$) and, after further conversions, it was possible to obtain L-arabinopyranoside derivatives possessing either a methyl, hydroxymethyl, or formyl side chain. Acid hydrolysis of methyl 2-*C*-vinyl-β-L-arabinopyranoside *(55)*, so obtained[40], gave 2-*C*-vinyl-L-arabinose *(56)* which was reduced to the alditol *(57)* and thence, on ozonolysis, to 2-*C*-hydroxymethyl-L-ribose (L-hamamelose) *(58)*.

(54) *(55)* *(56)* *(58)* *(57)*

Grignard additions to glycopyranosiduloses have been used to prepare the enantiomers of a number of antibiotic, branched-chain sugars. D-Mycarose (2,6-dideoxy-3-*C*-methyl-D-*ribo*-hexose)[38], D-cladinose (2,6-dideoxy-3-*C*-methyl-3-*O*-methyl-D-*ribo*-hexose)[38], and D-arcanose (2,6-dideoxy-3-*C*-methyl-3-*O*-methyl-D-*xylo*-hexose)[72] have been synthesized for the purpose of establishing the structures of the naturally-occurring L-forms.

Whereas the reaction of ketone *(54)* with Grignard reagents afforded branched-chain glycosides having the L-*arabino* configuration, addition of either methyllithium or *trans*-β-styryllithium[68] yielded branched-chain glycosides having the L-*ribo* configuration. Treatment of ketone *(54)* with a slight excess of diazomethane, followed by reduction of the mixture of epoxides *(59)* and *(60)* with $LiAlH_4$, gave[70] two isomeric 2-*C*-methylpentoside derivatives: the preponderant product had the L-*ribo* configuration. If the ketone *(54)* is epoxidized with dimethylsulfoxonium methylide[71], the major product obtained on treatment of the epoxide mixture with $LiAlH_4$ and partial acid hydrolysis is methyl 2-*C*-methyl-β-L-arabinopyranoside. Methyl 4,6-benzylidene-2-deoxy-3-*C*-methyl-α-D-*ribo*-hexopyranoside *(62)* is obtained analogously[71] on reduction of the epoxide *(61)*, formed on treatment of methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose with dimethylsulfoxonium methylide. These additions follow the generalization of *Corey* and *Chaykovsky*[73] that, with cyclic ketones, dimethylsulfoxonium methylide gives preferentially an equatorial addition product.



(59) *(60)* *(61)* *(62)*

3.7. Deoxy Sugars

There are several possible ways in which keto sugars might be transformed into deoxy sugars but none of these procedures appears to have been extensively investigated.

The carbonyl group in 2,4,6/3,5-pentahydroxycyclohexanone (*myo*-inosose-2) is reduced to a methylene group on treatment with Adams' catalyst and H_2 in acid solution[74]. Similar reductions of 2,3,5/4,6-pentahydroxycyclohexanone [(+)*vibo*-inosose][75] and (±)-2,3,4,5/6-pentahydroxycyclohexanone [*epi*-inosose-2][76] yielded the related methylene compounds but, additionally, cyclohexanetetrols and cyclohexanetriols were formed by reductive removal of hydroxyl groups. This procedure gave[56] methyl 3-deoxy-β-D-*ribo*-hexopyranoside when applied to methyl β-D-*ribo*-hexopyranosid-3-ulose but was unsuccessfully applied[3] to methyl 2,3-di-*O*-benzyl-α-D-*xylo*-hexopyranosid-4-ulose.

An alternative approach was used[77] in synthesizing 1,3,4/2,5-cyclohexanepentol [(−)*proto*-quercitol] *(66)*. Thus, (−)*proto*-inosose pentamethyl ether *(64)*, prepared by oxidation of the alcohol *(63)* with ruthenium dioxide-sodium periodate, was converted into the thioketal *(65)* on reaction with ethane-1,2-dithiol and, thence, by successive disulfurization over Raney nickel and demethylation into (−)*proto*-quercitol *(66)*.

(63) *(64)* *(65)* *(66)*

Methyl 4-deoxy-α-D-*xylo*-hexopyranoside was obtained[3] from methyl 2,3-di-*O*-benzyl-α-D-*xylo*-hexopyranosid-4-ulose by a route involving mercaptalation with ethanethiol and desulfurization of the thioketal thus formed.

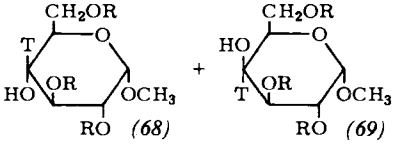
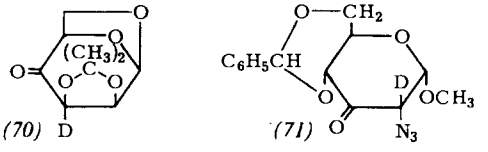
Treatment of *p*-tolylsulfonylhydrazones with either $LiAlH_4$, $NaBH_4$, or KBH_4 affords[78] a mild method for reducing carbonyl groups to methylene groups. This procedure was used to convert[79] D-glucose and L-arabinose *p*-tolylsulfonylhydrazones into 1-deoxy-D-glucitol and 1-deoxy-L-arabinitol, respectively, but failed[80] to achieve a similar conversion with 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose *p*-tolylsulfonylhydrazone. This hydrazone was unreactive towards the Wolff-Kishner conditions and it was suggested[80] that, in both cases, the approach of the base is sterically hindered.



3.8. Specifically-Labeled Sugars

Sugars in which one or more of the hydrogen atoms are replaced by either deuterium or tritium are increasingly used in metabolic experiments, in studies of enzymic reactions, and are also of potential interest for nuclear magnetic resonance and mass spectroscopic studies. Reduction to the epimeric pair of glycosides is routinely used to establish the location of the carbonyl group in unsubstituted glycopyranosiduloses and is applied equally well to more highly substituted keto sugars[2,3]. Reduction with deuterated or tritiated reductants ($NaBD_4$, $NaBT_4$, $LiAlT_4$) would appear to offer worthwhile syntheses of specifically-labeled sugars. Methyl 2,3,6-tri-*O*-benzoyl-α-D-*xylo*-hexopyranosid-4-ulose *(67)*, for example, was reduced with $NaBT_4$ in ethanol to give[81] a mixture of the tritiated glucopyranoside *(68)* and galactopyranoside *(69)* derivatives, which was converted into a mixture of [4-T]-D-glucose and [4-T]-D-galactose by debenzoylation and acid hydrolysis.



Horton and *Jewell*[61] applied the principle of stereochemical control of base-catalyzed enolization to introduce deuterium specifically into 1,6-anhydro-2,3-*O*-isopropylidene-β-D-*lyxo*-hexopyranos-4-ulose *(35)*. The ketone is deuterated rapidly at C-3 on treatment with NaOD in D_2O without change of configuration. The ring strain in the [3.2.1]bicyclic system prohibits the formation of the intermediate 4,5-enol, necessary for exchange with H-5, and the stereospecificity of the exchange at C-3 is predictable on the expectation of the thermodynamically more stable, *cis*-fused acetal *(70)* preponderating at equilibrium. Appropriate reduction of ketones *(35)* and *(70)* provides a route

(67)

(68) *(69)*

(70) *(71)*

R = COC_6H_5

to derivatives of D-talose that are deuterated at C-3, at C-4, or at both positions. An acid-catalyzed enolization effected[11] the introduction of deuterium at C-2 of methyl 2-azido-4,6-*O*-benzylidene-2-deoxy-α-D-*ribo*-hexopyranosid-3-ulose to give the deuterated azido-ketone *(71)*. This compound should be a valuable intermediate for the synthesis of specifically-labeled amino sugars.

I am grateful to my co-workers M. C. Cook, M. J. How, D. Portsmouth, A. Husain, J. G. H. Bryan, and (Miss) P. A. Gent for their work on keto and amino sugars. Thanks are also due to Professors M. Stacey and B. Lindberg, and Dr. O. Theander for their sustained interest in these investigations.

Sigma-Pi Rearrangements of Organotransition Metal Compounds

By M. Tsutsui, M. Hancock, J. Ariyoshi, and M. N. Levy[*]

σ-Bonded organic groups in transition-metal complexes can rearrange to π-bonding ligands and vice versa: the classic example is the formation of π-arenechromium complexes from σ-arylchromium compounds. Rearrangements of this kind can be induced, inter alia, by reactions of the metal or of the ligand, as well as by migration or insertion of a ligand. Rearrangements play a role in many industrial processes, including the polymerization and isomerization of olefins and the hydroformylation of olefins.

1. Introduction

Sigma (σ)-pi(π) rearrangements involve the rearrangement of an organic group that is σ-bonded to a transition metal to the corresponding π-bonded species. Not only these, but also the reverse, π-σ, rearrangements will be covered in this review. All rearrangements occur *intra*molecularly; it is possible that *inter*molecular rearrangements may occur but none have been reported.

A sigma compound involves ligand to metal bonding utilizing σ-orbitals (a sp^n hybrid) on the ligand and dσ-orbitals on the metal; in a π-complex bonding occurs by a σ-overlap between the ligand π-orbitals and dσ-acceptor metal orbitals and a "back-bond" resulting from flow of electron density from filled metal d_{xy} or other d_π-p_π hybrid orbitals into antibonding orbitals on the carbon atoms. The π-complex thus involves a certain amount of double bond character in the metal-ligand interaction.

The first example of this rearrangement in organometallic chemistry came with the characterization of the π-arenechromium complexes [1] (*Hein*'s complexes) and the isolation of the intermediate in their preparation, tri(σ-phenyl)chromium 3-tetrahydrofuran [2]. Since then such rearrangements have been observed in organometallic compounds of almost all the transition metals and with a large variety of ligands, including groups bound through an element other than carbon. Possibly the most important application of σ-π rearrangements is in the field of homogeneous catalytic reactions such as Ziegler-Natta polymerization of olefins (cf. Section 2.3.1) and the Oxo process (hydroformylation of olefins, cf. Section 2.3.3).

As will be seen later, the oxidation state and the stereochemistry of the metal atom change little during a rearrangement and thus the difference in ligation, lattice, and solvation energies (if any) will make only a small contribution to the energy difference between initial and final states. The stability of one state with respect to the other will therefore depend considerably upon the difference in ligand field stabilization energies. For σ-bonded compounds a correlation [3] has been drawn between their stability and the possibility of transition of electrons from the relatively high-energy filled d-orbitals into the lowest antibonding orbitals (here, the anti-bonding σ-orbitals) corresponding to the first step in the rupture of the metal-carbon bond. Thus, to get the most stable σ-organometallic compound, the energy of this transition, ΔE, should be maximized, and the best way to achieve this is to lower the energy of the d-nonbonding orbitals by combining them with π-type orbitals of low energy in suitable ligands (Fig. 1).

In the π-complexes, ΔE is increased by the interaction of the antibonding π-orbitals on the ligand and the nonbonding metal orbitals.

It can be seen that the σ-state will be destabilized with respect to the π-state on losing a ligand and a σ-π rearrangement can occur; the reverse will occur on addition of a ligand to a π-complex. In the latter case it has been pointed out that ligands with a large donor capacity increase the electron density on the metal thereby causing a rise in the energy of the d-orbitals. As a result, the π-group may also acquire a more negative charge, which leads to destabilization of the π-mode of bonding in favor of the σ-form. There may also be a relationship [4] between ligands effecting π-σ rearrangements and the *trans*-effect series [5].

The relative ease of the rearrangement can also be correlated in terms of the concept of "hard" and "soft" bases [6]. σ-Bonded organic groups are "harder" than corresponding π-bonded moieties because of the greater polarizability of the delocalized π-electron cloud compared with the localized σ-orbitals [7]. Thus "hardening" the metal will favor the σ-compound and "softening" it will favor the π-complex. "Hardening"

or "softening" the organic moiety can also initiate rearrangement.

Both approaches lead to the same conclusion, *i.e.* that addition of ligands which are strong π-bonders, *e.g.*, CO, CN^-, PR_3, dimethyl sulfoxide, will result in a π- to σ-rearrangement and removal of such ligands cause the reverse.

2. Mechanism of σ–π Rearrangements

The only mechanism which is well established is the rearrangement of σ-arylchromium compounds to π-arene complexes. Tri(σ-phenyl)chromium-3-tetrahydrofuran *(1)* at 60 °C, under high vacuum or on washing with ether, gives a black pyrophoric solid which on treatment with deoxygenated water gives the π-arene complexes, bis(biphenyl)chromium(0) *(5)* and benzene(biphenyl)chromium(0) *(6)*. The formation of radical intermediates (the black pyrophoric solid) *(2)*, *(3)*, and *(4)* has been proposed [9] and hydrolysis of these gives *Hein*'s π-complexes. The existence of a transition state involving π-radical hybridization has been postulated [10], the metal-carbon σ-bonds cleaving homolytically with a corresponding three-electron reduction of Cr^{III} to Cr^0. EPR investigations show homolytic fission of the chromium-carbon bond and possibly the formation of radical π-complexes [11]. π-radical formation, hydrogen abstraction, and hydrogen transfer all occur within the confines of the intermediate organochromium complexes [12, 13].

σ-Bonded allyl metal compounds *(7)* are readily protonated by hydrogen chloride or mineral acids to give π-allene complexes *(8)*. In the case of σ-allyliron compounds a bimolecular reaction is proposed; experiments with DCl show protonation to occur at C-3 [14].

2.1. Rearrangements Induced by Reactions on the Metal

As pointed out earlier (Section 1), groups capable of coordinating should be capable of inducing rearrangements by means of the *trans*-effect. However, only ligands high in the *trans*-effect series and able to participate in metal to ligand π-bonding can stabilize a σ-state or shift an equilibrium sufficiently towards the σ-compounds.

Tetrahydrofuran is a comparatively weak π-bonding ligand and stabilization of a σ-compound has only been reported with those organic groups which are themselves capable of π-bonding. The rearrangement of arylchromium compounds on losing tetrahydrofuran have already been discussed fully. When the σ-bonded ligand is a cyclopentadienyl group stabil-

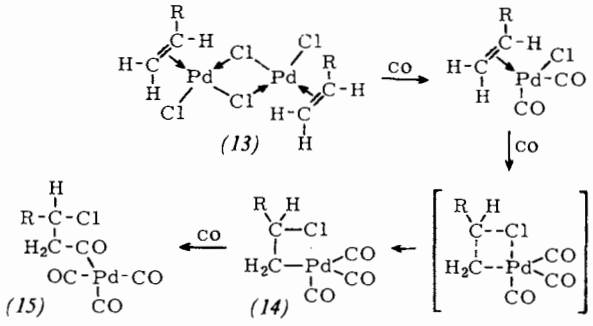
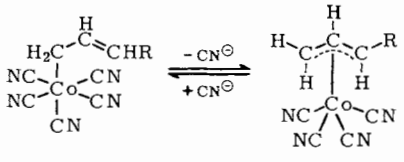
zation is reduced. Chlorobis(σ-cyclopentadienyl)iron(III)-tetrahydrofuran rearranges to the ferrocinium cation on losing the solvent ligand, this occurring above −50 °C, under vacuum at −60 °C, or on treatment with an organic solvent at −60 °C[15].

Diethyl ether has also been reported as a ligand in the alkali-metal salts of σ-bonded phenylchromate. Reactions of $Na_2[Cr(C_6H_5)_5(C_2H_5)_2O] \cdot 2\,(C_2H_5)_2O$ and $Li_3[Cr(C_6H_5)_6] \cdot 2.5\text{-}(C_2H_5)_2O$ with chromium trichloride 3-tetrahydrofuran in ether give black amorphous products which yied π-arene complexes on hydrolysis, the transformation taking place through σ-phenylchromium intermediates[16].



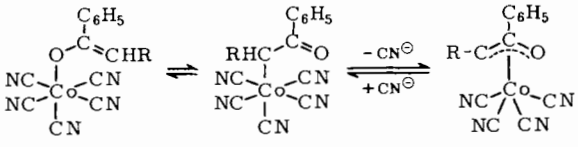
(9), M = Mo *(10)*, M = Mo
(11), M = W *(12)*, M = W



Loss of carbon monoxide from a σ-complex is induced by irradiation with ultraviolet light or by heating, and the reverse is achieved under a pressure of carbon monoxide. On irradiation with UV, the σ-allyltricarbonyl-π-cyclopentadienylmolybdenum[17] *(9)* and -tungsten[18] *(11)* give the π-allene complexes *(10)* and *(12)* with the loss of one molecule of carbon monoxide. On heating or irradiating with UV, tricarbonyl-π-cyclopentadienyl-σ-methylthiomethylmolybdenum rearranges with loss of carbon monoxide to give a π-complex, the structure of which could not be determined unambiguously[19]. The reaction between sodium tricarbonyl-π-cyclopentadienylmolybdate and benzyl chloride gives a σ-benzyl derivative. Irradiation in hexane gives, concurrent with loss of CO, a low yield of π-benzyl dicarbonyl-π-cyclopentadienylmolybdenum. The benzyl group is bonded through an allylic system involving three of the carbon atoms, and variable-temperature NMR measurements show that the molecule is stereochemically dynamic[20].

The reaction of allyl chloride with sodium (or lithium) pentacarbonylmanganate at room temperature gives σ-allylpentacarbonylmanganese which at 100 °C evolves one mol. equiv. of carbon monoxide leaving the π-allyltetracarbonylmanganese[21,22].

The reaction of π-olefinpalladium complexes such as *(13)* and carbon monoxide gives a β-chloroacylpalladium complex *(15)*. Initially, bridge cleavage takes place and on further carbonylation, rearrangement



occurs to the σ-complex *(14)* followed by alkyl migration to give *(15)*[23].

(16) *(17)*

Because of the formal similarity of RNC, CN^-, and NO^+ to CO, compounds containing these groups might be expected to undergo similar rearrangements, but only rearrangements involving addition and abstraction of CN^- have been reported. The σ-bonded compound *(16)* loses a cyanide ion to give the π-bonded complex *(17)*, the rearrangement being reversed on addition of cyanide ion.

(18) *(19)*

Rearrangement of the phenacyl group has also been observed, although the π-complexes *(18)* and *(19)* were not obtained in a pure state[24].

Analogous σ-π structures have been proposed as determining the stereoselectivity of the butene products obtained in the pentacyanocobaltate(II)-catalyzed hydrogenation of butadiene. In the presence of an excess of cyanide ion, 1-butene is the major product derived exclusively from a σ-butenyl intermediate. *trans*-2-Butene is the main product in the absence of an excess of cyanide and may derive from either a π-butenyl complex or an isomeric σ-butenyl compound in equilibrium with π-structures[25].

In the presence of Lewis acids π-allylhalogenonickel compounds catalyze the dimerization of propylene; the structure of the catalyst can be varied by addition of phosphines, NMR studies showed that 1:1 and 1:2 derivatives of triphenylphosphine and triphenylphosphite contain a π-allyl group, but the 1:2 complex

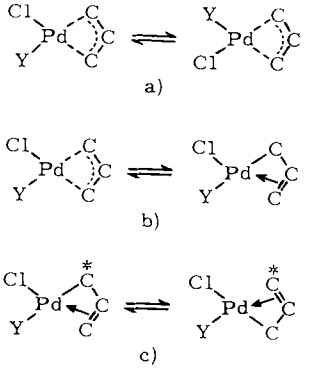
with triethylphosphine exists in a dynamic σ-bonded equilibrium whereas the 1:1 complex is π-bonded [26].

Considerable discussion on the nature of the stereochemically non-rigid allylmetal complexes has arisen from variable-temperature NMR measurements. Internal rotation [27,28] and σ-π rearrangements have been suggested for the palladium complexes. Allylchloropalladium is dimeric in the solid state [29] but in benzene and dioxane solution it is found from cryoscopic and dipole moment measurements that an equilibrium exists with about 75% dimer and 25% monomer [30]. NMR spectra of solutions of allylchloropalladium in dimethyl sulfoxide require that the allylic ligand be σ-bonded to the metal. Only one peak is found and a rapid equilibrium is therefore deduced between two equivalent σ-forms. The other coordination sites are probably occupied by one chloride and two dimethyl sulfoxide ligands [31]. During preparations of allylic palladium complexes, the same σ-π changes are noted [32].

(20)

Addition of triphenylphosphine to chloro-π-methallylpalladium (up to 2 moles $(C_6H_5)_3P$ per 1 g-atom Pd) has been followed by NMR. During reaction, changes observed in the spectrum indicate formation of a σ-allylic compound that undergoes a rapid exchange. The NMR spectrum of the product, chloromethallyltriphenylphosphinepalladium, suggest structure *(20)* with two carbons only weakly bonded to the palladium [33]. X-ray analysis of the compound supports the structure given in *(20)* [34]. NMR variable-temperature



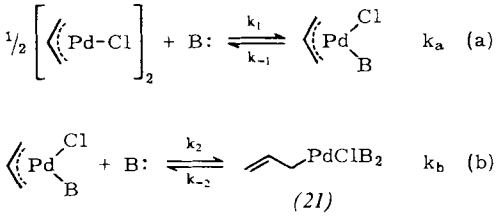


Fig. 2. Possible reactions of allylpalladium complexes (schematic): a) ligand exchange; b) π-σ equilibration; c) head-over-tail equilibration.

measurements from 25 °C to 65 °C suggest that allylchloropalladium in DMSO has a π-bonded structure in which hindered rotation of the CH_2 groups about the C–C bonds occurs at a rate dependent on the temperature [35]. The temperature dependence of the NMR spectra of a number of allylic complexes of palladium has been studied and the results explained by ligand exchange, followed by π- to σ-equilibration, which may then be followed by a head-over-tail equilibration [36].

Further work casts doubt upon the structure of the intermediate *(20)* proposed by *Shaw et al.* [33]. It is suggested from variable-temperature NMR studies on reactions between allylchloropalladium and the ligands $P(C_6H_5)_3$, $P(n\text{-}C_4H_9)_3$, 4-methyl-2,6,7,1-trioxaphosphabicyclo[2.2.2]octane, $As(C_6H_5)_3$, $Sb(C_6H_5)_3$ that an equilibrium is established even at low temperatures between σ- and π-bonded compound with the equilibrium being almost completely to the side of π-bonding. At higher temperatures, rotation of the π-allyl group is inferred for all ligands and at very high temperatures and high ligand to metal ratio, rapid formation of a σ-allyl group has to be postulated to explain the NMR spectra [37].

Temperature dependence studies of the NMR spectra recorded during reactions between π-allyl complexes and the ligands (B:) triphenylphosphine, dimethyl sulfoxide, and dimethyl sulfide show that σ-π rearrangements are occurring as in reactions (a) and (b). The disappearance of coordinated allyl and the appearance

(21)

of uncoordinated olefin absorptions in the infrared spectra demonstrate the formation of σ-bonded allyls, as in *(21)*. Equilibrium lies far to the right with $(C_6H_5)_3P$, but with DMSO and DMS it lies to the left [38].

The reaction between chloro-π-methylallylpalladium and triphenylarsine has also been studied by variable-temperature NMR. Three equilibria are occurring [eq. (c)–(e)]. In (e) two mechanisms are involved: between −70 °C and −40 °C triphenylarsine exchange is occurring and between +10 °C and +80 °C, ligand exchange occurs along with the formation of a σ-allyl compound or an activated state involving the σ-bonded compound [39].

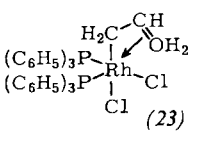
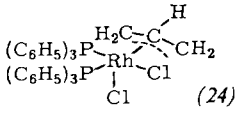
A study of NMR was carried out at 34 °C on aseries of complexes PdX(all)L where X = halogen, all = allylic ligand, and L = *tert.*-phosphine, triphenyl arsine, or triphenylstibine. As the ratio of L/Pd is varied from 0 to 2 several fast processes occur involving π-allylic to σ-allylic rearrangement, during which rotations about the C–C bond and Pd–C bond and exchange of coordinated ligand with free ligand occur. Carbon monoxide also coordinates to the palladium in $[PdClCH_2-C(CH_3)=CH_2]_2$ and the NMR spectrum in $CHCl_3$ corresponds to that of a dynamic σ-methallyl system [40].

A diastereoisomeric mixture is prepared in ethyl acetate by cleaving the chlorine bridge of dimeric 1-acetyl-2-methylallylchloropalladium with (*S*)-α-phenethylamine. Resolution is achieved by crystallizing the crude diastereoisomeric mixture from CCl_4. Optical-activity measurements performed on acetone solutions at very low and higher temperatures indicate that:



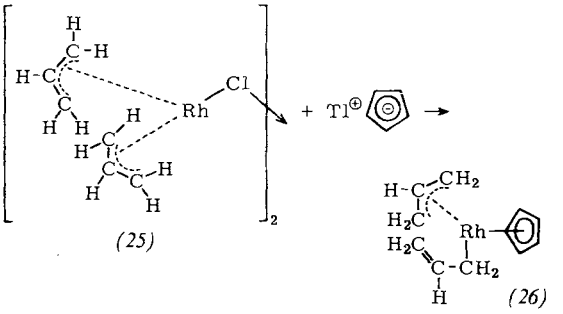
(a) Only one of the two diastereoisomers is quantitatively obtained in the CCl_4 crystallization through a "second-order asymmetric transformation"; (b) Epimerization of the pure (–)-diastereomer takes place very rapidly at temperatures above –20 °C.

The epimerization can only occur through a rotation around the C-2–C-3 bond, *i.e.* through a σ-bonded intermediate [41].

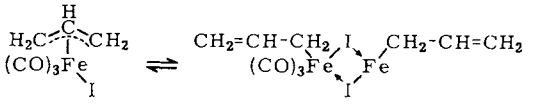


A similar rearrangement is reported for allylic platinum complexes on addition of triphenylphosphine. A variable-temperature study of the NMR spectrum indicates that σ-π equilibria are occurring [42]. Other studies on dichloro-π-methylallylbis(triphenylphosphine)rhodium or the triphenylarsine analog show that allyl interchange is occurring *via* a short lived σ-allyl intermediate [43].

(22)



(23)



(24)

The reaction of chlorotris(triphenylphosphine)rhodium with allyl chloride at 25 °C produces yellow crystals. In solution, the NMR spectrum agrees with the σ-bonded structure *(22)* but an infrared spectrum taken in a mull shows no band attributable to an uncoordinated double bond so that in the solid state the structure may be *(23)*. On refluxing the yellow crystals, a π allylic compound *(24)* is obtained whose structure is assigned on the basis of spectral data [44].

(25) *(26)*

Cyclopentadienide ion would be expected to exhibit a similar effect to carbonyl and especially to cyanide ion in ability to cause a π-σ rearrangement [45]. Allyl chloride reacts with a methanolic solution of carbonylchlororhodium in the presence of a little water to give a compound with the structure *(25)*. On addition of thallium cyclopentadienide the complex *(26)* is obtained, the NMR spectra of which indicates that one allyl group is π-bonded and one is σ-bonded [46].

(27) *(28)*

All the ligands reported to affect π–σ or σ–π rearrangements show a strong *trans*-effect and it might be expected that iodide ion would show a similar although weaker effect [47]. The reaction between allyl iodide and pentacarbonyliron gives a compound with an empirical formula $C_3H_5Fe(CO)_3I$. No olefin stretching frequency is observed in the infrared and so the structure would be expected to be *(27)*. In cyclohexane, however, a considerable degree of dimerization is found and a complicated NMR is obtained which could not be interpreted on the basis of structure *(28)*. Four carbonyl stretching frequencies are also found in the infrared rather than the expected three. It is suggested that an equilibrium occurs between *(27)* and *(28)* in solution [48].

A suspension of carbonylchlorobis(π-cyclooctene)iridium undergoes an oxidative addition in allyl chloride to give a white solid π-allylcarbonyldichloro-π-cyclooctene iridium, which decomposes above 14 °C but when dissolved in chloroform-methanol gives the more stable dimer. NMR and IR spectra are very complex and it is suggested that the dimer has σ-allyl groups and bridging chlorine atoms. The π-methallyl complex does not dimerize and hence no rearrangement is observed [49].

2.2. Rearrangements Induced by Reactions on the Ligand

This case differs from that discussed in Section 2.1 in that the basic stereochemistry of the metal is not changed and the metal remains coordinatively satu-

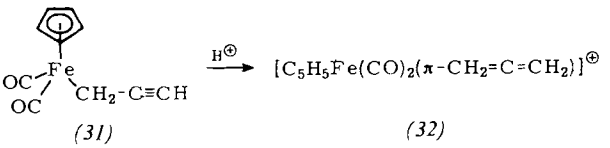
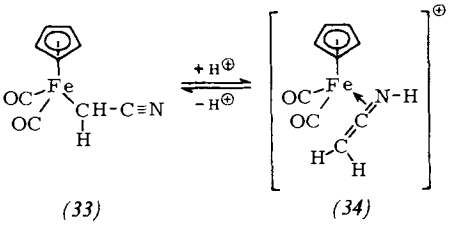
rated. Therefore any π-group formed will only be a two-electron donor: no delocalized π-systems are formed in the cases described below. The π-compounds, because the π-group is "softer" than te σ, will be the thermodynamically stable form but if the equilibrium is shifted chemically then one can stabilize the σ-compound.

Ethyltricarbonyl(π-cyclopentadienyl)molybdenum *(29)* on treatment with triphenylmethyl perchlorate yields the ethylene π-complex *(30)* while the abstraction is



(29) *(30)*

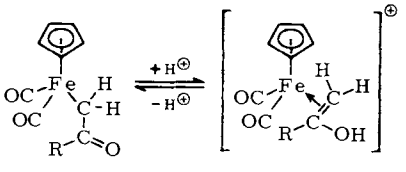
reversed on treatment with $NaBH_4$ [50]. Small amounts of π-ethylenepentacarbonylmanganese tetrafluoroborate are obtained on treating ethylpentacarbonylmanganese with triphenylmethyl tetrafluoroborate. The reaction is also reversed on addition of $NaBH_4$ [51].



It is also found that when a σ-alkyl-dicarbonyl-π-cyclopentadienyliron compound (alkyl = ethyl, *n*-propyl, and isopropyl) is treated with a stoichiometric amount of triphenylmethyl perchlorate, a fast reaction occurs giving a good yield of the corresponding π-complex [52]. In the above case when the alkyl group is primary, the abstraction is found to be reversible, reduction of the π-complex with $NaBH_4$ giving the σ-alkyl [53].

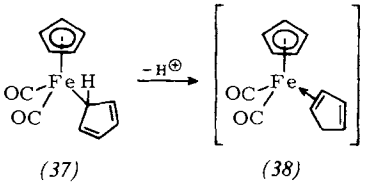
Protonation of σ-allyl compounds gives the corresponding π-olefins [19, 54, 55]. Dilute mineral acids or hydrogen chloride effect these protonations and rearrangements, but in the case of σ-allylpentacarbonylmanganese it has been found that the π-allyl is only obtained when perchloric acid is employed. Cleavage of the σ compound to give $(CO)_5MnA$ occurs when A is Cl, NO_3, CF_3COO, or SO_4H [56].

Using this reaction several unusual π-bonded groups have been obtained. The σ-propargyliron compound *(31)* gives a hexachloroantimonate *(32)* in concentrated hydrochloric acid which gives acetone on hydrolysis. The formation of acetone indicates that there may be a π-allene system present in the cation [57]. The π-

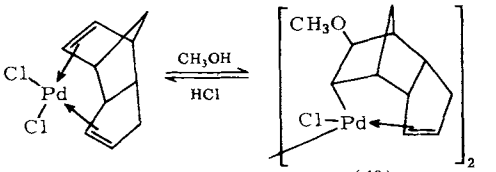


(31) *(32)*

(33) *(34)*



allene complex would be expected if the course of the protonation were similar to that of the isoelectronic compound *(33)*, which undergoes a reversible rearrangement to give a π-imine cation *(34)* [58]. Protonation of a σ-bonded α-ketone *(35)* "traps vinyl alcohol" in the rearranged product *(36)* [59]. Polyvinyl alcohol is becoming quite important industrially and thus this rearrangement could have considerable significance.



(35) *(36)*

Protonation of dicarbonyl-π-cyclopentadienyl-σ-cyclopentadienyliron *(37)* in concentrated hydrochloric acid gives a π-olefin complex *(38)* [60]; thus *(37)* shows the same behavior as the σ-bonded allyl compounds.

In recent years many complexes have been reported in which large ring diolefins are chelated to transition metals, particularly to platinum and palladium. These π-diolefin complexes undergo addition reactions to one double bond giving σ-bonded complexes. The

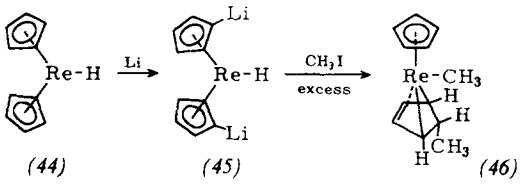
reaction of palladium dichloride with *endo*-dicyclopentadiene gives a monomeric π-complex *(39)*, which reacts with methoxide to give a dimeric σ-bonded compound[61] *(40)*. The reverse (elimination) is brought about by treatment with hydrochloric acid. 1,5-Cyclooctadiene reacts with sodium tetrachloropalladate(II) in methanol to give the π-complex, which then reacts with methanol in the presence of sodium bicarbonate to give a σ-bonded compound[62].

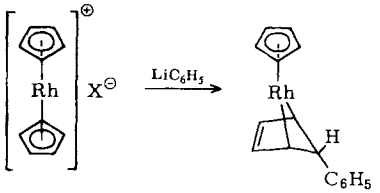
A similar reaction to that of the palladium complex *(39)* is reported for the analogous platinum complex, a reversible π-σ reaction occurring on treatment with methoxide or hydrochloric acid[63]. The reaction between π-dienemetal dihalides and an organic anion appears to be fairly general. It has been reported for cases with the diene being 1,5-cyclooctadiene, norbornadiene, 4-vinylcyclohexene, 1,5-hexadiene, dicyclopentadiene, and dipentene; rearrangements occurring with alcohols[64] in the presence of anhydrous sodium carbonate, acetate and propionate ions[65], diketones[66], and primary amines[67]. The reaction of methoxide ion with dichloro(norbornadiene)palladium proceeds *via* addition – as in all the above examples – to form the complex *(41)* in which the methoxy group has the *exo*-configuration, thus establishing that *trans* addition to the olefin has occurred[68].

(41)



We can consider, in the above category, *Malatesta*'s synthesis of π-cyclobutadienepalladium complexes. The reaction between diphenylacetylene and alcoholic palladium chloride gives a σ-bonded compound *(42)* which reacts with hydrogen halides to give dichloro-(tetraphenylbutadiene)palladium *(43)*[69].

(42) *(43)*



R = C_6H_5

It is also reported that the reaction of diphenylacetylene with palladium chloride in ethanol gives, *inter alia*, a compound $Pd(C_{28}H_{20}OC_2H_5)Cl$ assigned a structure with σ- and π-bonding. Refluxing this in an ethanol-hydrochloric acid (90:10) mixture again gives compound *(43)*[70].

(44) *(45)* *(46)*

π-Cyclopentadienyl rings appear to be resistant to rearrangement, although two reactions leading to σ-bonded compounds have been reported. Treatment of bis(π-cyclopentadienyl)hydridorhenium *(44)* with lithium gives the dilithium compound *(45)* which reacts with an excess of methyl iodide to form *(46)*, a compound in which the rhenium is σ-bonded to two carbon atoms and π-bonded to the ring double bond[71]. Compound *(47)* reacts similarly with phenyllithium to give a compound with the formula C_5H_5Rh-1-*exo*-$C_6H_5C_5H_5$. This compound is assigned the structure *(48)* on the basis of its NMR spectrum and

(47) *(48)*

its X-ray powder diffraction pattern, which showed that it is isomorphous with the corresponding cobalt compound, the structure of which had been elucidated by detailed X-ray analysis[72, 73].

2.3. Migration or Insertion Reactions

Migration reactions involve initially a coordinatively unsaturated organometallic compound, with one group σ-bonded. Coordination of a π-molecule occurs followed by rearrangement with the σ-group migrating to the olefin and then π-σ rearrangement of the olefin[8]. This mechanism is industrially important, being postulated for such processes as the polymerization of olefins (Ziegler-Natta catalysis) and the hydroformylation of olefins (Oxo process).

2.3.1. Olefin Polymerization

Ziegler and *Natta*[74, 75] found that a catalyst consisting of a transition metal halide, *e.g.*, $TiCl_4$, and a non-

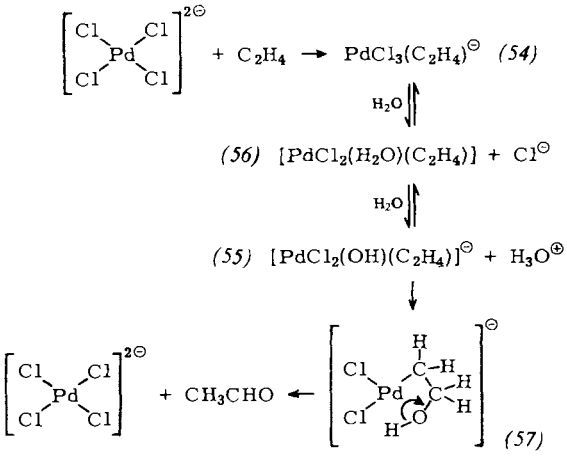
transition metal alkyl, *e.g.*, $Al(C_2H_5)_3$ [76,77], readily causes polymerization of olefins. Propagation of the polymerization involves alkylation of the titatinum by the aluminum alkyl to give *(49)*. Formation of a π-

(49) *(50)*



(51) *(52)* *(53)*

complex *(50)* between the olefin and the organotitanium compound *(49)* then occurs followed by "insertion" of the olefin into the titanium-carbon bond giving another σ-bonded compound *(53)*. This migration process leaves a vacant coordination site on the titanium which will act as an active center for the formation of another π-complex *(52)*. Again "insertion" occurs to give a σ-bonded compound with the growing polymer chain attached to either of two octahedral positions on the same metal atom [formula *(51)*].

2.3.2. Wacker Process

The oxidation of ethylene in aqueous solution to acetaldehyde using a palladium chloride-cupric chloride catalyst constitutes the Wacker process. The mechanism of the reaction is complicated but initially a π-olefin complex *(54)* is probably formed. Hydrolysis of the chloro complex occurs to give eventually the π-olefin hydroxy complex *(55)*. Subsequent migration of the coordinated OH^- group gives a σ-β-hydroxy compound *(57)*. This undergoes a hydride shift with rearrangement and elimination of acetaldehyde [78–81].

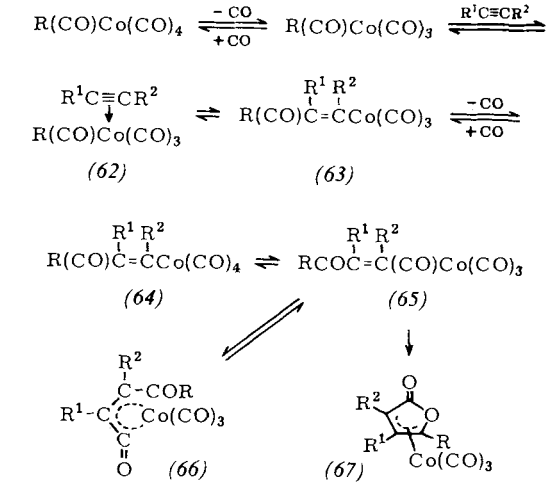
[81] *J. Halpern*, Proc. 3. Int. Congr. Catalysis, North-Holland Publ. Co., Amsterdam 1965, p. 146.

2.3.3. Oxo Reaction

The catalytic addition of hydrogen and carbon monoxide to olefins to give higher alcohols *via* the aldehyde (usually C_6–C_9) constitutes the important hydroformylation of the "oxo" process and has the overall stoichiometry.



$$R\text{–}CH{=}CH_2 + CO + H_2 \rightarrow R\text{–}CH_2\text{–}CH_2\text{–}CHO$$

The reaction is usually carried out at high pressure and temperatures of 150 °C or above using a carbonylcobalt catalyst. Initially monomeric tetracarbon-

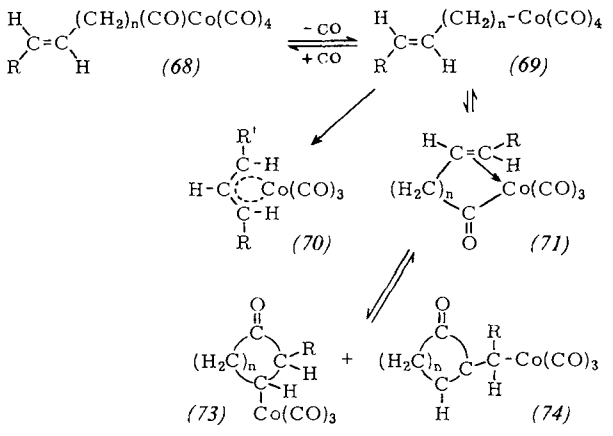
(58) *(60)* *(61)* *(59)*

ylhydridocobalt is formed, which loses carbon monoxide to give the tricarbonyl. Olefin addition occurs to give a π-complex *(58)*, which rearranges to the 5-complex *(61)*. Addition of CO to *(61)* gives *(60)*, which rearranges to *(59)* [82,83]. The complex *(60)* was isolated as the triphenylphosphine derivative.

(62) *(63)* *(64)* *(65)* *(66)* *(67)*

Closely allied to the hydroformylation of olefins is the reaction of acetylenes with acylcarbonylcobalt complexes. Formation of a π-complex *(62)*, is followed by rearrangement to the σ-compound *(63)*. Finally the π-allyl systems *(66)* and *(67)* are formed *via* the intermediates *(64)* and *(65)* [84].

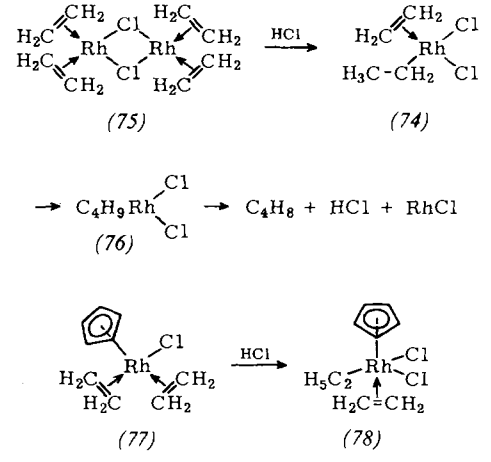
A similar σ-π rearrangement is postulated for the thermal decomposition of alkenoyltetracarbonylcobalt *(68)* in solution [85]. In dilute etheral solution *(68)* decomposes to give several products, including a π-allyltricarbonylcobalt *(70)*, a



[82] *R. F. Heck* and *D. S. Breslow*, Chem. and Ind. *1960*, 467.

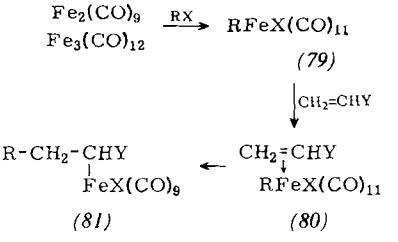
[83] *R. F. Heck* and *D. S. Breslow*, J. Amer. chem. Soc. *83*, 4023 (1961).

[84] *R. F. Heck*, J. Amer. chem. Soc. *86*, 2819 (1964).



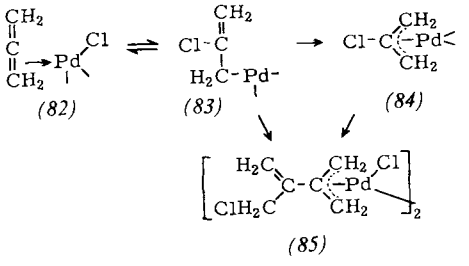
[85] *R. F. Heck*, J. Amer. chem. Soc. *87*, 4117 (1965).

π-alkenoyl tricarbonylcobalt *(71)*, and the σ-bonded complexes *(72)* and *(73)*. A σ-bonded tetracarbonyl *(69)* is postulated as forming initially[86].

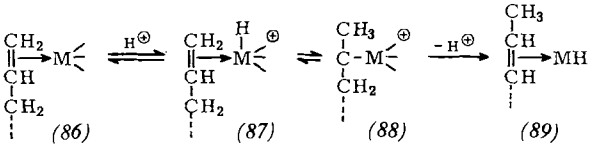


In favorable cases, the hydrogenation of olefins may be achieved through a π-σ-rearrangement by hydrogen transfer from a transitory hydridotransition metal complex. The homogeneous catalytic hydrogenation of fumaric acid in aqueous solution with ruthenium(II) chloride as catalyst proceeds *via* formation of a π-olefinhydridoruthenium-complex with subsequent insertion of the olefin into the metal-hydride bond giving a σ-alkyl compound. The hydrogenation is completed by an electrophilic attack on the metal-bonded carbon atom by a proton[87].

Hydration of unsaturated compounds catalyzed by transition metal complexes appears also to proceed *via* a π-σ mechanism. The catalytic hydration of acetylenic compounds by ruthenium(III) chloride involves the formation of an intermediate π-complex of the hydrated ruthenium compound followed by insertion of the acetylene across the metal-oxygen bond to give the σ-bonded compound, which then rearranges to give ruthenium(III) chloride and a ketone[88].



Studies on the rhodium-catalyzed dimerization of ethylene to linear butenes indicate (from NMR studies below −10 °C) that a σ-ethyl-π-ethylene compound *(74)* is formed by reaction of hydrogen chloride with the π-complex *(75)*. Ethyl migration then occurs to give the butyldichlororhodium *(76)* which collapses to give butene and Rh^I. Compound *(77)* reacts with hydrogen chloride to give σ-ethyl-π-ethylenedichlororhodium *(78)*[89].



The reaction of olefins with nonacarbonyldiiron or dodecacarbonyltriiron in the presence of organic halides gives initially a σ-compound *(79)*. Olefin addition then occurs to give the π-complex *(80)* followed by alkyl migration with the formation of another σ-compound *(81)*[90].

A σ-π insertion rearrangement is proposed to explain the formation of the π-complex *(85)* when allene is bubbled into a methanolic solution of sodium chloropalladite, or its formation, together with chlorobis(π-2-chloroallyl)palladium *(84)*, on passing allene into a benzene solution of bis(benzonitrile)dichloropalladium. A π-σ-π mechanism involving intermediates *(82)* and *(83)* is proposed to explain the formation of these compounds[91].

Double bond migration in olefins is catalyzed by a wide variety of Group VIII transition metal complexes and in many cases has been shown to involve formation of π-olefin complexes, such as *(86)*, which can be protonated to metal hydride intermediates *(87)*. Addition of M–H to the olefin double bond then occurs to give a σ-bonded alkyl metal compound *(88)*, and finally rearrangement to the isomeric olefin and the metal hydride *(89)*. With normal olefins the isomerization is catalyzed by, for example, hydrated rhodium trichloride, bis(benzonitrile)dichloropalladium, and rhodium heptanoate[92]. Using deuterated olefins, it

is found that the mechanism involved in this isomerization varies with the metal. With rhodium(III) compounds, the rearrangement proceeds *via* the π-olefin

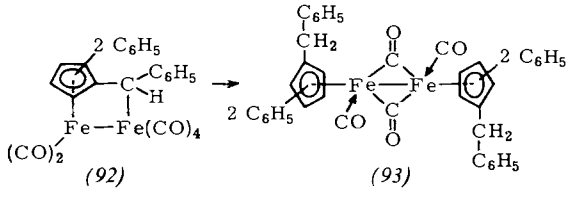
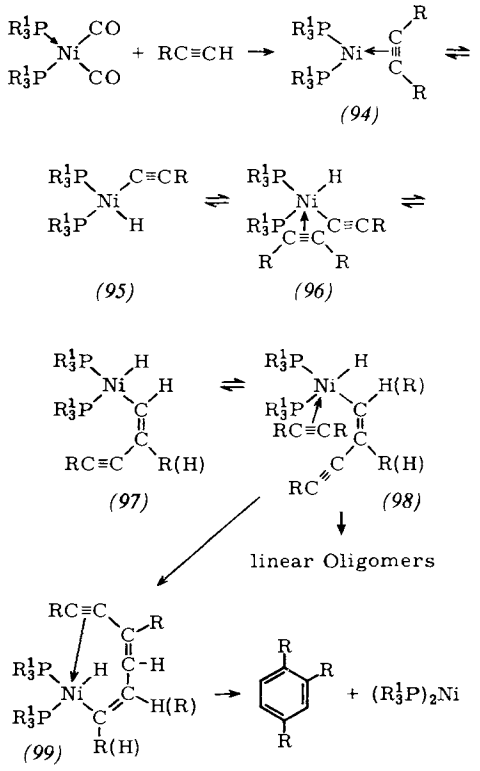
to the σ-alkyl compound, but for the corresponding palladium-catalyzed reaction the rearrangement appears to go through a π-allyl intermediate [93].



2.4. Other Rearrangements

Dicarbonyl(π-cyclopentadienyl)(σ-cyclopentadienyl)-iron *(37)* not only undergoes rearrangement on protonation but is thermally unstable, giving ferrocene and tetracarbonylbis(π-cyclopentadienyl)iron [94]. *(37)* is a member [95] of the rapidly growing group of compounds (including the allyl compounds discussed previously) that are stereochemically dynamic.

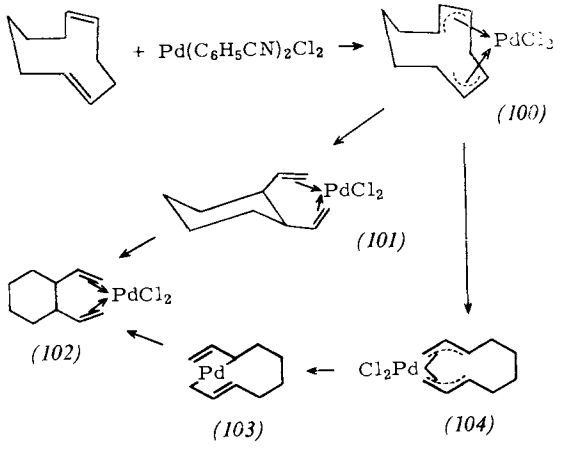
(90) *(91)*



The π-bonded complex *(90)* is found to be in equilibrium with the σ-compound, even at −10 °C in solution [96]. The reaction of phenylacetylene with dodecacarbonyltriiron gives, in addition to other products, a π-bonded compound *(92)* which rearranges to the π-complex *(93)* [97].

(92) *(93)*

Vinylcyclopropanes bearing *para*-substituted phenyl groups react with iron pentacarbonyl to yield π-complexes in which the cyclopropane ring has opened. The mechanism proposed involves formation of π- and σ-bonded intermediates [98].



In 1940 *Reppe* and *Schweckendick* found that carbonylphosphinenickel compounds catalyze the trimerization of acetylenes to aromatic compounds [99]. Later researchers have shown that linear oligomers of monosubstituted acetylenes are also formed [100]. Initial formation of a π-complex *(94)* is postulated and this undergoes oxidative addition to give a σ-compound *(95)*. Compound *(95)* reacts with more acetylene to

(94) *(95)* *(96)* *(97)* *(98)* *(99)*

linear Oligomers

form *(96)* and this π-complex undergoes a migration to give *(97)*. Repetition of this step [*(98)*, *(99)*] and subsequent ring closure lead to the benzene derivative. The linear oligomers are formed from *(98)*.

(100) *(101)* *(102)* *(103)* *(104)*

Cope arrangements can occur on thermal excitation. photolysis, and by reaction with metal compounds. A σ-π mechanism has been proposed for the metal-induced rearrangement. The reaction of bis(benzonitrile)dichloropalladium with *cis,trans*-1,5-cyclodecadiene gives a palladium complex *(102)* of 1,2-divinylcyclohexane. Initially, a π-allylic-complex *(100)* is postulated, the ring then opening to complex *(104)* or *(101)*. Rearrangement of *(104)* proceeds *via (103)* to give *(102)*, whereas *(101)* gives *(102)* directly [101].

A Cope rearrangement of *cis*-1,2-divinylcyclobutane catalyzed by nickel complexes with tri(2-biphenyl)-phosphite, triphenylphosphine, and tricyclohexyl-

phosphine is reported to go *via* a σ-π rearrangement [102].

Coupling reactions between Grignard reagents and various substrates are catalyzed by polyvalent transition metal salts in stoichiometric amounts or in traces. These free radical processes are characterized by dimerization of the radical from the organic halide. Such reactions have long been a mechanistic source of debate [103, 104] but with the elucidation of the structures of *Hein*'s complexes [1, 2] came the realization that coupling probably goes *via* a σ-π rearrangement and π-radical hybridization.

(105) *(106)*

In 1914, *Bennett* and *Turner* [105] obtained biphenyl, instead of the expected triphenylchromium, in good yield from the reaction of phenyl magnesium chloride with chromic chloride. It is now known that the σ-bonded compound *(105)* is initially formed but the chromium-carbon bond cleaves homolytically to give the π-radical complex *(106)* [106] which then, under the rigorous conditions used, couples to give biphenyl and chromium. Under milder conditions, as used by *Hein*, *(106)* gives dibenzenechromium(0) by hydrolysis [105, 106]. (Chromium(II) is shown rather than chromium(III) for simplicity.)

(107) *(108)*

cis- or *trans*-α-Phenyl-α-styrylmagnesium bromide reacts with chromium(III) chloride or cobalt(II) chloride to give *cis,cis*-1,2,3,4-tetraphenylbutadiene, but the reaction with nickel(II) bromide or palladium(II) chloride gives the *trans,trans* isomer, *i.e. cis*-coupling occurs with those transitional metal complexes that normally have an octahedral (d^2sp^3 hybridization) configuration, while *trans* coupling occurs with those that normally take a square planar form [107].

Double coupling occurs during the reaction of vinylmagnesium bromide with titanium tetrachloride yielding four organic compounds: 4-vinyl-1-cyclohexene, 2,6-octadiene, 3-methyl-1,5-heptadiene, and 3-methyl-1,4,6-heptatriene. Initially, σ-bonded tetravinyltitanium *(107)* is probably formed which yields the observed products *via* a π-radical complex and several π-bonded intermediates [108].

Corresponding to the stoichiometric coupling reaction of vinyl groups on titanium outlined above is the catalytic coupling of vinylmagnesium chloride by titanium tetrachloride in the presence of bromoethane, the reaction products being 3-methyl-1,5-heptadiene and 3-methyl-1,4,6-heptatriene. The mechanism proposed [108] again involves initial formation of σ-tetravinyltitanium which undergoes radical hybridization and coupling. Activated titanium is formed which reacts with the bromoethane to give ethyl radicals and titanium tetrabromide which re-enters the reaction cycle.

Phosphorus Isocyanates

By G. I. Derkatsch[*]

Compounds containing the PNCO grouping can be obtained e.g. from phosphorus halides and silver cyanate or esters of N-chloroiminocarbonic acid and by thermal decomposition of alkoxycarbonylimino-phosphoranes. The phosphorus(v) isocyanates resemble the "carbon" isocyanates in their chemical properties, whereas the phosphorus(III) isocyanates resemble the phosphorus(III) chlorides. Some of the compounds discussed have insecticidal or cytostatic actions.

Aryl, alkyl, and acyl isocyanates have been known for more than a century, and have been very extensively studied. On the other hand, compounds in which the NCO groups are bound to an element other than carbon (P, As, Si, Sn, B, *etc.*) have only recently been prepared.

The first phosphorus isocyanates were actually obtained as early as 1940, but until 1954 the substances in this class were difficult to prepare, and practically no investigations had been carried out on them. The rapid development of this field began only with the discovery of simpler and more convenient methods of preparation.

Phosphorus isocyanates are used, *inter alia*, for the preparation of phosphorylated urethanes and ureas. Some of them are physiologically very active, and have found practical use as insecticides and drugs (see Section 4).

The following types are known at present:

Phosphorus(III) isocyanates: X_2PNCO and $XP(NCO)_2$ with X = Hal, alkoxy, aryloxy, alkyl, and aryl; also $P(NCO)_3$ and $P_2(NCO)_4$.

Phosphorus(v) isocyanates: $X^1X^2P(O)NCO$ with $X^1 = X^2$ = Hal, alkyl, aryl, alkoxy, aryloxy, dialkylamino, diarylamino; X^1 = Hal, X^2 = alkoxy, aryloxy, alkyl, or aryl; X^1 = alkyl or aryl, X^2 = alkoxy, aryloxy, dialkylamino, diarylamino; $XP(O)(NCO)_2$ with X = Hal, alkoxy, aryloxy, alkyl, aryl; $(RO)_2P(X)NCO$ with R = alkyl or aryl, X = S, NCOR; also $P(O)(NCO)_3$, $P(S)(NCO)_3$, and $P_3N_3Cl_4(NH_2)NCO$ (2-amino-2,4,6,6-tetrachloro-4-isocyanato-1,3,5-triaza-2,4,6-triphospha^{V}cyclohexane).

The phosphorus isocyanates are very reactive, and they can be prepared from readily obtainable starting materials. Alcohols, phenols, amines, and other substances containing active hydrogen atoms add readily to the NCO group in these compounds. In some cases the NCO group reacts as a pseudohalogen, and can be replaced as a unit by other groups. Phosphorus isocyanates in which halogen atoms are also attached to the phosphorus atom can react at two points in the molecule.

1. Preparation of Phosphorus Isocyanates

1.1. Reaction of Cyanic Acid and its Salts with Phosphorus Halides

Alkyl and acyl isocyanates were until recently obtainable only from halogeno-alkanes or acyl halides and metal cyanates[1,2]. More convenient preparation methods were proposed only during the last few years[3–6], and the first phosphorus(III) isocyanates were prepared by a reaction based on the old method, *i.e.* from phosphorus halides and silver cyanate. *Anderson* and *Forbers*[7] showed that phosphorus triisocyanate is formed on reaction of silver cyanate with phosphorus trichloride in boiling benzene:

$$PCl_3 + 3\,AgOCN \rightarrow P(NCO)_3 + 3\,AgCl$$

This compound is also formed from silver cyanate and phosphorus triiodide in nitromethane[8,9].

When silver cyanate is slowly introduced into an excess of phosphorus trichloride Cl_2PNCO and $ClP(NCO)_2$ are obtained[10]. Cl_2PNCO can also be prepared by heating a mixture of phosphorus trichloride and phosphorus triisocyanate vapors[11]. Alkyl- and aryldichlorophosphines[12–14] and methyldibromophosphine[15] react similarly:

$$RPCl_2 + 2\,AgOCN \rightarrow RP(NCO)_2 + 2\,AgCl$$

Phosphorus(III) isocyanates (such as phosphorus triisocyanate) have recently been obtained from phos-

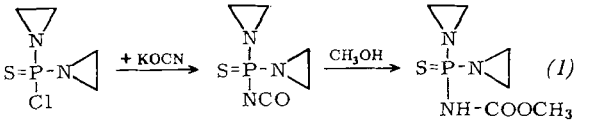
phorus chlorides and potassium, sodium, and lithium cyanates in benzene or sulfur dioxide [16–19].

The action of silver cyanate on phosphoryl or thiophosphoryl trichloride yields mixtures of phosphoryl triisocyanate and phosphoryl tricyanate or the corresponding thio compounds.

$$POCl_3 + 3\,AgOCN \rightarrow PO(NCO)_3 + PO(OCN)_3 + 3\,AgCl$$



The liquid isocyanates can be separated very readily from the solid cyanates by distillation [20, 21].

Alkyl- and arylphosphonic dichlorides react with silver cyanate to give only isocyanates [12, 22, 23]:

$$RPOCl_2 + 2\,AgOCN \rightarrow RPO(NCO)_2 + 2\,AgCl$$

Isocyanates can similarly be obtained from diphenylphosphinic chloride [24, 25] and tetraiodobiphosphine [26], whereas the reactions of $RO(CH_3)P(O)Cl$ [27], $ROP(O)ClF$ [28], and $RP(O)ClF$ [29] with NaOCN lead only to replacement of the chlorine atoms by the isocyanate group.

Potassium cyanate reacts with bis(aziridin-1-yl)thiophosphoryl chloride in methanol to form methyl *N*-[bis(aziridin-1-yl)-phosphoryl]-carbamate *(1)*. An isocyanate is probably formed as an intermediate. Compound *(1)* is very unstable, and readily forms polymers in the presence of water [30].

(1)

In the presence of triethylamine or pyridine alkoxydichlorophosphines react very readily with cyanic acid to form alkoxydicyanatophosphines in yields of about 50 to 60 %.

$$AlkOPCl_2 + 2\,HNCO \xrightarrow{2\,(C_2H_5)_3N} AlkOP(NCO)_2 + 2\,(C_2H_5)_3NHCl$$

Phosphoryl chlorides give only polymers on reaction with cyanic acid, and in many cases do not react at all [5].

1.2. Reaction of Difluorophosphoric Anhydride with Potassium Cyanate

Difluorophosphoric anhydride reacts with potassium cyanate to form phosphoryl difluoride isocyanate:

$$(F_2PO)_2O + KOCN \rightarrow F_2P(O)NCO + K(PO_2F_2)$$

After filtration of the reaction mixture, the product can be distilled off under normal pressure (yield 50 to 55 %) [31].

1.3. Thermal Decomposition of Alkoxycarbonyliminophosphoranes

Kirsanov found in 1955 that phosphorus pentachloride reacts very readily with alkyl carbamates. The reaction yields alkoxycarbonyliminotrichlorophosphoranes, which lose alkyl chloride when heated to form phosphoryl dichloride isocyanate [32–37]:

$$AlkOCONH_2 + PCl_5 \rightarrow 2\,HCl + AlkOCON{=}PCl_3 \rightarrow Cl_2P(O)NCO + AlkCl$$

The decomposition of the methyl and ethyl compounds begins at 21–25 °C, and proceeds to completion at 65–70 °C. The mixture must be heated very slowly since the reaction is strongly exothermic and much gas is evolved so that explosions may occur if heating is fast. The higher the molecular weight of the alkyl groups, the more stable are the phosphoranes and the less vigorous their decomposition. The methyl and ethyl compounds are the most suitable for the preparation of phosphoryl dichloride isocyanate. The intermediate of the reaction, which proceeds almost quantitatively, need not be separated [32, 34, 36].

The reaction of methyl carbamate with alkyl and aryltetrachlorophosphoranes such as CCl_3PCl_4, CH_3PCl_4, and $C_6H_5PCl_4$ yields mixtures of phosphonic chloride isocyanates and phosphonic dichlorides [38, 39].

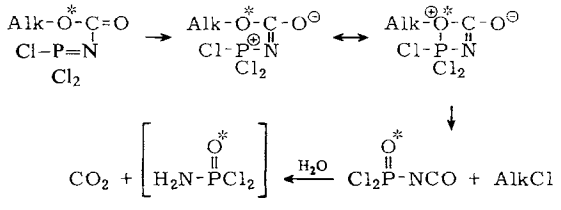
[39] *V. I. Shevshchenko*, *A. S. Stepanek*, and *A. V. Kirsanov*, Ž. obšč. Chim. *31*, 3062 (1961).

All chlorophosphazo compounds $AlkOCON{=}PX_2Cl$ with at least one chlorine atom attached to the phosphorus can decompose as follows [38–45]:

$$AlkOCON{=}PX_2Cl \rightarrow X_2P(O)NCO + AlkCl$$
(X = Alk, Ar, ArO, Cl, *etc.*)

However, unlike the trichlorophosphorane derivatives $AlkOCON{=}PCl_3$, the monochloro and dichloro compounds are obtained only in low yields or not at all by the Kirsanov reaction. In 1963 we found a new general and convenient method for the preparation of similar compounds [40–45], *i.e.* the reaction of *N*-chloroiminocarbonates with phosphorus(III) halides.

$$(AlkO)_2C{=}NCl + X_2PCl \rightarrow [(AlkO)_2C{=}NPX_2Cl]^{\oplus}Cl^{\ominus} \rightarrow AlkCl + AlkOCON{=}PX_2Cl \rightarrow X_2P(O)NCO + AlkCl$$



The intermediates need not be isolated.

This method is not suitable for the preparation of alkylphosphonic chloride isocyanates Alk(Cl)P(O)NCO, since the decomposition of the phosphorane proceeds in two directions simultaneously:

$$C_2H_5OCON{=}P(Alk)Cl_2 \rightarrow \begin{cases} AlkP(O)Cl_2 + (C_2H_5OCN)_n \\ Cl(Alk)P(O)NCO + C_2H_5Cl \end{cases}$$

The products can be separated only with great difficulty by distillation [45].

Phosphoryl dichloride isocyanate, $Cl_2P(O)NCO$, is obtained only in low yields from diethyl *N*-chloroiminocarbonate; the main product is a polymer of unknown structure [46].

The thermal decomposition of alkoxycarbonyliminotrichlorophosphoranes has also been studied with the aid of compounds labeled with ^{18}O [32, 33, 42, 47].

1.4. Thermal Decomposition of Alkyl Phosphorylcarbamates

Alkyl dialkoxy- or diaryloxyphosphorylcarbamates can be converted into phosphorus(v) isocyanates by heating to eliminate alcohol [48–50], the products in this case being diesters of isocyanatophosphoric acid. Since the reaction

$$(RO)_2P(O)NHCOOAlk \rightleftharpoons (RO)_2P(O)NCO + AlkOH$$

is reversible, the alcohol must be removed.

Several phosphorus(v) isocyanates can be prepared in good yields from the readily obtainable phosphoryl dichloride isocyanates (*via* the carbamates):

$$AlkOCONHP(S)(OR)_2 \rightarrow (RO)_2P(S)NCO + AlkOH \quad [51]$$

$$AlkOCONHP(O)[N(C_2H_5)_2]_2 \rightarrow [(C_2H_5)_2N]_2P(O)NCO + AlkOH \quad [45, 52]$$

$$AlkPO(NHCOOAlk)_2 \rightarrow AlkP(O)(NCO)_2 + 2\,AlkOH \quad [53]$$

1.5. Action of Oxalyl Chloride on Phosphoric Ester Amides

Carbonamides and sulfonamides react with oxalyl chloride to form acyl and sulfonyl isocyanates [2–4]. We found in 1965 that phosphoric and thiophosphoric diester amides react in a similar manner with oxalyl chloride to form diesters of isocyanatophosphoric and isocyanatothiophosphoric acids, frequently together with small quantities of phosphorylated oxalic amides:

$$(RO)_2P(X)NH_2 + (COCl)_2 \rightarrow (RO)_2P(X)NCO + 2\,HCl + CO \quad (X = O, S)$$

In the reaction of oxalyl chloride with diaryl phosphoramidates, it is possible to isolate the intermediate *(2)*:

$$(ArO)_2P(O)NH_2 + (COCl)_2 \rightarrow HCl + \underset{(2)}{(ArO)_2P(O)NHCOCOCl} \rightarrow HCl + CO + (ArO)_2P(O)NCO$$

Very reactive and thermally unstable *N*-phosphoryloxalamide chlorides probably also occur in the other cases. Depending on the substituents on the phosphorus atom, they decompose completely into phosphorus isocyanates or undergo partial reaction with the starting compound to form *N,N*-diphosphoryloxamides *(3)*.

Phosphorus(v) isocyanates can be prepared very conveniently by this method in yields of up to 70 to 80 % [54,55].

X = O, S
R = Alkyl, Aryl

(3)

The cyclotriphosphazene derivative *(4)* also reacts similarly with phosgene[56].

1.6. Other Syntheses of Phosphorus(v) Isocyanates

Alkyl and aryl isothiocyanates react very readily with mercuric oxide or silver oxide to form alkyl and aryl isocyanates[1,57]. The phosphorus(v) isothiocyanates, on the other hand, decompose under these conditions to give mercury dithiocyanate and esters of diphosphoric acid:

$$2(RO)_2P(O)NCS + HgO \rightarrow Hg(SCN)_2 + (RO)_2P(O)-O-P(O)(OR)_2$$

Phosphorus(v) isothiocyanates are converted by the action of chlorine into the very reactive *N*-dichloromethylenephosphoric diester amides, which react with formic acid to give phosphorus(v) isocyanates.

$$(RO)_2P(O)NCS + Cl_2 \rightarrow [(RO)_2P(O)NC(Cl)-SCl] \xrightarrow[-SCl_2]{+\ Cl_2}$$

$$(RO)_2P(O)N=CCl_2 \xrightarrow{+\ HCOOH} (RO)_2P(O)NCO + 2HCl + CO$$

N-Dichloromethylenealkylphosphonic amide chloride and *N*,*N*-bis(dichloromethylene)alkylphosphonamide react similarly with formic acid or acetic acid to give phosphorus(v) isocyanates[58–60]:

$$AlkP(O)(Cl)N=CCl_2 + HCOOH \rightarrow Alk(Cl)P(O)NCO + 2HCl + CO$$

Trialkyl and triaryl phosphites react with phosphorus triisocyanate and phosphoryl triisocyanate in accordance with the following scheme[61]:

$$(RO)_3P + P(NCO)_3 \rightarrow ROP(NCO)_2 + (RO)_2PNCO$$
$$(RO)_3P + PO(NCO)_3 \rightarrow ROP(O)(NCO_2) + (RO)_2P(O)NCO$$

The reaction of alkoxydiisocyanatophosphine with chlorine leads to phosphoryl chloride diisocyanate in a yield of about 70 %:

$$AlkOP(NCO)_2 + Cl_2 \rightarrow [AlkOP(NCO)Cl_2] \rightarrow ClP(O)(NCO)_2 + AlkCl$$

Bromine reacts similarly[62].

Alkyl chloroisocyanatophosphates are formed from dialkoxyisocyanatophosphine and chlorine.

$$(AlkO)_2PNCO + Cl_2 \rightarrow AlkO(Cl)P(O)NCO$$

These products can also be obtained by the reaction of dialkyl isocyanatophosphates with phosphorus(v) chloride or from the corresponding thio compound and chlorine[63].

The reaction of tetraisocyanatosilane with phosphoryl fluoride yields phosphoryl difluoride isocyanate[64]:

$$Si(NCO)_4 + POF_3 \rightarrow F_2P(O)NCO$$

(for further information on the preparation and/or properties of phosphoryl isocyanates, see[101,104–116]).

2. Properties of Phosphorus Isocyanates

All phosphorus isocyanates are highly reactive. The phosphorus(v) isocyanates behave similarly to "carbon" isocyanates. They react very readily with alcohols, phenols, some amines, and other compounds bearing active hydrogen atoms, and can therefore serve as important starting materials for the synthesis of derivatives of phosphoric acid, phosphonic acid, and phosphinic acid.

Phosphorus(III) isocyanates often exhibit chemical properties similar to those of phosphorus(III) chloride. The NCO groups show only a slight, if any, tendency to enter into addition reactions.

2.1. Chemical Properties of Phosphorus(III) Isocyanates

2.1.1. Stability

Phosphorus(III) isocyanates decompose even in the absence of air and moisture. Their stability increases in the series $P(NCO)_3 < ClP(NCO)_2 < Cl_2PNCO$.

$ClP(NCO)_2$ can be distilled under vacuum and kept for some time in a sealed vessel. On distillation under normal pressure

[62] *G. I. Derkatsch* and *E. I. Slussarenko*, Ž. obšč. Chim. *37*, 2069 (1967).

[63] *A. V. Narbut* and *G. I. Derkatsch*, Ž. obšč. Chim., in press.

[64] *O. Glemser*, *U. Biermann*, and *M. Field*, Chem. Ber. *100*, 1082 (1967).

it is completely converted into phosphorus triisocyanate and phosphorus dichloride isocyanate[7,11].

$$2ClP(NCO)_2 \rightarrow Cl_2PNCO + P(NCO)_3$$

2.1.2. Substitution of the NCO Groups

The reaction of phosphorus triisocyanate with antimony trifluoride yields phosphorus difluoride isocyanate and phosphorus fluoride diisocyanate[65]. The reaction of phosphorus triisocyanate and benzoyl chloride or aluminum chloride proceeds similarly[66]:

$$P(NCO)_3 + 2C_6H_5COCl \rightarrow Cl_2PNCO + 2C_6H_5CONCO$$
$$P(NCO)_3 + AlCl_3 \rightarrow PCl_3 + Al(NCO)_3$$

Phosphorus triisocyanate reacts very readily with chlorine to give phosphorus dichloride triisocyanate, and with iodine to give $P(NCO)_3 \cdot I$[67]. Other phosphorus(III) isocyanates (*e.g.* Cl_2PNCO, $(ArO)_2PNCO$, and Ar_2PNCO) can also add chlorine.

The reaction of sulfur tetrafluoride with phosphorus triisocyanate or phosphorus fluoride diisocyanate leads to $F_2S{=}NCOF$[68]. Phosphorus triisocyanate reacts with tetracarbonylnickel to form $Ni[P(NCO)_3]_4$[69] and with ethylene oxide to form isocyanato-bis(β-isocyanatoethoxy)phosphine. This reaction can also be carried out with other phosphorus isocyanates[70,71]:

$$P(NCO)_3 + (CH_2)_2O \rightarrow OCNP(OCH_2CH_2NCO)_2$$

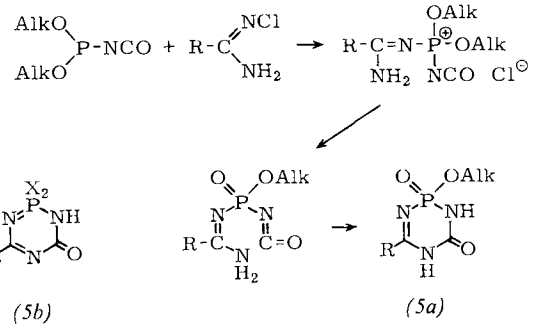
2.1.3 Other Reactions

The reaction of alkoxy- or aryloxyisocyanatophosphines with alcohols leads to substitution or addition[72].

$$ROP(NCO)_2 \xrightarrow{R'OH} ROP(OR')_2$$

$$ROP(NCO)_2 \xrightarrow{R'OH} ROP(NHCOOR')_2$$

Other phosphorus(III) isocyanates, like their phosphorus(V) analogs, undergo only addition with alcohols, amines, or ketones[12,13,73,74].



On reaction with SO_2Cl_2 or sulfur, the phosphorus(III) isocyanates are oxidized to phosphorus(V) compounds[20,75]:

$$C_6H_5OP(NCO)_2 + SO_2Cl_2 \rightarrow C_6H_5OP(O)(NCO)_2 + SOCl_2$$
$$P(NCO)_3 + S \rightarrow PS(NCO)_3$$

Dialkoxy- or diaryloxyisocyanatophosphines react with alkyl iodides in accordance with the Arbusov scheme to give alkylphosphonic ester isocyanates[76].

$$(RO)_2PNCO + AlkI \rightarrow RI + Alk(RO)P(O)NCO$$

whereas dialkoxyisocyanatophosphines and *N*-chloroamidines give very unstable phosphonium compounds, which are readily converted into phospha^{V}triazine derivatives *(5a)*.

(5b) *(5a)*

Diaryloxyisocyanatophosphines and dichloroisocyanatophosphines, on the other hand, react with *N*-chloroamidines *via* similar intermediates to form 2,2-diaryloxy- and 2,2-dichloro-3,4-dihydrophospha^{V}triazin-4-ones *(5b)*[76].

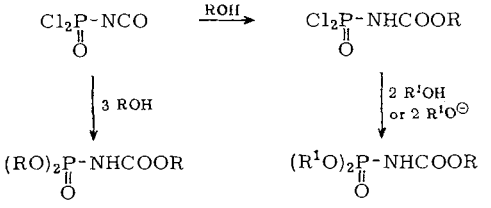
2.2 Chemical Properties of Phosphorus(V) Isocyanates

2.2.1. Reaction with Water

Phosphoryl dichloride isocyanate is very readily decomposed by water into carbon dioxide, hydrogen chloride, and ammonium dihydrogen phosphate; with concentrated hydrochloric acid at −20 °C, on the other hand, it forms *N*-(dichlorophosphoryl)carbamic acid, which slowly loses hydrogen chloride at room temperature and reacts with alcohols to give trialkyl phosphates. Reaction with phosphorus(V) chloride regenerates the starting material:

$$Cl_2P(O)NCO + H_2O \xrightarrow[HCl]{} Cl_2P(O)NHCOOH$$
$$Cl_2P(O)NHCOOH + PCl_5 \rightarrow Cl_2P(O)NCO + 2HCl + POCl_3$$

N-(Dichlorophosphoryl)corbomic acid changes under vacuum at 160 °C into phosphoryl dichloride isocyanate, hydrogen chloride, and polymers[77].



Diesters of isocyanatophosphoric acid are decomposed by water into phosphoric diester amides. The reaction probably proceeds *via* very unstable carbamic acid derivatives[35,49].

2.2.2. Reaction with Alcohols and Phenols

Phosphoryl isocyanates react very readily with equimolar quantities of alcohols and phenols to form phos-

phorylcarbamic esters [12, 13, 23, 34, 38, 53–55, 73, 75, 77–82]. The reaction is carried out in benzene, dioxane, petroleum ether, or ether [78, 79] (see also [35, 41, 49]).

Reaction with an excess of alcohol yields *N*-(dialkoxyphosphoryl)carbamic esters, which can also be prepared from *N*-(dichlorophosphoryl)carbamic esters and alcohols or alkoxides.

This stepwise reaction is recommended for the preparation of *N*(-(dialkoxyphosphoryl)carbamic esters with different alkyl groups [36, 78]. The phosphoryl dichloride isocyanate is first allowed to react with an equimolar quantity of one alcohol and then, without isolation of the carbamic ester, with two molar equivalents of another alcohol or alkoxide. Esters of *N*-(dialkoxyphosphoryl)carbamic acids with different alkoxy groups on the phosphorus can also be prepared [50].

N-(Dichlorophosphoryl)carbamic esters also react very readily with ammonia and with primary and secondary amines to form *N*-(diaminophosphoryl)carbamic esters [83–85].

Compounds with several phosphorylcarbamic acid groups in the molecule can be prepared by the action of polyhydroxy compounds on diesters of isocyanatophosphoric acid [80], *e.g.*:

$$2(RO)_2PONCO + p\text{-}HOC_6H_4OH \rightarrow p\text{-}[(RO)_2PONHCOO]_2C_6H_4$$

When *N*-(dialkoxyphosphoryl)carbamic esters are heated with aniline, urea derivatives are formed [87].

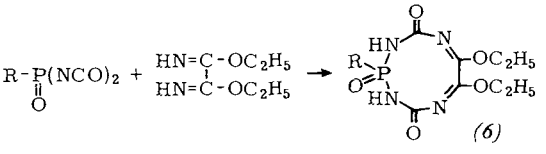
$$(AlkO)_2P(O)NHCOOAlk + C_6H_5NH_2 \rightarrow AlkOH + (AlkO)_2P(O)NHCONHC_6H_5$$

2.2.3. Reaction with Nitrogen Bases

Phosphoryl isocyanates react with amines and hydrazines to form phosphorylated urea and semicarbazide derivatives [86, 93]:

$$>P(O)NCO + HN< \rightarrow >P(O)NHCON<$$
$$>P(O)NCO + H_2NN< \rightarrow >P(O)NHCONHN<$$

If halogen atoms as well as NCO groups are bound to the phosphorus atom, these can also react with amines, though rather more slowly. Thus, reaction of these compounds with equimolar quantities of nitrogen bases leads almost exclusively to addition of NCO groups.



Phosphoryl dichloride isocyanate, phosphoryl difluoride isocyanate, and the mixed compound react with equimolar quantities of amines to form *N*-dihalogenophosphorylureas [86, 93]. Primary amines react with NCO groups more readily than do secondary amines.

Amidines and alkyl esters of imidic acids react only very slowly with phosphoryl isocyanates to form the expected products [35, 88–91].

The action of 2 mol. equiv. of *N*,*N*-dimethylhydrazine or an excess of hydrazine on phosphoryl dichloride isocyanate yields salts of dichlorophosphorylsemicarbazides [92]:

$$Cl_2P(O)NCO + 2(CH_3)_2NNH_2 \rightarrow (CH_3)_2N\overset{\oplus}{N}H_3Cl_2P(O)\overset{\ominus}{N}\text{–}CONHN(CH_3)_2$$
$$2Cl_2P(O)NCO + 3NH_2NH_2 \rightarrow 2NH_2\overset{\oplus}{N}H_3Cl_2P(O)\overset{\ominus}{N}\text{–}CONHNHCO\text{–}\overset{\ominus}{N}P(O)Cl_2$$

Esters of chloroisocyanatophosphoric acid and phosphonic chloride isocyanates react much more slowly than phosphoryl dihalide isocyanates with amines to give urea derivatives [38, 39]. Both isocyanate groups in phosphonic diisocyanates can react with amines to give cyclic compounds such as *(6)* [12, 13, 53, 62, 80].

(6)

The reaction of isocyanatophosphoric diesters with amines or ammonia yields *N*-phosphorylureas [53, 55, 59, 88, 89] or phosphoric ester amides [49, 75], whereas reaction with hydrazines leads to *N*-phosphorylsemicarbazides [92].

2.2.4. Other Reactions

When phosphoryl dichloride isocyanate is heated with PCl_5 in a closed ampoule at 200 °C, cyanogen chloride and phosphoryl chloride are formed [94].

Phosphoryl isocyanates behave in the same way as alkyl and aryl isocyanates in reactions with diesters of phosphorous acid in the presence of organic bases [95]. Phosphorylcarbamic acid derivatives are formed [96]:

$$(RO)_2P(O)NCO + (RO)_2POH \rightarrow (RO)_2P(O)NHCOP(O)(OR)_2$$

Phosphoryl triisocyanate reacts with acetone or acetophenone in boiling toluene to form acylamides [74]:

$$RCOCH_3 + P(O)(NCO)_3 \rightarrow P(O)(NHCOCH_2COR)_3$$

When treated with SbF_3, phosphoryl dichloride isocyanate gives a mixture of phosphoryl chloride fluoride and difluoride (5–10 and 50% yield respectively) [35,86,97]. The reaction of phosphoryl chloride diisocyanate with SbF_3 leads to phosphoryl fluoride diisocyanate and phosphoryl difluoride isocyanate [62].

2.3. IR and NMR Spectra of Phosphorus Isocyanates

In the IR spectra of phosphorus isocyanates, the NCO bands occur between 2430 and 2260 cm^{-1} [14,15,25,26,31,56,62,82,86].

In 1964, *Fluck* investigated the ^{31}P-NMR spectra of phosphorus isocyanates and phosphorus isothiocyanates. According to this work the NCO and NCS groups lie between Cl and Br on the electronegativity scale.

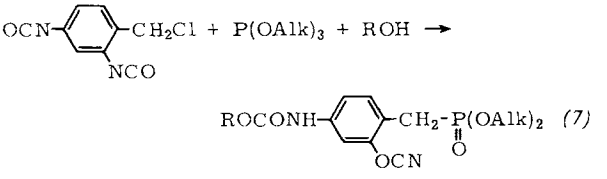
3. Organophosphorus Compounds Containing NCO Groups that are Not Directly Bound to the Phosphorus

The reaction of tris(chloromethyl) phosphate with AgOCN yields tris(isocyanatomethyl) phosphate [98]:

$$PO(OCH_2Cl)_3 + 3\,AgOCN \rightarrow 3\,AgCl + PO(OCH_2NCO)_3$$

Tris(*p*-nitrophenyl)phosphate, which can be obtained by nitration of triphenyl phosphate with concentrated nitric acid, can be hydrogenated in the presence of Raney nickel to form tris(*p*-aminophenyl) phosphate, which is converted into the isocyanate in the presence of phosgene.

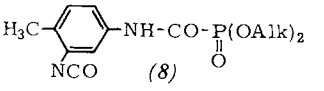
$$PO(OC_6H_5)_3 \xrightarrow{HNO_3} PO(OC_6H_4NO_2\text{-}p)_3 \xrightarrow{H_2} PO(OC_6H_4NH_2\text{-}p)_3 \xrightarrow{COCl_2} PO(OC_6H_4NCO\text{-}p)_3$$



Ester amides of phosphoric acid are not all resistant to phosgene. Whereas bis(*p*-aminophenyl) *N*-methylanilidophosphate is smoothly converted into the diisocyanate on phosgenation, the *N,N*-dimethylamido derivative is cleaved under the same conditions into *N,N*-dimethylcarbamoyl chloride and bis(*p*-isocyanatophenyl) chlorophosphate.

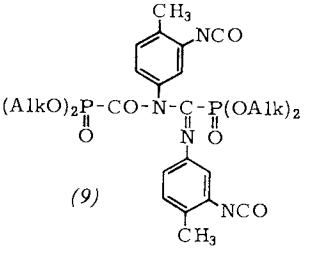
$$C_6H_5N(CH_3)PO(OC_6H_4NH_2\text{-}p)_2 \xrightarrow{COCl_2} C_6H_5N(CH_3)PO(OC_6H_4NCO\text{-}p)_2$$

$$(CH_3)_2NPO(OC_6H_4NH_2\text{-}p)_2 \xrightarrow{COCl_2} (CH_3)_2NCOCl + ClPO(OC_6H_4NCO\text{-}p)_2$$



Diethyl *p*-aminophenyl thiophosphate and (particularly smoothly) tris(*p*-aminophenyl) thiophosphate also react with phosgene to form the isocyanates. Bis(3-amino-4-methylphenyl) styrylphosphonate can also be readily converted into the corresponding isocyanato ester by reaction with phosgene [99,100].

Isocyanates containing phosphonic ester groups can be prepared by the Arbusov reaction. Thus the simultaneous action of equimolar quantities of trialkyl phosphite and alcohol on 2,4-diisocyanatobenzyl chloride yields phosphorylated isocyanates *(7)*. Reaction with trialkyl phosphite alone gives only polymers.



(7)

Similarly, *N*-(3-isocyanato-4-methylphenyl)carbamoyl chloride can be converted into the phosphonic esters *(8)* by reaction with trialkyl phosphites. The compound *(9)* has been obtained by a multistage process from1,3-bis(chlorocarbonylamino)-4-methylbenzene.

(8)

(9)

Esters of phosphoric acid containing isocyanate groups are used as starting materials for the production of polymers containing phosphorus [99,100]. Alkylphosphonic diisocyanates also react very readily with aliphatic and aromatic diols to give polyurethanes with phosphorus in the main chain. The reaction with diamines proceeds similarly (see Table 1) [12,13].

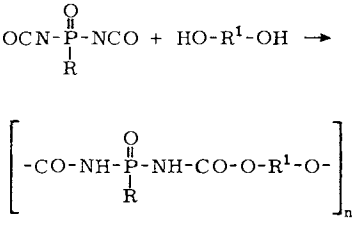


Table 1. Polymers from $C_2H_5P(O)(NCO)_2$ and diols or diamines.

Reactant	Product
1,6-Hexanediol	Colorless tacky mass, sparingly soluble in boiling ethanol, insoluble in water
Resorcinol	Solid, m.p. 75 °C, soluble in acetone, insoluble in toluene and chloroform
Hydroquinone	Vitreous, m.p. 200 °C, incombustible
p-Phenylenediamine	Solid, m.p. 300 °C, insoluble in water, ethanol, pyridine, 6N HCl

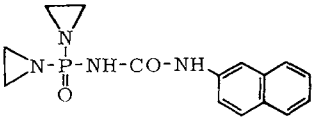
4. Physiological Action of Phosphorus Isocyanates

Phosphorus isocyanates hydrolyze very readily, and this limits their use as physiologically active substances. Only one phosphorus isocyanate derivative has so far been marketed as a herbicide [97]. It is quite possible that the action of the preparation is due not to the phosphorus isocyanate itself, but to its reaction products. *N*-Phosphorylated urethanes and ureas are accordingly of great interest as potential physiologically active substances [35, 42].



(10), R = R^1 = R^2 = CH_3
(11), R = R^1 = $(CH_3)_2CH$, R^2 = CH_3
(12), R = C_2H_5, R^1 = $(CH_3)_2CH$, R^2 = CH_3
(13), R = CH_3, R^1 = R^2 = $(CH_3)_2CH$
(14), R = C_2H_5, R^1 = R^2 = $(CH_3)_2CH$
(15), R = CH_3, R^1 = C_2H_5, R^2 = $(CH_3)_2CH$

N-Phosphorylated urethanes of the AlkOCONHPO-$(OR)_2$ type are systemic insecticides. *N*-(Dimethoxyphosphoryl)carbamic-acid methyl (K-20-35) *(10)* and isopropyl esters (avenin) *(11)* have proved to be particularly effective, and are completely harmless to warm-blooded animals. According to *Kagan*, rats fed with 15 daily doses of K-20-50 at a rate of 500 mg/kg showed no ill effects. A single peroral administration of more than 5000 mg and an intravenous administration of 500 mg of preparation per kg of body weight were also found to be harmless [102].

K-20-35 and avenin have a high toxicity for sugar-beet weevils (*Bothynoderes*) and some insects of the order Diptera; on the other hand, both preparations are practically ineffective against sucking insects. If the preparations are applied to sugar-beet seeds before sowing or to shoots, they provide protection during the dangerous early period of about two weeks. Avenin is more active and remains effective for a longer time (12–15 days) than K-20-35 (about 14 days). Some analogs of avenin with different alkoxy groups on the phosphorus atom have a contact action as well as an internal action. The activity of these compounds is strongly dependent on the nature and stage of development of the insect. The strongest contact action is shown by the compounds *(12)–(14)*, while *(13)* and *(15)* have the greatest internal activity.

N-[Bis(aziridin-1-yl)phosphoryl]urethanes and *N*-[bis-(aziridin-1-yl)phosphoryl]-*N'*-arylureas have a cytostatic action [103]. Thus the development of experimental tumors in animals is strongly hindered *e.g.* by *N*-[bis(aziridin-1-yl)phosphoryl]-*N'*-β-naphthylurea *(16)* (Preparation No. 484, BNMPh, dinaphthimine).

(16)

Dinaphthimine has a very low toxicity; its lethal dose (LD_{50}) for rats is 79.0 mg/kg by subcutaneous injection, and the therapeutic dose is 15 mg/kg. Dinaphthimine in therapeutic doses also has only a slight homotoxicity (the total quantity of leukocytes in the peripheral blood of the animal has fallen by not more than 50 % at the end of the treatment, and rapidly returns to the normal value). Unlike the azirine derivatives of phosphoric acid, which are suitable only for intravenous or intramuscular injection, the new preparation can be administered subcutaneously.

Dinaphthimine has proved to be a very active agent for the treatment of leukemia in rats and mice. When 15 mg of the preparation per kg of body weight were injected subcutaneously six or even eleven days after production of the disease, all the animals examined were cured after 10–15 injections, whereas control animals survived for only 13–18 days. The blood of the experimental animals was practically free from leukoblasts at the end of the treatment, and morbid changes in other organs had also disappeared. No harmful effect of dinaphthimine on other organs could be observed.

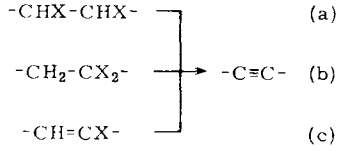
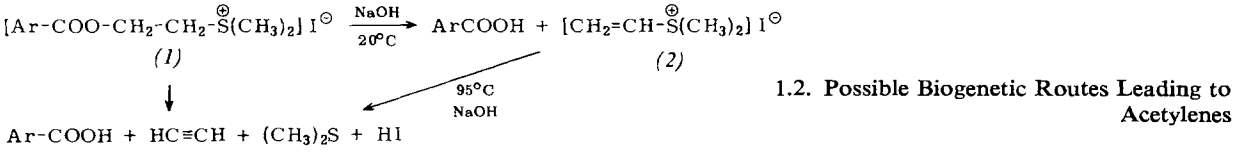
Synthesis of Alkynes from Enol Esters



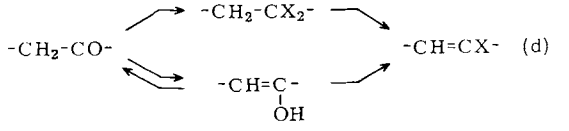
By J. Cymerman Craig, M. D. Bergenthal, I. Fleming, and J. Harley-Mason[*]

Eliminations leading from enol sulfonates, enol phosphates, and enol phosphonium salts to alkynes are reviewed. Olefin eliminations are usually the rate-determining step in the formation of the triple bond. Enol esters may also play a role in the biosynthesis of alkynes.

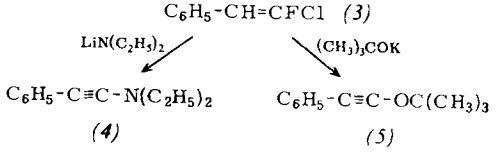


1. Introduction

1.1. General Elimination Methods Leading to Acetylenes



In the laboratory, acetylenes are usually prepared by elimination reactions according to equations (a), (b), or (c), where X = halogen or an equivalent "leaving group" (*e.g.*, tosylate), and the reagent is a strong base [1–5].



The alkaline fission of 2-aroyloxyethyldimethylsulfonium iodides *(1)*, which were found [6] to undergo double elimination to give acetylene, was regarded as an example of method (a). However, later studies revealed [7] that the reaction actually proceeds in two stages, of which the first leads to elimination of benzoate ion and the formation of dimethylvinylsulfonium iodide *(2)* which breaks down only at 95 °C. The step by which the triple bond is formed is therefore, in fact, an example of method (c).

The starting material in method (b) is generally the ketone; this may either be transformed into the dihaloderivative, and thence (by ready loss of hydrogen halide) into the halo-olefin, *or* halogenation of the enol form of the ketone may lead directly to the halo-olefin [equation (d)]. In either case it is clear that the acetylene-forming step is again an example of reaction (c).

The dehydrohalogenation of the fluoro-olefin 2-chloro-2-fluorostyrene *(3)* affords [8] the inamine *(4)* and the ethynyl ether *(5)*.

The present article will survey only the methods of carrying out the elimination reaction by procedure (c) when the olefinic derivative is an enol ester or a closely related compound.

1.2. Possible Biogenetic Routes Leading to Acetylenes

Whereas in 1950 only about seven naturally occurring acetylenes were known, this figure has now risen to a total of more than 450 and several valuable reviews exist [9–14]. All known natural acetylenes and polyacetylenes are long-chain compounds, sometimes cyclized in various ways, but never branched, and ranging in carbon content from C-8 to C-18. A relationship to the fatty acids therefore suggests itself

immediately, and direct experimental evidence testifying to the correctness of this assumption has been obtained.

It has been shown that the molecules of natural acetylenes are built up from acetyl-coenzyme A. Thus alternate carbon atoms of C-10 and C-18 acetylenes were found to be uniformly labeled when [1-^{14}C]acetate is incorporated, showing that the molecule is built up from acetate units in a regular fashion [15,16].

It has been demonstrated that the synthesis involves the repeated condensation of acyl-coenzyme A derivatives with malonyl-coenzyme A (formed by carboxylation of acetyl-coenzyme A). Thus it was shown by using [2-^{14}C]malonate, that the C-10 alcohol *(6)* from *Tricholoma grammopodium* (dehydromatricarianol) contained ^{14}C only in the C-1–C-8 part of the chain,

$$OH-CH_2-CH=CH-C\equiv C-C\equiv C-C\equiv C-CH_3$$
(6)

and not in the terminal two-carbon unit comprising C-9 and C-10, which was presumably formed directly from acetyl-coenzyme A [17,18]. This pattern may be described as the "acetate + *n*-malonate pathway", in which the overall reaction can be represented as in equation (e).

$$H_3C(C=O)X + CH_2(COO^{\ominus})-C(=O)X \rightarrow X^{\ominus} + CH_3-C\equiv C-C(=O)X + CO_2 + H_2O \quad (e)$$

X = SCoA

Whereas the overall reaction in fatty acid synthesis is as in equation (f).

$$H_3C(C=O)X + CH_2(COO^{\ominus})-C(=O)X \xrightarrow{4\,H} X^{\ominus} + CH_3-CH_2-CH_2-C(=O)X + CO_2 + H_2O \quad (f)$$

X = SCoA

In both cases the common intermediate is the acetylmalonate derivative *(7)*, and this led to the attractive suggestion [19] that acetylenes such as *(8)* might arise by the simultaneous decarboxylation and elimination reaction of enol derivatives of acylmalonic acid [equation (g)].

$$CH_3-C(=O)-CH(COO^{\ominus})-C(=O)X \quad (7)$$

The leaving group could be *e.g.* the pyrophosphate anion [19], and the resulting acetylenic coenzyme A derivative could then react further with malonyl-coenzyme A and repeat the process to build up a diacetylenic derivative, and then a polyacetylenic acid. This pathway for polyacetylene synthesis *via* acylmalonate enols could therefore be visualized as a variation on the mechanism of fatty acid biosynthesis, in which the decarboxylation of the acylmalonyl thiolester is delayed until an enol phosphate or pyrophosphate has been formed, when the concerted decarboxylation-elimination step occurs.

$$CH_3-C(OY)=C(O^{\ominus})-C(=O)X \rightarrow OY^{\ominus} + CH_3-C\equiv C-C(=O)X + CO_2 \quad (g)$$
(8)

$$CH_3-CO-CH_2-C(=O)X \quad (9)$$

If, however, the initial "acetate + malonate" condensation were also accompanied by a simultaneous decarboxylation (and the experimental evidence is not conclusive on this point [20]), then the product of the condensation would be the acylacetate *(9)* instead of the acylmalonate *(7)*, and the formation of the acetylene *(8)* would then have to proceed by a process equivalent to the dehydration of the acylacetate *(9)*. The hydration of the triple bond is well known both in the laboratory and also enzymically, *e.g.*, in the conversion of acetylenedicarboxylic acid into oxaloacetic acid [21]. However, in view of the high energy required for the direct dehydration of $-COCH_2-$ to $-C\vdots C-$, this conversion could be expected to occur more easily in 2 steps, through an enol ester leaving group with prior or simultaneous loss of a proton from the adjacent carbon of the double bond [equation (h)].

The phosphate ion was early suggested [9] as a possible leaving group for such a process, and the pyrophosphate ion involved in the acylmalonate model [19] would be even better for this purpose. The feasibility of such elimination reactions was supported, *e.g.*, by the ready transesterification of vinyl esters [22], which implies a degree of reversibility of the addition reaction to the triple bond [equation (i)].

$$CH_3-C(H)(OY)-C(=O)X \rightarrow HOY + CH_3-C\equiv C-C(=O)X \quad (h)$$
(8)

$$R^1-COO-C(R)=CH_2 + R^2-COOH \xrightarrow{Hg(OAc)_2} R^1-COOH + R^2-COO-C(R)=CH_2 \quad (i)$$

$$CH_3-C(OPO(OC_2H_5)_2)=CH-PO(OC_2H_5)_2 \xrightarrow{NaOC_2H_5} HOPO(OC_2H_5)_2 + CH_3-C\equiv C-PO(OC_2H_5)_2 \quad (k)$$

[22] *D. Swern* and *E. F. Jordan jr.*, Org. Syntheses, Coll. Vol. *4*, 977 (1963).

The only transformation of an enol phosphate into an acetylene recorded prior to 1961 was[23] the formation of diethyl propynephosphonate *(11)* by the action of sodium ethoxide on 2-(diethoxyphosphoryl)-1-methylvinyl diethyl phosphate *(10)* [equation (k)].

The close correspondence between the two pathways (e) and (f) suggested the possibility[13] that dehydrogenation of the fatty acids could lead to the corresponding acetylenes, as in equation (l).

$$CH_3-CH_2-CH_2-\underset{X}{C}=O \rightarrow CH_3-CH=CH-\underset{X}{C}=O \rightarrow CH_3-C\equiv C-\underset{X}{C}=O \quad (1)$$

The first step in this sequence represents a demonstrated pathway in the biosynthesis of long-chain monounsaturated fatty acids, where it has been shown[24,25] that the enzyme-catalyzed conversion of stearic acid to oleic acid takes place with positional and geometrical specificity. The second step would represent a similar thermodynamic sequence, and the first experimental proof of such a conversion has been recently provided[26,27] by the isolation of labeled crepenynic acid *(14)*, together with linolenic acid *(13)*, from *Trichoma grammopodium* supplied with [10-^{14}C]oleic acid *(12)*.

$CH_3-(CH_2)_7-CH=CH-(CH_2)_7-COOH$ *(12)*

$CH_3-(CH_2)_4-CH=CH-CH_2-CH=CH-(CH_2)_7-COOH$ *(13)*

$CH_3-(CH_2)_4-C\equiv C-CH_2-CH=CH-(CH_2)_7-COOH$ *(14)*

Both the acylmalonate [equation (g)] and the acylacetate [equation (h)] pathways to acetylene compounds have been realized in the laboratory (though not, as yet, enzymically). The dehydrogenation mechanism [equation (l)] on the other hand has been successfully demonstrated enzymically, but no laboratory model for such a reaction step exists up to date.

2. Eliminations from Enol Sulfonates

2.1. Acetylenes from Acylmalonate Enol Sulfonates

In pursuance of a biogenetic analogy, the decarboxylative elimination of enol sulfonates has been examined[28]. A number of enol sulfonates *(16)* were prepared by treatment of acylmalonates *(15)* with sodium ethoxide and arylsulfonyl chlorides. Yields were variable but, in general, were high for those compounds with a sterically unhindered enol group. In homogeneous alkaline aqueous dioxane solution saponification was followed by decarboxylative elimination giving acetylenic acids *(17)* in a number of cases[28,29].

$$R-\overset{O}{\overset{\|}{C}}-\underset{COOC_2H_5}{\overset{COOC_2H_5}{CH}} \xrightarrow[NaOC_2H_5]{ArSO_2Cl} R-\underset{OSO_2Ar}{\overset{COOC_2H_5}{C}}=\underset{COOC_2H_5}{C} \rightarrow R-C\equiv C-COOH$$

(15) *(16)* *(17)*

The product was a mixture of the acetylenic acid *(17)* and the starting acylmalonate *(15)*, the latter arising by hydroxide ion attack on the enol carbon followed by loss of sulfonate ion. This hydrolysis product *(15)*, as opposed to the elimination product *(17)*, was produced in greatest quantity from those enol sulfonates *(16)* which were least hindered for attack on this carbon atom. This tendency, taken in conjunction with the trend in the yield of the enol sulfonates mentioned above, gives rise to an overall yield (based on acylmalonate *(15)*) of acetylenic acid which is much the same (about 20%) for all compounds studied. Recovery of the starting material, however, raises the effective yield considerably (see Table 1).

Table 1. Enol sulfonates *(16)* and acetylenic acids *(17)* obtained from acylmalonates [28, 29, 46].

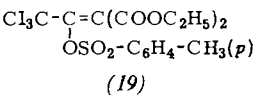
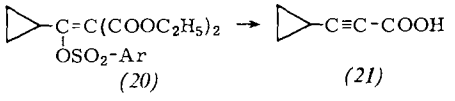
[28a] *I. Fleming* and *C. R. Owen,* unpublished results.



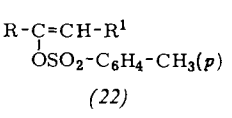
[29] *E. J. D. Brown* and *J. Harley-Mason,* J. chem. Soc. (London) *(C) 1966*, 1390.

The reaction fails when the developing triple bond is not conjugated with a double bond or an aromatic ring.

The diester *(18)*, R = C_2H_5, gave only the diacid *(18)*, R = H, under the usual alkaline conditions. Further treatment under a variety of conditions led only to the hydrolysis products, phenylacetone and phenylacetic acid.



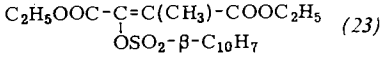
(18)



(19)

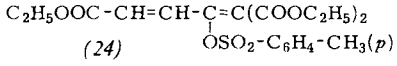
The enol-*p*-toluenesulfonate *(19)*, with a strongly electron withdrawing trichloromethyl group, gave no acetylenic acid in the crude reaction product. The only exceptions to this rule are the enol sulfonates *(20)*, Ar = p-Br-C_6H_4, *p*-MeC_6H_4, and β-$C_{10}H_7$, treatment of which with alkali gave cyclopropylpropiolic acid *(21)* in low yield [29].

(20) *(21)*



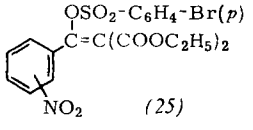
The conversion of the enol *p*-toluenesulfonate *(22a)* (obtained in 38% yield) to ethyl 2-butynoate (ethyl tetrolate) was reported [30] using sodium *tert*-butoxide in benzene. However, the yield of the acetylene was extremely low and the characterization of the product incomplete.

(22)



(a), R = CH_3, R^1 = $COOC_2H_5$
(b), R = C_6H_5, R^1 = $COOCH_3$
(c), R = CH_3, R^1 = $COCH_3$

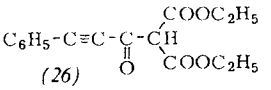
The enol *p*-toluenesulfonates *(22b)* and *(22c)* were prepared [30,48] in low yield, but no acetylenes were obtained from them. The enol naphthalene-2-sulfonate *(23)* from diethyl oxalopropionate similarly failed to give any acetylenic acid on alkaline treatment [29].



(23)

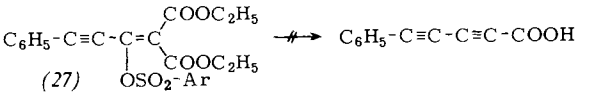
When the double bond, conjugated with the enol double bond, is further conjugated with a carbonyl group, as in the enol *p*-toluenesulfonate *(24)*, no elimination to give an acetylenic product was observed. Even the nitrobenzoylmalonate enol *p*-bromobenzenesulfonates *(25)*, *o*-, *m*-, and *p*-NO_2, afforded only traces of acetylenic products (detected by

(24)



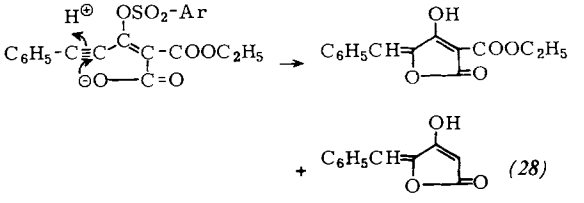
(25)

infrared spectroscopy). Similarly, the enol *p*-bromobenzenesulfonate *(16)*, R = C_6H_4–CO, Ar = *p*-Br–C_6H_4, from diethyl phenylglyoxalylmalonate failed to give any acetylenic product on alkaline treatment [29].



The possibility of extending the enol acylmalonate synthesis to the preparation of diacetylenic acids was examined using the ester *(26)*. However, the presence of a triple bond conjugated with the enol double bond led to the formation of tetronic acids before elimination to the expected diynoic acid could take place.

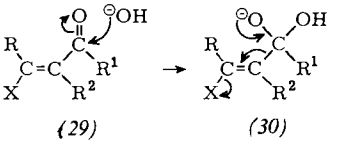
[30] *G. Nakaminami*, Bull. chem. Soc. Japan *35*, 1629 (1962).



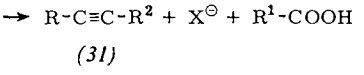
Presumably the reaction proceeds through ester hydrolysis and intramolecular attack by the carboxylate ion on the triple bond or the protonated triple bond [31]

(26)

(27)



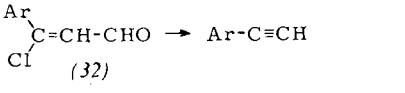
(28)



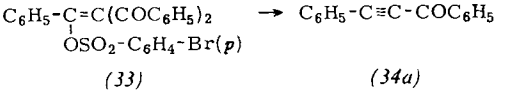
since both the ketoester *(26)* and its enol arenesulfonate *(27)* underwent cyclization to give the same γ-benzylidene tetronic acid *(28)* [47].

2.2. Acetylenes from Enol Sulfonates of α-Acyl-β-diketones and α-Acyl-β-keto Esters

An alternative process to decarboxylation as a source of electrons for the developing triple bond is the attack of hydroxide ion on an acyl group as in *(29)*→*(31)*.



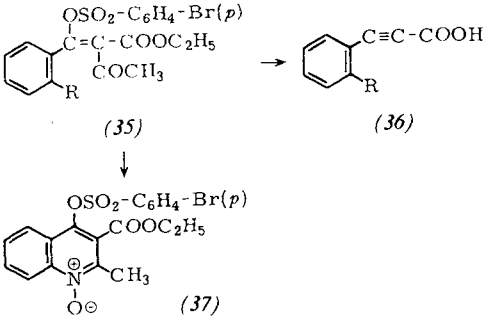
(29) *(30)*



(31)

This fragmentation has been observed, for example, in triple bond formation from β-aryl-β-chloroacroleins *(32)* with alkali [32]. In the enol sulfonate field it has been used for the synthesis of an acetylenic ketone *(33)*→*(34a)* [29].

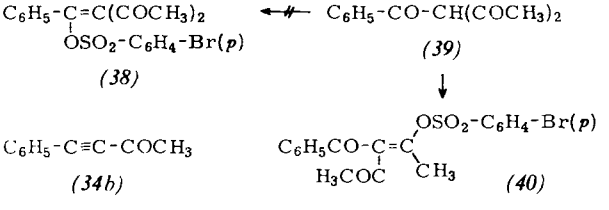
(32)



(33) *(34a)*

The enol sulfonates from the α-acylacetoacetates *(35)*, R = H and NO_2, gave the acetylenic acids *(36)*, R = H and NO_2, by loss of acetic acid rather than the ketones by decarboxylation. This was due to the *trans* configuration of the acyl and sulfonate groups about the

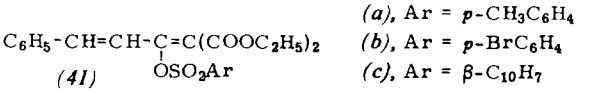
[31] *I. Fleming* and *J. Harley-Mason*, J. chem. Soc. (London) *1963*, 4778.



[32] *K. Bodendorff* and *P. Kloss*, Angew. Chem. *75*, 139 (1963); Angew. Chem. internat. Edit. *2*, 98 (1963).

double bond. The configuration was proved in the *o*-nitrophenyl case where reductive cyclization gave the quinaldine *N*-oxide *(37)*. It is interesting that the loss of acetic acid is a better source of electrons for the developing triple bond than decarboxylation: the yield of *o*-nitrophenylpropiolic acid from the enol sulfonate *(35)*, R = NO_2, was 65% compared with a trace from the corresponding malonate derived enol sulfonate *(25)*.

(35) *(36)* *(37)*

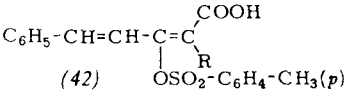


The utility of this fragmentation reaction is probably also limited to those cases where a double bond or aromatic ring is conjugated with the enol double bond. An attempt to prepare 4-phenylbut-3-yn-2-one *(34b)* from the enol sulfonate *(38)* was thwarted when the enol sulfonate actually obtained *(40)* was that in which enolization was not toward the phenyl group. This enol sulfonate *(40)* gave no acetylenic products with alkali [29].

(38) *(39)* *(34b)* *(40)*

2.3. Mechanistic Considerations

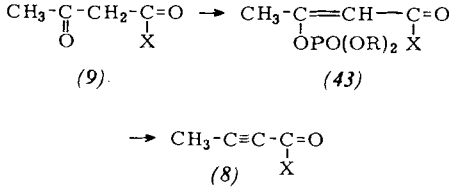
An examination of the gross features of both decarboxylative and deacylative eliminations reveals an interesting situation. The reaction rate is very dependent on the leaving group. For example, the three enol sulfonates *(41a)*, *(41b)*, and *(41c)* were treated with alkali under comparable conditions. It was found that the *p*-toluenesulfonate *(41a)* had undergone predominantly carboxylate ester hydrolysis to give the corresponding acid with very little elimination; the *p*-bromobenzenesulfonate *(41b)* had undergone elimination to phenylpropiolic acid; and the β-naphthalenesulfonate *(41c)* was intermediate in reactivity giving some elimination and some ester hydrolysis.



(41) *(a)*, Ar = *p*-$CH_3C_6H_4$; *(b)*, Ar = *p*-BrC_6H_4; *(c)*, Ar = β-$C_{10}H_7$

The group conjugated with the enol double bond has a large influence on the extent to which elimination is observed. In fact the groups which encourage elimination are those which most easily support a carbonium ion at the carbon atom bearing the sulfonate group and those groups which prevent elimination are those which would least tolerate such a carbonium ion.

The reaction also shows a dependence on the nature of the group which is the source of electrons for the developing triple bond. These observations support the expectation of a concerted elimination process (cf. also ref. [28a]). It is interesting to note that, for elimination to occur under the mild conditions cited, the range of groups in the various positions around the enol double bond is fairly narrow.



That base catalysis is indeed necessary was shown by examination of the behavior of the *p*-toluenesulfonate of 3-phenylpropenoylmalonic acid enol in a non-basic medium. When the diacid *(42a)* was heated in water for 15 min, decarboxylation *without* elimination occurred, affording the toluene-*p*-sulfonate *(42b)*, without formation of the acetylenic acid *(17)*, R = C_6H_5–CH=CH. On the other hand, treatment of *(42a)* in aqueous base is known [28] to give this acid by concerted elimination-decarboxylation.

(42) *(a)*, R = COOH; *(b)*, R = H

3. Eliminations from Enol Phosphates

Following the biosynthetic analogies discussed in Section 1.2, the conversion of the acylacetates *(9)* to the acetylenes *(8)* was investigated [33,34], using the biologically relevant phosphate leaving group [2,19] in the form of an enol phosphate derivative *(43)*.

(9) *(43)* *(8)*

3.1. Preparation of Enol Phosphates

Vinyl phosphates [35] may be obtained from enolizable ketones by reaction of the sodium enolate with a phosphoryl chloride; this reaction yields the *trans* isomers exclusively (*cis* and *trans* refer, as usual, to the carbon chain). With ketones that enolize little or not at all the interaction of the α-chloroketone with triethyl phosphite by the Perkow reaction [36,37,63] yields predominantly the *cis*-enol phosphate [equation (m)].

The Perkow reaction may also be used to obtain *cis*-enol phosphates from enolizable ketones. Finally, methyl ketones are transformed, through their chloromethyl derivatives, into vinyl phosphates containing a terminal methylene group. In all cases the yields of vinyl phosphates are good to excellent.

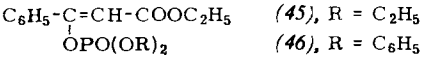
3.2. Acetylenes from Enol Phosphates

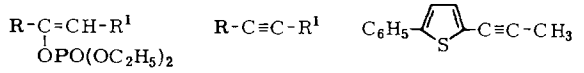


A number of enol phosphates *(44)* were prepared [34] and their base-catalyzed elimination was examined under various conditions [34].

Reaction of dilute aqueous sodium hydroxide on the *trans*-enol phosphate *(45)* in 50% aqueous dioxane or 50% aqueous ethanol at 5 °C or at 25 °C gave only acetophenone. Using potassium hydroxide in refluxing absolute ethanol gave up to 20% of phenylpropiolic acid, with much acetophenone. The findings that elimination was retarded by aqueous media and accelerated by using an alcoholic solution and a stronger base (ethoxide) suggested the characteristics of an E2 elimination in which, owing to the greater charge-dispersal in the E2 transition state, the E2 rate changes faster than the S_N2 rate with decreasing ion-solvating power of the medium [38].

Accordingly, the use of sodamide in liquid ammonia at −70 °C gave phenylpropiolamide smoothly in 72% yield. In agreement with the greater base strength of amide ion than of hydroxyl ion, the absence of acetophenone or of β-ketoester from the product showed that the competing substitution had been suppressed under these conditions. At −33 °C phenylacetylene was the sole product (75%), owing to a fission [40,41] which formally resembles the Haller-Bauer [39] cleavage of non-enolizable ketones by sodamide (see below).

Identical results were obtained when diphenyl *trans*-2-ethoxycarbonyl-1-phenylvinyl phosphate *(46)* was used.



(45), R = C_2H_5
(46), R = C_6H_5

The *cis*-enol phosphate *(45)*, subjected to the previously used conditions (sodamide in liquid ammonia at −33 °C), gave phenylacetylene in almost the same (65%) yield as the *trans*-isomer, and free from ketone or ester. At −70 °C most (80%) of the enol phosphate was recovered, with 12% (spectroscopic) of phenylpropiolamide.

The formation of phenylpropiolamide is in agreement with the known greater ease of conversion of esters into amides in α,β-acetylenic than in α,β-ethylenic systems. For instance, ethyl phenylpropiolate affords phenylpropiolamide with liquid ammonia alone, while both ethyl cinnamate and diethyl 2-ethoxycarbonyl-1-phenyl-vinyl phosphate *(45)* are unchanged by this reagent. It is evident that the elimination of the *trans*-enol phosphate *(45)* at −70 °C is appreciably faster than that of its *cis*-isomer, and that, if the *cis*-enol phosphate had under the conditions of this experiment (−70 °C) suffered isomerization to the *trans*-isomer, then the whole system would have undergone elimination. That this was not the case was shown by the recovery of 80% of the *cis*-enol phosphate.

It is well known that base-promoted *trans*-elimination is fast because the atoms concerned lie in a coplanar arrangement in which the dihedral angle between hydrogen and the departing anion is 180 °. However, in the *cis*-enol phosphate *(45)* in which the dihedral angle is 0 °, the transition state is still flat and coplanar, and a coplanar *cis*-elimination should thus readily take place. It was recently reported [42] that *trans*-2-phenylcyclopentyl toluene-*p*-sulfonate and its *cis*-isomer both underwent base promoted E2 elimination, with a ratio k_{trans}: k_{cis} of only 14:1, while the 2-phenylcyclohexyl ester had $k_{trans}:k_{cis} > 10^4:1$. The reason advanced was that the small dihedral angle in the *cis*-cyclopentyl system (*ca.* 12 °) approaches coplanarity whereas this would not be the case for the *cis*-cyclohexyl compounds in which the dihedral angle will remain at 60 °.

In our cases, the ratio $k_{trans}:k_{cis}$ is at least 6:1, and *cis*- and *trans*-coplanar eliminations both appear relatively easy. In agreement, the *trans*-enol phosphate *(44a)* from deoxyanisoin, and the *cis*-enol phosphate *(44b)* from deoxybenzoin, both gave the expected diphenylacetylenes in >90% yield. The enol phosphates *(44c)* and *(44d)* gave phenyl- and 4-diphenylylacetylene, respectively, in high yield.

Another example is the synthesis[43] of the natural product 2-phenyl-5-(prop-1-ynyl)thiophene *(48)*, isolated from *Coreopsis grandiflora*[44] together with its triacetylenic precursor 1-phenyl-1,3,5-heptatriyne, and illustrating the close biogenetic correspondence between the thiophene and the diacetylenes, which has been so elegantly proved by *K. E. Schulte*[45] by his conversion of the latter into the former.

Nakaminami and his colleagues have prepared[30,48,49] diphenyl *trans*-2-methoxycarbonyl-1-phenylvinyl phosphate *(49b)* and obtained phenylacetylene (28%) by action of sodamide in liquid ammonia, and phenylpropiolic acid in low yield by the use of sodium *tert*-butoxide in benzene. The enol phosphate from dibenzoylmethane *(49a)* was cleaved by sodamide to give phenylacetylene in low yield, but afforded 76% of the acetylenic ketone *(50a)* when sodium *tert*-butoxide in *tert*-butanol was used. No acetylenes were obtained from the enol phosphates of ethyl acetoacetate *(49c)* and acetylacetone *(49d)* (Table 3).

(49) *(50)* *(51)*

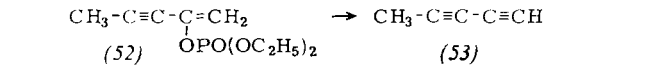
[a] Yield based on *(49)*.

[b] Using sodamide in liquid ammonia.



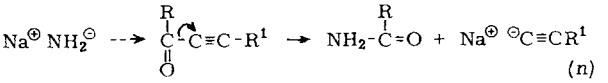
[c] Using sodium *tert*-butoxide in *tert*-butanol.

[d] Together with small amounts of phenylpropiolic acid.

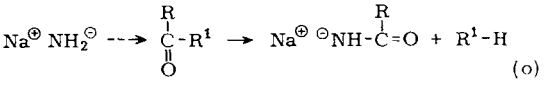
[e] Using sodium *tert*-butoxide in benzene.

The enol phosphate *(51)* was reported[28] to give only hydrolysis products on treatment with alkali under a variety of conditions, with no triple-bond absorption in the infrared spectrum.

Reaction of propyne with chloroacetyl chloride gave 1-chloropent-3-yn-2-one which readily formed the enol phosphate *(52)*. This acetylenic enol phosphate



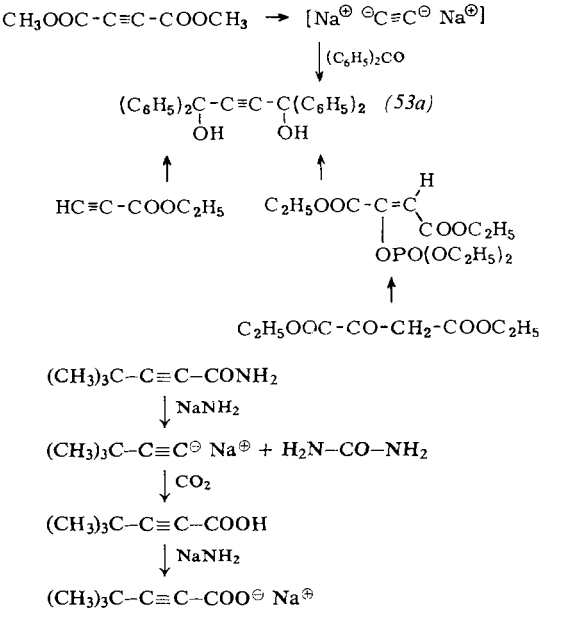
(52) *(53)*



underwent elimination smoothly[34] to give penta-1,3-diyne *(53)*. The method is thus applicable to the transformation of any terminal acetylene into a monosubstituted diacetylene.

The cleavage reaction with sodamide mentioned earlier was found[40,41] to be general for esters and amides derived from α,β-acetylenic acids which do *not* possess a γ-hydrogen atom. The product is the free terminal acetylene in high yield, accompanied by urea. Cinnamide is recovered quantitatively under these conditions.

The reaction [equation (n)] must be analogous to that of the Haller-Bauer reaction [equation (o)] in which sodamide cleaves a non-enolizable ketone to give an amide and a hydrocarbon after prolonged refluxing in toluene[39]. The new fission reaction is useful in a number of ways. It may, for instance, be used to protect a terminal acetylene by carboxylation and then to remove the protecting group at −33 °C converting the acid either to the ester or to the amide.



(n)

(o)

Thus, dimethyl acetylenedicarboxylate is cleaved, and on addition of benzophenone gives 1,1,4,4-tetraphenyl-2-butyne-1,4-diol *(53a)*. The same product is obtained from ethyl propiolate, and from oxaloacetic ester, *via* the enol phosphate. The amide of *tert*-butylpropiolic acid was completely cleaved to sodium 3,3-dimethylbut-1-yn-1-ide; no acid was produced. Therefore *no* additional activation of the triple bond is necessary for cleavage to occur. Carboxylation gave back the original acid. The acids themselves were completely stable after the same treatment. showing that the electron-repelling carboxylate ion resists attack by sodamide.

The sodamide-induced cleavage of the enol phosphates *(49a)* and *(49b)* and of the acetylenic ketone *(50a)*, to give phenylacetylene[30,48,49] are clearly further examples of the same reaction.

When the enol phosphate *(54)* contained a methylene group adjacent to the carbon-carbon double bond, allenic products *(55)* were obtained on base-catalyzed elimination[50,51]. The enol phosphates from propio-

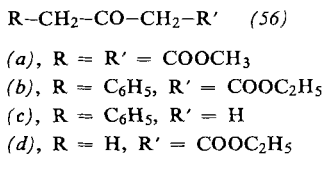
phenone and from pentadecan-2-one gave no acetylene or allene, only hydrolysis to the parent ketone occurring [34] (Table 4).



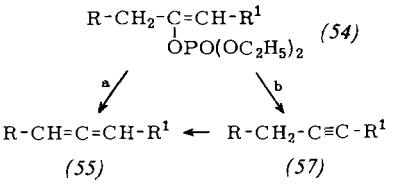
(54) *(55)*

Table 4. Enol phosphates *(54)* giving allenes *(55)* [34].

R	R′	Yield of *(54)* (%)	Yield of *(55)* (%)
C_6H_5	C_6H_5	87; *cis*	77
CH_3	C_6H_5	86; *cis*	75
C_6H_5	H	87;	77
C_6H_5	CH_3	85; *cis*	—
n-$C_{13}H_{27}$	H	not reported	—

The activation for an enol phosphate *(44)* to be transformed into an acetylene thus requires the presence of a double linkage in the group R′ in conjugation with the incipient triple bond; or, if R′ = H, that the group R contains a double bond similarly situated. These findings suggested that a natural β-polyketone, in which each methylene group is doubly activated by a carbonyl group, should be transformed into an acetylene or allene under even milder conditions than those for the enol esters.

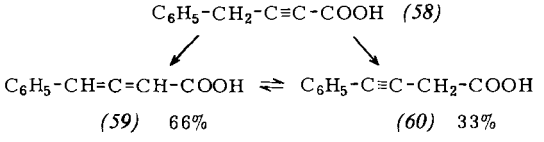
The simplest available model for a β-polyketone was acetonedicarboxylic ester *(56a)*. Its enol phosphate was easily transformed [52] into the allene, dimethyl penta-2,3-dienedioate *(55)*, R = R′ = $COOCH_3$, *e.g.*, with dilute aqueous alkali in 10 seconds at 0 °C, or with aqueous sodium carbonate solution in 90 min at room temperature.



(a), R = R′ = $COOCH_3$
(b), R = C_6H_5, R′ = $COOC_2H_5$
(c), R = C_6H_5, R′ = H
(d), R = H, R′ = $COOC_2H_5$

Some concurrent hydrolysis occurs in each case.

When one of the methoxycarbonyl groups was replaced by phenyl, the resulting γ-phenylacetoacetic ester *(56b)* gave an enol phosphate which required 24 h for complete reaction with alkali, giving a mixture of 66% of the allenic *(59)* and 33% of the 3-ynoic acid *(60)*. None of the 2-ynoic acid was found. Further removal of activating groups from the original ester left either acetoacetic ester *(56d)* or phenylacetone *(56c)*. Their enol phosphates gave neither allene nor acetylene even after 24 h with aqueous alkali.



Successful elimination with aqueous base at room temperature therefore requires the presence of activating groups on both sides of the three-carbon system in the enol phosphate, *i.e.*, in both R and R′, in a manner similar to that in a natural β-polyketone. It should be recalled, however, that in the enol phosphate which lacks the methylene group adjacent to the enol double bond, only hydrolysis occurred with aqueous alkali even if both R and R′ were activating groups. Thus the enol phosphate *(44)*, R = R′ = $COOC_2H_5$, undergoes only hydrolysis with aqueous base, while its higher homolog *(54)*, R = R′ = $COOC_2H_5$, is transformed into the allene under the same conditions.

[52] *J. C. Craig* and *M. Moyle*, J. chem. Soc. (London) *1963*, 5356.

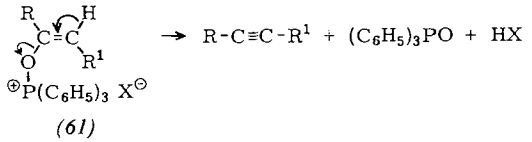
(54) *(55)* *(57)*

Formation of the allene *(55)* could take place from the enol phosphate *(54)* either by route a or by route b. Whereas only dimethyl penta-2,3-dienedioate is expected from acetonedicarboxylic ester, in the case of γ-phenylacetoacetic ester the product could be the allene or the acetylene. Since 4-phenyl-2-butynoic acid *(58)* on identical treatment gave a mixture of 66% of the allene *(59)* and 33% of the 3-ynoic acid *(60)*, it is not possible to say whether or not formation of the allene proceeded through the intermediate acetylene [52]. When the elimination reaction was carried out in deuterium oxide [53], the allene *(59)* produced was found to be uniformly deuteriated in both the 1- and 3-positions of the allene moiety, clearly due to intervention of *(60)*.

(59) 66% *(60)* 33%

In an effort to discover a base which might cause elimination of the phosphate from the enol *(54)* without also bringing about the acetylene → allene isomerization, ethyl 4-phenyl-2-butynoate was subjected to a range of bases of decreasing pK_a under otherwise identical conditions (6 h in boiling benzene). With triethylamine (pK_a 10.74), complete disappearance of the acetylenic ester was observed, and the product (which in the infrared spectrum showed only allenic absorption) consisted of 30% of ethyl 4-phenyl-3-butynoate and 70% of the allene ester as determined from the NMR spectrum.

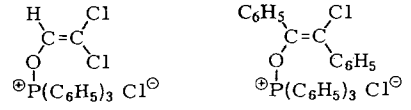
When benzyldimethylamine (pK_a 8.93) and 4-methylmorpholine (pK_a 7.41) were used, the acetylenic absorption in the infrared spectrum was completely replaced by the allene band, while with diethylaniline (pK_a 6.56) the acetylene was recovered quantitatively.



The enol phosphate *(54)*, in which R = C_6H_5, R′ = $COOC_2H_5$, under the same conditions gave 75% elimination when triethylamine was used (complete elimination required 8 h); 4-methylmorpholine afforded only recovered phosphate. It therefore follows that any base of pK_a >7.4 (necessary for the elimination) will also cause the rearrangement to the allene (and subsequently to the 3-ynoic ester), and that the acetylene intermediate, if present, can never be isolated from the reaction.

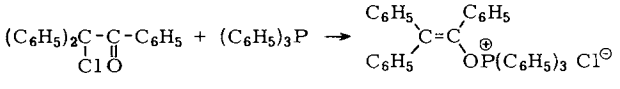
4. Eliminations from Enol Phosphonium Salts

In view of the successful conversion of enol phosphates and enol sulfonates into acetylenes, the corresponding



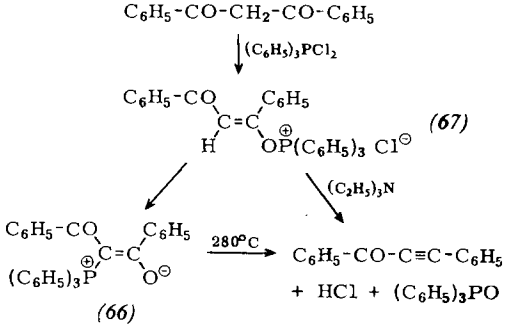
[53] *J. C. Craig* and *M. Moyle*, unpublished.

enol phosphonium ester *(61)* might be expected to react in the same manner.



(61)

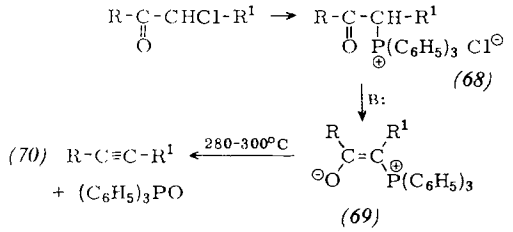
Such an enol phosphonium salt *(61)*, R = R′ = C_6H_5, is the possible intermediate in the production of diphenylacetylene from the reaction of triphenylphosphine and α-chlorodeoxybenzoin in refluxing benzene [62]. However, although such compounds have been postulated by *Trippett* [54] only two [*(62)* and *(63)*] could be isolated as unstable solids [55].



(62) *(63)*

The stable crystalline enol phosphonium salt *(65)* no longer has a hydrogen attached to the double bond [56].

(64) *(65)*

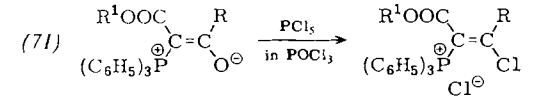


Enol phosphonium salts *(61)* are probable intermediates in the reaction of dihalotriphenylphosphoranes with β-keto esters and β-diketones [57] in the presence of base. However, in some cases [58] phosphoranes *(66)* are isolated which then require pyrolysis at 280 °C to give acetylenes, yet in other instances [55] the method gives enol phosphonium salts *(67)* which undergo elimination to form acetylenes merely by the action of triethylamine.

(66) *(67)*

In most other cases examined, a "normal" phosphonium salt *(68)* is formed in which phosphorus is attached to carbon, and which is converted into a phosphorane *(69)* by aqueous alkali. These phosphoranes are analogous to the *cis*-enol phosphates mentioned above, and have been successfully converted into the acetylenes *(70)* [58–60] by pyrolysis at 280–300 °C for 1 h.

The reaction requires that either R or R′ must be a phenyl or carbonyl group or the equivalent, but not hydrogen. The requirements for activation adjacent to the incipient triple bond are thus similar to those found in the other elimination reactions (Table 5).



(68) *(69)* *(70)*

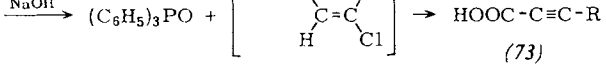


Table 5. Acetylenes *(70)* from phosphoranes *(69)*.

R	R′	Yield of *(70)* (%)	Ref.

The preparation of the phosphoranes from α-chloro ketones is however not a general method, and the phosphoranes *(69)* have usually to be synthesized by the action of acid chlorides on Wittig reagents [54,60]. The method has been markedly improved by conversion of the phosphoranes *(71)* to the chlorinated

(71) *(72)*

The Meaning and Use of the Arrhenius Activation Energy

By M. Menzinger and R. Wolfgang[*]

The nature of the Arrhenius activation energy and frequency factor is reexamined in terms of information now becoming available on the microscopic aspects of collisional reactions. It is pointed out that the activation energy is not generally equal to the threshold for reaction, and its correct conceptual meaning is discussed. The temperature dependence of this quantity and its relation to the threshold energy is developed for a number of representative forms of the energy dependence of the reaction cross-section (excitation function). The uses and limitations of the activation energy as a means of evaluating thresholds, excitation functions, and the presence of tunneling processes are discussed.

1. Introduction

The Arrhenius equation, now eighty years old, continues to play a dominant role in classical studies of chemical kinetics. It enables the experimentalist to express the dependence of the rate constant over a wide range of temperatures in terms of only two empirical parameters:

$$k(T) = A\exp(-E_{exp}/kT) \qquad (1)$$

These are the "experimental activation energy" (E_{exp}) and the "pre-exponential factor" (A). The meaning of these parameters has been the subject of much debate. While the Arrhenius equation deals with macroscopic aspects of chemical reactions, the field has recently been revolutionized by newer, non-classical techniques (molecular beams[1], photochemical[2–4], hot atom[5], mass spectrometric[6], trajectory calculations[7]) which emphasize the more fundamental microscopic nature of chemical collisions. These methods can give direct information on the dependence of the reaction rate on energy. Such data are usually presented as energy or velocity dependent cross-sections, ($\sigma(E)$ or $\sigma(v)$), also known as "excitation functions". It seems appropriate at this time to review our understanding of the meaning of the Arrhenius parameters in terms of this new knowledge.

The Arrhenius equation was first discovered by *Hood*[8] as a purely empirical relationship. Subsequently *van't Hoff*[9] and *Arrhenius*[10,11] showed that it was theoretically consistent with thermodynamical theory. They interpreted the activation energy as the height of the energy barrier which has to be overcome by the relative translational motion of the reactants in order for reaction to occur. This concept is basically correct but oversimplified since, as we now know, the probability of reaction is a complex function of internal as well as translational energy and also of geometrical configuration.

Various attempts[12–15] to theoretically justify the Arrhenius equation all lead to equations of the type

$$k(T) = B(T)\exp(-E_0/kT) \qquad (2)$$

Here E_0 is the threshold, the lowest relative translational energy at which reaction can occur. No single one of these forms has, however, been particularly successful. The reason for this is not hard to understand, for each presupposes a specific assumption as to which part of the total energy of the system is available to drive such reaction[15]. Every such model implies a specific excitation function – the translational energy dependence of the microscopic reaction

[15] Transition State Theory attempts to approximate the information contained in $\sigma(E)$ by estimates of partition functions and the transmission coefficient $\varkappa$. However, there exists to date no reliable method to compute these functions on an *a priori* basis. On the other hand, there is considerable promise that $\sigma(E)$ for many gas phase processes will be directly accessible through theory as well as experiment. This should in the future tend to favor an approach to gas phase kinetics based on microscopic collision dynamics.

cross-section $\sigma(E)$. For instance, the well-known "line-of-centers" model [13,16] implies a cross-section dependence of the form

$$\sigma = \sigma_{AB}\left(1 - \frac{E_0}{E}\right) \tag{3}$$

where E is the translational energy of the reactants, and σ_{AB} the hard sphere collision cross-section. But it seems reasonable that the excitation function $\sigma(E)$ can have many forms [7,17,18] depending on the nature of the reaction. Thus, no single version of Equation (2) is likely to be very widely applicable.

For this reason as well as for its simplicity, the original Arrhenius equation still provides by far the most useful format within which to summarize the data of classical kinetics. As a practical matter, it nearly always yields values of E_{exp} and A which are constant within the experimental temperature range and limits of accuracy.

If it is futile to search for a "better" equation than that of Arrhenius, it becomes all the more necessary to understand the precise meaning of the Arrhenius parameters. In particular, it should be a matter of practical importance to chemists to understand the difference between the activation energy and the threshold – two quantities which are commonly and erroneously assumed to be identical.

1.1. Arrhenius Parameters and Microscopic Reaction Cross-Section

The activation step of any chemical reaction always involves a collisional process. The Arrhenius activation energy reflects that collision step which is rate determining [19]. This is true even for unimolecular reactions since the decaying entity is always formed by some kind of bimolecular interaction.

The fundamental measure of the probability of any collisional reaction is the cross-section $\sigma(v)$, defined for collisions at relative velocity v by

$$\text{Rate} = -\left(\frac{dn_A}{dt}\right)_v = \sigma(v)v n_A n_B \tag{4}$$

Here n_A and n_B are the concentrations (molecules/cc) of reactants A and B. In order to interpret the Arrhenius parameters, they must be related to this cross-section. (At this point, we should note that the cross-section is defined for bimolecular reactions only, and that which follows is therefore inapplicable to higher order collisions. It should be meaningful for solution reactions, however, at least to the extent that effects of the medium can be included in the cross-section.)

The bimolecular rate constant k_v, for reaction between reactants A and B moving at relative velocity v, is defined by

$$\text{Rate} = -\left(\frac{dn_A}{dt}\right)_v = k_v n_A n_B \text{ (molecules/cc)} \tag{5}$$

Comparison of (4) and (5) gives

$$k_v = \sigma(v)v \tag{6}$$

If the reacting species possesses a distribution of velocities $f(T,v)$, then the rate constant (6) has to be weighted by this function to give the average rate constant

$$k(T) = \int_0^\infty f(T,v)\sigma(v)v\,dv \tag{7}$$

Note that the integrand of this equation gives the relative number of reactive collisions at velocity v. For a system at thermal equilibrium where $f(T,v)$ is given by the Maxwell Boltzmann distribution, the general relationship between the temperature dependent rate constant and the energy dependent cross-section [20] can be easily derived [7a,13]:

$$k(T) = \left[\left(\frac{2}{kT}\right)^{3/2}\left(\frac{1}{\mu\pi}\right)^{1/2}\int_0^\infty E\,\sigma(E)\exp(E_0-E)/kT)dE\right]\exp(-E_0/kT) \tag{8}$$

1.2. Activation Energy

The activation energy is in practice taken to be the slope of an Arrhenius plot of $(\ln k)$ vs. $(1/T)$. This means that its experimental definition is given by the following differential form of Equation (1) [21]:

$$E_{exp} = kT^2\frac{d\ln k(T)}{dT} = -k\frac{d\ln k(T)}{d(1/T)} \tag{9}$$

[16] *E. A. Moelwyn-Hughes*: Physical Chemistry. Pergamon Press, London 1957.

[17] *E. P. Wigner*, Physic. Rev. *73*, 1002 (1948).

[18] *M. E. Riley* and *A. Kuppermann*, Chem. Physics Letters *1*, 537 (1968).

[19] If a chemical reaction involves two or more bimolecular steps, the overall activation energy will be principally determined by the rate-limiting process. If different steps are limiting over different temperature ranges, the measured activation energy will, of course, change with temperature. This type of temperature dependence associated with a complex reaction sequence, or a change in mechanism, is obvious and will not be further discussed here.

[20] For simplicity, Equation 8 does not take internal degrees of freedom into account. The reaction cross-section is assumed to already represent a suitable average over the distribution of internal states of reactants, as obtained for instance from beam experiments without internal state selection. However, the distribution of internal states is a function of temperature, and the reaction cross-section for each vibrational-rotational state is in general different. Consequently, the averaged cross-section $\sigma(E,T)$ becomes temperature dependent. Over a limited temperature range, as accessible in classical thermal experiments, this effect will be small and has been neglected in the present calculation. For the more general formula, which assumes a separate excitation function $\sigma(E,i,j)$ for each internal state and finally sums up the distribution of final states, see Ref. [7a].

[21] The full differential form of Equation (1), allowing both A and E_{exp} to be temperature dependent, is

$$k\frac{d\ln k(T)}{d(1/T)} = k\frac{d\ln A}{d(1/T)} + E_{exp} - T\frac{dE_{exp}}{dT} \tag{9a}$$

In view of the experimental definition of E_{exp} as given in Equation (9), the temperature dependences of A and E_{exp} are related as follows:

$$\frac{d\ln A(T)}{dT} = \frac{1}{kT}\frac{dE_{exp}(T)}{dT} \tag{9b}$$

Differentiating the logarithmic form of Equation (8), we then have, as first derived by *Tolman* nearly 50 years ago [7a,22,23]

$$E_{exp} = \frac{\int_0^\infty \sigma(E)\, E^2 \exp(-E/kT)\mathrm{d}E}{\int_0^\infty \sigma(E) E \exp(-E/kT)\mathrm{d}E} - \frac{3}{2} kT \qquad (10)$$

Note that the integrand in the denominator is proportional to the energy distribution of reactive collisions $f(T,E)\sigma(E)v$ [Equation (7)]. Now the average value $\bar{g}(x)$ of a function $g(x)$, where $h(x)$ is the distribution of x, is given by

$$\bar{g}(x) = \frac{\int g(x)h(x)\mathrm{d}x}{\int h(x)\mathrm{d}x} \qquad (11)$$

Hence, the first term on the right-hand side of Equation (10) is identified as the average energy ($<E^*>$) of collisions in which reaction takes place. $\frac{3}{2} kT$ is, of course, the mean energy $<E>$ of all collisions (reactive and non-reactive) in the system. The activation energy is then simply [7a,22,23]

$$E_{exp} = <E^*> - <E> \qquad (12)$$

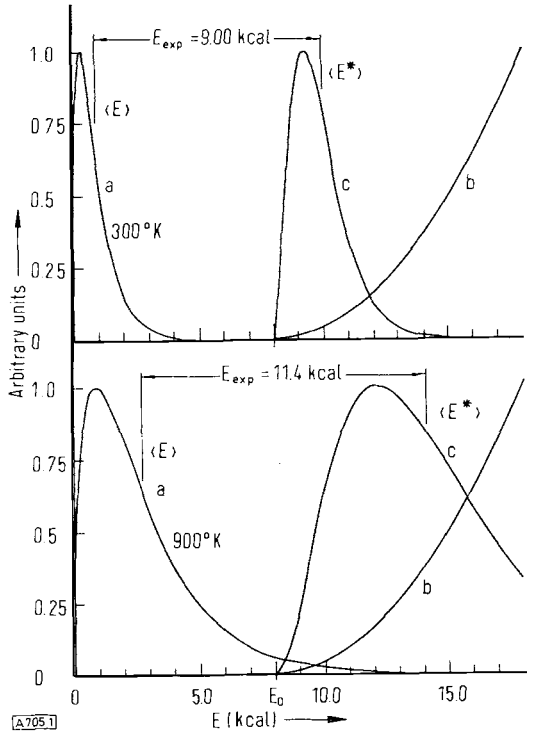

Fig. 1. Illustration of the temperature dependence of the activation energy, E_{exp}, using as an example the excitation function $\sigma(E) \propto (E-E_0)^2$, where E_0 is the threshold energy. The Maxwell-Boltzmann distribution of all collisions is shown at two temperatures together with the corresponding distribution of collisions which result in reaction. All three functions are arbitrarily normalized. The activation energy, given by the difference between the mean energy of reactive collisions $<E^*>$ and all collisions $<E>$, is seen to increase significantly with temperature. (For purposes of illustration, the ratio kT/E_0 has been chosen to be rather unrealistically high in the second part of the figure. Resulting non-equilibrium effects (see text) have been neglected but would result in some reduction of the actual $<E^*>$ and E_{exp}. Note that in Figs. 1 and 4, the energy is expressed in terms of kilocalories per mole, while the equations in the text refer to energy per molecule.

This can be visualized using Figure 1. This shows the equilibrium Maxwell Boltzmann distribution function of relative energies $f(T,E)$ of pairs of reactant molecules. Using the same energy scale, a typical cross-section function, $\sigma(E)$, is also given. The product $f(T,E)\,\sigma(E)\,v$ (see Equation 7) is then identified as the energy distribution of collisions resulting in reaction, a quantity which may be called the *reaction function.* Note that the average value of this function, $<E^*>$, will not in general coincide with its maximum, just as the average energy $<E> = \frac{3}{2}kT$ of all collisions does not coincide with the maximum of the Maxwell Boltzmann distribution function.

Several facts are qualitatively apparent from Figure 1. (1) Because of heavy damping by the Maxwell Boltzmann distribution, only reactions near threshold tend to be important in thermal systems. It is evident that knowledge of $\sigma(E)$ a few kilocalories beyond threshold allows the determination of the rate constant to high accuracy [24]. (2) As the temperature increases, the change in $<E^*>$ will not in general equal the increment in $<E>$. Hence, E_{exp} is temperature dependent. However, (3) this temperature dependence will be relatively small if E_0 or $<E^*>$ is large compared to kT, as is normally the case.

Point (3) thus accounts for the success of the Arrhenius equation, while Point (2) shows why it is not perfect.

1.3. Frequency Factor

Combining Equations (1) and (8), we obtain an expression for the pre-exponential factor in terms of the cross-section.

$$A = \left[\left(\frac{2}{kT}\right)^{3/2} (\pi\mu)^{-1/2} \int_{E_0}^\infty E\sigma(E) \exp\left(\frac{E_{exp}-E}{kT}\right) \mathrm{d}E\right] \qquad (13)$$

This expression basically consists of the product $\sigma(E)\,v$ weighted by a Maxwell Boltzmann distribution and multiplied by $\exp(E_{exp}/kT)$. It does not lend itself to as ready a conceptual interpretation as does the expression for E_{exp}. However, it is important to recognize that while the activation energy depends only on the shape of $\sigma(E)$, the frequency factor depends also on its magnitude.

1.4. Non-Equilibrium Effects

The derived relationships between the activation energy, frequency factor and the cross-section assume an equilibrium distribution of reactants. However, as reaction proceeds, the more energetic molecules will be removed. This leads to a perturbation of the Maxwell Boltzmann distribution which is counteracted by energy-exchange collisions tending to re-establish equilibrium. The net depletion of energetic molecules will tend to lower $k(T)$. This effect can be included

into the present treatment by introducing the steady state (non-equilibrium) distribution into Equation (7) instead of the Maxwell Boltzmann distribution (Figure 2a, b).

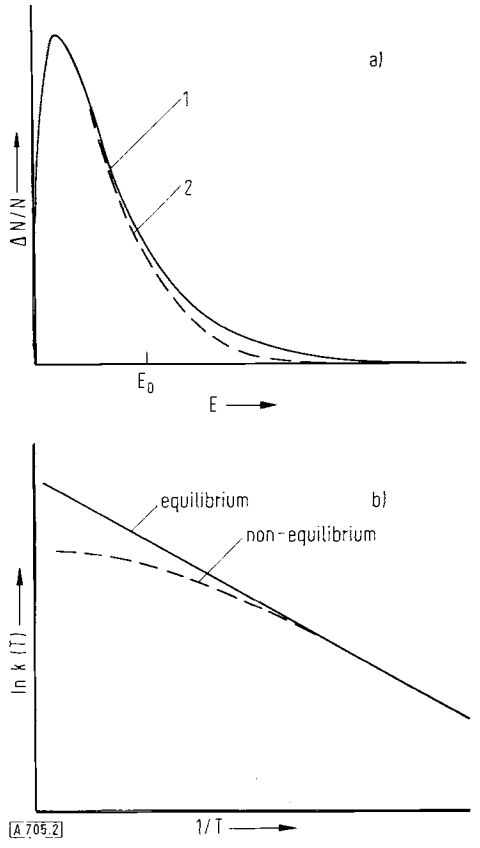

Fig. 2. a) Non-equilibrium effects for a reaction occurring at high thermal energies relative to threshold or activation energy ($E_{exp}/kT \gtrsim 5$) are schematically illustrated. Reaction depletes the number of higher energy collisions (even below E_0), so that the stationary state distribution lies below the Maxwell-Boltzmann distribution. The effect on the reaction function would be similar.
b) Schematic representation of non-equilibrium effects on the form of an Arrhenius plot.

Because of lack of detailed information on thermal relaxation mechanisms and rates, there has been relatively little work[25–35] on the exact magnitude of non-equilibrium effects. However, making reasonable assumptions, the conclusion has been reached[27] that for $(E_{exp}/kT) = 5$ the rate constant lies only about 8% below that calculated for equilibrium conditions. This deviation decreases rapidly as (E_{exp}/kT) increases. Thus, non-equilibrium effects are a limitation on the present treatment only for reactions having a very low activation energy occurring at high temperatures.

2. Calculations

We now examine the temperature dependence of the activation energy and its relation to the threshold for a variety of plausible forms of the excitation function $\sigma(E)$. This will permit us to develop more quantitatively our notions of the significance and limitations of the Arrhenius activation energy.

As accelerator[1], photochemical[2–4], and theoretical[7] methods for the study of hot reactions are developed, we can expect a great deal of information on the shape of $\sigma(E)$ for various reactions[17,18]. At this time, however, very little is known about these functions for processes having appreciable thresholds. We shall therefore assume various forms of $\sigma(E)$, some of which appear reasonable from studies of analogous nuclear processes. Only the low energy portion of the excitation function is of concern here, since as mentioned earlier, it is its behavior in the vicinity of the threshold that governs the reaction rate constant.

Calculations have been made for excitation functions having the general form

$$\begin{aligned} \sigma(E) &= C(E-E_0)^n \qquad E > E_0 \\ \sigma(E) &= 0 \qquad\qquad\quad E \leqslant E_0 \end{aligned} \tag{14}$$

where n has the values 0, 1, 2 and 3. Results on the excitation function

$$\begin{aligned} \sigma(E) &= C\,\frac{(E-E_0)}{E} \qquad E > E_0 \\ \sigma(E) &= 0 \qquad\qquad\quad E \leqslant E_0 \end{aligned} \tag{15}$$

are also presented. This corresponds to the frequently used assumption of elementary collision theory that only the relative energy along the line-of-centers of colliding hard spheres is available to drive the reaction[13,16]. In addition, calculations on the function

$$\begin{aligned} \sigma(E) &= C\,\frac{(E-E_0)^{1/2}}{E} \qquad E > E_0 \\ &= 0 \qquad\qquad\quad E \leqslant E_0 \end{aligned} \tag{16}$$

have been made. This dependence has been shown earlier[7a] to be the only one yielding temperature-independent Arrhenius parameters.

For each of the excitation functions (14), (15), and (16), the temperature dependences of the activation energies have been evaluated using equation (8) and (9). This can be done numerically but analytical forms (due to *LeRoy* and *Blakley*[36]) are preferred. These are

$$\frac{E_{exp}}{E_0} = 1 + \frac{kT}{E_0}\left[\left(n-\frac{1}{2}\right)+\left(1+\frac{E_0}{(n+1)kT}\right)^{-1}\right]; \qquad \text{where } \sigma(E) = C(E-E_0)^n \tag{17}$$

$$\frac{E_{exp}}{E_0} = 1 + \frac{kT}{2E_0}; \qquad \text{where } \sigma(E) = C\left(\frac{E-E_0}{E}\right) \tag{18}$$

$$\frac{E_{exp}}{E_0} = 1; \qquad \text{where } \sigma(E) = C\,\frac{(E-E_0)^{1/2}}{E} \tag{19}$$

[36] *R. LeRoy* and *C. Blakley*, private communication.

Results are shown in Figure 3, where the reduced activation energy E_{exp}/E_0 is plotted against the reduced temperature kT/E_0.

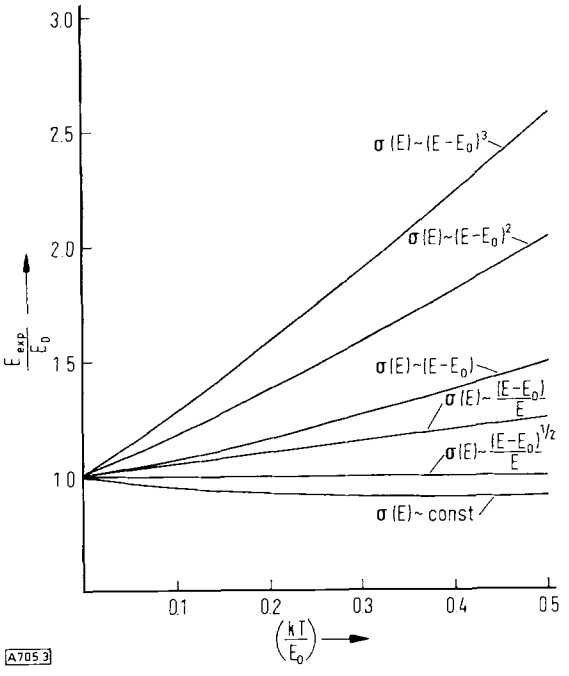

Fig. 3. Dependence of the reduced Arrhenius activation energy E_{exp}/E_0 on the reduced temperature kT/E_0 for various forms of the onset of the excitation function E_0. (Non-equilibrium effects are neglected and would become significant when $kT/E_0 \lesssim 0.2$.)

3. Discussion

Inspection of Figure 3 shows that the activation energy normally equals the threshold energy only when the mean thermal energy is extremely small compared to reaction energies. As the temperature increases, so does the difference between the activation and threshold energies. Only in the very improbable situation where the excitation function is given by Equation (16) will E_{exp} be constant and equal E_0. This is the only case in which the Arrhenius equation is "true" in the sense that its parameters are temperature invariant. Figure 4b shows that this is a result of the Maxwell Boltzmann distribution $f(T,E)$ and the reaction function $f(T,E)\sigma(E)v$ having the same temperature dependence.

If $\sigma(E)$ rises more rapidly than the function $(E-E_0)^{1/2}/E$ then E_{exp} will be less than E_0 and will show a negative temperature dependence. Figure 4a illustrates the basic reason for this, using the step function $\sigma(E)$ = constant as an example. It is seen that the reaction function is narrower than the Maxwell Boltzmann distribution, which means that the difference $<E^*>-<E>$ = E_{exp} is less than E_0. Furthermore, as the temperature rises, $<E^*>$ increases less rapidly than $<E>$, resulting in a decline in E_{exp}.

A more likely situation is one in which the excitation function rises less rapidly than $(E-E_0)^{1/2}/E$. This will

[37] *H. Labhart*, Chem. Physics Letters *1*, 263 (1967).

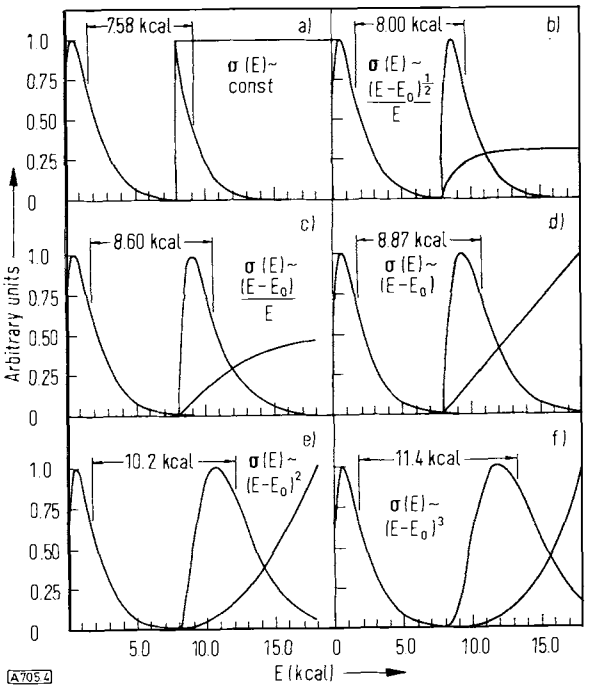

Fig. 4. Effect of the shape of the excitation function $\sigma(E)$ on E_{exp}. (For the temperature 600 °K and threshold, 8 kcal — chosen for clarity of illustration — non-equilibrium effects will have some importance, but are neglected.)

result in E_{exp} being greater than E_0 and having a positive dependence on temperature. Cases of this type are illustrated in Figures 1 and 4(c–f). The reaction function is wider than the Maxwell Boltzmann distribution resulting in the trends in E_{exp} which are shown in Figure 3.

3.1. Information on the Excitation Function from Thermal Data

Figure 4 demonstrates that knowledge of the temperature dependence of the Arrhenius activation energy can in principle be used to estimate the shape of the onset of the excitation function[38]. Such information is obtained from deviations from linearity of an Arrhenius plot of ln k vs. $1/T$. However, the temperature range over which accurate thermal rate data can be obtained is rarely great enough to make the deviations detectable. Hence, while rate constants can readily be estimated from data on the microscopic cross-section, there is generally little chance of doing the reverse.

The potential barrier for certain reactions (internal rotation) can, however, be measured directly, for instance, by microwave techniques. Information on the activation energy could then be used to estimate the low energy portion of the excitation function. This may be conveniently done by use of Figure 3. No such studies appear to have been made as yet, but such a procedure could lead to some interesting results.

[38] It has been shown [13] that $\sigma(E)$ is proportional to the Fourier transform of $k(T)$. The inversion of Equation (7) is mathematically quite feasible; however, practically it is almost hopeless.

3.2. Tunneling

As deviations from linearity of Arrhenius plots have been sought as evidence for possible tunneling [39,40], a discussion of this phenomenon in the present context is relevant. In principle, tunneling can take place through any energy level of the barrier [41–43]. Strictly speaking, this means that the threshold will be zero for an exoergic reaction and correspond to the energy of reaction for an endoergic process. In actuality, however, there is unlikely to be significant reaction until considerably higher energies are reached.

Tunneling will thus provide additional cross-section for reaction below the classical threshold for surmounting the barrier [37]. This is shown in Figure 5. The shape of this tunneling excitation function and the effective "threshold" for tunneling is a complex function of the shape of the barrier and the nature of the transmitted particle. However, the net effect of tunneling will be to make the total excitation function at very low energies be quite concave. It will resemble a function of the type $\sigma(E) \propto E^n$ where n is fairly large. As has been seen from Figure 4, this means that E_{exp} will decrease makedly at low temperatures. The present formulation can easily be made to include tunneling, by requiring $\sigma(E)$ in Equation (7) to include barrier penetration effects. In fact, every experiment which directly measures $\sigma(E)$ yields this compound excitation function.

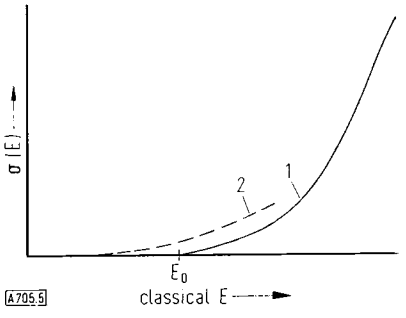

Fig. 5. Schematic illustration of the effect of quantum mechanical tunneling on the excitation function $\sigma(E)$.

A non-linearity of the Arrhenius plot showing a negative dependence of the Arrhenius activation energy on the temperature can thus be caused by tunneling [39,40,44,45]. However, such behavior can also occur if there is no tunneling but if the low energy portion of the cross-section for over-the-barrier reaction rises very slowly. Such behavior of the normal excitation function is by no means implausible, and has in fact been indicated by classical calculations [7] on potential barrier crossing in the system H + H_2. This implies that it is risky to draw firm conclusions as to the extent of tunneling on the sole basis of non-linearities in Arrhenius plots.

3.3. Activation Energy as a Measure of Threshold Energy

Figure 3 shows that for reactions having a high threshold compared to thermal energies, the activation energy will generally provide an accurate estimate of the threshold. Thus for a reaction with E_0 = 20 kcal/mole and $\sigma(E) \sim E^2$, the activation energy measured at room temperature will be E_{exp} = 21 kcal/mole.

However, the activation energy can differ quite significantly from the threshold and barrier [46] for low energy reactions. This has presented no real problem until recently, since truly fast reactions were not accessible by the more classical methods of chemical kinetics. Now, however, very rapid processes can be measured by thermal relaxation of systems following shock wave passage [47,48], flash photolysis [49,50] or temperature jump [51–53]. Line broadening techniques [54] also offer effective means of following fast reactions. With all these methods, the ratio kT/E_0 can be sufficiently large to make the activation energy an inaccurate measure of the threshold. Simple examples are atomic reactions [55–57], such as

[39] *K. J. Laidler* and *J. Polanyi*, Progr. Reaction Kinetics *3*, 1 (1965).

[40] *W. R. Schultz* and *D. J. LeRoy*, J. chem. Physics *42*, 3869 (1965).

[45] *H. S. Johnston*, Advances chem. Physics *3*, 131 (1961).

[46] It should be noted that the lowest pass across a potential energy surface, called the barrier or saddle point, is not necessarily equal to the threshold or lowest energy at which reaction can occur. Such a pass may not be kinematically accessible for a normal reaction trajectory across the multidimensional surface. Since the reaction paths usually show considerable curvature around the saddle point [14], the resulting centrifugal potential will cause the trajectory to follow a path of higher energy than the saddle point. This effect has only recently been given detailed consideration [58–60]. The results of *Karplus*, *Porter*, and *Sharma* [7a] show dramatically the extent of the effect of a curved reaction path. While their effective barrier height (the barrier height minus the zero point energy of the reactant molecule) for the hydrogen exchange reaction is 2.93 kcal, the reaction threshold, as obtained by classical trajectory calculations, lies at 5.69 kcal and above, depending on the rotational state of the reactant. Their Arrhenius Activation Energy is 7.435 kcal, in good agreement with experiment [40].

$H^{\bullet} + Br_2 \rightarrow HBr + Br^{\bullet}$ $E_{exp} = 900$ cal/mole [55]

$O^{\bullet} + H_2 \rightarrow OH^{\bullet} + H^{\bullet}$ $= 6000$ cal/mole [57]

$F^{\bullet} + H_2 \rightarrow HF + H^{\bullet}$ $= 1710$ cal/mole [56]

Theoretical calculations of the corresponding potential energy surfaces have been performed for a number of simple reactions[39] leading to the height of the energy barrier. Great care has to be taken, however, in comparing E_{exp} and the calculated barrier heights, and conversely in fitting an empirical surface to the activation energy of a kinetic experiment. Yet one frequently finds examples[39,61] in the literature where activation energies are erroneously equated to the barrier height or threshold.

This work was supported by the U.S. Atomic Energy Commission. We are grateful to R. LeRoy and C. Blakley for permitting us to use results of their calculations prior to publication and to Dr. D. R. Davis for pointing out several numerical errors in the original draft of this paper.

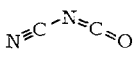
Reaction of Silver Cyanate with Cyanogen Chloride

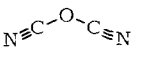
By *E. Mayer* and *K. Kleboth*[*]

Silver cyanate reacts quantitatively with an excess of cyanogen chloride at room temperature in a bomb tube to yield silver chloride and a yellow polymeric compound.



$$AgNCO + ClCN \rightarrow AgCl + (C_2N_2O)_x$$

The reaction proceeds very slowly at room temperature, and requires several weeks for completion; its course can readily be followed by IR spectroscopy. After the excess of ClCN has been pumped off the product, $(C_2N_2O)_x$, which is involatile at room temperature, remains behind together with AgCl.



The yellow product is highly sensitive to hydrolysis; on reaction with water evolution of gas occurs and cyanate is formed. The IR spectrum of the polymer contains bands at 2275 and 1770 cm^{-1} that are characteristic for the stretching vibrations of $C \equiv N$ and $C=O$.

When heated to about 140 °C at a pressure of 10^{-2} torr, about 80% of the polymer undergoes depolymerization. At low pressure, the gaseous degradation product can be fed through a vacuum apparatus and condensed in a cold trap with liquid nitrogen. If the condensate is warmed, polymerization sets in even at a low temperature and a yellow, involatile substance is again formed whose IR spectrum is identical with that of $(C_2N_2O)_x$.

The mass spectrum of the gas formed on depolymerization contains peaks corresponding to $C_2N_2O^+$ (m/e = 68, 100%; molecular ion) and CN_2^+ (m/e = 40, 75%). The structures most likely for a molecule having the composition C_2N_2O are *(1)* (cyanogen isocyanate) and *(2)* (dicyanogen oxide),

(1)

(2)

neither of which has previously been reported. The mass spectrum provides no conclusive evidence in favor of either one of these structures. However, the high intensity of the peak m/e = 40 (CN_2^+) is more consistent with structure *(1)*.

Owing to the high polymerizability of the gas no IR spectrum could be recorded at room temperature. The low-temperature IR spectrum (condensation of the gas onto KBr at −196 °C) contains bands at 2340 s, 2250 vs, 2208 s (sh), 1458 m, 1080 w, 869 m, 608 s, 561 s, 487 m, 470 w (sh), and 462 s cm^{-1}. Both the very strong band at 2250 cm^{-1} (ν_{as} NCO)[1] and the absence of intense bands in the C–O stretching region[2] indicate the presence of cyanogen isocyanate.

Comparison with chlorine isocyanate[3] shows that replacement of chlorine by cyanogen strongly increases the polymerizability of the system.

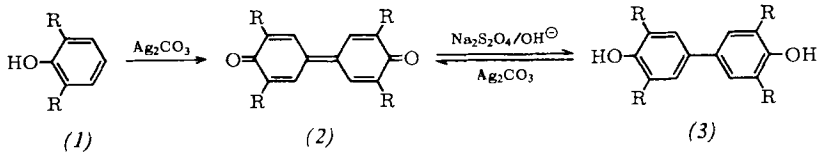
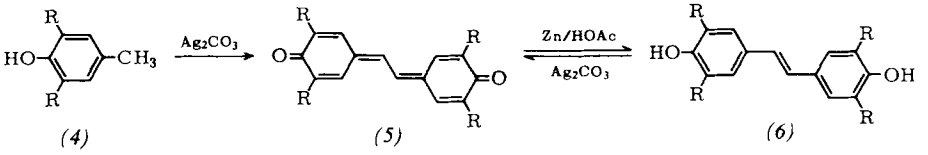
Selective Oxidative Coupling of Phenols by Silver Carbonate/Celite



By *V. Balogh*, *M. Fetizon*, and *M. Golfier*[*]

The reaction of phenols with most oxidizing agents[1] gives a complicated mixture of quinones, dimers, and polymers and therefore the yield of a desired product is frequently poor. In the case of 2.6-dimethylphenol, where coupling between the *para* positions is enhanced, the best yields of the tetramethyl-*p*-diphenoquinone are 55–75% when such oxidizing agents as chromium trioxide, peroxides, and ferric chloride[2] are used.



Silver carbonate precipitated on Celite is known to be a suitable reagent for selective oxidation, in a neutral medium, of very sensitive alcohols to aldehydes or ketones[3]; quantitative oxidation of hydroquinone to quinone has been carried out in the same manner.

We have now found that silver carbonate on a Celite support in refluxing benzene is also a very efficient reagent for the oxidative coupling of phenols *(1)* and *(4)* to give the *p*-diphenoquinones *(2)* and stilbenequinones *(5)*, respectively, in high yield (see Table).

The quinones *(2)* and *(5)* are easily reduced either by sodium hydrosulfite in dilute alkaline solution [*(2)*] or by zinc dust in acetic acid medium [*(5)*]. The resulting diphenols *(3)* and *(6)* can also be oxidized in high yield to *(2)* and *(5)*, respectively, by silver carbonate on celite. Attempts to oxidize the *pp'*-biphenyldiol to *p*-diphenoquinone were unsuccesful owing to the limited solubility of the starting material.

(5a)	(6a)	237–240	239–240 [6]	81
(5b)	(6b)	244–246	240–241 [4]	80

[a] The structure of the products is confirmed by satisfactory elemental analysis, IR, UV, and NMR measurements.

[b] These values are the highest ones reported in the literature.

Oxidation of 2,4,6-*tert*-butylphenol *(7b)* by silver carbonate/Celite in benzene under nitrogen gives a deep blue solution of the stable radical *(8b)*. In the presence of oxygen, *(8b)* affords the peroxide *(9b)* in high yield.

It is expected that the easy preparation of the reagent[3], the simplicity of the oxidizing procedure, and the high purity of the final products will lead to further applications of the silver carbonate/Celite reagent in oxidative coupling of phenols.

3,3',5,5'-Tetramethyldiphenoquinone (2a)

30 g of purified celite[**] is added to a mechanically stirred solution of 34 g (200 mmoles) of silver nitrate in 200 ml distilled water.

A solution of 30 g (105 mmoles) $Na_2CO_3 \cdot 10\,H_2O$ [or 21 g (210 mmoles) of $KHCO_3$] in 300 ml distilled water is then added slowly to the resulting homogeneous suspension. When the addition is complete, stirring is continued for a further 10 minutes. The yellow-green precipitate which is formed is then filtered off, washed with distilled water until neutral, and finally dried in a rotary evaporator over a period of several hours. The silver carbonate/celite reagent contains about 1 mmole Ag_2CO_3/0.57 g.

2,6-Dimethylphenol (1.2 g) was refluxed for 30 minutes in benzene (150 ml) with silver carbonate/Celite reagent (25.1 g). Removal of the solid phase and evaporation of benzene leaves 1.16 g (98%) of practically pure *(2a)* (m.p.217–218 °C). Recrystallization does not raise the melting point.

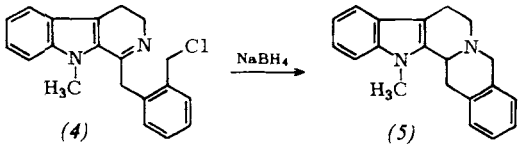
New Two-stage Synthesis of the Yohimbane Ring System[1]

By *W. Meise* and *F. Zymalkowski*[*]

We recently prepared a Berberis alkaloid, (±)-xylopinine, in a simple two-stage synthesis from homoveratrylamine and 6,7-dimethoxyisochroman-3-one[2]. The ring system of yohimbane can be built up in the same way.



N_b-Methyltryptamine *(1)* and isochroman-3-one *(2)* give a 92% yield of *N*-[2-(1-methyl-3-indolyl)ethyl]-*o*-(hydroxymethyl)phenylacetamide *(3)*, which affords 1-[2-(chloromethyl)benzyl]-3,4-dihydro-9-methyl-β-carboline *(4)* by a Bischler-Napieralski reaction with phosphorus oxychloride. If *(4)* is isolated by the usual methods, by-products are formed whose separation is difficult and involves losses. These

(1) (2) (3)

side reactions are, however, avoided if crude *(4)* is dissolved in methanol and treated directly with $NaBH_4$; under these conditions reduction of the C=N double bond and ring-closure to the benz[*g*]indolo[2,3-*a*]quinolizine derivative *(5)*

occur. The melting point of the base and its picrate, as well as the UV, IR, and NMR spectra, accord with expectation; distillation and purification by way of the picrate are unnecessary in this process [3,4].

(4) (5)

The synthesis can be applied also to tryptamine and to its derivatives with substituents in the benzene ring; use of substituted isochromanones gives a simple method of preparing alkaloids of yohimbane type.

15,16,17,18,19,20-Hexadehydro-1-methylyohimbane (5)

8.7 g (50 mmoles) of *(1)* and 8.9 g (60 mmoles) of *(2)* are boiled under reflux in 50 ml of ethanol for 18 h. 14.2 g of *(3)*, having m.p. 151–153 °C, crystallizes from the solution and a further 0.65 g (total yield 92%) is obtained on concentration of the mother-liquors. The product is recrystallized from ethanol, giving colorless needles of m.p. 153–154 °C.

3.22 g (10 mmoles) of *(3)* is boiled under reflux with 30 g of phosphorus oxychloride for 2 h, then cooled and treated with 50 ml of light petroleum; *(4)* separates as an oil. The upper layer is decanted and the crude *(4)* is digested five times with light petroleum (50-ml batches) and taken up at once in methanol (50 ml). This solution is treated with 5 g of $NaBH_4$ during 1.5 h, with stirring and cooling in ice, and then boiled for 0.5 h under reflux. Next the methanol is removed in a vacuum and the residue is suspended in 50 ml of water and shaken out with five portions, each 50 ml, of chloroform. Material recovered on evaporation of the organic phase solidified when kept. Rubbing this with 5 ml of methanol, collecting it, and washing it with a total of 10 ml of methanol gave 2.00 g of *(5)*, m.p. 133–135 °C; adding water to the filtrate gives an additional 0.25 g (total 78%). NMR ($CDCl_3$; TMS as internal standard): τ = 5.95 (2H on C-21, s); 6.30 ($N-CH_3$, s).

Formation of Benzindenes on Photolysis of Phenyl-substituted Diazocyclopentadienes in Alkynes[1]

By *H. Dürr* and *L. Schrader* [*]

Photolysis of substituted diazocyclopentadienes *(1)* in benzene [2] to give benzocycloheptenes or cyclopentacyclooctenes made it of interest to study the photolysis of *(1)* in alkynes. If phenyl-substituted diazo-compounds *(1)* are photolyzed in ethyl propiolate *(2a')* or in dimethyl acetylenedicarboxylate *(2b')*, the carbenes formed from *(1)* react in participation with the phenyl substituents. The benzindenes *(4)* are thus formed in moderate yield from 5-diazo-1,4-diphenyl-*(1a)* and 5-diazo-1,2,3,4-tetraphenyl-cyclopentadiene *(1b)* [3]. The structure of the benzindenes *(4)* is shown in particular by the spectra. For instance, the NMR spectrum of *(4aa')* shows the signals of the aromatic protons at δ = 7.4–9.3 ppm; the olefinic proton at C-2 appears as a triplet (δ = 6.79 ppm,

(1) (2) (3) (4)

Reactants		Products	R^1	R^2	R^3	M.p. (°C)	Yield (%)
(1a)	*(2a')*	*(4aa')*	H	H	$CO_2C_2H_5$	155–156	47
(1a)	*(2b')*	*(4ab')*	H	CO_2CH_3	CO_2CH_3	208–210	21
(1b)	*(2a')*	*(4ba')*	C_6H_5	H	$CO_2C_2H_5$	[a]	7
(1b)	*(2b')*	*(4bb')*	C_6H_5	CO_2CH_3	CO_2CH_3	204–206	40

[a] M.p. of an inseparable mixture of *(4ba')* (70%) and an unknown substance (30%) is 81–99 °C (proportions determined by NMR spectroscopy).

^3J = 2.0 Hz), the methylene protons on C-1 as a doublet (δ = 3.86 ppm) with the coupling constant ^3J = 2.0 Hz typical of indenes; the ester protons appear at 4.59 ppm (q, ^3J = 7.5 Hz) and at 1.46 ppm (t, ^3J = 7.5 Hz) in the ratio 10:1:2:2:3. The structure is further proved by degradation of *(4aa')* by hydrogenation, hydrolysis, and decarboxylation to the known 3-phenylbenz[*e*]indane [4].

On photolysis (Philips HPK 125-W high-pressure lamp) of *(1b)* in *(2b')*, the dimethyl 2,3,4,5-tetraphenyl-2,4-cyclopentadienespiro-2'-cyclopropene-2',3'-dicarboxylate *(3bb')* postulated as intermediate could be isolated by chromatography in $CHCl_3$ on silica gel as red crystals, m.p. 143–144 °C, in 31% yield. Typical for *(3bb')* was the NMR spectrum which indicated a highly symmetrical molecule with δ = 3.78 ppm (6H, s) and 6.9–7.3 ppm (20H, m) also the cyclopropene bands at 1865 cm^{-1} and the molecular ion at *m/e* = 510.

Ethyl 3-phenylbenz[e]*indene-5-carboxylate (4aa')*

2.00 g (8.2 mmoles) of *(1a)* [3] in 150 ml of *(2a')* were irradiated with a Philips HPK 125 Hg high-pressure lamp (Pyrex filter; 18–20 °C) until the theoretical amount of N_2 had been evolved (~1.5 h). When the ester *(2a)* was removed under vacuum, yellowish-brown crystals were precipitated. The whole residue was taken up in benzene and chromatographed on silica gel with benzene/light petroleum (1:1; b.p. 40–80 °C). 1.20 g (47%) of *(4aa')*, m.p. 155–156 °C, were obtained from the eluate after recrystallization from CH_2Cl_2/methanol IR spectrum (KBr): 1715 cm^{-1} (s, C=O), 1585 (m), 1495 (m), 1465 (m).

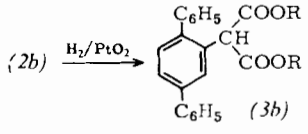
A New Benzocyclopropene Synthesis[1]

By *H. Dürr* and *L. Schrader* [*]

The photolysis of phenyl-substituted diazocyclopentadienes in dimethyl acetylenedicarboxylate affords benzindenes [2] *via* the corresponding spirocyclopropenes. Our interest lay in establishing whether photolysis of the spiro-3*H*-pyrazoles *(1a)–(1c)* [3], which are formed by 1,3-dipolar addition of

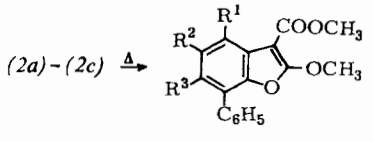


the diazo compound to acetylenedicarboxylate, also yields spirocyclopropenes (in analogy to the findings of *Ege*[4]) or their subsequent reaction products. We found, however, that irradiation of *(1a)–(1c)* in benzene leads to benzocyclopropenes *(2a)–(2c)*.

(1a)-(1c) *(2a)-(2c)*

	R^1	R^2	R^3	M.p. (°C)	Yield (%)
(a)	C_6H_5	C_6H_5	C_6H_5	175	85
(b)	C_6H_5	H	H	187	86
(c)	*o*-phenylene		C_6H_5	158	30

The NMR and IR spectra of *(2a)–(2c)* show few signals and bands respectively, and demonstrate the high degree of symmetry of the molecules. Thus the two methoxycarbonyl groups appear as a singlet at $\delta = 3.81$ ppm (6H) in the NMR spectrum of *(2a)*, and a multiplet due to the aromatic protons is observed at 6.8–7.4 ppm (20 H) (in $CDCl_3$ with TMS as internal reference). Catalytic hydrogenation of *(2b)* in acetic ester with PtO_2 as catalyst affords the terphenylylmalonic ester *(3b)* [$\delta = 3.37$ ppm (6H, s); 4.98 ppm (1H, s); 7.2–7.8 (12H, m); 7.94 (1H, d)]. This finding is in accord with observations by *Vogel et al.*[5], who obtained benzene derivatives in addition to cycloheptanes on catalytic hydrogenation of benzocyclopropene.



(2b) *(3b)*

Hydrolysis of the diesters *(2a)* proceeds without rearrangement to give the dicarboxylic acid *(4a)*, which can be esterified by treatment with diazomethane to *(2a)*. In quinoline, *(4a)* undergoes rearrangement, with decarboxylation, to tetraphenylcoumaranone *(5a)* (IR: ν(CO) 1820 cm^{-1}).

(4a) *(5a)*

(6a)-(6c)

If *(2a)–(2c)* are heated above their melting points, they isomerize to the substituted benzofurans *(6a)–(6c)* (cf. ref.[6]). All these reactions are typical of benzocyclopropenes.

Dimethyl 2,3,4,5-tetraphenylbenzocyclopropene-1,1-dicarboxylate (2a) and methyl 2-methoxy-4,5,6,7-tetraphenylbenzo[b]furan-3-carboxylate (6a)

Compound *(1a)* (1.40 g, 2.6 mmole) is dissolved in anhydrous benzene (150 ml). After passage of N_2 for 15 min, the solution is irradiated for 90 min (Philips HPK 125 W, $\lambda \geq 280$ nm, Pyrex filter). Removal of the solvent leaves a reddish oil which is taken up in methylene chloride and treated with methanol, whereupon colorless needles of *(2a)* (m.p. 175 °C, yield 1.13 g, 85%) are precipitated [ν(CO) = 1755 cm^{-1}; M^+ = 510, *m/e* = 479 ($M-OCH_3$), 451 ($M-COOCH_3$)][7].

If *(2a)* (1.00 g) is heated at a temperature slightly above its melting point the melt soon solidifies. Colorless needles of *(6a)* (m.p. 227 °C, yield 0.92 g, 92%) are precipitated from a methylene chloride/methanol solution of the solidified melt[7].

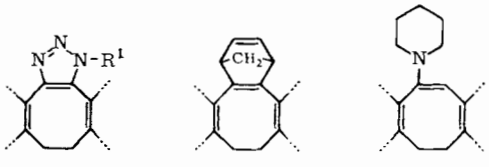
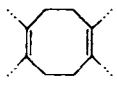
5,6-Didehydro-11,12-dihydrodibenzo[*a*,*e*]-cyclooctene

By *G. Seitz, L. Pohl*, and *R. Pohlke*[*]



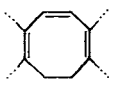
It was to be expected that, because of its greater classical ring strain, 5,6-didehydro-11,12-dihydrodibenzo[*a*,*e*]cyclooctene *(2a)* would be less stable and more reactive than cyclooctyne[1]. We have prepared *(2a)* and its 2,3,8,9-tetramethoxy derivative *(2b)* and have found that *(2b)* in particular is very stable. Whereas *(2a)* decomposes within a few days at room temperature, *(2b)* has been stored unchanged for three years. This compound *(2b)* is also not unusually reactive, in contrast to cyclooctyne which can be stored for only a short time. Azides, cyclopentadiene, and piperidine add as expected to afford *(3)*, *(4)*, and *(5)*, respectively, but heating is usually required to effect these reactions, whereas cyclooctyne reacts spontaneously with phenyl azide. Also, *(2a)* reacts only very slowly with phenyl azide at room temperature.

For preparation of *(2a)* and *(2b)* the 5,6-dibromo derivatives *(1a)* and *(1b)* were dehydrobrominated with a mixture of potassium *tert*-butoxide and 1-methylpiperazine. On hydrogenation of *(2b)* over a palladium catalyst, two moles of



(1) *(2)*

(a), R = H; *(b)*, R = OCH_3



(3), R^1 = C_6H_5, CH_3, $COOC_2H_5$, CH_2-$COOC_2H_5$ *(4)* *(5)*

hydrogen were absorbed with formation of the known 5,6,11,12-tetrahydro-2,3,8,9-tetramethoxydibenzo[*a*,*e*]cyclooctene *(6)*[2]. If the reaction is interrupted after absorption of one mole of hydrogen, one obtains 5,6-dihydro-2,3,8,9-tetramethoxydibenzo[*a*,*e*]cyclooctene *(7)*, which has also been prepared previously[2].

(6)

(7)

The triple bond in *(2)* has a bond angle that deviates from 180° and thus causes severe ring strain. As a result, the $-C\equiv C-$ stretching vibration that is strictly forbidden on symmetry grounds appears in the IR region, so that, *e.g.*, *(2b)* gives a weak band at 2155 cm^{-1}; that this is really the vibration of the triple bond is shown by a very strong band at 2153 cm^{-1} in the Raman spectrum; this is comparatively broad and lies at longer wavelengths than for tolane (2220 cm^{-1}), which again is an indication of the increase in ring strain due to the angled substituents [**].

The UV spectrum of diphenylacetylene type [3] [*(2b)*: λ_{max} = 332 nm, ε = 28000], which is much shifted to longer wave lengths, can be explained only on similar grounds.

Further proofs of the structure of *(2)* are provided by the NMR (Varian HA-100) and mass spectra (LKB 9000). The methylene protons of *(6)* and *(7)* give a singlet at δ = 2.95 and 3.09 ppm, respectively, and are thus magnetically equivalent, but for *(2b)* there are two multiplets at δ = 2.35 and 3.20 ppm with J_{gem} = 11 Hz. The reason for the large chemical shift between the geminal methylene protons is the molecular distortion on conversion of *(7)* into *(2b)*, whereby one proton is caused to lie in the plane of the neighboring benzene ring while the other is transferred to above the $-C\equiv C-$ bond.

The mass spectrum of *(2b)*, measured at 70 eV, indicates, in analogy to the chemical findings, an unusual stability of this compound, for it consists of only three groups of lines: M^+ at *m/e* = 324 with $\%\sum_{30}$ = 57, (M-15) with $\%\sum_{30}$ = 10, and M^{2+} with $\%\sum_{30}$ = 7. The molecular mass and the fragmentation support the structure proposed.

5,6-Didehydro-11,12-dihydrodibenzo[a,e]cyclooctene (2b)

Bromine (16 g, 0.1 mole) is added dropwise, with stirring, to 5,6-dihydro-2,3,8,9-tetramethoxydibenzo[*a,e*]cyclooctene *(7)* (32.6 g, 0.1 mole) [2] in benzene (325 ml). The solution becomes almost colorless within a short time. The benzene is distilled off in a vacuum, the residue is dissolved in ethyl acetate, and the solution is filtered from a small amount of a red decomposition product. Crystallization in the cold affords *(1b)* (42.7 g, 88%), m.p. 173 °C.

A solution of potassium (15.6 g, 0.4 mole) in *tert*-butyl alcohol (400 ml) is treated with 1-methylpiperazine (150 g) and then diluted with anhydrous ether (250 ml). Compound *(1b)* (48.6 g, 0.1 mole) is then added and the whole is stirred for 3 days at room temperature. The mixture is then evaporated to dryness without removal of the precipitate and the residue is freed from potassium bromide by repeated treatment with water and filtration. The residue is dried in a vacuum and on recrystallization from acetonitrile affords colorless crystals of *(2b)* 21.2 g, 65%), m.p. 221 °C.

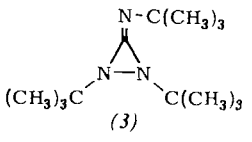
A Diaziridine Imine



By *H. Quast* and *Edeltraud Schmitt* [*]

Although increasing attention [2, 3] has been paid to aziridinones and diaziridinones since the first discovery of an α-lactam [1], the analogous imines have so far been unknown [4]. Compounds of this type would be interesting in respect of their behavior on thermolysis [2, 5] and as possible intermediates in the rearrangement of *N*-haloguanidines to semicarbazide derivatives [6, 6a]. We now report the first synthesis of a diaziridine imine and some of its properties.

In the few cases studied, the action of hypochlorite on *N,N',N''*-trisubstituted guanidines has given only very unstable *N*-haloguanidines [7]. However, from two moles of *N,N',N''*-tri-*tert*-butylguanidine *(1)* [8] and one mole of *tert*-butyl hypochlorite in carbon tetrachloride or *n*-pentane we obtained smoothly (80–85% yield) the diaziridine imine *(3)* alongside one mole of *(1)* · HCl.

(1), X = H
(2), X = Cl

(3)

The *N*-chloroguanidine *(2)* must be assumed to be an intermediate, undergoing ring closure in an intramolecular S_N reaction under the influence of a second molecule of the strong base *(1)* [9]. A corresponding mode of reaction has been proved for the formation of 1,2-di-*tert*-butyldiaziridinone [3]. The imine *(3)* can be prepared even more conveniently from *N,N',N''*-tri-*tert*-butylguanidinium perchlorate, *(1)* · $HClO_4$ and *tert*-butyl hypochlorite in *tert*-butyl alcohol/carbon tetrachloride in the presence of an excess of potassium *tert*-butoxide.

The structure of *(3)* is proved by elemental analysis and molecular-weight determination (calc. 225.4; found 229, osmometrically in benzene) and also by the IR and NMR spectra. The IR spectrum in CCl_4 contains no trace of NH bands [*(1)*: 3465 cm^{-1} (NH)]; the C=N vibration [*(1)*: 1650 cm^{-1}] is, as expected [2, 3], at very high frequency (1790 cm^{-1}). The UV spectrum shows no maximum above 200 nm, only a slightly developed shoulder at 226 nm (log ε = 2.95, in *n*-hexane).

The NMR spectrum contains three singlets of equal intensity (+10 °C, CCl_4, δ = 1.09, 1.17, 1.25 ppm). The two upfield signals are temperature-dependent; they broaden as the temperature is raised and coalesce at 50 °C ($\Delta\nu$ = 5.0 Hz, $\Delta G_c^{\ddagger}$ = 17.4 kcal/mole); at 100 °C there are two sharp singlets in the intensity ratio 2:1. This behavior can be ascribed to inversion at the imino-nitrogen atom [10].

The imine *(3)* is thermally less stable than the corresponding carbonyl compound; whereas the latter survives for 2 h at 175 °C, *(3)* decomposes wholly within one hour at 150 °C, giving 2,2'-azoisobutane and *tert*-butyl isocyanide which can be isolated in more than 80% yield. This reaction strongly supports structure *(3)*; it is paralleled by the decomposition of imino α-lactones into carbonyl compounds and isocyanides [2], and by the thermolysis of several three-membered ring compounds [11] in which an olefin and CO, N_2, N_2O, or SO_2 are formed.

N-(1,2-Di-tert-butyldiaziridin-3-ylidene)-tert-butylamine (3)

tert-Butyl hypochlorite (7.6 g, 70 mmoles) is added to a solution of potassium (4.1 g, 0.105 mole) and *(1)* · $HClO_4$ (11.5 g, 35 mmoles) in 1:1 *tert*-butyl alcohol/CCl_4 (240 ml) at −30 °C under nitrogen. After being stirred for 4 h at −30 ° to −8 °C with exclusion of light, the solution is washed with ice-water, dried over K_2CO_3, and evaporated under reduced

pressure; vacuum distillation of the residue gives a colorless oil, b.p. 29–31 °C/0.005 torr, in 77–79% yield (6.07–6.24 g).

Reversible Valence Isomerization of Diaziridine Imines

By *H. Quast* and *Edeltraud Schmitt* [*]

The reversible thermal isomerization of the methylenecyclopropane system *(1a)*⇄*(1b)* [1] has been thoroughly studied in respect of its kinetics [2] and stereochemistry [3] because of the theoretically interesting diradical intermediates involved. An analogous irreversible rearrangement in the heterocyclic series was postulated [4] as one step *(2a)* → *(2b)* in the complex reaction of *cis*-3-chloro-3-methyl-1,2-diphenylaziridine with potassium *tert*-butoxide in boiling *tert*-butyl alcohol and as an explanation for the formation of carbonyl compounds and isocyanides in the pyrolysis of α-lactams *(4a)* [5]. However, isomerization of *(3a)* (at 190 °C) [4] or *(6a)* (at 175 °C) [6] could not be observed. The valence isomerization of allene oxides to cyclopropanones, *(5a)* → *(5b)*, repeatedly discussed, has only recently been proved [7].

The first proof has now been found for the equilibrium *(a)* ⇄ *(b)* of a diaziridine compound [7a]. The diaziridine imine *(7)* is, however, not suitable for this purpose, since

(a) *(b)*

	X	Y	Z
(1)	CR_2	CR_2	CR_2
(2)	CH_2	CHC_6H_5	$N\text{-}C_6H_5$
(3)	CH_2	CH_2	$N\text{-}C_2H_5$
(4)	O	CR_2	N-R
(5)	CR_2	CR_2	O
(6)	O	$N\text{-}C(CH_3)_3$	$N\text{-}C(CH_3)_3$
(7)	$N\text{-}C(CH_3)_3$	$N\text{-}C(CH_3)_3$	$N\text{-}C(CH_3)_3$

there is no line broadening in the NMR spectrum at 150 °C (signal width < 1 Hz, $k < 3$ sec^{-1}, $\Delta G^{\ddagger} > 24.1$ kcal/mole) and because thermal decomposition [8] prevents use of higher temperatures. To demonstrate a slow rearrangement we synthesized diaziridine imines in which one nitrogen atom was substituted differently from the others.

From *N,N'*-di-*tert*-butyl-*N''*-methylguanidine and *tert*-butyl hypochlorite we obtained (cf. ref. [8]) an 83% yield of a mixture of the isomeric diaziridine imines *(8a)* and *(8b)* in the ratio 3:2, and at −20 °C part of the *(8a)* crystallized (yield 31%). The structures were assigned on the basis of the differing IR and NMR spectra (neat liquids). *(8a)*: colorless crystals, m.p. 18–19.5 °C (from *n*-pentane), which according to the NMR spectrum contain 0.3% of *(8b)*; NMR, 1.10 (9H, s), 1.13 (9H, s), 3.03 (3H, s); IR, 1810 cm^{-1} with a shoulder at 1835 and a weak side band at 1925 cm^{-1} (C=N), and a band at 1403 cm^{-1}, but no absorption at 1070–1190 cm^{-1} in contrast to *(8b)*.

Repeated distillation of the residual oil at 0.2 torr through a 75-cm Normag spinning-band column enriched the *(8b)* content to 82%. *(8b)*: colorless oil, b.p. 14–15 °C/0.2 torr; NMR, 1.09 (9H, s), 1.24 (9H, s), 2.76 (3H, s), and signals corresponding to the presence of 18% of *(8a)*; IR, 1805 cm^{-1} with weak side bands at 1778, 1890, and 1920 cm^{-1} (C=N), bands at 928, 1130, and 1158 cm^{-1}, but no absorption at 1390–1440 cm^{-1} in contrast to *(8a)*.

Whereas *(8a)* and *(8b)* remain unchanged at −20 °C, at 60–90 °C use of either *(8a)* or *(8b)* leads to an equilibrium mixture of the two in which the IR and NMR spectra show less than 2% of isocyanide (produced by thermal decomposition [8]) to be present. The rate of equilibration was followed by NMR spectroscopy of undiluted, degassed samples.

(8b) *(8a)* *(9)*

Table 1. Equilibrium and rate constants for the isomerization *(8a)* ⇄ *(8b)*.

Starting cpd.	Temp. (±0.1 °C)	$K = \frac{k_b}{k_a}$ (±0.1)	$10^5 \times (k_a + k_b)$ (sec^{-1})
(8b)	60.0	9.75	1.335 ± 0.005
(8a)	70.0	8.35	4.65 ± 0.12
(8b)	70.0	8.35	4.685 ± 0.028
(8b)	80.0	7.85	15.08 ± 0.06
(8b)	90.0	7.20	44.03 ± 0.07

From Table 1 can be calculated: $\Delta H = -2.3 \pm 0.3$ kcal/mole; $\Delta S = -1.1 \pm 0.4$ cal degree^{-1} mole^{-1}; and the activation parameters $\Delta H_a^{\ddagger} = 29.4 \pm 0.4$ kcal/mole, $\Delta S_a^{\ddagger} = 2.6 \pm 1.2$ cal degree^{-1} mole^{-1}, and $\Delta H_b^{\ddagger} = 27.1 \pm 0.2$ kcal/mole, $\Delta S_b^{\ddagger} = 0.1 \pm 0.5$ cal degree^{-1} mole^{-1}.

A possible intermediate in the rearrangement is the planar molecule *(9)*, which is comparable with trimethylenemethane[2,3,9] and would be formed by disrotatory opening of the three-membered ring[10] if the two substituents in the ring are *trans* to one another[11]. We are currently investigating some of the preparative and mechanistic consequences of this first reversible valence isomerization of a hetero analog of methylenecyclopropane.

Bis(trimethylsilyl) Monoperoxosulfate[1]

By *A. Blaschette, B. Bressel*, and *U. Wannagat*[*]

The only derivatives of Caro's acid (monoperoxosulfuric acid) described so far are the alkali-metal salts M^IHSO_5. Attempts to prepare other derivatives from the free acid failed because of its tendency to decompose and its marked oxidizing action.

We have obtained the first ester of monoperoxosulfuric acid, namely, bis(trimethylsilyl) monoperoxosulfate *(2)*, by a quantitative, exothermic insertion reaction[2] of bis(trimethylsilyl) peroxide *(1)* with an equimolar amount of sulfur trioxide:

$$\underset{(1)}{(CH_3)_3Si\text{-}O\text{-}O\text{-}Si(CH_3)_3} + SO_3 \xrightarrow{CH_2Cl_2,\ -30^\circ C}$$

$$(CH_3)_3Si\text{-}\overset{SO_3}{\overset{\uparrow}{O}}\text{-}O\text{-}Si(CH_3)_3 \rightarrow (CH_3)_3Si\text{-}O\text{-}\overset{O}{\overset{\|}{S}}\text{-}O\text{-}O\text{-}Si(CH_3)_3$$
$$\underset{(2a)}{\qquad\qquad} \qquad\qquad \underset{O}{\qquad\qquad} \underset{(2)}{\qquad}$$

The ester *(2)* (M.wt. 258; cryoscopic in CCl_4: 243) is a water-clear liquid that is very viscous at −30 °C, solidifies to a glass below −80 °C, and distills only with decomposition. It is readily soluble in CH_2Cl_2, CCl_4, and diethyl ether, sparingly soluble in light petroleum, and reacts with benzene and cyclohexane with development of a brown color. Warming pure *(2)* to room temperature soon leads to violent deflagration with evolution of clouds of SO_3. In dilute CH_2Cl_2 solution the ester decomposes at 20 °C in 1–2 days with rearrangement of the $(CH_3)_3SiOO$ to a $(CH_3)_2(CH_3O)SiO$ group[3].

The ^{1}H-NMR spectrum of *(2)* at 32 °C consists of a single signal at $\tau = 9.60$, which is split below −20 °C into two lines of approximately equal intensity at $\tau = 9.58$ and 9.72 (at −50 °C) (measured in and against CH_2Cl_2, τ values converted to TMS as standard). This behavior indicates a rapid exchange between the two trimethylsilyl groups above −20 °C. *(2)* is a very strong oxidizing agent. When it is dropped on to paper or on to cotton soaked in light petroleum it causes inflammation. It reacts violently with solid NaCl or KI with liberation of Cl_2 or I_2 and formation of hexamethyldisiloxane *(3)* and alkali-metal sulfate. It is reduced by gaseous HCl in CH_2Cl_2 at −20 °C with formation of Cl_2, *(3)*, and H_2SO_4. Pyridine is oxidized instantaneously and quantitatively to its *N*-oxide by *(2)* in CH_2Cl_2 at −30 °C; pyridine · SO_3, which would be expected to be formed if the adduct *(2a)* were present, is not formed in this reaction. *(1)* reacts under the above conditions neither with solid NaCl nor with pyridine, and with gaseous HCl gives Cl_2, *(3)*, and H_2O only slowly. On cautious hydrolysis of *(2)* with a little water there is formed, together with *(3)*, an aqueous phase that gives the specific reactions of Caro's acid (instantaneous oxidation of I^- to I_2, oxidation of aniline to nitroso- and nitro-benzene and of acetone to 3,3,6,6-tetramethyl-1,2,4,5-tetroxane[4]). Gaseous NH_3 ammonolyzes *(2)* in CH_2Cl_2 at −30 °C instaneously and exothermally to hexamethyldisilazane and unstable NH_4HSO_5.

Experimental:

SO_3 (1.601 g, 20.0 mmoles) in CH_2Cl_2 (20 ml) is added very slowly with continuous stirring and rigid exclusion of moisture to the peroxide *(1)* (3.568 g, 20.0 mmoles) in very pure CH_2Cl_2 (30 ml) at −30 °C. The mixture is then stirred for a further 30 min at the same temperature, whereafter the solvent is removed cautiously by means of an oil-pump. *(2)* remains quantitatively as residue.

Mono-, Bis-, and Tris(phenylseleno)methyllithium (Selenium-Stabilized Carbanions)

By *D. Seebach* and *N. Peleties*[*]

Unlike anisole[1], thioanisole is metalated in the side chain by butyl lithium[2] whereas selenoanisole is cleaved by this reagent to phenyllithium and methyl butyl selenide [eq.

(a)][2a]. The reaction does not throw any light on the stability of the hitherto unknown α-seleno carbanions[3].

$$C_6H_5\text{–}Se\text{–}CH_3 + C_4H_9Li \rightarrow C_6H_5Li + CH_3\text{–}Se\text{–}C_4H_9 \quad (a)$$

We have found that the lability of the Se–C bond can be exploited for the preparation of lithium derivatives of such anions. According to eq. (b), reaction of bis(phenylseleno)methane *(1)* (prepared in the same manner as the sulfur compound[2b]) and *n*-butyllithium in THF affords phenylselenomethyllithium *(2)*[5]. This was established by reaction with D_2O (according to NMR analysis > 95% $C_6H_5SeCH_2D$), isolation of the butyl phenyl selenide[6], and preparation of the benzophenone adduct *(3)*.

$$(C_6H_5Se)_2CH_2 \;(1) + C_4H_9Li \xrightarrow[-78\,^\circ C]{1.5\ h}$$

$$C_6H_5\text{-}Se\text{-}CH_2Li \;(2) + C_6H_5\text{-}Se\text{-}C_4H_9 \quad (b)$$

$$\downarrow$$

$$C_6H_5\text{-}Se\text{-}CH_2\text{-}C(OH)(C_6H_5)_2 \;(3)$$

Reaction of tris(phenylseleno)methane *(6)* (prepared in a similar way to the sulfur compound[4a]) with butyllithium (−40 to −100 °C), however, always leads to a mixture of the lithium derivatives *(4)* and *(7)*. The pure compounds *(4)* and *(7)* are formed by metalation of bis- and tris(phenylseleno)-methane, *(1)* and *(6)* respectively, with lithium diisobutylamide according to equations (c) and (d).

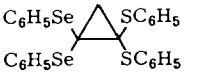
$$(1)\ (C_6H_5Se)_2CH_2 + LiN[CH_2\text{-}CH(CH_3)_2]_2 \xrightarrow[-78\,^\circ C]{1\ h} (C_6H_5Se)_2CHLi\ (4) \quad (c)$$

$$(4) \xrightarrow[(C_6H_5)_2C=O]{14\ h,\ -20\,^\circ C} (5)\ (C_6H_5Se)_2CH\text{-}C(OH)(C_6H_5)_2$$

$$(C_6H_5Se)_3CH\ (6) + LiN[CH_2\text{-}CH(CH_3)_2]_2 \quad (d)$$

$$\xrightarrow[-78\,^\circ C]{1\ h} (C_6H_5Se)_3CLi\ (7) \xrightarrow[-78\,^\circ C]{1\ h} (8)\ (C_6H_5Se)_4C + C_4H_9Li \quad (e)$$

As shown in eq. (e) loss of a C_6H_5Se group[5] from the orthocarbonic acid derivative *(8)* [prepared from *(7)* and $(C_6H_5Se)_2$] yields amine-free solutions of the metalated triselenoorthoformic ester *(7)*. The presence of the lithium compounds *(4)* and *(7)* is proved, not only by hydrolysis with D_2O (> 95% deuteration in each case), but also by the formation of the derivatives *(5)* and *(8)–(12)*. Yields and characteristic data for the new selenium compounds are given in the Table.



The colorless solutions of mono- *(2)* and bis(phenylseleno)-methyllithium *(4)* are stable at temperatures up to 0 °C, whereas the greenish-yellow solutions of tris(phenylseleno)-methyllithium *(7)* gradually become discolored at temperatures in excess of −20 °C.

Preparation of 1,1-diphenyl-2-phenylselenoethanol (3) via phenylselenomethyllithium (2):

A solution of butyllithium (5.0 mmole, 2.3 M in *n*-hexane) is added to a stirred solution of *(1)* (1.63 g, 5.0 mmole) in THF (30 ml) at −78 °C. After 1.5 h, a solution of benzophenone (0.90 g, 5.0 mmole) in *n*-hexane (15 ml) is added all at once. The reaction vessel is sealed under argon and kept at −35 °C for 14 h and then at +20 °C for 1 h. The contents are poured into water and the resulting product taken up in $CHCl_3$. Drying over K_2CO_3 and removing the solvent leaves an oil, which on treatment with pentane and on cooling to 0 °C affords colorless crystals of *(3)* (yield 1.50 g, 85%; m.p. 88.9–89.1 °C, needles precipitated from $CHCl_3$ with pentane).

$(C_6H_5Se)_2C{=}P(C_6H_5)_3$ *(9)* $\qquad$ $(C_6H_5Se)_3C\text{-}CH_3$ *(10)*

$(C_6H_5Se)_3C\text{-}CHOH\text{-}C_6H_5$ *(11)*

tert-Butyl-α-hydroxyalkyldiazenes from *tert*-Butyldiazenes

By *S. Hünig* and *G. Büttner*[*]

Although phenyldiazene[1,3], a compound characterized by its extreme oxygen-sensitivity, and *tert*-butyldiazene *(4)*[2] can be prepared as short-lived species in highly dilute solutions, attempts to intercept them in a manner such that the original diazene structure is retained[1c] have hitherto been unsuccessful. We have now found that *tert*-butyldiazene *(4)*,

formed according to routes A or B, can be intercepted in high yields by aliphatic aldehydes *(5)* in aqueous-alkaline media without any need for exclusion of oxygen.

The resulting *tert*-butyl-α-hydroxyalkyldiazenes *(6)* [4–6] are distillable, yellow liquids [7] which can be stored, but which slowly rearrange to the isomeric hydrazides [*(3)*-HCl] [5] and partly decompose to give polymeric products. This rearrangement is proton-catalyzed and on addition of HCl gas in ether leads quantitatively to the hydrochlorides *(3)*. Reaction with acetic anhydride in pyridine gives the esters *(2)* (cf. ref. [5]). The trans configuration of *(2)* and *(6)* follows from the low intensity of the n-π* band [8]. The OH band at 3390–3370 cm^{-1} (CS_2), which remains unchanged when the sample is diluted, confirms the presence of the intramolecular hydrogen bond in *(6)*.

	R^1	*(6)* λ_{max} (nm)	ε	*(2)* λ_{max} (nm)	ε
		[a]		[a]	
(a)	H	340	18.8	359	16.3
(b)	CH_3	345	18.9	360	16.3
(c)	$CH_2CH_2CH_3$	343	19.6	363	17.2
(d)	$CH(CH_3)_2$	346	20.8	360	19.3

[a] In cyclohexane.

Route A: The characteristic absorption band of *(1)* at 373 nm disappears at pH 7–8. Subsequent addition of formaldehyde *(5a)* brings about no change since the *tert*-butyldiazene *(4)* formed transiently has already decomposed. However, if *(1)* is decomposed in the presence of *(5a)*, the spectrum of *(6a)* is immediately established. The adducts *(6a)*–*(6d)* are isolable on a preparative scale.

Route B: The alkoxydiazenium salts *(10)* [7,9] prepared from the nitrosamines [7] and trialkyloxonium fluoroborates (R^2 = CH_3, C_2H_5) are deprotonated by bases to the zwitterions *(7)* [10] which decompose with addition of water (or hydroxide ions), probably *via (8)*, to give *(4)* and *(5)* (as well as HOR^2). *(4)* and *(5)* combine immediately to give the adduct *(6)*. UV-spectroscopic measurements during the reaction of, *e.g.*, *(10a)* at pH 10 show that the band due to *(6a)* does not appear until ≈15% of *(10a)* has decomposed. This oxygen-independent induction period disappears completely if the solution contains an excess of formaldehyde right from the outset. It may thus be seen that the R^1–CH group in *(7)* does not migrate intramolecularly, *e.g. via (9)*, but that *(6)* results from a bimolecular reaction of *(4)* and *(5)*. Formation of *(6)* is reversible. If *(6c)* is treated for 1 h with 1.2 equivalents of formaldehyde at pH 10, then 20% of *(6a)* is formed (determined by gas chromatography). It would therefore appear that formation of *(6)* proceeds *via* the anion of *(4)*, *i.e.* in a manner analogous to the cyanohydrin reaction. The presence of formaldehyde during the reaction *(10c)* → *(6c)* also leads to the formation of *(6a)*.

The compounds *(13)* and *(16)* have been detected in solution (UV, NMR) as products of the reaction of *(11)* [11], *(14a)* [5], and *(14b)* [7,12] with bases, thus showing that both alkyldiazenes having an α-methylene group and those having the *cis* configuration can be intercepted by aldehydes. *(16)* is, however, much less stable than 3,5,5-trimethyl-1-pyrazolin-3-ol (described in ref. [6]) which carries no hydrogen atoms in the immediate vicinity of the functional group.

(a), R = H
(b), R = CH_3

tert-Butylazo-2-methyl-1-propanol (tert-butyl-α-hydroxypropyldiazene) (6d)

Route A:

Methyl *tert*-butyldiazenecarboxylate (2.16 g, 15 mmole) is hydrolyzed with KOH (1.23 g, 22 mmole) in H_2O (10 ml), first at room temperature and then at 50–60 °C. The homogeneous solution is concentrated by evaporation under reduced pressure and the voluminous yellow precipitate *(1)* is added portionwise to *(5d)* (2.16 g, 30 mmole) in phosphate buffer solution (20 ml). During the ensuing reaction (evolution of CO_2), the pH is kept at 7–8 by addition of more

phosphate buffer. The reaction mixture is then extracted with three 25-ml portions of ether. Distillation of the residue left by the dried ether solution at 20–22 °C/0.05 torr gives 0.900 g (38%) of *(6d)* as a pale yellow liquid.

Route B:

5.2 g (20 mmole) of *(10d)* ($R^2 = CH_3$) in 50 ml H_2O is added dropwise with stirring to 2.07 g (15 mmol) of K_2CO_3 in 10 ml of H_2O at 40–45 °C. After one hour the filtered solution is extracted with four 40-ml portions of ether. Working up as for route A gives 1.722 g (55%) of a yellow liquid that is identical with *(6d)* prepared *via* route A.

New Stationary Phase for Chromatography

By *I. Halász* and *I. Sebestian* [*]

The esterification of polysilicic acids with alcohols has already been described [1]. *Rossi et al.* [2] resolved C_1 to C_4 hydrocarbons in gas chromatographic columns packed with silica esterified with benzyl or lauryl alcohol. This separation, however, was not faster than those on other stationary phases.

We have esterified the porous glass "Porasil C" [2a] (having silanol groups on its surface, specific surface area 50 m^2/g, pore radius 100–200 Å) with 3-hydroxypropionitrile at 180 °C. The esterified product was extracted with methylene chloride and dried.

The gas and liquid chromatographic equipment used in these experiments was similar to that used in previous studies [3]. The rapid gas chromatographic separation of C_1 to C_3 hydrocarbons is shown in Fig. 1a. The vapor pressure of the stationary phase is extremely small; the noise level of the baseline could be neglected although the sample weighed only 10^{-8} g. This is of considerable importance if quantitative analysis is desired. The rate of separation achieved in this packed column is extremely high: 42 theoretical (n) or 23 effective plates (N), are generated per second. Values of only 0.1 to 2 effective plates per second are obtained with conventional packed columns [4].

Other hydrocarbons were resolved in the same column as shown in Fig. 1b. The peak due to the polar ether is symmetrical although the partition ratio is unusually high ($k' = 12.4$).

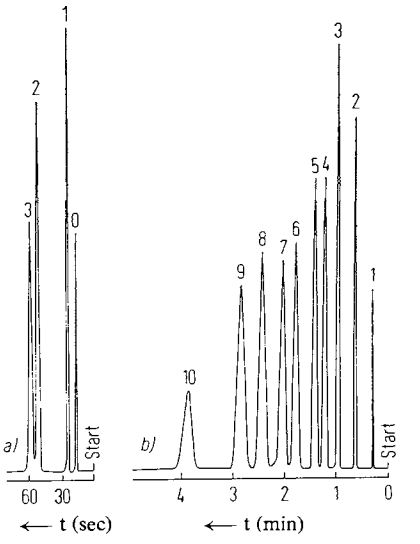

Fig. 1a) Gas chromatographic separation in a packed column. Stationary phase: Porasil C/3-hydroxypropionitrile (conditions not optimized). 0 = methane, 1 = ethane, 2 = propane, 3 = propene. T = 28 °C. Internal diameter of the column (i.d.): 2 mm; column length (L): 1 m; sieve fraction (d_p): 75–100 μm; carrier gas: N_2; time averaged linear velocity of the carrier gas ($\bar{u}$): 6.3 cm/sec; sample weight (s): 1–100 μg.

Fig. 1. b) 1 = methane, 2 = *n*-pentane, 3 = cyclohexane, 4 = 2,4-dimethylpentane, 5 = methylcyclohexane, 6 = 2,2,4-trimethylpentane, 7 = 2,3,4-trimethylpentane, 8 = *n*-octane, 9 = 2,2,5-trimethylhexane, 10 = diethylether.

Column and carrier gas as in Fig. 1a. Δp = 5.5 atm; $\bar{u}$ = 5.7 cm/sec; T = 121 °C.

Characteristic data for propene (Fig. 1a), cyclohexane, and ether (Fig. 1b).

partition ratio k'	2.9	2.27	12.4
number of theoretical plates n	2500	1950	2350
number of effective plates N	1380	950	2020
n/t (sec^{-1})	42	34	10.2
N/t (sec^{-1})	23	16.5	8.8

A liquid chromatographic separation on the same stationary phase with a narrower sieve fraction is illustrated in Fig. 2. Almost one effective plate per second was generated for *N,N*-dimethylaniline, this rate being comparable with values achieved in routine gas chromatographic separations.

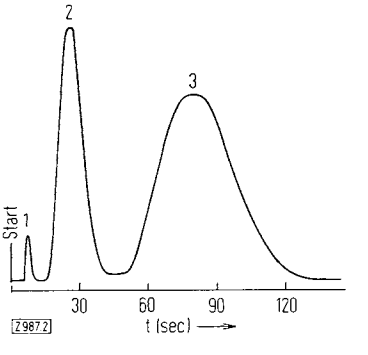

Fig. 2. Liquid chromatographic separation at 20 °C. Stationary phase: Porasil C/3-hydroxypropionitrile (conditions not optimized). 1 = toluene ($k' = 0$); 2 = *N,N*-dimethylaniline ($k' = 2.5$); 3 = 2,6-xylidine ($k' = 9.6$).

i.d. = 3 mm; L = 40 cm; d_p = 60–75 μm; mobile phase: *n*-heptane (liquid); Δp = 29 atm; u = 5 cm/sec; s = 40 μg; UV detector (cell volume 1 μl).

Characteristic data for *N,N*-dimethylaniline and 2,6-xylidine.

height equivalent to an theoretical plate h (mm)	12	13
hight equivalent to an effective plate H (mm)	6.2	11
n/t (sec^{-1})	1.2	0.36
N/t (sec^{-1})	0.9	0.32

The organic compounds of the stationary phase described above are orientated like bristles on the surface of the inorganic compounds[1,5]. Consequently the speed of the mass transfer is considerably higher here than in liquid stationary phases.

Further gas chromatographic experiments with columns packed with such "brushes" have shown, that the height equivalent to a theoretical plate (h) is independent of: (i) the nature of the sample (paraffins, aromatics, ether, esters, chlorinated hydrocarbons have been injected); (ii) the temperature of analysis (70–140 °C); (iii) the partition ratio ($k' = 1$–140); and (iv) the sample size (10^{-8} to 10^{-3} g in a column with internal diameter of 2 mm).

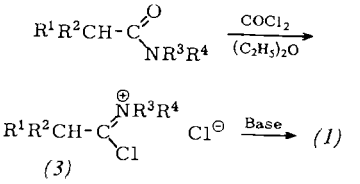
Alkyl and Aryl α-Chloro Enamines



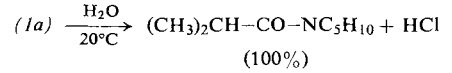
By *L. Ghosez, B. Haveaux*, and *H. G. Viehe*[*][1]

To the best of our knowledge α-chloroenamines *(1)* without stabilizing electronegative β-substituents[2] such as fluorine, chlorine, or carbonyl are hardly known. A brief report[3] on two representatives of this class has remained unconfirmed since 1929.

(1) *(2)*

(1) or *(2)* have been postulated as intermediates in the synthesis of ynamines from α-halogeno iminium salts[4] and in the reaction of ynamines with protonic acids[5], alkylating agents[5], or ketenes[6]. We have now prepared alkyl- or aryl-substituted α-chloro enamines by controlled dehydrochlorination of the readily available α-chloro iminium chlorides[7] *(3)*.

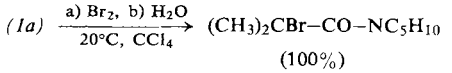
(3)



(1)	R^1	R^2	R^3	R^4	Base [a]	Temp. (°C)	Yield (%)	B.p. (°C/torr)
(a)	CH_3	CH_3	$-(CH_2)_5-$		A	20	70	95–100/15
(a)	CH_3	CH_3	$-(CH_2)_5-$		B	20	62	95–100/15
(b)	CH_3	H	$-(CH_2)_5-$		A	20	57	85–90/14
(c)	C_2H_5	H	$-(CH_2)_5-$		A	20	57	98/8
(d)	C_6H_5	H	C_2H_5	C_2H_5	A	−20	60–70 [b]	– [c]
(d)	C_6H_5	H	C_2H_5	C_2H_5	B	20	60–70 [b]	– [c]
(e)	C_6H_5	H	$-(CH_2)_5-$		A	−20	60–70 [b]	– [c]
(f)	C_6H_5	H	$-(CH_2)_2O(CH_2)_2-$		A	−20	60–70 [b]	– [c]

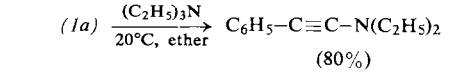
[a] A = triethylamine, B = pyridine.
[b] Yields 60–70%; determined by titration with bromine or with NaOH after hydrolysis.
[c] Distillation of *(1d)*–*(1f)* gave the corresponding cyclobutenecyanines *(5)*, possibly *via* the ynamines.

Physical and spectroscopic data for the α-chloro enamines exclude the presence of a substantial amount of the polar form at equilibrium. However, the compounds show the expected versatile behavior as exemplified in the following reactions:

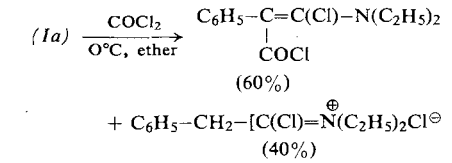


1. Addition

1.1. Hydrolysis:



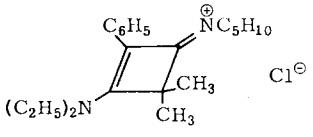
1.2. Formation of α-chloro iminium salts:



2. Eliminations yielding ynamines. α-Chloro enamines *(1)* may produce ynamines as well as their corresponding α-chloro iminium chlorides by elimination of hydrogen chloride. The stepwise formation of phenylynamine with triethylamine at room temperature shows the unusually mild conditions of this acetylene synthesis:

3. Acylation. α-Chloro enamines are less readily acylated than enamines or ynamines; even the relatively more reactive β-monosubstituted α-chloro enamines condense only with the most powerful acylating agents. This indicates that the α-chlorine substituent effectively reduces the nucleophilicity of the β-carbon atom.

4. Nucleophilic chlorine substitution. One outstanding chemical characteristic of α-chloro enamines is their exceptional reactivity in nucleophilic substitution reactions.



For example, *(1a)* affords enamines and *S,N-*, *O,N*, and *N,N*-ketene acetals of the type *(4)*.

$(CH_3)_2C{=}C(R)NC_5H_{10}$ *(4)*

R	Reagent	Conditions	Yield (%)	B.p. (°C/torr)
CH_3	CH_3Li	20 °C, 3 h, Ether	70	
C_6H_5	C_6H_5MgBr	20 °C, 3 h, Ether	65	90/0.4
SC_2H_5	C_2H_5SNa	20 °C, THF	90	76/0.3
OC_2H_5	C_2H_5ONa	20 °C, THF	80	80/8
$N(C_6H_{11})_2$	$LiN(C_6H_{11})_2$	0 °C, Ether	80	155/0.9

5. Cycloadditions. The reaction of α-chloro enamines with ynamines yields cyclobutenecyanines:

(1a) + $C_6H_5{-}C{\equiv}C{-}N(C_2H_5)_2$ $\xrightarrow[(C_2H_5)_2O]{20°C,\ 30\ min}$

(5) (70%)

It is of preparative value that diaryl derivatives of *(5)*, *e.g.* diethyl(3-diethylamino-2,4,4-triphenyl-2-cyclobutenylidene)-ammonium chloride, are obtained in high yields from α-chloro iminium salts with stoichiometrical amounts of tertiary amines or simply by thermal HCl elimination (in example: 55% yield, $(C_2H_5)_3N$, 20 °C, in ether).

N-(1-Chloro-2-methylpropyl)piperidine (1a)

Phosgene (17 g, 0.17 mole) was passed slowly into a cooled (0 °C) solution of *N*-piperidinoisobutyramide (21 g, 0.135 mole) in dry ether (150 ml). After 5 h the excess of phosgene was removed at water pump vacuum and the resulting mixture was treated with triethylamine (14 g, 0.138 mole) at room temperature. Complete precipitation of the triethylamine hydrochloride was effected by addition of 60 ml of pentane. After filtration of the reaction mixture in the absence of moisture, the solution was concentrated *in vacuo*. Distillation through a short Vigreux column yielded 16.3 g (70%) of *(1a)*, b.p. 95–100 °C/15 torr.

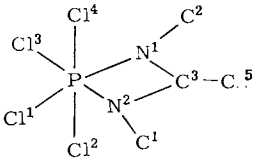
Crystal Structure of $PCl_4(NCH_3)_2CCl$, a Four-Membered Ring System containing Hexavalent Phosphorus[1]

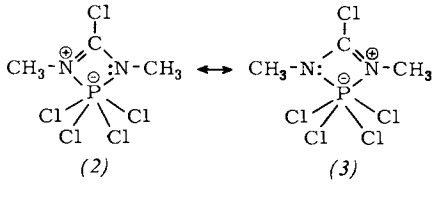


By *M. L. Ziegler* and *J. Weiss* [*]

By reaction of *N,N'*-dimethylchloroformamidine hydrochloride with PCl_5, *Latsche* and *Hormuth*[2] recently obtained a compound with the composition $C_3H_6Cl_5N_2P$ which they formulated as a four-membered ring compound with six-fold coordinated phosphorus, $Cl_4P^{\ominus}(NCH_3)_2C^{\oplus}Cl$ *(1)* on account of the ^1H- and ^{31}P-NMR spectra.

We have established the structure of this unusual compound by X-ray analysis. Because of its extreme sensitivity to moisture the crystal used for measurement was sealed in three Lindemann-glass tubes placed one inside the other, the outermost tube being filled with P_4O_{10} at each end; in spite of this, it was not possible to prevent gradual hydrolysis during the photography.

Crystallographic data: monoclinic, space group $C_{2h}^5-P2_1/c$; $a = 12.813$, $b = 6.915$, $c = 13.215$ Å, $\beta = 114.6°$; $N = 4$; $d_{X\text{-ray}} = 1.72$ g/cm³.



Weissenberg photographs (Cu–K_α radiation) about the c^*-axis ($l = 0$–7) gave 451 independent reflections, whose intensities were estimated visually and corrected in the usual way. The structure determined by three-dimensional Patterson and Fourier syntheses was refined by the method of least squares with isotropic temperature factors to give an *R* factor of 0.13.

Bond lengths (Å; with standard deviations) and bond angles (degrees).

P–Cl^1	2.15 (2)	N^2–P–N^1	70.7	Cl^2–P–N^1	88.8
P–Cl^2	2.09 (1)	P–N^1–C^3	81.4	Cl^2–P–N^2	90.2
P–Cl^3	2.07 (2)	N^1–C^3–N^2	119.3	Cl^3–P–N^1	97.2
P–Cl^4	2.10 (1)	C^3–N^2–P	88.6	Cl^3–P–N^2	167.7
P–N^1	1.91 (4)	Cl^1–P–Cl^2	88.4	Cl^4–P–N^1	88.8
P–N^2	1.85 (6)	Cl^1–P–Cl^3	95.5	Cl^4–P–N^2	90.2
N^1–C^2	1.45 (6)	Cl^1–P–Cl^4	91.8	P–N^1–C^2	133.8
N^1–C^3	1.34 (5)	Cl^2–P–Cl^3	92.0	P–N^2–C^1	131.0
N^2–C^1	1.48 (6)	Cl^2–P–Cl^4	178.5	C^3–N^1–C^2	143.2
N^2–C^3	1.19 (6)	Cl^3–P–Cl^4	89.6	C^3–N^2–C^1	138.4
C^3–Cl^5	1.84 (4)	Cl^1–P–N^1	167.1	N^1–C^3–Cl^5	111.0
		Cl^1–P–N^2	96.7	N^2–C^3–Cl^5	129.7

The four-membered ring is planar. In the ring plane there lie also two of the chlorine atoms bound to the phosphorus, the chlorine atom bound to carbon, and the carbon atoms of the two methyl groups. The phosphorus atom is in an approximately octahedral environment. The P–Cl distances are normal, with a mean of 2.10 Å. The P–N distances are distinctly greater than the P–N single-bond distance (1.77 Å) and the C–N bond lengths in the ring appear to be shorter than for a C–N single bond (1.48 Å). This shows that the

(2) *(3)*

positive charge is not localized on the carbon atom (cf. *(1)* [2]) but on the nitrogen atoms with formation of a partial double bond; thus one comes to the mesomeric limiting structures *(2)* and *(3)*. The bond lengths between the methyl

carbon atoms and the nitrogen atoms are within the limits for a C–N single bond.

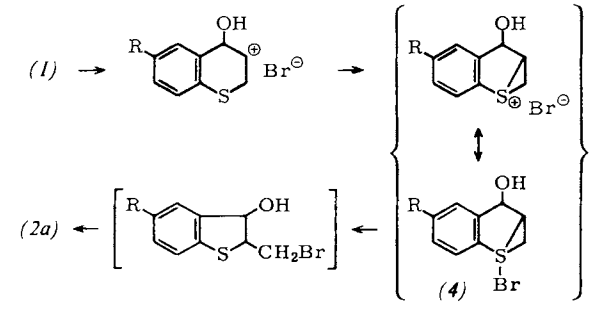
Ring Contraction of 1-Thiochromans to Benzo[*b*]thiophenes

By *H. Hofmann* and *G. Salbeck* [*]



Reduction of 3-bromo-1-thio-4-chromanone (R = H) with $NaBH_4$ or $LiAlH_4$ leads to the formation of *trans*-3-bromo-1-thio-4-chromanol *(1)*, R = H, in high yields [1]. On heating in dioxane under reflux, compound *(1)* rearranges with loss of water to 2-bromomethylbenzo[*b*]thiophene *(2a)*, R = H. The same rearrangement takes place when *(1)* is distilled with potassium hydrogen sulfate at 0.1 torr. If the rearrangement is carried out in aqueous dioxane (2-benzo[b]thienyl)-methanol *(2b)*, R = H, is formed. *trans*-3,4-Dihalogeno-1-thiochromans *(3)*, R = H, which can easily be prepared from the hydroxy compound *(1)* or from the known 1-thio-2*H*-chromene, also rearranges to *(2b)* with loss of halogen hydride on heating in dioxane/water.

The structure of the rearrangement products *(2a)* and *(2b)* follows from their UV-, IR-, and ^{1}H-NMR spectra as well as from independent syntheses from the correspondingly substituted benzo[*b*]thiophene-2-carboxylic acid [2].

3-Bromo-2-methyl-1-thiochroman-4-ol, prepared in a similar manner, likewise rearranges on heating in dioxane to 2-(α-bromoethyl)benzo[*b*]thiophene; however, in aqueous dioxane further elimination of hydrogen bromide takes place and 2-vinylbenzo[*b*]thiophene [3], m.p. 55–58 °C, is formed.

We assume that in the case of *(1)* and *(3)* loss of bromide ion is facilitated and the carbonium ion already formed is stabilized by neighboring group participation of the thioether group. We cannot as yet decide how the rearrangement itself is initiated.

An indication of the participation of *(4)* is reflected in the stability of the acetate of *(1)*, which does not undergo rearrangement; the acetoxy group on C-4 evidently stabilizes the carbonium ion on C-3. The same argument can be used for the stability of the 3,3-dibromo-1-thio-4-chromanols and of 3-bromo-3-methyl-1-thio-4-chromanol.

2-Bromomethylbenzo[b]thiophene (2a), R = H

A solution of 3-bromo-1-thio-4-chromanol *(1)*, R = H [1] (2.8 g; 11.4 mmoles) in anhydrous dioxane (40 ml) is heated under reflux for 3 h and then evaporated under vacuum. After crystallization of the residue from 25 ml of petroleum ether at −20 °C, 2.3 g (89%) of *(2a)*, R = H, was obtained (m.p. 48–52 °C, which on recrystallization from petroleum ether increased to 58–59 °C). UV (ethanol): λ_{max} = 206 nm (ε = 2.5 × 10⁴); 229 (2.5 × 10⁴); 273 (1.5 × 10⁴); 300 (0.5 × 10⁴). IR (KBr): benzo[*b*]thiophene skeletal vibration 1530 cm^{-1}; ν-CH_2– 1428 cm^{-1}. ^{1}H-NMR ($CDCl_3$): τ = 5.35 (CH_2, s).

(5-Methyl-2-benzo[b]thienyl)methanol (2b) R = CH_3

A solution of 3-bromo-6-methyl-1-thio-4-chromanol *(1)*, R = CH_3, (1.5 g; 6 mmoles) in dioxane (20 ml) and water (5 ml) is heated under reflux for 10 h and then poured into 0.4 l of water with stirring. The colorless precipitate, 1.0 g, is then recrystallized from 15 ml of ligroin. 0.87 g (83% yield) of *(2b)* (R = CH_3; m.p. = 92–93 °C) is obtained. UV (ethanol): λ_{max} = 206 nm (ε = 3 × 10⁴); 233 (3.7 × 10⁴); 265 (1.3 × 10⁴); 295 (0.4 × 10⁴); 305 (0.4 × 10⁴). IR (KBr): νOH 3400 cm^{-1}; benzo[*b*]thiophene skeletal vibration 1500 cm^{-1}; νCH_2 1450 cm^{-1}. ^{1}H-NMR ($CDCl_3$): τ = 5.2 (CH_2, s); 7.2 (OH, s); 7.6 (CH_3, s).

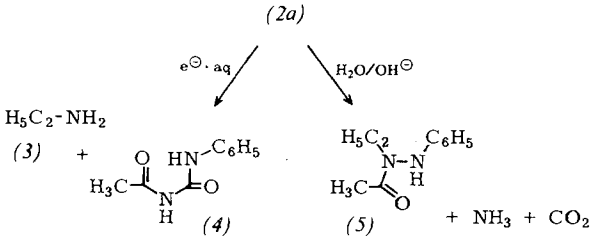
Thermal Rearrangement of Phenylazomethyl Isocyanates

By *H. Schildknecht* and *G. Hatzmann* [*]

Oxidation of semicarbazones usually leads to the formation of 1,2,4-triazolones or 1,3,4-oxadiazoles. In the case of 2-phenylsemicarbazones of ketones, however, a direct oxidative cyclization is not possible. With chromyl acetate or lead tetraacetate they are oxidized to phenylazomethyl isocyanates *(1)* [1,2], which subsequently can be cyclized to 1,2,4-triazolones *(2)*. For example, if *(1a)* is heated in the absence of solvent for a few minutes at 140 °C migration of the ethyl group and ring closure take place resulting in the formation of *(2a)*, m.p. 113–114 °C; λ_{max} ($CHCl_3$) = 263 nm (log ε = 3.94).

The structure of the rearrangement product can be deduced from the results of elemental analysis and from IR and NMR spectra. The IR spectrum of *(2a)* does not show the isocyanate band at 2220 cm^{-1}. Instead, a new band appears at 1678 cm^{-1}; NH-bands are absent. The ^{1}H-NMR spectrum ($CDCl_3$) of *(2a)* indicates migration of the ethyl group to a N-atom or O-atom. The spectrum shows, in addition to the multiplet of the aromatic protons (τ = 2.62; 5H) and the singlet for the protons of the C-methyl group (τ = 7.60; 3H),



(1) (2)

(2)	R	R^1	M.p. (°C)	Yield (%)
(a)	CH_3	C_2H_5	113–114	96
(b)	CH_3	CH_3	174–176	94
(c)		$-(CH_2)_5-$	150–152	92
(d)	CH_3	$CH_2-C_6H_5$	142–144	94
(e)	C_6H_5	C_6H_5	236–238	90

a quadruplet (τ = 6.17; 2H) and a triplet (τ = 8.98; 3H) due to an ethyl group that is bound to a N- or O-atom.

The structure of *(2a)* can be proved unequivocally to be 2-ethyl-3-methyl-1-phenyl-1,2,4-triazol-5-one by electron pyrolysis[3], which furnishes ethylamine *(3)* and *N*-acetyl-*N'*-phenylurea *(4)* as main fragmentation products.

(2a)

Like *(1a)*, compounds *(1b)–(1e)* can also be converted into the corresponding triazolones *(2)*. Yields are almost quantitative. Reaction of *(1b)* does not start until a temperature of 170 °C is reached; in the case of the other compounds, however, a temperature of 140 °C suffices.

1,2,3-Substituted triazolones are very soluble in water and, unlike the 1,2,4-substituted triazolones, are stable toward acid hydrolysis. However, they dissociate on treatment with aqueous alkalis with formation of the corresponding acyl hydrazines; *e.g.*, *(2a)* yields *(5)*.

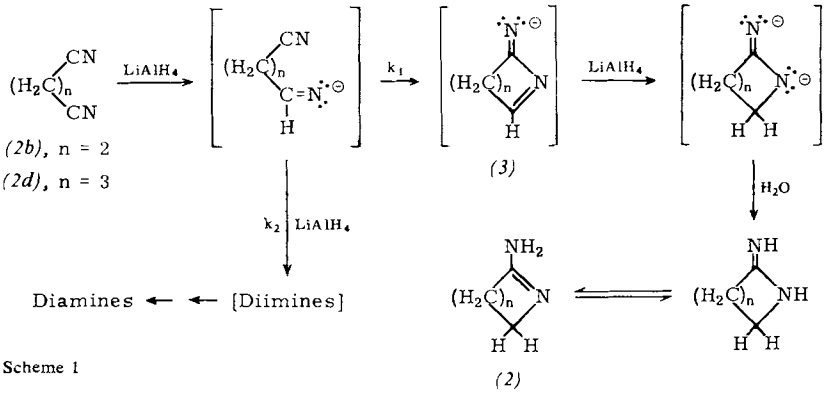
Preparation of Cyclic Amidines by Reduction of Dinitriles with $LiAlH_4$



By *H. U. Sieveking* and *W. Lüttke*[*]

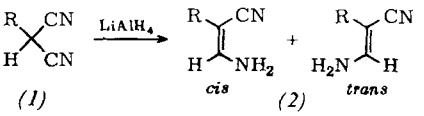
In an attempt to prepare 1,2-bis(aminomethyl)cyclobutane from a mixture (40:60) of *cis*- *(1a)* and *trans*-cyclobutanedicarbonitrile by reduction with an excess of $LiAlH_4$ we obtained only 35% of the expected product instead of the 65% reported in ref.[1]. Instead, we isolated the cyclic amidine *(2a)*, which was formed only from the *cis*-dinitrile as shown by treatment of the pure isomer with $LiAlH_4$; the *trans*-form gave mainly the diamine.

To test the generality of application of this ring-closure reaction the dinitriles *(1a)–(1d)* were treated with $LiAlH_4$ (see Table).

	Dinitrile *(1)*	Amidine *(2)*	Yield (%)	B.p. (°C/torr)	M.p. (°C)	M.p of picrate (°C)
(a)	*cis*-		22	88/0.5	41–49	202–204
(b)			30	65/0.1	77–79 78–80 [2]	190–192
(c)			45	125/1.0	110–112	232–233
(d)			8	82/0.1	95–97	200–201 207 [3]

In agreement with previous results[4,5] we consider the most probable mode of reaction to be that in Scheme 1.

Scheme 1



Because of its negative charge the imino group formed in the first step is protected against further nucleophilic attack by the tetrahydroaluminate; if it stands close to the second nitrile group it protects the latter from reduction and with its favorable steric orientation attacks that group itself in a nucleophilic reaction that leads to ring closure. As a Schiff base the intermediate amidine anion *(3)* is readily reduced further, so that the more stable amidine *(2)* can be isolated.

Reduction of *(1b)* and *(1c)*, where $n = 2$ can give a strain-free five-membered ring; here $k_1 \gg k_2$, so that the cyclic amidines *(2b)* and *(2c)* are the only monomeric products.

When the nitrile groups are further apart ($n \geqq 3$), k_2 is greater, since the negatively charged imino group can protect the nitrile group only to a smaller extent, whilst k_1 decreases owing to the sterically less favorable position of the reacting groups; thus reduction of *(1d)* gives comparable amounts of diamine and amidine *(2d)* ($k_1 \approx k_2$) with a little piperidine.

That open-chain amidine can be formed analogously from mononitriles (where $n = \infty$) is shown by the reaction of benzonitrile with an excess of $LiAlH_4$; we were able to isolate

N^1-benzylbenzamidine [b.p. 170 °C/0.8 torr, m.p. 77 °C (77–78 °C in ref.[6]) as well as the products obtained by *Soffer*[7] (benzylamine, benzylidenebenzylamine, triphenyltriazine); however, since $k_1 < k_2$ the yield of the amidine is only 2.5%.

(1) *cis* *(2)* *trans*

(a), R = H; *(b)*, R = CH_3

	M.p. (°C)	B.p. (°C/0.4 torr)	IR (cm^{-1}) (N–H)	(C≡N)	(C=C)	NMR (H)	(R)	J_{R-H}(Hz)
cis-(2a)	8	67–68	3470, 3360	2180	1595	6.79	3.88	8.3
trans-(2a)						7.03	4.20	13.5
cis-(2b)	70–71	70	3470, 3350	2170	1600	6.79	1.66	1
trans-(2b)						6.95	1.73	1

The reaction of dinitriles with $LiAlH_4$ gives open-chain and cyclic anions that can undergo intramolecular condensation with unattacked nitrile groups[4,8]. More than 50% of oligomers and polymers are formed, but this can be reduced by dilution, use of an excess of $LiAlH_4$, and short reaction times.

The amidines were characterized by their IR, NMR, and mass spectra as well as by analysis. In the monomeric state the cyclic amidines of the type studied appear to exist primarily in the tautomeric form *(2)* containing an endocyclic double bond, since, in all the C_2Cl_4 solution spectra, increasing dilution increases only the intensity of the bands at 3500 and 3400 cm^{-1} which, according to *Moritz*[9], can be assigned to the stretching vibrations of the NH_2 group.

2-Amino-1-pyrroline (2b)

A solution of *(1b)* (26 g, 0.325 mole) in ether/THF (4:1, 250 ml) is added dropwise to a suspension of $LiAlH_4$ (26 g, 0.72 mole) in ether/THF (6:1, 1.6 l). The mixture is stirred for 2 h at room temperature, washed with, successively, H_2O (25 ml), 20% NaOH solution (25 ml), and H_2O (75 ml), filtered, and dried over K_2CO_3. Crude *(2b)* (12 g) crystallized on concentration and could be purified by distillation in a vacuum; the yield of pure product was 30% (8 g).

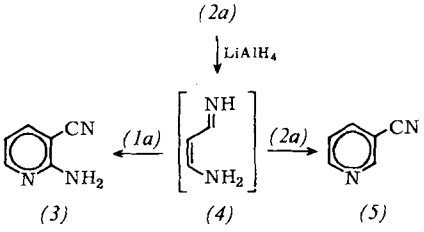
Preparation of Enamino Dinitriles and Pyridines by Reduction of Geminal Dinitriles with $LiAlH_4$

By *H. U. Sieveking* and *W. Lüttke*[*]

In contrast to longer-chain α,ω-dinitriles, malonodinitrile *(1a)* and methylmalonodinitrile *(1b)* do not give cyclic amidines on reduction by $LiAlH_4$[1]. Instead, the imino nitrile first formed stabilizes itself by tautomerization, which leads to the new enamino nitriles *(2a)* and *(2b)* as sole monomeric products in about 40% yield.



Metalation of all the acidic protons of *(2)* gives an anion that is relatively stable toward further attack by hydride[2] because of its negative charge and, in particular, because a sparingly soluble complex is formed.

The initial products formed from *(1a)* and *(1b)* are *cis-trans*-mixtures; however, only the more stable *cis*-enamino nitriles can be isolated since the *trans*-form rearranges to the *cis*-form on distillation[3,4].

The structures of *(2a)* and *(2b)* were elucidated primarily by their NMR spectra, the H–R coupling constants and the chemical shifts permitting assignment of the tautomeric forms; as in the case of the 3-aminoacrylic esters[4], coupling with the NH_2 group (J_{H-NH_2} = 10 Hz) was observed. *(2a)* and *(2b)*, which are very useful starting materials for the synthesis of substituted heterocycles, behave in many respects like 3-aminocrotononitrile[5]. Thus, thiocytosine and methylthiocytosine can be prepared by reaction with thiourea, in analogy to *Polonowski*'s work[6]; unlike 3-aminocrotononitrile, however, *(2a)* reacts with the less nucleophilic urea giving cytosine, which is thus now available in two steps. By reaction of phenylhydrazine with *(2a)* we obtained 5-amino-1-phenylpyrazole by way of the phenylhydrazone, in analogy to *Mohr*'s work[7].

On reduction of *(1a)* with $LiAlH_4$ we isolated, not only *(2a)*, but also a 10% yield of 2-aminonicotinonitrile *(3)* (m.p. 132.5–134 °C), which is otherwise more difficulty accessible[8]; on slow reduction by an excess of $LiAlH_4$, 2% of nicotinonitrile[5] was also formed, being recognizable by its typical NMR spectrum and its molecular ion in the mass spectrum. The formation of this product can be described formally by condensation of *(1a)* or *(2a)* with 3-imino-1-propenylamine *(4)*, which can arise by further reduction of the enamine *(2a)*[2,5,9].

No pyridine derivative could be obtained from *(1b)*, since the latter contains no mobile hydrogen that is necessary for aromatization.

(3) *(4)* *(5)*

β-Aminoacrylonitrile (2a) and 2-aminonicotinonitrile (3)

A solution of *(1a)* (20 g, 0.30 mole) in ether/THF (1:2; 100 ml) is added to $LiAlH_4$ (10 g, 0.26 mole) in ether/THF (4:1; 1.2 l), and the mixture is treated as in ref.[1]. *(3)* (1.8 g) crystallizes from the crude product (13.2 g); recrystallization from ether (charcoal) gives 7% (1.2 g) of pure *(3)*. The mother liquors, containing an approximately 90% yield of 1:1 *cis-trans*-mixture *(2a)*, is fractionated through a 10-cm Vigreux column, whereupon 40% (8 g) of *cis-trans-(2a)* (5:1) is obtained; a second distillation gives 5 g of the pure *cis*-isomer.

A New Method for the Preparation of α,β-Unsaturated Azo Compounds

By *E. Gründemann* [*]

During attempts to prepare the hydrazones *(2a)* and *(2b)* by reaction of equimolar amounts of 4-methyl-3,4-epoxy-2-pentanone *(1)* [1] with methyl- and phenylhydrazine α,β-unsaturated azo compounds were obtained as deep yellow and red compounds, respectively, whose spectra and analytical data are consistent with structures *(4a)* and *(4b)*.

cis-(4) *trans-(4)*

(a), R = CH_3; *(b)*, R = C_6H_5

The electron shift to give *(3)*, which is induced by deprotonation of the hydrazone intermediate *(2)* by unreacted hydrazine [2], leads to epoxide ring cleavage; re-addition of a proton then gives α,β-unsaturated azo compounds *(4)*. Compounds of this type may also be prepared by reaction of α-halogeno ketones with methylhydrazine [3] or by oxidation of α,β-unsaturated monoalkyl hydrazones with lead(IV) acetate [4].

Reaction of *(1)* with 2,4-dinitrophenylhydrazone does not proceed beyond the hydrazone *(2)*. Although the presence of the two nitro groups considerably enhances formation of the hydrazone anion, the nucleophilic character of the anion is nevertheless reduced at the same time. An electron shift, which can be brought about by the use of high temperatures or prolonged reaction times, leads to complete decomposition. *Eschenmoser et al.* [5] have suggested that fragmentation of the *p*-toluenesulfonylhydrazone of an epoxy ketone proceeds, *inter alia*, by way of α,β-unsaturated azo compounds as intermediates.

According to their NMR and IR spectra, the azo compounds *(4)* exist as a mixture of the *cis* and *trans* isomers. Investigation of the undistilled reaction product shows that it contains 90% of the *trans* isomer, whereas after distillation the *cis* isomer can predominate. Since intramolecular hydrogen bonding can only take place in the cis form, measurement of the ν-OH vibrations and the resonance of the hydroxyl group permit assignment of the configuration. *cis-* and *trans-(4a)* can even be separated by distillation. As expected, *cis-(4a)* has a lower boiling point than *trans-(4a)* and the resonance of its hydroxyl group appears downfield from that of *trans-(4a)*. In the OH stretching region, the IR spectrum of *trans-(4a)* (5×10^{-3} N in CCl_4) contains only a sharp band at 3600 cm^{-1}, and at higher concentrations also a broad band at 3400 cm^{-1}, whereas the spectrum of *cis-(4a)* shows only a broad band at 3400 cm^{-1}, which is also observed in dilute solution and which is assigned to an associated OH stretching vibration.

2-Methyl-4-methylazo-3-penten-2-ol (4a) and 2-methyl-4-phenylazo-3-penten-2-ol (4b)

Methylhydrazine (4.6 g, 0.1 mole) or phenylhydrazine (10.8 g, 0.1 mole) is added to compound *(1)* (11.4 g, 0.1 mole). The heat evolved during reaction is removed by cooling with water. After 20 hours' standing at room temperature, the reaction mixture is treated with ether (25 ml), water evolved during the reaction is separated off, and the ethereal phase is dried over calcium chloride and distilled under vacuum.

The reaction with methylhydrazine affords 12.7 g (89%) of a yellow liquid containing 75% of *trans-(4a)* and 25% of *cis-(4a)*, b.p. 78–93 °C/12 torr. *cis-* and *trans-(4a)* can easily be separated by fractional distillation over a Widmer spiral.

trans-(4a), b.p. 92–93 °C/12 torr; UV: λ_{max} = 394.6 nm (log ε = 1.907); NMR: (C_6D_6, TMS as internal standard) τ = 8.65 (6H, s); 7.91 (3H, d, *J* = 1.1 Hz); 7.50 (1H, s, –OH); 6.28 (3H, d, *J* = 0.5 Hz); 3.28 (1H, m).

cis-(4a), b.p. 77–78 °C/12 torr; UV: λ_{max} = 389.1 nm (log ε = 2.072); NMR: (C_6D_6) 8.53 (6H, s); 8.30 (3H, d, *J* = 1.1 Hz); 6.49 (3H, d, *J* = 0.7 Hz); 4.13 (1H, s, –OH); 4.05 (1H, m).

The reaction with phenylhydrazine yields 16.2 g (80%) of a red liquid containing 40% of *trans-(4b)* and 60% of *cis-(4b)*, b.p. 102–108 °C/0.1 torr.

The Scope of NMR Studies on Paramagnetic Compounds

By *K. E. Schwarzhans*[*]

NMR techniques were originally assumed to be suitable only for the study of diamagnetic substances, in the same way that ESR methods are only applicable to paramagnetic compounds. About 10 years ago *McConnell*[1] developed a model showing that paramagnetic compounds also give NMR spectra in almost all cases in which the electron relaxation times are shorter than 10^{-6} seconds. The most striking feature of the NMR spectrum of a paramagnetic compound is the exceptionally large shift of the resonance signals compared to those in the spectra of comparable diamagnetic substances. According to *McConnell*, these shifts arise from the delocalization of unpaired electrons over the whole molecule.

Contradictions between the McConnell model and experiment became apparent during NMR studies on the paramagnetic representatives of the bis(cyclopentadienyl)metal complexes of the 3d elements. The ^{1}H-NMR spectra of this class of substances becomes readily interpretable, however, if direct transfer of unpaired electrons from partly occupied d orbitals of the central metal atom to s orbitals of the ligand hydrogen atoms is assumed to occur in addition to electron delocalization.

This postulate was tested by means of the ^{1}H- and ^{14}N-NMR spectra of a large number of substituted bis(cyclopentadienyl)metal complexes and bis(salicylaldehydato) and bis(salicylideneiminato) complexes of cobalt(II) and nickel(II) containing pyridine and picolines as axial ligands. In every case the sign and magnitude of the shift showed a strong dependence on the position of the relevant nucleus in the molecule. Shifts of up to 1% of the resonance frequency were observed. In extreme terms, a strong direct electron transfer, *e.g.* in the bis(cyclopentadienyl)metal complexes studied, can be regarded as leading to a metal-hydrogen-carbon bond. Results obtained by *I. A. Ronova*[2] from electron diffraction studies on bis(cyclopentadienyl)metal complexes, which show the cyclopentadienyl protons to be deflected out of the plane of the ring in the direction of the metal atoms, lend support to this concept.

The Structure of Molten Alloys in Relation to their Properties

By *S. Steeb*[*]

Results of wide-angle X-ray studies on molten metals and alloys were used for the plotting of electron distribution curves from which four pieces of information could be obtained: Classification of the melt; partial and total coordination numbers; the Cowley short range order parameter; and finally, as the most recent development, the quantitative resolution of certain alloys into their structural components. We employed our new technique for measurement of the small-angle scattering of melts at temperatures up to 800 °C. For molten aluminum, the isothermal compressibility calculated from small-angle scattering agrees well with that obtained from measurements on the velocity of sound (2.387×10^{-6} bar^{-1}). Small-angle studies on molten Al–Sn alloys evidence the presence of Sn clusters.

According to recent theories, the compressibility[1] and electrical resistance[2] of alloys can also be calculated from X-ray diffraction data.

Chemical Applications of Electron Microscopy: Topotactic Reactions

By *H. R. Oswald*[*]

In 1919 *V. Kohlschütter* introduced the term "Topochemical Reaction" for chemical processes in which the properties of the solid reaction products are determined by reactions which take place on or in a solid substance, *i.e.* locally. "Topochemistry" ought to include all influences of structure and morphology of the starting materials and end products on the course of reactions between solids and solids, solids and liquids, and solids and gases.

Modern electron microscopy has proved itself an invaluable tool for investigations in this field of chemistry. In addition to the direct picture method – often carried out with the aid of heating, cooling, and goniometer accessories – various reproduction methods have been successfully introduced. In the investigation of topochemical processes, electron microscopical (*i.e.* morphological) findings must always be combined with the results obtained by structural methods, usually X-ray methods. Fine-range electron diffraction is an important method in this connection; also of importance are thermal analysis and specific surface area measurements.

In recent times, the term "topotaxy" or "topotactic reaction" has developed within the broad field of topochemistry; it is used to describe "reactions in which a product is formed that has a crystalline orientation related to that of the starting material". The mutual structure relations and course of the topotactic rearrangement have been studied in detail on the basis of the following three reactions:

1. Conversion of solid copper hydroxide salts (fluoride, nitrate, nitrite, perchlorate, sulfate) into copper hydroxide in sodium hydroxide solutions.

2. Oxidation of manganese(II) hydroxide with molecular oxygen (*e.g.* for a solid/gaseous system; influence of topotaxy on the reaction kinetics).

3. Conversion in cobalt chloride solutions of zinc hydroxide nitrate crystals, into zinc-cobalt hydroxide chlorides, which can be prepared only by a topotactic route.

The definition of topotaxy as crystal structure nucleation and growth relation of two or more solid phases has been discussed on the basis of these studies. The three dimensional structure analogy of the topotactic partner claimed by several authors can be dispensed with, for one- and two-dimensional structure relations obviously also suffice. To delineate it from epitaxy the topotactic reaction must embrace the whole starting lattice.

Topotactic reactions occur in all processes involving participation of solids; they occur much more frequently than has hitherto been assumed and must always be taken into consideration in investigations on the interelation of structure, appearance and chemical reactivity. Thus, topotaxy plays an important role in numerous branches of applied chemistry such as sintering processes and corrosion in aqueous solutions or in hot gases. The interesting biological process of bone formation also involves topotactic reactions.

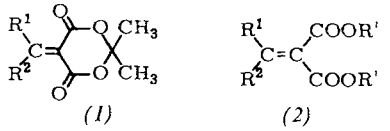
Stable Organic Lewis Acids

By *O. E. Polansky* [*]

Olefins of structure L (in which X^1 and X^2 are strongly electron accepting groups that are fully conjugated with the C=C double bond and R^1 and R^2 are groups that have little or no acceptor or donor properties) usually behave as electrically neutral, reversibly titratable organic Lewis acids. They combine with bases *via* the β-carbon atom with polarization of the C=C double bond, the negative charge being distributed over the site of the X^1 and X^2 groups so that only a relatively slight partial charge results on the β-carbon atom in the anion $A^{\ominus}$.

L $\qquad$ $A^{\ominus}$



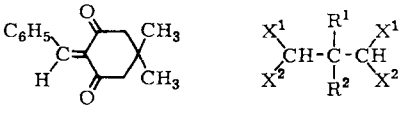
The apparent pK'_L values of the Lewis acids L can be determined, *inter alia*, by potentiometric titration with the base conjugated to the solvent

$$pK'_L = pK_L + pK_{HB}$$

(pK_L = true pK of Lewis acid, K_{HB} = ionic product of the solvent).

The substituents R affect the pK'_L of the Lewis acids to a greater extent than they do the pK values of the corresponding carboxylic- or ammonium acids; increasing acceptor strength of the substituent X^1 and X^2 lowers the pK'_L value.

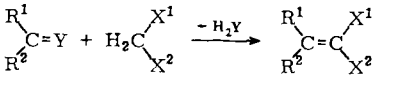
The relatively low pK'_L values of *(1)* compared with those of *(2)* are due to the positive entropy of reaction in the reaction of bases with *(1)*. In *(1)* the two COO groups are coplanar; in *(2)* repulsive forces between the two COOR' groups presumably lead to coplanarity of only one COOR' group and to decoupling of the other. Accordingly, the K band of *(1a)* ($\nu' = 31600\ cm^{-1}$) lies bathochromic to that of *(2a)* ($\nu' = 36000\ cm^{-1}$), which actually corresponds more to the K band of methyl cinnamate ($\nu' = 36500\ cm^{-1}$).



(1) $\qquad$ *(2)*

(a), $R^1 = C_6H_5$, $R^2 = H$

The structure of the anion $A^{\ominus}$ has been established by synthesis and by UV- and NMR spectroscopy.

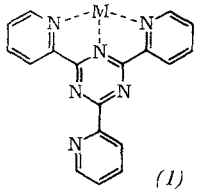


The stability of the Lewis acids under discussion is limited by hydrolytic cleavage of the C=C double bond (retro Knoevenagel reaction). This reaction follows a complicated multistep mechanism according to an overall first order rate law; the rate constant of the overall reaction is dependent on pH and has a maximum when $pH \approx pK'_L$. In the pK'_L determination the retro Knoevenagel reaction is taken into consideration by extrapolation to time $t = 0$.

The Lewis acid character of the olefins L is occasionally adversely affected by acid H atoms or by acidification of H atoms in the R^1 and R^2 groups.

(3) $\qquad$ *(4)*

The synthesis of the above Lewis acids can be achieved either by direct condensation in a water extractor (in the case where Y = O) or by reaction of the corresponding *N*-alkylamine (Y = NR^1) in a glass autoclave.



The synthesis is limited: 1. Aldehydes of the constitution RCH_2CHO have hitherto always afforded resinous products; 2. strong Lewis acids (such as *(3)*) obviously immediately react with $X^1CH_2X^2$ to form Michael-addition products *(4)*.

In accord with their Lewis acid character the olefins L catalyze the etherification of alcohols by diazo compounds as well as the rearrangement of epoxides to carbonyl compounds. They react with diazoalkanes at low temperature to give, among other things, thermally labile pyrazol-1-ines. At room temperature, on the other hand, the reaction is usually characterized by spontaneous evolution of N_2; depending on the substitution the reaction products that can be isolated are, cyclopropanes, dihydrofurans, alkylation- or rearrangement products.

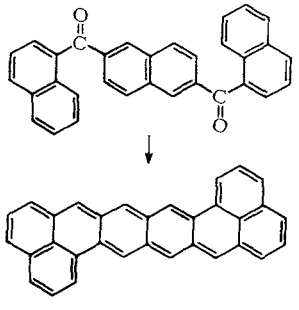
The lanthanide complexes of 2,4,6-tri-α-pyridyl-1,3,5-triazine (L) have been studied by *D. A. Durham, G. H. Frost,* and *F. A. Hart.* L was found to form complexes having metal: ligand ratios of 1:1 *(1)* and 3:1 *(2)*. $M(NO_3)_3LOH_2$ crystallizes from alcoholic lanthanide nitrate solutions (M = La–Nd, Sm–Lu, and Y), and loses water at 100 °C/0.1 torr to form the yellow compounds $M(NO_3)_3$. (The cerium(III) complex is orange.) These complexes are stable even at

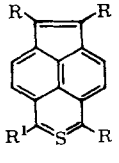


(1)

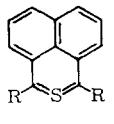
(2)

300 °C. The chlorides behave similarly. The IR spectra show that the complexes are in the form of *(1)*. As expected, complexes of the type $Eu(C_{18}H_{12}N_6)_3(ClO_4)_3$ are formed with the poorly coordinating perchlorate anion. / J. inorg. nuclear Chem. *31*, 571 (1969) / –Kr. [Rd 5 IE]

Dibenzo[*lm,yz*]hexacene (octazethrene) *(2)*, an aromatic hydrocarbon with six formally fixed double bonds (in the "middle" four rings), has been obtained by *R. Kemalettin Erünlü* from 2,6-dinaphthoylnaphthalene *(1)* by ring closure to form the quinone, reduction, and dehydrogenation. *(2)* is very reactive and was therefore not prepared in large quantities; the color of its hot solution in trichlorobenzene fades on cooling. The absorption spectrum of *(2)* (λ_{max} = 623 and



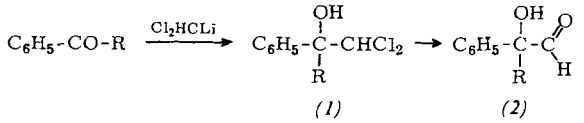
(1)



(2)

403 nm) may be compared with the spectra of zethrene (dibenzo[*hi,qr*]naphthacene) and heptazethrene (dibenzo[*jk,uv*]-pentacene). Octazethrene fits perfectly into *Clar*'s ring fusion series for aromatic compounds. / Liebigs Ann. Chem. *721*, 43 (1969) / –Kr. [Rd 6 IE]

New aromatic heterocycles containing tetravalent sulfur have been described by *R. H. Schlesinger, J. M. Hoffman jun.,* and *I. S. Ponticello.* The compounds are obtained by dehydration of cyclic sulfoxides, or by reaction of 1,5-diketones with phosphorus sulfides. The compounds *(1)–(4)*, which contain 14 (4n + 2, n = 3) peripheral π electrons, are stable, whereas *(5)* and *(6)*, having 12 peripheral π electrons, occur only as intermediates. / 157th Meeting Amer. chem. Soc. 1969, ORG N 21 / –Ma. [Rd 14 IE]



(1), R = Br, $R^1 = C_6H_5$

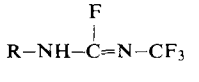
(4), $R = R^1 = C_6H_5$

(5), R = H
(6), $R = C_6H_5$

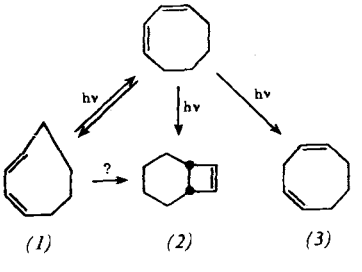
The synthesis of α-hydroxy aldehydes *(2)* from ketones and dichloromethyllithium is reported by *P. Blumbergs* and *M. P. LaMontagne.* Alkyldichloromethylphenylmethanols *(1)* are prepared by addition of dichloromethyllithium to alkyl phenyl ketones in THF at –100 °C (yield 75–80%). Hydrolysis of *(1)* by K_2CO_3 in aqueous isopropanol affords α-hydroxy aldehydes *(2)* in yields between 33 and 44%. Alkyl-



(1) *(2)*

R = cyclopropyl, cyclobutyl, cyclopentyl, isopropyl

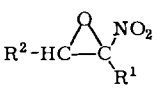
phenyltrichloromethylmethanols can be prepared from ketone and trichloromethyllithium in a similar manner but they are not hydrolyzed in acid or in weakly alkaline solutions, and treatment with strong alkali yields the starting ketone. / 157th Meeting Amer. chem. Soc. 1969, ORG N 40 / –Ma. [Rd 15 IE]



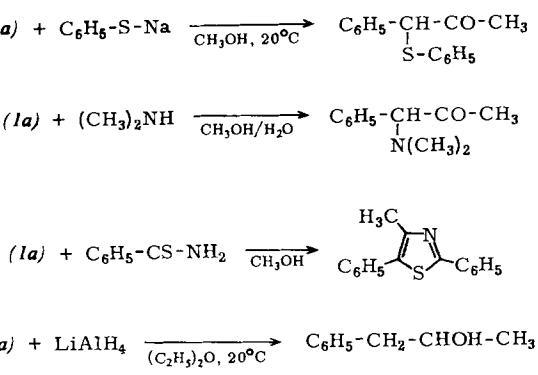
Derivatives of N^2-(trifluoromethyl)fluoroformamidine have been obtained by *K. O. Alt* and *C. D. Weis* by reaction of cyanogen chloride in liquid HF at –60 °C with fluoroalkanes. For example, reaction of fluorocyclohexane with 2 mol. equiv. of ClCN in the presence of catalytic amounts of KF gives N^1-cyclohexyl-N^2-trifluoromethylfluoroformamidine *(1)* (m.p. 68–70 °C, yield 84%). Similarly, 2-fluoronorbornane gives compound *(2)*. Compounds *(1)* and *(2)* are probably formed by way of a fluorinated linear dimerization

(1), R = cyclohexyl
(2), R = 2-norbornyl

product of ClCN. Only secondary fluoro compounds react in the manner described. / Helv. chim. Acta *52*, 812 (1969) / –Ma. [Rd 16 IE]



Photolysis of *cis,cis*-1,3-cyclooctadiene (25 °C, λ = 248 ± 4 nm, in hexane) has been reinvestigated by *W. J. Nebe* and *G. J. Fonken.* The authors found three photoproducts in proportions that varied with the reaction time. Formation of the known bicyclo[4.2.0]oct-7-ene *(2)* proceeds alongside



(1) *(2)* *(3)*

geometrical isomerization to *cis,trans*-1,3-cyclooctadiene *(1)*. A small amount of *cis,cis*-1,4-cyclooctadiene *(3)* is also formed. / J. Amer. chem. Soc. *91*, 1249 (1969) / –Ma. [Rd 17 IE]

Nitrooxiranes (α-nitro epoxides), a new class of compounds, form the subject of a report by *H. Newman* and *R. B. Angier*. The compounds are produced by the action of H_2O_2/dilute NaOH on nitroolefins in methanol, provided that the C atom attached to the NO_2 group also carries a further substituent. The nitrooxiranes behave similarly to the electronegatively substituted epoxides toward nucleophilic reagents (see formulas). Examples: *(1a)*, b.p. 77–78 °C/0.1 torr, pale yellow liquid, from β-methyl-β-nitrostyrene, yield 67%; *(1b)*: m.p. 108–110 °C, from α-nitrostilbene,

(1a), $R^1 = CH_3$, $R^2 = C_6H_5$
(1b), $R^1 = R^2 = CH_3$
(1c), $R^1 = CH_3$, $R^2 = c\text{-}C_6H_{11}$

85%; *(1c)*, b.p. 68–71 °C/0.1 torr, from 2-cyclohexyl-1-methyl-1-nitroethylene, 91%. / Chem. Commun. *1969*, 369 / –Ma. [Rd 18 IE]

Repression of RNA synthesis by actinomycin D is reversible, as has been reported by *I. J. Lorch* and *K. W. Jeon* on the basis of transplantation studies on amoebas. Since actinomycin D is used in the chemotherapy of cancer and in the investigation of cell metabolism, it is important to know whether the cell nuclei suffer irreversible damage. Amoebas were chosen for the studies because their cell nuclei are transplanted particularly readily. After treatment of normal amoebas with actinomycin D, this substance can be detected in the nucleus and in the cytoplasm. When nuclei that had received a lethal dose of actinomycin D were transplanted into normal cytoplasm, the cells became viable again and resumed synthesis of RNA. Conversely, cytoplasm treated with actinomycin D caused changes in the nucleoli (clubbing) of transplanted normal nuclei that are characteristic for this antibiotic; the resulting cells were not viable. Autoradiography showed that nuclei damaged by actinomycin D release the bound antibiotic in normal cytoplasm, *i.e.* that the damage is reversible. / Nature (London) *221*, 1073 (1969) / –He. [Rd 19 IE]

The "decoupling" of oxidative phosphorylation (respiratory chain phosphorylation) has been studied by *E. C. Weinbach* and *J. Garbus*. On the basis of numerous findings the authors suggest the following decoupling mechanism: The decoupler (the best known one is 2,4-dinitrophenol) crosses the mitochondrial membrane in the non-ionized state. In the mitochondrion it ionizes and interacts with the charged groups of the mitochondrial proteins, probably ε-amino groups, thus leading to conformational changes of the proteins. The differing reactions of oxidized and reduced cytochromes on trypsin, and the suppression of electron transfer by antimycin A suggest that conformational changes play a role in electron transport. This would make possible that conformational changes induced by decouplers can block the function of proteins in the coupling of phosphorylation and electron transfer. / Nature (London) *221*, 1016 (1969) / –He. [Rd 20 IE]

The first crystalline compounds of einsteinium (element 99) have been obtained and studied by *K. Fujita, B. B. Cunningham*, and *T. C. Parsons*. The extremely high radioactivity of the α-emitter ^{253}Es ($T_{1/2}$ = 20.47 d) necessitated special experimental techniques. Since the common ion-exchange resins are rapidly decomposed by high concentrations of einsteinium, the Es, which has been purified at high dilution on Dowex 50, was adsorbed onto active charcoal from 6 M HCl. Subsequent ignition of the charcoal in a stream of O_2 affords white einsteinium oxide, which reacts with HCl gas at 500 °C to give the trichloride $EsCl_3$. Reaction with a mixture of HCl gas (500 torr) and water vapor (10 torr) yields the oxide chloride EsOCl. Because of the rapid destruction of the crystal lattice by α particles, interpretable X-ray photographs can only be obtained when destruction of the lattice is compensated by a correspondingly rapid annealing of the defects, *i.e.* at high temperatures, in this case 400–435 °C. At 430 °C EsOCl possesses the tetragonal PbFCl lattice with $a = 3.97 \pm 0.01$ Å, $c = 6.75 \pm 0.02$ Å. At 425 °C $EsCl_3$ has the hexagonal UCl_3 structure with $a = 7.47 \pm 0.01$ Å and $c = 4.10 \pm 0.01$ Å; extrapolation of these figures to room temperature gave $a = 7.40 \pm 0.01$ Å and $c = 4.07 \pm 0.02$ Å. The ionic radius of Es^{3+} was found to be 0.97 Å. / Inorg. nuclear Chem. Letters *5*, 307 (1969) / –FW. [Rd 21 IE]

Determination of the equilibrium EMF in molten salts by a new galvanostatic method has been performed by *G. M. Campbell*. The metal is precipitated from a compound onto the working electrode and then removed by reversal of the current, the EMF between the working electrode and the reference electrode being recorded as a function of time. The presence of the pure metal is necessary only for a short time. The technique was used for EMF measurements on the cell

$$Pu(s,l)/PuCl_3,\ LiCl\text{–}KCl/N_2(g),\ PuN(s)$$

between 714 and 1032 °K. Reaction of Pu with N_2 hinders EMF determinations by other methods. Above the melting point of Pu, the free energy of formation of PuN is

$$-G_T^0 = 73.8 - 0.0225\ T\ (\text{kcal/mole}).$$

With the aid of additional data, it was found that S_{298}^0 (PuN) = 16.17 cal deg^{-1} mole^{-1} and $-\Delta H_{298}^0$ = 72.5 kcal/mole. The method should be of fairly general use at high temperatures; at lower temperatures problems arise from the neglect of the overpotential for oxidation and reduction of the electroactive species at the working electrode. / J. physic. Chem. *73*, 350 (1969) / –Hz. [Rd 22 IE]

The photolysis of gaseous trichlorobromomethane at 365 nm, which has been studied by *H. W. Sidebottom, J. M. Tedder*, and *J. C. Walton*, represents a convenient route to trichloromethyl radicals. The following reactions occur between 92 and 200 °C:

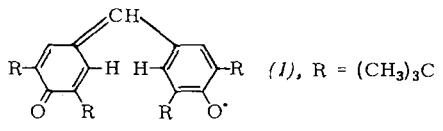
$$CCl_3Br \xrightarrow{h\upsilon} CCl_3^{\bullet} + Br^{\bullet} \quad (a)$$

$$CCl_3^{\bullet} + CCl_3Br \rightarrow CCl_4 + CCl_2Br^{\bullet} \quad (b)$$

$$CCl_2Br^{\bullet} + CCl_3Br \rightarrow CCl_2Br_2 + CCl_3^{\bullet} \quad (c)$$

$$CCl_3^{\bullet} + CCl_3^{\bullet} \rightarrow C_2Cl_6 \quad (d)$$

$$Br^{\bullet} + Br^{\bullet} + M \rightarrow Br_2 + M \quad (e)$$



(M = third body)

No dark reaction is observed. The rate of radical formation in reactions (a)–(c) is always lower than that of the termination reactions (d) and (e). With the aid of known data for (d), the rate of (b) could be represented in the form of the Arrhenius equation

$k_b = (7.1 \pm 1.0) \times 10^6 \exp -(10500 \pm 800)/RT$ l mole^{-1} sec^{-1}.

Trans. Faraday Soc. *65*, 755 (1969) / –Hz. [Rd 25 IE]

The structure of galvinoxyl [2,6-di-*tert*-butyl-4-(3,5-di-*tert*-butyl-4-oxo-2,5-cyclohexadienylidenemethyl)phenoxyl] *(1)*, a stable phenoxyl radical, in the crystalline state has been determined by *D. E. Williams* using X-ray diffraction. In the crystal, the molecules are separated from one another by normal van der Waals distances and have a twofold axis of rotation. The CCC angle at the methine carbon atom is 134°, and the phenyl groups are twisted out of the plane of conjugation by 12° in order to avoid interaction between the two hydrogen atoms shown in formula *(1)* (separation 2.37 Å). The CO bond length is 1.27 Å and is thus intermediate between the values for C=O in aldehydes and ketones (1.215 Å) and C–O in phenols (1.36 Å). / Molecular Physics *16*, 145 (1969) / –Hz. [Rd 26 IE]

(1), R = $(CH_3)_3C$

An exceptionally reactive form of silica gel is obtained, according to *C. Morterra* and *M. J. D. Low*, when Aerosil is esterified with methanol vapor at 350 °C and the product is degassed at 600–830 °C. SiOH and SiH_2 groups are formed on the surface, which on prolonged heating and pumping off give up hydrogen leaving Si radicals in the surface, which can be detected by means of an ESR signal at $g = 2.002$. These surface radicals are able to chemisorb molecular hydrogen with dissociation, even at room temperature. SiOH and SiH_2 are re-established *via* the SiH centers in the surface. Adsorbed water does not react to any great extent with the surface silanes; they are stable towards oxygen up to 350 °C. / J. physic. Chem. *73*, 321, 327 (1969) / –Hz. [Rd 23 IE]

BOOK REVIEWS

The Refractory Carbides. By *E. K. Storms*. Vol. 2 in the Series "Refractory Materials" edited by *J. L. Margrave*. Academic Press, New York, London 1967. 1 st Edit., xiii + 285 pp., 74 figs. and 83 tables; $ 12.50.

The author gives a good account of the chemical, physical, and metallurgical properties of transition metal carbides that are stable at high temperatures. Metal-carbide systems are discussed on the basis of the literature in the case of Ti, Zr, Hf, V, Nb, Ta, Cr, Mo, W, Th, U, and Pu. The discussion comprises the preparation, phase relationships, lattice constants, crystal structure, appearance, chemical characteristics, hardness, and thermodynamic properties. The last chapter deals with these aspects in a more general manner. The magnetic and electric properties of carbides are not discussed. A subject index, an author index, and a bibliography, which contains over 600 works and extends into 1966, complete the book. This is an outstanding monograph and can be recommended to chemists, metallurgists, physicists, and materials scientists. *J. Nickl* [NB 793 IE]

Microbial Transformations of Steroids. By *W. Charney* and *H. L. Herzog*. Academic Press, Inc. New York-London 1967. 1st Edit., xi, 728 pp., $ 21.00.

Investigations on the microbial transformations of steroids were started some 30 years ago by *Mamoli* and *Vercellone*. At that time such reactions were primarily of theoretical interest, and it was not until 1950, when results concerning large-scale fermentation for the production of antibiotics became available, that the subject received new, hitherto undreamed-of impetus from Peterson and Murray's discovery that progesterone is converted almost quantitatively by molds into 11α-hydroxyprogesterone, a readily accessible starting material for the production of cortisone and hydrocortisone. Subsequently, hundreds of microorganisms were investigated to establish whether they could promote steroid reactions, and systematic studies of possible points of attack on the steroid skeleton were carried out.

The present book has succeeded admirably in collecting the results of these studies in tabular form, and covers the literature in its entirety, including United States patents, up to the end of January 1964. Moreover, a large number of further relevant scientific publications up to and including those publishing in December 1966 are also cited.

The introductory chapter on historical developments is followed by an extremely lucid description of reactions of steroids that can be carried with the aid of microorganisms: 1. Oxidation, 2. Reduction, 3. Esterification, Amide Formation, and Hydrolysis, 4. Isomerization, 5. Addition, Rearrangement, Elimination, 6. Asymmetrical Reactions, Resolutions of Racemates.

The main part of the book is taken up by two large tables. The first one "Transformation by Products" (140 pages) gives a list of the substances (arranged according to their empirical formula) obtained from steroids by microbial reaction, as well as the type of reaction, yield, microorganism, melting point, optical rotation, and literature reference.

A survey of the systematics of the microorganisms and of the typical representatives for certain reactions is given in a number of smaller tables "Taxonomy" (40 pages). The book is concluded by the largest table "Transformation by Genus" (420 pages) in which the microorganisms used for steroid reactions are arranged according to genus and subgroup species. Sources for the strains, the steroid used as substrate, the reaction performed, and the literature are all listed. – The bibliography contains 1234 references.

The book is a mine of information for anybody who has worked with microbiological reactions or intends to enter the field, and is an invaluable aid in the laboratory. Even though the literature has been considered only up to 1964, this does not detract from the value of the work since very few substantially new results have been obtained in this field since that time. Thus the book is an excellent survey and can be recommended without reservation.

J. Schmidt-Thomé [NB 805 IE]

Wasserähnliche Lösungsmittel (Water-like Solvents). By *J. Jander* and *Ch. Lafrenz*. Vol. 3 of "Chemische Taschenbücher", edited by *W. Foerst* and *H. Grünewald*. Verlag Chemie GmbH., Weinheim/Bergstrasse 1968. 1st Edit., 209 pp., 7 illustrations, 33 tables, DM 16.–.

The authors have chosen protic solvents as the first group to be discussed: ammonia, hydrogen fluoride and higher hydrogen halides, sulfuric and fluorosulfuric acid, acetic acid,

hydrogen sulfide, and hydrogen cyanide. This is followed by a section on aprotic solvents such as sulfur dioxide, halogens and interhalogen compounds, mercury bromide, dinitrogen tetroxide, and other ionizing solvents. A brief account is also given of halogen compounds of semi-metals and organic solvents, particularly amines.

Each section begins with data for the physical properties of the solvent discussed. The acid-base theory occupies a central position. The Arrhenius theory, expanded as "solvent theory", which assigns particular importance to the ions of the solvent itself, can be used in the most general way to display analogies to the aquo system, provided that the solvent undergoes even minimal self-dissociation. A special section is devoted to treatment of the relevant acid-base theories as a group, their utility being discussed with special reference to the general applicability of the ionotropy theory.

A great number of reactions is discussed in this book, showing again and again how their course can be influenced by varying the solvent used. For instance, different solubilities of reactants in water and in ammonia can reverse the direction of a reaction; and the proton affinities of the solvent molecule or of the ions derived from it can decide, for example, whether a reaction leads to salt-formation or to solvolysis. A chapter on solutions of alkali metals in liquid ammonia gives a very nice, short review of the present state of research in this field.

The book can give the advanced student an insight into the topic of water-like solvents, should he be unable to attend a special lecture course on the subject, and it is certainly apposite for this purpose. The authors have thoroughly thought out the way to cover the wide field; they have doubtless put the recently published comprehensive book on reactions in liquid ammonia to good use. This masterly exposition of water-like solvents is also to be warmly recommended to all scientists working in related fields who spurn a too detailed bibliography.

The publishing program for the Chemische Taschenbücher, which has appeared meanwhile, lists a number of interesting subjects, mainly from theoretical chemistry but also from preparative chemistry, with a long series of authors who are recognized experts. The series will doubtless direct the attention of scientists to the most varied fields of chemistry as well as to borderline areas. *R. Juza* [NB 810 IE]

Lösungsmittel-Effekte in der organischen Chemie (Solvent Effects in Organic Chemistry). By *Chr. Reichardt*. Volume 4 of "Chemische Taschenbücher", edited by *W. Foerst* and *H. Grünewald*. Verlag Chemie GmbH, Weinheim/Bergstr. 1969. 1st Edit., 180 pp., 23 figures, 22 tables, DM 16.–.

The use of solvents in chemical reactions and for the spectral examination of substances has become so commonplace that the role of the solvent is often overlooked. The reaction equations deduced from experiments are usually presented with no mention of the solvent, so that the young chemist usually has to acquire a knowledge of solvent effects by purely empirical means. In the past few decades, many series of experiments have been carried out and theoretical ideas presented on the (often dramatic) effects of the solvent, but these have rarely been treated from the same point of view. This shortcoming is made good by *Chr. Reichardt* with his introduction to the field.

The book deals first with the types of interaction that occur between solvents and solutes, clearly showing *e.g.* the difference between ionization and dissociation, and including hydrophobic interaction and selective solvation (18 pages). After a discussion of various principles for the classification of solvents (11 pages), their effect on chemical equilibria (acid-base, keto-enol) is explained (11 pages). The important and manifold solvent effects in chemical reactions, which should be familiar to every chemist to enable him to plan his experiments, are discussed at length (49 pages). Here, as elsewhere, instructive examples, often supported by tables, are used to show how the effect of the solvent on the reaction path and rate as well as on the steric course depends on the polarity and charge of the reactants and on the reaction type. 23 pages are devoted to the effect of the solvent on electronic spectra (solvatochromism) and on IR, NMR, and EPR spectra. The final chapter (27 pages) describes the empirical solvent polarity parameters, which are particularly useful in practice for the choice of solvents. An appendix presents hints on the use of organic solvents for spectroscopic and preparative purposes. A selected bibliography for further reading is found at the end of each chapter.

The text is written critically and informatively. The author avoids simplifications, but presents rules that have proved useful in sectors of this extremely complex field. The treatment leaves little to be desired, apart from a distinction between contact and solvent-separated ion pairs, as well as a detailed discussion of the resonance-solvatochromism problem. The print and formulas are easily legible. Since the book will undoubtedly see considerable use, it would probably benefit from a more durable cover. *S. Hünig* [NB 820 IE]

Ullmanns Encyklopädie der technischen Chemie, Bd. 2/2: Betriebsüberwachung mit Dokumentation und Patentrecht (Ullmann's Encyclopedia of Technical Chemistry, Vol 2/2: Process Control, and Documentation and Patent Law). Chief editor: *W. Foerst*. Editor: *Hertha Buchholz-Meisenheimer*. Urban und Schwarzenberg, München-Berlin-Wien 1968. 1st Edit., viii + 677 pp., 547 illustrations, DM 160.–.

The new Ullmann volume is a self-contained work, extracted from the alphabetically arranged Encyclopedia[1] and independent thereof. A self-coherent important complex of themes is considered under the following headings: Control Techniques (132 pp.), Measuring Processes in Industry (121 pp.), Pure Air Conservation (91 pp.), Calculation by Computer, An Introduction to Programming (60 pp.), Waste Water (57 pp.), Documentation (39 pp), Industrial Toxicology (34 pp.), Patent and Trademark Law (31 pp.), Safety in the works (26 pp.), Statistical Methods of Planning and Evaluation of Experiments (25 pp.), Non-destructive Testing of Materials (20 pp.), Dust Explosions and their Prevention (9 pp.), Waste Disposal (9 pp.).

The chapter on measuring techniques deals not only with methods for measurement of temperature, pressure, and quantities, but also with modern analytical procedures. The sections on transducers and analog-digital converters are worthy of note. The chapter on control techniques gives, in 49 pages, an elementary and instructive introduction with information that is intelligible to the user and in general sufficient for him. A second section on this subject, "Mathemathical Methods" (49 pp.) goes deeper into the matter. The chapter on "Calculation by Computer" is also written in such an elementary way that the non-expert can by himself extract the details required for use of this new method of thinking. The chapter on "Statistical Methods in the Planning and Evaluation of Experiments" provides deeper insight into what was previously called determination of error. The methods of variance and regression analysis are briefly developed, these being particularly valuable for control and optimization of complicated processes. In such cases it is often necessary to determine by purely empirical means the relation between objectives (yield, economics, quality of a product) and factors of influence thereon (pressure, temperature, throughput, concentrations of reactants, *etc.*), so that it becomes a matter of determining the relations with the minimum number of single measurements. This chapter is well written but requires concentrated reading.

The section on "Patent Rights" is especially timely because important changes in patent law became operative between January 1st and October 1st, 1968. In contrast to the previous patent law, which in chemistry permitted only the patenting

[1] Cf. Angew. Chem. *80*, 855 (1968); Angew. Chem. internat Edit. *7*, 834 (1968).

of processes, the new patent law no longer forbids the patenting of substances prepared chemically or of foods and drugs. This is a considerable reversal of German patent procedure, introduced in cooperation with neighboring European countries in order to ease agreement on uniform European patent rights.

The chapters on "Pure Air Conservation", "Waste Water", and "Waste Disposal" treat serious problems that are not the chemist's first love but can no longer be side-stepped since industrial production interferes increasingly with the maintenance of equilibria in nature. Methods for study and control of air and limitation of its pollution have developed into an exact science. Sulfur dioxide and carbon monoxide stand at the head of the list of impurities. 5.4 million tons of the former are emitted annually in England alone. Emission of CO_2 is not considered in the present chapter since it is not generally considered an impurity; yet at present 14 billion tons of CO_2 are produced annually by combustion, a quantity that suffices to increase the CO_2 content of the atmosphere by about 10 % in 15–20 years; such disturbances already exert a permanent effect on climate and vegetation and, if uncontrolled, will lead to catastrophies. The need to conserve also water is shown by the figures for water consumption and waste water given in the chapter on "Waste Water". In respect of solid waste it is noteworthy that not only is the amount per head increasing (at present 0.7 kg per person per day in the Federal Republic of Germany, but also that its calorific value increases annually by 70–80 kcal/kg.

Among the social tasks discussed in this book must be included safety at work and industrial toxicology. From the statistics of accidents in chemical industry one can see that only 10–12 % of all accidents have a specific "chemical" cause; most accidents occur during "transport and manual activity". The chapter on "Industrial Toxicology" is written by *H. Oettel* who wrote the alphabetized articles on special toxicological subjects in the complete encyclopedia and now provides a summarizing survey of this field. He shows, *inter alia*, that there is a list of notifiable "recognized occupational diseases" which the public has more or less come to accept. The statistics of the 15 diseases that were most commonly notified and compensated amounted during 1952 and 1953 to 464000 cases, of which 25 % were compensated. Apparently 3/4 of the notifications were not accepted as occupational diseases.

In its choice of subjects this book not only provides a valuable extension of the Encyclopedia but also fills a gap in the literature of industrial chemistry. Happily, all the articles are written for the layman and not for the specialist. This volume therefore is a valuable contribution to the mutual understanding between those in various modern types of work.

H. Sachsse [NB 786 IE]

Bestimmung der Isotopenverteilung in markierten Verbindungen (Determination of the Isotope Distribution in Labeled Compounds). By *H. Simon* and *H. G. Floss*. From the series: Anwendung von Isotopen in der Organischen Chemie und Biochemie (Use of Isotopes in Organic Chemistry and Biochemistry), Vol. 1. Springer-Verlag, Berlin-Heidelberg-New York 1967, 1st Edit., x, 247 pp., 5 figures, stitched DM 54.–, $ 13.50.

The rapid development of organic chemistry and biochemistry in recent years was made possible only by the introduction of new methods and their improvement. Particularly important among these methods is the use of compounds labeled with isotopes. To make use of the isotope technique, however, it is necessary to determine the distribution of the isotope over the various positions of the molecule in the reaction product as accurately as possible. The authors of this book have collected the experimental data that were formerly scattered throughout the literature, and which were sometimes difficult to find, and have presented them clearly and critically.

The book deals mainly with chemical and enzymatic degradation reactions for the location of hydrogen and carbon isotopes, while the reader is referred to reviews for oxygen, sulfur, and phosphorus isotopes.

After a survey of the principles of degradation processes, some general reactions (Kuhn-Roth reaction, iodoform reaction, *etc.*) and the manipulation of the most important fragments (CO_2, HCOOH, *etc.*) formed in degradation reactions are described. The next nine chapters describe the best degradation processes for carboxylic acids, aliphatic hydrocarbons, alcohols and amines, aldehydes and ketones, carbohydrates, aromatic compounds, cycloaliphatic compounds, heterocycles, and several groups of natural products from plants and microorganisms. Special attention is given to the difficulties, sources of error, and problems of degradation reactions. The book thus offers a very useful collection of carefully checked procedures. The use of the book is facilitated by rigid classification and a formula index arranged according to the empirical formula, which also lists the parts of the molecules that can be isolated.

The author's intention "to fill a particularly serious gap in the literature on isotope methods" has been fully realized, and it is therefore with great interest that we look forward to the second (Isotope Effects) and third (Analysis) volumes of the present series.

W. Barz [NB 804 IE]

Die Chemie der Kunststoffe (The Chemistry of Plastics). By *K. Hamann*. From the Göschen Series, Vol. 1173/1173a. Walter de Gruyter und Co., Berlin 1967. 2nd Edit., 177 pp., numerous figures, stitched DM 5.80.

This volume has long been a recognized textbook providing the chemistry student with a first glimpse of the field of macromolecular chemistry. It is therefore with pleasure that we greet this new edition, which is practically the same size as the first edition, but in which certain chapters are presented more clearly and go into greater detail, and which also takes into account more recent results (*e.g.* thermal polymerization of styrene, copolymerization, average molecular weight). It should be mentioned in particular that the chapter on anionic polymerization now contains a section on polymerization by electron transfer. A section on polymerization with complex catalysts has also been added under the title "Coordination Polymerization", as well as one on cyclopolymerization. A new chapter, "Structure and Properties", briefly explains the concepts of structure and texture and deals in particular with elementary considerations on the coil density of the macromolecule in solution. The author adheres to current nomenclature throughout the new edition. It is to be hoped that the second edition will be as well received as the first.

H. Höcker [NB 794 IE]

Anorganikum. Lehr- und Praktikumsbuch der Anorganischen Chemie mit einer Einführung in die Physikalische Chemie (Textbook of Theoretical and Practical Inorganic Chemistry with an Introduction to Physical Chemistry). Edited by *L. Kolditz*. VEB Dt. Verlag der Wissenschaften, Berlin 1967. 1st Edit., xxxiv, 1032 pp., numerous figures and tables, stitched DM 56.–.

The "Anorganikum", which now takes its place alongside the "Organikum", again carries the names of a collection of authors and, according to notes on the cover, is intended to present in one book the principles of physical chemistry as well as preparative and analytical inorganic chemistry.

The book is divided into eight sections: A. "Laboratory equipment and laboratory methods" (38 pp.), B. "Structural components of materials" (116 pp.), C.I. "Chemical kinetics and reaction mechanisms" (50 pp.), C. II. "Equilibria and chemical thermodynamics" (82 pp.), C. III. "Electrochemistry" (32 pp.), D. "Compounds and reactions in inorganic chemistry" (299 pp.), E. "Practical preparations"

(108 pp.), F. "Qualitative Analysis" (102 pp.), G. I. "Principles of quantitative analysis" (118 pp.), G. II. "Electrochemical methods in quantitative analysis" (47 pp.), G. III. "Optical methods in quantitative analysis" (10 pp.), and H. "Research by the student" (5 pp.). A bibliography and subject and author indexes are included.

It is mentioned in the Preface that the "Anorganikum" is the outcome of a desire to reorganize the basic practical textbooks in general and inorganic chemistry, and is traceable to suggestions by a number of scientists at the Humboldt-Universität, Berlin. The problem of making the study of chemistry more concise and more effective is under discussion everywhere at present, and it is therefore pleasing when the innovations tried out so far pass beyond the walls of the institutes concerned. The reviewer wholeheartedly supports the authors in their efforts to replace the historically-based amalgamation of "general and inorganic chemistry" by an introduction to physical chemistry on an exact basis at the beginning of the study. It would, however, have been preferable to provide the student with an introductory textbook of physical chemistry as well as an "Anorganikum". This would have reduced the size of the book, and would have also impressed on the student that physical chemistry is now an independent subject even in German-speaking areas.

In the discussion of the sections, some of which differ widely in their merit, the excellently written Chapter B deserves to be placed first. This section deals with the constitution of atoms and molecules and the nature of the chemical bond on the basis of modern quantum theory. The spectroscopic methods used in chemistry nowadays for structural investigations are also mentioned. Chapters C.I to C.III, which are also very valuable to students, would have benefited from the use of more examples, particularly in the discussion of reaction mechanisms. The discussion of the kinetics of redox processes and ligand exchange reactions of complexes is left for a later section, and is very brief.

Chapter D, which is probably the most important part of the book as far as students of inorganic chemistry are concerned, leaves something to be desired in the reviewer's opinion, particularly with respect to the subject matter. One pleasing point is the numerous demonstration experiments, many of which are well thought out, and which are particularly suitable for an introductory practical course. On the other hand, the arrangement of Sections D.II and D.III warrants some criticism. In a discussion *e.g.* of the elements of the third main group in three separate sections (D.II.11, D.III. 3, and D.III. 8), the relations within a group cannot be adequately described. The division of the group VIII b triad is also not altogether wise.

In addition to many omissions [HN_3, SF_4, S_n ($n \neq 8$), metal-carbonyl compounds], there are also a number of inaccuracies. For example, the first known compound of an inert gas did not have the simple formula $Xe[PtF_6]$ (p. 460); the inert gas fluorides XeF_3 and KrF_4 have not yet been verified (p. 462); the statement (foot of p. 482) that fluorine can force an element into its highest positive oxidation state is not generally true (see RuF_6, OsF_6, but RuO_4, OsO_4); the NI_3 molecule (p. 517) is not known in the free form; boranes are not restricted to the formulae B_nH_{n+4} and B_nH_{n+6} (p. 545), and finally "rhenides" (p. 598) do not exist.

The practical character of the "Anorganikum" is shown in the introductory Chapter A and in Chapters E, F, and G, the last two being of a very high level. The emphasis in the section "Qualitative analysis" is placed on semimicro techniques, and separations without the use of hydrogen sulfide are discussed. The theoretical explanations could have been more detailed in places (*e.g.* F.2.1.7). Electrochemical and optical methods (but not flame photometry) are considered in the section "Quantitative analysis".

The reviewer finds that the section "Practical preparations", unlike Chapters F and G, is not entirely satisfactory. The procedures given relate almost exclusively to the preparation of oxides, salts of oxo acids, and halides, while the synthesis of hydrides, metal complexes, and some other classes of compounds is dealt with too briefly. Transport reactions and reactions in non-aqueous solvents are not mentioned at all. Moreover, a modern inorganic practical textbook should also contain some reference to the handling of substances that are sensitive to air or that are thermally unstable.

In view of the lack of good German-language theoretical and practical textbooks on inorganic chemistry, the author had great hopes regarding the present work. To his regret, however, these hopes have not been satisfactorily fulfilled, and it is doubtful whether the "Anorganikum" in its present form can win the place that has indisputably been gained by the "Organikum". The "Anorganikum" can be recommended only with reservations. *H. Werner* [NB 802 IE]

Hagers Handbuch der Pharmazeutischen Praxis für Apotheker, Arzneimittelhersteller, Ärzte und Medizinalbeamte. 1. Bd. Allg. Teil. Wirkstoffgruppen I (Hager's Handbook of Pharmaceutical Practice for Druggists, Drug Manufacturers, Physicians, and Medical Officials. Vol. 1, General Part. Groups of Active Materials I). Edited by *P. H. List* and *L. Hörhammer* in collaboration with *H. J. Roth* and *W. Schmid*. Springer-Verlag, Berlin 1967. 4th Edit., xxxii + 1270 pp., 267 illustrations, DM 120.–.

There is always the same problem with Handbooks – enormous labor and trouble is enshrined in them, it takes years before they are finally ready, and the moment they appear they no longer correspond to the current state of knowledge. Moreover, in a collective work to which various authors have contributed it is unavoidable that a certain lack of balance will be apparent on completion – some aspects receive too much emphasis, others have insufficient weight. The present volume does not avoid these insufficiencies, which are inherent in the traditional handbook: it was "closed" in October 1966 and the Foreword begs forgiveness for the time taken in printing and difficulties of its final preparation, which were much increased by the death of the original editor, Professor *W. Kern*.

The "Handbuch der Pharmazeutischen Praxis" is to comprise seven volumes, divided into four main sections: General Part, Groups of Active Materials, Chemicals and Drugs, also Drug Forms.

It is aimed primarily at druggists and drug manufacturers; the technical side is emphasized too much for physicians and the sections that are important for the latter (*e.g.* physiological-chemical studies and pharmacological properties of the drugs dealt with as groups of active materials) are not treated in sufficient detail.

The General Part (772 pp.) contains chapters on the testing of drugs and their preparation, on general physical testing procedures, on optical methods of analysis, chromatography, and chemical detection. Quantitative methods and investigation of fats, waxes, and ethereal oils are to be treated in detail in other sections. Pharmacognostic questions, such as the evaluation of drugs and drug preparations, and the microscopical study of drugs, receive the attention they deserve. The chapter on radioactive isotopes treats the radiation properties of several isotopes and their use in pharmacy and medicine, but the section on their use in pharmaceutical research is too cursory and the references leave much to be desired. The chapter on physiological-chemical methods of investigation corresponds approximately to the content of a medical-diagnostic pocketbook.

The list of reagents (96 pp.), arranged alphabetically, contains the designations given in books on drugs and in pharmacopoeia and provides a collection that is useful and important in pharmaceutical practice.

The second Part begins its presentation of the groups of active materials with the analgesics, which are followed by anthelmintics, antibiotics, *etc.* In general, technical data required in pharmacies are given, but the pharmacological properties are treated too briefly. Of the preparations included, those currently on the German market receive particular attention,

but some of the special materials and trade names in use elsewhere are also mentioned. Not only the groups of active materials of diagnostic and therapeutic use are mentioned, but also those concerned in preservation and technical use, such as antioxidants. It is not possible, on the basis of the groups treated in the first Volume, to form a picture of the division of the total material among the groups of active materials, but one misses, for instance, analeptic drugs, antacids, and cardiac drugs – though these may well appear under other titles. The designation anticonvulsive drugs would have been preferable to antiepileptic drugs. Some preparations considered nowadays as obsolete (Filix derivatives, santonin) are treated in detail among the anthelmintics; it would perhaps be useful to emphasize the most important preparations.

Reviewing a volume of a handbook is difficult and always incomplete, since the reviewer is unable to spend sufficient time on the assembled material. Handbooks are works of reference: only those who require them for their work and use them continuously can judge whether they meet the requirements and achieve the object set.

F. Gross [NB 788 IE]

Catalysis Reviews, Volume 1. Edited by *H. Heinemann*. Marcel Dekker, Inc., New York 1968. 1st Edit., vii, 333 pp., numerous illustrations and tables, bound $ 17.50.

H. Heinemann, the research director of the M. W. Kellogg Company and expert in industrially oriented catalysis research, is the editor of the first volume of "Catalysis Reviews". Why is this new series so welcome? Handbooks written more than 20 years ago are out of date; a wealth of empirical data lies buried in patents and scattered over innumerable journals, a discouraging chaos of scientific facts that are of great technical importance since almost half of our industrial products are the outcome of catalytic processes.

The "Catalysis Reviews" are intended to cover the entire field of homogeneous and heterogeneous catalysis: the physics and chemistry of the solid state, electrochemistry, metallurgy, corrosion, polymerization, and biochemical processes, a truly tremendous undertaking. The object of this work is to replace empiricism by a comprehensive understanding of the elementary processes, which should allow the reliable prediction of the catalytic behavior of matter.

Does the first volume in this series succeed in its purpose? The first requirement is to scrutinize the data in the hope that some pattern will emerge. An excellent example of this is the article by *J. Turkevich* on "Zeolites as Catalysts" (33 pages with 44 references). Another successful article is "Reactions Catalyzed by Pentacyanocobaltate(II)" by *J. Kwiatek* (30 pages with 114 references). As might be expected from the complexity of the subject, the chapter by *E. W. Stern* on "Reactions of Unsaturated Ligands in Pd(II) Complexes" is very long (70 pages with 203 references). The article by *S. S. Grover* on "Application of Computers to Systems of Chemical Reactions" (10 pages with 14 references) is intended for specialists. *P. Mark*'s article on "Electronic Surface States of Ionic Lattices" (40 pages with 33 references) is particularly important. Two chapters for the experimental worker are "Reflection Spectroscopy as an Aid to the Study of the Surfaces of Finely Dispersed Solids" (*K. Klier*, 22 pages with 56 references) and "Static Volumetric Methods for the Determination of Adsorbed Gases on Solid Surfaces" (*Z. Knor*, 50 pages with 231 references). *F. Solymosi*'s chapter "Importance of the Electrical Properties of Support Materials to the Catalytic Properties of Adsorbed Substances" (20 pages with 39 references) is very informative. Five of the eight chapters in the first volume are by Americans and the other three by Europeans. *H. Heinemann* will undoubtedly manage to keep this gigantic work on an international basis.

L. Horner [NB 811 IE]

Kunststoff-Handbuch (Plastics Handbook). Edited by *R. Vieweg* and *E. Becker*. Volume X: Thermosets. Preparation Properties, Processing, and Use. Carl Hanser Verlag, München 1968. 1st Edit. xxii, 749 pp., 473 figures, 110 tables, cloth DM 210.–; by subscription for the complete set (12 volumes) DM 168.–.

Though the production of condensation plastics is increasing more slowly than that of polymerization plastics, thermosets account for an important fraction (about 20%) of the total production because of their special properties. After the modified natural products, the production of synthetic organic materials started with the condensation resins produced by *Baekeland* from phenol and formaldehyde. These were later joined by the urea and melamine resins. Phenol, urea, and melamine are still the mainstays of thermosetting plastics.

Volume X of the Plastics Handbook is divided into the following main sections: resins, thermosets for the bonding and processing of wood, compression molding compositions, semifinished products, laminates, and the production of compression molded objects. An introduction with an historical review and a possibly rather brief section on the economic development are followed by an excellently arranged, comprehensive section on the phenolic, urea, and melamine resins, which deals with preparation, analysis, technological testing, and use both for compression molding and for adhesives and lacquers. As was said earlier in the review of the polyamide volume[1], condensation resins for textile finishing should be discussed in a textile volume. The section on the use of thermosets as adhesives presents the chemical and physical, as well as describing the technical aspects. The chapter on compression molding compositions is divided into structure, processing, properties, and uses for the various types. Apart from semifinished products (casting resins and foams), laminates with paper, fabrics, wood, vulcanized fiber, and mica provide a wide field of application for thermosets. The book closes with a chapter on compression molding, transfer molding, and injection molding.

The collaboration of experts in this volume has again led to excellent results. Processors and users (engineers, designers, and architects), as well as chemists and development workers, are presented with numerous suggestions, and extensive reference is made to the relevant literature. The volume can be warmly recommended to all those interested.

Divalent Silicon Intermediates

By W. H. Atwell[*] and D. R. Weyenberg

Like carbenes, silylenes are assumed to occur as intermediates in many reactions. A detailed account of the reactivity of the silylenes is given and the reductive and thermolytic methods used for their preparation are discussed. Insertion and interception reactions emphasize the formal relationship between these species and the carbenes. Silacyclopropenes and silacyclopropanes have not, as yet, been isolated.

1. Introduction and Nomenclature

The considerable attention devoted to divalent carbon compounds (carbenes) has had a great impact on organic chemistry. Although the systematic and sustained investigation of the chemistry of divalent silicon compounds (silylenes) is of more recent origin and much less complete, it is already apparent that it will have an equivalent impact on the field of organosilicon chemistry.

Because these divalent species overlap the traditional domain of both organic and inorganic chemistry, several different nomenclatures are currently being used to name the specific species as well as the generic class of intermediates.

In this review compounds are referred to as "silylenes" if the silicon radical is either unsubstituted or partially substituted (*e.g.* :SiH_2 = silylene, :SiHF = fluorosilylene) or if a parent group directly attached to silicon is capable of being substituted (*e.g.* :$SiMe_2$ = dimethylsilylene). When fully substituted by groups that cannot be further substituted, derivatives of divalent silicon are frequently given inorganic binary-type names (*e.g.* :SiF_2 = silicon difluoride, :$Si(CN)_2$ = silicon dicyanide)[1].

Although the name "silenes" has been previously applied to the general class of divalent silicon intermediates, it has been recently suggested[1,2] that this generic name is inappropriate because of possible confusion with unsaturated silicon compounds, should they exist. The alternative name, "silicenes" has also been proved as inappropriate[3]. In this review, we will use the more appropriate term "silylene" when referring to the generic class of divalent silicon intermediates. Also, since the division in nomenclature based on the substituent (and its ability to be further substituted) appears to be somewhat arbitrary, we will refer to all specific intermediates as derivatives of "silylene."

While the preparation and the spectral observation of the inorganic silylenes (dichlorosilylene in particular) were reported over thirty years ago[4], only recently have detailed studies of these intermediates appeared[5]. Silylenes have been suggested as intermediates in the "direct" synthesis of chlorosilanes[6–8], and have been demonstrated as intermediates in the preparation of silicon by the hydrogen reduction of chlorosilanes[9–14].

The objective of this review will be to discuss the reported silylene syntheses and to place in perspective those reports which contribute most to our present knowledge of the preparation, structure, and properties of these intermediates [15].

2. Methods of Preparation

Essentially all reactions used for the preparation of silylenes can be divided into two general methods: (A) The reduction of halosilanes, and (B) the thermal decomposition of appropriate substrates. Variations of each of these have been employed for the preparation of inorgano- as well as organosilylenes.

2.1. Reduction Methods

Of the reactions included under this method, the most intensely studied have been those involving the reaction of silicon with silicon tetrahalides. Reactions

$$SiX_{4(g)} + Si_{(s)} \rightleftharpoons 2\ :SiX_{2(g)}$$

of this type have been reported for a variety of silicon halides in which (X = fluorine [16,17], chlorine [9,14,18–22], bromine [23], and iodine [24–26]). These reactions take place only at temperatures above 800 °C and most of the above studies were carried out by passing the silicon tetrahalide over silicon at 1000 to 1500 °C; excellent yields of difluorosilylene (90%) [27] and dichlorosilylene (95%) [22] have been obtained at 1450 and 1350 °C, respectively. Various forms of silicon, such as silicon carbide, silicon alloys, and binary silicides of polyvalent metals have been used in the synthesis of difluorosilylene [16]. In addition, the reduction of other metal halides by silicon has been reported.

$$2\ CuCl + Si \rightarrow 2\ Cu + :SiCl_2 \qquad [7]$$

$$CaF_2 + Si \rightarrow Ca + :SiF_2 \qquad [27, 28]$$

Related vapor phase reductions have also been employed for the preparation of dimethylsilylene.

$$Me_2SiCl_2 + 2\ K_{(Na)} \xrightarrow{260-280\,^\circ C} 2\ KCl + :SiMe_2 \qquad [29]$$

Many of the products obtained from the reaction of dichlorodiorganosilanes and metals, in various aprotic solvents, have been explained in terms of silylene intermediates [5]. However, we do not feel that the formation of silylenes has been well established in many of the reactions and a more complete discussion of this area is included in Section 5 of this review.

Several reports show that the high-temperature reduction of silicon tetrachloride to silicon with hydrogen involves the intermediate formation of dichlorosilylene [10–13]. However, utilization of the dichlorosilylene produced *via* this route for other syntheses have not been reported.

$$SiCl_4 + H_2 \rightarrow 2\ HCl + :SiCl_2$$

2.2. Thermal Methods

The second general method for generating silylenes involves the thermal degradation of an appropriate substrate. Two of these methods, the thermolysis of polysilanes and of 7-silanorbornadienes, have provided a very convenient source of silylenes at moderate temperatures (170–300 °C).

The thermal degradation of hexahalodisilanes, first noted by *Friedel* and *Ladenburg* [30], gives silanes and higher polysilane compounds [5,31–33]. However, it is

$$Si_2I_6 \xrightarrow{\Delta} SiI_4 + (SiI_2)_n \qquad [30]$$

only during recent years that the intermediacy of silylenes in these thermolysis reactions has been established.

$$Si_2F_6 \xrightarrow{700\,^\circ C} SiF_4 + :SiF_2 \qquad [31]$$

The much more facile thermolysis of alkoxydisilanes [34] has rendered organosilylenes available at considerably lower temperatures. These thermolyses occur at 170

[15] A vast amount of work concerned with the suboxides and subsulfides of silicon is considered beyond the scope of this review.

to 300 °C (with half-lives of 1–3 h) in sealed tubes and lead to a silane and a series of polysilanes *via* a formal redistribution of silicon-silicon and silicon-oxygen

$$n(\mathrm{MeO})\mathrm{Me_2SiSiMe_2(OMe)} \xrightarrow{225\,^\circ\mathrm{C}} (n-1)\mathrm{Me_2Si(OMe)_2} + \mathrm{MeO(SiMe_2)}_{n+1}\mathrm{OMe}$$

bonds. Recent successful attempts to intercept reactive intermediates and kinetic studies with *sym*-dimethoxytetramethyldisilane provide convincing evidence that these reactions involve a rate-determining and unimolecular thermolysis of the disilane to give a silane and a silylene.

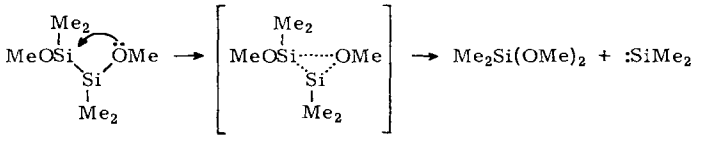
$$\mathrm{MeO(SiMe_2)_2OMe} \xrightarrow{-\mathrm{Me_2Si(OMe)_2}} [:\mathrm{SiMe_2}]$$

$$[:\mathrm{SiMe_2}] \xrightarrow{\mathrm{MeO(SiMe_2)}_{n-1}\mathrm{OMe}} \mathrm{MeO(SiMe_2)}_n\mathrm{OMe}$$

$$[:\mathrm{SiMe_2}] \xrightarrow{\text{interceptor}} \text{adduct}$$

The thermolysis of *sym*-dimethoxytetramethyldisilane is first-order in disilane and is not accelerated by the presence of trapping agents (such as acetylenes, dienes, alcohols, *etc.*) which efficiently intercept the silylene intermediate. Although the alkoxypolysilanes offer a new and convenient source of silylenes, it should be noted that the reactivity of the starting disilane toward the silylene can be a complicating factor in synthesis, *i.e.*, the trapping agent must compete with the starting disilane. The capture of the silylene by the disilane (*via* insertion into the silicon-oxygen bond) and other trapping agents will be discussed in Section 4 of this review.

This reaction appears to be quite general for alkoxypolysilanes with the more highly alkoxylated compounds undergoing thermolysis at lower temperatures. The reactions



$$(\mathrm{MeO})_6\mathrm{Si_2} \xrightarrow{175\,^\circ\mathrm{C}} (\mathrm{MeO})_4\mathrm{Si} + :\mathrm{Si(OMe)_2}$$

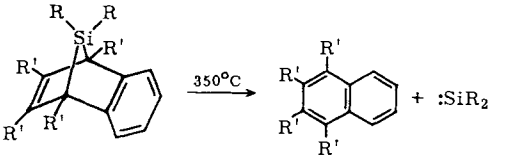
$$(\mathrm{MeO})_2\mathrm{MeSiSiMe(OMe)_2} \xrightarrow{200\,^\circ\mathrm{C}} \mathrm{MeSi(OMe)_3} + :\mathrm{SiMe(OMe)}$$

$$(\mathrm{MeO})\mathrm{Me_2SiSiMe_2(OMe)} \xrightarrow{225\,^\circ\mathrm{C}} \mathrm{Me_2Si(OMe)_2} + :\mathrm{SiMe_2}$$

$$(\mathrm{MeO})\mathrm{Me_2SiSiMe_2SiMe_2(OMe)} \xrightarrow{275\,^\circ\mathrm{C}} \mathrm{Me_2Si(OMe)_2} + 2:\mathrm{SiMe_2}$$

also proceed quite nicely in the vapor phase at 400 °C with reaction times of only a few seconds. They most likely involve an α-elimination mechanism, *e.g.*,

and, thus, constitute another variation of the type of α-elimination reaction which leads to the formation of carbenes. This appears to be a fairly general reaction of hetero-substituted polysilanes, where the heteroatom possesses an unshared electron pair [34,35].



It should be noted that the above considerations are applicable to only the thermal redistributions of polysilanes. A variety of base-catalyzed redistributions of silicon-silicon bonds with silicon-halogen and silicon-oxygen bonds are known [5,36], but there is no evidence that these reactions involve silylenes [34c,36]. In fact, no silylenes have been intercepted by acetylenes in the base-catalyzed redistribution of alkoxydisilanes [34c].

The thermal decomposition of polydimethylsilylene has been reported [5,37–39] to give dimethylsilylene.

$$(\mathrm{Me_2Si})_n \xrightarrow{\approx 300\,^\circ\mathrm{C}} n:\mathrm{SiMe_2} \qquad (n \approx 55)$$

The fact that not all polydimethylsilylenes decompose with such ease [40] and that the yields of silylene "trapped" products are generally low (1–6%) [37], renders this route somewhat unattractive for the production of such intermediates [41].

A second thermal method which has been useful in elucidating the chemistry of silylenes is the thermolysis of 7-silanorbornadienes. This reaction has been utilized [5,40,42] for the preparation of dimethyl- and diphenylsilylene.

R′ = Ph, R = Me or Ph.

It has been suggested [43] that silylenes are formed in the photolytic and thermal decomposition of a variety of metal silyls.

$$\mathrm{AlMe_2(SiMe_3)} \rightarrow \mathrm{AlMe_3} + :\mathrm{SiMe_2}$$

$$\mathrm{Hg(SiMe_2)}_n \rightarrow \mathrm{Hg} + n:\mathrm{SiMe_2}$$

While the synthetic utility of such methods has not been demonstrated, their potential as photolytic or low-temperature sources of silylenes seems worthy of further investigation.

Silylene formation has also been suggested in the thermal decomposition of a variety of monosilanes,

$$HSiCl_3 \xrightarrow{> 1000\,^\circ C} HCl + :SiCl_2 \quad [11]$$

$$SiX_4 \xrightarrow{> 900\,^\circ C} X_2 + :SiX_2$$

X = Cl [18, 44], I [23b, 26]

$$SiH_4 \xrightarrow{\approx 400\,^\circ C} H_2 + :SiH_2 \quad [45]$$

as well as in related decompositions using other energy sources such as photolysis [46–48], glow discharge [4,49,50], and neutron irradiation [2].

$$H_3SiX \xrightarrow[\text{photolysis}]{\text{flash}} H_2 + :SiHX \quad [46]$$

X = Cl and Br

$$MeSiH_3 \xrightarrow[UV]{\text{vacuum}} H_2 + :SiHMe \quad [48]$$

$$SiF_4 \xrightarrow[\text{discharge}]{\text{glow}} F_2 + :SiF_2 \quad [49, 50]$$

3. Structure and Physical Properties

The recent and extensive studies on difluorosilylene by *Margrave* and co-workers [27] have provided our most definitive picture of the spectral and physical properties of the silylenes. Difluorosilylene with a half-life of approximately 150 seconds at ambient temperature and 0.1 torr pressure is the most stable of the silylenes and is considerably more stable than its carbon analog, difluoromethylene. This exceptional stability allows the transport of difluorosilylene away from the reaction zone in the gas phase for study of its physical properties and of its chemistry. Although quantitative data are absent, none of the related silylenes are sufficiently stable to allow this kind of treatment.

Difluorosilylene has been studied in the gas phase by microwave [27, 51], electron spin resonance [52], ultraviolet absorption [27, 53, 54], by infrared spectroscopy [55] – and in a solid matrix at low temperature by infrared spectroscopy [56]. The structures of several other silylenes have been determined from spectral studies (see Table 1). In all cases the angle (Θ) formed by the two substituents on the silicon is considerably less than the tetrahedral angle. This same phenomenon is noted in carbenes where the bond angle in difluoromethylene has been recently shown to be 104.9° [58].

Table 1. Structural parameters of silylenes.

R, R¹ Si:	Θ (°)	r_0SiR (Å)	r_0SiR¹ (Å)	Lit.
R = H, R¹ = Cl	102.8	1.56	2.06	[46]
R = H, R¹ = Br	102.9	1.56	2.23	[46]
R = H, R¹ = H	92 [b]	1.52	1.52	[47]
R = F, R¹ = F	101 [c]	1.59 [c]	1.59 [c]	[27, 51]

[a] Values refer to the singlet ground state of the molecules.

[b] Predicted value was 95° (see ref. [57]).

[c] Previous values were $\Theta = 124°$ and r_0 SiF = 1.49 Å (see ref. [50]).

The heats of formation of the dihalosilylenes are given in Table 2. These data with the reported [23, 59] heats of formation of the corresponding silicon tetrahalides give the enthalpies for the reaction,

$$Si + SiX_4 \rightarrow 2\ :SiX_2$$

which are shown in Table 2. These data suggest that $:SiF_2$, which has the greatest life-time of the halosilylenes, is actually the least stable of the halosilylenes relative to the zero- and tetravalent silicon species. This instability may be related to the previously observed thermodynamic stability associated with the accumulation of fluorine about a silicon atom [60].

Table 2. Heats of formation of dihalosilylenes and calculated heats of reaction for $Si + SiX_4 \rightarrow 2\ :SiX_2$.

$:SiX_2$	$\Delta H^0_{f,298}$ (kcal mol^{-1})	$\Delta H^0_{R,298}$ (kcal mol^{-1})
$:SiF_2$	−139 [28]	108
$:SiCl_2$	−39.5 [21, 23a] [a]	82.6
$:SiBr_2$	−10.0 [23a]	79.8

4. Reactions

It is only in recent years that the chemistry of the silylenes has been examined and that reagents have been discovered that will intercept (trap) them. As with any highly reactive intermediate, the chemistry of a silylene is basically a consideration of the competitive reactions available to it under the conditions in which it is generated. These are summarized in Scheme 1 below, where, after generation by reduction or thermolysis (see Section 2), the silylene may either polymerize, react with its precursor, or react with a "trapping reagent" which is added to intercept the species. The fate of the silylene and the products of the reaction will depend on the relative rates of these three processes. In this

Scheme 1

section we will attempt to classify the known chemistry of silylenes into a limited number of rather general reactions. The reactions we will consider are polymerization, insertion into single bonds, and the addition to multiple bonds – three reactions which also characterize most of the known chemistry of carbenes.

4.1. Polymerization

Silylenes, when generated in the absence of other reagents, usually undergo polymerization to give polysilanes. The many examples of such silylene polymer-

$$n\ :SiX_2 \rightarrow (SiX_2)_n$$

ization include cases where X = F [16,17,31], Cl [22,23,44,61], Br [33,62], and I [24,26,30,63].

This reaction may be analogous to the dimerization of carbenes to form olefins [64], with the difference in

$$2\ :CF_2 \rightarrow F_2C{=}CF_2$$

products being due to the known [3] instability of multiple bonds between silicon atoms.

In all cases, with the possible exception of difluorosilylene, a variety of trapping agents can compete with the polymerization process. Difluorosilylene is quite unreactive in the gas phase [17] but undergoes reaction on co-condensation at low temperatures with a variety of substrates. Under these conditions the majority of products contain silicon-silicon bonds and it appears that partial polymerization (dimerization, trimerization, *etc.*) occurs prior to reaction with the added "trapping" agents. A recent electron spin resonance

$$(:SiF_2) \rightarrow (Si_2F_4) \rightarrow (Si_3F_6) \xrightarrow{etc.} (SiF_2)_n$$

study [28] of SiF_2/SiF_4 mixtures has confirmed the presence of paramagnetic species under these conditions which may represent diradical species, $[\cdot(SiF_2)_n\cdot]$.

4.2. Insertion into Single Bonds

A rather wide variety of reactions has been reported which involve the insertion of silylene into a single bond. In all cases either X or Y has been a hydrogen or one of the more electronegative elements such as a halogen or an alkoxy group.

$$R_2Si + XY \rightarrow R_2Si\begin{matrix}X\\Y\end{matrix}$$

The insertion of silylenes into a variety of MX bonds (where M represents boron, carbon, or phosphorus and X represents halogen or alkoxy) may be a rather general reaction. Both dichlorosilylene [22] and difluorosilylene [27,65] react with boron and phosphorus

$$:SiCl_2 + BCl_3 \rightarrow Cl_3SiBCl_2 \quad [22]$$

$$:SiCl_2 + PCl_3 \rightarrow Cl_3SiPCl_2 \quad [22]$$

halides. In the case of difluorosilylene and phosphorus trifluoride, unstable silicon-phosphorus compounds were formed [27]. The difluorosilylene-boron trichloride and dibromosilylene-boron trifluoride systems give similar products but are complicated by halogen exchange reactions.

$$:SiBr_2 + BF_3 \rightarrow FBr_2SiBF_2 \xrightarrow[\text{exchange}]{\text{halogen}} F_3SiBF_2 \quad [66]$$

Related reactions with alkyl halides have also been reported. Also, the reactions of difluorosilylene and

$$:SiCl_2 + CCl_4 \rightarrow Cl_3SiCCl_3 \quad [22]$$

$$n\ :SiF_2 + MeF \rightarrow MeSi_nF_{2n+1} \quad [67]$$
$$(n = 2\text{–}4)$$

trifluoroethylene or fluorobenzene (see Section 4.3.2) are formally an insertion into the carbon-fluorine bond. The anomalous behavior of difluorosilylene is

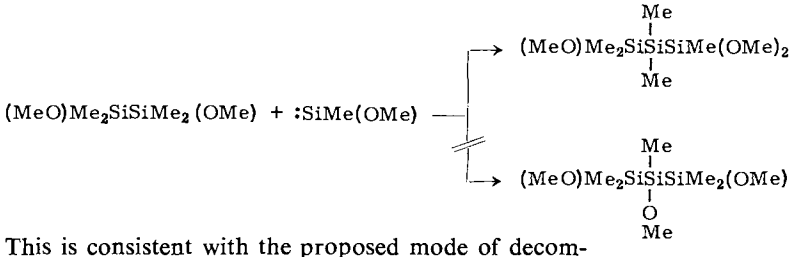
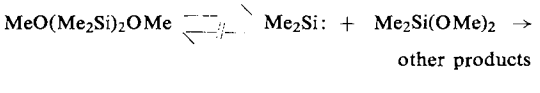
again illustrated in the above examples, however, 1:1 adducts being obtained with other MX compounds.



$$:SiF_2 + Br_2 \rightarrow Br_2SiF_2 \quad [16]$$

There are now several examples of silylenes reacting with alkoxy- or halo-substituted polysilanes. While

$$MeO(SiMe_2)_nOMe + :SiMe_2 \rightarrow MeO(SiMe_2)_{n+1}OMe \quad (n \geqslant 2) \quad [34a]$$



$$Cl(SiCl_2)_nCl + :SiCl_2 \rightarrow Cl(SiCl_2)_{n+1}Cl \quad (n \geqslant 2) \quad [32]$$

the above products could arise *via* reaction with the silicon-silicon bond, the following example shows that this reaction proceeds *via* insertion in the Si–X bond.

This is consistent with the proposed mode of decomposition of these alkoxy-substituted polysilanes which involves an α-elimination of the terminal silicon, *i.e.*, the reverse of the above silicon-oxygen insertion reaction [34c].

While the above data suggest that the reaction of silylenes with the silicon-oxygen or silicon-halogen bonds of polysilanes is rather general, several attempts to carry out related reactions with monosilanes have been unsuccessful. Thus, silicon tetrafluoride did not react with difluorosilylene, and the reaction of dimethylsilylene with dimethyldimethoxysilane was shown to be kinetically unimportant in the thermolysis of the corresponding disilane [35]. With additional data on the relative reactivities of various SiX bonds, this

reaction could become a valuable synthetic route to polysilanes.

Silylenes react with a variety of X–H bonds to give 1:1 adducts:

$$:SiMe_2 + Me_3SiH \rightarrow Me_3SiSiMe_2H \quad [29, 35]$$

$$:SiH(SiMe_3) + Me_3SiH \rightarrow (Me_3Si)_2SiH_2 \quad [68]$$

$$:SiMe(OMe) + MeOH \rightarrow MeHSi(OMe)_2 \quad [35]$$

$$:Si(OMe)_2 + MeOH \rightarrow HSi(OMe)_3 \quad [35]$$

$$2{:}SiF_2 + HBr \rightarrow HF_2SiSiF_2Br \xrightarrow[\text{exchange?}]{\text{halogen}} HF_2SiSiF_3 \quad [69]$$

$$:SiF_2 + H_2S \rightarrow HF_2SiSH \quad [67]$$

$$3{:}SiF_2 + 2GeH_4 \rightarrow H_3GeSiF_2H + H_3GeSiF_2SiF_2H \quad [66]$$

[68] *P. S. Skell* and *P. W. Owen*, J. Amer. chem. Soc. *89*, 3933 (1967).

[69] *A. G. MacDiarmid* and *Y. L. Baay*, unpublished.

The last two reactions are additional examples of 1:1 adducts from difluorosilylene. It has been suggested that the "direct" synthesis of trichlorosilane from silicon and hydrogen chloride involves this type of insertion reaction.

$$:SiCl_2 + HCl \rightarrow HSiCl_3 \quad [8]$$

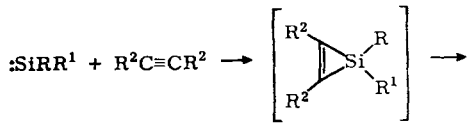
The similarity of these reactions of silylenes to the reactions of carbenes with hydrogen halides [70], alcohols [64, 70, 71], and silicon and germanium hydrides [70] is very striking. However, insertion into carbon-hydrogen bonds, which is a common reaction with carbenes, has not been observed with silylenes. The low efficiency of dimethylsilylene insertions into the

(ref. [35])

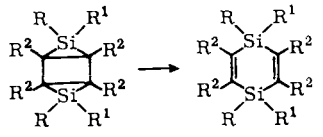
carbon-hydrogen bonds of ethane and trimethylsilane has been cited in support of the suggested decreased reactivity of this silylene relative to methylene [29].

4.3. Carbon-Carbon Multiple Bonds

Certainly the most popular and probably the most general method for intercepting carbenes involves trapping with unsaturated hydrocarbons. Most of our information regarding carbene chemistry has come from these reactions which yield cyclopropanes or cyclopropenes. Silylenes also appear to react with a variety of unsaturated organic compounds; however, to date, no stable, isolable silacyclopropanes or silacyclopropenes are known [72].



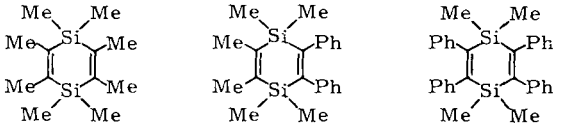
4.3.1. Alkynes



Since the initial report [37] that diphenylacetylene could be employed as a "trapping" agent for dimethylsilylene and the original incorrect assignment of the structure of the products was corrected [5, 34c], a variety of acetylenes and silylenes have been employed in this reaction. In all cases the product is the corresponding 1,4-disilacyclohexadiene. It is generally assumed that the disilacyclohexadiene arises *via* a silacyclopropene and it has been further suggested [40] that a dimerization through the π-system was involved.

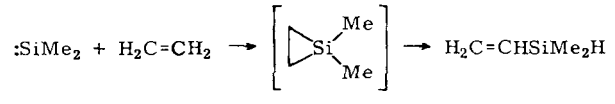
[70] *D. Seyferth* in: Proc. R. A. Welch Foundation Conference Chem. Res. IX Organometallic Compounds, Robert A. Welch Foundation, Houston, Texas, 1966, p. 84ff.

[71] *A. M. Trozzolo, W. A. Yager, G. W. Griffin, K. Kristinsson*, and *I. Sarkar*, J. Amer. chem. Soc. *89*, 3357 (1967).

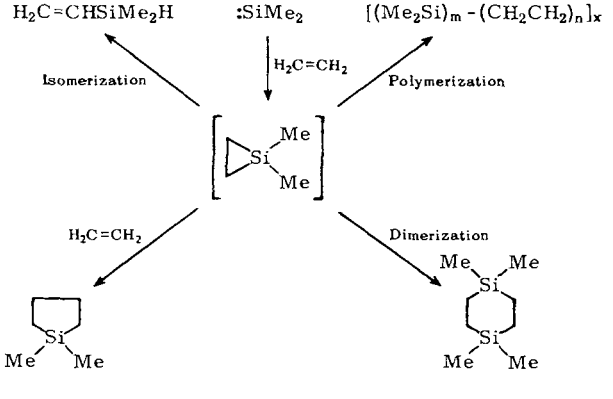


[72] *K. A. Andrianov* and *L. M. Khanashvili*, Organometallic Chem. Rev. *2*, 141 (1967).

R = R¹ = Me, R² = Ph [5, 34, 37, 40]
R = R¹ = Me, R² = Et [35]
R = R¹ = Ph, R² = Ph [42]
R = Me, R¹ = OMe, R² = Ph [34]
R = Me, R¹ = OMe, R² = Me [35]
R = Me, R¹ = OMe, R² = H [35]



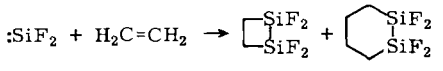
However, reaction of dimethylsilylene with a mixture of dimethyl and diphenylacetylene gave only three disilacyclohexadienes. The structure of the "mixed" disilacyclohexadiene eliminated from further consideration the π-dimerization mechanism for disilacyclohexadiene formation. An alternative route involving



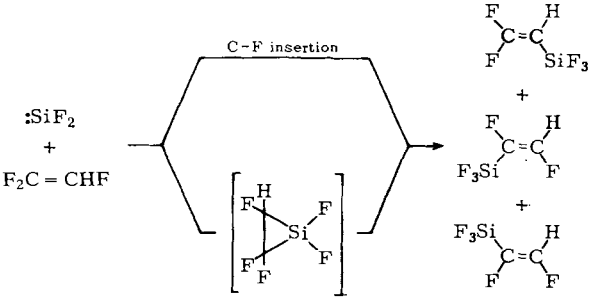
a rather specific dimerization across the carbon-silicon ring bonds of the silacyclopropene intermediates has been suggested [34c].

4.3.2. Alkenes

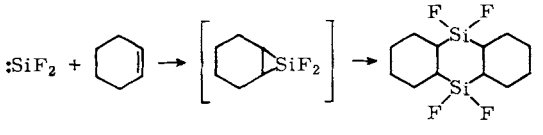
The reaction of dimethylsilylene with ethylene in the vapor phase has been reported [29]. While the product isolated is vinyldimethylsilane, it has been suggested [29]



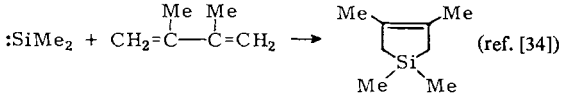
that this reaction involves formation and isomerization of 1,1-dimethyl-1-silacyclopropane rather than direct insertion of the silylene into the carbon-hydrogen bond. The condensed phase reaction of dimethyl silylene (from 7-silanorbornadienes) and ethylene



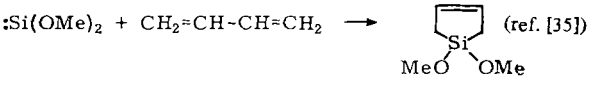
gives, in addition to vinyldimethylsilane, cyclic and polymeric products which are also viewed as derivatives of the silacyclopropane [5]. It should be noted that although the above examples demonstrate that dimethylsilylene reacts with simple olefins, the non-conjugated olefins cannot successfully compete with simple alkoxydisilanes for the silylenes, and, therefore, this convenient source of silylenes is not satisfactory for this class of reactions. The relative reactivities of various unsaturated organic compounds are compared in Section 4.4.



The reactions of difluorosilylene with ethylene [16], acrylonitrile [16], and tetrafluoroethylene [16, 73] had been reported to give solid polymeric products. In a recent study, however, two monomeric products were identified from the ethylene reaction [73].

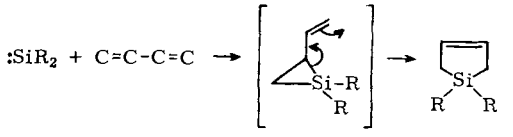


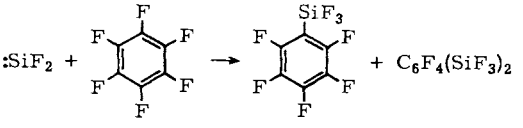
Reaction of difluorosilylene and trifluoroethylene gave several vinylsilane derivatives [73]. While these products may be accounted for *via* insertion into the



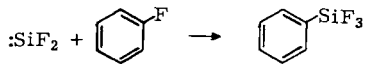
C–F bonds (see Section 4.2), their formation may also be rationalized by isomerization of a silacyclopropane intermediate. The reaction of difluorosilylene and cyclohexene has been thoroughly studied [74], and, again, the products are most easily explained *via* dimerization of a silacyclopropane.

Conjugated olefins such as butadienes have also been utilized as trapping agents. Difluorosilylene and 2,3-dimethylbutadiene gave only solid polymeric products [16]. Silylenes generated *via* pyrolysis of alkoxydi-



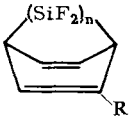


[73] *J. C. Thompson, P. L. Timms,* and *J. L. Margrave,* Chem. Commun. *1966,* 566.



[74] *A. G. MacDiarmid* and *F. M. Rabel,* unpublished.

silanes and of 7-silanorbornadienes, however, gave silacyclopentenes. The dienes, like the acetylenes, compete successfully with the alkoxydisilanes for the silylenes. While the silacyclopentene is formally a product of 1,4-addition of the silylene, a reaction path involving formation and thermal isomerization of a vinyl-substituted silacyclopropane is favored [34].



Dimethylsilylene from the pyrolytic methods is not intercepted by simple aromatic compounds [35,40,42]. However, a variety of derivatives have been isolated from the co-condensation of difluorosilylene with

benzene or fluorobenzenes [75]. Reaction with benzene or toluene, however, follows a different path to give structures of the type shown below.

R = H, $n = 3$
R = Me, $n = 3$
R = Me, $n = 2$

4.4. Relative Reactivities

The trapping of silylenes from the pyrolysis of methoxydisilanes provides some insight into the relative reactivity of the trap, for it must always compete with the precursor disilane for the silylene. From these and related studies with the 7-silanorbornadienes, we see that saturated hydrocarbons and benzene are quite inert and do not compete with the polymerization of the silylene. Ethylene reacts with the silylene but cannot compete with the disilane. Acetylenes and conjugated dienes are more reactive than the methoxydisilane with the dimethylsilylene. Thus, we have the following series of relative reactivities toward dimethylsilylene.

benzene < ethylene < dimethoxytetramethyldisilane < dienes and alkynes

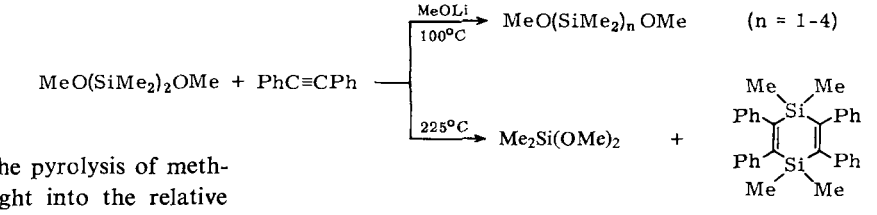
5. Concerning the Proposed Intermediacy of Silylenes in Other Organosilicon Reactions

A number of organosilicon reactions are known (in addition to those previously discussed) which involve the formal transfer of an $R_2Si=$ moiety. Although some of these reactions are closely related to known methods of generating silylenes and have been interpreted in terms of silylene intermediates, present evidence suggests alternative mechanisms. In some cases, even the intermediacy of "silylenoid" [76] species is unlikely.

5.1. Catalyzed Disproportionation of Polysilanes

A number of base-catalyzed disproportionation reactions of substituted polysilanes have been reported [79]. Silylene intermediates have been suggested [5] for some of these reactions which are formally similar to the thermal disproportionations (Section 2.2) – reactions known to involve silylenes.

$$n\ Si_2Cl_6 \xrightarrow{\text{amine or ammonium halide}} n\ SiCl_4 + (SiCl_2)_n \quad [80, 81]$$



$$n\ EtCl_2SiSiCl_3 \xrightarrow{Me_3HNCl} n\ EtSiCl_3 + (SiCl_2)_n \quad [80]$$

$$4\ Si_2Cl_6 \xrightarrow{Me_3HNCl} 3\ SiCl_4 + Si_5Cl_{12} \quad [82, 83]$$

$$n\ Me_3SiSiMe_2CN \xrightarrow{\Delta} (n\text{-}1)\ Me_3SiCN + Me_3Si(SiMe_2)_nCN \quad [84]$$
$$n = 2\text{–}5$$

$$2\ MeO(SiMe_2)_2OMe \xrightarrow{MeOLi} Me_2Si(OMe)_2 + MeO(SiMe_2)_3OMe \quad [36]$$

However, to date, there is no direct evidence to support this suggestion and the one attempt to examine this point suggests a quite different mechanism. Thus, while the thermolysis of 1,2-dimethoxytetramethyldisilane in the presence of diphenylacetylene gives a disilacyclohexadiene derivative, none of the latter is obtained in the base-catalyzed reaction of this disilane [34c].

These base-catalyzed reactions are best explained in terms of a silicon-silicon (SiSi) and silicon-ligand (SiL) redistribution of the general type [36,79,85]:

$$-\overset{*}{Si}Si- + SiSiL \rightarrow \overset{*}{Si}-L + -SiSiSi-$$

---

[75] *P. L. Timms, D. D. Stump, R. A. Kent,* and *J. L. Margrave,* J. Amer. chem. Soc. *88*, 940 (1966).

[76] The term "silylenoid" analogous to "carbenoid" [77, 78] is suggested for the general class of intermediates which exhibit reactions qualitatively similar to those of silylenes without necessarily being free divalent silicon species.

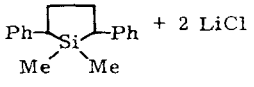
[85] An exception to this may be the thermally induced reactions of the cyano-substituted polysilanes [84].

5.2. Reaction of R_2SiX_2 with Metals

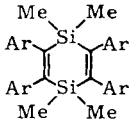
Although some of the most convincing evidence for dimethylsilylene has come from the reaction of dichlorodimethylsilane and potassium in the gas phase[29] (Section 2.1), the nature of the reaction of alkali metals and dihalodiorganosilanes in the condensed phase is much more obscure. Dihalodiorganosilanes react rapidly with alkali metals in a variety of solvents to yield polysilanes[79,86], and a similar reaction occurs more slowly with halotriorganosilanes[79,86].



$$R_2SiCl_2 + 2\ M \rightarrow (R_2Si)_n + 2\ MCl$$

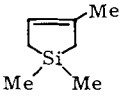
$$2\ R_3SiCl + 2\ Na \rightarrow R_3SiSiR_3 + 2\ NaCl$$

An attempt to intercept silylene intermediates in the reaction of dichlorodiphenylsilane and lithium using cyclohexene was unsuccessful[87].



Of specific interest is the class of reactions where the combination of an alkali metal, a dichlorodiorganosilane, and an unsaturated organic compound yield organic products containing the $R_2Si=$ unit. The reactions have been cited[5] as examples of syntheses involving silylenes.

$$Me_2SiCl_2 + 2\ PhCH{=}CH_2 + 2\ Li \rightarrow$$



$+ 2\ LiCl$ [5,88]

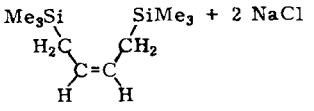
$$2\ Me_2SiCl_2 + 2\ ArC{\equiv}CAr + 4\ Na \rightarrow$$

$+ 4\ NaCl$ [37,89]

$$Me_2SiCl_2 + CH_2{=}CH{-}\underset{\displaystyle Me}{\underset{|}{C}}{=}CH_2 + 2\ Na \rightarrow$$

$+ 2\ NaCl$ [90]

It is highly unlikely that any of the above reactions involve silylenes as nearly identical reactions are obtained in each case with a chlorotriorganosilane. These reactions involve the trapping, *via* reaction with a chlorosilane, of short-lived organometallic reagents from the alkali metal made olefin, *i.e.*, a "disilylation" reaction[88,90]. This latter scheme is more consistent with the effects of stoichiometry, solvent, and metal on the structure and stereochemistry of the products than is one involving silylene intermediates.

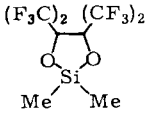


$$2\ Me_3SiCl + 2\ PhCH{=}CH_2 + 2\ Li \rightarrow$$

$$Me_3SiCHCH_2CH_2\overset{\displaystyle Ph}{\overset{|}{C}}HSiMe_3 + 2\ LiCl \quad [88]$$

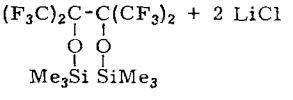
$$2\ Me_3SiCl + PhC{\equiv}CPh + 2\ Na \rightarrow$$

$$(Me_3Si)PhC{=}CPh(SiMe_3) + 2\ NaCl \quad [91]$$



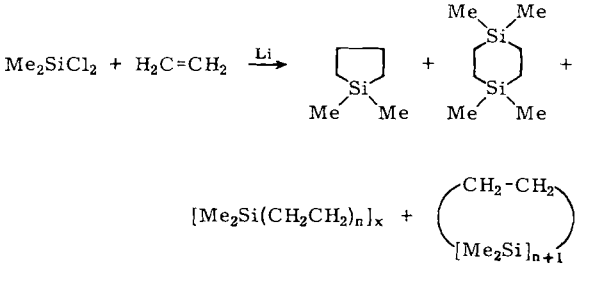
$$2\ Me_3SiCl + CH_2{=}CH{-}CH{=}CH_2 + 2\ Na \rightarrow$$

$+ 2\ NaCl$ [90]



Likewise, the related reaction with hexafluoroacetone was initially thought[92] to involve a silylene, but most likely involves initial reaction of the alkali metal and the ketone[93,94].

$$Me_2SiCl_2 + 2\ (CF_3)_2CO + 2\ Li \rightarrow$$



$+ 2\ LiCl$ [92,93]

$$2\ Me_3SiCl + 2\ (CF_3)_2CO + 2\ Li \rightarrow$$

$+ 2\ LiCl$ [93]

Related reactions with olefins which react less readily with alkali metals may indeed involve initial reaction between the chlorosilane and metal. Particularly, the reaction of dimethyldichlorosilane, lithium, and ethylene is more consistent with

a silylene or "silylenoid" intermediate (Section 4.3)[39a]. Because of these complicating factors, the reaction of alkali metals and halosilanes in aprotic solvents has been of limited value in the study of silylenes.

The authors are grateful to Drs. A. G. MacDiarmid, J. L. Margrave, and P. L. Timms for allowing use of their data prior to publication.

Hetero Analogs of Sesquifulvalene[1]

By G. Seitz[*]

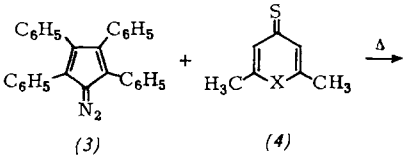
Heterosesquifulvalenes containing sulfur or oxygen as hetero atom may be prepared, e.g., by condensation of cyclopentadienes with thiopyrones or pyrones in acetic anhydride. Heterosesquifulvalenes containing nitrogen can be obtained from the oxygen compounds by O,N-exchange. The ground state of all these compounds is determined mainly by the nonpolar resonance formula.

1. Introduction

Both the increasing pharmacological significance of cyclopentadienylidenes [2] and the considerable interest shown by theoretical chemists have provided impulse to the search for new syntheses of heterosesquifulvalenes [3]. These compounds are formally derived from sesquifulvalene *(1)* [4], replacement of a $-CH=CH-$ group of the carbocyclic seven-membered ring by a hetero atom such as oxygen [5,4c], sulfur [5,4c], or nitrogen [6], giving cyclopentadienylidenepyrans, -thiopyrans, and -1,4-dihydropyridines, respectively. Compound *(1)* and its hetero analogs *(2)* are characterized by cyclic cross-conjugated π-bond systems, which can be described to a first approximation by a covalent resonance structure and a dipolar one.

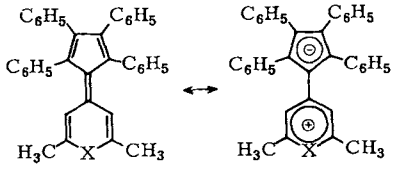
(1) *(2)*

X = O, S, N-R



If the dipolar form were to make a large contribution to the resonance hybrid, a situation that would be favored by the gain in resonance energy of two aromatic 6π systems, then stable molecules having high dipole moments would result and the bond order of the intercyclic C=C double bond would be reduced. Such predictions [7], based on simple HMO calculations, prove inapplicable [4a] to sesquifulvalene, which is in fact a highly unstable compound whose properties resemble more those of a reactive polyolefin. In contrast, the nitrogen-containing heterosesquifulvalenes *(2)*, having X = N–R [6], are relatively stable.

With this in mind, our interest became focused on the chemical behavior of the oxygen and sulfur analogs. The present article reports on a simple method of synthesis and a number of chemical and physical properties of these heterosesquifulvalenes.



2. Synthesis of Heterosesquifulvalenes containing Oxygen and Sulfur as Hetero Atoms

Two methods for the preparation of cyclopentadienylidenepyrans and -thiopyrans have hitherto become known. The first method is restricted to phenyl-substituted cyclopentadienes and is based on the reaction of diazocyclopentadienes *(3)* with 4-thiopyrones *(4)* in xylene at elevated temperatures to give *(5)* [5].

The second synthetic route utilizes the finding that substituents exhibiting a –M or –I effect increase the

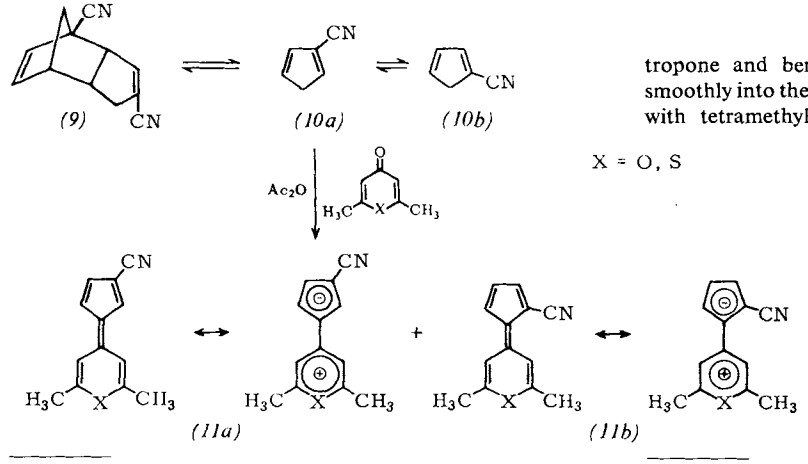
reactivity of the cyclopentadienes *(6)* and promote their condensation with ketones such as *(7)*, X = O,S, or –CH=CH–, in acetic anhydride[4c,1]. A number of heterosesquifulvalenes *(8a)–(8e)* that have been prepared by the "anhydride method"[8] are listed in Table 1.

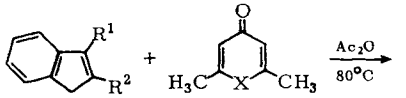
(6) *(7)*



(8)

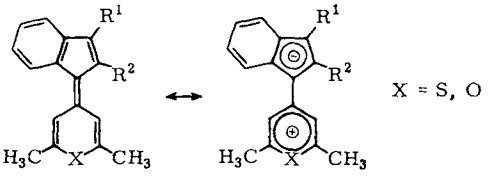
Table 1. Cyclopentadienylidenepyrans and -thiopyrans prepared by the "anhydride method".

(8)	R^1	R^2	R^3	R^4	X	M.p. (°C)	Yield (%)
(a)	CO_2CH_3	CO_2CH_3	CO_2CH_3	CO_2CH_3	O	227	52
(b)	Cl	Cl	Cl	Cl	O	>150 (decomp.)	45
(c)	CO_2CH_3	H	CO_2CH_3	H	S	171	12
(d)	CN	CN	H	H	O	>260 (decomp.)	25
(e)	CN	H	H	H	S	168	19



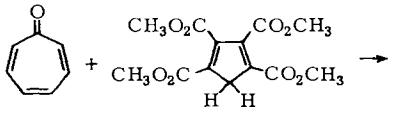
Even those cyclopentadienes formed by retro-Diels-Alder reaction at elevated temperatures are activated sufficiently by only one such substituent, and can consequently be intercepted in the equilibrium *(9)* ⇌ *(10)* by pyrone or thiopyrone. The resulting monosubstituted heterosesquifulvalenes *(11a)* and *(11b)* are also stable compounds; the major product *(11b)* can be separated from the minor component of the isomeric mixture by adsorption chromatography on silica gel.

(9) *(10a)* *(10b)*



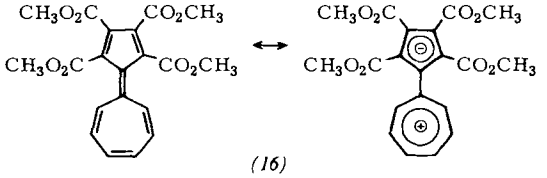
(11a) *(11b)*

Provided that the indene system *(12)* carries electron-attracting substituents, the anhydride method can also be used for the synthesis of the hetero analogs of 9,10-benzosesquifulvalenes[10], indenylidenepyrans and -thiopyrans *(13)*, X = O,S[9].

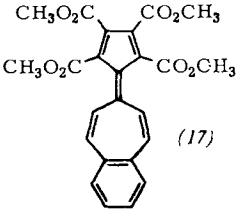


(12a), $R^1 = CO_2CH_3$, $R^2 = H$

(12b), $R^1 = R^2 = CO_2C_2H_5$



(13)



The success of these experiments provided some justification for the expectation that, like the heterocyclic ketones, the iso-π-electronic system tropone *(14)* should also condense with activated cyclopentadienes in acetic anhydride. Indeed, both

(14) *(15)*

(16)

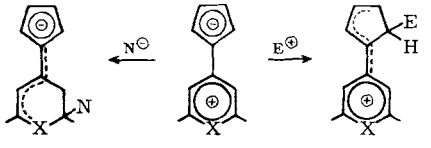
(17)

tropone and benzotropone could be converted extremely smoothly into the sesquifulvalenes *(16)* and *(17)* by treatment with tetramethyl cyclopentadienetetracarboxylate[11] *(15)*.

[8] Regarding condensation reactions of other CH acids with 4-pyrones, cf. *L. L. Woods*, J. Amer. chem. Soc. *80*, 1440 (1958); *F. Eiden*, Angew. Chem. *71*, 747 (1959); Arch. Pharmaz. *293*, 404 (1960); *M. Ohta* and *H. Kato*, Bull. chem. Soc. Japan *32*, 707 (1959); *J. Kelemen* and *R. Wizinger*, Helv. chim. Acta *45*, 1908 (1962).

[9] *G. Seitz*, Arch. Pharmaz. *300*, 1016 (1967).

[10] *H. Prinzbach*, *D. Seip*, and *G. Englert*, Liebigs Ann. Chem. *698*, 57 (1966).



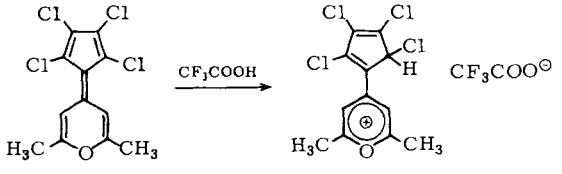
[11] *G. Seitz*, Angew. Chem. *78*, 680 (1966); Angew. Chem. internat. Edit. *5*, 670 (1966).

An analogous synthesis of the tetrachloro derivative *(16)*, Cl instead of CO_2CH_3, has also been reported[12].

The synthesis of substituted heterosesquifulvalenes and a number of hetero analogs of 9,10-benzosesquifulvalene, as well as the condensation of tropone and benzotropone, illustrate the scope of the anhydride method. The limitations of this synthetic technique become apparent when one considers the unsuccessful attempts to condense unsubstituted cyclopentadiene, indene, or fluorene with pyrones.

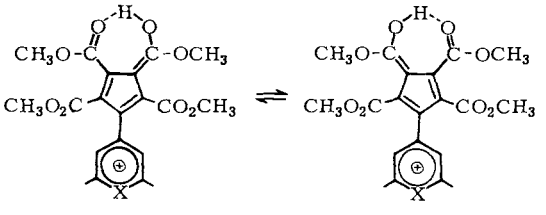
3. Reactivity of Heterosesquifulvalenes

A highly polar ground state of the heterosesquifulvalenes, in line with the dipolar formula *(18)*, would suggest amphoteric character and therefore permit electrophilic reactions in the five-membered ring and nucleophilic reactions in the six-membered ring.



(18)

Both such reactions do take place, as shown in the following examples.

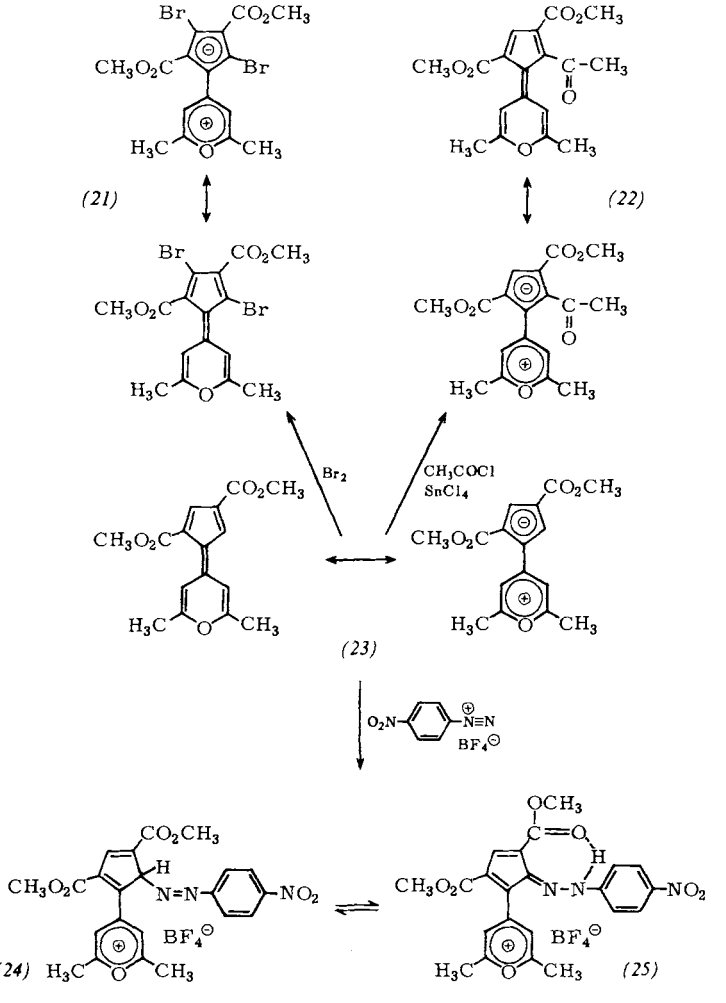


3.1. Electrophilic Addition

Heterosesquifulvalenes are relatively strong "π bases". For instance, in strong acids, such as perchloric acid or trifluoroacetic acid, *(8b)* undergoes regiospecific

(8b) *(19)*

quantitative *C*-protonation to give *(19)*[1,4a,5,6b,13]; the structure of the product is proved by NMR and UV spectra.

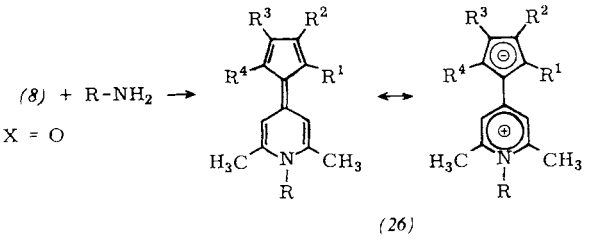


(20a), X = O
(20b), X = S
(20c), X = -CH=CH-

(8a), the analog having X = S, and *(16)* are all protonated in a uniform manner, though at the ester carbonyl group; NMR and electronic spectra suggest the structures *(20a)*, *(20b)*, and *(20c)*, having a symmetrical hydrogen bond[1,4d].

3.2. Electrophilic Substitution

Electrophilic substitutions occur in good yields, even at room temperature. Friedel-Crafts acylation of *(23)* with acetyl chloride/$SnCl_4$ affords the monoacetylated compound *(22)*. An excess of bromine converts *(23)* into the dibromo derivative *(21)*, whereas reaction with *p*-nitrobenzenediazonium fluoroborate probably yields the phenylhydrazone *(25)*, which is tautomeric with *(24)*.

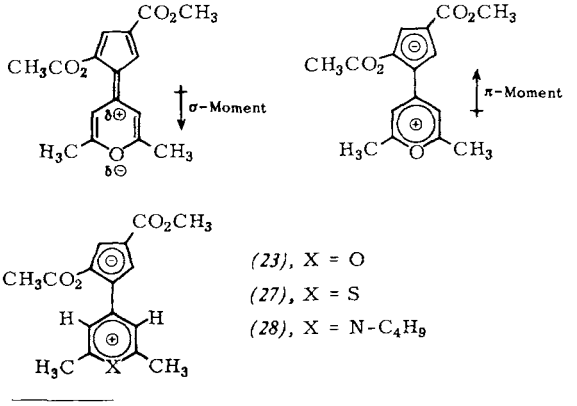


(21) *(22)* *(23)* *(24)* *(25)*

3.3. Nucleophilic Reactions

Pyrones and pyranylidene compounds are known to be readily convertible into pyridine derivatives by treatment with primary amines[5,14]. By analogy, replacement of oxygen in cyclopentadienylidenepyrans should also be feasible. Indeed, heterosesquifulvalenes containing oxygen as hetero atom react almost quantitatively, irrespective of substituents, with aliphatic amines to give the aza analogs *(26)*. This nucleophilic

[12] *E. D. Bergmann*, Chem. Reviews *68*, 74 (1968).
[13] *E. D. Bergmann* and *I. Agranat*, Tetrahedron *22*, 1275 (1966).



substitution proves a useful addition to the known syntheses of unsubstituted or annelated nitrogen analogs of sesquifulvalene.

4. Polarity and Electron Distribution

NMR data provide no unequivocal information regarding the shielding of the protons attached to the five- and six-membered rings of heterosesquifulvalenes; the anisotropic effects of the substituents do not permit direct relationships to be observed between the chemical shifts and the π-electron density distribution. On the other hand, solvatochromism effects[15] should at least furnish qualitative information about the polarity of the ground state. All the heterosesquifulvalenes having oxygen or sulfur as hetero atom that have been isolated so far show, to a greater or lesser extent, a pronounced positive solvatochromism. The ground state is therefore determined primarily by the nonpolar resonance formula. However, measurements of dipole moments and determination of the free energy of activation $\Delta G_c^{\neq}$ for rotation around the central C–C double bond suggest that the dipolar form also contributes to the resonance hybrid.

Compound *(23)* has a dipole moment of 5.1 D (20 °C, benzene), a finding that becomes all the more remarkable when one considers that the sense of the σ moment (disregarding the effect of the two ester groups, which is not readily estimable) is opposed to that of the π moment[16].

The heterosesquifulvalenes *(23)*, *(27)*, and *(28)*, whose five-membered rings are substituted in two positions, are suitable for determination of the free energy of activation $\Delta G_c^{\neq}$ for rotation around the intercyclic bond. (Figure 1 reproduces sections of the relevant NMR spectra measured at 40 °C.)

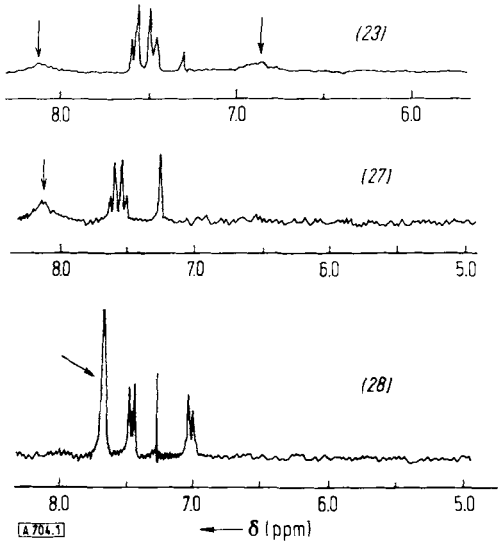


Fig. 1. Partial NMR spectra (60 MHz) of *(23)*, *(27)*, and *(28)*. The signals due to the pyran protons are indicated by arrows.

In addition, $\Delta G_c^{\neq}$ was also determined for the acylated product *(22)* and *(8e)*. The different rates of rotation around the central bond can be calculated from the signals of the pyran protons (shown by arrows). The shapes and positions of the peaks are temperature dependent (Figure 2).

The relevant $\Delta G_c^{\neq}$ values could be calculated from the temperature of coalescence T_c and the maximum

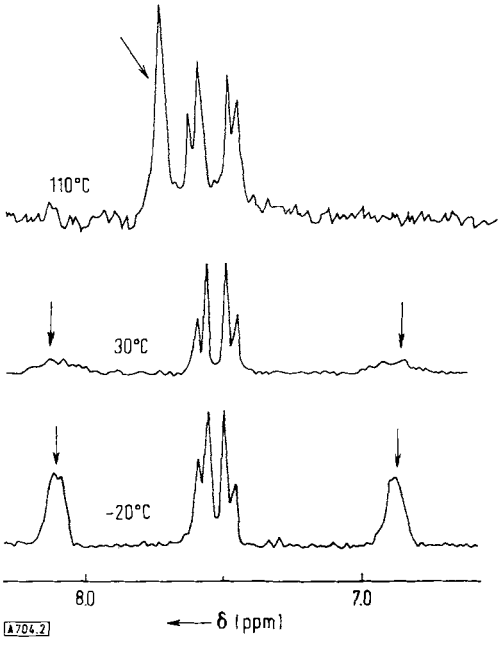

Fig. 2. Temperature dependence of the peaks due to the pyran protons (shown by arrows) in *(23)*.

Table 2. $\Delta G_c^{\neq}$ values [17] (solvent $CDCl_3$; D_3CSOCD_3 for *(8e)*).

Cpd.	Δν (Hz)	T_c (°K)	$\Delta G_c^{\neq}$ (kcal/mole)	X
(22)	47	279	13.7	O
(23)	73	339	16.5	O
(27)	48	280	13.8	S
(8e)	52	384	19.0	S

splitting Δν of the signals at low temperature by means of the Eyring equation [17] (see Table 2).

The low $\Delta G_c^{\neq}$ values obtained for all the heterosesquifulvalenes investigated indicate participation of the dipolar structure in the ground state. The results demonstrate quite impressively that the bond order of the central C–C double bond depends both on the number of electron-accepting groups attached to the five-membered ring and on the donor properties of the hetero atom. The nitrogen atom in *(28)* proves to be the best electron donor; rotation around the central bond is still so fast at −50 °C that the two protons on the six-membered ring in *(28)* are equivalent in the NMR spectrum. As expected, the sulfur atom is more readily polarizable than the more electronegative oxygen. In this connection it is interesting to note that $\Delta G_c^{\neq}$ for *(29)* is 17.7 kcal/mole, while the energy barrier for the corresponding oxygen compound *(30)* is so high that no rotation occurs, even at temperatures as high as 160 °C, in dimethyl sulfoxide [18].

(30), X = O

5. Conclusion and Outlook

Within certain limits the anhydride method has proved a simple and effective process for the preparation of substituted sesquifulvalenes and of the iso-π-electronic cyclopentadienylidenepyrans and -thiopyrans. Only a selection of the possible reactions has been described in this article. Preliminary experiments have shown that various other ketones that are iso-π-electronic with tropone and contain more than one hetero atom also undergo condensation to heterosesquifulvalenes by the same synthetic route. Similarly, the benzotropone analogs furo[3,4-*d*]tropone and thieno[3,4-*d*]-tropone can also be converted into heterosesquifulvalenes that may be considered as vinylogs of the cyclopentadienylidenepyrans and -thiopyrans, respectively.

The author wishes to thank the Deutsche Forschungsgemeinschaft for their support of his investigations described in this article.

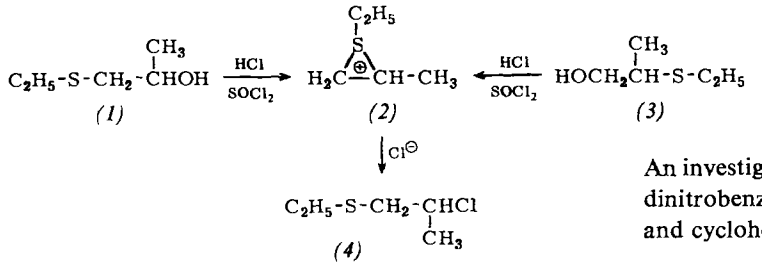
Thiiranium Ions as Reaction Intermediates

By Wolfgang H. Mueller[*]

The addition of sulfenyl chlorides or sulfur dichloride to unsaturated compounds proceeds via thiiranium ions. The present article reviews the electronic and steric factors influencing the nature of these ions and their effects on subsequent ring opening and product formation. For the purpose of this discussion results primarily from electrophilic ring opening have been chosen to illustrate these factors. Solvent and temperature effects have been disregarded.



1. Introduction

Thiiranium ions (episulfonium ions) as chemical intermediates were first proposed during studies of the neighboring group effect of sulfur in extremely reactive β-haloalkyl thioethers of the "mustard gas" type, $S(CH_2CH_2Cl)_2$ [1,2]. For instance, the intervention of a thiiranium ion *(2)* was postulated [1] to account for a single product *(4)* obtained on chlorination of the isomeric alcohols *(1)* and *(3)*.

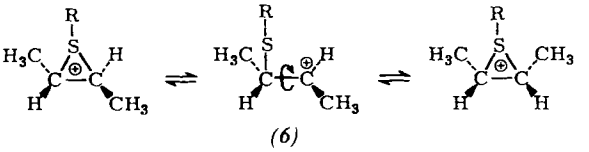
[2] *P. D. Bartlett* and *C. G. Swain*, J. Amer. chem. Soc. *71*, 1406 (1949).

(1) (2) (3) (4)

Similarly, thiiranium ion intermediates *(5)* have been proposed for the polar addition of sulfenyl halides to double bonds [3–6].



(5)

The present review will concern itself mainly with the factors influencing the nature of thiiranium ions formed in the course of such additions and the less extensively studied reaction of thiiranes (episulfides) with electrophiles. These reactions frequently allow a differentiation between kinetic and thermodynamic factors controlling the ring opening. An abundance of data obtained in the same or similar solvents is available and thus excludes the added complication of solvent effects.

2. Formation of Thiiranium Ions

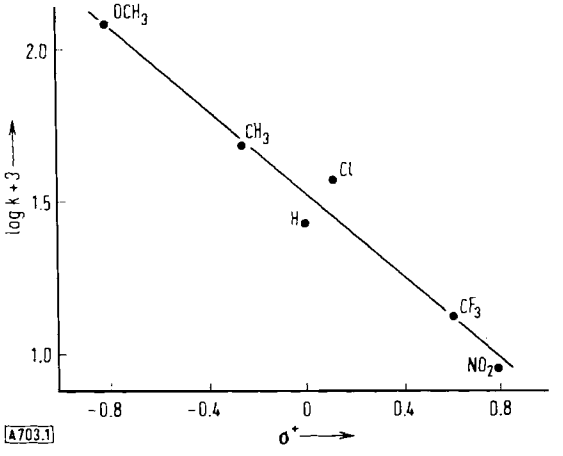
Support in favor of the proposed intermediacy of thiiranium ions during sulfenyl chloride additions was derived from the almost exclusive *trans*-stereospecific addition observed with *cis*- and *trans*-2-butene [7–9]. Although in some cases the possibility of contributions from open ions cannot be ruled out [10], strong evidence against a nonrotating open carbonium ion *(6)* has recently been supplied by the stereospecific uniformity of this addition reaction over a wide temperature range [11].

(6)

An investigation of the kinetics of the reaction of 2,4-dinitrobenzenesulfenyl chloride or bromide with styrene and cyclohexene revealed it to be second order [12–14]:

$$-\mathrm{d\,RSX/d}t = k[\mathrm{RSX}]\,[\mathrm{olefin}]$$

Enhanced rates were observed in more polar solvents, *e.g.*, the addition proceeded 1400 times faster in acetic acid than in carbon tetrachloride. In addition, a salt effect was observed; the presence of sodium perchlorate in acetic acid further enhanced the reaction rate. The sum of the kinetic evidence is consistent with the development of charge in the rate determining transition state, but does not require the general postulate of a thiiranium ion intermediate. More recently, an examination of the reaction rates of addition of several *para*-substituted, *ortho*-nitrobenzenesulfenyl chlorides to cyclohexene demonstrated the need to allow for an enhanced mesomeric electron release from *para*-substituents by the use of σ^+ values (Fig. 1) [15]. This



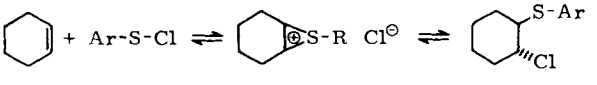


Fig. 1. Hammett relationship for the addition of *p*-substituted *o*-nitrobenzenesulfenyl chloride to cyclohexene in acetic acid at 25 °C; $\rho = -0.714$ [15].

strongly supports the postulate of an intermediate thiiranium ion, rather than an open carbonium ion. A rate-limiting first step involving a transition state closely resembling the intermediate *(7)*, stabilized by electron releasing *para*-substituents, was invoked to explain the sign and magnitude of ρ.

(9) (10)

The reversible formation of an intermediate analogous to *(7)* has been observed as an unusual case in the reaction of dimethylaminosulfenyl chloride and 3,3-dimethyl-1-butene[16]. Attempts to distill compound *(8)* under reduced pressure afforded 85% of the starting materials.

(8)

A study of relative rates of the addition of methanesulfenyl chloride (and chlorine[18]) to a variety of methyl-substituted olefins has also provided further insight into the first step, the formation of the thiiranium ions[17] (Table 1). It is obvious that the rate of addition of chlorine is directly related to the relative

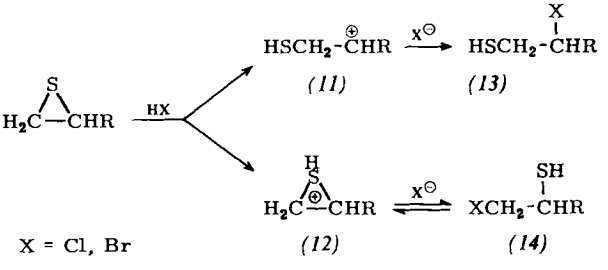

Table 1. Relative reactivities of olefins toward methanesulfenyl chloride and chlorine in nonpolar media [17].

Olefin	k_{rel} Cl_2	k_{rel} CH_3SCl
1-Butene	1.0	1.0
cis-2-Butene	63	13.0
trans-2-Butene	50	0.72
Isobutylene	58	0.75
2-Methyl-2-butene	11000	8.26
2,3-Dimethyl-2-butene	430000	12.9

nucleophilicity of the olefin, *i.e.*, to the number of electron releasing substituents on the double bond. The data for methanesulfenyl chloride, however, show that the reaction with this compound is considerably less sensitive to the electronic environment of the double bond. This implies that in the transition state little or no charge is being developed on the carbon atoms of the double bond and, therefore, that methyl substituents do not significantly lower the transition state energy. This is again consistent with the formation of a thiiranium ion, the positive charge residing mostly on sulfur. The rate enhancement observed with *cis*-2-butene relative to *trans*-2-butene clearly shows the importance of steric effects which somewhat obscure the net electronic effect.

The reaction of electrophilic reagents with thiiranes has been considered to involve either thiiranium ions or open carbonium ions, depending on the reagent. The stereospecific desulfurization of *cis*-2,3-dimethylthiirane *(9)* to *cis*-2-butene with methyl iodide was explained by a mechanism involving the formation of a thiiranium ion *(10)* in the first step[19,20].

A carbonium ion intermediate *(11)* was proposed for the reaction of anhydrous hydrogen chloride and hydrogen bromide with substituted thiiranes[21]. This proposal was based on the reaction's second order kinetics[21] and the reported formation of primary thiols *(13)*[22]. A recent reinvestigation[23] of this reaction, however, revealed that the kinetically controlled products are predominantly primary halogen compounds *(14)* which can isomerize to the primary thiols *(13)*. These data are more consistent with a thiiranium ion intermediate *(12)* undergoing ring opening at the least substituted carbon atom to form the kinetically controlled product *(14)*.

(11) *(13)* *(12)* *(14)*

This compound may then isomerize through *(12)* to the thermodynamically favored product *(13)*. Similar results (discussed in Section 3.3) obtained for a variety of electrophiles allow the general postulate of a thiiranium ion intermediate rather than that of an open ion.

Very convincing support for the existence of thiiranium ions has been provided by the successful preparation of several crystalline thiiranium salts *(5)*. The 2,4,6-trinitrobenzenesulfonate[24a] or the hexafluoroantimonate[24b] have been found to be suitable anions permitting the isolation of such salts.

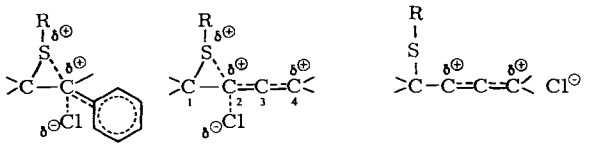
3. Effects on Thiiranium Ion Ring Opening

3.1. Steric Effects

Recent studies on the addition of sulfenyl chlorides to terminal olefins have revealed that steric factors can control the ring opening of the thiiranium ion intermediate [25,26]. With olefins of the type CH_2=CH-Alkyl the kinetically controlled products were predominantly of the anti-Markovnikov structure *(15)* [27].

The selectivity to this type of adduct increases with the size of the alkyl substituent R (Table 2), thus demonstrating the importance of the steric requirements of the alkyl substituents on the ring carbon atoms.

Table 2. Percentage isomer ratio from ring opening of alkyl substituted thiiranium ions by chloride ion.

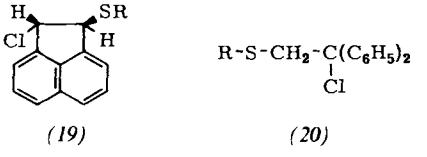


R \ R^1	*(15)* CH_3	*(15)* C_6H_5	*(15)* $(CH_3)_2N$	*(16)* CH_3	*(16)* C_6H_5	*(16)* $(CH_3)_2N$
CH_3	82	68	78	18	32	22
$CH(CH_3)_2$	94	87	>90	6	13	<10
$C(CH_3)_3$	95		95	5		5

This finding is unambiguous evidence for a bridged thiiranium ion and is completely consistent with the expectation of a nucleophilic attack of the chloride ion on the thiiranium ion intermediate. In these cases little positive charge seems to be developed on the ring carbons in the transition state.

3.2. Polar Effects of Substituents on Carbon

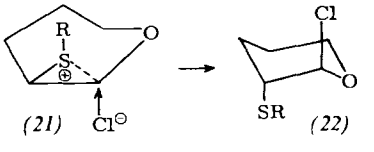
Phenyl substituents on the ring carbon atoms of a thiiranium ion cause ring opening at the benzylic position leading to Markovnikov [27] oriented adducts [3,12,28]. This effect is caused by a lower transition-state energy of *(17)* relative to that arising from attack of the chloride on the terminal carbon.



Stabilization of the transition state *(17)* is due to π-bond overlap of the p orbital of the electron-deficient

α-carbon with the π cloud of the phenyl ring. A similar transition-state *(18a)* also explains the kinetically controlled formation of 1,2-Markovnikov adducts from sulfenyl chlorides and conjugated dienes [29], *e.g.*,

$$R\text{-}S\text{-}Cl + CH_2\text{=}CH\text{-}CH\text{=}CH_2 \rightarrow R\text{-}S\text{-}CH_2\text{-}CHCl\text{-}CH\text{=}CH_2$$



Strong sulfur bridging to the exclusion of contributions from an allylic or benzylic carbonium ion can be deduced from several observations made during sulfenyl chloride additions to conjugated systems. Acenaphthylene afforded exclusively *trans*-adducts *(19)*, and 1,1-diphenylethylene exhibits a lower selectivity (90%) for the Markovnikov adduct *(20)* than was found with styrene (98%). Apparently, two geminal phenyl groups cause some competition between the steric requirements and the electronic factors governing the ring opening. This would be less likely for an S_N1-type reaction.

The kinetically favored attack of the chloride on C-2 rather than on C-4 of the thiiranium ion intermediate is derived from the relative degree of electron deficiency of the two carbons in question. The partial positive charge residing on C-2 receives its enhanced stabilization from overlap of the electron deficient orbital on carbon with the sulfur orbitals.

The lower reactivity of dienes *versus* simple olefins toward sulfenyl chlorides [17,30] is also in accord with a transition-state *(18a)* where relatively little positive charge is developed on carbon. Higher reactivity of dienes would be expected from the participation of a resonance stabilized allylic carbonium ion *(18b)*.

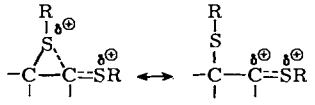
As one might expect in the light of the previous examples, ring opening of thiiranium ions *(21)* derived from vinylic ethers takes place exclusively on the carbon *alpha* to the hetero atom [31].

[25] *W. H. Mueller* and *P. E. Bulter*, J. Amer. chem. Soc. *88*, 2866 (1966).

[26] *G. M. Beverly* and *D. R. Hogg*, Chem. Commun. *1966*, 138.

[27] In the present paper "Markovnikov" orientation indicates adducts with the chlorine on a secondary or tertiary carbon atom while "anti-Markovnikov" adducts have the chlorine on the terminal carbon.

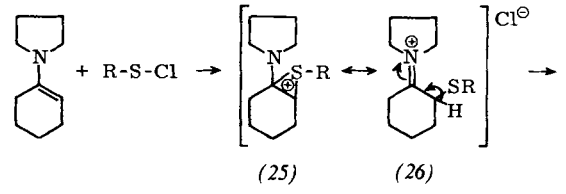
[28] *W. H. Mueller* and *P. E. Butler*, J. Amer. chem. Soc. *90*, 2075 (1968).



[29] *W. H. Mueller* and *P. E. Butler*, Chem. Commun. *1966*, 646.

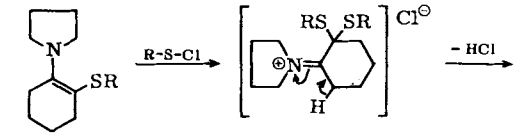
[30] *W. H. Mueller* and *P. E. Butler*, J. org. Chemistry *33*, 2642 (1968).

[31] *M. J. Baldwin* and *R. K. Brown*, Canad. J. Chem. *46*, 1093 (1968); *45*, 1195 (1967).

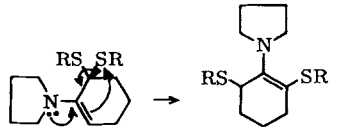


In a similar manner to that shown in the transition states *(17)* and *(18)*, oxygen orbitals stabilize the transition state by overlap with the p orbital of the electron deficient carbon. The *trans*-stereochemistry of product *(22)* appears to rule out significant contributions by an open ion.

Addition of sulfenyl chloride to vinylic thioethers[32] results in the same adduct orientation as that observed with vinylic ethers. There are, however, no data available which would allow one to differentiate between the bridged intermediate *(23)* or the stabilized carbonium ion *(24)*.

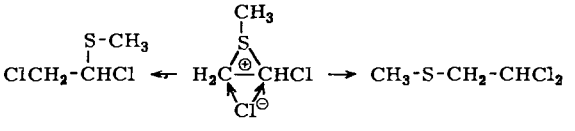


(23) *(24)*



The addition of sulfenyl chlorides to enamines yields products *(27)* and *(30)* with the mercapto group *beta* to nitrogen[33]. Monoadducts such as *(27)* have been isolated only in special cases and the involvement of a thiiranium ion *(25)* seems unlikely. The preponderant ability of nitrogen *versus* that of sulfur to stabilize a positive charge on an adjacent carbon can be assumed and serves to explain the formation of products *(30)*. Addition of a second equivalent of sulfenyl chloride to compound *(27)*, dehydrochlorination of *(28)*, and subsequent rearrangement of the enamine *(29)* has been postulated[33b].

(25) *(26)*



(27) *(28)*

(29) *(30)*

Chloride substituents play well-recognized dual roles in the stabilization (destabilization) of an electron-deficient center; however, a chloride substituent on carbon has little apparent influence on the charge distribution in a thiiranium ion *(32)*[28].

(31) 77% *(32)* *(33)* 23%

[32] *W. H. Mueller*, unpublished results.

[33] a) *G. H. Alt* and *A. J. Speziale*, J. org. Chemistry *29*, 789 (1964); b) *M. E. Kuehne, ibid. 28*, 2124 (1963).

Predominant anti-Markovnikov orientation of the ring opening product *(31)* indicates that overlap of the central p orbital of the α-carbon with a p orbital of the adjacent chlorine does not contribute significantly to the lowering of the energy of the transition state resonance hybrid. Rather, destabilization of an electron deficient α-carbon by the electron withdrawal, along with possible steric hindrance to attack by the incoming nucleophile, explains the product distribution.

Reactions of sulfenyl chlorides with several other ethylenes substituted with electronegative groups have already been reviewed[34]; however, later reports have been somewhat contradictory[35]. A recent reinvestigation of a number of these cases has allowed a correlation of the seemingly unrelated results[36]. A marked difference exists in the ability of electronegative groups on the thiiranium ion ring to direct the attack of chloride ion. Examination of Table 3 reveals that the

Table 3. Isomer distribution (%) from ring opening of functionally substituted episulfonium ions by chloride ion.

	$CH_3SCH_2-C(Cl)-RX$		$ClCH_2-C(S-CH_3)-RX$	
X	R = H	R = CH_3	R = H	R = CH_3
COCl	94	52	6	48
CO_2CH_3	83	24	17	76
CN	51	–	49	>98
SO_2CH_3	–	–	>98	–

tendency for a functional group to favor formation of the Markovnikov isomer follows the same order as the reactivity of the functional group toward solvolysis. Thus the decreasing reactivity of the functional groups toward nucleophiles (COCl > $COOCH_3$ > CN > SO_2CH_3) is paralleled by the decrease in the relative amount of Markovnikov isomer from sulfenylchloride addition to the corresponding substituted ethylene. This order of reactivity is also reminiscent of nucleophilic displacement reactions of α-halocarbonyls and related compounds. Dramatic activation of the α position to nucleophilic attack, in which the activating ability of the functional groups follows the above sequence, is well established[37,38]. The enhanced rate of nucleophilic substitution on α-halocarbonyl compounds has been attributed to the important contribution of transition state structures in which the incoming nucleophile is bonded to both the carbonyl carbon and the α-carbon simultaneously[38,39].

The striking resemblance between α-activation in nucleophilic displacement on α-halocarbonyl compounds and α-activation in the direction of thiiranium ion ring opening suggests that similar transition state structures *(34)*, in which the carbonyl group is at right angles to the entering and leaving groups, are important and serve to lower the energy for α attack (Markovnikov product formation).

(delocalized orbitals) *(34)* (localized orbitals)

As the ability of the functional group to accommodate a nucleophile decreases, contribution of such resonance structures to the transition state also diminishes and a progressively greater amount of β attack (anti-Markovnikov product) occurs.

The tendency is to favor sterically controlled β attack by chloride ion; therefore, only those electrophilic substituents which can most effectively participate in a transition state such as *(34)* are capable of extensively diverting the attack by chloride ion to the α position. Functional groups such as sulfones, which do not effectively participate in such structures, exhibit strong steric effects which deactivate the α position [40,41].

The importance of steric effects on the ring opening of thiiranium ions again becomes evident in the rather drastic change in the product ratio that occurs on introduction of a methyl substituent *alpha* to the carbonyl group (Table 3, R = CH_3). In this case, ring opening on the unsubstituted β-carbon becomes increasingly favored.

3.3. Polar Effects of Substituents on Sulfur

The nature of the substituent on sulfur also has an important influence on the ring opening of thiiranium ions. This can be most dramatically demonstrated in the addition of various sulfenyl chlorides to isobutylene [28,42,43] and by the reaction of 2,2-dimethylthiirane with certain electrophilic reagents [23]. Both reactions can produce products *(35)*, *(37)*, and *(38)*. From Table 4 it becomes apparent that the product ratio is strongly dependent on the nature of R.

As expected, the adduct distribution from methanesulfenyl chloride and isobutylene shows little difference from that of propylene (see Table 2), *i.e.*, sterically controlled ring opening of the thiiranium ion favors the formation of product *(35)*. Similar, although less

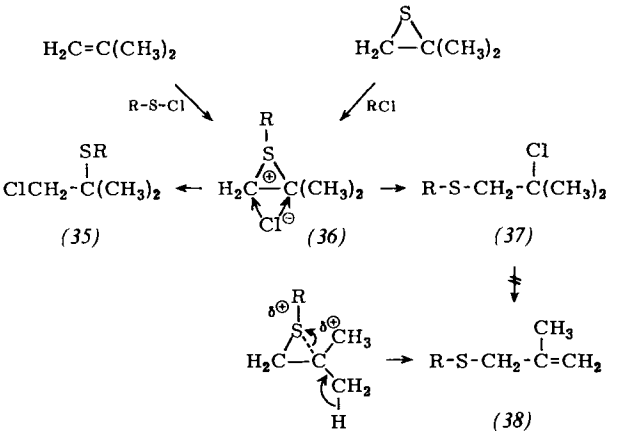

Table 4. Influence of the group R attached to sulfur on the product distribution.

R	*(36)* (%)	*(37)* (%)	*(38)* (%)
CH_3 [a]	80	20	0
H [b]	66	34	0
CH_3CO-S [a]	32	68	0
$(CH_3O)_2P(O)$ [a]	19	57	21
CH_3CO [b]	9	60	31

[a] Sulfenyl chloride addition. [b] Reaction of 2,2-dimethylthiirane with HCl or CH_3COCl.

pronounced, is the result obtained from ring opening of 2,2-dimethylthiiranium *(36)*, R = H. In contrast, the electron-withdrawing effect of an acetylthio group [*(36)*, R = CH_3-CO-S] tends to destabilize the positive charge on the ring sulfur atom contributing to the development of an electron-deficient center on the substituted carbon atom of *(36)*, which results predominantly in the formation of the Markovnikov oriented compound *(37)*. Although no evidence for a true carbonium ion intermediate had been detected in an extensive study of acetylthiosulfenyl chloride additions to a variety of unsaturated compounds [42], it appears that in the case of isobutylene the transition state must have significant charge on carbon in order to be stabilized by the methyl substituents.

The effect of an electron-withdrawing R group on the charge distribution in the thiiranium ion *(36)* becomes even more apparent when R = $(CH_3O)_2P(O)$ or CH_3CO. In contrast to R = CH_3-CO-S, here the electronegative phosphoryl or acetyl group is directly bonded to the sulfur atom participating in the thiiranium ion. This evidently impairs the sulfur's bridging ability to such an extent as to allow for the formation of olefin *(38)*. The expulsion of a proton and formation of product *(38)* is strongly reminiscent of the disciplines observed in carbonium ion chemistry, particularly since no indication for its formation *via* dehydrohalogenation of *(37)* has been found.

In summary, sterically controlled ring opening decreases with the decreasing ability of R to support a positive charge on sulfur in the following order: $CH_3 > H > CH_3-CO-S > (CH_3O)_2P(O) > CH_3CO$ (Table 4).

Additional data demonstrating the above tendency have been obtained from the reaction of methylthi-

[40] *D. I. Relyea*, J. org. Chemistry *31*, 3577 (1966).

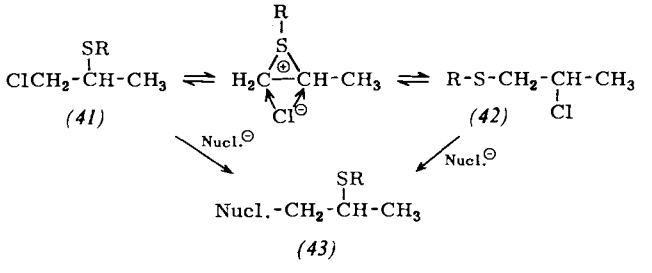
irane with hydrogen halides or acyl chlorides (Table 5)[23].

Although the effect observed with various *para*-substituted benzoyl chlorides is relatively small, the decreasing proportion of product *(39)* can be correlated directly with the electron-withdrawing ability of the electrophilic group.

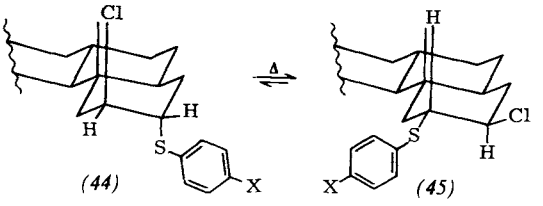


(39) *(40)*

Table 5. Influence of the group R attached to sulfur on the product distribution.

R	*(39)* (%)	*(40)* (%)
H	76	24
CH_3CO	54	46
p-CH_3O–C_6H_4–CO	71	29
p-CH_3–C_6H_4–CO	67	33
C_6H_5–CO	64	36
p-Cl–C_6H_4–CO	59	41
p-NO_2–C_6H_4–CO	57	43

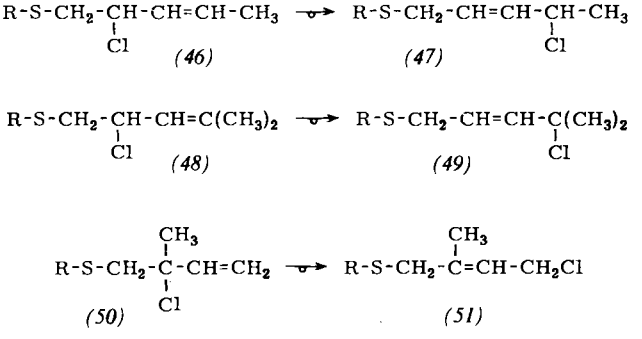
Further evidence for the important influence of R on the sulfur atom participating in the thiiranium ion stems from the differing propensity for rearrangement of the initial kinetically controlled ring opening products *(41)* to the thermodynamically more stable Markovnikov products *(42)*.



(41) *(42)* *(43)*

Ready isomerization is observed when R is methyl. Phenylthio compounds, however, rearrange much more slowly[28], whereas little or no tendency for post-isomerization has been found when R is acetylthio[42] or *O,O*-dimethylphosphoryl[43], respectively. Increasing electronegativity of R decreases the availability of unshared electrons on the sulfur atom and impairs or prevents participation in S_N2 displacement of the chlorine.

Strong support for the intermediacy of a bridged ion during the rearrangement is derived from displacement reactions with various nucleophiles, *e.g.*, acetate ion[28] or thiourea[23], on compound *(41)* or *(42)*. Displacement on either the anti-Markovnikov oriented compound *(41)* or the Markovnikov compound *(42)* affords products of identical composition. The reaction leads to the isomer *(43)* in high selectivity, and to a similar product ratio as was obtained from kinetically controlled ring opening by chloride ion, provided that the nature of nucleophile (Nucl.) does not allow post-isomerization of product *(43)*.

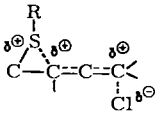


Quantitative data on the influence of the electronic nature of R on this rearrangement was obtained with *para*-substituted benzenesulfenyl chloride adducts of α-cholest-2-ene. The kinetically controlled diaxial adduct *(44)* rearranges on heating to the diequatorial compound *(45)*[44]. The first order rate constants of

(44) *(45)*

this rearrangement were found to vary with the nature of the *para*-substituent X and to follow the sequence $CH_3O > H > NO_2$[45]. This finding is in accord with the qualitative assessment of the relative propensity for the rate of rearrangement to depend on the availability of the unshared electrons on sulfur for the S_N2 displacement of chlorine[28].

This tendency for post-isomerization has also been detected with certain 1,2-Markovnikov adducts, *e.g.* *(46)* and *(48)*, derived from sulfenyl chloride additions to conjugated dienes[29, 30].



(46) *(47)* *(48)* *(49)* *(50)* *(51)*

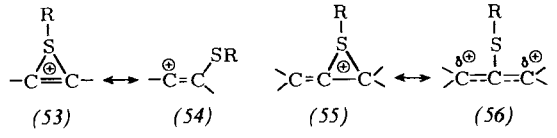
Two major factors determing the rate of rearrangement were recognized with the models investigated:

(i) Only adducts with R = CH_3 rearrange while none of those having R = C_6H_5 rearranges under the same conditions.

(ii) Methyl substituents on C-4 or C-2 of the initial adduct facilitate this rearrangement.

This differing propensity for rearrangement depending on the nature of R is strong evidence that the rearrangement involves the same thiiranium ion intermediate as the initial addition reaction. It also follows that formation of this intermediate is reached through transition state *(18)*. Isomerization then proceeds through a higher energy transition state, such as *(52)*, to form the thermodynamically favored 1,4-products *via* S_N2' displacement by the chloride.

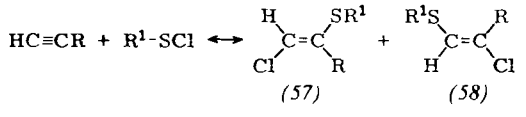
(52)



[44] *J. F. King* and *K. Abikar*, Canad. J. Chem. *46*, 1 (1968).
[45] *J. F. King* and *K. Abikar*, Canad. J. Chem. *46*, 9 (1968).

This step is essentially irreversible since it would require an unfavorable S_N2' displacement of a chlorine atom on C-4 by the methylthio group.

The methyl substituents effect additional stabilization of the transition state *(18)* by electron release at C-2 or C-4. In compounds bearing methyl substituents on C-1 or C-3 no contribution by the substituent to lowering the transition state energy would be expected. This is consistent with the failure of such compounds to rearrange[30]. Furthermore, methyl substituents on C-4 can also contribute to lowering the energy of the transition state *(52)* by stabilizing a partial positive charge on C-4. This finds support in the greater ease of rearrangement of *(48)* to *(49)* compared to that of *(46)* to *(47)*.



4. Unsaturated Thiiranium Ions

This section will deal with thiiranium ions containing endo- or exocyclic double bonds. The involvement of such species, whose existence is not well-established, may be postulated for sulfenyl chloride additions to acetylenes, allenes, and ketenes.

(53) *(54)* *(55)* *(56)*

The possibility of forming intermediates such as *(53)* has to be considered in a discussion of sulfenyl chloride additions to acetylenes. From terminal acetylenes and either arene-[46–48] or alkanesulfenyl chlorides[16,43,49,50], adducts of predominantly anti-Markovnikov orientation *(57)* have been reported.

(57) *(58)*

In solvents such as chlorinated hydrocarbons or ethyl acetate both alkyl- and aryl-substituted acetylenes afford mostly products of structure *(57)*. However, in acetic acid the reaction of phenylacetylene with either 2,4-dinitrobenzenesulfenyl chloride[51] or methanesulfenyl chloride[50] produced predominantly the opposite adduct orientation *(58)*. A similar dependence of the adduct orientation on solvent has also been observed in a study with *para*-nitrobenzenesulfenyl chloride and phenylacetylene[52a]. *trans*-Configuration of these adducts has been established in only a few cases[53]. NMR spectral evidence supports a *trans*-structure *(57)* in the case of the major *O,O*-dimethoxyphosphorylsulfenyl chloride-propyne adduct[43], and for both positional isomers obtained from 2,4-dinitrobenzenesulfenyl chloride and 1-phenylpropyne[54]. As an added complication one has to deal with the possible *trans-cis* isomerization of such adducts[49].

The addition of 2,4-dinitrobenzenesulfenyl chloride to either phenylacetylene or 3-hexyne follows second order kinetics, as in its addition to olefins[51]. The formally equivalent reactions, however, appear to differ in details. In contrast to the addition of *para*-substituted benzenesulfenyl chlorides to olefins[15], which follows the Hammett relationship when Brown σ^- values are used, no definite trend was observed with either aryl-[52b] or alkyl-substituted acetylenes[55]. The rate constants increase, however, by an order of magnitude from *para*-nitro to *para*-methoxy substituents, which is consistent with some positive charge being developed on sulfur. The rate of addition of *para*-toluenesulfenyl chloride to *para*-substituted diphenylacetylenes correlates well with Brown σ^+ values (Figure 2) at fairly high negative values of ρ[52b]. This suggests an intermediate in which there is development of an electron deficient carbon *alpha* to the *para*-substituted phenyl ring. It is also in accord with the nucleophilic role of acetylenes as reflected by the ~10 times faster addition of methanesulfenyl chloride to 2-butyne relative to propyne[17].

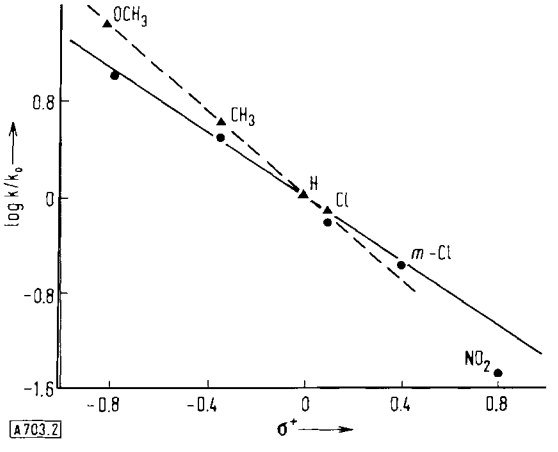


Fig. 2. Hammett relationship for the addition of *p*-toluenesulfonyl chloride to *p*-substituted diphenylacetylenes; in ethyl acetate at 25 °C (▲); $\rho = -1.8$; in chloroform (●), $\rho = -1.3$ [52b].

While the anti-Markovnikov adduct orientation, as in *(57)*, could be attributed to an intermediate such as *(53)* with the positive charge mainly on sulfur, some of the kinetic data suggest the intervention of vinylic carbonium ions *(54)* or at least a strong development of charge on the vinylic carbon in the case of bridged species.

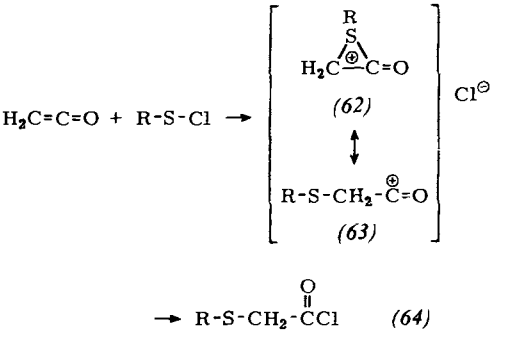
Structure *(59)* has been assigned to the initial adducts obtained from sulfenyl chlorides and allenes[49,56].

The existence of substantial coupling of the allylic and vinylic protons with the phosphorus nucleus supplied unambiguous NMR evidence for structure *(59)* when R is $(CH_3O)_2P(O)$[57].

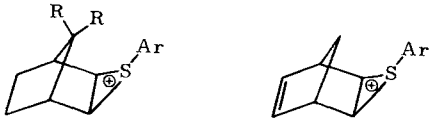


Products of structure *(59)* would be expected from ring opening of a bridged intermediate *(55)* at the terminal sp^3 carbon or from an allylic carbonium ion *(56)*. Addition of 2,4-dinitrobenzenesulfenyl chloride to the optically active allene *(60)* afforded the optically active product *(61)*[58]. This is strong support for a

(60) *(61)*

bridged ion intermediate such as *(55)*. However, the possibility of an allylic ion *(56)* cannot be rigorously ruled out since the optical purity of neither starting material *(60)* nor product *(61)* is known.

Sulfenyl chloride additions to ketene may also involve an thiiranium ion intermediate *(62)* having an sp^2 hybridized ring carbon[59,60].

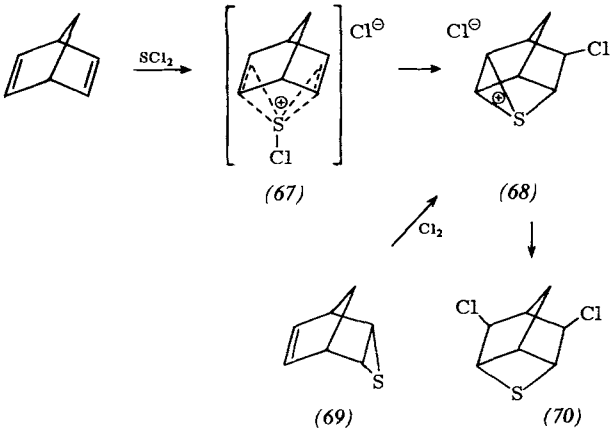


The formation of the acid chloride *(64)* is consistent with contributions by structures *(62)* and *(63)* to the intermediate but does not allow an assessment of their relative importance. Ring opening of the thiiranium ion *(62)* would be expected to take place preferentially at the carbonyl carbon, in analogy with nucleophilic displacement reactions on chloroacetyl chloride. The products *(64)* are most likely those of kinetic control since chloromethyl thioacetate does not isomerize to methylthioacetyl chloride[61].

5. Thiiranium Ions Fused on to Bicyclic Systems

The contribution of sulfur bridging in reaction intermediates derived from the addition of sulfenyl chlorides or sulfur dichloride to either unsaturated cyclic compounds or systems leading to cyclic products comprises a subject of recent interest. Frequently the stringent geometric requirements in these systems accommodate only a distorted thiiranium ion with unsymmetrical carbon-sulfur bonds in the ring. These cases may closely resemble a carbonium ion.

The addition of benzene- or substituted benzenesulfenyl chlorides to norbornene[57,62,63], 7,7-dimethylnorbornene[28], and norbornadiene[62] involves the *exo*-thiiranium ions *(65a)*, *(65b)*, and *(66)*, respectively. Ring opening by the chloride ion subsequently



(65a), R = H
(65b), R = CH_3

(66)

takes place by attack from the *endo*-side. The formation of a thiiranium ion on the *exo*-side is particularly remarkable in the case of the reaction of 7,7-dimethylnorbornene *(65)*, R = CH_3, with the relatively bulky benzenesulfenyl chloride.

Sulfur dichloride, however, approaches norbornadiene from the *endo*-side to give product *(70)*[64], which is also obtained from chlorinolysis of the thiirane *(69)*[65]. A transition state such as *(67)* leading to the intermediate *(68)* would most readily explain the observed *endo*-attack. Similar transition states may be invoked to explain the preponderant transannular addition of sulfur dichloride to both 1,4-cyclohexadiene[66] and 1,5-cyclooctadiene[66–68]. Structures such as

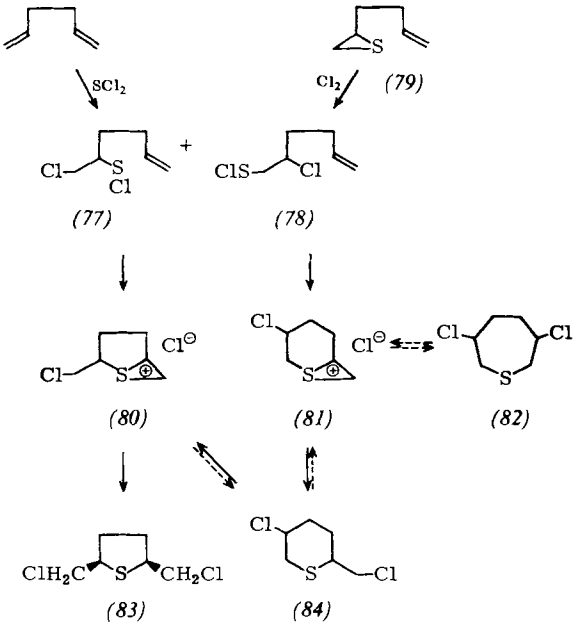
(71), reminiscent of transition metal π-complexes, may be envisioned for the reaction of sulfur dichloride with the tub-shaped 1,5-cyclooctadiene. Ring opening of the thiiranium ion *(72)*, which is also obtained from chlorinolysis of the thiirane *(73)*[69], produces 4,8-dichloro-1,5-epithiocyclooctane *(74)*.

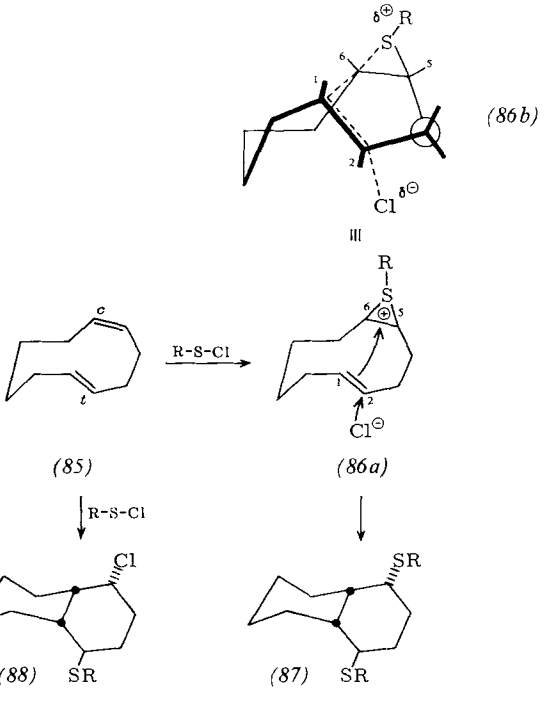
(71) *(72)* *(73)* *(74)*



Product *(75)*, which was obtained from sulfur dichloride and cyclooctatetraene[70], forms an unstable coordination complex with antimony pentachloride in benzene[65]. Its NMR spectrum in nitromethane shows only a singlet which is 1.7 ppm downfield from the olefinic protons of cyclooctatetraene. These NMR data are consistent with a planar ring structure *(76)* and lend strong support to the transition states discussed above whose geometry allows simultaneous interaction of two double bonds with electrophilic sulfur.

(75) *(76)*

The reaction of sulfur dichloride with linear diolefins is an excellent route to cyclic sulfides[69]. The heterocycles formed appear to be, in most cases, the thermodynamically favored products. From the examples investigated thus far, it seems that formation of five-membered rings is strongly preferred. Unless additional steric or electronic factors are introduced, which make it necessary sometimes to consider open ions rather than thiiranium ion intermediates, the following order of preference for ring formation is observed: $5 > 6 \gg 7 > 8$-membered.



The thiiranium ions and possible equilibria in such systems are exemplified by the reaction of sulfur dichloride with 1,5-hexadiene or chlorinolysis of the thiirane *(79)*. Both reactions afford the tetrahydrothiophene derivative *(83)*. Based on the considerations discussed above (Section 3.3) one would expect initial formation of both intermediate products *(77)* and *(78)* from either reaction, with *(77)* being somewhat predominant in the product mixture[71]. Internal attack on the second double bond would then lead to the ions *(80)* and *(81)*.

(77) *(78)* *(79)* *(80)* *(81)* *(82)* *(83)* *(84)*

Ring opening of these thiiranium ions at the least hindered side by chloride affords products *(83)* and *(84)*, respectively. [The kinetically less favored ring opening on the more substituted carbon would produce either product *(84)* or *(82)*.] If one accepts the very likely formation of isomer *(78)* in the first step, then one also has to postulate the involvement of the thiiranium ion *(81)* and the transient formation of product *(84)* during cyclization. The isolation of *(83)* as the sole product, however, can be reconciled with post-isomerization of *(84)* through the thiiranium ion *(80)*. The fact that the chloromethyl substituents on *(83)* have a *cis* stereorelationship further supports thiiranium ion-product equilibria resulting in the thermodynamically most stable structure. It appears that a quasi-equatorial position of *cis*-2,5-substituents in this five-membered ring is thermodynamically preferred, as is the case with 1,3-substituted cyclohexanes[72].

Finally, a unique case of transannular carbon-carbon bond formation during methanesulfenyl chloride addition to *cis*,-

(86b) *(85)* *(86a)* *(88)* *(87)*

[71] The addition of sulfur dichloride to propylene occurs with ~65% anti-Markovnikov orientation.

[72] *M. Mousseron* and *R. Granger*, Bull. Soc. chim. France *5*, 1618 (1938); *E. L. Eliel*: Stereochemistry of Carbon Compounds McGraw Hill, New York, N.Y., 1962.

trans-1,5-cyclodecadiene *(85)* has recently been reported[73]. The interaction of a double bond with a cationic center across the ring is well established in this and other ring systems[74]. A similar behavior with a thiiranium ion, however, is unprecedented and particularly surprising in the case of the strongly bridging methylthio group, since all evidence regarding such ions points toward little charge being developed on carbon (Section 3.1).

It is not known whether one or both of the stereoisomeric *cis*-decalins are formed. Compound *(88)* would arise from attack on the *trans* double bond of *(85)* which has been shown to be the preferred reaction site with addends not involving a carbonium ion intermediate. However, on the basis of the considerably faster rate of sulfenyl chloride addition to *cis*-butene compared to its *trans*-isomer[17] one would expect preferential attack at the *cis* double bond of *(85)* and subsequent formation of decalin *(87)*.

The possibility of initial 1,2-addition, as in the case of conjugated dienes, and transannular post-isomerization to *(87)* or *(88)* must also be considered. It is, therefore, tempting to suggest transition state *(86b)* which is strongly reminiscent of the intermediate *(52)* previously proposed for the rearrangement of the 1,2-adducts from methanesulfenyl chloride and conjugated dienes. Inspection of a model shows that C-1 and C-6 in *(86b)* can approach sufficiently closely for the lobe of the p orbital on C-1 to overlap with the electron deficient orbital on C-6.

Topochemical Investigations on Peptide Systems[**]

By **M. M. Shemyakin, Yu. A. Ovchinnikov, and V. T. Ivanov**[*]

The basic principles of the topochemical approach to the investigation of the structure-function relation in peptide systems are formulated. This approach makes use of the new possibility of transforming natural peptides, consisting in the modification of the molecule as a whole and utilization of the resultant analogs to elucidate the boundaries of the stereoelectronic complementarity of the biologically active peptide to the corresponding receptor. In particular, on the example of depsipeptide antibiotics and their topochemical analogs the fruitfulness of using such compounds as tools in elucidating the physicochemical basis of functioning of biological membranes is shown. The topochemical principle has also been applied in preparing specific competitive inhibitors of proteolytic enzymes, whose study may shed light on the nature of the forces binding the substrate to the contact site of the corresponding enzyme.

1. Introduction

The structure-function relation of biologically active compounds, one of the cardinal problems in modern chemistry and biology, owes its importance not only to the fact that knowledge of such a relation is essential for the rational search of compounds with valuable physiological properties, but in no less degree to the fact that it serves as guide into the innermost details of the mechanism of interaction between the biologically active substance and the corresponding receptor.

It is common knowledge that such an interaction requires not only steric correspondence between the molecules but also an appropriate electron density distribution, in the absence of which interaction, if it takes place at all, is reduced by several orders of magnitude. It stands to reason, therefore, that for the rational search for substances with similar, modified, or antagonistic biological effects, and also for the proper understanding of their mode of action, one must know the limits of such stereoelectronic complementarity requirements of the molecules participating in the given biochemical act.

In order to determine the complementarity boundaries it has been usual to modify stepwise the biologically active molecule and to see how the structural changes affect the biological activity. Such a largely empirical approach, probably the only possible one in the early stages of investigating this problem, has of course been ineffective. Only occasionally has it yielded tangible results and still more rarely has it lead to concepts of a predictive nature.

[**] This paper is an enlarged version of the reports read to the 8th European Symposium on Peptide Chemistry (Nordwijk, Holland, 1966), to the 1st, 2nd European Meetings on Stereochemistry (Bürgenstock, Switzerland, 1966, 1967) and to the 1st All-Union Symposium on peptide chemistry (Riga, 1967).

Peptide systems have been no exception here, and "trial and error" methods are still widely prevalent. In biologically active peptides, chiefly hormones and antibiotics[1–3], one amino acid is replaced by another. While many hundreds of preparations have been synthesized during the last decade, most of them proved to be completely inactive. True, a few active preparations had been found (some of whose activity even exceeded that of the parent compound) and a certain number of them have found practical application; however such an approach could not be expected to give rise to rational methods, nor could it yield information elucidating the underlying principles of the action of biologically active compounds. At best only a few limited relationships could be established (see, *e.g.*[4]).

At first, our work on the structure-antimicrobial relation of enniatin antibiotics[5–7] also bore the same empirical character. From a critical survey of the results, however, we were able to recognize the outlines of the topochemical principles, which later proved to be generally applicable to a wide variety of peptide systems, both cyclic and linear.

2. Enniatin Antibiotics and Their Analogs

The investigations involved, first of all, the synthesis of linear and cyclic analogs of enniatin antibiotics, differing in the size of the chain or of the ring and in the nature and configuration of the amino and hydroxy acid constituents (see Table 1).

Table 1 [a]. Antimicrobial activity of the enniatins and some of their analogs [b].

No.	Compound	Minimal growth inhibiting concentration (μg/ml)

(10)	L-MeVal → D-MeVal	>50	>50	>50	>50	>50
(11)	D-HyIv → L-HyIv	>50	>50	>50	>50	>50
(12)	(D-MeVal-L-HyIv)$_3$ enantio-enniatin B	9.0	18	25–37	9–12	9–12
(13)	(L-MeLeu-D-HyIv)$_3$ enniatin C	>50	>50	>50	>50	>50
(14)	(L-MeVal-D-HyIv)$_4$	3.0	4.5	>100	18–25	>100

[a] The standard symbols and abbreviations for amino acids are used in the Table; HyIv, HyMev and HyIc designate α-hydroxyisovaleric, α-hydroxy-β-methylvaleric and α-hydroxyisocaproic acid residues respectively. The arrows indicate substitution of one amino or hydroxy acid for another; thus compound *(7)* is an analog of enniatin B in which one *N*-methyl-L-valine residue has been replaced by an *N*-methyl-L-leucine residue.

[b] All the linear analogs of the compounds tabulated here are completely devoid of antimicrobial activity.

As can be seen from the table the antimicrobial activity of the cyclodepsipeptides is strongly dependent on the ring size. The highest activity and broadest spectra are displayed by the cyclohexadepsipeptides [naturally occurring antibiotics *(2)* and *(6)* and their analogs *(3)*, *(7)*, and *(8)*]; the cyclotetradepsipeptides *(1)* and the actadepsipeptides *(14)* exhibit the opposite behavior. Furthermore, it can be seen that the structure of the amino acid radicals of the antibiotic molecules can be modified considerably (albeit on a limited part of the chain) without marked loss of activity [compounds *(3)* and *(7)*]. On the other hand modification of the hydroxy acid residues [cf. *e.g.*, compound *(9)*] causes

sharp loss of activity. Finally, changes in the configuration of even one of the amino and hydroxy acid residues [compounds *(10)* and *(11)*] lead to complete loss of activity[8,9], Analogous relations were obtained with the cyclododecadepsipeptide valinomycin [10].

2.1. Topochemistry of the Enniatins

These results show the important role played by steric factors in the manifestation of biological activity by these compounds, and they lead to the conclusion that the mode of action of the enniatin and valinomycin antibiotics is connected with a biochemical process, which demands that the entire molecule as an integral whole must correspond to a certain site in the receptor. Further conclusions could not be drawn from the data at our disposal. In pursuit of further information we found that not only certain parts but the entire molecule could be so modified that the general features of the spatial structure, *i.e.* the topology of the new molecule would remain similar to that of the initial molecule; however, the electron density distribution among the individual functional centers would more or less differ. Such a topochemical approach to the structure-activity relation is applicable not only to depsipeptides but to peptides as well (see Sections 3 and 4).

One of the first substances to be synthesized by a topochemical approach was the enantiomer of enniatin B *(6)*, enantio-enniatin B *(12)*, in which all the amino and hydroxy acid residues are of opposite configuration to those in the natural antibiotic.

(6) *(12)*

Since enantio-enniatin B is the mirror image of the naturally occurring compound a stereoselective receptor would be expected to behave quite differently to the two stereochemically non-equivalent molecules.

Provided no fundamentally different mechanism for the biological action existed (cf. the L-isomer of the antibiotic cycloserine [11]) one would suppose enantio-enniatin B to be biologically inactive. The same holds for the antipodes of such naturally occurring peptides as bradykinin [12,13], angiotensin [14], oxytocin [15], actinomycin C_1 [16], *etc.*

Nevertheless, it appeared likely to us that enantio-enniatin B should display a biological activity equal or close to that of enniatin B. In fact, if one of the formulas *(6)* or *(12)* be turned by 60° in the plane of the drawing all the like chirality centers become superimposed; each ester group takes the place of an *N*-methylamide group and *vice versa*. Hence the antipodes differ with respect to the receptor not spatially, but only structurally. However, the ester group not only models the amide group quite well spatially, but also electronically [17,18]. Since both these topochemically similar antipodes display the same high complementarity to one and the same stereoselective receptor one would expect them to exhibit similar activities. This assumption is supported by the fact that in many naturally occurring peptides the amide group could can be substituted by the ester group and *vice versa* without essentially affecting their biological activity [19–23].

Enantio-enniatin B *(12)* was synthesized by the same method as was used for the synthesis of enniatin B *(6)* [6]. Compound *(12)* proved to be identical to the naturally occurring antibiotic in all physicochemical properties (excepting the rotatory dispersion curves, which, although of the same shape are of opposite sign). As expected, microbial tests showed that with all the microorganisms studied enantio-enniatin B displayed exactly the same activity, both qualitatively and quantitatively as enniatin B (see Table 1) [24].

This is the first proven example of a polyasymmetric naturally occurring compound and its antipode having equivalent activity along the entire microbial spectrum. The latter circumstance practically precludes any difference in the mode of action of the two compounds.

In the example of enniatin B and its antipode we have a special case since the molecules are very similar both

topologically and with respect to the nature of their functional groups. Retaining the latter and changing only the effective size of the radicals in the depsipeptide molecule renders possible a study of the degree of topological correspondence between biologically active compound itself and the receptor. Thus, the antipode of enniatin A *(2)*, enantio-enniatin A *(4)* (Fig. 2), which we synthesized [25], was found to have the same antimicrobial activity as the parent compound (see Table 1). This is not surprising if one takes into account the topological similarity of the valine and isoleucine side chains in eniatins A and B (branching at the β-carbon atom in both compounds). In fact not

only the similarity but the constancy of the optical rotatory dispersion curves of enniatins A *(2)* and B *(6)* in various solvents bears evidence on the similarity of their preferred conformations in these solvents [26] (see Fig. 1).

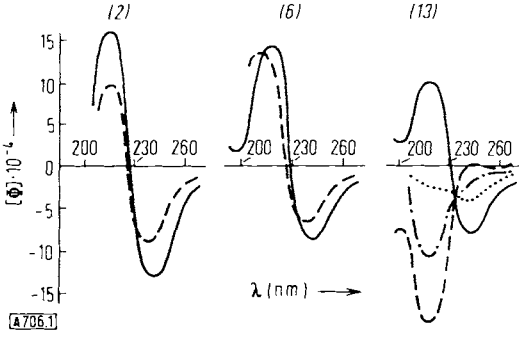

Fig. 1. Optical rotatory dispersion curves of enniatin A *(2)*, enniatin B *(6)*, and enniatin C *(13)*.
Solvent: ———— heptane; ····· heptane/ethanol (94:6); —·—·— heptane/ethanol (92:8); — — — heptane/ethanol (50:50).

However, if all the *N*-methylvaline residues in enniatin B are replaced by *N*-methylleucine residues, the resultant compound, known as enniatin C *(13)* [27], turns out to be practically inactive (see Table 1). The reason for this apparently lies in the stereochemical specificity of the valine and isoleucine residues, the β-branched chains of which, in contrast to the γ-branched chains of leucine, have a strong steric screening effect [28]. One could expect therefore that the side chains of enniatins A and B fix the relative orientation of the radicals and groups, giving rise to a sufficiently rigid conformation of the 18-membered ring, whereas enniatin C should have a more flexible structure and be more easily subjected to conformational changes. This was confirmed by optical rotatory dispersion studies of enniatins A, B, and C [26]. As is shown in Fig. 1 all three enniatins have similar conformations in a non-polar solvent (heptane). Solvents of higher polarity (heptane with increasing amounts of ethanol) have very little effect on the conformations of enniatins A and B, but considerably change the conformations of enniatin C. Apparently, under conditions obtaining in the biological medium enniatin C assumes a conformation not suitable for interaction with the receptor for enniatins A and B.

In this connection it should be emphasized that with the topochemical analogs of the naturally occurring peptides, obtained by modifying the entire molecule, one could expect the occurrence of biological activity only when the modification does not entrain changes in the biologically specific conformation of the peptide. Hence transformations of the molecule based only on formal structural principles may lead to abrupt change in or to disappearence of the biological activity, for even very small structural modification of the molecule can cause marked changes in its conformation.

Another striking illustration of this behavior, besides the case of enniatin C, is afforded by cyclohexadepsipeptide *(5)* [25]. This depsipeptide can be regarded as an analog of enniatin A in which all the ester groups are replaced by *N*-methylamide groups and *vice versa*.

Formally, almost all requirements of topochemical correspondence appear to be fulfilled, but the minute structural differences between compound *(5)* on the one hand and enantio-enniatin A *(4)* or enantio-enniatin B *(12)* on the other proved sufficient to impart considerably differing conformations to the compounds (as evidenced in the optical rotatory dispersion curves, Fig. 2). As a consequence the compounds differ greatly in antimicrobial properties;

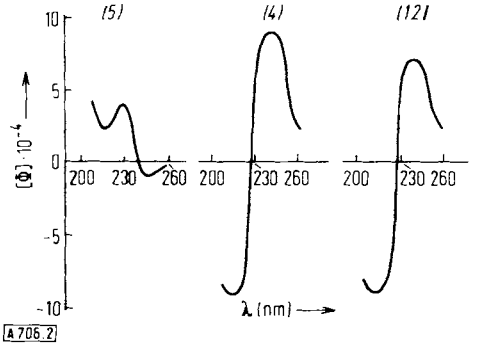

Fig. 2. Optical rotatory dispersion curves of "false" enniatin A *(5)*, enantio-enniatin A *(4)*, and enantio-enniatin B *(12)*.

compound *(15)*, in contrast to enniatins A and B and their enantiomers, displays low activity against all microorganisms studied (see Table 1) – a fact that led to its being named "false" enniatin A.

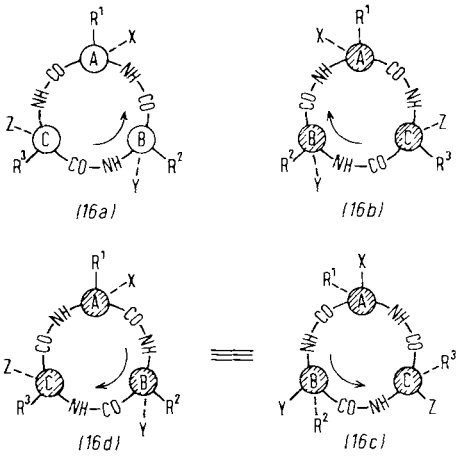
2.2. Mode of Action of Enniatins

Besides the above described studies on enniatin antibiotics the topochemical principles were also useful in the study of the problem of the mode of action of these and other depsipeptide antibiotics. According to *Pressman* depsipeptide antibiotics are capable of selectively inducing the active transport of some monovalent ions in mitochondria[29,30]. Further joint study of this phenomenon by *Pressman* and us on a number of valinomycin and enniatin analogs synthesized in our laboratory led to the conclusion that there is a definite parallelism between the antimicrobial activity of the depsipeptides and their ability to induce active cation transport – a parallelism that is not only of a qualitative nature (active transport of K^+, but not Na^+), but, to a certain degree, also of a quantitative nature.

These results suggested that the antibiotic activity of the depsipeptides is connected with their interaction with the receptors (lipoproteids) of the biological membranes controlling the active cation transport[8,10,31]. Another inference that could be drawn was that the depsipeptide antibiotics influence the ion transport not only by stereospecific interaction with the receptor in the membrane, but also by interaction with the corresponding cation. Cyclodepsipeptides appear to form complexes with monovalent metal ions such that the ion is included in the internal sphere of the cyclic molecule by means of ion-dipole interaction with the amide and/or ester groups, reproduced schematically in formulas *(15a)* and *(15b)*.

(15a) *(15b)*

This we were able to demonstrate experimentally[26] (cf.[32,33]), showing not only the fact of complex formation in solution and the participation of ester groupings in the complex (Fig. 5)[*], but also that there is a correspondence between the ability of enniatin cyclodepsipeptides to form complexes, their conformational states in solutions, and their antibiotic activity. The complexes were either isolated in the crystalline state or their formation in solution was established by electroconductivity and ORD measurements.



Whereas enniatins A and B, and their enantiomers, all belong to a single topochemical group and readily form complexes with potassium ions, the cyclohexapeptide *(5)* was found in general to be incapable of forming complexes with alkali metal ions. This is in accord with the results of the optical rotatory dispersion measurements on these compounds (cf. Figs. 1 and 2), and also with their biological properties.

The results served as a starting point in the investigation of the mechanism of membrane functioning. One of the first results of these studies was discovery of the fact that complexation of the enniatins and valinomycin with cations occurs only in a lipophilic medium[26], *i.e.* takes place on the membrane after the binding of the depsipeptide molecule to the latter.

3. Topochemical Investigations on Other Peptides

The topochemical approach to the structure-function relations may be useful not only with such highly symmetric systems as the anniatin antibiotics, but in principle can be applied to cyclopeptides regardless of their symmetry. This is clearly illustrated in the transformations of the hypothetical cyclopeptide *(16a)*.

For the sake of simplicity a tripeptide is depicted in the figure, but conclusions hold for any ring size and for any set of configurations of the amino acid residues.

(16a) *(16b)* *(16d)* *(16c)*

Compound *(16b)* is the antipode of this cyclopeptide and compound *(16c)* [which is identical with *(16d)*] is the retro-form of *(16b)* with reversed direction of acylation (cyclodiastereomer according to *Prelog's* nomenclature[34,35]). It can easily be seen that the cyclopeptides *(16a)* and *(16d)* are very similar topologically, differing only by reversed arrangement of the atoms in the amide groups (CO–NH and NH–CO); in other words they are topochemical analogs. The

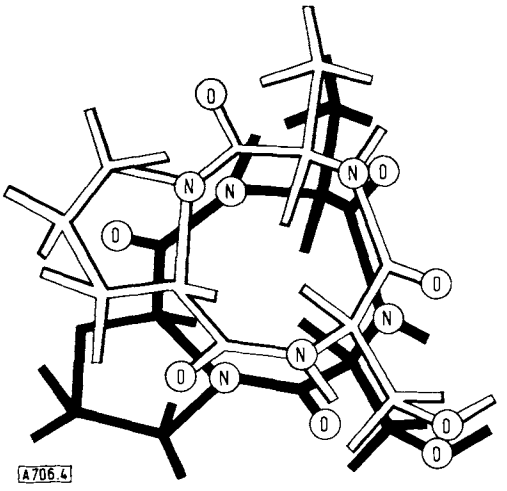
similarities and differences between cyclopeptide *(16a)* and its retro-enantiomer *(16d)* come particularly to the fore in Fig. 3, which depicts the latter compound

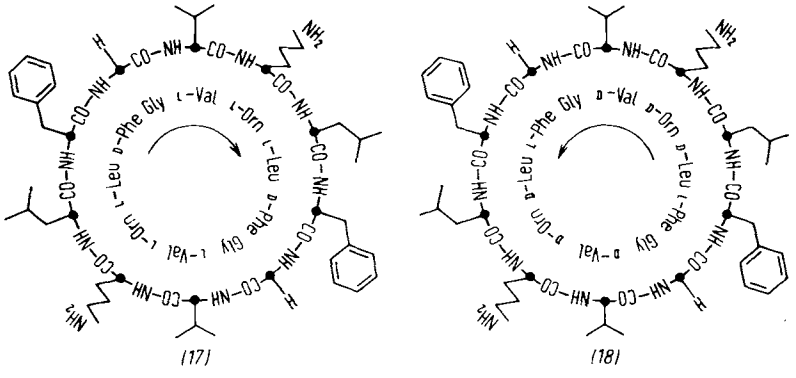


A706.3

Fig. 3. Structural and spatial relationships between a cyclopeptide and its retro-enantiomer.

as the "shadow", or replica, as it were, of the former, thus showing why it can play the role of a "double" in biological processes and may often possess closely similar biological properties to the parent compound. The highly biologically active Gly^5, Gly^{10}-gramicidin S *(17)* [37, 38] and its retro-enantio analog *(18)* (Fig. 8) furnished further proof of the validity of this assumption [36].

Gly^5, Gly^{10}-gramicidin S was chosen instead of the naturally occurring gramicidin S since it does not contain the proline residues of the latter, that would introduce extra complications in the topochemical



A706.4

Fig. 4. Topological difference between a proline-containing cyclopeptide and its retro-enantiomer.

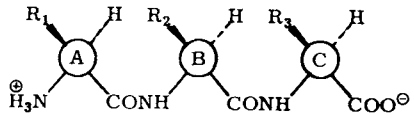
Retro-enantio-Gly^5,Gly^{10}-gramicidin S *(18)* was synthesized by stepwise construction of the peptide chain, beginning with the C-terminus, and using the doubling reaction to cyclize the linear penta peptide. As predicted, the resultant compound displayed high antimicrobial activity, comparable with the activity of gramicidin S.

4. Topochemical Investigations on Linear Peptides

Of particular interest would be extension of the principles discussed here to linear peptides since this could open up new possibilities in the studies of many important peptide bioregulators. For the topochemical transformation principles to be effective in the case of

(17) *(18)*

transformations. Indeed, with the proline residues the retro-enantio isomer would differ much more greatly in the topochemical sense from the initial compound, because, as can be seen in the example of the proline-containing cyclotripeptide (Fig. 4), the proline rings would not coincide on superimposing the two molecules.



linear peptides certain prerequisites must be fulfilled. For instance the principles cannot be applied to peptides with free carboxyl and amino end groups. While considerable topological conformity is retained on the antiparallel superposition of the hypothetical linear peptide *(19)* and its retro-enantiomer *(20)*, these two, contrary to the internally compensated cyclopeptides (Fig. 6), still differ by the reversed position of the charged end groups.

Naturally such difference in the compounds of type *(19)* and *(20)* should cause them to behave differently from the receptor and it would be difficult to expect the retro-enantiomer *(20)* to display the biological activity

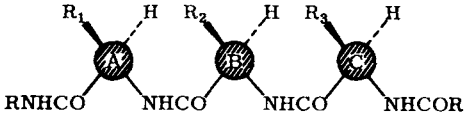
(19)



(20)

of the linear peptide *(19)*. Herein probably lies the reason for the inability of *Vogler et al.*[13] and *Stewart*[39] to detect any essential biological activity in the retro-enantio-bradykinin they have synthesized (cf. also[40]).

We believe that such difficulties could often be overcome by appropriately blocking the end groups. With suitable choice of the blocking groups the conditions could be created for establishing the same topochemical correspondence as in the case of cyclopeptides. In the case of the substituted amides of acyl peptides the topochemical analogs *(21)* and *(22)* differ only by reversal of the amide groups, including the end groups.

(21)

(22)

Thus one can also put the search for analogs of biologically active linear peptides, in particular of some peptide hormones and antibiotics (for instance α-melanophoro-stimulating hormone, gastrin and its highly active C-terminal fragments, and gramicidin A) on a rational footing. Since the retro-enantiomers of such peptides are built up of only D-amino acid residues they should be resistant towards the inactivation by the proteolytic enzymes in the organism and consequently should have a more durable biological action.

With respect to linear peptides we considered it of particular interest to apply the topochemical concept in making specific analogs of substrates and inhibitors of proteolytic enzymes, which could yield additional valuable information on the nature of the enzyme-substrate interaction.

If the protected dipeptide *(23)* serves as a specific substrate, its topochemical analog *(24)*, which is practically its equal with respect to the hydrophobic and functional periphery, will differ from it only in the reversed disposition of the atoms in the amide groupings (see Table 2). Therefore, such an analog [*(24)*]

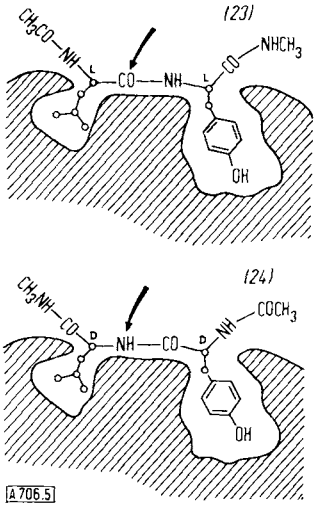


Fig. 5. Schematic representation of a specific substrate of a proteolytic enzyme — protected peptide *(23)* — and its retro-enantiomer *(24)*, both complementarily bound to the binding site of the enzyme.

should in all probability bind with the same efficacy to the same contact site of the enzyme as compound *(23)* (see Fig. 5); such an assumption is supported by the numerous data that show that the major role in the binding process belongs to hydrophobic interactions. But this retro-enantio isomer *(24)*, built up of D-amino acid residues should not be subject to enzymatic hydrolysis, owing to the high configurational specificity of this reaction (cf. however[41]). Hence such a compound should prove to be an effective competitive inhibitor. Kinetically its behavior would be manifested in its inhibiting constant K_I being close in value to the Michaelis constant for the corresponding substrate, *i.e.* $K_I \simeq K_M$.

With this in mind we synthesized a number of C- and N-terminus protected leucine and tyrosine containing dipeptides [compounds *(23)* to *(29)* in Table 2] and carried out a kinetic study of their interaction with pepsin[42] and chymotrypsin[43]. The results, treated according to the Lineweaver-Burk method, are presented in Table 2.

As predicted, the dipeptide *(24)* which is the retro-enantiomer of the substrate *(23)* proved to be an effective inhibitor of pepsin with an inhibiting constant very close to that of the Michaelis constant of the substrate. A similar behavior is displayed by the pairs of related dipeptides *(25)* and *(26)*, and *(27)* and *(28)* which are in retro-enantio relations to each other and possess practically identical K_I values. These results assume a particular significance in the light of the be-

(29)	Ac-Leu-Tyr-$NHCH_3$ DD	K_I [b] $= 7.5 \times 10^{-3}$	$\sim 10^{-1}$

[a] Competitive inhibition. [b] Mixed inhibition.

havior of all the dipeptides *(25)–(29)* which are not topochemical analogs of *(23)*. Their interaction with pepsin cannot be described by equations for competitive inhibition. These peptides exhibit "mixed" inhibition with noncompetitive inhibition strongly predominating ($\alpha = 1.8$–3.2).

Even more definite results were obtained in studies of the interaction of protected dipeptides *(23)*, *(24)*, *(26)*, and *(27)* with chymotrypsin. The process studied was the inhibition by these dipeptides of chymotrypsin-catalyzed hydrolysis of *p*-nitrophenyl pivalate. In this case the inhibition constants of the dipeptides could be compared without determination of the Michaelis constant which gives only an approximated picture of the binding of the substrate to the enzyme. As is shown in Table 2, the K_I values for the retro-enantiomers *(23)* and *(24)* coincide within the limits of experimental error. The dipeptide *(26)* binds with chymotrypsin less efficiently, and compound *(29)*, which is an antipode of the dipeptide *(23)*, and is usually *a priori* regarded as an inhibitor, showed no inhibiting effect under the experimental conditions.

Hydration Structure and Intermolecular Interaction in Polyelectrolytes

By G. Zundel[*]

In hydration, the intermolecular interaction is of decisive importance, since the ions modify the properties of the hydration water molecules, and the water molecules in turn have a strong influence on the interaction between the ions. These processes can be studied in detail with the aid of IR spectroscopy, which in addition provides a picture of the hydration structure. IR spectroscopy also shows that the excess protons are in energy bands and allows the detection of the proton dispersion forces acting between tunneling protons. The results of IR studies on polyelectrolytes contribute to our understanding of the many biological processes that depend on the behavior of ions.

1. Introduction

In biological events, intermolecular interaction is just as important as chemical bonding. This "intermolecular" interaction is due to weak bonds, *e.g.* hydrogen bonds, linking molecules or the functional groups of a macromolecule. It is important in particular to the hydration processes, and hence to all biological processes involving ions.

Methods of molecular physics that have little effect on the system are particularly suitable for the investigation of intermolecular interaction. Since IR quanta have relatively low energies, they cause no appreciable changes in the systems, and IR spectroscopy accordingly offers a promising method.

The intramolecular vibrations occur in the middle infrared region. The bands in this region provide information about the changes in the molecules due to the intermolecular interactions, since these interactions influence the potential wells in the molecules and so displace the IR bands. Moreover, the bands due to intermolecular vibrations can be observed in the far infrared. This could yield direct information about the intermolecular bonds, which are very important to our knowledge of the nature of the liquid state. Practically no such investigations in the far infrared have however been carried out as yet.

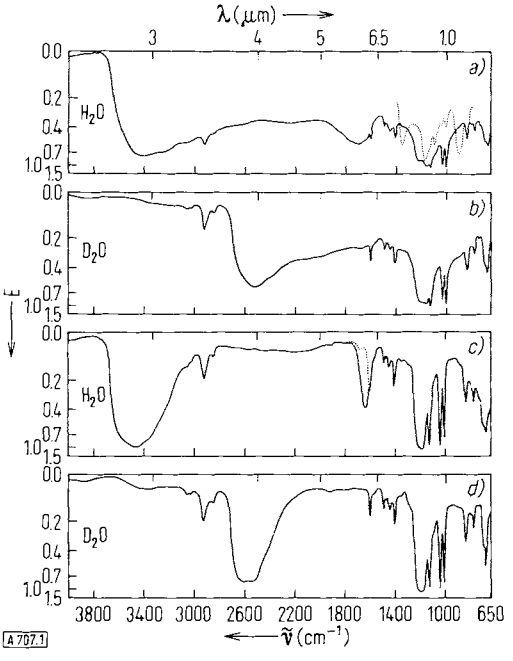
One difficulty that arises in the spectroscopic study of homogeneous liquid electrolyte solutions is that in addition to the water of hydration, such solutions usually also contain water that is influenced little or not at all by the ions, and the IR bands of this water mask the bands due to the water of hydration. IR spectroscopy is therefore best suited to the investigation of very concentrated solutions, and particularly to the study of polyelectrolytes.

The present article deals with investigations on organic ion exchangers (salts and acids derived from polystyrene). In these substances, the ions of the one kind are fixed to a polymeric network (fixed ions), while

[*] Priv.-Doz. Dr. G. Zundel
Physikalisch-Chemisches Institut der Universität
8 München 2, Sophienstrasse 11 (Germany)

those of the other kind move more or less freely in this network. Ion exchangers of this type are simple model substances for systems of biopolymers.

A brief survey of the IR bands that provide information about the intermolecular interaction in these substances [*] will serve as a basis for later discussion. These are firstly the bands due to vibrations in the anions. Figure 1 shows the antisymmetric (1200 cm^{-1})



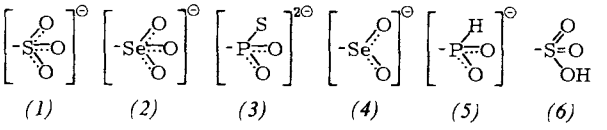


Fig. 1. IR spectra of a) polystyrenesulfonic acid hydrated with H_2O — — at 98% relative humidity [*], ... thoroughly dried membrane; b) polystyrenesulfonic acid hydrated with D_2O —— at atmospheric humidity over saturated $BaCl_2$ solution in D_2O; c) Na^+ salt of polystyrenesulfonic acid hydrated with H_2O —— at 98% relative humidity .... thoroughly dried membrane; d) Na^+ salt of polystyrenesulfonic acid hydrated with D_2O —— at atmospheric humidity over saturated $BaCl_2$ solution in D_2O. For positions of the bands due to vibrations of the anions and acid groups see Table 1. Stretching vibrations H_2O (3700—2800 cm^{-1}), D_2O (2750—2050 cm^{-1}), scissor vibrations H_2O (about 1640 cm^{-1}), D_2O (about 1206 cm^{-1}, masked in Fig. 1).

[*] The spectrum was recorded while the membrane was in equilibrium with water vapor.

and the symmetric (1040 cm^{-1}) SO stretching vibrations of the $-SO_3^-$ ions *(1)* in the sodium salt of polystyrenesulfonic acid, as well as the antisymmetric and the symmetric stretching vibrations of the S=O double bonds (1350 and 1172 cm^{-1}) and the stretching vibration of the SO single bond (907 cm^{-1}) of the $-SO_2OH$ group *(6)* in the undissociated polystyrenesulfonic acid. Secondly there are the bands due to the water of hydration (stretching vibrations and scissor vibration). Thirdly, interesting information can be derived from an absorption continuum in the case of the acids if they are dissociated. If the acids are not dissociated, but associated, this is shown by a pair of bands due to the OH or OD groups of the acid (see Fig. 5).

2. The Salts

The fixed ions *(1)–(5)* each contain either three or two substantially equivalent XO bonds (Fig. 2 together with Table 1). The mesomeric bond resonance

is therefore very extensive in the anions. The $-SO_3^-$ and $-SeO_3^-$ ions, so far as they are isolated from their surroundings, thus have a pyramidal structure, *i.e.* C_{3v} symmetry.

2.1. Cation-Anion Interaction [7]

The antisymmetric stretching vibration of a group having C_{3v} symmetry is degenerate, *i.e.* two vibrations have the same wave number [8]. However, in the spectra of thoroughly dried membranes of the salts of polystyrenesulfonic acid a doublet is found (Fig. 3) instead of the expected single band at 1200 cm^{-1} [*], showing that the degeneracy is removed. This splitting generally increases as the cation becomes smaller and as its valency increases, *i.e.* as the field of the cation at the anion increases. It is greater for the $-SO_3^-$ than for the $-SeO_3^-$ ion, and hence increases with increasing polarizability of the anion. The removal of the degeneracy is due to asymmetrical polarization of the anions by the cations, *i.e.* to a disturbance of the mesomeric bond resonance in the anions. It is therefore closely connected with the cation-anion ion-induced dipole interaction.

Other types of cation-anion interaction increase the splitting of the bands if they change the structure of the anion *e.g.* the covalent interaction. The splitting in the presence of transition element ions is thus much greater than one would expect from the cation field. This is illustrated by comparison of the Zn^{2+} ion with Mg^{2+} ion in Fig. 3a. Finally, the splitting with very small polyvalent cations is not so great as it should be on the basis of the cation field. This is due to the influence of the fields of the neighboring anions [1].

2.2. Location of the Cations with Respect to the Anions

The cation must be situated asymmetrically with respect to the O atoms of the $-SO_3^-$ ion, since only then can it disturb the C_{3v} symmetry. It can also be deduced

that the cation must be associated with a certain one of the three O atoms, in the direction of one of the SO bonds. One finds only the two bands that result from the removal of the degeneracy, and no band due to a degenerate vibration at 1200 cm^{-1}. It follows that a cation must be present on every anion. The polyvalent cations link their anions as shown in the formula. This is presumably the reason for the membrane-tightening action of Ca^{2+} in biological systems [9].

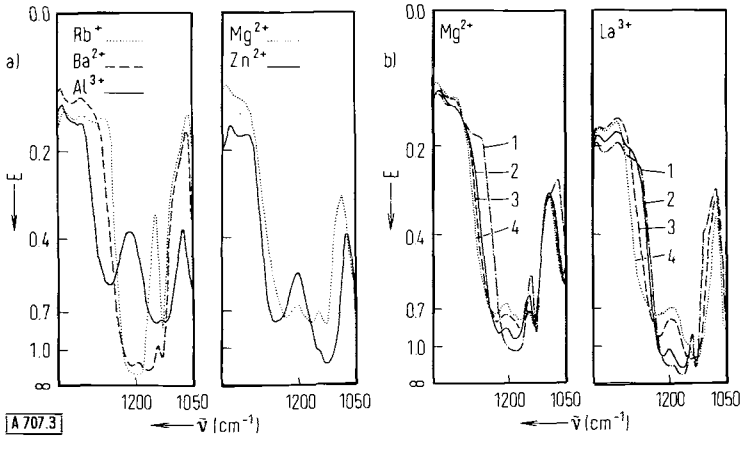
2.3. The Dissociation Process in Salts and the Nature of the Ion Pairs [10]

The splitting of the bands decreases with increasing degree of hydration [*] (see Fig. 3b) but is still present at a degree of hydration >5, as is shown by comparison with the water adsorption isotherms of these substances [11–15]. The bonds between the cations and anions therefore become progressively weaker as the degree of hydration increases; however, the cations remain with their corresponding anions even at very appreciable degrees of hydration. These processes in the dissociation of the salts are illustrated in Graph 1. The cations lie in a potential well at the O atom of their corresponding anions. This potential well is influenced by the fields of the hydration water molecules



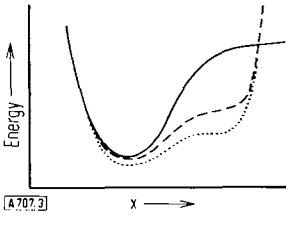


Fig. 3. Band doublets of the antisymmetric stretching vibrations of $-SO_3^-$ ions a) in the presence of Rb^+, Ba^{2+}, Mg^{2+}, Al^{3+}, and Zn^{2+}; spectra of dried membranes b) as a function of the degree of hydration; 1 to 4 in decreasing order of degree of hydration.

in such a way as to favor the temporary release of a cation from an anion. The strength of the bonding in ion pairs is thus a function of the degree of solvation and of the solvating medium. The temporary removal of the ion is the source of the electric conductivity. A cation "jumps" to the neighboring anion and forces

values [17], which provide a relative measure of the strength of the cation field at the H nuclei of the water molecules. In the cation groups, this band moves toward lower wave numbers with increasing cation field. The monovalent cations and the ions of the transition elements are exceptions to this rule. The shift shows that the strength of the hydrogen bonds linking the water molecules to neighboring groups increases with increasing cation field, since the cation field polarizes the OH groups of the water molecules. The dipole moment becomes stronger and the H atoms become more increasingly positively charged. The hydrogen bond donor property of these groups increases [17]. In addition the hydrogen bond acceptor property of the O atoms of the neighboring anions also becomes stronger with increasing cation field, since these are also polarized by the cation. This polarization involves rearrangement of the electrons in the anions in such a way that two of the three O atoms become stronger acceptors, as is shown by the findings with acids. In the presence of transition element ions, the bands show much larger shifts to lower wave numbers than would be expected from the cation fields (comparison of values for transition element ions and Mg^{2+} in Table 2). Thus the water molecules are also polarized by covalent interaction of their lone electron pairs with incompletely occupied d orbitals of the cations [18].

2.4.2. Anion-Water Interaction

At low degrees of hydration the stretching vibrations of the OH groups of the hydration water molecules in the hydrogen bonds are shifted toward lower wave numbers in the series of the Na^+ salts with the anions *(1)–(5)* (Fig. 4).

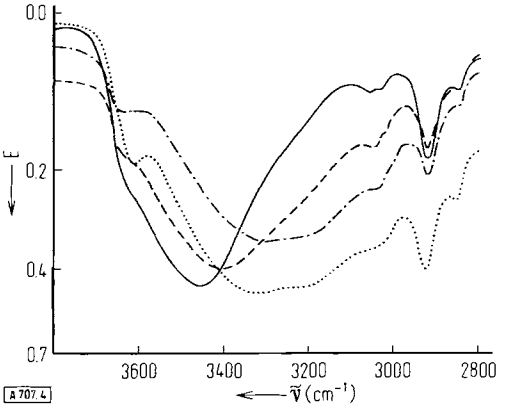

Fig. 4. IR spectra of the Na^+ salt of —— polystyrenesulfonic, ---- polystyreneselenonic, —·—· polystyreneseleninic, ... polystyrenephosphinic acids hydrated with H_2O, all membranes at a relative humidity of 11%. [Anions *(1)*, *(2)*, *(4)*, and *(5)*].

The strength of the hydrogen bonds linking the OH groups of the water molecules to the O atoms of these anions thus increases in the same order. Since the proton acceptor property of the anions also increases in this order [19], it is not surprising that the hydrogen bond acceptor property of the O atoms in the anions shows a similar tendency [20].

[20] *G. Zundel*, Ž. strukturnoj Chim. *6*, 384 (1965).

The magnitude of the dipole moment μ of the water, which is of fundamental importance to both the cation-water and the anion-water interactions, thus depends not only on the dipole moment of the free water molecule, but also contains a component due to the interaction with the cation and the anions. The cation-water and anion-water interactions are accordingly not independent at low degrees of hydration, but reinforce each other.

2.5. Position of the Water Molecules with respect to the Ions

At low degrees of hydration the water molecules are located between the cation and the neighboring anions as shown by the formula (this page). This is deduced from the fact that the water molecules interact with both the anions and the cation. It must, however, be remembered in considering the pictures of the hydration structure obtained by IR investigation, that the absorption of an IR quantum takes place extremely rapidly. One obtains a picture of the temporary equilibrium position, for, as is known, the hydration structures undergo frequent rearrangements as a result of thermal motion of the hydration water molecules [21–26]. IR-spectroscopy of electrolyte solutions thus affords data about structures which exist for only a short time in dynamic equilibrium with analogous structures.

The stretching vibrations of the free OH groups (*i.e.* those that are not involved in hydrogen bonding) of the hydration water molecules can be observed for some salts as a weak but sharp band at 3615 cm^{-1} (Fig. 4) [*]. Since this band is frequently absent, however, it must be concluded that disintegration of the network of ion pairs and hydration water molecules is only slight. The intensity of the shoulder increases from the Sc^{3+} to the La^{3+} salt. The hydrogen bond donor property of the OH groups of the hydration water molecules decreases in the same order, *i.e.* the number of free OH groups increases as the hydrogen bond donor property of the OH groups of the hydration water molecules decreases [28]. The number of free OH groups in the series of anions *(1)* to *(5)* investigated should decrease from $-SO_3^-$ to $-PHO_2^-$, since the hydrogen bond acceptor property of the O atoms increases in this order. This is not, however, in agreement with observations. The reason is that the number of free OH groups of the water molecules depends not only on the hydrogen bond acceptor property of the O atoms of the anions, but also in particular on the number of O atoms available on the anions to act as acceptors [28].

There is thus a usually only slightly disintegrated network of hydration water molecules and ions. The hydrogen bonds in this network are often strongly bent, and vary slightly in their length [29]. As has been shown by *Luck* [30], bending can occur if it allows the formation of more hydrogen bonds. The H_2O molecules should give an antisymmetric and a symmetric stretching vibration, *i.e.* a doublet; instead of this a wide OH stretching band is observed. Due to the fact that the hydrogen bonds are of different strengths, the two OH groups of each water molecule have become so different that they no longer vibrate together [**]. This results from the differences in stretching and bending of the hydrogen bonds.

2.6. Water Structure and Ions with Very Weak Fields

The shift of the wide OH stretching band behaves anomalously in the presence of alkali metal ions (Table 2), for which there is practically no change in the position of the band with changing cation field [33]. Now, the hydrogen bonds that link the water molecules to the O atoms of the $-SO_3^-$ ions are weaker in the presence of alkali metal ions than in liquid water; this is indicated by the OH stretching vibration band of the water molecules, which occurs at higher wave numbers in the presence of alkali metal ions than in pure liquid water [3420 cm^{-1} (25 °C)] [1]. According to the results obtained so far, the band should shift toward lower wave numbers from Cs^+ to Li^+. Since

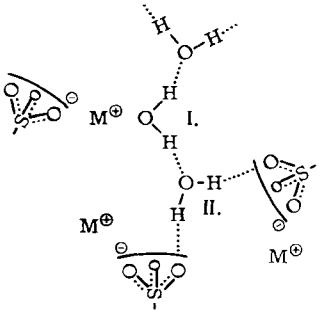
the cation-water interaction decreases from Li^+ to Cs^+, the bonding between the cations and the hydration water molecules becomes weaker in this direction. The OH groups of water molecules can displace the cations from the lone electron pairs of their hydration water molecules and form hydrogen bonds with the latter. Thus from Li^+ to Cs^+, the association of the water molecules with one another is increasingly favored in relation to the insertion of water molecules between the cation and the neighboring anions.

This discussion explains the anomalous behavior of this band in the case of the alkali metal ions, since the transition from Li^+ to Cs^+ is accompanied by increasing formation of a network of "pure" water structure. The OH stretching vibration band of these water molecules is situated, however, at lower wave numbers than that of the water molecules inserted between the cation and the neighboring $-SO_3^-$ ions, and therefore an opposing shift is superimposed. The two shifts practically cancel each other out, with the result that the position of the band is almost the same for all the alkali metal ions.

The formation of the "pure" water structure is still more noticeable in the case of the alkylammonium ions[32]. The band is situated at 3449 cm^{-1} for the $(CH_3)_4N^+$ salt and even at 3430 cm^{-1} for the $(C_2H_5)_4N^+$ salt. Thus, as expected, it has shifted much farther toward the wave number for pure liquid water than in the case of the Cs^+ salt. The position of the OH stretching vibration band is a measure of the water-structure forming action of the apolar groups in these ions.

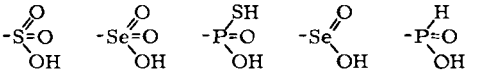


This water-structure formation is the cause of the hydrophobic interaction[34–36]. One should therefore expect a stronger interaction of the alkylammonium than of the alkali metal ions with the $-SO_3^-$ ions, and this is what is actually found, as is shown by the splitting of the antisymmetric SO stretching vibration band of the $-SO_3^-$ ion[32].

2.7. Hydration with Increasing Degree of Hydration

As the number of water molecules increases, the bonding between the cations and the anions becomes looser; this leads to two changes in the bands of the hydration water molecules.

1. If more water molecules are inserted between the cation and the anions, the polarizing effect of the cation is distributed over these water molecules, with the result that the hydrogen bonds formed by the OH groups of these water molecules become weaker[37]. The acceptor property of the O atoms of the anions also decreases somewhat, since the polarization of the anions by the cations decreases as the cation-anion bond becomes weaker. The stretching vibration band of the OH groups in hydrogen bonds of the hydration water consequently moves toward higher wave numbers with increasing hydration. In other words, the shift of the band toward smaller wave numbers decreases with increasing hydration.



2. Two or more layers of water molecules are inserted between the cations and the neighboring anions, *i.e.* a "second hydration shell" is formed[38]. It is possible to follow this in the presence of cations

having a very strong field, *e.g.* in the Al^{3+} salt. The OH stretching vibration band of the hydration water molecules of attachment type II appears at about 3430 cm^{-1} with increasing degree of hydration. In the case of cations having strong fields, the band due to the OH stretching vibration of the hydration water molecules of attachment type I appears merely as a more or less pronounced shoulder on the low wave number flank of the hydration water band complex.

3. The Acids

When the acid proton is present on the anions, it rearranges the bonding electrons in such a way that the groupings *(6)–(10)* are formed from the fixed ions *(1)–(5)* (Fig. 2 and Table 1). The acid proton greatly reduces the mesomeric bond resonance of its anion[19].

(6) *(7)* *(8)* *(9)* *(10)*

3.1. Dissociation

The anion vibration bands of polystyrenephosphinic and polystyreneseleninic acids do not change with increasing degree of hydration. In polystyrenesulfonic and polystyreneselenonic acids, on the other hand, the rearrangement of the bonding electrons due to the acid proton disappears with increasing degree of hydration (Fig. 2). The integral extinction of these bands can be used as a measure of the removal of the proton from the anion, *i.e.* as a measure of the true degree of dissociation. According to this, the true degree of dissociation decreases from polystyrenesulfonic to polystyrenephosphinic acid in the series of acids investigat-

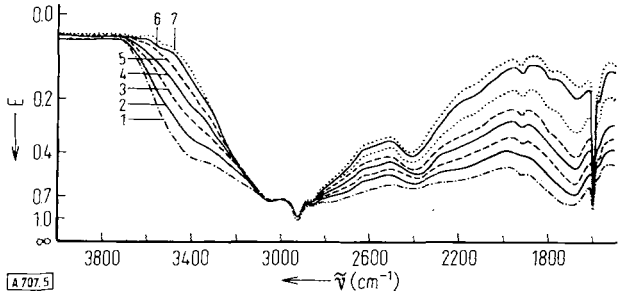
ed. It is understandable that the true degree of dissociation should be much lower for the –SeOOH *(9)* and –PHOOH *(10)* groups, since on dissociation of these groups the charge has only two instead of three XO bonds over which it can be distributed [19,44].

3.2. Association of the Acid Groups

After thorough drying all these acids exhibit a pair of bands (Fig. 5), which is due to the OH or OD group of the acid. When this pair of bands occurs, the acid



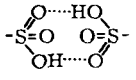


Fig. 5. IR spectra of polystyrenesulfonic acid hydrated with H_2O (two membranes superimposed on each other). The membranes were kept in the sample cell at a fixed relative humidity for about 6 hours before the spectra were recorded. The drying steps were carried out successively without interruption. 1% crosslinked [*], 1.50 acid groups/benzene ring 1 → 6 decreasing relative humidity, 7 thoroughly dried membranes; pair of bands at 2950 and 2405 cm^{-1} (OH) or at 2240 and 1805 cm^{-1} (OD) (not shown here).

[*] Crosslinking with divinylbenzene added during the polymerization.

groups are linked as shown in *(11)* [39], though not always in pairs.

According to *Hadži et al.* [40,41], the pair of bands is due to the stretching vibration and the overtone of the bending vibration of the acid OH or OD groups, these

(11)

two vibrations being coupled by Fermi resonance [*]. Such strong coupling of bands situated so far apart is possible only if a very anharmonic, *i.e.* asymmetrical, potential well exists in the hydrogen bonds formed by these groups.

These hydrogen bonds are very strong, as is shown by the position of the bands and the strong anharmonicity of the potential well. It seems at first surprising that the strong polystyrenesulfonic acid is associated *via* hydrogen bonds as strong as those formed in the weak polystyreneseleninic acid. An IR-spectroscopic and an ebullioscopic study of anhydrous *p*-toluenesulfonic acid in chlorinated hydrocarbons showed that this acid is dimeric and gives the same pair of bands [39]. How can the relatively strong polystyrenesulfonic acid form such strong hydrogen bonds? We have seen that the acid proton rearranges the electrons in these anions in such a way as to give $-SO_2OH$ groups *(6)*. Since the doubly bonded O atoms are much stronger acceptors for hydrogen bonds than the O atoms in the $-SO_3^-$ ions, the strong polystyrenesulfonic acid can form hydrogen bonds as strong as those formed by the weak polystyreneseleninic acid.

These bands are a measure of the association of the acid groups [**]. In the case of polystyrenesulfonic acid, the band at 2405 cm^{-1} appears only with increasing drying, whereas in the case of polystyreneselenonic acid the corresponding band is already faintly visible even when the membrane has been hydrated at a relative humidity of 98%; it too intensifies with increasing drying. For polystyrenethiophosphonic acid, polystyreneseleninic acid, and polystyrenephosphinic acid, the band is as intense after hydration of the membrane at 98% relative humidity as after intensive drying. The tendency to associate increases from the $-SO_2OH$ *(6)* to the –PHOOH *(10)* groups. It thus shows the opposite course from the true degree of dissociation [44].

3.3. Excess Proton, IR Continuum, and Proton Dispersion Forces

In the ion exchangers, the degree of hydration can be reduced to any desired extent without modification of the amorphous structure of the liquid state by crystallization. These substances have therefore proved particularly suitable for the investigation of the nature of the excess proton, which is hydrated with only a few water molecules [45–47,58].

Curves on the right-hand side of Figure 6 show a plot of the number of water molecules available to the excess proton against the true degree of dissociation α_t of the polystyrenesulfonic acid. α_t was determined from the integral extinction of the bands of the $-SO_2OH$ groups *(6)*. The acid proton in polystyrenesulfonic acid is released from the anion when it has two water molecules available (extrapolation of the curves on the right hand side in Fig. 6).

Polystyrenesulfonic acid gives an intense absorption continuum extending from the OH or OD stretching vibration bands toward lower wave numbers (see Figs. 1a, 1b). The extinction of this absorption continuum increases in proportion to the true degree of dissociation at low excess proton densities (curves on left-hand side in Fig. 6). Since the dissociation of poly-

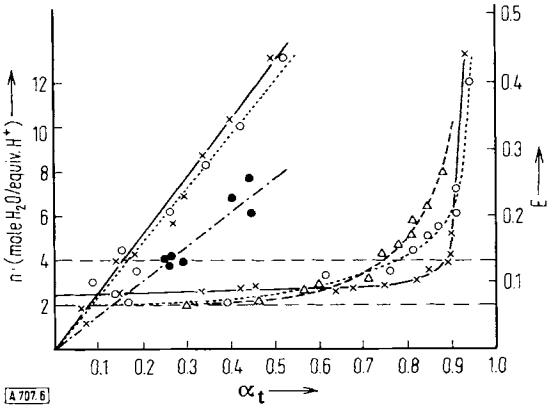

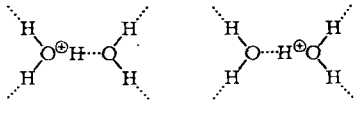

Fig. 6[*]. a) Number (n*) of water molecules available to the excess proton as a function of the true degree of dissociation α_t of polystyrenesulfonic acids (three curves on the right-hand side of the Figure; left ordinate). b) Extinction of the absorption continuum (at 2000 cm^{-1}) as a function of the true degree of dissociation α_t of polystyrenesulfonic acids (three straight lines on left-hand side of the Figure; right ordinate).

Each of the sets of three curves shows curves for membranes having different degrees of crosslinking and sulfonation.

styrenesulfonic acid occurs when there are two water molecules available to the acid proton, this result shows that the continuum arises when $H_5O_2^+$ groupings are formed.

In crystals containing the grouping H_3O^+, the symmetric bending vibration of this grouping is observed at about 1200 cm^{-1} [48–50]. When the spectrum contains a symmetric bending vibration of the grouping H_3O^+, the band of this vibration at about 1200 cm^{-1} should disappear on transition from H_2O to D_2O hydration, and should be replaced by the D_3O^+ band at about 890 cm^{-1}. However, no appreciable change is observed on transition from H_2O to D_2O hydration. The grouping H_3O^+ accordingly does not execute any vibrations as an entity in the non-crystalline medium. This can be explained only if the life-time of the H_3O^+ grouping is very short under these conditions.

The excess proton thus moves extremely rapidly between the two water molecules in $H_5O_2^+$. This grouping can therefore be represented by the two boundary structures [51]. The absorption continuum is closely connected with this mobility of the excess proton in $H_5O_2^+$.

The absorption continuum is not temperature-dependent between 292 and 85 °K [52]. Thus no activation energy is required for the movement of the excess proton in $H_5O_2^+$. The proton tunnels accordingly in the hydrogen bond of this grouping. A potential well is present, as is shown in Fig. 7.

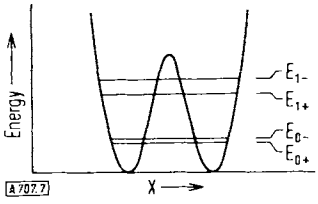

Fig. 7. Symmetrical double minimum potential well in a symmetrical hydrogen bond (spatial coordinate x in arbitrary units).

Do the two water molecules of the $H_5O_2^+$ retain their individuality as vibrating groups while the excess proton is tunneling between them? At low degrees of hydration, *i.e.* when the $H_5O_2^+$ groupings are being formed, the extinction of the absorption continuum increases linearly with the integral extinction of the scissor vibration. This is possible only if the water molecules in $H_5O_2^+$ vibrate as individuals [45].

Many authors have studied and discussed the special stability of the $H_9O_4^+$ grouping. (For reviews see [1, 53, 54].) The integral extinction of the scissor vibration increases strongly while the first four water molecules are adding to the proton that has been removed from the anion. Hence the extinction coefficient of the scissor vibration of the outer water molecules in the grouping $H_9O_4^+$ is very much higher than that of the water molecules in pure liquid water [1, 46].

All this shows the special position of this grouping in the network of the hydration structure. The extinction of the continuum does not change on transition from $H_5O_2^+$ to $H_9O_4^+$. Owing to the symmetry of the grouping $H_9O_4^+$, however, none of the three hydrogen bonds can be favored, *i.e.* they must all have a potential well with a low barrier, the potential being so symmetrical that the protons can tunnel. Thus the three inner protons in $H_9O_4^+$ act as the excess proton.

The continuum is due to the tunneling excess protons, which have a continuous energy distribution, *i.e.* are in energy bands. How do these energy bands arise? The tunneling of a particle in a potential well, as shown in Figure 7, always causes splitting of the energy levels, but never broadening. The continuum must therefore be due to some other factor. The transition of an excess proton from one boundary position to the other is associated with a fluctuation of the electromagnetic field in the neighborhood. This field fluctuation changes the potential at the position of a neighboring excess proton. It is very large, since the center of the charge is displaced much more on tunneling of a proton than the tunneling H nucleus itself. This is because the transition of the H nucleus causes a considerable displacement of the electrons, *i.e.* of the negative charge, in the opposite direction, and the field fluctuation depends on the amount of displacement, not of the H nucleus alone, but of the center of the charge. Neighboring tunneling protons are coupled *via* this fluctuating field, and this coupling leads to a shift of the energy levels. Estimation of the shift of the levels by these coupling forces for pairs of tunneling protons with the

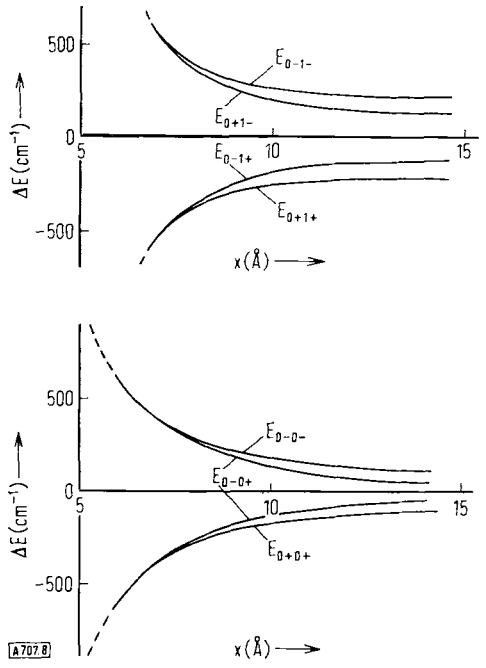

Fig. 8. Shift and splitting ΔE of the energy terms of the tunneling protons as a function of the distance from the center of the hydrogen bonds.

perturbation calculation for nearly degenerate states [55] gives the energy terms of the tunneling protons as a function of the distance between the centers of the two hydrogen bonds Fig. 8 [56].

The shift of the lowest level by the fluctuating fields associated with the tunneling of the proton is

$$\Delta E_{0+0+} = h\nu_0 \left[1 - \sqrt{1 + \left(\frac{p^2}{\varepsilon h\nu_0}\frac{g}{R^3}\right)^2}\right]$$

where ν_0 is the tunneling frequency in the ground state, p is the dipole moment of the grouping $H_5O_2^+$ when the proton is in one of the boundary positions, ε is the dielectric constant of the medium between the tunneling protons, and g is a factor that takes into account the orientation of the two hydrogen bonds with respect to each other. It passes through values from -2 to $+2$. R is the distance between the hydrogen bonds with the tunneling protons. Similar relations exist for the shifts of the other levels.

If we consider many pairs of tunneling excess protons in a liquid, the orientation factor g and the distance R pass through a random statistical multiplicity of values. The shifts of the energy levels consequently pass through a continuous range of values. This is the cause of the energy bands of the tunneling protons, and hence of the absorption continuum.

The lowest energy level, which is preferentially occupied by the tunneling protons, is lowered. The tunneling protons thus attract one another. The term "proton dispersion forces" is suggested by the processes involved in their occurrence. These forces are as strong as the other intermolecular forces.

When the concentration of tunneling protons in polystyrenesulfonic acid exceeds 1.5 mequiv. of H^+/g, the extinction of the continuum no longer increases appreciably with increasing concentration [*]. The extinction of the continuum per tunneling proton thus decreases at approximately the same rate as the concentration is being increased at high concentrations of tunneling protons. The extinction of the continuum shows a saturation effect, which presumably corresponds to the transition from coupling in pairs to coupling of all the tunneling protons [58].

This absorption continuum is not confined to dissociated polystyrenesulfonic acid. It was observed by *Suhrmann* and *Breyer* [59] as early as 1933 in the investigation of aqueous acid and base solutions in the overtone region, and later by *Ackermann* [60,61] in the fundamental vibration region. It occurs with all polyelectrolytes having dissociated acidic and basic (Fig. 9a) groups [1]. It is observed when an excess proton

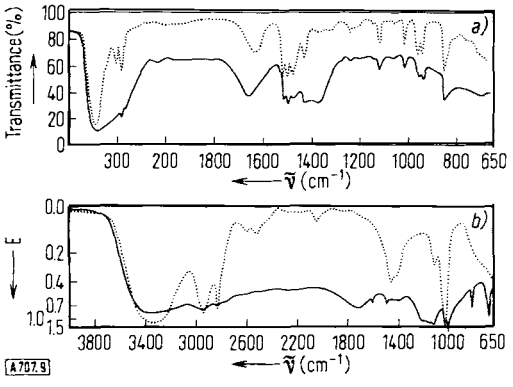

Fig. 9. IR spectra. a) —— poly-*p*-trimethylammoniumstyrene hydroxide [31, 62], hydrated; .... poly-*p*-trimethylammoniumstyrene iodide [31, 62], hydrated; b) —— saturated solution of *p*-toluenesulfonic acid monohydrate in CH_3OH; .... CH_3OH.

tunnels between molecules such as methanol (Fig. 9b) and dimethyl sulfoxide [1], and has recently also been discovered in biopolymers [1]. Energy bands of tunneling protons and proton dispersion forces thus play a part in many systems.

The rate-determining step in the anomalous conductivity of protons is the structure migration (or structure diffusion), as discussed in particular by *Eigen et al.* [63]; the structure migration of a grouping of the size $H_5O_2^+$ is sufficient. In this process, the H nucleus can tunnel and so migrate in the field direction if the bridges formed by the outer water molecules in $H_5O_2^+$ or $H_9O_4^+$ are linearized during thermal motion [1]. This H nucleus then assumes the role of the excess proton.

[*] The concentration of the tunneling protons cannot be varied directly *via* the concentration of fixed ions incorporated, since the latter are no longer uniformly distributed in the membrane at low concentrations, as is shown by the kinetics of the sulfonation reaction [57].

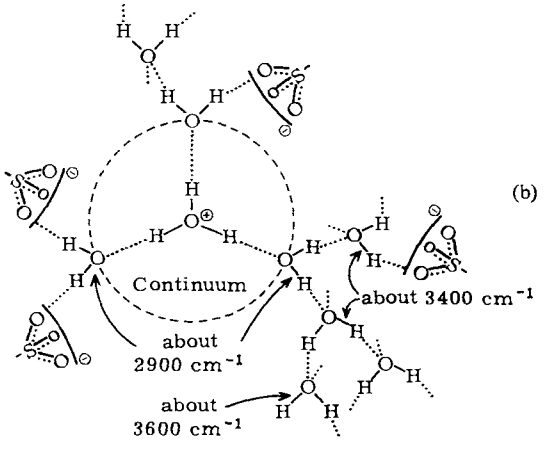
3.4. The Hydration Structure of the Acids

3.4.1. Polystyrenesulfonic Acid[47]

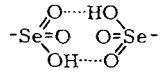


The $-SO_2OH$ groups of polystyrenesulfonic acid dissociate only when two water molecules are available per acid group. If this acid is slowly dried, the last water molecule per acid group is attached as shown in (a).

(a)

This water molecule is presumably often bound, not merely to one acid OH group, but to two, *i.e.* by one on each lone electron pair. The OH stretching vibration bands of the OH groups in the two different hydrogen bonds are found at 3210 and 3050 cm^{-1}. If two water molecules are present, the acid proton is removed from the anion. However, the number of water molecules on the excess proton increases only slowly at first with increasing degree of dissociation (curves on right-hand side in Fig. 6). This situation changes only when most of the $-SO_2OH$ groups have dissociated.

If no further water molecules are available, the $H_5O_2^+$ or $H_9O_4^+$ groupings formed are linked to the O atoms of the $-SO_3^-$ ions *(1) via* hydrogen bonds, as is shown by the following findings: 1. A stretching vibration band due to free OH groups at about 3600 cm^{-1} is at best indistinct. 2. The degeneracy of the antisymmetric stretching vibration band at about 1200 cm^{-1} is removed (cf. the doublet in Fig. 1a). The stretching vibration band of the OH groups in the hydrogen bonds formed by the outer water molecules of $H_5O_2^+$ or $H_9O_4^+$ is very broad and is situated at about 2900 cm^{-1}, while that of the OD groups occurs at

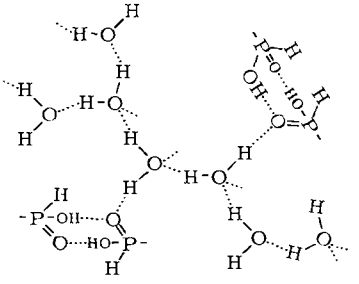


(b)

2100 cm^{-1}. The stretching vibration band of the OH groups of the water molecules attached to the $H_9O_4^+$ grouping appears at about 3400 (H_2O) or 2500 cm^{-1} (D_2O) with increasing degree of hydration. The resulting network of the hydration structure is shown schematically in (b). For the sake of clarity only one excess proton is shown.

3.4.2. Polystyreneselenonic Acid

The hydration structure of polystyreneselenonic acid does not differ very greatly from that of polystyrenesulfonic acid, except that the true degree of dissociation of the $-SeO_2OH$ groups *(7)* is smaller than that of the $-SO_2OH$ groups *(6)*. Thus the $-SeO_2OH$ groups are mostly not yet dissociated when they have two water molecules available. Moreover, the groupings *(12)* are



(12)

not yet all dissociated even when the membranes have been hydrated at 98% relative humidity. Therefore, hydrated $-SeO_2OH$ groups, which are probably mostly still associated even at relatively high degrees of hydration, are situated between the hydration structures around the dissociated acid proton[44].

3.4.3. Polystyreneseleninic and Polystyrenephosphinic Acids

Quite different hydration is found in polystyreneseleninic and polystyrenephosphinic acids[44]. The $-SeOOH$ *(9)* and $-PHOOH$ *(10)* groups dissociate only to an extremely small extent, and they remain associated even when these membranes are considerably hydrated. The band that arises at 3390 (H_2O) or 2490 cm^{-1} (D_2O) with increasing hydration thus corresponds to the stretching vibration of the OH or OD groups in the hydrogen bonds of the water molecules by which the latter are linked to O atoms of the acid groups or to one another. Finally, the shoulder at about 3640 (H_2O) or 2680 cm^{-1} (D_2O) shows that there are a considerable number of free OH or OD groups in the network of the hydration structure, which consequently shows appreciable disintegration, particularly in polystyrenephosphinic acid. This is understandable in view of the strong hydrogen bonds between the associated acid groups, which strain the structure. A hydration structure is thus present in these two acids, as is shown schematically in (c).

Bis(*N*-fluorosulfonylimido)sulfur and Bis(*N*-fluorosulfonylimido)sulfur Difluoride[1]

By *H. W. Roesky* and *D. P. Babb* [*]

UV irradiation of *N*-(fluorosulfonyl)sulfur oxide imide[2] *(1)* leads to bis(*N*-fluorosulfonylimido)sulfur *(2)*.

$$2\,FSO_2-N=S=O \rightarrow FO_2S-N=S=N-SO_2F + SO_2$$
(1) *(2)*

Compound *(2)* (molecular weight 226; cryoscopic in benzene 226) is a yellow liquid having an unpleasant odor: b.p. 42 to 43 °C/0.01 torr, $d_4^{20} = 1.9104$, $n_D^{20} = 1.4802$. The IR spectrum (capillary film) shows bands at 1450 vs, 1390 vs, 1220 vs, 1180 vs, 1090 vs, 1020 vs 770–850 vs, 680 m cm^{-1} in the NaCl region. The ^{19}F-NMR spectrum (in substance) contains a singlet at −58.5 ppm measured against CCl_3F as external reference.

Compound *(2)* reacts with fluorine when exposed to UV radiation to give bis(*N*-fluorosulfonylimido)sulfur difluoride *(3)*.

$$(2) + F_2 \rightarrow FO_2S-N=S=N-SO_2F \quad (3)$$
(F on the S atom)

Compound *(3)* (molecular weight 264; cryoscopic in benzene 259) is a water-clear liquid: b.p. 53 °C/12–14 torr; as expected, it is more volatile than *(2)*. The IR spectrum (capillary film) contains bands at 1460 vs, 1330 vs, 1220 vs, 1120 w, 1030 w, 930 w, 780–900 vs, 740 m, 675 m cm^{-1} in the NaCl region. The ^{19}F-NMR spectrum (in substance) consists of two triplets of equal area at −45.3 and −62.0 ppm measured against CCl_3F as external reference. The signal at −45.3 ppm is tentatively assigned to the fluorine atoms of the SF_2 group, and that at −62.0 ppm to the fluorine atoms in the FSO_2 groups. $J_{FF} = 6.9$ Hz.

Bis(N-fluorosulfonylimido)sulfur (2)

50 g of compound *(1)* is placed in a quartz vessel and subjected to UV irradiation[3] for 48 h. The SO_2 liberated is collected in a cold trap (acetone/Dry Ice). After removal of unreacted *(1)* under oil-pump vacuum, the residue is distilled twice under reduced pressure. Yield 26 g (65%).

Bis(N-fluorosulfonylimido)sulfur difluoride (3)

Fluorine is passed at a rate of 60 bubbles per minute through a quartz vessel with 50 g of *(2)* that is exposed to UV irradiation. During the reaction gaseous products collect in a condensation trap (acetone/Dry Ice). [Caution! The gas mixture is explosive. During experiments a violent explosion occurred in the gas phase.] After 36 hours the liquid remaining in the reaction vessel is distilled at water-pump vacuum. Yield: 9 g (15%).

3,5-Bis(trifluoromethyl)-1,2,4,6-thiatriaza-2,5-cyclohexadiene-1,1-dione[1]

By *H. W. Roesky* [*]

N-Chlorosulfonyliminotrichlorophosphorane $ClSO_2-N=PCl_3$, prepared from amidosulfuric acid and phosphorus pentachloride[2], reacts with trifluoroacetic acid to give 3,5-bis(trifluoromethyl)-1,2,4,6-thiatriaza-2,5-cyclohexadiene-1,1-dione *(1)*. The formation of $POCl_3$, SO_2Cl_2, and $HN(SO_2Cl)_2$ as additional products was established by IR spectroscopy, thus suggesting the following reaction scheme:

The structure of *(1)* is indicated by elemental analysis, ^{19}F- and ^1H-NMR data, and its mass and IR spectra. Compound *(1)* is a solid at room temperature, can be sublimed in a sealed tube, and is readily soluble in water. Addition of tetraphenylphosphonium and tetraphenylarsonium chloride to an aqueous solution of *(1)* leads to the precipitation of the corresponding salts:

$[(C_6H_5)_4P]^+[C_4F_6N_3O_2S]^-$, m.p. 160 °C

$[(C_6H_5)_4As]^+[C_4F_6N_3O_2S]^-$, m.p. 158 °C

The mass spectrum of *(1)* contains the molecular ion at *m/e* 269 (25.5%) in addition to the fragments *m/e* 250 (4.5%; *(1)* − F) and 205 (75.8%; *(1)* − SO_2), and a large number having smaller masses.

The ^{19}F-NMR spectrum (CD_3CN) shows a singlet at +73.0 ppm measured against CCl_3F as external reference. A singlet is observed in the ^1H-NMR spectrum at −11.5 ppm (TMS as external reference).

IR spectrum (NaCl and KBr regions): ≈ 3200 m, ≈ 3100 m, 1690 s, 1515 s, 1385 m, 1375 vs, 1325 m, 1250 vs, 1170 vs, 792 vs, 758 m, 736 w, 682 vs, 597 vs, 568 s cm^{-1}.

Procedure:

A mixture of *N*-chlorosulfonyliminotrichlorophosphorane (1 mole) and trifluoroacetic acid (1 mole) is heated to 60–70 °C for 24 h. Compound *(1)* can be isolated from the semi-solid reaction mixture in a distillation-sublimation apparatus (oil-pump vacuum); it was purified by subliming twice at 175–180 °C/0.05 torr. Yield: 33.5 g (50%).

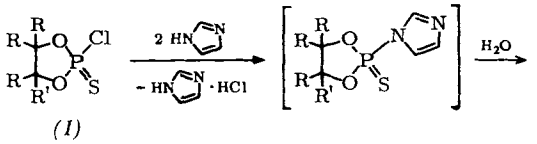
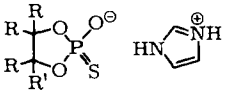
Geometric Isomerism in Cyclic Five- and Six-Membered Monothiophosphoric Acid Derivatives[**]

By *M. Mikolajczyk* and *H. M. Schiebel*[*]



Monothiophosphoric acids (*A*) are chiralic compounds with the phosphorus atom as asymmetric center[1]. Because of their high reactivity they prove most suitable as starting

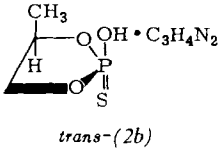


(A)

materials for the synthesis of other optically active phosphorus compounds containing P=O- or P=S-groupings[1,2].

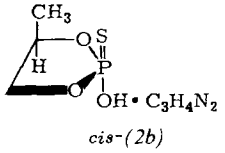
We report here on the geometric isomerism of cyclic monothiophosphoric acid derivatives[3] which occurs when the molecule contains at least one asymmetric center at a ring carbon atom.

(1)



(2)

	R	R'	(2) M.p. (°C) [a]	Yield (%)	$\delta_{31}P$ (ppm) [b]
(a)	H	H	119–123.5	72	−154.3
(b) [c]	H	CH_3	74–99	88	−160 [d]
(c)	CH_3	CH_3	177–180	68	−144.3

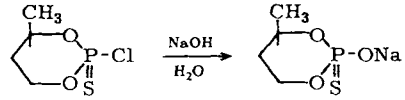


[a] From *n*-propanol/ether. [b] Measured in H_2O.
[c] Mixture of *cis* and *trans* forms. [d] Two signals.

By reaction of the cyclic thiophosphoryl chlorides *(1)*[4] with imidazole in tetrahydrofuran, we were able to prepare the corresponding imidazolides, which, on account of their instability, were converted without isolation into the imidazolium salts *(2)* of thiophosphoric acids by reaction with water.

As is to be expected, the imidazolium propylenethionophosphate *(2b)* prepared in this way is a mixture of the *cis* and *trans* isomers[5].

trans-(2b)



cis-(2b)

The ^{1}H-NMR spectrum at 100 MHz shows two doublets of equal intensity at 1.40 and 1.41 ppm (J_{H-CH_3} = 6.1 Hz) (measured in D_2O with sodium 2-trimethylsilylpropanesulfonate as internal standard), which can be ascribed to the protons of the methyl group.

In the ^{31}P-NMR spectrum (measured in H_2O with 80% phosphoric acid as external standard), two signals appear at −160.0 ppm which are separated by about 22 Hz. We have been able to obtain one isomer in the pure state [m.p. 122 to 125 °C, δ = 1.41 ppm (CH_3)] by repeated recrystallization of the mixture from *n*-propanol/ether. The other isomer can be isolated from the mother liquor in about 90% purity (m.p. 78.5–83 °C). Assignment of the *cis* and *trans* forms has not, as yet, been possible.

The sodium salt of 2-hydroxy-4-methyl-1,3,2-dioxaphosphor^V-inane-2-thione *(3)* (sodium 1-methyltrimethylenethionophosphate) was prepared in 92% yield by alkaline hydrolysis of the chloride, according to the method of *Edmundson*[6]. The isomers were separated by fractional crystallization.

(3)

The *cis* and *trans* isomers of compound *(3)* are likewise distinguishable from each other in their ^{1}H- and ^{31}P-NMR spectra.

δ = 1.27 ppm (CH_3, q)	δ = 1.28 ppm (CH_3, q)

(measured in D_2O with DSS as internal standard)

J_{H-CH_3} = 6.2 Hz	J_{H-CH_3} = 6.2 Hz
$J_{P-O-CH-CH_3}$ = 2 Hz	$J_{P-O-CH-CH_3}$ = 1.7 Hz
δ_{31P} = −112.9 ppm	δ_{31P} = −120 ppm

(measured in H_2O with 80% H_3PO_4 as external standard)

(Two signals, separated by 60 Hz)	(Two signals, separated by 48 Hz)

(For assignment of data to the *cis* and *trans* forms see [7].)

Good results were obtained in the elemental analyses of all the compounds investigated. The ^{31}P-NMR measurements were carried out with a Perkin Elmer R 10 spectrometer in combination with a Northern Scientific NS 544 Digital Memory Oscilloscope.

Stereospecific Synthesis of *cis*-2-Hydroxy-4-methyl-1,3,2-dioxaphosphor^V-inane-2-thione[**]

By *M. Mikolajczyk*[*]

The sodium salt of 2-hydroxy-4-methyl-1,3,2-dioxaphosphor^V-inane-2-thione (sodium 1-methyltrimethylenethionophosphate)[1] can exist in two geometrical forms, which are distinguishable from each other in their ^{1}H- and their ^{31}P-NMR spectra. In oder to assign the NMR data to the isomers

and to avoid fractional crystallization of the mixture of *cis* and *trans* compounds – which leads to very low yields – we synthesized the tetramethylammonium salt of the *cis*-thiophosphoric acid *(3)* [1a].

The more stable form [1a] of 2-methoxy-4-methyl-1,3,2-dioxaphosphorV-inane *(1)* [2, 3b] ($\delta_{31P} = -301.4$ ppm), which was contaminated with up to 10% of the other isomer ($\delta_{31P} = -292.8$ ppm; measured in ether with 80% H_3PO_4 as external standard), served as starting material. Compound *(1)* adds on sulfur in a strongly exothermic reaction and is thus converted into 2-methoxy-4-methyl-1,3,2-dioxaphosphorV-inane-2-thione *(2)* (b.p. 78–80 °C/0.3 torr; $n_D^{20} = 1.4922$; yield 80%). The ratio of the two isomeric thiophosphates is unchanged after the addition. The last step in the synthesis is the reaction of *(2)* with trimethylamine in benzene at room temperature, which leads to formation of the tetramethylammonium salt of the thiophosphoric acid *(3)* (m.p. 205–208 °C, yield 75%; NMR spectra: $\delta = 1.27$ ppm (CH_3), (measured in D_2O with sodium 2-trimethylsilylpropanesulfonate (DSS) as internal standard); $J_{H-CH_3} = 6.2$ Hz; $J_{P-O-CH-CH_3} = 2$ Hz; $\delta_{31p} = -112.8$ ppm (measured in H_2O with 80% H_3PO_4 as external standard).

(1) *cis*-*(2)* *cis*-*(3)*

Since the configuration at the phosphorus atom is unchanged during the demethylation, and addition of sulfur proceeds stereospecifically with retention of configuration [3], the thiophosphate *(3)* obtained is the *cis* isomer.

Further, we have found that the tetramethylammonium salt of the *cis* acid *(3)* can also be prepared by reaction of trimethylamine in benzene with the 1:1 mixture of the isomeric thiophosphates *(2)* [4]. Practically only *cis*-*(3)* precipitates from the reaction solution after *ca.* 8–10 hours at room temperature; it can be purified by a single recrystallization from *n*-propanol/acetone. Unreacted *trans*-*(2)* can be isolated from the filtrate by evaporation and subsequent distillation.

As a result of this investigation we have been able to assign the NMR values of the *cis* and *trans* forms of compounds *(2)*. *cis*-*(2)*: $\delta_{CH_3} = 1.41$ ppm; $\delta_{OCH_3} = 3.82$ ppm (at 100 MHz, measured in $CDCl_3$ with TMS); $\delta_{31P} = -148.6$ ppm (measured in ether). *trans*-*(2)*: $\delta_{CH_3} = 1.39$ ppm; $\delta_{OCH_3} = 3.75$ ppm (at 100 MHz, measured in $CDCl_3$ with TMS); $\delta_{31p} = 141.4$ ppm (measured in ether).

The difference in the reactivity of the two isomeric forms of *(2)* toward trimethylamine is probably due to the presence of the methyl group on C-4, which sterically hinders attack of the amine on the methoxy group of the *trans*-thiophosphate *(2)*.

Pulse Radiolysis at High Pressure: Pressure Dependence of the Absorption Spectrum and the Lifetime of Hydrated Electrons [**]

By *U. Schindewolf*, *H. Kohrmann*, and *G. Lang* [*]

The physical and chemical properties of solvated electrons in liquid ammonia [1] (electrical conductivity [2], absorption [3], reflection [4], and ESR spectrum [5], physical [6] and chemical equilibria [7]) show a marked dependence upon pressure. Solvated electrons produced in metal-ammonia solutions by dissociation of the metal react only slowly with the solvent and have a long lifetime (months).

In order to carry out comparative studies of the influence of pressure on hydrated electrons [8], *i.e.* electrons dissolved in water, these electrons must be produced under pressure and fast-registering methods must be available for their detection owing to their fast reaction with water (lifetime <1 ms).

We have now succeeded in measuring the pressure dependence of the absorption spectrum and the lifetime of hydrated electrons produced by radiolysis of aqueous solutions by high-energy electrons from a pulsed linear electron accelerator (up to 300 pulses of 5-μs duration per second; 15 MeV, 0.5 A). Irradiation was performed in a high-pressure cell [9] (wall thickness 2.5 mm) placed in the crossed beam paths of the accelerator and of a spectrophotometer having a photocathode detector.

The radiation-induced ionization of water gives rise to hydrated electrons,

$$H_2O \rightarrow H_2O^+ + e^- \qquad (1)$$

which react with added substrates, with other radiolysis products (H^+, OH, H, *etc.*), and with water itself. The "bimolecular" reaction with water yields hydrogen ($k \approx 10^{10}$ l/mole sec) [8]

$$2\,e^- + 2\,H_2O \rightarrow H_2 + 2\,OH^- \qquad (2)$$

and limits the lifetime of the electrons, even in the absence of any other reactive substances. To study this reaction alone, the other radiolysis products are intercepted with hydrogen and hydroxide ions [8] (stock solution: 0.01 M NaOH, saturated with hydrogen under normal pressure):

$$H_2O^+ \rightarrow H^+ + OH \qquad (3)$$

$$H^+ + OH^- \rightarrow H_2O \qquad (4)$$

$$OH + H_2 \rightarrow H_2O + H \qquad (5)$$

$$H + OH^- \rightarrow H_2O + e^- \qquad (6)$$

The yield of hydrated electrons is actually doubled by reaction (6). Since the electrons in solution only react with water according to reaction (2) – provided that no impurities are present – and the reactions (1) to (6) balance one another, the solution undergoes no permanent change on irradiation.

Following a pulse of electrons, the transmittance of the solution in the range of about 0.4 to 1.0 μm is reduced, owing to the direct and delayed formation of hydrated electrons, for a period of up to 50 μs, after which it returns to the value for the non-irradiated solution within 1 ms as a result of reaction (2) (in all previous experiments performed in steel autoclaves, a first order reaction involving an undefined impurity was superposed upon reaction (2), which is second order with respect to the electrons).

The variation with wavelength of the optical density of the solution (proportional to $\varepsilon \times c_{e^-}$) yields the absorption spectrum of the hydrated electrons. The time dependence of the concentration of electrons, and thus their rate of reaction, can be deduced from the time-dependence of the optical density.

a) *Pressure dependence of the absorption spectrum*

In Fig. 1, the relative optical density of the solutions, extrapolated back to the time of pulse termination, at 1 and at 1000 atm pressure is plotted against the wavelength. The

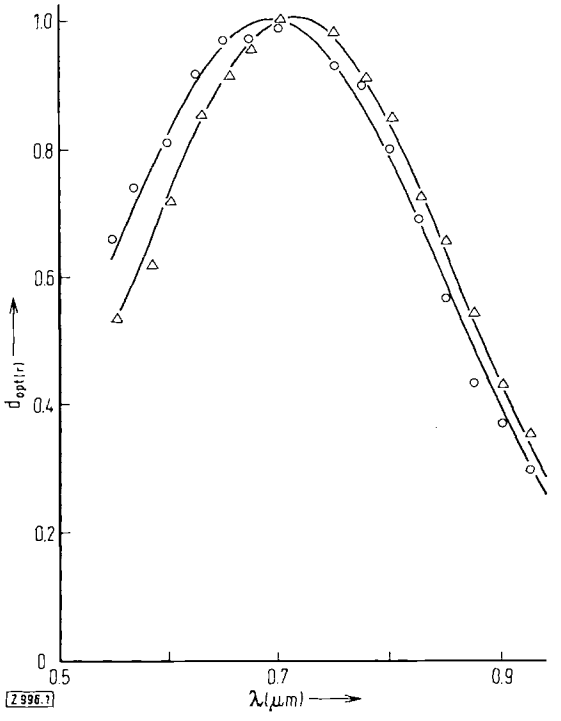

Fig. 1. Absorption spectrum of hydrated electrons at 24 °C and 1 atm (Δ) and 1000 atm (○). The points shown are mean values of five individual measurements.

1000-atm curve is normalized to the 1-atm curve. Both curves were calculated from the measured points by the method of least squares, assuming a Gaussian form.

In agreement with the data given in the literature[8] the absorption maximum of the 1-atm spectrum lies at 0.72 μm; that of the 1000-atm curve is shifted by 200 ± 50 Å towards the blue end of the spectrum. According to *Jortner*'s cavity model[10], this blue shift, which we have also found for solvated electrons in ammonia[3,4] and which must be considered in conjunction with the red shift with increasing temperature[1,3,4,8], can be interpreted as a compression of the space occupied by the dissolved electrons.

Fig. 1 shows that the product of ε_{max} and c_{e^-} is independent of pressure within the limits of experimental accuracy. Since the investigations by *Hentz et al.*[11], who studied the yield of stable radiolysis products on γ-irradiation of aqueous solutions under pressure, show the radiolysis yield of hydrated electrons to be independent of pressure, it follows that their maximum extinction coefficient must also be independent of pressure.

b) *Pressure dependence of the rate of reaction*

Fig. 2 shows the variation with time of the relative optical density (proportional to c_{e^-}) at 1 and 1000 atm, in each case for the wavelength of maximum absorption. Within the limits of experimental accuracy, the measured points for both pressures lie on one curve, thus demonstrating that the rate of reaction, or the mean lifetime of the hydrated electrons, with regard to reaction (2) – and with regard to the reaction with the unidentified impurity – is independent of pressure, *i.e.* that the activation volume of these reactions is vanishingly small. These direct measurements of the rate of reaction under pressure confirm the results obtained by *Hentz*[11] by indirect methods.

In a number of preliminary measurements[12] on the extremely slow reaction between solvated electrons and water in liquid ammonia (20% H_2O, 80% NH_3; lifetime of electrons in the order of 10 s to 1 min; activation energy <3 kcal/mole) we have found that an increase in pressure of 1000 atm causes a three- to fourfold acceleration of the reaction, corresponding to an activation volume of about −25 ml/mole. The difference in the pressure dependence of the reaction rate in water and

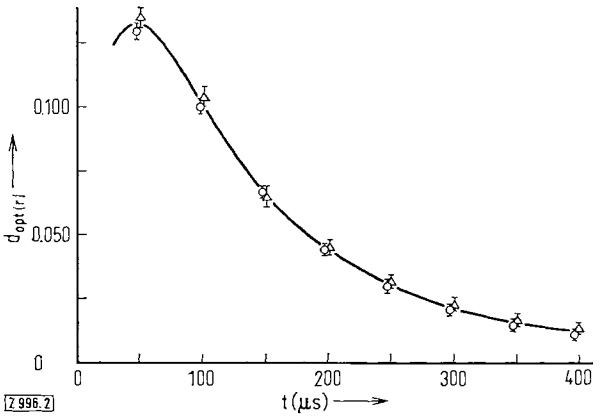

Fig. 2. Variation of the optical density of an aqueous solution with time after irradiation with a pulse of electrons at 24 °C and 1 atm (Δ) and 1000 atm (○). The points shown are mean values of five individual measurements.

in ammonia reflect the different space requirements of solvated electrons in these two solvents (<20 ml/mole in water, 60 to 90 ml/mole in ammonia).

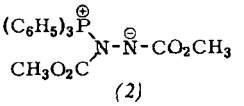
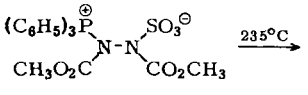
Structure and Reactivity of the Betaine Derived from Triphenylphosphine and Dimethyl Azodicarboxylate[**]



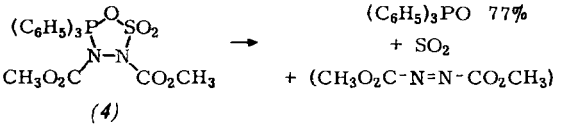
By *E. Brunn* and *R. Huisgen*[*]

The reaction of triphenylphosphine with dimethyl azodicarboxylate has repeatedly been interpreted[1–3] as a nucleophilic attack on the carbonyl oxygen of the ester as shown in

(1). We consider that the chemical properties of the labile adduct, which is usually subjected to further reaction *in situ*, are more nearly consistent with the original formulation *(2)*[4]; moreover, such a formulation corresponds to the known high electrophilic activity of the nitrogen of dimethyl azodicarboxylate[5]. The quasi-1,3-dipole *(2)* can be intercepted by cycloaddition processes. The fact that only strongly electrophilic dipolarophiles prove suitable for this reaction suggests a multi-step mechanism initiated by attack on the anionic nitrogen atom of *(2)*.

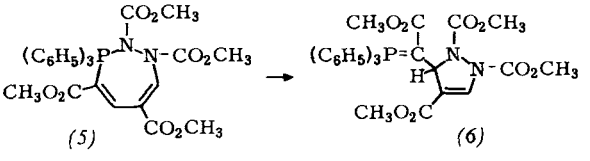


(1)

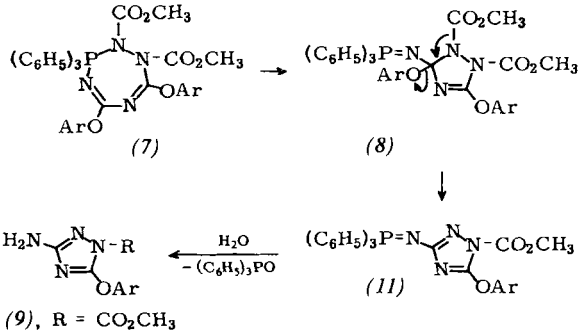


(2)

Distillation of sulfur trioxide into a solution of *(2)* in 1,2-dichloroethane affords the adduct *(3)*, m.p. 195.5–197 °C (decomp.), in 82% yield; IR (KBr): ester carbonyl = 1740 and 1721 cm^{-1}; ^{31}P-NMR ($CDCl_3$): −53 ppm. Thermolysis is in accord with the following scheme involving *(4)* as intermediate. Cleavage of *(3)* by boiling water gives triphenylphosphine oxide and sulfate ion.

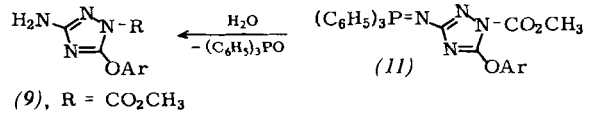


(3)



(4)

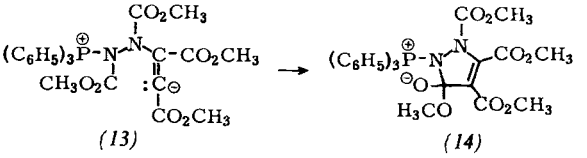
The quasi-1,3-dipole *(2)* reacts with 2 equivalents of methyl propiolate to give the heterocyclic methylenephosphorane *(6)* in 58% yield, which is presumably formed *via* ring contraction from a cycloadduct *(5)* having a seven-membered ring. The ^{31}P resonance signal at −21.5 ppm ($CHCl_3$) and the broadening of the OCH_3 signal (τ = 6.74) of the ester group attached to the ylide carbon atom (slow interconversion of *cis-trans* isomeric forms[6]) provide support for *(6)*; m.p. 201–202 °C (decomp.); the ^{1}H-NMR signal of the



(5) *(6)*

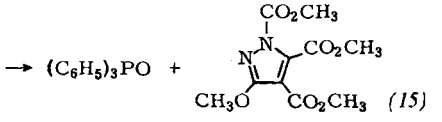
proton in the β position to the phosphorus at τ = 4.91 shows J_{PH} = 12.0 Hz and an allylic coupling of J_{HH} <1 Hz. Acetolysis of *(6)* at 100 °C proceeded *via* elimination of CO_2 to give methoxycarbonylmethylenetriphenylphosphorane (81%) and dimethyl 1,4-pyrazoledicarboxylate (m.p. 122.5–124 °C,

(7) *(8)*



(9), R = CO_2CH_3
(10), R = H

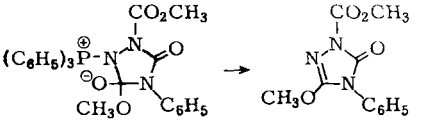
+ ArO-CO_2CH_3 *(12)*



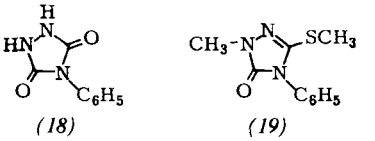
Ar = 2,4-Dimethyl-phenyl

68%), which was identified by alkaline degradation to 4-pyrazolecarboxylic acid.

Reaction of *(2)* with 2,4-dimethylphenyl cyanate[7] also resulted in consumption of two equivalents of the latter. We suppose that an analogous initial addition to *(7)* occurs. The ring-contraction product *(8)* is not isolable but eliminates the methyl aryl carbonate *(12)* (66%, b.p. 120–130 °C (bath temp.)/10 torr) to give the triazolyliminophosphorane *(11)*; 72%, m.p. 164–165 °C; IR (KBr): CO_2CH_3 = 1754 cm^{-1}; ^{31}P-NMR ($CDCl_3$): −18.5 ppm. Treatment with hot 90% acetic acid converts *(11)* into triphenylphosphine oxide and *(9)* [76%, m.p. 177–178.5 °C (decomp.)]. Compound *(10)* (m.p. 140.5–142 °C), produced on alkaline hydrolysis of *(9)*, was synthesized by an independent route.



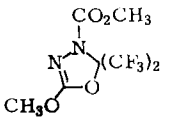
(13) *(14)*



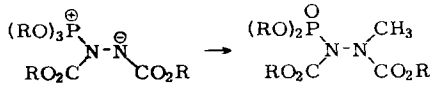
(15)

Surprisingly, *(2)* reacted with only one equivalent of dimethyl acetylenedicarboxylate. We isolated a 71% yield of trimethyl 3-methoxy-1,4,5-pyrazoletricarboxylate *(15)* (m.p. 141 to 142 °C), which may possibly be formed *via* elimination of phosphine oxide from *(13)*. The magnetic non-equivalence of the *O*-methyl groups (in $CDCl_3$, τ = 5.89, 5.91, 5.96, 6.13) supports the chemical evidence obtained by *Cookson* and *Locke*[2] for the analogous pyrazole derivative obtained from *(2)*, C_2H_5 instead of CH_3, and dimethyl acetylenedicarboxylate.

(16) *(17)*



(18) *(19)*



Like dimethyl acetylenedicarboxylate, isocyanates and isothiocyanates react with one equivalent of *(2)* at room temperature. From the reaction with phenyl isocyanate we obtained 1,2,4-triazolone *(17)* (80%) along with triphenylphosphine oxide. The structure of *(17)* (m.p. 168–170 °C; ^{1}H-NMR ($CDCl_3$): OCH_3 s τ = 5.90, 5.97) was established by conversion into 4-phenylurazole *(18)*. Methyl isocyanate and *p*-phenylene diisocyanate gave products analogous to *(17)* in yields of 73 and 68%, respectively.

Phenyl isothiocyanate combined with *(2)* to give 1,2,4-triazolinethione [*(17)*, =S in place of =O] in 71% yield; m.p. 152–153 °C, ^{1}H-NMR ($CDCl_3$): OCH_3 s τ = 5.93, 5.88. Alkaline hydrolysis afforded 5-methoxy-4-phenyl-1,2,4-triazoline-3-thione, whose composition was proved by synthesis of a degradation product. Thermolysis at 200 °C yielded *(19)* *via* elimination of CO_2 and a shift of two methyl groups. In a similar manner, reaction of methyl isothiocyanate and allyl isothiocyanate with *(2)* proceeded by way of phosphine-oxide elimination to give adducts.

Hexafluoroacetone reacted with *(2)* at −40 °C to give triphenylphosphine oxide (86%) and an adduct of probable structure *(20)* (75%).

(20)

(21) (22)

An oily adduct obtained from triethyl phosphite and diethyl azodicarboxylate was regarded by *Morrison*[4] as *(22)*, whereas *Ginsburg et al.*[1] suggested an alternative structure. Interception of the precursor *(21)* by a cycloaddition process provides evidence in favor of *(22)*. On slow addition of dimethyl azodicarboxylate to trimethyl phosphite and phenyl isocyanate in benzene, we were able to isolate *(17)* in 84% yield; the reaction probably proceeds *via* an intermediate analogous to *(16)* having OCH_3 instead of C_6H_5 attached to the phosphorus.

The Crystal Structure of Pentacarbonyl-(2,3-diphenylcyclopropenylidene)chromium(0) [**]

By *G. Huttner, S. Schelle*, and *O. S. Mills*[*]

We have determined the crystal structure of pentacarbonyl-(2,3-diphenylcyclopropenylidene)chromium(0), recently prepared by *Öfele*[1], in an attempt to understand the unusual bonding in this remarkably stable complex.

The compound crystallizes in the triclinic system, space-group $P\bar{1}$ (C_i^1, No. 2) with $a = 13.31$, $b = 9.25$, $c = 9.93$ Å, $\alpha = 91.3$, $\beta = 104.2$, and $\gamma = 129.2°$, $d_m = 1.427$, $d_c = 1.423$ gcm^{-3}, $Z = 2$. The intensities of 1976 reflexions were measured, with molybdenum radiation ($\lambda = 0.71069$ Å), on a Stoé automatic Weissenberg diffractometer. The structure was solved by conventional Patterson and Fourier methods. At present, the agreement index, after partial refinement of anisotropic temperature factors, is R = 0.086.

Pentacarbonyl(2,3-diphenylcyclopropenylidene)chromium(0) is the first mononuclear carbene complex in which the carbene ligand is not stabilized by heteroatom substitution. The chromium atom is coordinated octahedrally (Fig. 1). Five of the positions are occupied by CO groups ($Cr-C_{CO}$ 1.88–1.92 Å, C–O 1.10–1.15 Å) and the sixth by the 2,3-diphenylcyclopropenylidene fragment. The Cr–C distance, 2.05 ± 0.01 Å, is appreciably shorter than that expected for a single bond between Cr^0 and a sp^2-hybridized carbon (2.21 Å)[2] and indicates appreciable double-bonding.

Z 5.1

Fig. 1. Crystal structure of pentacarbonyl(2,3-diphenylcyclopropenylidene)chromium(0).

The distances C^2-C^{21} and C^3-C^{31} (Fig. 1) are somewhat shorter than the single-bond separation between two sp^2-hybridized carbon atoms (1.48 Å)[3]. One of the phenyl rings lies in the plane of the three-membered ring whilst the other is twisted out of this plane by 7.5°, presumably by repulsions of the phenyl *ortho*-hydrogens.

The mean C–C distance in the three-membered ring is not significantly different from that found for the aromatic triphenylcyclopropenylium cation (1.37 Å)[4]. However, whereas all the distances in the aromatic three-membered ring are equal within experimental error, in the complex the C^1-C^2 and C^1-C^3 separations are somewhat different from C^2-C^3. This difference is probably significant and points to a small distortion of the ring towards a cyclopropene system. This observation is also in accord with the suggestion of double-bond character in the $Cr-C^1$ bond.

Diphenylborane Derivatives Containing Boron-Tin Bonds

By *H. Nöth, H. Schäfer*, and *G. Schmid*[*]

Whereas bis(dimethylamino)trialkylstannylboranes are accessible from R_3SnLi (R = alkyl) and $ClB[N(CH_3)_2]_2$[1], the synthesis of dialkyl- and diphenyl-trialkylstannylboranes

could not be accomplished by this method. No boron-tin compounds could be detected on reaction of $(C_6H_5)_3SnLi$ with BCl_3, $RBCl_2$, and R_2BCl; instead, hexaphenyldistannane was identified as the main reaction product.

Bis(diphenylboro)bis(tetraphenyldiphosphinoethane)-cobalt(II) [2, 3] has proved a suitable reagent for the introduction of diphenylboryl groups into inorganic and organic compounds. It reacts with methyltin chlorides or bromides according to equation (1) to give the methylstannyldiphenylboranes *(1)–(3)* (see Table) in 60–80% yield and thus permits the formation of several Sn–B bonds in one molecule. Reaction with $SnBr_4$ affords tetrakis(diphenylboryl)stannane *(4)*.

$$\frac{n}{2}\ Ph_2B\text{–}[Co]\text{–}BPh_2 + (CH_3)_{4-n}SnX_n \rightarrow \frac{n}{2}\ [Co]X_2 + (CH_3)_{4-n}Sn(BPh_2)_n \quad (1)$$

X = Cl, Br; Ph = C_6H_5;
[Co] = $[(C_6H_5)_2P\text{–}CH_2\text{–}CH_2\text{–}P(C_6H_5)_2]_2Co$

The colorless crystalline compounds are of low thermal stability and are extremely sensitive to oxygen. They react rapidly even with traces of oxygen to give tetraphenyldiboron oxide and the corresponding stannoxanes *via* intermediates containing Sn–O–B bonds. Degradation with bromine yields diphenylboron bromide and $(CH_3)_{4-n}SnBr_n$.

The magnetic equivalence of all the B atoms in the molecules *(1)–(4)* can be deduced from the single broad ^{11}B resonance signal, whose almost constant position shows that the boron atoms are exposed to a similar shielding in all four compounds, which is determined mainly by the phenyl groups. The area ratio of the proton resonance signals are in good agreement with the calculated intensities. The signals of the CH_3 groups in *(1)–(3)* are shifted upfield compared to the corresponding signals of the methyltin chlorides.

Table: Characteristic data for diphenylborylstannanes.

	M.p. (°C)	$\delta^{11}B$ (ppm) [a]	δCH_3Sn (ppm) [b]	δC_6H_5 (ppm) [b]	Yield (%)
$(CH_3)_3SnB(C_6H_5)_2$ *(1)*	110–115 (decomp.)	−66	−0.22	−7.28	61
$(CH_3)_2Sn[B(C_6H_5)_2]_2$ *(2)*	118–121 (decomp.)	−67	−0.57	−7.26	79
$CH_3Sn[B(C_6H_5)_2]_3$ *(3)*	112–118	−68	−1.15	−7.38	69
$Sn[B(C_6H_5)_2]_4$ *(4)*	119–124	−66	–	−7.19	76

[a] In benzene, $BF_3{\cdot}OR_2$ as external standard.
[b] In cyclohexane, $Si(CH_3)_4$ as external standard.

Tetrakis(diphenylboryl)stannane (4):

$[(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2]_2Co[B(C_6H_5)_2]_2$ (6.41 g) is treated with $SnBr_4$ (1.18 g) in 100 ml of anhydrous benzene under highly pure nitrogen or argon for four hours with stirring; $[(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2]_2CoBr_2$ (5.3 g) is then filtered off and the solvent removed under vacuum. Compound *(4)* is extracted from the residue by stirring for eight hours with cyclohexane (50 ml). The product is recrystallized from the same solvent.

Existence of the Oxalyl Dication $[C_2O_2]^{2+}$ [1]

By *M. Adelhelm* [*]

Reaction of acyl halides RCOX with Lewis acids MX_n can lead to two different products [2–4]:

X-ray analysis has established the structures of the representatives *(1a)* and *(2a)* [5] of both types of compounds, *i.e.* of the oxocarbonium (or acylium) salt *(1)* and the adduct *(2)*. Compounds *(1)* and *(2)* can also be distinguished by means of their CO bands in the vibrational spectra, which show a characteristic shift compared to the free acyl halide [3,4,6]. Thus the CO stretching vibration of *(1a)* is observed at 2294 cm^{-1} [7] and that of *(2a)* at 1548 cm^{-1} [4], corresponding to an increase and a decrease of the CO bond order, respectively.

We have attempted to prepare the oxalyl dication, an interesting species owing to its bonding, and to examine it by vibrational spectroscopy. It is the simplest representative of the "acyl dications", which were first described by *Olah* and *Comisarow* [8].

It proved expedient to carry out the reaction between oxalyl chloride and antimony pentafluoride directly in an IR low-temperature cell of the usual type [9]. Thin films of $C_2O_2Cl_2$ and an excess of SbF_5 were condensed onto the inner cell plate (AgCl) [10], which was cooled with liquid air. The dotted curve in Figure 1 reproduces the infrared spectrum measured at this stage [11]: it arises by superposition of the individual spectra of the unchanged starting materials. Gradual increase of the temperature to −35 °C initiates the reaction, as is evidenced by the appearance of small gas bubbles on the plate. After cooling to about −50 °C (to avoid decomposition), the spectrum represented by the continuous line in Figure 1 was recorded. By turning the AgCl plate out of the beam path the gaseous product could be identified spectroscopically as COFCl with traces of CO (and COF_2?) (see dashed curve in Figure 1). After the gases had been pumped off, the spectrum of the solid, colorless reaction product was recorded at −78 °C (Figure 2).

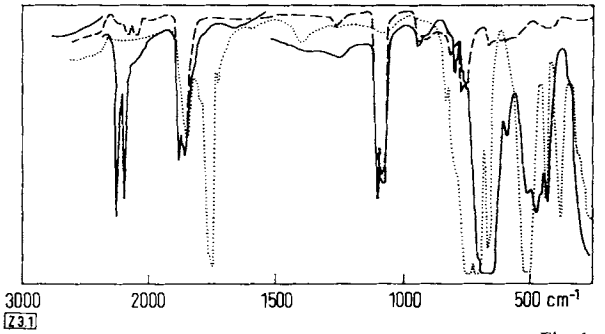

Fig. 1.

The absorptions in the CO-triple bond region at 2235 and 2182 cm^{-1} indicate an oxocarbonium structure *(1)*. On warming, both bands decreased irreversibly in intensity – that at 2235 cm^{-1} particularly rapidly – owing to formation of COFCl. The varying intensity ratio of these two bands indicated two species of different stability in the solid. Since

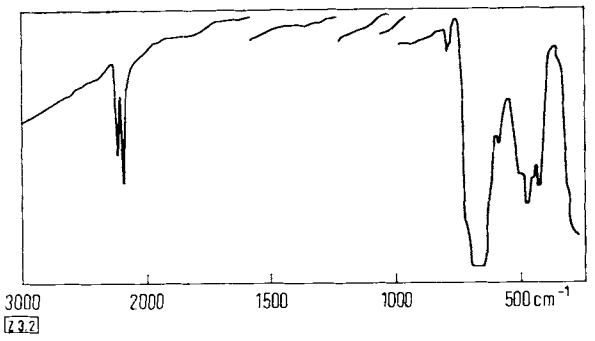

Fig. 2.

only one CO band can be attributed to each one of these species, they must be highly symmetrical ions that form COFCl with the counter-ions at elevated temperatures. The spectra can be interpreted in terms of the following reaction scheme:

$$C_2O_2Cl_2 + 2\,SbF_5 \rightarrow [C_2O_2]^{2+}\,2\,[SbF_5Cl]^-$$
$$\nu_{as}CO = 2235\ cm^{-1}$$

$$[C_2O_2]^{2+} \longrightarrow 2\,[CO]^+$$
$$\nu_{as}CO = 2235\ cm^{-1} \qquad \nu CO = 2182\ cm^{-1}$$

$$[C_2O_2]^{2+}\ 2[SbF_5Cl]^- \searrow$$
$$2\,COFCl + [SbF_3 \cdot SbF_5]$$
$$2\,[CO]^+[SbF_5Cl]^- \nearrow$$

The initially formed oxalyl dication $[C_2O_2]^{2+}$ is stable at low temperature ($< -50\,°C$). It decomposes with cleavage of the CC bond into radical ions $[CO]^+$, and COFCl is formed *via* a redox reaction with the anionic component.

The surprising dissociation of *(3)* into radical ions

$$:\overset{+}{O}\equiv C-C\equiv\overset{+}{O}: \leftrightarrow \ddot{O}=\overset{+}{C}-\overset{+}{C}=\ddot{O}$$

(3)

is probably a result of the double positive charge and is paralleled in the pseudohalogen character of the isoelectronic cyanogen. The wave number of the free $[CO]^+$ is known from the band spectrum to be 2183.9 cm^{-1} [12].

The existence of the anion formulated as $[SbF_5Cl]^-$ and its reaction products have not yet been proved because no suitable spectra are available for comparison; the situation is also complicated by the presence of an excess of SbF_6.

The antisymmetric stretching vibration of the linear $[C_2O_2]^{2+}$ is consistent with those of comparable molecules. $\nu_{as}C\equiv X$ (cm^{-1}): $HC\equiv C-C\equiv CH$, 2020; $N\equiv C-C\equiv N$, 2149; $[O\equiv C-C\equiv O]^{2+}$, 2235.

The Tribromine Cation in $[Br_3]^+[AsF_6]^-$

By *O. Glemser* and *A. Šmalc* [*]

The dibromine cation $[Br_2]^+$ has recently been produced by reaction of bromine pentafluoride, bromine, and antimony pentafluoride, and isolated in the form of $[Br_2]^+[Sb_3F_{16}]^-$ [1]. In contrast, the tribromine cation $[Br_3]^+$ has hitherto only been detected in solution [2]. By reaction of dioxygenyl hexafluoroarsenate(v) with bromine

$$[O_2]^+[AsF_6]^- + 3/2\ Br_2 \rightarrow [Br_3]^+[AsF_6]^- + O_2$$

and by reaction of bromine trifluoride or pentafluoride, bromine, and arsenic pentafluoride we have now succeeded for the first time in obtaining $[Br_3]^+$ as $[Br_3]^+[AsF_6]^-$. The composition of the compound, which is chocolate brown at room temperature and carmine red at the temperature of liquid nitrogen, was determined as the mean value of ten analyses. The substance sublimes at +30 to +50 °C; under nitrogen (1 atm) it decomposes above 70 °C with evolution of bromine.

The mass spectrum exhibits the following fragments: (*m/e*): 162, 160, 158 Br_2^+ (49.4, 100.0, 52.7%); 151 AsF_4^+ (59.3%); 132 AsF_3^+ (10.4%); 113 AsF_2^+ (13.2%); 100, 98 BrF^+ (11.5, 12.1%); 94 AsF^+ (6.6%); 81, 79 Br^+ (38.5, 39.6%); 75 As^+ (5%); 40.5, 39.5 Br^{2+} (3.3, 3.3%) [3].

IR spectrum (film of substance condensed directly onto the AgCl plates of a low temperature cell): In the 4000–400 cm^{-1} region, the strong band characteristic of $[AsF_6]^-$ was observed at 709 cm^{-1} (ν_3).

^{19}F-NMR spectrum (solution in BrF_5, CCl_3F as external standard): A broad signal at 62.5 ppm that is assigned to the $[AsF_6]^-$ ion (unresolved quadruplet; strong line broadening due to the quadrupole moment of As).

UV spectrum (solution in HSO_3F): Two bands are observed at 310 and 375 nm, which are ascribed to the $[Br_3]^+$ cation in solution [2].

Magnetic measurements: The expected diamagnetism was confirmed on a magnetic balance; solid Br_3AsF_6 did not give an ESR spectrum.

Procedure:

BrF_5 (19 g) and Br_2 (4.7 g) are condensed into a quartz vessel together with AsF_5 (5 g, 29% excess) at −196 °C. After permitting the reaction mixture to reach a temperature of −50 °C, the excess of BrF_5 and AsF_5 is pumped off, first for 1/2 h at −50 °C and then for 1–2 h at 0 °C. The reaction proceeds almost quantitatively to give 9.0 g of $[Br_3]^+[AsF_6]^-$.

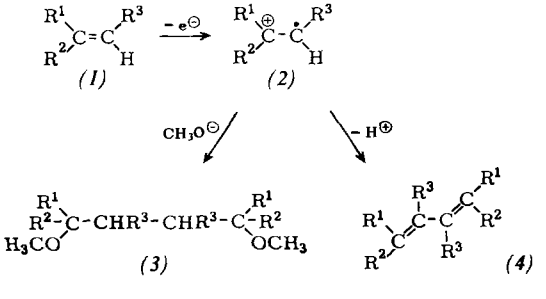
Oxidative Dimerization of Olefins[1]

By *H. Schäfer* and *E. Steckhan*[*]



Organic anions, for example alkali metal salts of aliphatic nitro or 1,3-dicarbonyl compounds, undergo oxidative addition to non-activated double bonds at a platinum anode[2,3]. We have now found that such additions are almost completely suppressed at graphite electrodes; instead, the dimers of the olefins present are formed. Electrolysis of olefin/methanol mixtures (2:3 v/v) between graphite electrodes with sodium iodide or sodium perchlorate/sodium methoxide as conducting salt at anode potentials between +0.5 and +1.4 V (measured against Ag/AgCl) and temperatures between −20 and +20 °C we obtained the products listed in the Table[4].

Olefin	Product [a]	Yield (%) [b]
Styrene	1,4-Diphenyl-1,4-dimethoxybutane	60
Vinyl ethyl ether	1,4-Diethoxy-1,4-dimethoxybutane	51
α-Methylstyrene	1,4-Diphenyl-1,4-dimethylbutadiene	45
Butadiene	*trans,trans*-1,8-Dimethoxy-2,6-octadiene	13
	trans-1,6-Dimethoxy-2,7-octadiene	13
	3,6-Dimethoxy-1,7-octadiene	13
	trans,trans-1,10-Dimethoxy-2,6,11-dodecatriene	6.6
	all-trans-1,12-Dimethoxy-2,6,10-dodecatriene	5.5
1-Ethoxy-1-cyclohexene	2,2'-Bicyclohexanone [c]	27
Indene	1,1'-Dimethoxy-2,2'-bisindanyl [d]	38

[a] The products were characterized by IR, ^{1}H-NMR, and mass spectrometry, and C, H analyses, or by comparison with authentic material.— [b] Based on current consumption. — [c] After acid hydrolysis of the crude product. — [d] In addition to 19% of 1,2-dimethoxyindan.

By simultaneous linkage of two carbon atoms and introduction of substituents or double bonds this oxidative dimerization of olefins affords derivatives of 1,4-dimethoxybutane and butadiene in one step. Furthermore, aldehydes or ketones can be coupled *via* the enol ethers to give 1,4-dicarbonyl compounds[5].

We assume the oxidation of the olefin *(1)* to a radical cation *(2)* to be the initial step, the lone electron and the positive charge in unsymmetrical olefins being localized in such a manner that the cation experiences the greater stabilization by substituents. The butane derivatives *(3)* and *(4)* are formed from *(2)* by dimerization of two radicals and S_N1 and E_1 reaction of the carbonium ions, respectively. With butadiene the isomeric octadiene derivatives are formed by methanolysis of the allyl cations in positions 1 and 3; 1,4-addition of *(2)* to butadiene leads to the dodecatrienes.

1,4-Diethoxy-1,4-dimethoxybutane:

A solution of NaI (1.4 g) in methanol (120 ml) and vinyl ethyl ether (80 ml) is electrolyzed between graphite electrodes[6] at −5 °C, a current density of 40 mA/cm², and an anode potential of +0.6 to +0.9 V (measured against Ag/AgCl) in a cell without diaphragm until 0.232 Faraday has been consumed. After removal of the solvent by distillation, water (20 ml) is added to the residue which is then extracted with ether, the extract being worked up in the usual way. Distillation affords 1,4-diethoxy-1,4-dimethoxybutane (yield 12.3 g, b.p. 93–95 °C/14 torr). ^{1}H-NMR spectrum: δ (ppm measured against TMS): 4.3 (broadened triplet, 1 H), 3.5 and 3.45 (two q, 2 H); 3.2 (s, 3 H); 1.55 (m, 2 H); 1.18 (t, 3 H). The bisphenylhydrazone shows no lowering of melting point when mixed with the corresponding derivative of succinic dialdehyde.

A New Method for the Formation of S–S Bonds

By *E. Lindner* and *G. Vitzthum*[*]

Reaction of mononuclear carbonyl complexes of metals of Groups VI and VIII with organosulfenyl chlorides in polar solvents yields organic disulfides:

$$M(CO)_n + 2\,RSCl \xrightarrow[THF]{<0°C} MCl_2 + RSSR + n\,CO \qquad (1)$$

[M = Cr, Fe, Ni (n = 6, 5, 4); R = alkyl, aryl, perhaloalkyl]

This new method has an advantage over all previously known techniques[1] in that it is generally applicable and proceeds under particularly mild conditions – below 0 °C – to give high yields (> 90%) of disulfide.

In the case of perchloro- or perbromoalkanesulfenyl chlorides, formation of the S–S linkage is followed by an additional partial dehalogenation of the alkyl groups:

$$2\,\underset{(1)}{CCl_3CCl_2SCl} + \underset{(2)}{Fe(CO)_5} \xrightarrow[THF]{-80°C} \underset{(3)}{Fe(CO)_4Cl_2} + CO + \underset{(4)}{(CCl_3CCl_2)_2S_2} \qquad (2)$$

$$4\,(2) + 3\,(4) \rightarrow 4\,FeCl_3 + 20\,CO + 3\,\underset{(5)}{(CCl_2{=}CCl)_2S_2} \qquad (3)$$

$$4\,(3) + (4) \rightarrow 4\,FeCl_3 + 16\,CO + (5) \qquad (4)$$

If pentacarbonyliron *(2)* is used for reduction of perchloroethanesulfenyl chloride *(1)*, tetracarbonyldichloroiron(II) *(3)* is formed as intermediate and is responsible, together

with the excess of *(2)*, for the dehalogenation of the alkyl groups. Proof that *(3)* is actually formed as intermediate is provided by the reaction of trifluoromethanesulfenyl chloride *(6)* with *(2)* in the absence of a solvent in a sealed tube:

$$(2) + 2\ (6) \xrightarrow{-20\,^{\circ}C} (3) + CF_3SSCF_3 + CO \qquad (5)$$

Owing to the considerably stronger C–F bond, the reaction does not proceed further than the saturated disulfide *(7)* so that compound *(3)* can be detected by elemental analysis and by its IR spectrum.

Bis(trichlorovinyl)disulfide *(5)*, a compound that acts as an insecticide, nematocide, and fungicide, has hitherto been prepared from $(CCl_3CHCl)_2S_2$ and triethylamine[2]; the yield is low if the unsaturated disulfide *(5)* is required in high purity. With our method, the yield of *(5)* is 40% after chromatographic purification [ν(C=C) = 1532 and 1507 cm^{-1}; ν(C–Cl) + ν(C–S) = 975, 882, 865, and 750 cm^{-1} (film)]. It is absolutely essential that polar solvents be employed; in nonpolar solvents, *e.g. n*-heptane, secondary reactions occur. Thus compound *(5)*, formed according to equations *(2)–(4)*, reacts with *(2)* or $Ni(CO)_4$ to give the high-polymeric iron and nickel complexes $[Fe(CO)_2(SCCl{=}CCl_2)_2]_n$[3] and $[Ni(SCCl{=}CCl_2)_2]_n$[4], which were characterized by their elemental analyses and their IR spectra.

Experimental:

Bis(trichlorovinyl) disulfide (5):

A solution of C_2Cl_5SCl (7.3 g, 27 mmoles) in THF (200 ml) is treated with $Fe(CO)_5$ (5.6 g, 28 mmoles) at −80 °C. After eight hours, the THF is removed under vacuum and the residue is taken up in *n*-heptane and filtered (G3). The filtrate *(5)* can be purified by column chromatography on basic Al_2O_3, Activity I (Woelm) with *n*-heptane as eluant.

Bis(trifluoromethyl) disulfide (7):

CF_3SCl (6 ml) is condensed into a solution of $Fe(CO)_5$ (7.3 g, 37.3 mmoles) in THF (75 ml) at −80 °C. After elimination of gas has ceased, the colorless precipitate ($FeCl_2 \cdot 1.5$ THF) is filtered off. Compound *(7)* (b.p. 33–34 °C) can be distilled from the filtrate.

Hydrido and Alkyl(aryl)hydrido Complexes of Nickel

By *K. Jonas* and *G. Wilke*[*]

Jolly and *Jonas*[1] recently reported on bis[bis(tricyclohexylphosphine)nickel]dinitrogen $(L_2Ni)_2N_2$ (L = $(C_6H_{11})_3P$) *(1)*, the first Ni^0 complex containing molecular nitrogen as ligand. The nitrogen molecule in *(1)* is bonded only weakly to the nucleus; when a stream of argon is passed through a solution of the complex in toluene the nitrogen is released with formation of L_2Ni *(2)*, the deep red color of the original solution changing to a yellowish red.

Reaction of bis(tricyclohexylphosphine)nickel *(2)* with acidic compounds HR such as HCl (a), acetic acid (deuterioacetic acid) (b), phenol (c), pyrrole (d), or cyclopentadiene at room temperature leads to yellow, crystalline hydridonickel complexes having the composition $L_2Ni(H)R$ *(3)*; in the case of cyclopentadiene one of the ligands is replaced to give $LNi(H)C_5H_5$ *(4)*. Compound *(3a)* has also recently been prepared from L_2NiCl_2 and $NaBH_4$[2]. Further reaction of *(3b, c)* with trimethylaluminum or phenyllithium at room temperature yields pale yellow hydridomethyl- or hydridophenyl-bis(tricyclohexylphosphine)nickel, *(5a)* or *(5b)*, respectively, *e.g.*

Compounds *(5a)* and *(5b)* are stable at room temperature.

As is shown by the reaction of *(3b)* with triethylaluminum, no corresponding hydrido ethyl compound is stable at room temperature. β-Elimination of hydrogen leads to loss of ethylene, and the known compound ethylenebis(tricyclohexylphosphine)nickel[3] is formed *via* evolution of H_2 (HD) (exactly 1 mole per g-atom of Ni). Unlike *(3)* and *(4)*, compounds *(5)* are sensitive to light; they turn red and lose CH_4 (CH_3D) and C_6H_6, respectively. Treatment of *(3d)* with deuterioacetic acid affords the acetato hydrido complex *(3b)*; under the same conditions *(5a)* also gives *(3b)* along with the calculated amount of CH_3D.

The IR spectra of the compounds *(3)*, *(4)*, and *(5)* exhibit intense absorption bands (νNi–H) in the region between 1800 and 1940 cm^{-1}; in the corresponding deuterated derivatives *(3b)* and *(5a)* these bands are shifted to longer wavelengths (νNi–D).

$L_2Ni(H,D)R$	R =	νNi–H(D) (cm^{-1}); (KBr)
(3a)	Cl	1910
(3b)	$OOCCH_3$	1920 (νNi–H)
		1360 (νNi–D) masked
(3c)	OC_6H_5	1940
(3d)	NC_4H_4	1910
(5a)	CH_3	1800 (νNi–H)
		1300 (νNi–D)
(5b)	C_6H_5	1805
$LNi(H)C_5H_5$	*(4)*	1920

The ^{1}H-NMR spectrum of *(3a)* contains a triplet at 34.6 τ (J_{P-H} = 73.5 Hz) due to the hydrogen bonded to the nickel[2]. In *(5a)* we have established the presence of a hydrogen atom bonded to the nickel by means of its coupling with the methyl group: deuterated *(5a)* shows a triplet due to the methyl group at 10.6 τ ($J_{P-Ni-CH_3}$ = 6.5 Hz); this appears in the spectrum of the corresponding hydrogen compound *(5a)* showing a twofold splitting at 10.7 τ ($J_{P-Ni-CH_3}$ = 6.6 Hz, $J_{H-Ni-CH_3}$ = 1.6 Hz).

Preparation of (3b) and (5a):

Argon is passed through a solution of *(1)* (3.2 g, 2.5 mmoles) in toluene (80 ml) until the color of the solution changes from dark red to yellowish red. After extensive concentration of the resulting solution under vacuum, addition of a solution of CH_3COOH (0.3 ml, 5 mmoles) in ether (25 ml) precipitates crystals of *(3b)* (2 g, 60%).

$Al(CH_3)_3$ (0.28 ml, 3 mmoles) is added to *(3b)* (2 g, 3 mmoles) in toluene (40 ml) at −30 °C. The mixture is allowed to reach room temperature, 30 ml of toluene is removed under vacuum, 10 ml of ether is added, and the solution is again cooled

to −30 °C. Compound *(5a)* (1.2 g, 65%) precipitates on standing.

Crystalline Tetrazolinyl Radical

By *F. A. Neugebauer* [*]

The formation [1], constitution [2], and spin density distribution [3] of the tetrazolinyls, the free-radical intermediates between formazans and tetrazolium salts, have been studied in detail by means of ESR spectroscopic examination of free radical solutions. We have now been able to prepare 5-*tert*-butyl-2,3-bis(4-nitrophenyl)tetrazolinyl, the first tetrazolinyl radical *(1)* to be isolated, by dehydrogenation of 3-*tert*-butyl-1,5-bis(4-nitrophenyl)formazan (m.p. 212–213 °C) with di-*p*-tolylaminyl in benzene at 40 °C; it precipitates from benzene/light petroleum as green-black needles (decomp. 126 – 127 °C).

(1)

The radical *(1)* is monomeric in the solid state and in solutions at temperatures down to 77 °K; UV-spectrum in dioxane: λ_{max} = 590 mm (log ε = 3.59), 432 (4.09), 385 (4.03), and 275 (4.18). The low-temperature spectrum at 80 °K shows only slight spectral changes corresponding to the known temperature dependence of electron spectra. The magnetic moments μ_{eff}/μ_B as measured with a magnetic balance are 1.67 at 298 °K, 1.66 at 195 °K, and 1.65 at 90 °K. The values correspond to a free-radical content of 94%. The ESR spectrum in benzene consists of nine groups: $a_{1,4}^{N}$ = 5.6, $a_{2,3}^{N}$ = 6.1, $a^{H(o)}$ = 1.0, and $a^{H(m)}$ = 0.5 gauss.

In weakly acid media (*e.g.* methanol), compound *(1)* immediately decomposes to the reactant formazan and 5-*tert*-butyl-2-(4-nitrophenyl)tetrazole.

As in the case of diphenylpicrylhydrazyl [4] and verdazylene [5] the stability of *(1)* is due to the nearly equal spin densities at the nitrogen pairs N-1, N-4, and N-2, N-3.

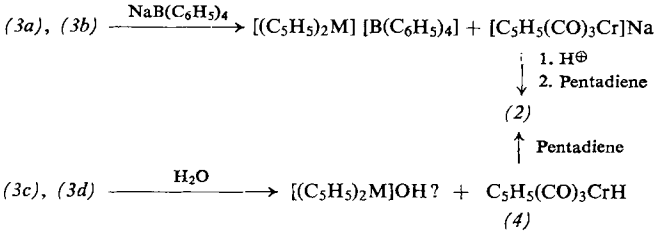
Dinuclear Complexes Containing the Tricarbonylcyclopentadienylchromium Group



By *A. Miyake, H. Kondo*, and *M. Aoyama* [*]

Chemically, the tricarbonylcyclopentadienylchromium group behaves like a halogen atom; thus, the hydrogenation of polyenes with tricarbonylcyclopentadienylhydridochromium *(4)* [1] resembles the classical reductions carried out with hydrogen iodide [2]. We have now investigated oxidation [3] with the iodine analog bis(tricarbonylcyclopentadienylchromium) *(2)*. A benzene solution of *(2)* is added dropwise at room temperature to a benzene solution of the bis(cyclopentadienyl)metal *(1)*; a smooth redox reaction takes place resulting in the formation of the dinuclear complex *(3)*.

$$\underset{(1)}{2\,(C_5H_5)_2M} + \underset{(2)}{[C_5H_5(CO)_3Cr]_2} \rightarrow 2\,\underset{(3)}{[(C_5H_5)_2M]\,[C_5H_5(CO)_3Cr]}$$

(a), M = Co
(b), M = Cr
(c), M = V
(d), M = Ti

The compositions of both the known complexes *(3a)* and *(3b)* [7] and the complexes *(3c)* and *(3d)* first obtained by the above method were confirmed by elemental analysis. Compound *(2)* can be recovered in good yield from the complexes *(3)* (Scheme 1).

Scheme 1.

As already reported, the complexes *(3a)* and *(3b)* have a salt-like structure and are sparingly soluble in benzene. On the other hand, the complexes *(3c)* and *(3d)* are very soluble in benzene, thus indicating the presence of a covalent metal-metal bond. Further evidence of the existence of a covalent metal-metal bond is afforded by the distinct increase in frequency of the CO stretching vibration in *(3c)* and *(3d)*. The shift [8] to shorter wavelengths of the CO band is explained by the decreased negative charge of the chromium atom

Table 1. CO stretching vibrations of $[C_5H_5(CO)_3Cr]$ complexes.

Compound	ν_{CO} (cm^{-1})		
(3a)	1888		1765
(3b)	1890	1881	1767
(3c)	2020	1928	1840
(3d)	2020	1930	1870
(2)	2015	1942	1912
(7)	1974	1908	1885
(8)	1973	1903	1885

The above mentioned redox reaction applies to many other systems, *e.g.* the reaction of *(2)* with organohydridotin proceeds analogously. If a solution of *(2)* and tribenzylhydridotin *(5)* or triphenylhydridotin *(6)* in benzene is warmed to 80 °C, tricarbonylcyclopentadienyl(tribenzyltin)-chromium *(7)*, m.p. 97–99 °C, and the known tricarbonylcyclopentadienyl(triphenyltin)chromium *(8)* [9], m.p. 220 to 222 °C, are obtained. We could detect both *(4)* and hydrogen in this two-step reaction.

$R_3SnH + (2) \rightarrow C_5H_5(CO)_3CrSnR_3 + (4)$

(5), R = $CH_2C_6H_5$ (7), R = $CH_2C_6H_5$

(6), R = C_6H_5 (8), R = C_6H_5

$2\,(4) \rightarrow (2) + H_2$

The complexes (3), like (2) [1], react as selective hydrogenation catalysts. The complexes (3c) and (3d) have a hydrogenation activity comparable with that of (2), whereas the salt-like compounds (3a) and (3b) exhibit only weak activity. Compound (7) does not catalyze hydrogenation.

Bis(cyclopentadienyl)vanadium-tricarbonylcyclopentadienylchromium (3c)

A solution of (2) (1.07 g) in benzene (140 ml) is treated dropwise with a solution of (1c) (1.03 g) in benzene (15 ml). The mixture is stirred during the addition and the color changes from green to dark-brown, it is concentrated to about 40 ml under vacuum, filtered free of decomposition products, and treated with 200 ml of pentane. The almost black crystals which separate are filtered off and washed with pentane. On cooling, (3c) crystallizes as black-brown needles, m.p. 147 to 149 °C [yield 1.07 g (51%)]. The analogous reaction of (1d) with (2) leads to the formation of (3d) in 56% yield (dark brown crystals that decompose at temperatures above 160 °C). Both complexes are extremely sensitive to air and undergo spontaneous combustion.

tert-Butyl Acetate as Alkylating Agent

By *H. Fernholz* and *H. J. Schmidt* [*]

Dedicated to Professor O. Horn on the occasion of his 65th birthday

tert-Alkyl esters of carboxylic acids are readily accessible by addition of tertiary olefins to a carboxylic acid in the presence of polyphosphoric acid as catalyst [1]. The action of the polyphosphoric acid in such additions is extraordinarily selective and limited exclusively to addition of tertiary olefins. This fact is made use of, for example, in a process for the separation of isobutylene from olefin fractions on a technical scale – the olefin fraction is passed through a polyphosphoric acid-acetic acid mixture [2].

The readily accessible *tert*-butyl acetate that is formed not only very easily decomposes into its components, isobutylene and acetic acid, but also reacts like isobutylene and thus can be trapped and used as "masked" isobutylene. *tert*-Butyl acetate is, in fact, superior to isobutylene as regards manipulation and yields.

Table 1. Examples of the *tert*-butylation of aromatic compounds and conversion of nitriles into *N-tert*-butylcarboxamides (Ritter reaction).

Starting material	mole/mole of TBA	g H_2SO_4/mole TBA	T (°C)	Reaction products	Yield (%)
Benzene	2	100	45	*tert*-Butylbenzene + 1,4-di-*tert*-butylbenzene	76 19
Toluene	2	100	60	1-*tert*-Butyl-4-methylbenzene	96
Phenol	0.7	67	20	*p-tert*-Butylphenol + 2,4,6-tri-*tert*-butylphenol	5 86
Phenol	1.1	20	125	*p-tert*-Butylphenol	96
Hydroquinone	0.5	20	50	2,5-Di-*tert*-butylhydroquinone	87
Anisole	2	20	125	*p-tert*-Butylanisole	86
Acetonitrile	1	100	40	*N-tert*-Butylacetamide	91
Acrylnitrile	1	100	40	*N-tert*-Butylacrylamide	88
Benzonitrile	1	108	40	*N-tert*-Butylbenzamide	94
3-Nitrobenzonitrile	1	108	40	3-Nitro-*N-tert*-Butylbenzamide	95
Malonodinitrile	0.5	100	40	*N,N'*-Di-*tert*-butylmalonodiamide	92

The alkylation of aromatic compounds is best carried out by adding the amount of *tert*-butyl acetate shown in Table 1, with stirring, to a mixture of aromatic compound and conc. sulfuric acid over a period of 2 h and then stirring the reaction mixture for a further 1–3 h before separating and purifying the reaction product. To carry out the Ritter reaction the nitrile is mixed with *tert*-butyl acetate, and concentrated sulfuric acid is added dropwise to the stirred and cooled mixture, the temperature of the reaction mixture not being allowed to exceed the temperature given in Table 1.

The reaction mixture is finally stirred for a further 1–2 h and then poured into ice-water. The precipitated amide is isolated and purified.

Isomerizations of *N*-Silylated Cyclosilazanes [1]

By *W. Fink* [*]

After metalation, the hydrogen atoms attached to nitrogen in hexamethylcyclosilazane can be replaced by silyl groups [2, 3]. In the case of trimethylsilyl-substituted compounds, intact

cyclosilazane structures are assumed. We have now observed that partial isomerizations take place in these reactions which depend strongly on the reaction conditions.

The monosilylation of hexamethylcyclotrisilazane with butyllithium/trimethylchlorosilane in diglyme at temperatures between −60 and +60 °C affords 2,2,4,4,6,6-hexamethyl-1-trimethylsilylcyclotrisilazane *(1)*. Formation of *(2)*, the isomer of *(1)*, which melts at 36 °C and which can be prepared by ammonolysis of 2,2,4,4-tetramethyl-1-dimethylchlorosilyl-3-trimethylsilylcyclodisilazane, was not observed. Whereas the doubly silylated hexamethylcyclotrisilazane *(3)* is obtained when hexamethylcyclotrisilazane is silylated in diglyme at

(1) *(2)* *(3)* *(4)* *(5)* *(6)*

R = CH_3; Bu = n-C_4H_9

−60 °C, only the cyclodisilazane derivative *(4)*, which is isomeric with *(3)*, can be isolated when the silylation is carried out at +60 °C in the same solvent or at 160 °C in hexane (under pressure). Similarly, the triple silylation of hexamethylcyclotrisilazane in diglyme at −60 °C affords hexamethyl tris(trimethylsilyl)cyclotrisilazane *(5)* in yields of over 62%. A mixture of *(5)* and the isomer *(6)* is obtained when the silylation is carried out at +60 °C (or at 160 °C in benzene). (The physical properties of a few cyclosilazanes are given in Table 1.)

^{1}H-NMR measurements between −60 and 100 °C show that neither hexamethylcyclotrisilazane itself nor the pure compounds *(1)* to *(6)* isomerize. The rearrangements are base-catalyzed and occur during the metalation step. Thus *(2)*, in diglyme or hexane, is already converted to a great extent at 20 °C into *(1)* as a result of a rapid but spectroscopically observable reaction that is catalyzed by small amounts of butyllithium. Likewise, in the presence of equivalent amounts of butyllithium, compounds *(3)* and *(4)* isomerize until equilibrium is established, which, at low temperatures, lies wholly on the side of *(3)*. Thus, 78% of the isomer *(5)* and only 11% of compound *(6)* are obtained by metalation, at −60 °C, and subsequent silylation of *(4)*.

Table 1. Physical properties of a few cyclosilazanes.

Synthesis of Metal Complexes Having Fluorine-Containing Phosphine Ligands[1]

By *Th. Kruck*, *M. Höfler*, *H. Jung*, and *H. Blume*[*]

As previously reported[2,3] for the case of strong bases of high or low concentration, the nucleophilic replacement of fluorine atoms by $RO^{\ominus}$ and $HO^{\ominus}$ ions affords a general synthetic route for the preparation of trialkoxy-, difluoroalkoxy-, and difluorohydroxyphosphine complexes, which are either inaccessible or difficultly accessible by conventional methods. We have now extended the use of these solvolyses to systems involving reaction of PF_3 ligands in complexes with amines (as prototype of relatively weak bases). Since tetrakis (trifluorophosphine)nickel(0) *(1)* is readily obtainable we have now directed our attention to all model reactions which are required for a formulation of the reaction; the applicability of the method to the PF_3 complexes of other metals has meanwhile been established.

To avoid polymerization[4], only secondary amines were reacted with *(1)* (molar ratio 12:1) in the preliminary experiments.

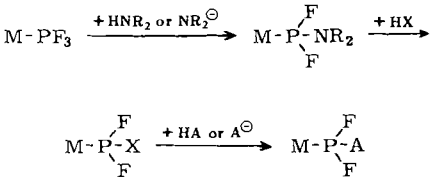
$$\underset{(1)}{Ni(PF_3)_4} \xrightarrow[-n[R_2NH_2]F]{+2nR_2NH} \underset{(2)}{Ni(PF_3)_{4-n}(PF_2NR_2)_n} \quad (n=4,3,2)$$

We have found that these reactions proceed rapidly and almost quantitatively with separation of ammonium fluoride according to the above equation – even at temperatures between 0 and 25 °C. Such aminolyses, which have also been investigated for the case of primary amines and sodamide, yield monomeric homogeneous reaction products, *i.e.* n is constant for a particular amine. A few of the difluoroaminophosphine complexes of nickel that have previously been prepared by this method are given in the following Table.

Compounds *(2)* render possible for the first time the synthesis of, *inter alia*, definite complexes of chlorodifluorophosphine, whose attempted preparation by substitution reactions of $PClF_2$ with tetracarbonylnickel leads instead to the formation

Base	Reaction product *(2)*	Properties
$(CH_3)_2NH$	$Ni[PF_2N(CH_3)_2]_4$	colorless crystals, m.p. 106 °C
$(C_2H_5)_2NH$	$Ni(PF_3)_2[PF_2N(C_2H_5)_2]_2$	colorless oil
$(n\text{-}C_3H_7)_2NH$	$Ni(PF_3)_2[PF_2N(n\text{-}C_3H_7)_2]_2$	colorless oil
Piperidine	$Ni(PF_3)(PF_2NC_5H_{10})_3$	colorless crystals, m.p. 41 °C

of a complex mixture[5] owing to dismutation of the free ligands. Here we utilized the ready fission of the P–N bond[6] by subjecting the complex *(2)* to acid cleavage in ether at room temperature, *e.g.*:



$$Ni[PF_2N(CH_3)_2]_4 + 8\ HCl_{(g)} \rightarrow Ni(PF_2Cl)_4 + 4[(CH_3)_2NH_2]Cl$$
(3)

After filtering off the ammonium chloride and removal of the ether there remains the previously unknown tetrakis(chlorodifluorophosphine)nickel(0) *(3)* as a clear, colorless liquid (yield *ca.* 70%), which can be purified by recondensation under high vacuum or by distillation (b.p. ≈ 64 °C/0.5 torr).

Because of the high reactivity of the P–Cl bond and the low nucleophilicity of the chloride ion, nucleophilic Cl substitutions in the PF_2Cl complexes are possible with weak and very weak bases; they are thus the first members of a series of PF_2Y complexes (Y = OR, CN) of metals in low oxidation states. As prototype of this reaction only methanolysis of *(3)*, which proceeds quantitatively at room temperature in the absence of solvent, need be mentioned.

$$(3) + 4\ CH_3OH \rightarrow Ni(PF_2OCH_3)_4 + 4\ HCl$$
(4)

The difluoromethoxy compound *(4)* can be isolated, after removal of the excess of methanol, as a colorless oil that is soluble in pentane and distillable under vacuum. Starting from the trifluorophosphinemetal complex, the reaction scheme outlined below opens up a route for the preparation of a wide variety of metal complexes having fluorine-containing phosphine ligands.

(R = H, organic group; X = acid radical; HA, $A^{\ominus}$ = weak to medium-strength nucleophile.)

$Xe(OTeF_5)_2$, Xenon Bis(pentafluoroorthotellurate)

By *F. Sladky*[*]

Xenon difluoride reacts with equimolar amounts of pentafluoroorthotelluric acid[1] with loss of HF to give fluoroxenon pentafluoroorthotellurate, $FXeOTeF_5$[2], in quantitative yield. If a five-fold excess of $HOTeF_5$ is used, the second fluorine atom is also replaced by a F_5TeO group.

$$XeF_2 + 2\ HOTeF_5 \rightarrow 2\ HF + Xe(OTeF_5)_2$$
(1)

$Xe(OTeF_5)_2$ is also formed in small amounts when $FXeOTeF_5$ is distilled in a glass apparatus in presence of traces of HF.

$$SiO_2 + 4\ HF \rightarrow SiF_4 + 2\ H_2O$$
$$FXeOTeF_5 + H_2O \rightarrow HOTeF_5 + HF + Xe + {}^1/_2\ O_2$$
$$FXeOTeF_5 + HOTeF_5 \rightarrow HF + Xe(OTeF_5)_2$$

Xenon bis(pentafluoroorthotellurate) *(1)* (m.p. 35–37 °C) is a colorless substance, which is solid at room temperature and which readily crystallizes: IR (solution in CCl_4; range 4000 to 400 cm^{-1}), 780 w, 705 vs, 628 s, 475 m. As expected, the band due to the Xe–F stretching vibration at 520 cm^{-1} in the spectrum of $FXeOTeF_5$ is absent. ^{19}F-NMR (CCl_4 solution; CF_3COOH as external standard): AB_4 type; $\delta_{TeF} = 34.9$ ppm; $J_{TeF} = 1830$ Hz. The stability of *(1)*, which is probably only kinetic, is comparable with that of XeF_2. Compound *(1)* reacts slowly with H_2O in which it is only slightly soluble; in a strongly alkaline medium decomposition takes place with vigorous development of xenon and oxygen and is complete within a few seconds.

$$Xe(OTeF_5)_2 + H_2O \rightarrow 2\ HOTeF_5 + Xe + {}^1/_2O_2$$

(1) is very soluble in CH_3CN and CCl_4; solutions in CCl_4 are also stable over long periods of time. Explosive or very vigorous reactions take place in the presence of ethanol, acetone, and benzene. Compound *(1)* is stable up to temperatures of about 120 °C in prefluorinated Monel vessels.

At higher temperatures, bis(pentafluorotellurium) oxide, TeF_5OTeF_5[3], is obtained along with Xe, O_2, and TeF_6; the still unknown bis(pentafluorotellurium)peroxide TeF_5OOTeF_5 was not formed.

Experimental:

All reactions are carried out gravimetrically and tensimetrically in readily weighable reaction vessels (Kel-F). XeF_2 was prepared by irradiation of Xe/F_2 mixtures with sunlight[4]. 7.40 g of $Xe(OTeF_5)_2$ (97% yield) could be obtained by reaction of 2.12 g of XeF_2 with 14 g of $HOTeF_5$.

XeF_4, purified by treatment with AsF_5 in BrF_5[5], does not react with $HOTeF_5$ under similar reaction conditions.

Determination of the n-Ionization Potential of 2-Trimethylsilylpyridine by Photoelectron Spectroscopy[1]

By *E. Heilbronner* and *V. Hornung*[*], and *H. Bock*, and *H. Alt*[**]

It is still uncertain whether the first ionization potential of pyridine ($IP_{1,\,adiabatic} = 9.27$ eV[2,3]) is to be described as an ionization of the nitrogen lone pair or of the highest occupied π-molecular orbital π_3 (C_{2v} : A_2). No decision can be reached from an analysis of the electronic spectrum, in which one can recognize the fine-structured $\pi^* \leftarrow n$ absorption as a shoulder at the longwave end of the ^1L_b band[4].

It has previously been reported[5] that the strong positive inductive effect of trimethylsilyl substituents raises the energy of the orbitals of a molecule. If the perturbed orbital has π symmetry and if a finite overlap with unoccupied orbitals of the silicon atoms occurs, then the destabilization due to the inductive effect is either over-compensated (π^* level[6]), or largely compensated (π level[7]) by ($Si \leftarrow \pi^*$) back donation, depending on the energy gap between the interacting orbitals. For example, the influence of a $(CH_3)_3$ Si group on the highest occupied molecular orbital of a carbon-π-system is about the same as that of a methyl group[7]. Therefore, one would expect the following characteristic deviations of the orbital energies of 2-trimethylsilylpyridine from those of 2-methylpyridine:

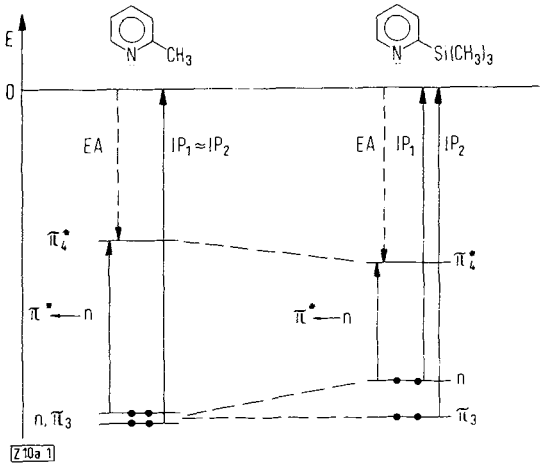

Fig. 1. Qualitative energy-level diagram for the inner molecular orbitals of 2-methyl- and 2-trimethylsilylpyridine.

The following experimental data are in agreement with this prediction:

X	$E^{Red}_{1/2}$ (V)	$\tilde{\nu}_{max}$ (cm^{-1})/ε_{max} (l mol^{-1} cm^{-1})		
		$\pi^* \leftarrow n$	^1L_b	^1L_a
CH_3	−2.17	–	39000/2500	49400/5800
$Si(CH_3)_3$	−2.06	$(35000/500)_{sh}$	39300/3000	47600/8400

sh = shoulder

The fact that the halfwave reduction potential $E^{Red}_{1/2}$ (*i.e.* the electron affinity EA; Fig. 1) of the trimethylsilyl derivative is the more positive one, is an indication of the lowering of the π_4*-orbital (C_{2v} : B_1).

Presumably, this lowering also accounts for the reduced ^1L_a excitation energy. The slightly intensified[8], but unshifted ^1L_b band is preceeded by a pronounced shoulder that shifts towards shorter wavelengths in polar solvents and thus may be ascribed to a $\pi^* \leftarrow n$ transition. Additional information can be obtained by comparing the photoelectron spectra[11] of 2-trimethylsilyl- and 2-methylpyridine (Fig. 2).

The photoelectron spectrum of 2-methylpyridine differs from that of pyridine[3,9] in a predictable way. In the section

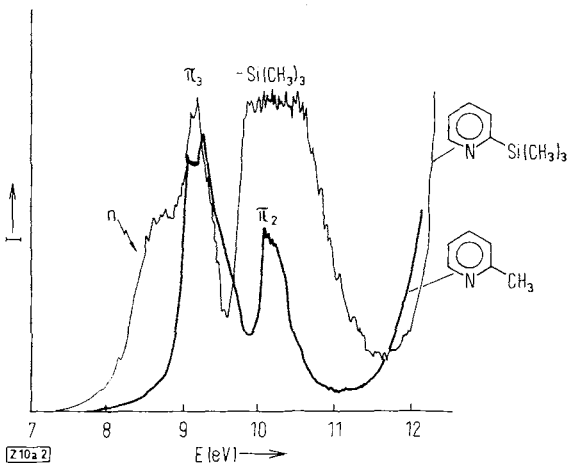

Fig. 2. Photoelectron spectra of 2-trimethylsilyl- and 2-methyl-pyridine. Intensity in arbitrary units.

of the spectrum shown in Fig. 2 one observes bands at 9 and 10 eV which can be assigned to ionization from $\pi_3(A_2)$ and $\pi_2(B_1)$ respectively. These bands occur at lower energies than in unsubstituted pyridine. The bands corresponding to the n-orbital ionization presumably still coincide with the π_3 band.

In contrast, the photoelectron spectrum of 2-trimethyl-silylpyridine shows a well detached fine-structured shoulder in front of the π_3 band. Based on the qualitative energy-level diagram of Fig. 1 and on other experimental data we ascribe this new band to the ionization of the nitrogen lone pair, which now takes place at lower potentials as a consequence of the inductive effect of the trimethylsilyl substituent. Due to the absence of a finite overlap, there is no $Si \leftarrow n$ back donation which would compensate the inductive effect[5]. On the other hand, the previously discussed $Si \leftarrow C_\pi$ back donation, which reduces the donor effect of a trimethylsilyl group to that of a methyl group, is confirmed by the fact that the position of the π_3 band is the same as that observed with the methyl derivative. The broad band occurring between 9.5 and 11 eV is due mainly to the σ-orbital ionization of the trimethyl-silyl residue ($IP_{Si(CH_3)_4} = 9.98$ eV[10]).

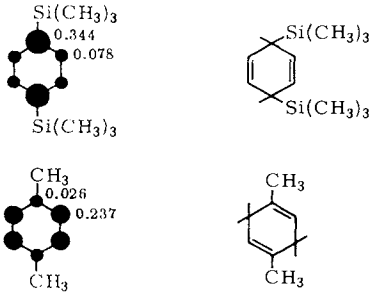
Birch Reductions of Trimethylsilyl Substituted Aromatic Compounds Controlled by (Si ← C_π) Interactions[1]

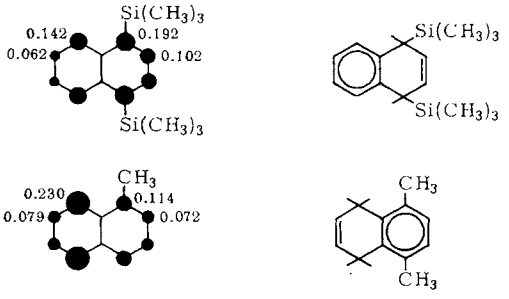
By *H. Alt, E. R. Franke,* and *H. Bock* [*]

Silyl and alkyl substituents exert a differing electronic influence on the lowest unoccupied ψ_{-1} molecular orbital of π-electron systems: Half-wave reduction potentials[2] and ESR coupling constants[3] verify that alkyl groups act as electron donors, whereas the stronger positive inductive effect of silyl groups is overcompensated by a coupled (Si← C_π) acceptor function of the unoccupied silicon atomic orbitals. Consequently, trimethylsilyl substituents stabilize anions in which the ψ_{-1} molecular orbital is occupied. (Si← C_π) interactions, therefore, should also determine the products of reactions of π systems which proceed *via* anionic transition states or intermediates.



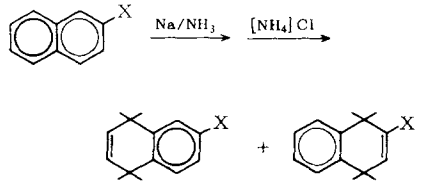
A suitable model reaction is the Birch reduction of aromatic compounds in which dianions or radical anions occur as intermediates and are subjected to kinetically controlled protonation at the center of greatest electron density[4]. In the case of monosubstituted or 1,4-disubstituted benzenes two different reaction products are possible depending on whether the electrons will occupy the antisymmetric ψ_{as} or symmetric ψ_s of the antibonding e_{2u} molecular orbitals[3]. The

electron density distribution in the singly occupied ψ_{-1} molecular orbitals of radical anions can be inferred from the ESR coupling constants a_H, which according to the McConnell relation $a_H = {}_iQ_\mu \rho_\mu^\pi$ [5] are proportional to the π-spin populations and hence, within the HMO approximation, to the squared coefficients $(c_{-1\eta}^{HMO})^2$ at the individual centers μ. From the "experimental MO pictures" thus obtained it should be possible to predict, in the case of alternant aromatic compounds, the centers of greatest electron density and, therefore, the structures of the Birch reduction products. In fact, in the reaction of 1,4-bis(trimethylsilyl)benzene with sodium and ammonium chloride in liquid ammonia[6] one obtains, in agreement with the ESR data[3], exclusively the 1,4-dihydro derivative to be expected on account of the (Si← C_π) acceptor function. On the other hand, as is already known[4], the 1,2-dihydro compound is obtained from *p*-xylene because of the electron donor functions of the alkyl groups.



The monosubstituted benzenes (X = CH_3, $Si(CH_3)_3$) are reduced similarly.

π-spin populations [7] reduction product



In the Birch reduction of silyl- and of alkyl-naphthalenes the electrons occupy the same molecular orbital ψ_6. However, alkyl donor and silyl acceptor substituents lead, in accordance with ESR data[3,8], to different electron-density distributions so that in the case of the 1,4-dimethyl derivative the unsubstituted ring is reduced whereas only the substituted ring is reduced in the case of the 1,4-bis(trimethylsilyl)-derivative.

π-spin populations [7] reduction product

Once again, analogous results are obtained with 1-substituted naphthalenes. On the other hand, 2-substituted naphthalenes, in which according to HMO coefficients ($c_{61}^2 = 0.181$, $c_{62}^2 = 0.069$) an essentially less directing influence of the substituents is to be expected, yield mixtures of isomers.

X = CH_3:	75%	25%
X = $Si(CH_3)_3$:	20%	80%

The different isomeric ratios, however, are to be ascribed to the opposite electronic effects of alkyl and silyl substituents.

The structures of the reaction products as predicted from ESR spin populations confirm that the anionic intermediates of the Birch reduction are protonated in each case at the centers of greatest electron density. The different types of dihydro derivatives of alkyl and silyl substituted aromatic compounds thus confirm the (Si← C_π) acceptor function of trimethylsilyl groups already proved by physical measurements.

Organosilicon Chemistry

The Second International Symposium on Organosilicon Chemistry at Bordeaux (July 9–12, 1968) – like the previous Symposium at Prague in 1965 – aroused world-wide interest; it was organized by *J. Valade*. 13 plenary lectures and almost 100 discussion lectures, presented in three concurrent subconferences, confronted the participants, numbering about 400, with such a broad spectrum of the present state of organosilicon chemistry that, apart from a few notable exceptions, the reasoning and scientific depth of individual papers became somewhat lost in the sheer volume of subject material.

Organosilicon technology (direct synthesis as well as manufacture and characterization of polymers) seems to make few bounds forward; developments appear to be overshadowed by the more academically oriented investigation of the "monomeric" compounds. Before very long there will probably be only few chemists working with organosilicon compounds that will remember their benefactors who provided, and still generously provide, the "minerals" that form the very basis of this field.

Plenary Lectures

Except for the contributions by *V. Bažant* (Prague): "Studies on the mechanism of direct synthesis", *K. A. Andrianov* (Moscow): "Polymerization of ring-shaped organosilicon compounds", and *H. Kriegsmann* (Berlin): "Intramolecular and intermolecular interactions in some organosilicon compounds", which were concerned with vibration spectroscopic, mass spectrometric, and ^{1}H-NMR spectroscopic studies on polysiloxane chains, and particularly with the range of electronic effects in a siloxane chain, all the plenary lectures were about the chemistry of monomeric organosilicon compounds.

Attention was focused primarily on papers dealing with formation and cleavage of SiC linkages. *H. Gilman* (Ames, Iowa) reported on the silylation of halogenohydrocarbons after metalation with Li or Mg. Thus propyne, hexahalogenobenzenes, and hexachloropropene react with Li and $(CH_3)_3SiCl$ *in situ* to give $[(CH_3)_3Si]_2C{=}C{=}C[Si(CH_3)_3]_2$; under these conditions perchloroalkanes and ethylene yield $(CH_3)_3SiC{\equiv}CSi(CH_3)_3$; and trichlorobenzene and pentachloropyridine afford tris(trimethylsilyl)trichlorobenzene and 4-trimethylsilyltetrachloropyridine, respectively. Novel reaction routes have also become available *via* copper compounds such as R_3SiCu and R_3GeCu, which can be obtained from the corresponding lithium compounds and C_6H_5Cu or C_6Cl_5Cu. *D. R. Weyenberg* (Midland, Michigan) has found the pyrolysis of alkoxypolymethylsilanes at 225 °C to be a suitable reaction for the production of dimethylsilylene $(CH_3)_2Si$:, which can be detected by mass spectrometry and intercepted, *e.g.*, by diphenylacetylene to form the 1,4-disila-2,5-cyclohexadiene system. Pyrolytic formation of the silylene occurs only when the $(CH_3)_2Si$ group is bonded to an atom bearing a lone pair of electrons; the same applies to the silylenes $(CH_3)CH_3OSi$: and $(CH_3O)_2Si$:. In the absence of a silylene interceptor such as an alcohol or a diene the resulting R_2Si: can also be used for the lengthening of the alkoxypolysilane chain. Investigations on the tributylamine-catalyzed addition of trichlorosilane to phenylacetylene were the subject of a paper delivered by *R. A. Benkeser* (Lafayette, Indiana). An essential step in this reaction is the formation of the ion pair $R_3NH^+SiCl_3^-$. The primary products, α- and *cis*-β-trichlorosilylstyrene, react further with $HSiCl_3$ to give α,β-bis(trichlorosilyl)ethylbenzene. *trans*-β-Trichlorosilylstyrene is also found as a product but its formation is attributed to isomerization of the *cis*-β compound. On the basis of the analogy between CH and CSi bonds, *C. Eaborn* (Brighton) presented a review of the cleavage of SiC bonds and compared this bond with GeC, SnC, and PbC bonds. Triorganosilyl-substituted aryl carboxylic acid derivatives, whose reactivity is determined by the interplay of inductive and resonance effects, represent suitable model substances. Ethynyl-Si compounds behave similarly to their aryl analogs; the high reactivity of the ≡CSi bond has permitted the development of a new synthesis of polyacetylene compounds.

E. Frainnet (Bordeaux) gave an account of the addition of triorganosilanes to carbonyl compounds such as ketones, aldehydes, esters, carboxylic anhydrides, and carboxylic acid halides, and of the reaction of alkoxysilanes with aromatic compounds, esters, and lactones for an extremely wide range of reactants. Anionic rearrangements of organosilicon compounds were discussed by *R. West* (Madison, Wisconsin). They are responsible for the isomerization of silyl hydrazines in the presence of catalytic amounts of alkyllithium, proceed *via* an intramolecular mechanism, and occur frequently in organosilicon chemistry because silicon can expand its valence shell and thus stabilize the intermediates required by the rearrangement. Thermodynamic preference of the 1,1-disilylhydrazines is probably due to the increased stability of the SiNSi group. On the other hand, disilylethylenediamines undergo 1,4 rearrangement; electronic effects such as phenyl-substitution can reverse the direction of rearrangement. A report on the preparation, structure, and reactions of silyl-substituted alkali-metal amides was presented by *U. Wannagat* (Braunschweig). It appears from recent publications that the great versatility and reactivity of the alkali-metal bis(triorganosilyl)amide is exceeded by $LiN(SiCl_3)_2$. Vibration-spectroscopic and other physicochemical measurements on $LiN[Si(CH_3)_3]_2$ indicate the presence of dimeric molecules in the fused compound and in solution, whereas an X-ray structure analysis has established that the crystalline compound exists as the trimer in the form of a six-membered $(LiN)_3$ ring having ∢ SiNSi = 118 ° and *d* SiN = 1.72 Å [1].

The impressive advances made in the chemistry of silicon-metal compounds in recent years became evident in two lectures: *G. A. Razuvaev* (Gorki) dealt mainly with the silyl and germyl derivatives of main-group elements such as Hg [2], and *A. G. MacDiarmid* (Philadelphia, Pennsylvania) concentrated on carbonyl complexes containing SiMn, SiFe, and SiCo bonds. The thermal stability of such bonds is strongly dependent on the nature of the substituents and decreases in the series SiFe–SiMn–SiCo; these bonds show a remarkable stability toward, *e.g.*, PF_3, PF_5, and SO_2. The energy of the SiCo bond (105–124 kcal/mole, as determined by mass spectrometry) is exceptionally high and suggests $SiCo{-}d_\pi d_\pi$ bonds. In $Cl_3SiCo(CO)_4$, the Si atom occupies an axial position of a trigonal bipyramid; the CO groups *cis* to the Si are displaced by 4.8 ° toward the latter. $(CH_3)_3SiMn(CO)_5$ has an octahedral structure; *d* MnSi is 2.50 ± 0.02 Å, a value lower than that expected for a single bond.

M. G. Voronkov (Riga) reported on the biological activity of compounds containing silicon. Thus compounds containing SiC bonds occur in certain bacteria, and silicon compounds are undoubtedly partly responsible for silicosis. The silatranes, polycyclic alkoxysilanes of the general formula $RSi(OCH_2{-}CH_2)_3N$, are unexpectedly poisonous; with a lethal dosage of 0.2 mg/kg they are considerably more toxic than strychnine. Their toxicity is strongly dependent on the nature of the substituent R: the compound with R = *p*-tolyl is more than 10^4 times more poisonous than that with R = methyl.

Preparation and properties of monomeric organosilicon compounds were also dealt with in most of the discussion lectures. In a number of cases the part of the molecule investigated was so far removed from an organosilicon group that the effects observed could hardly be attributed with certainty to the silicon. This report will now consider an arbitrary selection of the topics that were discussed.

Whereas the papers presented by *M. Dvořak* (Prague), *N. P. Lobusevich* (Moscow), and *H. Ya. Zueva* were devoted to the catalyst systems used in direct syntheses and the effects of foreign atoms, that by *A. I. Gorbunov* (Moscow) dealt with kinetic aspects of direct synthesis. *M. Bartholin* (Villeurbanne) has succeeded in incorporating Al and Cr into phenylpolysiloxanes in aqueous media at pH values between 2.5 and 5, and *J. A. C. Watt* (Stevenston) has found the perphenylpoly-*p*-silphenylene/asbestos system to be a stable combination up to 400 °C. *I. M. White* (Farnborough) has introduced P(O)R and isophthaloyl groups into neopentyl-substituted polysiloxanes by co-condensation; however, the properties of the products are no more favorable than those of the usual silicones. The stereochemistry of the polymerization of a trimethyltriphenylcyclotrisiloxane in the presence of various catalysts has been studied by *E. E. Bostick* and *J. B. Bush Jr.* (Schenectady, New York).

SiC Compounds

Silylboranes, which possess considerable potential as polymer building units, were presented by *S. Papetti* (New Haven, Connecticut), silicon-containing four-, five-, and ten-membered rings having C–C, C=C, and C≡C groups by *G. Fritz* (Karlsruhe), and a sila-steroid by *S. Barcza* (Hanover, New Jersey). According to *Sheng-lieh Liu* (Taipeh), four $(CH_3)_2C_6H_5Si$ groups may be bonded to a central carbon atom. *H. Schmidbaur* (Würzburg) has observed stabilization of the P=C bond by $(CH_3)_3Si$ groups in $(CH_3)_3P{=}CHSi(CH_3)_3$; the silyl shift involved in the conversion of $(CH_3)_3SiCH_2P(CH_3)_2{=}CHSi(CH_3)_3$ into $(CH_3)_3P{=}C[Si(CH_3)_3]_2$ is remarkable. According to *M. J. Newlands* (Manchester), 1,3-disilacyclobutanes can undergo either electrophilic or nucleophilic cleavage. On cleavage with bromine, the reactive dislacyclobutane $CH_3(C_6H_5)SiCH_2SiCH_3(Br)CH_2$ can be intercepted and the Br replaced by H on treatment with $LiAlH_4$. The rate of catalytic chlorination of arylsilanes and the σ constants of various organosilyl groups, determined from half-wave potentials and the rate of bromination of phenylsilanes, respectively, were shown by *V. Chvalovský* (Prague) and *F. Mareš* (Prague), respectively, to evidence pronounced (p→d)π interactions in the Si-phenyl bond.

SiO and SiN Compounds

Siloxycarbenes have been obtained by *A. G. Brook* (Toronto) on irradiation of α-silyl ketones. They are nucleophilic in character and may be intercepted with ketones and fumaric esters. *J. Caussé* (Bordeaux) reported that triorganosilanes add to ketenes to form enoxysilanes; both possible stereoisomers are formed with ketenes of the type RR'C=C=O. Careful examination of the reaction of $(RO)_2PONa$ with triorganochlorosilanes led *N. L. Orlov* (Leningrad) to the conclusion that the reaction product is not $(RO)_2P(O)SiR_3$ but a mixture of $(RO)_2POSiR_3$ and $R(RO)P(O)OSiR_3$, the latter arising by isomerization of the former. The major product on irradiation of acetone/triorganosilane mixtures has been found by *A. Ritter* (Mülheim) to be isopropoxysilane; with benzophenone, on the other hand, *O*-triorganosilylbenzopinacol could be isolated as main product. Optically active 2-sila-5-oxazolidones have been obtained by *J. F. Klebe* (Schenectady, New York) on reaction of optically active *N*-substituted amino acids with diaminosilanes at room temperature. The diastereomers differ in their proton magnetic resonance spectrum; equilibrium is established in solution within a few days. *K. Rühlmann* (Berlin) discussed the merits of bis(trimethylsilylimino) compounds for the synthesis of new heterocycles. Olefins add to silyl azides to give *N*-silyltriazolines, which yield silylaziridines on thermolysis. Benzimidazolines bearing a metal substitutent (Li, Na, Fe) attached to the nitrogen atom constituted the subject of the paper by *D. Kummer* (Karlsruhe). These thermally unstable compounds can be converted into the *N,N*-bis(trimethylsilyl) derivatives; in their chemical behavior they resemble alkali-metal disilylamides. *I. Schumann-Ruidisch* (Würzburg) reported on the synthesis of mono- and bis(trimethylsilyl)-*tert*-butylamine; one of the Si atoms can also be replaced by Ge, Sn, or Pb. The long-sought-after pale blue compound, bis(trimethylsilyl)diimine (azotrimethylsilane)[3], which decomposes to tetrakis(trimethylsilyl)hydrazine and N_2 at −35 °C has been prepared by *N. Wiberg* (München). The diimine ignites in the presence of O_2; controlled oxidation affords bis(trimethylsilyl) peroxide. *R. P. Bush* (Barry) has studied the rearrangement of *N*-metalated six- and eight-membered siloxane rings; ring contraction to cyclodisilazanes and six-membered rings, respectively, always proceeds *via* excision of a $OSiR_2$ unit. As shown by *V. L. Sheludjakov* (Moscow), β-eliminations in SiNCX systems (→ SiX + −NC−) determine the courses of many reactions in SiN chemistry: decomposition of *N*-silylurethanes, *N*-silylcarbamoyl chlorides, *N*-silylimino carboxylic acid derivatives. *O. J. Scherer* (Würzburg) has shown scission of SiN bonds by thionyl halides to be a universally applicable reaction for the preparation of sulfinylamine derivatives such as $(CH_3)_3SiN{=}S{=}O$, NC–N=S=O, and RS–N=S=O. Alkali-metal silylamides $[MNR'(SiR_3)]$ react with transition-metal carbonyls M'–C≡O to give $MOSiR_3$ and M'–C=NR'. *G. Schirawski* (Braunschweig) has elucidated the mechanism of this reaction and exploited it for the preparation of new isocyanide complexes.

Other Silicon Compounds

The synthesis of $(C_6F_5)_3SiSi(C_6F_5)_3$ has been accomplished by *E. Hengge* and *G. Starz* (Graz); the intermediate $(C_6F_5)_3SiH$ is characterized by an unusually high νSiH vibration at 2295 cm^{-1}. *E. A. Chernyshev* (Moscow) has studied interception reactions of dichlorosilylene $:SiCl_2$ with naphthylsilanes and obtained a large number of derivatives of 1,2-disilacyclopentane and -hexane. Preparation and vibration spectra of methylated isotetrasilanes and neopentasilane were treated in the lecture by *U. Goetze* (Braunschweig). The compound $[(CH_3)_3Si]_3SiH$, with νSiH = 2051 cm^{-1} and $J(^1H^{29}Si)$ = 155 ± 2 Hz, provides a particularly clear illustration of the extreme electron-releasing effect of the $(CH_3)_3Si$ group. Like other phosphines, $[(CH_3)_3Si]_3P$ can also act as ligand in transition-metal complexes; according to *H. Schumann* (Würzburg), it forms air-stable compounds, admittedly of low thermal stability, with the groups $Ni(CO)_3$, $Fe(CO)_4$, $Cr(CO)_5$, and $Co(CO)_2NO$.

Silicon-Metal Compounds

In addition to the Si-alkali-metal compounds [*E. Amberger* (München)] and tris(trimethylsilyl)thallium, which was reported upon by *A. G. Lee* (Cambridge), Si-transition-metal compounds received considerable attention. Homolysis of $(R_3Si)_2Hg$ produces R_3Si radicals, which add readily to unsaturated systems [*W. P. Neumann* (Giessen)]. Compounds having Si–Ti linkages have also been obtained for the first time: according to *H. Zimmermann* (Graz), reaction of $TiCl_4$ and $(C_6H_5)_3SiK$ affords $[(C_6H_5)_3Si]_4Ti$[4]; the synthesis of silyl cyclopentadienyltitanium derivatives has also been accomplished by *M. F. Lappert* (Brighton). ^{57}Fe-Mössbauer and IR spectra show the compounds $(SiH_3)_nFeH_{2-n}(CO)_4$ (n = 1,2) to have a *cis*-octahedral structure; other SiH_3 compounds such as $H_3SiCo(CO)_4$ and $H_3SiMn(CO)_5$ have also been prepared and studied by *B. J. Aylett* (London). *F. Glockling* (Durham) has utilized the reaction between PtH and HSi groups, which is exothermic to the extent of 20 kcal/mole, for the synthesis of new SiPt compounds. H_2, HCl, CH_3I, and H_2O cleave the SiPt bond under mild conditions.

Physicochemical Measurements

In conclusion, a broad selection of physicochemical studies were reported, ranging from structure determinations on new cage-type disilylmethylenes by nuclear magnetic resonance and mass spectrometry [*W. J. Owen* (Barry)] to quantum-chemical calculations on benzyl, aryl-, and alkenylsilanes [*J. Nagy* (Budapest)]. *H. Bock* (München) considered why silyl ketones are yellow, as opposed to the colorless aryl ketones. On the basis of ionization energies, half-wave reduction potentials, and charge-transfer and electron-excitation energies, he has drawn up an experimental MO scheme which shows that the reduced excitation energy of the long-wavelength $n \rightarrow \pi^*$ transition is to be attributed to promotion of the oxygen n-electron pair by the strong inductive effect of the R_3Si group and a simultaneous lowering of the π^* energy level by back-donation of electrons in the sense $(O=C)_\pi \rightarrow Si$. Dipole-moment measurements and $p_\pi d_\pi$ contributions have been correlated by *S. Ferenczi-Gresz* (Budapest) for organo-oxysilanes and by *V. Vaisarová* (Prague) for phenylhalogenosilanes. Interactions between proton donors of the type −CH, −NH, or −OH and SiO or SiN compounds have been detected by infrared spectroscopy [*M. Jakoubková* (Prague)], and the assignment of the infrared spectra of siloxanes and alkoxysiloxanes was reported on by *A. Marchand* (Bordeaux). A simple universal set of force constants for representation of vibration spectra of phenyl-Si compounds was presented by *F. Höfler* (Münster). The paper read by *H. Bürger* (Braunschweig) was concerned with normal coordinate analysis of all trimethylsilyl compounds of Group IV–VII elements (El) that contain a full complement of $(CH_3)_3Si$ groups. The relevant calculations afford not only the SiEl stretching force constants and the limits of the SiElSi bond angle but also correlations between C_3Si deformation vibrations and the mass of the fourth substituent. With the aid of nuclear magnetic resonance studies, *E. G. Rochow* (Cambridge, Massachusetts) has shown that methylpolysilazane chains are flexible and that their flexiblity is increased by branching; free rotation of the CH_3 group is retained in such chains. *J. Schraml* (Prague) has analyzed the ^{1}H-NMR spectra of a large number of silyl-2,2-dichlorocyclopropanes and reached the conclusion that no π bond can be detected, at least by NMR spectroscopy, between the cyclopropane ring and Si. *H. Bürger* [VB 202 IE]

Polyoxymethylenes

By *H. Cherdron* [*]

Polyoxymethylenes can be prepared in a number of ways:

1) Cationic or anionic polymerization of formaldehyde,

2) Polycondensation of formaldehyde in aqueous solution (*via* the unstable methylene glycol),

3) Cationic polymerization of cyclic trimers and tetramers of formaldehyde.

The homopolymerization and copolymerization of trioxane, which exhibit a variety of particular features, have been thoroughly studied. These ring-opening polymerizations are characterized by various side reactions of the growing polyoxymethylene cations such as chain transfer, transacetalization, and hydride shifts. Not only do the side reactions determine the nature of the end group and the molecular weight, but they are also responsible for the chemical and molecular regularity of the polyoxymethylene.

Owing to their predominantly regular molecular structure polyoxymethylenes crystallize extremely readily, two crystal modifications being encountered: an orthorhombic modification and an hexagonal one. The former rearranges irreversibly to the latter at temperatures above 80 °C. Many of the physical properties arise from this highly crystalline state, as for example the insolubility of polyoxymethylenes in organic solvents at room temperature, the high modulus of elasticity, and the favorable combination of hardness and rigidity.

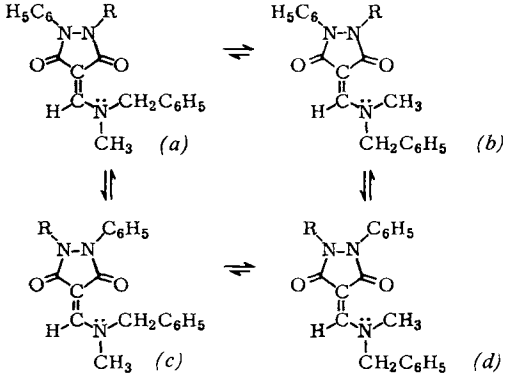
Intramolecular Motions in Enamines and Hydrazones. Separation of Rotational Isomers

By *A. Mannschreck* and *U. Kölle* [*]

Rotation about the =C–N bond of enamines *(1)* occurs more slowly than the corresponding process in saturated amines, whereas *cis-trans* isomerization at the C=C bond in *(1)* is faster than in alkenes containing no hetero atom [1,2]. Some



(1), X = CH
(2), X = N

(3), X = CH
(4), X = N

indications of similar phenomena in hydrazones *(2)* have been obtained [1]. However, the free enthalpies of activation $\Delta G^{\neq}$ for rotation about the =N–N bond in *(2)* are lower by about 4 kcal/mole than the values for the corresponding motion at =C–N in *(1)*. This was concluded, for example, from the coalescence of the ^{1}H-NMR methyl signals of *(3)*, $\Delta G_c^{\neq}$ = 21.5 kcal/mole at 160 °C, and of *(4)*, $\Delta G_c^{\neq}$ = 17.6 kcal/mole at 73 °C, in diphenyl ether. These findings are in agreement with the fact, deduced from ^{1}H/^{1}H coupling constants in fulvenes [3], that dipolar resonance structures contribute more to the ground state of enamines than to that of hydrazones.

The high barrier to rotation about the =C–N bond in *(3)* led us to attempt the separation of isomers in suitable cases. For instance, *(5b)*, m.p. 185–186 °C, was obtained in the pure

(5), R = C_6H_5
(6), R = CH_3
(7), R = H

state by crystallization, whereas the samples of *(5a)*, m.p. 185–186 °C, isolated by chromatography still contained 7% of *(5b)*. When *(5a)* or *(5b)* is dissolved in $CDCl_3$ at 28.5 °C an equilibrium is established which shows 40% of *(5a)*. The chemical shifts for the alkyl protons of the two isomers differ markedly. This represents the first identification and separation of enamines which are rotational isomers with respect to the =C–N bond.

(5a) and *(5c)*, as well as *(5b)* and *(5d)*, cannot be distinguished. However, four isomers are possible for *(6)*, the pyrazolidine ring of which is unsymmetrically substituted. Crystallization of the reaction product obtained from *(7)* and CH_3I yielded a 1:1 mixture of *(6b)* and *(6d)* having m.p. 130 °C. When equilibrated, the $CDCl_3$ solution at 13 °C contained 20% each of *(6a)* and *(6c)* as well as 30% of *(6b)* and of *(6d)*. The time dependence of the isomer ratio resulted in $\Delta G^{\ddagger}$ = 21.3 kcal/mole for the =C–N isomerization process *(6b)* → *(6a)*, whereas $\Delta G^{\ddagger}$ = 19.2 kcal/mole was measured by coalescence at 70 °C in $Cl_2CHCHCl_2$ for *(6b)* → *(6d)*, the corresponding motion at the C=C bond. Therefore, in such enamines the transition state of C=C rotation is more favorable than that of =C–N isomerization.

Lecture at München on May 12, 1969 [VB 204]

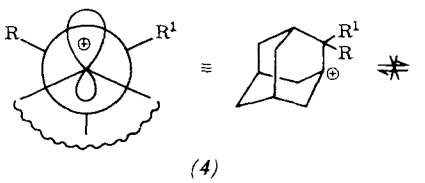
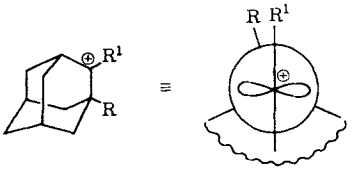
Recent Developments in the Chemistry of Adamantane and Diamondoid Molecules



By *P. v. R. Schleyer* [*]



In the adamantane series, intermolecular hydride shifts occur very readily. Under ordinary Koch-Haaf conditions, *(1)* is converted into *(3)* [1]. However, when the reaction is carried out in the same way but with *(1)* in high dilution, the unrearranged product *(2)* is formed. If the rearrangement of *(1)* to the carbonium ion precursor of *(3)* is unimolecular, there should have been no effect of dilution; however, dilution should inhibit bimolecular, intermolecular hydride transfers.

This behavior is quite general. Under ordinary concentrations the Koch-Haaf reaction of 2-adamantanol gives only adamantane-1 carboxylic acid, while under high dilution conditions the unrearranged adamantane-2 carboxylic acid is formed [2]. This result demonstrates that 1,2-hydride shifts do not occur intramolecularly under these conditions.

Although there are many cases of apparent 1,2-shifts in adamantane chemistry, *e.g.*, the interconversion of 1- and 2-adamantanol in sulfuric acid [3], we believe that these shifts do not take place by the simple intramolecular rearrangement *(4)* ⇌ *(5)*. The relationship of the vacant orbitals and the migrating groups is highly unfavorable in *(4)* and *(5)*, and the 1,2-migration transition state is badly distorted.

Further, direct examples of the inability of simple intramolecular 1,2-shifts to occur in adamantane are provided by NMR studies of stable adamantyl cations themselves, in SbF_5 solution [4]. Even though only a seemingly simple sequence of 1,2-shifts should convert the 3-methyladamantyl-1 cation to the more stable 2-methyladamantyl-2 cation [*(5)*, $R^1 = CH_3$; R = H], no rearrangement occurs and both cations are indefinitely stable in SbF_5 [5]. Even more strikingly, the 2,2-dimethyladamantyl-1 cation [*(4)*, $R = R^1 = CH_3$] does not rearrange to its more stable isomer, the 1,2-dimethyl-adamantyl-2 cation [*(5)*, $R = R^1 = CH_3$].

Although hydride shifts can occur intermolecularly, methyl shifts cannot. Despite this, there are many cases of apparent 1,2-methyl shifts in adamantane [3], *e.g.*, the interconversion of 1-methyl and 2-methyladamantane and the rearrangement of 2,2-dimethyladamantane first to 1,2-dimethyladamantane and then to the 1,3-dimethyl isomer with AlX_3 catalysis. Although work in progress is not complete, we believe that these rearrangements probably are not simple 1,2-shifts, but rather follow more complicated paths. Ring expansion-contraction or rearrangement through skeletal isomers of adamantane, such as protoadamantane [5], are the most likely alternatives.

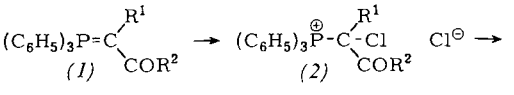
Unusually large Stokes shifts and fluorescence decay times have been found by *G. Briegleb, J. Trencséni,* and *W. Herre* for the charge-transfer fluorescence of donor-acceptor ion pairs of *N*-methylpyridinium salts with the anions Br^-, I^-, N_3^-, SCN^-, and 1,2,3,4,5-pentakis(methoxycarbonyl)cyclopentadienide. The Stokes shifts, *i.e.* the difference between the maxima of the absorption and fluorescence bands, amount to 11000–20000 cm^{-1}, and the decay times to 10^{-4} to 10^{-5} s. These findings are explained in the following way: In the ground state the donor D and the acceptor A are held together by strong electrostatic forces; in the excited state the picture is rather one of a relatively loosely bound radical pair $D^{\bullet}\cdot\cdot A^{\bullet}$; the equilibrium distances $D^{-}\cdot\cdot A^{+}$ in the ground state and $D^{\bullet}\cdot\cdot A^{\bullet}$ differ considerably. Since the bonding forces in the excited state are relatively weak, the nuclear coordinates can assume equilibrium values during the lifetime of the excited state. If the symmetry properties of the equilibrium configuration in the excited state are not conducive to electron demotion to the ground state, then an unusually long fluorescence decay time will be observed. / Chem. Physics Letters *3*, 146 (1969) / –Hz. [Rd 24 IE]

The products of charge transfer on collision of H^+, H_2^+, and He^+ with H_2, N_2, O_2, CO_2, H_2O, NH_3, and CH_4 have been investigated by *D. W. Koopman.* The charged products whose kinetic energies are not too high are removed from the collision region by means of electric fields and analyzed in a simplified mass spectrometer. Uncharged products and those having a high kinetic energy are not registered. With all target gases, collision with He^+ gives cleavage products, whereas only charge transfer occurs with H_2^+ and H^+. The results are discussed in terms of the potential energy curves of the participating molecules and molecular ions in their ground states and excited states. In the case of the polyatomic molecules, the investigations provide information about the energy of states from which dissociation can take place. / Physic. Rev. (2) *178*, 161 (1969) / –Hz. [Rd 27 IE]

The ^{19}F-NMR spectra of 3-substituted 2-chloro-1,1,2-trifluorocyclobutanes have been studied by *R. R. Ernst.* The compounds were present as *cis,trans* isomeric pairs; each isomer can exist in two conformations, depending on whether the substituent attached to C-3 is in the axial or the equatorial position. All the signals of the isomers could be assigned by comparison of the chemical shifts of the ^{19}F resonances. The F–F coupling constants were investigated with regard to their dependence on the dihedral angle between the two neighboring C–F bonds: in the regions of 0° and 180° they are negative, and for angles of about 90° they are positive. Analysis of the spectra was simplified by irradiation with a strong noise spectrum in the region of the proton resonances in order to suppress H–F coupling. / Molecular Physics *16*, 241 (1969) / –Hz. [Rd 28 IE]



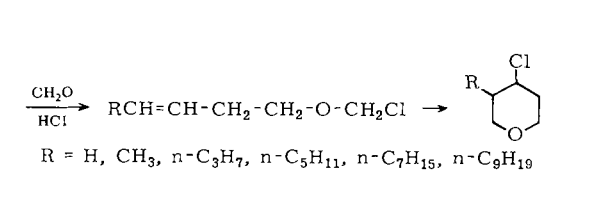
The fluorescence spectrum of estrone, which has been discussed by *A. Weinreb* and *A. Werner,* is distinguished by the presence of two strong emission bands at 310 and 430 nm. The fluorescence of freshly prepared solutions in ethanol is independent of concentration and of the wavelength of the exciting light. The first finding rules out excimer fluorescence as the cause of the band at 430 nm; the second finding makes the presence of impurities appear unlikely. Comparison with related steroids containing only one of the two chromophores present in estrone (aromatic ring and carbonyl group) suggest that the short-wave band should be assigned to the aromatic ring and the long-wave band to the carbonyl group. For this to apply, an energy transfer from the aromatic ring to the carbonyl group must occur in estrone; the remarkably low fluorescence quantum yield of estrone lends further support to this assumption. / Chem. Physics Letters *3*, 231 (1969) / –Hz. [Rd 29 IE]

Variation of the dielectric properties of weakly polar liquids with temperature and pressure has been studied by *F. I. Mopsik.* It was found that the polarization, calculated by the Clausius-Mosotti equation

$$[(\varepsilon - 1)/(\varepsilon + 2)]\ (M/\rho) = P$$

(ε = dielectric constant, M = molecular weight, ρ = density), falls linearly with increasing density, the gradient being independent of the temperature. The dipole moment of the substance investigated can be determined from the temperature dependence of P at constant density. As expected, $\mu = 0$ was found for CCl_4 and CS_2; other values obtained were $\mu = 0.085$ D for *n*-hexane, $\mu = 0.105 \pm 0.004$ D for isopentane, and $\mu = 0.332 \pm 0.006$ D for toluene. The method runs into difficulties with dipole moments as high as the last-mentioned example since the slope of the P-ρ curve then becomes temperature dependent. / J. chem. Physics *50*, 2559 (1969) / –Hz. [Rd 30 IE]

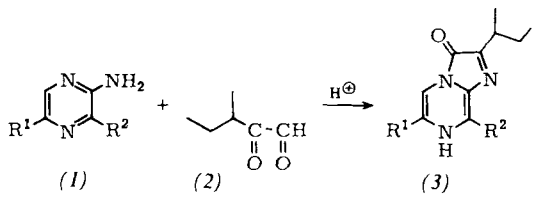
A new method for the synthesis of non-symmetrical α-chloro ketones is given by *E. Zbiral* and *M. Rasberger.* β-Oxoalkylenephosphoranes *(1)*, which are readily accessible from alkylenephosphoranes and acyl chlorides, react with an equimolar amount of $C_6H_5ICl_2$ in benzene at room temperature to form the phosphonium chlorides *(2)* (yield 70 to



(1) *(2)*

$$R^1\text{-}CHCl\text{-}CO\text{-}R^2 \quad (3)$$

95%). On treatment with dilute Na_2CO_3 solution at 0–25 °C, these compounds decompose into $(C_6H_5)_3PO$ and the α-chloro ketones *(3)* (50–90%). The ease with which the carbon skeleton is removed from the positive phosphorus atom is remarkable. / Tetrahedron *25*, 1871 (1969) / –Ma. [Rd 31 IE]

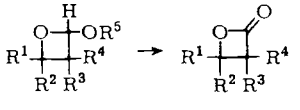


A new tetrahydropyran synthesis has been described by *P. R. Stapp.* α-Olefins condense with paraformaldehyde and hydrogen halide in a non-aqueous medium to give 3-alkyl-4-halogenotetrahydropyrans. The best yields (50–80%) are obtained at –70 to –60 °C and with HCl. Trioxane does not react

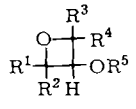
R = H, CH_3, n-C_3H_7, n-C_5H_{11}, n-C_7H_{15}, n-C_9H_{19}

under such conditions. Reaction probably proceeds, with participation of carbonium ions, *via* homoallyl alcohols, which cyclize with formaldehyde and acid. / J. org. Chemistry *34*, 479 (1969) / –Ma. [Rd 32 IE]

A new route for the synthesis of Cypridina luciferin and its analogs is described by *S. Inoue, S. Sugiura, H. Kakoi,* and *T. Goto*. α-Keto aldehydes can condense with 2-aminopyrazines in dilute HCl under mild conditions to give dihydroimidazopyrazinone derivatives. A solution of etioluciferin dihydrobromide *(1)* and racemic 1-formyl-2-methyl-1-butanone react in boiling aqueous methanol in the presence of HBr to give racemic luciferin dihydrobromide *(3)*, m.p.



(1) *(2)* *(3)*

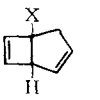


R^1 = 3-Indolyl; $R^2 = (CH_2)_3\text{-}NH\text{-}C(=NH)\text{-}NH_2$

252–253 °C in 70% yield (yield of pure product *ca.* 30%). The bioluminescence activity corresponds to that of the natural luciferin. The same synthesis can be applied to 2-aminopyridines: 2-aminopyridine and phenylglyoxal afford 2-phenylimidazo[1,2-*a*]pyridin-3-ol. / Tetrahedron Letters *1969*, 1609 / –Ma. [Rd 33 IE]

A new β-lactone synthesis is described by *S. H. Schroeter*. Reaction of photoexcited carbonyl compounds R^1R^2CO with vinyl or enol ethers $R^3R^4C{=}CH{-}O{-}R^5$ affords a mixture of 2- and 3-alkoxyoxetanes *(1)* and *(2)*, the product ratio depending primarily on the nature of the substituents R^3–R^5. In the presence of an excess of carbonyl compound, the amount of *(1)* decreases as the duration of irradiation increases since it reacts with the photoexcited carbonyl compound to give the β-lactone *(3)*. For example, 2-methoxy-,

(1) *(3)*

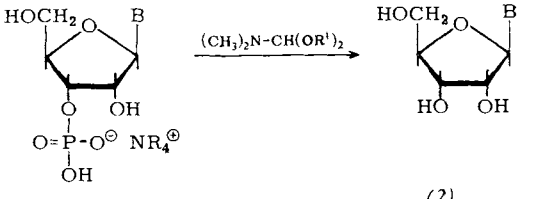


(3a), R^1-R^4 = CH_3

(2)

2-ethoxy-, 2-*n*-propoxy-, or 2-*n*-butoxy-3,3,4,4-tetramethyloxetane reacts with acetone giving tetramethyl-β-propiolactone *(3a)*, m.p. 131 °C. Compound *(3a)* (yield 37%) is obtained in one step, *e.g.*, by irradiation of methyl or *n*-propyl β,β-dimethylvinyl ether (0.2 mole) and acetone (1 mole) in acetonitrile with a 450 W Hg lamp; 29% of a 1:1 mixture of *(1)* and *(2)* is also formed. The β-lactone formation is of a general nature and probably proceeds *via* dehydrogenation at C-2 and subsequent decomposition of the resulting dialkoxy radical into an alkyl radical and the β-lactone. / Tetrahedron Letters *1969*, 1591 / –Ma. [Rd 34 IE]

Detection of the cyclobutadienocyclopentadienide ion *(2a)*, an antiaromatic molecule, has been accomplished by *R. Breslow, W. Washburn,* and *R. G. Bergman*. These authors first prepared the chlorodiene *(1b)* by reaction of *(1a)* with BCl_3 at –75 °C; when allowed to stand with $KOC(CH_3)_3$ in THF, *(1b)* loses HCl. The resulting *(2b)* dimerizes immediately. If *(1b)* is treated with $KOC(CH_3)_3$ in the presence of C_4H_9OD, the dimer is then formed in 40% yield; 65% of the product contained 2.0 atoms of D per molecule of dimer. The 60% of

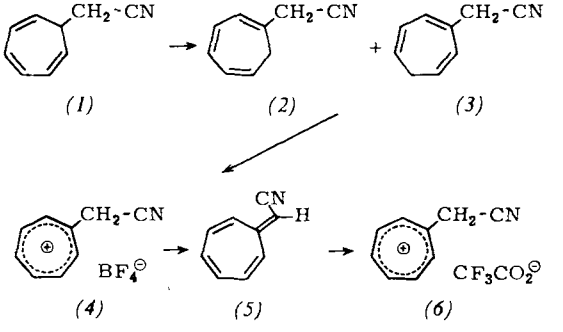


(1a), X = OCH_3
(1b), X = Cl

(2a), X = O
(2b), X = H
(2c), X = D

unchanged *(1b)* contained no deuterium; no H/D exchange occurs with the dimer. Addition of $[D_6]$-DMSO gives a product containing 100% of molecules having 2.0 atoms of D per molecule of dimer. The NMR spectrum of the dimer is in accord with the assumption that it is formed from *(2c)*. These facts appear to confirm the HMO prediction that *(2b)* and *(2c)* are readily converted into the anion *(2a)*. / J. Amer. chem. Soc. *91*, 196 (1969) / –Kr. [Rd 35 IE]

A new method for the dephosphorylation of ribonucleoside 2'- or 3'-phosphates is recommended by *J. Žemlička* and *S. Chládek*. The nucleotide is first converted into the tetra-*n*-butylammonium salt *(1)*, which is then dried and heated with dimethylformamide dimethyl or dineopentyl acetal in DMF. The nucleotide *(2)* can be obtained in very high yield from the mixture after it has been dried under vacuum, *e.g.*,



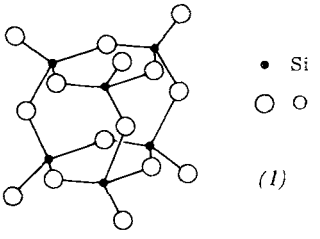
(+ 2'-Isomer)

(1) *(2)*

R = $n\text{-}C_4H_9$
R' = CH_3, $(CH_3)_3C\text{-}CH_2$

by paper chromatography. If the acetals mentioned are replaced, for example, by triethylamine and methanol the yields are reduced considerably. / Tetrahedron Letters *1969*, 115 / –Kr. [Rd 36 IE]

The synthesis of 8-cyanoheptafulvalene *(5)* has been accomplished by *M. Oda* and *Y. Kitahara* from 7-cyanomethylcycloheptatriene *(1)*, which was isomerized to *(2)* and *(3)* by



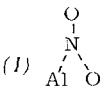
(1) *(2)* *(3)*

(4) *(5)* *(6)*

heating it to 140–150 °C. Treatment of this mixture with triphenylmethyl fluoroborate yielded the tropylium fluoroborate *(4)*, which exists as moderately stable, colorless, hygroscopic crystals of m.p. 108–109 °C (decomp.). Compound *(5)* could be obtained as a red liquid by reaction of *(4)* with triethylamine in CH_2Cl_2. According to the NMR spectrum, the protonated form *(6)* is present in trifluoroacetic acid. Compound *(5)* reacts with dimethyl acetylenedicarboxylate to give dimethyl 1-cyanoazulene-2,3-dicarboxylate, m.p. 175 to 176 °C. / Chem. Commun. *1969*, 352 / –Kr. [Rd 37 IE]

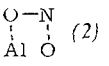
A new method for the production of titanium compounds having low iron content from ilmenite is given by *P. T. Joseph* and *P. M. Mathew*. In laboratory experiments, these authors oxidized the iron(II) of the ilmenite to iron(III) with air at temperatures above 1000 °C. The product is mixed with carbon and a catalyst (*e.g.* iodine) and heated to 700 °C in the absence of air. On heating to 500 °C with NH_4F, the cooled, powdered mass affords iron-free TiF_4. On chlorination in the presence of a little NaCl and iodine, $TiCl_4$ distills over at 200–250 °C. It contains less than 0.1 % of iron. The halogenation residue consists of iron carbide. / Chem. Commun. *1969*, 374 / –Kr. [Rd 38 IE]

A novel silicon-oxygen anion has been found by *Yu. L. Smolin* in $[Ni(NH_2{-}CH_2{-}CH_2{-}NH_2)_3]_3$, Si_6O_{15}, 26 H_2O, one of the few silicates that crystallizes from aqueous solution at room temperature. The most important components of the



(1)

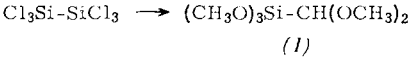
hexagonal crystals (space group $P6_3$, $a = 17.37 \pm 0.01$, $c = 15.18 \pm 0.01$ Å, $Z = 6$) are the $Ni(en)_3^{2+}$ cation and the novel anion $Si_6O_{15}^{6-}$ *(1)*. Bond angles and bond lengths are in the usual range. Cation and anion are joined by hydrogen bonds. / Chem. Commun. *1969*, 395 / –Kr. [Rd 39 IE]



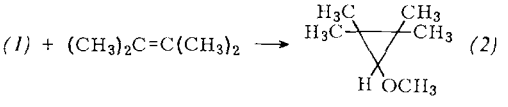
The oxidation of sulfur hexafluoride by oxygen has been studied by *B. Siegel* and *P. Breisacher*. These authors started the reaction of the highly inert SF_6 by explosion of electrically heated platinum or copper wire. Reaction of $\approx 9.7 \times 10^{-3}$ mole of SF_6, in which only 1.13 % of the starting material were consumed (conditions: 220–230 torr of SF_6, approx. equal partial pressure of O_2, 60 torr of Ar, 0.1 mg of Pt vaporized), yielded SOF_4, SOF_2, SO_2F_2, and SO_2 in the ratio 53:33:12:1.4. Under the same conditions, SF_4 reacts extremely rapidly with O_2 to give SOF_2 (major product), SOF_4, SO_2F_2, SO_2, and SF_6. The oxidation of SF_5Cl is also fast compared to that of SF_6; the main product is SOF_2. / J. inorg. nuclear Chem. *31*, 675 (1969) / –Kr. [Rd 40 IE]

The molecular geometry of tricarbonylcyclobutadieneiron, $Fe(CO)_3(C_4H_4)$, has been determined by *H. Oberhammer* and *H. A. Brune* by electron diffraction in the vapor phase. In agreement with the results of NMR measurements in liquid crystal solutions a square structure was found for the cyclobutadiene ring. The most important geometric parameters are: $C_{ring}{-}C_{ring}$ = 1.440 Å; $Fe{-}C_{ring}$ = 2.053 Å; $Fe{-}C_{carb}$ = 1.780 Å; $C_{carb}{-}O$ = 1.148 Å; $C_{carb}{-}Fe{-}C_{carb}$ = 98.1 °. The hydrogen atoms of the cyclobutadiene ring are bent about 8.6 ° towards the iron. The position of the carbonyl groups relative to the cyclobutadiene ring could not be ascertained; there is evidence of free rotation. / Z. Naturforsch. *24a*, 607 (1969) / –Hz. [Rd 43 IE]

The ESR spectrum of NO adsorbed on a Linde molecular sieve, Type 4A, has been investigated by *B. M. Hoffman* and *N. J. Nelson*. Two types of spectra are obtained, depending on the pre-heating temperature of the molecular sieve: after activation at *ca.* 300 °C, two signals appear in the spectrum; after activation at *ca.* 500 °C three signals occur; at intermediate heating-out temperatures both spectra are superposed. At 300 °C the NO is in an axially symmetric environment; in the case of a strongly heated sieve one can, by comparison of the ESR spectra of molecules that can be regarded as substituted NO radicals, exclude single bonding between



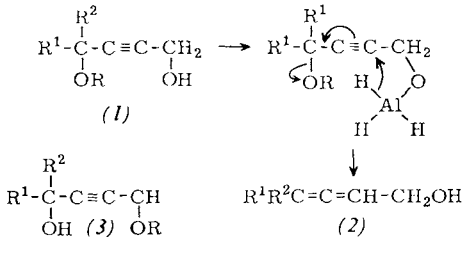
(1)



(2)

NO and surface. The adsorption models *(1)* and *(2)* are in accord with findings on strongly heated sieves. / J. chem. Physics *50*, 2598 (1969 / –Hz. [Rd 44 IE]

The formation of methoxycarbene $H(CH_3O)C$: on thermolysis (125 °C) of (dimethoxymethyl)trimethoxysilane *(1)* has been observed by *W. H. Atwell, D. R. Weyenberg*, and *J. G. Uhlmann*. In the reaction of hexachlorodisilane with methyl orthoformate, compound *(1)* was obtained in 20% yield along with bis(trimethoxysilyl)methoxymethane and tetramethoxysilane. The thermolysis of *(1)* in the presence of 2,3-dimethyl-2-butene yields almost quantitatively 3-methoxy-1,1,2,2-tetramethylcyclopropane *(2)* while the decomposition



(1)

(2)

of *(1)* in cyclohexene affords 7-methoxynorcarane in 48% yield. In *trans*-2-butene and *cis*-2-butene, 1-methoxy-*trans*-2,3-dimethylcyclopropane and *exo*/*endo*-1-methoxy-*cis*-2,3-dimethylcyclopropane were formed in 66 and 75% yields respectively. The reactions indicate the formation of methoxycarbene as intermediate. Methoxycarbene produced in this way reacts further with methanol, vinylsilanes, *etc.* / J. Amer. chem. Soc. *91*, 2025 (1969) / –Ma. [Rd 47 IE]

A new route for the synthesis of allene alcohols *(2)* is, according to *J. S. Cowie, P. D. Landor*, and *S. R. Landor*, afforded by elimination of tetrahydropyranyloxy residue from monotetrahydropyranyloxy derivatives *(1)* of 2-butyne-1,4-diols by reduction with $LiAlH_4$. Compounds *(1)* are readily accessible from 2-propyn-1-ols and dihydropyran and subsequent reaction with C_2H_5MgBr and CH_2O gas. For example: 4-(tetrahydropyran-2-yloxy)-2-heptyn-1-ol *(1a)* → 2,3-heptadien-1-ol *(2a)* 95% yield; *(1b)* → *(2b)*, 75% yield. This method is also suitable for the synthesis of terminal allene

(1) *(3)* *(2)*

(a), R = tetrahydropyran-2-yl, $R^1 = C_3H_7$, R^2 = H
(b), R = tetrahydropyran-2-yl, $R^1 = C_2H_5$, $R^2 = CH_3$

alcohols; in this case one starts from substituted 2-butyne-1,4-diols having a protected primary OH group *(3)*. / Chem. Commun. *1969*, 541 / –Ma. [Rd 48 IE]

Anorganische Chemie (Inorganic Chemistry). By *F. A. Cotton* and *G. Wilkinson*. Transl. from the American by *H. P. Fritz*. Verlag Chemie GmbH., Weinheim/Bergstr./ Interscience Publishers, New York-London 1968. 2nd Edit., xiv, 1066 pp., 292 illustrations, 145 tables. Plastic-cover DM 69.–.

The enthusiastic reception given to the German translation of *Cotton* and *Wilkinson*'s book "Advanced Inorganic Chemistry" is now confirmed by the fact that a second edition has become necessary after barely a year and a half. Since it is a new edition of a translation there have been no large alterations, but the opportunity has been taken to correct some misleading typographical errors in the first edition and also to make some additions to the references.

Naturally some things have been overlooked; for instance, the so-called γ-tin, whose existence has been refuted. Also the guidelines of the Nomenclature Commission have sometimes not been observed: for example, in the Periodic Table the element 103 is given the symbol Lw whereas the symbol Lr was recommended by IUPAC three years ago; further, the name "zircon" should be reserved for the mineral and the element should be called "zirconium". In the structural chemistry section the reader may be led to false conclusions where on page 42 it is stated that cesium chloride, zinc sulfide, and rutile structure types are representatives of "typical important ionic lattices", whereas these structure types include numerous compounds of both mainly metallic and mainly covalent valence type.

Since this book is certainly not intended for first year students, it would have been worthwhile to express this in the title. Although the text has been translated literally and German idiom suffers occasionally in consequence, literal translation of the title has been avoided: "Advanced Inorganic Chemistry" could have been rendered by, *e.g.*, "Vertiefte Anorganische Chemie".

These few remarks should, however, not be taken as serious criticism of the arrangement, content, or presentation. The new edition can be expected to enjoy the same favor as was given to the first edition of this excellent book.

V. Gutmann [NB 806 IE]

Analyse von Mineral- und Syntheseölen mit radiometrischen Methoden (Analysis of Mineral Oils and Synthetic Oils by Radiometric Methods). By *G. Brunner*, *E. Dahn*, and *M. Geisler*. Akademie-Verlag, Berlin, 1968, xii + 225 pp., 40 figures, 38 tables, DM 21.–.

This book surveys the radiometric methods applicable in the analysis of mineral and lubricating oils. The radiometric determination of hydrogen is particularly useful, partly because the hydrogen content of hydrocarbons is correlated with many important industrial characteristics, and partly because the conventional determinations of hydrogen are too involved for routine petrochemical plant control. Nearly half of the book therefore deals with the determination of hydrogen. By contrast, only about 50 pages are devoted to the determination of sulfur, which is perhaps even more important (catalysis in the petroleum industry, quality of fuels, lubricating oil additives), the reason being that only low-energy irradiation can be used here. However, the procedure can be extended to other elements such as chlorine.

The authors also discuss neutron activation analysis, which is sometimes very sensitive, and is used mainly to determine traces of metals such as V, Ni, Cu, Mn, Mo, Cr, Zn, and Au in mineral oil, and to determine oxygen and additives in lubricating oils. X-ray fluorescence analysis has also been used for years to determine metals and additives in oils. The fourth part of the book deals with the use of radionuclides as sources of exciting radiation instead of X-ray tubes, and gives a description of the method modified accordingly.

Each chapter starts with the physical basis of the technique discussed. This is followed by the description of the procedure and the evaluation of the method. Then comes a discussion of commercial equipment and related problems. Radiometric methods are compared with one another and with conventional methods in connection with experimental publications and selected analyses. This part greatly benefits from the use of instructive tables. Each chapter ends with a bibliography. While no detailed analytical procedures are given, this book will be of great help in the choice of fast, nondestructive, contactless methods for the analysis of mineral and synthetic oils.

B. Knoll [NB 813 IE]

Radiochemisches Lexikon der Elemente und ihrer Isotope. Wichtige Eigenschaften und Anwendungen. (Radiochemical Dictionary of the Elements and their Isotopes. Important Properties and Uses). By *M. Haïssinsky* and *J. P. Adloff*. Translated from the English by *Peter Mayer*. Ferd. Dümmlers Verlag, Bonn-Hannover-München 1968. 1st Edit., 229 pp., stitched DM 19.–.

Radiochemical textbooks usually contain a considerable quantity of theory on radioactive decay, nuclear reactions, *etc.* A detailed description of the nuclear properties of the elements is understandably avoided as a collection of largely repetitive facts.

The practical industrial scientist, to whom a knowledge of the radiochemical properties of an element is a prime necessity for the solution of special problems, has until now had only the nuclide cards for reference. To be able to extract all the necessary information from these, however, detailed radiochemical knowledge is essential. This gap has now been filled by the present dictionary with a somewhat dry but, for the practical worker, very useful account of the nuclear data for all the elements up to atomic number 104. The book is a sort of supplement to radiochemical textbooks, and should be particularly useful to practical workers and engineers.

F. Baumgärtner [NB 803 IE]

Grundbegriffe der Kybernetik (Fundamental Concepts of Cybernetics). By *H.-J. Flechtner*. Wiss. Verlagsgesellschaft mbH, Stuttgart 1969. 4th Edit., xi + 423 pp., 152 figs., stitched; DM 40.–.

This is already the fourth edition of this book, which was first published in 1966. The good reception given to it can be seen from the fact that the third edition sold out in a few months. The new edition differs only by "minor changes", and it still has 423 pages.

This is an introduction to Cybernetics, but not in the same sense of the word as used in the titles of textbooks. Instead, it is intended for those "who are interested in Cybernetics, but lack the mathematical and technical prerequisites for studying it as a branch of science". The indispensible mathematics is at secondary-school level.

In the first chapter entitled "What is Cybernetics?", in which the historical aspects are dealt with, the author gives the answer: "Cybernetics is the general, formal science of structure, relationships, and the behavior of dynamic systems". The fundamental concepts of general Cybernetics are then discussed under the following headings: Communication (behavior of systems, effect of information, control, *etc.*); Information (signs, codes, signals, combinations, redundance, *etc.*); Transmission of Information (sources, channels, decoders, receivers, stores, *etc.*); Processing of Information (connections, cybernetic models and machines, *etc.*); and Behavior of Systems (learning and thinking in the cybernetic sense, regulation, *etc.*). Interesting illustrations are taken from special Cybernetics (*e.g.* theory and construction

of computers, learning machines, and biological and sociological models) and from applied Cybernetics (application of cybernetic concepts, methods, and knowledge to *e.g.* Physics, Chemistry, Biology, Physiology, Medicine, and Sociology). The reader is greatly aided by the inclusion of many references and a subject index.

Theory-of-science considerations complete the description of Cybernetics as a fundamental and as an "auxiliary science, which resembles mathematics in the role it plays in natural sciences".

H. Weber [NB 800 IE]

Transition Metal Intermediates in Organic Synthesis. By *C. W. Bird.* Logos Press – Academic Press, London-New York, 1967, 1st Edit., vii + 280 pp., many illustrations and tables, $ 13.00.

The author, who is a lecturer in Chemistry at Queen Elizabeth College, University of London, has written this book mainly for Organic Chemists, informing them of the many preparations made possible by transition metal intermediates. A variety of topics, such as the oligomerization of acetylenes and olefins, hydroformylation, and hydrogenation, is treated in such a way that the result is a comprehensive literature survey combined with connective passages. The fact that both Russian literature and the patent literature are also covered deserves praise. This book is valuable to all chemists using transition metal compounds in organic syntheses. On the other hand, the superabundance of the material may frighten many uninitiated Organic Chemists from reading and utilizing this book.

The main advantages of organic syntheses with the aid of transition metal compounds are not specified clearly, and they are often submerged in a multitude of apparently anarchic reactions. Despite the price and the fact the literature is covered only up to 1966, this book can be recommended to those who are specialists in this field. Organic Chemists wanting to learn about this new branch of preparative organic chemistry, however, may find the book too expensive for what they can derive from it.

P. Heimbach [NB 815 IE]

Problems for Introductory University Chemistry (With Complete Solutions). By *J. N. Butler, B. A. Dunell,* and *L. G. Harrison.* Addison-Wesley Publ. Comp., London 1967. 1st Edit., vii, 213 pp., 22 s.

The present book contains problems in stoichiometry and important fields of physical chemistry, as well as exercises from analytical and inorganic chemistry. It is intended mainly for beginners, and contains, *inter alia,* problems on fundamental laws of thermodynamics and electrochemistry, *e.g.* on the applications of the *Clausius-Clapeyron, van't Hoff,* and *Nernst* equations. The problems set can be solved on the basis of an elementary knowledge of algebra. Solutions to all the problems are given at the end of the book, which is therefore particularly suitable for private study. A total of 241 problems are given in 13 chapters. A guide to the solution of the problems set in each section is provided in the Appendix. This book can be recommended without reservation as excellently suited for the introduction of students to the quantitative relations of chemistry. The teacher will also find it a useful source of problems for practice and for tutorials. The book is therefore warmly recommended to both students and teachers.

A. Haas [NB 796 IE]

Extrusion Reactions. By *B. P. Stark* and *A. J. Duke.* Pergamon Press, Oxford 1967, 1st Edit., x, 190 pp., numerous figures, 63 s.

In view of the rapidly growing volume of facts in organic chemistry, any attempt to systematize organic reactions seems very sensible and worthwhile. "Extrusion Reactions" is therefore very welcome from this point of view.

Extrusion reactions are processes in which part of the ring of an organic compound is removed as a small, usually inorganic, fragment (CO, CO_2, SO_2, oxygen, sulfur, nitrogen, *etc.*), with formation of a cyclic end product, the ring system of which is smaller or less condensed than that of the starting compound.

A classification of extrusion reactions is followed by the discussion of the experimental results in sections arranged as far as possible according to the fragment removed. Numerous literature data are included; however, evaluation of the aldol-like addition of diazocarbonyl compounds to di- and triketones would have been welcomed in Chapter 10, which deals with the problem of the formation of 1,2,3-oxadiazolines (from diazo compounds and ketones) and the removal of N_2 therefrom.

Otherwise this stimulating book can be wholeheartedly recommended to those involved in research in this direction.

M. Regitz [NB 798 IE]

Marine Chemistry. Vol. 1: Analytical Methods. By *D. F. Martin,* Marcel Dekker Inc., New York 1968, 1st Edit., viii + 280 pp. with many illustrations and tables, $ 5.75.

This book deserves attention, because it gives very clear and logical schemes for analysis. The author has thought of everything, including many tips for avoiding difficulties. However, it is not only a very good "cookbook", but also contains many chapters on general subjects, such as the analysis of polluted water. In addition, the instructions are preceded by a general discussion of analytical possibilities and of interference encountered in analysis. This book requires no specialized knowledge, and seems particularly suitable for training nonchemists in the analysis of water. The main stress is on the analysis of the most important substances featuring in the routine analysis of water, carried out mainly by the latest variants of the conventional methods. Many points can be applied to the analysis of freshwater as well. There is also a brief discussion of the more complicated methods such as atomic absorption spectroscopy and the measurement of bioproduction with ^{14}C.

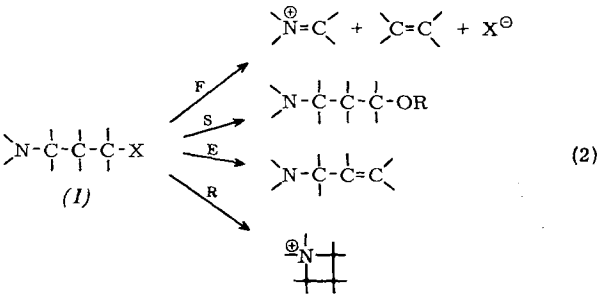
Mechanisms and Stereochemistry of Heterolytic Fragmentation

By C. A. Grob[*]

Heterolytic fragmentation can proceed by several mechanisms. A study of the solvolysis of γ-aminoalcohol derivatives N–C–C–C–X, where X equals halogen or –OSO_2R, shows that fragmentation may occur by a one-step mechanism or by several multi-step mechanisms depending on structural, electronic, and steric factors. The one-step synchronous mechanism has rigorous stereoelectronic requirements. It is associated with an increased reaction rate as evidenced by the "frangomeric" effect. Ketoxime derivatives RR'C=N–X may undergo Beckmann fragmentation by the synchronous mechanism or by prior rearrangement depending on their α-substituents. Fragmentation is frequently accompanied by conventional substitution, elimination, and rearrangement reactions. Under such circumstances knowledge of all possible mechanisms of a given substrate is essential to bring about a desired transformation.

1. Introduction

Heterolytic fragmentation is a widely occurring type of reaction in organic chemistry[1]. Molecules containing certain combinations of carbon and hetero atoms, such as O, N, S, P, and halogens, undergo a regulated cleavage (fragmentation) into three fragments[2]. In the general formulation of equation (1)



$$a\text{–}b\text{–}c\text{–}d\text{–}X \rightarrow a\text{–}b + c{=}d + :X \qquad (1)$$

a–b denotes an electrofugal group[3], which leaves as the fragment a–b without the bonding electron pair. The middle group –c–d affords the unsaturated fragment c=d, while the nucleofugal group[3] –X leaves in the form of a fragment :X with the bonding electron pair. A number of these groups, combinations of which lead to the principal classes of fragmentable compounds[1], are listed in Table 1.

Table 1. Groups leading to heterolytic fragmentation.

Electrofugal groups a–b	Middle groups –c–d	Nucleofugal groups –X
HO–CR_2	–CR_2–CR_2	–Cl
RO–CR_2	–CR=CR	–Br
HOOC	–CR_2–NR	–I
R_2N–CR_2	–CR_2–O	–SO_3R
R_3C	–CO–O	–OCOR
RCO	–N=N	–$OH_2^{\oplus}$
$R_2\overset{\ominus}{C}$–CR_2	–CO	–$NR_3^{\oplus}$
H_2N–NH		–$SR_2^{\oplus}$
HN=N		–$N_2^{\oplus}$

Of the many fragmentation reactions known, only a few have to date been subjected to mechanistic and stereochemical studies. Probably the most fundamental investigation of this type has been carried out with

(2)

F = fragmentation, S = substitution, E = elimination, R = ring closure

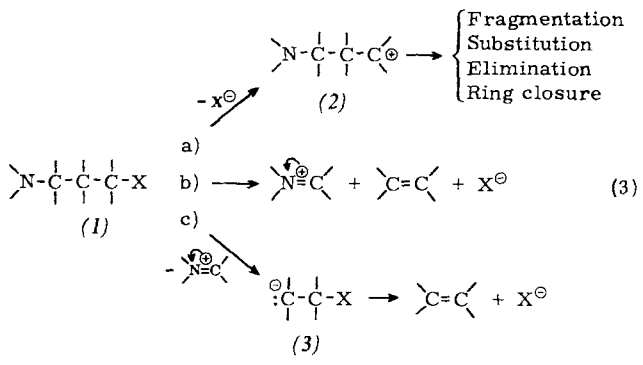
γ-aminohalides and γ-aminosulfonates (1) (X = halogen or $-OSO_2R$), fragmentation of which leads to an imonium salt and an olefin [eq. (2), route F]. These compounds are obtainable in acyclic, monocyclic, and bicyclic variants, though often only by rather involved syntheses. Compounds of the type (1) react directly in aqueous and alcoholic solutions. Since the courses and rates of their reactions can be readily determined, they are particularly suitable for the study of heterolytic fragmentation.

Similarly certain ketoxime derivatives and their α-amino derivatives, fragment in polar solvents into nitriles and carbonium or imonium ions (see Section 10)



2. Review of the Reaction Paths of the System N–C–C–C–X

Amines *(1)* with nucleofugal substituents in the γ position can react in several ways. In addition to fragmentation into an imonium salt and an olefin [path F in eq. (2)], at least three other reaction paths are possible. In nucleophilic solvents, such as water or alcohols, they can undergo substitution (S) and elimination (E) as well as ring closure (R) to form an azetidinium salt. Examples will be given to show that the course of the reaction depends on the structure, configuration, and conformation of the substrate. The mechanism (and hence the products formed) thus depends on steric as well as electronic factors.

3. The Three Basic Mechanisms

Though the structural and electronic requirements and the number of bonds broken are the same in all fragmentations in accordance with eq. (1), the sequence with which bond rupture occurs may be different. The process may thus take place in one or two steps, *i.e.* the fragments a–b and –X may be released from the central group –c–d either simultaneously or successively. For amines *(1)* with nucleofugal substituents in the γ position, three basic mechanisms are therefore possible [eq. (3)]. These are the one-step process (b) and two-step processes (a) and (c), all of which follow the first order kinetic law.

The two-step process (a) begins with the loss of the nucleofugal group –X to form a γ-amino carbonium ion *(2)*. This then breaks down in a faster step into an imonium ion and an olefin, thus completing the fragmentation. The cationic intermediate *(2)* may, however, react further by substitution, elimination, and ring closure.

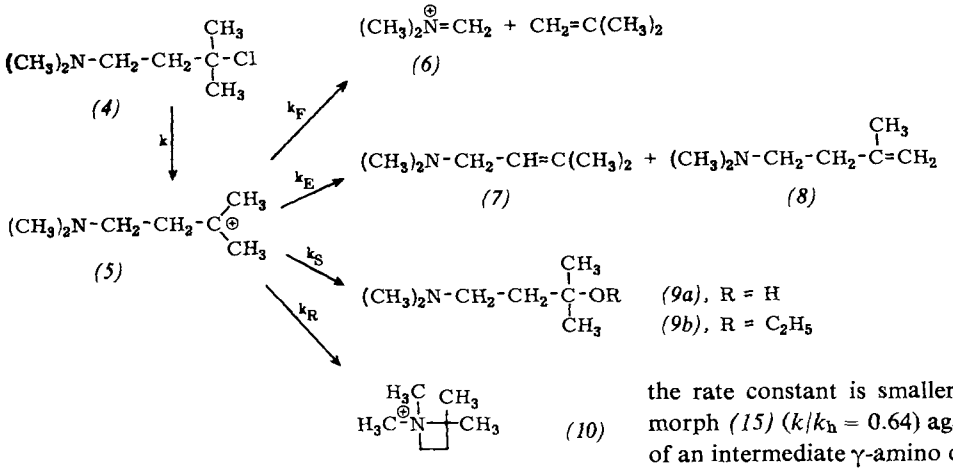
(3)

In the one-step or synchronous process (b), the electrofugal imonium ion and the nucleofugal group –X leave simultaneously from C_β and C_α, respectively. In the third case (c), the imonium ion leaves first. The remaining carbanion (3) is stabilized by conversion into an olefin and $X^\ominus$ or by protonation.

These three basic mechanisms have certain structural and stereo-electronic requirements, and may be compared to the three known mechanisms of 1,2-elimination to form olefins [4]. In the elimination, however, a hydrogen or halogen atom is split off as an electrofugal species by an external base or reducing agent, whereas in fragmentation a polyatomic group leaves spontaneously [eq. (1)].

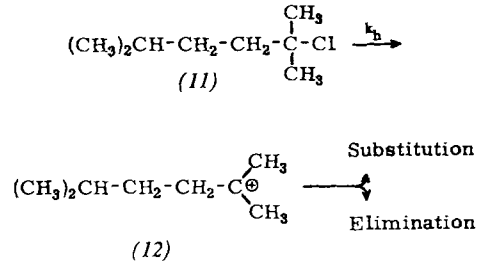
The two-step fragmentation mechanism (a) and the synchronous mechanism (b) have been detected in many cases. The rare two-step mechanism (c) was only recently confirmed by experiment.

4. The Two-Step Carbonium Ion Mechanism



The rate-determining step in this mechanism is the ionization to form a carbonium ion [path (a) in eq. (3)]. It is thus identical with that of unimolecular substitution (S_N1) and elimination (E1) [4]. As in these cases, the tendency to ionize is greatest when a tertiary, and hence particularly stable, carbonium ion is formed. This applies *e.g.*, to 3-chloro-*N*,*N*,3-trimethylbutylamine *(4)* [5].

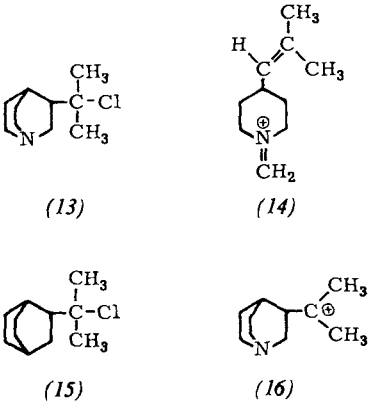
The reaction of this compound in 80 vol-% ethanol [6] leads to 38% of fragmentation products, *i.e.* isobutene together with dimethylamine and formaldehyde, the latter arising from hydrolysis of the imonium ion *(6)*. In addition 37% of the aminoolefins *(7)* and *(8)* are formed by elimination, 23% of the alcohol *(9a)* and of the ethyl ether *(9b)* by substitution, and 2% of the azetidinium ion *(10)* by ring closure. The product ratio is almost unchanged when the bromide or



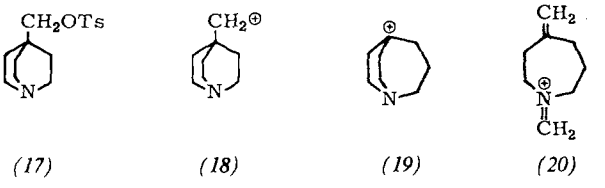
[4] *C. K. Ingold*: Structure and Mechanism in Organic Chemistry. Cornell University Press, Cornell 1953, p. 419ff; J. chem. Soc. (London) *1962*, 265.

[5] *C. A. Grob* and *F. Ostermayer*, Helv. chim. Acta *45*, 1119 (1962); *C. A. Grob*, *F. Ostermayer*, and *W. Raudenbusch*, *ibid. 45*, 1672 (1962).

[6] Except where otherwise specified, the reactions described in this article were carried out in 0.01–0.001 M solution in 80 vol.% ethanol.



iodide corresponding to *(4)* is used (for example, the bromide gave 40% of fragmentation products, the iodide 42%). The reaction rate, on the other hand, increases in the order customary for ionization reactions, *i.e.* Cl < Br < I. These observations indicate that the rate-determining step k leads to the formation of the γ-aminocarbonium ion *(5)*, which reacts further in fast secondary steps k_F, k_E, k_S, and k_R.



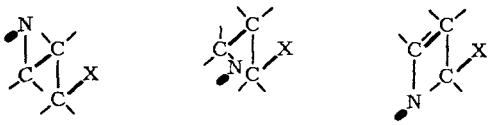
Further support of this mechanism is provided by a comparison of the rate constants for the γ-chloroamine *(4)* with those for the sterically equivalent *i.e.* homomorphous chloroalkane *(11)*. Tertiary chloroalkanes of this type are known [4] to react *via* carbonium ions *(12)* under solvolytic conditions. The comparison of the rate constants k of *(4)* and k_h of *(11)* provides information about the possible participation of the nitrogen atom in the ionization step. If it does not participate, k should be equal to or smaller than k_h ($k/k_h \leq 1$). If, however, the ionization of the γ-chloramine is favored by the nitrogen atom, the chloroamine should react more rapidly than the homomorphous chloroalkane ($k/k_h > 1$).

The ratio of the rate constants of the compounds *(4)* and *(11)* is 0.52 at 25 °C. Thus the only effect of the nitrogen atom is its electron-withdrawing inductive effect which causes the γ-chloroamine *(4)* to react more slowly than its homomorph, *i.e.* the ionization to give the carbonium ion *(5)* is more difficult.

Another example of the two-step carbonium ion mechanism is provided by 3-(chlorodimethylmethyl)-quinuclidine *(13)*, which reacts to give 62% of the fragmentation product *(14)* together with 30% of substitution products and 6% of elimination products [7]. The formation of several products and the fact that the rate constant is smaller than that of the homomorph *(15)* ($k/k_h = 0.64$) again point to the formation of an intermediate γ-amino carbonium ion, *i.e. (16)* in the rate-determining step.

A fragmentable γ-amino carbonium ion can also be produced by rearrangement of an amine with a nucleofugal substituent in the δ position. Thus the ionization of the *p*-toluenesulfonyl ester *(17)* leads to the primary carbonium ion *(18)*, which undergoes a Wagner-Meerwein rearrangement into the bicyclic γ-amino carbonium ion *(19)*, the precursor of the fragmentation product *(20)* [8].

5. The Synchronous Mechanism



Since five atomic centers of one molecule are involved in the transition state it was expected that this mechanism would have rigorous structural and stereoelectronic requirements. Thus the synchronous mechanism should operate only if both the C_α–X bond and the orbital of the lone pair of electrons on the nitrogen (N-electron pair) are *anti* and parallel anti-periplanar [9] to the C_β–C_γ bond.

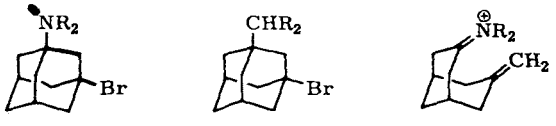
These conditions are satisfied by the staggered conformation *(21)*, and by all rotamers derived from it by rotation of the amino group about the C_β–C_γ

[7] *H. G. Enderle*, Dissertation, Universität Basel 1967.

[8] *C. A. Grob*, *R. M. Hoegerle*, and *M. Ohta*, Helv. chim. Acta *45*, 1823 (1962).

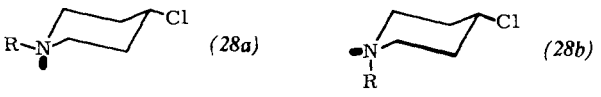
[9] *W. Klyne* and *V. Prelog*, Experientia *16*, 521 (1960).

(21) (22) (23)



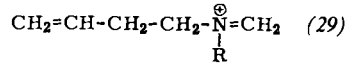
(24)

bond. Two rotamers of this type are the skew *(22)* and the eclipsed conformation *(23)*. Only such conformations permit maximum overlap of the p orbitals of the sp^2-hybridized atoms formed in the unsaturated fragments in the transition state *(24)*. Rotations about the $C_\alpha-C_\beta$ and $C_\gamma-N$ bonds, on the other hand, lead to energetically less favorable transition states with the result that the synchronous process is suppressed. However, the stereoelectronically favorable conformations are not always the sterically most favorable ones as *e.g.* the eclipsed form *(23)*.



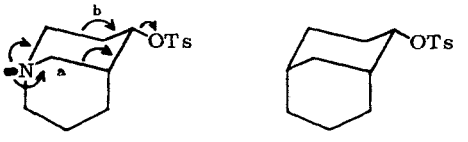
The synchronous mechanism can be detected mainly on the basis of kinetic criteria. The positive charge formed on the cation in the ionization process is transferred to the relatively stable imonium ion. Therefore N–C–C–C–X systems that undergo synchronous fragmentation react more rapidly than homomorphous compounds without nitrogen, in which the positive charge remains localized on the C_α atom. A k/k_h ratio greater than 1 thus indicates the participation of the amino group and points to a synchronous process.

Another kinetic criterion for the participation of this group is provided by comparison of the rate constants for γ-nucleofugally substituted amines, in which the substituents R on the N atom are varied. Since the amino group acquires the positive charge in the transition state *(24)* of the synchronous fragmentation, the reaction rate must depend on the number and nature of these substituents.



(25) (26) (27)

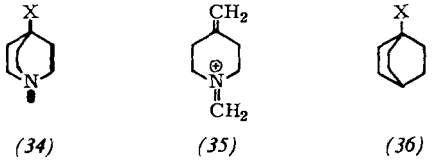
3-Bromoadamantylamines *(25)* (R = H or CH_3) react faster than the homomorphous 1-alkyl-3-bromoadamantanes *(26)* (R = H or CH_3), and undergo quantitative fragmentation with formation of the imonium salts *(27)* [10]. As the number of methyl groups on the nitrogen atom is increased, the absolute and relative rates with respect to the homomorphs *(26)* increase. Thus k/k_h is 30 for the primary amine, 222 for the secondary amine, and 520 for the tertiary amine. The increase in the reactivity with the number of *N*-methyl substituents corresponds to the increasing electromeric effect of the amino group, as also observed in the electrophilic substitution of aniline derivatives. The atoms taking part in the synchronous fragmentation have the staggered conformation *(21)* and so satisfy the antiparallelism principle mentioned above. (The antiparallel electron pairs are indicated by bold type.)



(28a) (28b)

(29)

4-Chloropiperidine and its *N*-alkyl derivatives *(28)* react about 100 times as rapidly as chlorocyclohexane, with quantitative fragmentation to give the imonium ions *(29)* [11]. When the N-electron pair assumes the equatorial position *(28b)*, these compounds *(28)* have the skew conformation *(22)*. However, in the conformational equilibrium *(28a)* ⇌ *(28b)* the population of the less favorable form *(28a)* (N-electron pair in the axial position) will increase with the size of the substituent R. This is the only explanation for the fact that 4-chloropiperidine *(28)* (R = H) reacts somewhat faster than the *N-tert*-butyl derivative *(28)* [R = $C(CH_3)_3$].



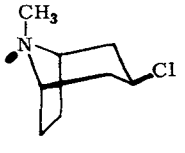
(30) (31)

(32) (33)

The more rigid *exo*-4-*p*-toluenesulfonyloxy-1-azabicyclo[3.3.1]nonane *(30)*, which reacts 16 times as fast as the homomorphous *exo*-2-*p*-toluenesulfonyloxybicyclo[3.3.1]nonane *(31)*, has the same conformation as *(28b)*. It is interesting to note that the reaction of *(30)* leads exclusively to the relatively strained imonium ion *(32)* of the *cis*-1-aza-4-cyclooctene (path a), and none of the imonium ion *(33)* of the 3-vinylpiperidine (path b) is formed [12]. The preferred formation of the thermodynamically less stable product *(32)* is difficult to explain, since paths a and b are stereoelectronically equivalent.

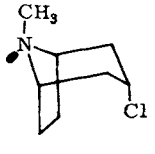
(34) (35) (36)

[10] *C. A. Grob* and *W. Schwarz*, Helv. chim. Acta *47*, 1870 (1964).



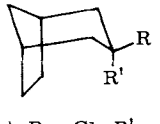
[11] *R. D'Arcy*, *C. A. Grob*, *T. Kaffenberger*, and *V. Krasnobajew*, Helv. chim. Acta *49*, 185 (1966).

[12] *T. Kaffenberger*, Dissertation, Universität Basel 1966.

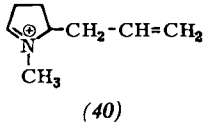


The eclipsed conformation *(23)* is present in the 4-halogeno- and 4-*p*-toluenesulfonyloxyquinuclidines *(34)* (X = halogen or OTs). These compounds undergo quantitative fragmentation at different rates, with formation of the 1,4-dimethylenepiperidinium ion *(35)*. The reaction rates are extremely high in comparison with those of the homomorphous 1-substituted bicyclo[2.2.2]octanes *(36)*. Thus 4-bromoquinuclidine *(34)* (X = Br) reacts about 50000 times as fast as 1-bromobicyclo[2.2.2]octane *(36)* (X = Br), even though bridgehead halides are normally very inert It is worthy of note that the ratio of the rate constants of the *p*-toluenesulfonate and of the bromide k_{OTs}/k_{Br} is approximately 10^3 in both systems It must therefore be concluded that the rupture of the C–X bond is advanced to the same degree in the transition state in both cases [13], despite the fact that the homomorphs *(36)* give a localized carbonium ion whereas the 4-substituted quinuclidines lead to a cation with a delocalized charge.

6. Stereochemistry and Mechanism

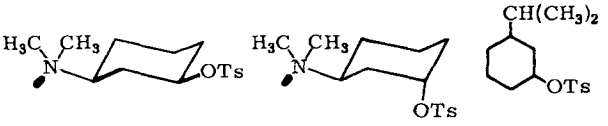


The examples in Section 5 show that systems that satisfy the antiparallelism principle undergo synchronous fragmentation. This does not, however, prove that the aforementioned stereochemical conditions are essential. Such proof can be obtained by a comparison of the reactivity of two stereoisomers only one of which satisfies the stereoelectronic conditions. The form that does should fragment by the synchronous mechanism, while its stereoisomer should react by the two-step carbonium ion mechanism. In the latter case, therefore, fragmentation should be accompanied by conventional reactions, *i.e.* by substitution, elimination, and ring closure, in accordance with path (a) in eq. (3).

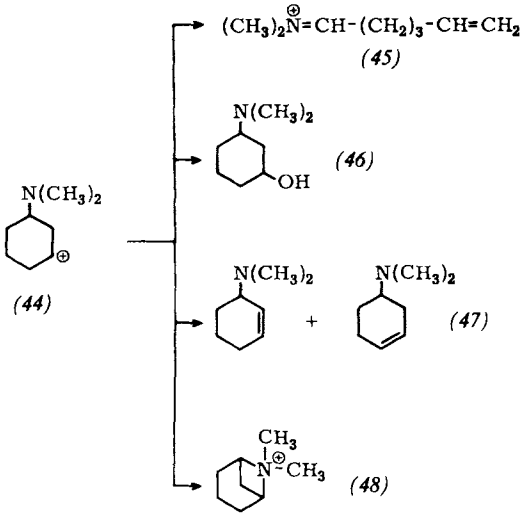


(37)

(38)



(39a), R = Cl, R' = H'
(39b), R = H, R' = Cl



(40)

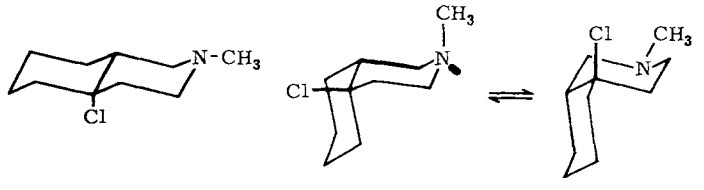
This hypothesis can be checked with the aid of the stereoisomeric 3-chlorotropanes *(37)* and *(38)*. The 3β-chloride *(37)* contains the skew conformation *(22)*, and should thus fragment by the synchronous mechanism, not however the 3α-chloride *(38)*, since its C–Cl bond is not antiparallel to the C_β–C_γ bond. It is in fact found that the 3β-chloride reacts 13500 times as fast as the homomorphous *exo*-3-chlorobicyclo[3.2.1]-octane *(39a)*, and gives only the fragmentation product *(40)*. The 3α-chloride, on the other hand, does not react appreciably faster than the homomorph *(39b)*, and gives only substitution and elimination products [14].

(41) *(42)* *(43a), cis* *(43b), trans*

A similar situation is found for the stereoisomeric 3-dimethylaminocyclohexyl *p*-toluene sulfonates *(41)* and *(42)* [15]. The *cis* form *(41)*, which satisfies the stereoelectronic requirements, reacts 39 times as fast as the homomorphous *cis*-3-isopropylcyclohexyl *p*-toluenesulfonate *(43a)*, with quantitative fragmentation to form the imonium ion *(45)*. The *trans* form *(42)*, on the other hand, reacts more slowly than the homomorphous *trans*-3-isopropylcyclohexyl *p*-toluenesulfonate *(43b)* (k/k_h = 0.64) and yields the expected products of the γ-amino carbonium ion *(44)*, *i.e.* the fragmentation product *(45)*, the *cis* and *trans* forms of the amino alcohol *(46)*, the aminoolefins *(47)*, and the bicyclic ion *(48)*.

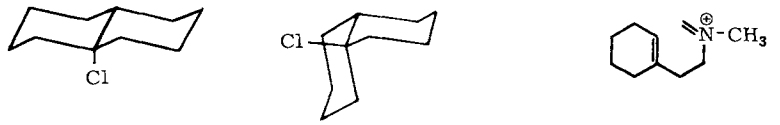
(44) *(45)* *(46)* *(47)* *(48)*

The influence of configuration on the reaction course is very pronounced in the case of the stereoisomeric 10-chloro-*N*-methyldecahydroisoquinolines *(49)* and *(50)* [16]. Whereas the *trans* isomer is fixed in the rigid double chair conformation *(49)*, the *cis* isomer is an equilibrium mixture of the conformers *(50a)* and *(50b)*. The position of the chlorine atom favors synchronous fragmentation only in the form *(50a)*, but not in the conformation *(50b)* or in the *trans* isomer *(49)*.



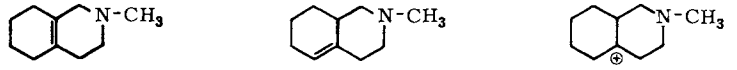
As expected *cis*-10-chloro-*N*-methyldecahydroisoquinoline *(50)* reacts about 128 times as fast as the

[13] *C. H. DePuy* and *C. A. Bishop*, J. Amer. chem. Soc. *82*, 2535 (1960); *H. M. R. Hoffmann*, J. chem. Soc. (London) *1965*, 6753.



[14] *A. T. Bottini, C. A. Grob, E. Schumacher*, and *J. Zergenyi*, Helv. chim. Acta *49*, 2516 (1966).

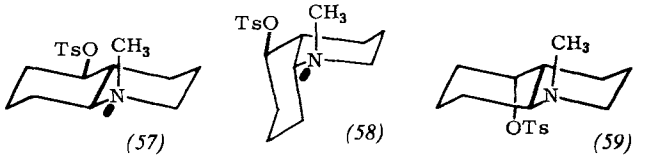
[15] *U. Burckhardt, C. A. Grob*, and *H. R. Kiefer*, Helv. chim. Acta *50*, 231 (1967).



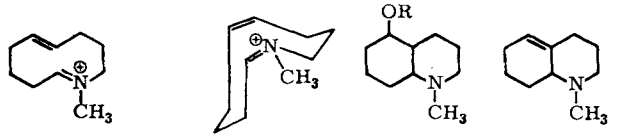
[16] *C. A. Grob, R. A. Wohl*, and *M. Geisel*, unpublished results.

(49) (50a) (50b)

(51) (52) (53)

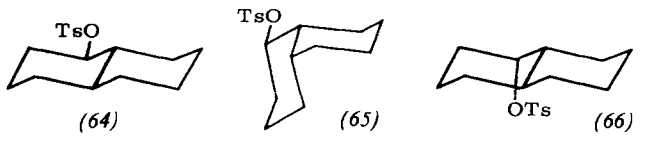


(54) (55) (56)



homomorphous *cis*-9-chlorodecalin *(52)*, with exclusive fragmentation to give the imonium ion *(53)*. The reaction of the *trans* isomer *(49)*, however, is slower by a factor of 4.5 than that of the homomorph *(51)*, and leads to the imonium salt *(53)* besides the olefins *(54)* and *(55)*. [The reasonable assumption is made that the absence of a methyl group on C-3 of the homomorphs *(51)* and *(52)* has little or no effect on their reaction rates.] Thus the *cis* isomer *(50)* must undergo synchronous fragmentation, while the *trans* isomer *(49)* fragments in two steps *via* the carbonium ion *(56)*. The *trans* homomorph *(51)* significantly gives the corresponding olefins, *i.e.* 1,2,3,4,5,6,7,8- and 1,2,3,4,4a,5,6,7-octahydronaphthalenes [CH_2 instead of NCH_3 in *(54)* and *(55)*]. The example *(50)* shows further that γ-halogeno amines react by the synchronous mechanism even when they give rise to stable tertiary carbonium ions.

The high stereospecificity of the synchronous fragmentation is even more clearly demonstrated in the case of the three stereoisomeric *N*-methyldecahydroquinol-5-yl *p*-toluenesulfonates *(57)*, *(58)*, and *(59)* [17]. Of these only the 5α-*trans* *(57)* and the 5α-*cis* isomers *(58)* with equatorial *p*-toluenesulfonyloxy groups exhibit the theoretically necessary antiparallelism of the electron pairs involved, while the 5β-*trans* isomer *(59)* does not. The two compounds *(57)* and *(58)* are in fact found to undergo exclusive fragmentation to give the unsaturated ten-membered imonium ions *(60)* and *(61)* (or their hydrolysis products). Whereas the *trans* olefin *(60)* is formed in the first case, the *cis* olefin *(61)* is obtained in the second. That these are synchronous processes is apparent from the fact that the reaction rates are higher for the compounds *(57)* and *(58)* than for the homomorphous 1-decalyl *p*-toluenesulfonates *(64)* and *(65)*.



The 5β-*trans* *p*-toluenesulfonate *(59)*, on the other hand, reacts more slowly by a factor of about 8 than the homomorphous 1-decalyl *p*-toluenesulfonate *(66)*, *i.e.* $k/k_h = 0.12$. Since only the substitution and elimination products *(62)* and *(63)* are formed, this reaction must proceed by the two-step carbonium ion mechanism.

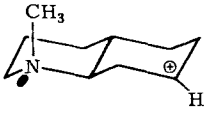
(57) (58) (59)

(60) (61) (62) (63)

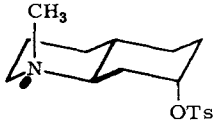
(64) (65) (66)

The steric orientation of the N-electron pair has not been considered so far. Instead it has been tacitly assumed that because of the fast inversion of the nitrogen atom, this electron pair can adopt the antiparallel orientation required for the synchronous mechanism. The compounds *(57)* and *(58)*, as well as the *N*-methylamines mentioned earlier that undergo synchronous fragmentation, were formulated accordingly, though it must be assumed that the *N*-methyl group will more often occupy the equatorial position. The following study on the 7α- and 7β-*trans*-1-methyldecahydroquinolyl *p*-toluenesulfonates *(67)* and *(68)* is of particular interest with respect to the influence of the orientation of the N-electron pair [17].

In these compounds the N-electron pair cannot occupy the orbital antiparallel to the $C_\beta-C_\gamma$ bond, since



[17] *C. A. Grob, H. R. Kiefer, H. J. Lutz,* and *H. J. Wilkens,* Helv. chim. Acta *50*, 416 (1967).



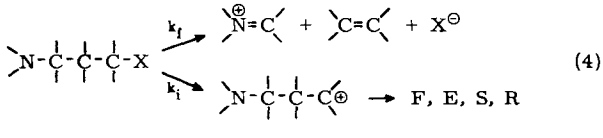
(67)

(70)

(69)

(68)

(71)



this space is taken up by the σ-electron pair of the bond between N and C-2. The N-electron pair must oscillate in a plane perpendicular to the ring. Thus in the equatorial 7α-*p*-toluenesulfonate *(67)* fragmentation by the synchronous mechanism should not be possible even though the C_α–OTs and the C_β–C_γ bonds are antiparallel. The two-step fragmentation *via* the γ-amino carbonium ion *(69)* should also be impossible for the same reason.

In fact neither the 7α nor the 7β *p*-toluenesulfonate *(67)* or *(68)* undergoes fragmentation. Both compounds exhibit only substitution and elimination *via* the carbonium ion *(69)* by the S_N1 and E1 mechanisms. (In both cases, mixtures of the 7α- or 7β-alcohol and ethyl ether, as well as 1,2,3,4,4a,5,8,8a- and 1,2,3,4,4a-, 5,6,8a-octahydro-1-methylquinoline are obtained.) The non-participation of the amino group also follows from a comparison of the rate constants with those of the homomorphous 2-decalyl *p*-toluenesulfonates *(70)* and *(71)*; the k/k_h values are 0.37 and 0.43. The ionization rates are thus appreciably reduced by the inductive effect of the nitrogen atom. These results show that the orientation of the electron pair on the donor atom is decisive for fragmentation.

7. The Frangomeric Effect

A synchronous fragmentation can occur only if the rate constant k_f of this process is comparable with or greater than the rate constant k_i of ionization to the γ-amino carbonium ion, *i.e.* if $k_f \geq k_i$ in eq. (4). As shown by previous examples, the synchronous process k_f always predominates when the stereoelectronic requirements are satisfied.

For convenience the increase in reactivity due to synchronous fragmentation has been called the frango-

(4)

meric effect *f*. It is defined as the ratio of the rate constants k_f and k_i.

$$f = k_f/k_i$$

With few exceptions [11], however, k_f and k_i cannot be determined for a single compound, since only one of the two processes is generally observable. To determine k_i for cases in which the synchronous mechanism predominates, it is necessary to use the ionization rate of a homomorphous compound. In cases where it can be measured directly, however, the constant k_i is always smaller than the constant k_h of the homomorphous compound by a factor *i*, as a consequence of the inductive effect of the nitrogen atom. The inductive factor *i*

$$i = k_h/k_i$$

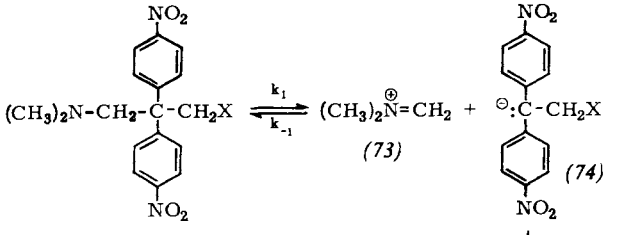
has values between 2 and 8 for cyclic γ-halogeno amines and γ-amino sulfonates. It depends on the environment and direction of the dipoles in these compounds as well as on the solvent. (The inductive factor *i* increases with the degree of transmission of the effect inside the molecule, *i.e.* through a region of low dielectric constants.) Frangomeric effects *f* (see Table 2) can be calculated approximately from the known rate constants for homomorphous compounds with the aid of an estimated inductive factor.

$$f = k_f \times i/k_h$$

Table 2. Approximate values of the frangomeric effect *f*.

Compound	k/k_h	*f*
(25), R = CH_3	520	10^3
(28), R = H	113	280
(28), R = $C(CH_3)_3$	34	85
(30)	16	80
(34), X = Br	5.4×10^4	10^5
(37)	1.35×10^4	10^4
(41)	39	10^2
(50)	128	6×10^2
(57)	46	2×10^2
(58)	1.5	10

The *f* values vary considerably. As an aid to understanding these figures it must be noted that they are based on a comparison of the rates of two different reactions, and that steric effects on each may be different. For example, in the case of 4-bromoquinuclidine *(34)* (X = Br) k_f is high because of the decrease in steric strain in the transition state of fragmentation, whereas the rate of formation k_i of a carbonium ion on the bridgehead of a bicyclic system is low. The value of *f* is consequently very large. (If several equivalent fragmentation paths are available, *e.g.* three for *(34)* and two for *(37)*, a statistical correction must be made to the *f* values.) For 5α-*cis*-*N*-methyldecahydroquinolyl *p*-toluenesulfonate *(58)*, on the other hand, fragmentation leads to the strained ten-membered *cis*-*cis*-imonium ion *(61)*, with the result that the value of k_f is decreased. The ionization of the *p*-toluenesulfonyl group, however, is sterically accelerated by the *cis* C4–C1 bond (*cis*-2-alkyl effect) [18], and k_i is accordingly increased. The result is a relatively low *f* value. Finally in the determination of the *f* values in Table 2 no allowance was made for the fact that in flexible systems, the conformation leading to synchronous fragmentation is often present only to a small extent. This results in a decrease in k_f, as in the



[18] *C. A. Grob* and *S. W. Tam*, Helv. chim. Acta *48*, 1317 (1965).

case of 4-chloropiperidines *(28)*. An accurate treatment of the frangomeric effect thus entails corrections for steric and inductive effects, the reliability of which is questionable.

A frangomeric effect is thus always observed when a system fragments by the synchronous mechanism. A comparison of the activation energies and activation entropies with those of homomorphous compounds suggests that the increased reactivity is largely due to a more positive activation entropy[19]. This tendency becomes more pronounced as the number of degrees of freedom lost in the transition state of the fragmentation decreases, as *e.g.* in the rigid molecules of 4-bromoquinuclidine *(34)* (X = Br) and 1-dimethylamino-3-bromoadamantane *(25)* (R = CH_3). In the more flexible *cis*-3-dimethylaminocyclohexyl *p*-toluenesulfonate *(41)*, for example, the activation entropy is only slightly more positive than in the homomorph, since both the rotation of the amino group and the movements of the cyclohexane ring are suppressed in the transition state.

8. The Two-Step Carbanion Mechanism

In the cases considered so far, the fragmentation process was either initiated by the release of the nucleofugal moiety $-X$ or it involved the simultaneous release of $-X$ and the electrofugal group [paths (a) and (b) in eq (3).] In the third basic mechanism, the electrofugal imonium ion separates from a carbanion in a reversible reaction [path (c) in eq. (3)]; subsequently $-X$ leaves in a fast secondary reaction. This mechanism can occur only if the carbanion is stabilized by electron-attracting substituents and if the nucleofugal activity, *i.e.* the tendency of $-X$ to leave, is low.

(72), X = OH
(72a), X = C_6H_5COO
(72b), X = p-$CH_3C_6H_4COO$
(72c), X = p-$CH_3OC_6H_4COO$
(72d), X = p-$NO_2C_6H_4COO$

These requirements are satisfied by the esters *(72a–d)* of 3-dimethylamino-2,2-bis(*p*-nitrophenyl)propanol *(72)*[20]. As free bases, these esters decompose into 1,1-bis(*p*-nitrophenyl)ethylene *(75)* [*via* the carbanion *(74)*] and the imonium ion *(73)* or its hydrolysis products dimethylamine and formaldehyde.

The two-step carbanion mechanism is supported primarily by the fact that the first order rate constants of the esters *(72a–d)* differ by only a small factor. Thus, the ionization of X alone cannot be the deciding factor. The observed rates are in fact probably determined by the ratio k_2/k_{-1}, as is the case with other reactions involving the reversible formation of a short-lived intermediate. Further evidence of the existence of the carbanion intermediate *(74)* is provided by the fact that esters of structure *(72a–d)* without *p*-nitro substituents undergo ester hydrolysis instead of fragmentation under the same conditions. Systematic studies on this fragmentation mechanism are, however, still in their early stages.

9. Combined Mechanisms

As was shown in Section 4, the open-chain, freely rotating 3-chloro-*N*,*N*,3-trimethylbutylamine *(4)* reacts by the two-step carbonium ion mechanism, though it can adopt a conformation suitable for the synchronous fragmentation, such as *(21)*, *(22)*, or *(23)*. An explanation for this unexpected behavior is that owing to thermal motion, the molecule does not remain in these conformations often or long enough and that the synchronous process is disturbed by rotations about the C_α–C_β and C_γ–N bonds. The formation of the transition state is thus associated with the loss of degrees of freedom. It is therefore unfavorable on entropy grounds.

We are now faced with the question whether acyclic systems with free rotation are in fact capable of undergoing synchronous fragmentation. To this end the reactivities of primary, secondary, and tertiary γ-

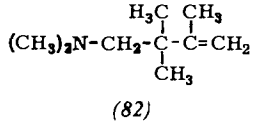
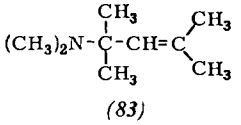
[a] R = ring closure, F = fragmentation, E = elimination, S = substitution.

[19] A relatively positive activation entropy is often observed in reactions in which several bonds are broken in the transition state; cf. *B. G. Gowenlock*, Quart. Rev. (Chem. Soc., London) *14*, 133 (1960).



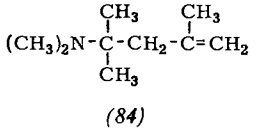
[20] *C. A. Grob, F. M. Unger, E. D. Weiler*, and *A. Weiss*, unpublished results.

chloroamines with varying numbers of methyl groups in the α, β, and γ positions have been compared (Table 3).



The primary chloroamines *(76)* and *(77)* exhibit exclusive ring closure. The high k/k_h values show that intramolecular nucleophilic substitution is accelerated by neighboring group participation, *i.e.* anchimerically[21]. The fact that the rate for the β-dimethylated compound *(77)* is about 10 times higher than *(76)* illustrates the geminal dialkyl effect, which increases the frequency of the quasi-cyclic conformations that lead to ring closure.

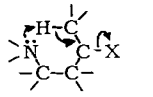
In the secondary chlorine compound *(78)*, ring closure is still the only reaction, but the rate of the intramolecular substitution (and hence also k/k_h) is lower because of the greater steric hindrance at the α carbon atom. The introduction of two geminal methyl groups into the β-position, as in compound *(79)*, again increases the reaction rate and the k/k_h value considerably. However, since fragmentation now occurs as well as ring closure, the problem arises whether an anchimerically accelerated ring closure reaction is combined with a synchronous fragmentation.



The tertiary chlorine compound *(4)* is the prototype of a γ-chloro amine that reacts by the two-step carbonium ion mechanism. The mechanism surprisingly changes on introduction of additional geminal methyl groups into the β and γ positions. Thus the α,α,β,β-tetramethylated compound *(80)* and the α,α,γ,γ-tetramethylated isomer *(81)* react 125 and 24 times as fast as their respective homomorphous chloroalkanes. The ionization is therefore assisted by the nitrogen atom in both cases. Since the only products formed aside from fragmentation products are the aminoolefins *(82)* or *(83)* and *(84)*, the accelerated fragmentation must be accompanied by accelerated elimination.

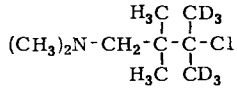
(82)

(83)



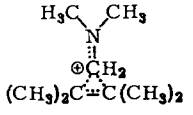
(84)

Both reactions are independent of the addition of external bases. The aforementioned aminoolefins must therefore be formed by a hitherto unknown elimination mechanism in combination with accelerated fragmentation[22].

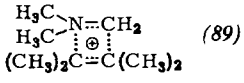


This result cannot be explained by the accelerated formation of an azetidinium salt *(85)* that subsequently suffers fragmentation and elimination, since these salts are stable or else they are not formed under the conditions of the reaction[23]. (This was demonstrated in the case of the symmetrical 2,2,4,4-tetramethylazetidine by labeling with ^{14}C[24].) The combination of a synchronous fragmentation and an anchimerically accelerated elimination in accordance with *(86)*[25] is also unlikely, since the reaction of the deuterated γ-chloroamine *(87)* shows no primary isotope effect such as would be expected for the removal of a proton in the transition state in accordance with *(86)*[26].

(85)

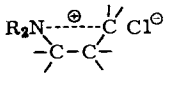


(86)

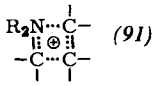


(87)

The formation of a symmetrical π complex *(88)*, which could conceivably be a precursor of the fragmentation and elimination products, was excluded by experiments with the γ-chloroamine *(80)* labeled with ^{14}C[27]. Although the alternative unsymmetrical π complex *(89)* has not been ruled out, its formation is unlikely since tetramethylethylene cannot be condensed with the imonium salt from dimethylamine and formaldehyde to give the aminoolefin *(82)*.



(88)



(89)

(90)

(91)

We suggested several years ago[23] that the ionization of the tertiary chlorine atom in γ-chloro amines such as *(80)* could be assisted by the nitrogen atom without leading to covalent ring closure. According to this view, an internally solvated carbonium ion pair *(90)* is formed as an intermediate. This can fragment *via* the transition state *(91)*, lose a proton to give an aminoolefin such as *(82)*, or form the azetidinium salt *(85)* by covalent ring closure.

In the internally solvated cation *(90)*, which corresponds to the transition state of a nucleophilic substitution, the amino group assumes the stabilizing role normally played by the solvent. For the formation of the cation *(90)*, the nitrogen must be able to approach the α carbon atom from the rear, and the quasi-cyclic conformation must be easily attainable. This effect is achieved by geminal methylation in the β and γ positions. However, ring closure does not occur readily in the chlorides *(80)* and *(81)*, owing to the strain in the four-membered ring and the steric hindrance at the tertiary α carbon atom. In the secondary chloride *(79)*, on the other hand, steric hindrance is sufficiently less that ring closure can compete with the fragmentation. It is interesting to note that 3-(chlorodimethylmethyl)quinuclidine *(13)*, in which internal solvation is impossible for steric reasons, reacts by the two-step carbonium ion mechanism.

The reactive behavior of the diastereoisomeric forms *(92)* and *(93)* of 3-dimethylamino-1,2-diphenylpropyl methanesulfonate can also be reconciled with this hypothesis[28]. The *erythro* form *(92)* reacts 77 times as fast as the homomor-

[21] *S. Winstein et al.*, J. Amer. chem. Soc. *75*, 147 (1953).

[22] Of the elimination mechanisms known at present, two (E2 and E1cB) are base-induced. The third (E1) proceeds *via* a carbonium ion, and should be slower by the inductive factor *i* than the reaction of the homomorph, *i.e.* $k/k_h < 1$.

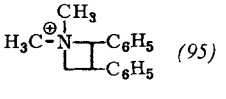
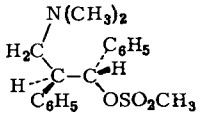
phous compound *(92)* [$(CH_3)_2CH$ instead of $(CH_3)_2N$] in ethanol, with exclusive fragmentation and ring closure to give *trans*-stilbene *(94)* and the *trans*-azetidinium ion *(95)*,

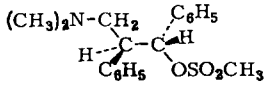


(92)

(93)

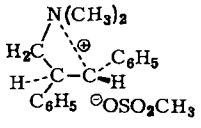


(94) 

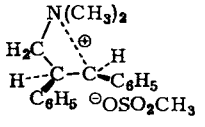


(95)

$(CH_3)_2N-CH_2-CH(C_6H_5)-CH(C_6H_5)-OC_2H_5$ *(96)*



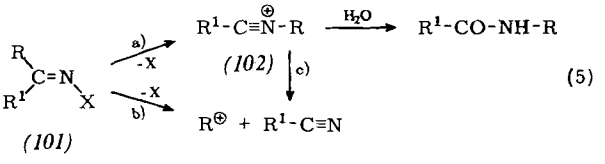
respectively. The *threo* isomer *(93)*, on the other hand, reacts more slowly than its homomorph ($k/k_h = 0.75$), indicating a two-step carbonium ion mechanism. (The question whether phenonium ions occur as intermediates in the latter case is not relevant in this connection.) This is in agreement with the formation of *threo* and *erythro* ethers *(96)* and *cis* and *trans* azetidinium ions *(95)* together with *trans*-stilbene *(94)* by fragmentation.



(97)

(98)

(99)

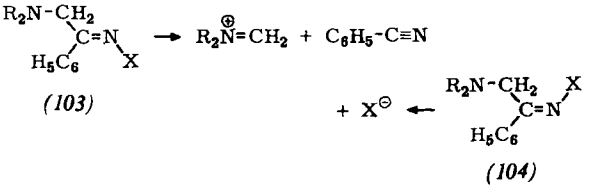


(100)

The fact that the *erythro* isomer *(92)* reacts faster than its homomorph proves the participation of the nitrogen atom. However, it is not clear whether ring closure and fragmentation are competing reactions of two rotamers *(97)* and *(98)* or both reactions proceed *via* the same internally solvated carbonium ion pair *(99)*. In the latter structure the bulky phenyl groups are *trans* to each other. In the cation of the *erythro* form *(100)*, the phenyl groups are *cis* to each other. The resulting steric hindrance appears to rule out any participation of the nitrogen atom.

The amines with nucleofugal substituents in the γ position have available to them a variety of reaction paths and mechanisms that is practically unequaled in other classes of organic compounds. The three expected basic mechanisms are observed, depending on their structure, configuration, and conformation, as well as on the electron influence of the substituents. More higly substituted acyclic members of this class exhibit an unexpected participation of the nitrogen atom, which is ascribed to internal solvation. If this interpretation proves to be correct, current views on the course of many substitution and elimination reactions may have to be reexamined [29].

[29] It has recently been postulated that the transition states of many substitutions and eliminations are similar; cf. *A. J. Parker, M. Ruane, G. Biale*, and *S. Winstein*, Tetrahedron Letters *1968*, 2113.

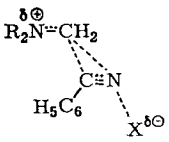


When the hydroxyl group of a ketoxime *(101)* (X = OH) is converted into a more active nucleofugal group by protonation or esterification, a Beckmann rearrangement generally occurs. The group R in the *trans* position with respect to X migrates to form a nitrilium ion *(102)*, which gives an amide with water [path (a) in eq. (5)]. If, however, R is potentially electrofugal, it can be split off with simultaneous formation of a nitrile [path (b) in eq. (5)]. This reaction is thus one of the group of nitrile-forming fragmentations [1].

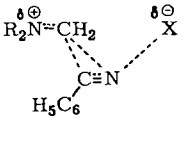
(101) *(102)* (5)

The fragmentation could again proceed synchronously, *i.e.* in one step (path b) or in more than one step, as in the previously described N–C–C–C–X system. An additional possibility in this case is an initial rearrangement to form the nitrilium ion *(102)*, which then fragments (path a,c). The fragmentation would then proceed indirectly *via* a Beckmann rearrangement. As will now be shown, both the synchronous mechanism (path b) and the rearrangement-fragmentation mechanism (path a,c) are observed, depending on the electrofugal group R.

The synchronous mechanism is observed with α-amino ketoxime derivatives, both with *anti* forms such as *(103)* and with corresponding *syn* forms *(104)* [30].



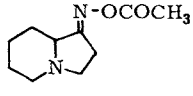
(103) *(104)*



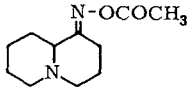
This follows from the observation that the reaction rate is strongly dependent on the substituents on the amino group and on the nature of the nucleofugal group –X. For example, *anti*-α-pyrrolidinoacetophenone oxime benzoate [*(103)*, R–R = $-(CH_2)_4-$, X = C_6H_5COO] reacts about 3000 times as fast as the *anti*-α-methylanilino derivative [*(103)*, R_2N = $C_6H_5(CH_3)N$]. Moreover, *p*-toluenesulfonates (X = *p*-$CH_3C_6H_4SO_3$) react about 10^6 times as fast as benzoates [31]. It must therefore be concluded that the electrofugal fragment $R_2\overset{\oplus}{N}=CH_2$ and the nucleofugal fragment –X are released simultaneously from the middle group in the rate-determining step, in accordance with the formulations of the transitions states for the *anti* form *(105)* and the *syn* form *(106)*.

[30] *H. P. Fischer, C. A. Grob*, and *E. Renk*, Helv. chim. Acta *45*, 2539 (1962).

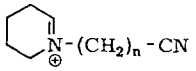
[31] *H. P. Fischer* and *C. A. Grob*, Helv. chim. Acta *46*, 936 (1963).



(105)



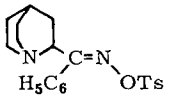
(106)



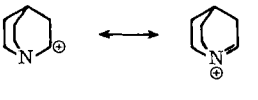
In the *anti* form the process corresponds to a *trans* elimination, while in the *syn* form it represents the unusual case of a *cis* elimination. The superiority of *trans* fragmentation is shown by the fact that its rate is about 10^3 times as high as that of the *cis* form. α-Amino ketoxime derivatives such as *(103)* and *(104)* also react very much faster than homomorphous ketoxime derivatives which contain no amino group and which in the absence of an active electrofugal group undergo a Beckmann rearrangement [path a in eq. (5)]. The large frangomeric acceleration in turn demonstrates the participation of the amino group in a synchronous fragmentation process. There is, however, no direct relation between the basicity of the amino group and the reaction rate. This also holds for the acidity of the acid HX corresponding to X.

(107)

(108)

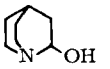


(109a), n = 2

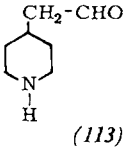


(109b), n = 3

The synchronous Beckmann fragmentation also occurs very readily with monocyclic and bicyclic α-amino ketoxime derivatives[32,33]. For example, 1-oxooctahydroindolizine oxime acetate *(107)* and 1-oxoquinolizidine oxime acetate *(108)* in 80% ethanol give quantitative yields of the imonium nitriles *(109a)* and *(109b)*, which rapidly undergo secondary reactions. The compounds *(107)* and *(108)* react about 10^4 and 10^8 times as fast as their respective homomorphous oxime acetates, *i.e. cis*-hexahydro-1-indanone oxime acetate [*(107)*, CH instead of the bridgehead N] and *trans*-1-decalone oxime acetate [*(108)*, CH instead of the bridgehead N]. The magnitude of these frangomeric effects is surprising in view of the fact that the conformation favorable for synchronous fragmentation, *i.e.* with antiparallel arrangement of the N-electron pair and the C–C bond to be broken, is not the most stable conformation. On the other hand, the two substituents on the C=N double bond are rigidly held in the most favorable coplanar arrangement. Synchronous fragmentation thus predominates even when the stereoelectronically optimal conformation is present to a lesser extent.



Because of the wide applicability of the Beckmann fragmentation this reaction lends itself to the detection and degradation of natural and synthetic α-aminoketoximes. No exceptions have been found to date, though the rate of the fragmentation may be greatly decreased by steric factors. This is illustrated by the



(110)

(114)

(115)

(116)

(117)

reaction of *anti*-2-quinuclidyl phenyl ketoxime *p*-toluenesulfonate *(110)* in aqueous media[34].

The fragmentation of this compound leads to benzonitrile and the 1,2-didehydroquinuclidinium ion *(111)*. Since the structure of this bicyclic cation hinders the formation of a double bond at the bridgehead (Bredt's rule), it can be regarded only with reservations as a resonance-stabilized imonium ion in accordance with *(111a)*↔*(111b)*. The electrofugal activity of the quinuclidyl group must therefore be greatly reduced.

It is in fact found that the compound *(110)* in 80% ethanol reacts only about twice as fast as the homomorphous bicyclo[2.2.2]oct-2-yl phenyl ketoxime *p*-toluenesulfonate *(116)*, which undergoes exclusive Beckmann rearrangement. The ionization of *(110)* is thus only slightly accelerated by the nitrogen atom. The reaction nevertheless yields the fragmentation product benzonitrile and 4-piperidylacetaldehyde *(113)*, (the tautomeric form of 2-quinuclidinol *(112)*) as a secondary reaction product of the cation *(111)*. The principal product, however, is *N*-(2-quinuclidyl)-benzamide *(115)*. On the basis of earlier findings, it may be concluded that this amide results from recombination of part of the benzonitrile with the cation *(111)* to give the nitrilium ion *(114)* after the manner of a Ritter reaction[32]. This in turn affords the amide *(115)* in aqueous solution, thus simulating the result of a Beckmann rearrangement.

The fact that the cation *(111)* is formed as an intermediate shows that it must be more stable than the bicyclo[2.2.2]oct-2-ylium ion *(117)*, and that some delocalization of the positive charge to the bridgehead nitrogen atom must occur in accordance with the limiting form *(111b)*. It follows from these experiments that Bredt's rule is not strictly valid for high-energy intermediates and transition states.

If the electrofugal activity of the group R of an oxime derivative falls below its migratory aptitude, the Beck-

mann rearrangement [path a in eq. (5)] takes precedence, as in the case of bicyclo[2.2.2]oct-2-yl phenyl ketoxime *p*-toluenesulfonate *(116)*. However, as the following examples show, indirect fragmentation can occur by loss of a carbonium ion $R^{\oplus}$ from the initially formed nitrilium ion *(102)* (path ac, in eq. (5) [35]).

(118)

(119)

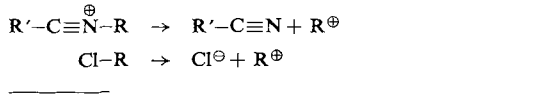

Table 4. Relative reaction rates and degree of fragmentation of ketoxime *p*-toluenesulfonates *(118)* at 23 °C and relative ionization rates of alkyl and aralkyl chlorides *(119)*.

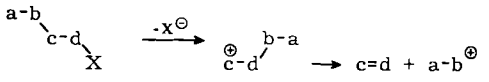
R	*(118)* k_{rel}	*(118)* Fragmentation (%)	*(119)* k_{rel}
CH_3	1	0	
C_2H_5	60	0	
$CH(CH_3)_2$	810	0	<0.001
$C(CH_3)_3$	870	10	1
$CH(C_6H_5)_2$	40	54	186
$C(CH_3)(C_2H_5)(C_6H_5)$	820	80	572

Table 4 lists a number of alkyl and aralkyl methyl ketoxime *p*-toluenesulfonates *(118)* in which the variable group R is always *anti* with respect to the nucleofugal group –OTs. The relative reaction rates (based on R = CH_3) and the degree of fragmentation into acetonitrile and the carbonium ion $R^{\oplus}$ are also given. The reaction rate increases in the order $CH_3 < C_2H_5 < CH(CH_3)_2 < C(CH_3)_3$ with the last compound giving about 10% fragmentation. The first three compounds afford only substituted acetamides $CH_3-CO-NHR$ by Beckmann rearrangement. The reaction rate decreases appreciably with the next ketoxime *p*-toluenesulfonate, which is a benzhydryl derivative, and then increases again for the α-ethyl-α-methylbenzyl derivative.

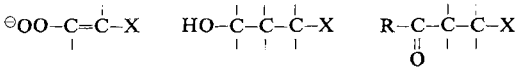
Thus no relation is apparent between the reaction rate and the degree of fragmentation. Fragmentation cannot therefore occur in the rate-determining step, but in a subsequent step. The k_{rel} values in Table 4 are a measure of the migratory aptitude of the groups in question, which in turn depends on inductive and steric effects [35]. They therefore correspond to the rate of formation of nitrilium ions *(102)*, the necessary intermediates of the Beckmann rearrangement [35]. These in turn are known to break down into nitriles and carbonium ions when the latter are sufficiently stable, as in the case of the *tert*-butyl, benzhydryl, and α-ethyl-α-methylbenzyl cations.



The heterolysis of nitrilium ions proceeds in the same manner as that of secondary and tertiary alkyl halides:

[35] *C. A. Grob, H. P. Fischer, W. Raudenbusch,* and *J. Zergenyi,* Helv. chim. Acta *47,* 1003 (1964).

It is therefore understandable that the fragmentation yields in Table 4 increase in the same order as the ionization rates of the alkyl and aralkyl chlorides *(119)* (see last column in Table 4).



The compounds *(118)* thus react by a multistep rearrangement-fragmentation mechanism, as represented by the following general formulation:

The two conditions for the occurrence of this mechanism are that the migratory aptitude of the group a–b is greater than its electrofugal activity, and that the unsaturated fragment c=d has nucleofugal character, since it leaves the electrofugal group a–b after the rearrangement, taking with it the pair of bonding electrons. This second condition is satisfied not only by nitriles, but also by cyanate ions. No other systems that fragment by this mechanism are known at present.

11. Outlook

There now remains the question whether the findings for amines with nucleofugal substituents in the γ position and for oxime derivatives can be applied to other systems that can undergo heterolytic fragmentation. The experimental data available, though still scanty, already indicates that the same rules are valid, *e.g.* for the solvolytic decarboxylation of α,β-unsaturated β-halogeno acids *(120)* [36]. The dependence of reactivity on steric factors is easier to recognize in unsaturated systems because of the fairly rigid structures. On the other hand, there are many systems whose investigation is complicated by the fact that the fragmentable particle is formed only as a result of a prior reaction. Examples of this are the base-induced fragmentation of alcohols *(121)* with nucleofugal substituents in the γ-position [37] and of carbonyl compounds *(122)* with nucleofugal substituents in the β-position [38].

Antioxidants

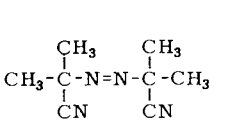
By L. R. Mahoney[*]

The free radical initiated liquid phase oxidation of hydrocarbons is inhibited by phenols and aromatic amines. In the present article the recent results of kinetic and thermodynamic studies of the inhibition are discussed.

1. Introduction

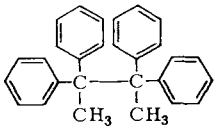
The liquid phase oxidation of organic compounds by molecular oxygen at temperatures less than 100 °C may be represented by the equation

$$RH + O_2 \rightarrow RO_2H$$



where RH is a hydrocarbon or aldehyde and RO_2H is the corresponding hydroperoxide or peracid. In cases in which the oxidizable material is a vinyl monomer then a copolymer of oxygen and the vinyl monomer is obtained [1]. The reaction has the characteristics of a free radical chain reaction; its rate is strongly catalyzed by light and accelerated by compounds which decompose to form free radicals.

Since the process of oxidation is frequently accompanied by the accumulation of insoluble materials and the concurrent loss of desirable physical properties of the original material, the inhibition of the oxidation process is a subject of considerable technological importance. Thus an enormous number of different additives have been empirically tested and utilized by industry for the purpose of increasing the useful lifetimes of air-sensitive products.



Scientific interest in the inhibition of oxidation has been centered primarily upon the elucidation of the free radical mechanisms by which low concentrations of phenols and aromatic amines are capable of inhibiting the rate of oxidation of hydrocarbons. During the past few years systematic studies have revealed the complexities of the reactions occurring in oxidizing hydrocarbons containing these antioxidants. As a result the accepted mechanisms of antioxidant behavior, particularly those involving phenols, have undergone several dramatic revisions and earlier reviews [2,3] of the subject have become somewhat dated.

2. Kinetics and Mechanism of the Non-Inhibited Oxidation

The measurement of the oxygen absorption as a function of time by an oxygen saturated liquid solution of the hydrocarbon, neat, or in an inert solvent, is the most convenient and widely used technique for the kinetic studies of the oxidation of hydrocarbons. For laboratory studies a compound which decomposes at a known rate and known efficiency to form free radicals is added to the hydrocarbon system. The concentrations of these compounds are such that the rate of formation of free radicals from their decomposition is many orders of magnitude higher than the rate of radical formation produced by the decomposition of the hydroperoxide formed during the measurement. Among the compounds most frequently employed as initiators are azodiisobutyronitrile *(1)*, and 2,2,3,3-tetraphenylbutane *(2)*.

(1)

(2)

The observed initial rates of oxygen absorption are found to be (i) independent of oxygen when the partial pressure of oxygen above the solution exceeds *ca.* 100 torr, (ii) one half order with respect to the concentration of the initiator, and (iii) first order with respect to the concentration of the hydrocarbon. The generally accepted chain mechanism which satisfactorily accounts for these results is the following:

$R - R \rightarrow 2\,R^{\bullet}$	(1)	Initiation
$R^{\bullet} + O_2 \rightarrow RO_2^{\bullet}$	(2)	Propagation
$RO_2^{\bullet} + RH \rightarrow RO_2H + R^{\bullet}$	(3)	Propagation
$2\,RO_2^{\bullet} \rightarrow$ Inert Product	(4)	Termination

where R–R is the initiator and $R^{\bullet}$ and $RO_2^{\bullet}$ represent the carbon radical and the chain-carrying peroxyl radical respectively. At sufficiently high oxygen pressures the rate of reaction (2) is quite high and the possible bimolecular termination reaction of carbon radicals is not significant. Under these conditions reaction (3) is the rate controlling step.

$$dO_2/dt = k_3[RO_2^{\bullet}]\,[RH] \qquad (5)$$

At steady state, the rate of formation of radicals from the initiator is equal to their rate of disappearance from the system *via* reaction (4).

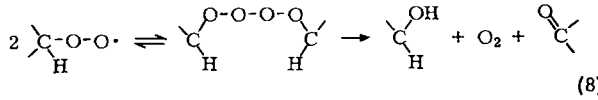
[3] *G. Scott*: Atmospheric Oxidation and Antioxidants. Elsevier, New York 1965.

$$2k_1[R{-}R] = 2k_4[RO_2^{\bullet}]^2 \quad (6)$$

Solving for $[RO_2^{\bullet}]$ and substituting in equation (5)

$$\frac{dO_2}{dt} = \frac{k_3}{(2k_4)^{1/2}} \left\{ 2k_1[R{-}R] \right\}^{1/2} [RH] \quad (7)$$



in agreement with experiment.

Provided that the value of $2k_1$ is known, the value of the ratio of rate constants, $k_3/(2k_4)^{1/2}$ may be determined by such oxidation studies. The use of a combination of photochemical initiation and non-steady state techniques allows a determination of the absolute values k_3 and k_4 [4,5,6]. *Howard* and *Ingold* [7] have recently determined the absolute values of these constants for a large number of hydrocarbons. In Table 1 are presented values of k_3, corrected for the number of reactive hydrogens, for some of the hydrocarbons which they examined. Examination of the table reveals the dramatic increase in the value of k_3 upon the introduction of a π-electron system into a position adjacent to the reactive hydrogen.

Table 1. Absolute value of k_3 per reactive hydrogen for hydrocarbons [7].

Hydrocarbon	T (°C)	k_3/reactive hydrogen ($l \cdot mol^{-1} \cdot s^{-1}$)
Cyclohexane	65	0.0061
Cyclohexene	30	1.5
Octalin	30	1.6
9,10-Dihydroanthracene	30	44.0
Cyclopentene	30	7.0
Indan	30	1.2
Toluene	30	0.08
Cumene	30	0.18

From their results *Howard* and *Ingold* have also been able to define a range of values for k_4 as a function of the structure of the hydrocarbon moiety of the peroxyl radical. Primary peroxyl radicals have values of k_4 in the range of 10^8 lmole^{-1} sec^{-1}, secondary peroxyl radicals 10^6–10^7 lmole^{-1} sec^{-1}, and tertiary peroxyl radicals in the range of 10^3–10^5 lmole^{-1} sec^{-1} at 30 °C. This ordering of values of k_4 fully supports the mechanism of the peroxyl radical termination reaction first proposed by *Russell* [8] in his classic study of the oxidation of ethylbenzene. This mechanism (8) involves the formation of a tetraoxide, which in the case of primary and secondary peroxyl radicals decomposes to form O_2 [9,10] with

(8)

the simultaneous formation of a carbonyl compound and alcohol. In the case of tertiary peroxyl radicals the disproportionation reaction cannot occur and termination is highly inefficient and complex in nature [10,11].

3. Inhibition Period Studies

In Figure 2 is presented a typical plot of the oxygen absorption *versus* time curves obtained from the introduction of a phenolic antioxidant into a system consisting of the reactive hydrocarbon and an initiator. After a period of strong inhibition the rate of oxygen absorption of the sample increases rapidly and finally reaches a rate equal to that observed in the absence of the antioxidant.

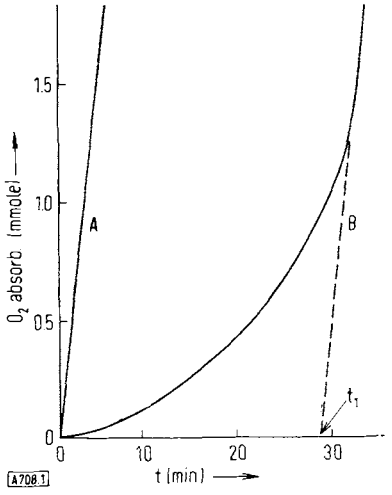


Fig. 1. The oxygen absorption of a chlorobenzene solution of 148 mmoles 9,10-dihydroanthracene at 60 °C containing 31 mmoles 2,2,3,3-tetraphenylbutane and, Curve A: no inhibitor; Curve B: 1 mmole hydroquinone.

In many cases the length of this inhibition period, t, is proportional to the original concentration of the antioxidant. If the initiator is azodiisobutyronitrile *(1)* or tetraphenylbutane *(2)* it is possible to calculate the ratio of the number of radicals produced from the initiator during the inhibition period to the initial concentration of the inhibitor.

$$\frac{1}{[\text{Inhibitor}]_0} \int_0^t 2k_1[R{-}R]dt = n \quad (9)$$

The quantity n, known as the stoichiometric factor [12], is frequently found to have small integral values. Such a result strongly suggests that the inhibitor molecule terminates chains by reacting with peroxyl radicals in stoichiometrically simple processes. For example, hydroquinones manifest values of n equal to two and thus the overall termination reaction corresponds to reaction (10) [13].

[13] *A. F. Bickel* and *E. C. Kooyman*, J. chem. Soc. (London) *1954*, 3211.

(10)

These results imply that in those cases in which large and non-integral values of the stoichiometric factor are observed, a more complex and perhaps non-free radical reaction may be superimposed upon the free radical termination process. For example, large values of n are observed for the highly specific antioxidant $FeCl_3$ in the liquid phase oxidation of arylalkylhydrocarbons[14]. It was demonstrated that the initial action of $FeCl_3$ in such systems is the highly efficient catalysis of the rearrangement of the small amounts of hydroperoxide to produce acetone and the antioxidant, phenol [Eq. (11)].

(11)

The phenol produced in the reaction then functions as the antioxidant and the end of the inhibition period corresponds to that point in which the catalytic effect of $FeCl_3$ is destroyed by complexing with donor molecules (*i.e.* water, acetone, *etc.*) produced during the inhibition period.

4. Kinetics and Mechanism of Inhibition by Phenols

The uninhibited rate of oxidation of a hydrocarbon at a constant rate of formation of free radicals is dependent upon the rate of two reactions (see Section 2). The first is reaction (3), hydrogen abstraction by the chain-carrying peroxyl radical from the hydrocarbon; the second is reaction (4), the bimolecular termination reaction of two peroxyl radicals. The rate of oxidation of a hydrocarbon inhibited by a phenolic antioxidant requires consideration of a larger number of reactions (see Scheme 1).

$R-R \xrightarrow{k_1} 2\,R^{\bullet}$		(1)
$R^{\bullet} + O_2 \xrightarrow{k_2} RO_2^{\bullet}$		(2)
$RO_2^{\bullet} + RH \xrightarrow{k_3} RO_2H + R^{\bullet}$		(3)
$2\,RO_2^{\bullet} \xrightarrow{k_4}$ inert product		(4)
$RO_2^{\bullet} + AH \underset{k_{-12}}{\overset{k_{12}}{\rightleftharpoons}} RO_2H + A^{\bullet}$		(12, −12)
$RO^{\bullet}{}_2 + A^{\bullet} \xrightarrow{k_{13}} AO_2R$		(13)
$2\,A^{\bullet} \xrightarrow{k_{14}} A-A$		(14)
$A^{\bullet} + RH \xrightarrow{k_{15}} AH + R^{\bullet}$		(15)

Scheme 1.

[14] *G. S. Hammond, L. R. Mahoney,* and *U. S. Nandi,* J. Amer. chem. Soc. *88*, 737 (1963).

Where AH and A$^{\bullet}$ represent the phenol and the free radical derived from the phenol respectively. By means of this scheme it is possible to subdivide all phenolic antioxidants into two classes with respect to their kinetic and mechanistic behavior.

The first class consists of sterically hindered phenols, *i.e.* 2,6-di-*tert*-butylphenol and hydroquinones. In hydrocarbon systems containing these compounds the rates of the radical termination, reaction (13) and (14), greatly exceed the rates of reactions (−12) and (15). As a result the peroxyl radical is the sole chain carrying free radical, and the rate of oxygen absorption is given by Eq. (16).

$$-dO_2/dt = 2k_1[R-R] + k_3[RO_2^{\bullet}]\,[RH] \qquad (16)$$

The slow step in termination is reaction (12) and under equilibrium conditions the concentration of free radicals is given by Eq. (17).

$$2\,k_1[R-R] = 2k_{12}[RO_2^{\bullet}]\,[AH] \qquad (17)$$

The rate of oxidation is a function of the values of k_3 and k_{12}.

Non-hindered phenols constitute the second class of antioxidants and their kinetic behavior is consistent with the view that the rates of reaction (−12) and (15) are competitive with the rates of the termination reactions (13) and (14). Under these conditions there are two chain-carrying free radicals, the peroxyl radical and the phenoxyl radical.

$$-dO_2/dt = 2k_1[R-R] + k_3[RO_2^{\bullet}]\,[RH] + k_{15}[A^{\bullet}]\,[RH] \qquad (18)$$

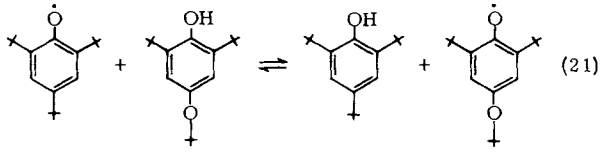
Since reaction (12) is not the slow step in the termination at steady state the rate of oxidation for these systems must be a function of a large number of kinetic parameters.

$$2\,k_1[R-R] = 2\,k_4[RO_2^{\bullet}]^2 + 2k_{13}[RO_2^{\bullet}]\,[A^{\bullet}] + 2\,k_{14}[A^{\bullet}]^2 \qquad (19)$$

4.1. Hindered Phenols and Hydroquinones

A number of studies of the initial rates of oxygen absorption of solutions of hydrocarbons containing hindered phenols and hydroquinones have been reported[15–17]. The rates of oxidation are first order in initiator concentration and independent of oxygen pressure. These results strongly suggest that the rate controlling steps in termination and propagation are first order in peroxyl radicals. The replacement of hydrogen by deuterium on the phenolic −H−O group of the antioxidant increases the rate of the inhibited oxidation by a factor of *ca.* 10[16] for sterically hindered phenols. Thus the O−H bond of the antioxidant is broken in the slow step of the termination process. Since the rate of oxygen absorption is inversely pro-

[15] *A. F. Bickel* and *E. C. Kooyman,* J. chem. Soc. (London) *1956*, 2215.



[16] *J. A. Howard* and *K. U. Ingold,* Canad. J. Chem. *40*, 1851 (1962).

[17] *L. R. Mahoney,* J. Amer. chem. Soc. *88*, 3035 (1966).

portional to the antioxidant concentration and at sufficiently high concentrations of the antioxidant the rate is reduced to a value equal to $2k_1[RR]$ [15,17], reaction (15) is negligible for these compounds. Reaction (−12) may also be excluded from the kinetic analysis of these compounds since the addition of high concentrations of hydroperoxide has no effect upon the inhibited rates of oxygen absorption [16–18]. These results are summarized by the rate expression (20), derived from equations (16) and (17).

$$-dO_2/dt = 2k_1[R-R] + \frac{k_3}{2k_{12}}\left\{2k_1[R-R]\right\}\frac{[RH]}{[AH]} \qquad (20)$$

Since the efficiency of these compounds as antioxidants is determined by the value of k_{12}, the effects of the substitution of the *p*-position of the sterically hindered phenols and the structure of the hydroquinones upon the antioxidant efficiency have been the subject of a number of recent studies. The effect of the substituent at the *p*-position upon the rate of reaction (12) has been examined by *Howard* and *Ingold* [19,20]. These workers found that a correlation existed between log $2k_{12}/k_3$ and the σ^+ values of the *p*-substituent. The ρ values equaled −1.36 and −1.12 with tetralin and with styrene as the hydrocarbons at 65 °C. These relatively large ρ values have been interpreted by *Howard* and *Ingold* as being due to a strong polar character in the activated complex of the atom transfer reaction. An alternative explanation involves the effect of the *p*-substituent upon the thermodynamic stability of the product phenoxyl radical. *Cook et al.* [21] examined the equilibrium between 2,4,6-tri-*tert*-butylphenoxyl radical and 2,6-di-*tert*-butyl-4-*tert*-butoxyphenol [Eq. (21)].

(21)

† = $C(CH_3)_3$

At 25 °C in benzene the value of the equilibrium constant is 51.7 ± 4.1. Since the ratio of values of k_{12}/k_3 for these two phenols is approximately 4, the relative rates of the hydrogen abstraction reaction may be merely a manifestation of the product radical stability.

A correlation between the values of log k_{12}/k_3 and the energy of the highest occupied molecular orbitals of the hydroquinones as calculated by the Hückel technique has recently been demonstrated [22]. The theoretical basis for the correlation comes from *Fueno et al.* [23] who argue that for a given series of compounds the rate of reaction (12) should depend upon the dissociation energy of the −OH bond of the hydroquinone. A separation of the dissociation energy into σ and π energy terms may be made and the π energy is related to the energy of the highest occupied molecular orbital of the hydroquinone.

4.2. Non-Hindered Phenols

The kinetic behavior of non-hindered phenols is complex. A systematic study of a number of non-hindered phenols utilizing 9,10-dihydroanthracene as the hydrocarbon and tetraphenylbutane as the initiator has recently been reported [22].

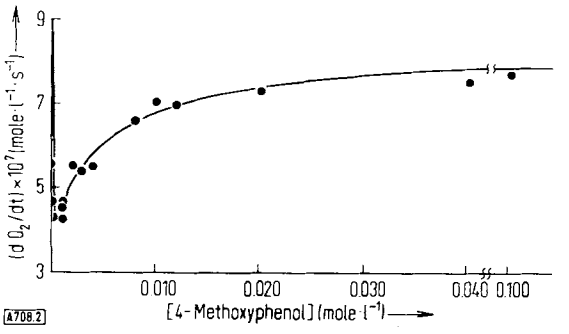


Fig. 2. The rate of oxygen absorption of a chlorobenzene solution of 99 mmoles 9,10-dihydroanthracene at 60 °C containing 31 mmoles 2,2,3,3-tetraphenylbutane as a function of the concentration of 4-methoxyphenol.

In Figure 2 are presented typical results observed in the 9,10-dihydroanthracene-tetraphenylbutane system containing 4-methoxyphenol in chlorobenzene at 60 °C. Since 4-methoxyphenol manifests many of the peculiar kinetic dependencies observed with other non-hindered phenols, it will serve in this discussion as a general example for all of the antioxidants of this class. At sufficiently long kinetic chain lengths the rate of oxygen absorption is accurately one-half order with respect to the initiator concentrations over the entire range of 4-methoxyphenol concentrations and at high concentrations of 4-methoxyphenol the rate is independent of the concentration of 4-methoxyphenol but is first order in hydrocarbon. Thus, in contrast to the hindered phenols, the slow steps in the termination reactions are second order in radical concentration and, moreover, the oxidation rate is not completely suppressed by increasing the concentration of the antioxidant. The addition of the hydroperoxide of 9,10-dihydroanthracene accelerates the rate at low concentrations of 4-methoxyphenol, has little effect in the regions of the minimum, and finally decreases the oxygen absorption rate at higher concentration of 4-methoxyphenol.

All of these results may be accounted for if the non-hindered radical engages in chain restarting reactions with hydroperoxide [18,24–26], reaction (−12), and with

[24] *J. R. Thomas*, J. Amer. chem. Soc. *86*, 4807 (1964).

[25] *J. A. Howard* and *K. U. Ingold*, Canad. J. Chem. *42*, 2324 (1964).

[26] *L. R. Mahoney* and *F. C. Ferris*, J. Amer. chem. Soc. *85*, 2345 (1963).

hydrocarbon [26, 27], reaction (15). If under the conditions of the experiment the kinetic chain is long and the non-hindered phenoxyl radical efficiently restarts chains by reaction (−12) and/or (15) we may write

$$k_{12}[RO_2^{\cdot}]\,[AH] = k_{-12}[A^{\cdot}]\,[RO_2H] + k_{15}[A^{\cdot}]\,[RH] \qquad (22)$$

Combining this equation with equations (18) and (19), the general rate expression

$$\frac{1}{\{2k_1[R\text{–}R]\}^{1/2}[RH]}\left\{\frac{dO_2}{dt} + 2\,k_1[R\text{–}R]\right\} = \frac{1+\alpha}{\{(2k_4/k_3^2) + (2k_{13}/k_3k_{15})\alpha + (2k_{14}/k_{15})\alpha^2\}^{1/2}} \qquad (23)$$

where $\alpha = \dfrac{[AH]}{\{(k_3/k_{12})[RH] + (k_{-12}k_3/k_{15}k_{12})[RO_2H]\}}$

may be derived.

This general rate equation is of the same form as would be obtained in the analysis of the co-polymerization of two vinyl monomers in which one monomer is very reactive and yields a radical which is much less reactive toward polymerization than the radical derived from the second monomer. A well known example of this phenomenon in vinyl-polymerization is the styrene-vinyl acetate system in which the addition of a trace amount of styrene strongly inhibits the rate of polymerization of vinyl acetate [28]. The occurrence of the strong minimum in the rate of oxygen absorption of the 4-methoxyphenol-9,10-dihydroanthracene system also has a strong analogy in the theory of copolymerization. *Palit* [29] predicted the occurrence of a minimum in the rates of polymerization of methyl methacrylate and 4-methoxystyrene. However, a minimum could not be clearly deduced from the experimental rate data available. The minimum in the rate of oxygen absorption is readily calculated from the general rate equation. At constant concentrations of R–R, RH, and RO_2H, the concentration of non-hindered phenol at which the minimum occurs is given by Eq. (24). In the case of 4-methoxyphenol

$$[AH] = \frac{k_3}{k_{12}}[RH] + \frac{k_3k_{-12}}{k_{12}k_{15}}[RO_2H]\left\{\frac{(k_{13}/k_3k_{15}) - (2k_4/k_3^2)}{(k_{13}/k_3k_{15}) - (2k_{14}/k_{15}^2)}\right\} \qquad (24)$$

the terms in the bracket are approximately unity, therefore the position of the minimum is proportional to the concentration of the hydroperoxide.

of the concentration of 4-methoxyphenol. The ratio of $(dO_2/dt)_{OD}$ to $(dO_2/dt)_{OH}$ decreases continuously from 2.9 at low concentrations of 4-methoxyphenol to unity at high concentrations. At very low concentrations of 4-methoxyphenol the slow step in the inhibition is reaction (12) and the isotope effect on the rate of oxygen absorption will be approximately proportional to $[(k_{12})_{OD}(k_{12})_{OH}]^{1/2}$. The square of the relative rates is 8.4, in agreement with the isotope effect for the transfer reaction directly measured with the hindered phenol. As the concentration of 4-methoxyphenol is increased, the isotope effect decreases until the reactions (14) and (15) determine the oxygen absorption rates. Under these conditions there will be no isotope effect since the slow step in the rate of oxygen absorption, propagation or termination, does not involve the hydrogen atom transfer, reaction (12).

The general rate equation has been utilized with considerable success for the quantitative analysis of the rate data obtained in our laboratory with the tetraphenylbutane-9,10-dihydroanthracene system [22] and for the analysis of experimental data of earlier workers who employed the azodiisobutyronitrile-tetralin system [25, 26]. The values of the parameters of $2k_4/k_3^2$ and $2k_{14}/k_{15}^2$ are very readily obtained from studies of the uninhibited and the fully inhibited rates of oxidation. The other parameters are conveniently determined by curve fitting using computer techniques. The solid curve in Figure 2 was obtained by means of such curve fitting techniques. This procedure may appear tenuous. However, there is an essentially independent technique (cf. Section 5.3) which yields values of one of the parameters, k_{12}/k_3, in excellent agreement with those derived from the general equation. The values of the adjustable parameters obtained from this analysis have yielded previously unattainable information regarding the relative rates of formation, of hydrogen abstraction, and the termination reaction of phenoxyl radicals. In Table 2 values of parameters for a number of non-hindered phenols are presented.

Table 2. Kinetic parameters calculated from Equation (23) for typical non-hindered phenols [22].

Compound	k_{12}/k_3	k_{-12}/k_{15}	$\{k_{13}/2(k_4)^{1/2}(k_{14})^{1/2}\}$ ($l \cdot mol^{-1} \cdot s^{-1}$)	$k_{15}/(2k_{14})^{1/2} \times 10^3$ ($l^{1/2} \cdot mol^{-1/2} \cdot s^{-1/2}$)
Phenol	9.7	110	2.2	13.2
m-Cresol	1.4	49.1	1.5	1.4
p-Phenylphenol	78.0	59.5	3.5	9.1
4-Methoxyphenol	284	17.5	49.0	19.8
Pyren-3-ol	4400	31.0	1020	29.1

By means of the general rate equation (23) it is possible to analyze the variable isotopic effects observed with non-hindered phenolic antioxidants. *Howard* and *Ingold* [25] have shown that the magnitude of the isotope effect upon the rates of oxygen absorption of 4-methoxyphenol and the *O*-deuterated compound in the tetralin-azodiisobutyronitrile system is a function

The structure of the aromatic ring system from which the phenol is derived has a remarkably large effect on the values of two of the parameters. Values of k_{12}/k_3 derived from the studies of the tetraphenylbutane-9,10-dihydroanthracene system increase from 9.7 for phenol to 4400 for pyren-3-ol.

For hydroxy compounds derived from alternate hydrocarbons a plot of the value of $\log(k_{12}/k_3)$ *versus* the energy of the highest occupied molecular orbital yields a straight line. However, the straight line is displaced from that obtained for hydroquinones (cf. Section 4.1.). Since systematic variation of the values for the coulomb and bond integrals fails to yield

[27] *A. F. Bickel* and *E. C. Kooyman*, J. chem. Soc. (London) *1956*, 2215.

[28] *C. Walling*, J. chem. Soc. (London) *1949*, 1930.

[29] *S. R. Palit*, Trans. Faraday Soc. *51*, 1129 (1955).

a single straight line for both classes of compounds a difference in the σ energy terms for the hydroxy and dihydroxy compounds must exist.

Values of the ratio $k_{13}/(k_4)^{1/2}(k_{14})^{1/2}$ manifest a similar sensitivity to the structure of the phenoxyl radical. Since k_4 is a constant for a given hydrocarbon this quantity represents the ratio of the rate constant for the peroxyl radical-phenoxyl radical termination, to the square root of the rate constant for the bimolecular termination reaction of the phenoxyl radical. An analysis of the available data indicates that the increase in the value of this ratio by a factor of 500 in the series phenol to 3-hydroxypyrene arises primarily from a decrease in the value of k_{14} as the phenoxyl radical becomes more resonance stabilized.

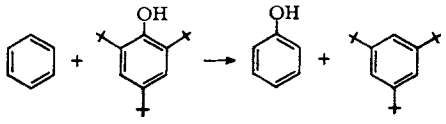
The effect of the structure of the phenoxyl radical on the value of the ratio k_{-12}/k_{15} is quite small; the value for this ratio is in the range of 20–100 for a wide variety of phenols in the tetraphenylbutane-9,10-dihydroanthracene system at 60 °C. This result is consistent with the view that the stability of the phenoxyl radical affects both reactions to approximately the same extent. It should be noted, however, that this ratio for a given phenoxyl radical will vary with the hydrocarbon system since the value k_{15} is very sensitive while k_{-12} should be insensitive to the structure of the hydrocarbon.

A detailed interpretation of the relative values of $k_{15}/(2k_{14})^{1/2}$ is difficult since the values k_{14} and presumably k_{15} also decrease with increasing stability of the phenoxyl radical. However, the value of the reactivity ratio, k_{15}/k_{15}', for a phenoxyl radical, A$^\cdot$ [Eq. (25) and (26)], in hydrogen abstraction from two hydrocarbons, R_1H and R_2H, may be calculated by comparison of the parameters $k_{15}/(2k_{14})^{1/2}$ and $k_{15}'/(2k_{14})^{1/2}$ and k_{-12}/k_{15} and k_{-12}/k_{15}' obtained from the general equation with R_1H and R_2H as the hydrocarbons and AH as the non-hindered phenol.

$$A^\cdot + R^1H \xrightarrow{k_{15}} AH + R^{1\cdot} \qquad (25)$$

$$A^\cdot + R^2H \xrightarrow{k_{15}'} AH + R^{2\cdot} \qquad (26)$$

Such an analysis has been carried out for phenol and 4-methoxyphenol with 9,10-dihydroanthracene and tetralin as the hydrocarbons [22]. Reactivity ratios for hydrogen abstraction were calculated to be approximately 70 for the unsubstituted phenoxyl radical and somewhat larger than 200 for the 4-methoxyphenoxyl radicals. For the corresponding peroxyl radicals, $(k_3)/(k_3')$ was found to be in the range of 17 to 25 at 60 °C. This ratio compares very favorably with the value of 27 at 30 °C calculated from the absolute values of k_3 for the two hydrocarbons.



5. Thermodynamic Properties of Hindered and Non-Hindered Phenolic Antioxidants

The thermodynamic properties of the two classes of phenolic antioxidants and the phenoxyl radicals derived from them are fully in accord with and provide a sound basis for the interpretation of the kinetic studies presented in the preceding sections.

5.1. Strain Energy in 2,4,6-Tri-*tert*-butylphenol

Arnett et al. [30] have recently demonstrated that the strain energy in 1,2-di-*tert*-butylbenzene systems amounts to 22 kcal/mole. This strain can be partially relieved upon the loss of a hydrogen atom [31] to form the corresponding 2,6-di-*tert*-butylphenoxyl radical.

A quantitative estimate of the strain energy in 2,4,6-tri-*tert*-butylphenol compared to simple phenols may be made by means of the following analysis. Consider the hypothetical reaction (27)

(27)

in the gas phase at 298 °K. Utilizing the recently determined heats of formation of 1,3,5-tri-*tert*-butylbenzene [32] and 2,4,6-tri-*tert*-butylphenol [33], the heats of sublimation of these compounds [34], and the known heats of formation in the gas phase of benzene and phenol, the heat of the reaction is calculated as -8.0 ± 2.0 kcal/mole. The magnitude of this strain energy is unique to 2,6-di-*tert*-butylphenol systems since the heat of the reaction of benzene with 2-methylphenol or 2,6-dimethylphenol to yield phenol and the corresponding hydrocarbon is equal to 0 ± 0.5 kcal/mole.

5.2. Bond Energies of Hindered and Non-Hindered Phenols

The relief of the strain in a sterically hindered phenol upon the formation of the hindered phenoxyl radical results in an abnormally low value for the OH bond energy for these compounds.

The heat of the reaction of 2,4,6-tri-*tert*-butylphenoxyl radical with hydrazobenzene to form 2,4,6-tri-*tert*-butylphenol and *trans*-azobenzene has recently been measured calorimetrically [35]. From the results of that measurement and estimates of the heat necessary to transfer the phenol and the phenoxyl radical from solution to the gas phase the value of the –OH bond energy is calculated as 79.9 ± 0.5 kcal/mole. This value is approximately 10 kcal/mole lower than that previously suggested for the OH bond energy of simple phenol [36]. This large difference in the –OH bond energies of hindered and non-hindered phenols of course directly affects the values of the equilibrium constant, k_{12}/k_{-12}, for the two classes of antioxidants.

[36] *S. W. Benson*, J. Amer. chem. Soc. *87*, 972 (1965).

Our laboratory has recently determined the value of the equilibrium constant as a function of temperature for the reaction where $RO_2^{\cdot}$ is the tetralyl peroxyl

(28)

radical[37]. The absolute values of k_{-12} were directly measured utilizing stop-flow techniques[38] for the study of the reaction of 2,4,6-tri-*tert*-butylphenoxyl radical with tetralin hydroperoxide. The inhibition of the oxidation of tetralin by 2,4,6-tri-*tert*-butylphenol provided values of $2k_{12}/k_3$, from which absolute values of k_{12} were calculated utilizing the previously determined absolute values of k_3 for tetralin[39]. The value of k_{12}/k_{-12} calculated from these results is given by the expression (29).

$$\frac{k_{12}}{k_{-12}} = 1.98\, e^{[5400 \pm 1000]/RT} \qquad (29)$$

The extremely large value of this equilibrium constant, 3×10^4 at 60 °C, accounts for the lack of effect of hydroperoxide on the efficiency of the hindered phenol as an antioxidant.

In contrast to hindered phenols, the value of k_{12}/k_{-12} for non-hindered phenols is quite small. From the value of the absolute rate constant for the dimerization of the unsubstituted phenoxyl radical[40,41] and the values of the parameters determined from the kinetic study of phenol as an antioxidant[22], the value of k_{12}/k_{-12} for phenol at 60 °C is calculated as 0.05.

6. Synergistic Behavior of Mixtures of Phenolic Antioxidants

For some time it has been recognized that certain mixtures of two phenolic compounds, AH and BH, are much more effective in inhibiting autooxidation than either AH or BH alone[42]. A mechanism has recently been proposed which quantitatively accounts for the synergistic behavior of such mixtures where AH is a non-hindered phenol and BH is a hindered phenol[43].

[37] *L. R. Mahoney* and *M. A. DaRooge*, unpublished results.

[38] *M. A. DaRooge* and *L. R. Mahoney*, J. org. Chemistry *32*, 1 (1967).

[39] *A. J. Howard* and *K. U. Ingold*, Canad. J. Chem. *44*, 1119 (1966).

[40] *G. Dobson* and *L. I. Grossweiner*, Trans. Faraday Soc., *61*, 708 (1960).

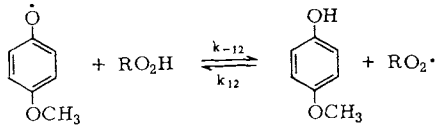
[41] *E. J. Land*, *G. Porter*, and *E. Stracken*, Trans. Faraday Soc. *64*, 2016 (1963).

[42] *K. U. Ingold*, J. Inst. Petroleum *117*, 375 (1961).

[43] *L. R. Mahoney* and *M. A. DaRooge*, J. Amer. chem. Soc. *89*, 5619 (1967).

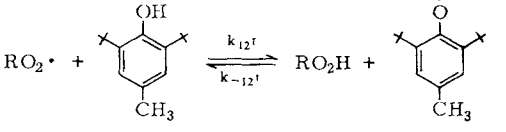
The main feature of the mechanism involves a decrease in the steady state concentration of A$^{\cdot}$ and regeneration of AH by the transfer equilibrium (30).

$$A^{\cdot} + BH \underset{k_{-30}}{\overset{k_{30}}{\rightleftharpoons}} AH + B^{\cdot} \qquad (30, -30)$$



The equilibrium will lie far to the right since the O–H bond energy of BH is much lower than that of AH. (cf. Section 5.2). As a result of the decrease in the steady state concentration of A$^{\cdot}$ the chain restarting reactions of this species with hydroperoxide and hydrocarbon are decreased. Termination of chains in the mixture then occurs through B$^{\cdot}$ *via* the reactions,

$$B^{\cdot} + RO_2^{\bullet} \xrightarrow{k_{13}'} BO_2R \qquad (13')$$



$$B^{\bullet} + A^{\cdot} \xrightarrow{k_{31}} AB^{\bullet} \qquad (31)$$

We shall now consider in some detail the quantitative aspect of the mechanism utilizing as an example 4-methoxyphenol and 2,6-di-*tert*-butyl-4-methylphenol in the 9,10-dihydroanthracene-tetraphenylbutane system.

The ratios of rate constants for the reaction of the 4-methoxyphenoxyl radical with 2,6-di-*tert*-butyl-4-methylphenol and with hydroperoxide, k_{30}/k_{-12}, and with the hydrocarbon, k_{30}/k_{15}, have been obtained

(32)

(33)

from the following analysis. The value of the equilibrium constant, k_{30}/k_{-30}, for the 4-methoxyphenoxyl radical-di-*tert*-butyl-4-methylphenol system is equal to the products (34) of the equilibrium constants for the reactions (32) and (33).

$$\frac{k_{30}}{k_{-30}} = \frac{k_{-12} \cdot k_{12}'}{k_{12} \cdot k_{-12}'} \qquad (34)$$

Rearranging, we obtain (35).

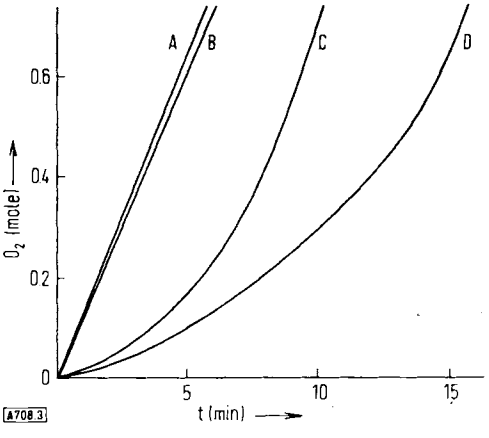
$$\frac{k_{30}}{k_{-12}} = \frac{k_{12}' \cdot k_{30}}{k_{12} \cdot k_{12}'} = \frac{k_{12}' \cdot k_{-30} \cdot k_3}{k_3 \cdot k_{-12} \cdot k_{12}} \qquad (35)$$

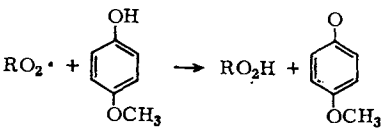
The values of k_{12}'/k_3 and k_3/k_{12} are obtained from the oxidation studies of the hydrocarbon inhibited by the hindered and by the non-hindered phenol. The absolute values of k_{-30} and k_{-12}' are obtained from kinetic studies of the reaction of the 2,4,6-tri-*tert*-butylphenoxyl radical with 4-methoxyphenol and with

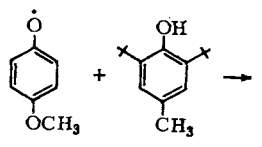
hydroperoxide[44]. The value of k_{30}/k_{-12} for 4-methoxyphenol at 60 °C calculated from equation (35) is found to be equal to 650. A value of 10^4 is then calculated for the ratio k_{30}/k_{15} from the product of k_{30}/k_{-12} and the value of the parameter k_{-12}/k_{15} obtained from the study of the 4-methoxyphenol-9,10-dihydroanthracene system.

The results of oxidation studies of hydrocarbons containing mixtures of 4-methoxyphenol and hindered phenols are in quantitative agreement with the view that the chain restarting reactions of the 4-methoxyphenoxyl radical are effectively suppressed in the presence of the hindered phenol. For example, the rate of oxygen absorption of tetraphenylbutane (2)-9,10-dihydroanthracene system in the presence of a mixture of 4-methoxyphenol and 2,6-di-*tert*-butyl-4-methylphenol when the ratio of RH to 2,6-di-*tert*-butyl-4-methoxyphenol is less than 10^4 is accurately given by expression (36). Moreover the values of $k_3/2k_{12}$ and $k_3/2k_{12'}$ obtained from these results are in excellent agreement with those obtained from the oxidation study of the individual compounds.

The dramatic effect of the addition of small amounts of hindered phenols on the inhibition period manifested by 4-methoxyphenol (cf. Figure 3) is also fully in accord with the regeneration of 4-methoxyphenol *via* the rapid transfer reaction (30).







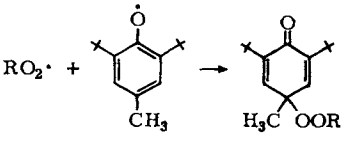


Fig. 3. The oxygen absorption of a chlorobenzene solution of 148 mmoles 9,10-dihydroanthracene at 60 °C containing 124 mmoles 2,2,3,3-tetraphenylbutane and, Curve A: no inhibitor; Curve B: 0.1 mmole 2,6-di-*tert*-butyl-4-methylphenol; Curve C: 0.1 mmole 4-methoxyphenol; and Curve D: 0.1 mmole 2,6-di-*tert*-butyl-4-methylphenol and 0.1 mmole 4-methoxyphenol.

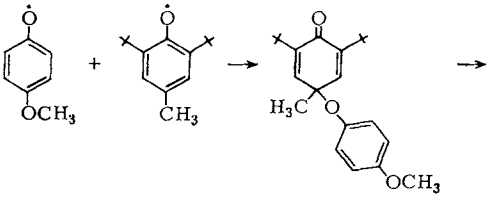
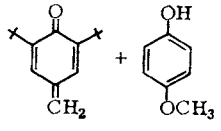
The results of kinetic and product studies under conditions where the rate of reaction (−30) is appreciable, *i.e.*, high concentrations of 4-methoxyphenol, suggest that termination reactions, such as (40) also occur.

This mechanism gives a good account of the synergistic effects observed in practice. Since the necessary step



(slow) (37)



(fast) (38)

(fast) (39)

for synergism to be observed is the favorable competition of the hindered phenol with hydroperoxide and hydrocarbon for the non-hindered phenoxyl radical,

$$\frac{-dO_2}{dt} = 2k_1[R{-}R] + \frac{k_3\,\{2k_1[R{-}R]\}\,[RH]}{2k_{12}[\text{4-methoxyphenol}] + 2k_{12'}[\text{2,6-di-}tert\text{-butyl-4-methylphenol}]} \quad (36)$$

(40)

i.e. the value of k_{30}/k_{-12}, the magnitude of the synergistic effects observed will depend upon the value of this ratio. The values of k_{30}/k_{-12} for 4-*tert*-butylphenol, 4-methoxyphenol, and 2,4,6-trimethylphenol are 100, 600, and much greater than 600 respectively. The values which have been reported for the amount of synergism manifested by these phenols in admixture with 2,6-di-*tert*-butyl-4-methylphenol in a mineral oil at 160 °C are 5, 45, and 160 min[42]. Compounds which failed to manifest a synergistic effect with 2,6-di-*tert*-butyl-4-methylphenol are those which do not restart chains *via* reactions (−12) and (15), namely α-naphthol and 2,4,6-tri-*tert*-butylphenol.

6.2. Mixtures of Non-Hindered Phenols

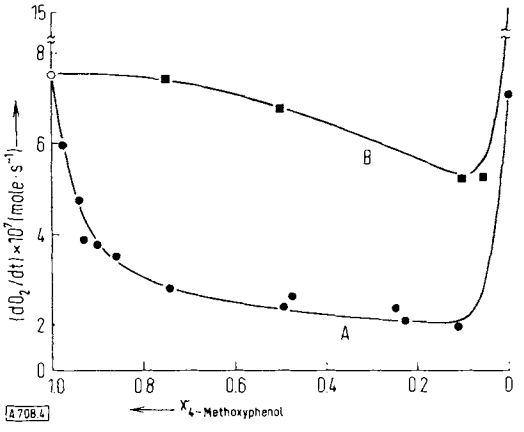
A number of these systems have recently been studied in our laboratory[45]; at sufficiently high concentrations of a non-hindered phenol the rate of oxidation of

[44] The ratio of hydrogen atom transfer for 2,6-di-*tert*-butyl-4-methylphenol and for 2,4,6-tri-*tert*-butylphenol are very similar, see [42].

[45] *L. R. Mahoney* and *M. A. DaRooge*, unpublished results.

$$\frac{-dO_2}{dt} = 2k_1[R{-}R] + \frac{k_{15}}{(2k_{14})^{1/2}} \left\{ 2k_1[R{-}R] \right\}^{1/2} [RH] \qquad (41)$$

a hydrocarbon is given by expression (41). Under these conditions the propagating free radical is the non-hindered phenoxyl radical and the termination reaction is the dimerization of the chain-carrying phenoxyl radical. If one employs a mixture of two non-hindered phenols, both at a sufficiently high concentration such that equation (41) is obeyed, a system for the study of the independent and the cross reactions of the two non-hindered phenoxyl radicals is available. The results of the oxygen absorption of the tetraphenylbutane (*2*)-9,10-dihydroanthracene system containing 4-methoxyphenol in admixture with phenol and in admixture with 3,5-di-*tert*-butylphenol are shown in Figure 4.



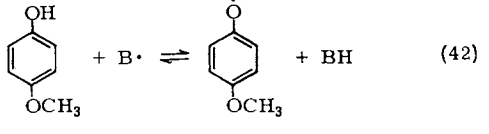


Fig. 4. The rates of oxygen absorption of a chlorobenzene solution of 99 mmoles 9,10-dihydroanthracene at 60 °C containing 31 mmoles 2,2,3,3-tetraphenylbutane, and Curve A: 3,5-di-*tert*-butylphenol + 4-methoxyphenol; Curve B: phenol + 4-methoxyphenol. The total concentrationof the two antioxidants for both curves is equal to 100 mmoles.

An extension of the mechanism which accounts for the synergistic behavior of mixtures of hindered and non-hindered phenols to mixtures where both phenols are non-hindered seems quite logical. For both of the non-hindered mixtures the equilibrium

(42)

where B· is the 3,5-di-*tert*-butylphenoxyl radical or the unsubstituted phenoxyl radical should lie to the right. We come to this conclusion since the values of k_{12}/k_3 which should, in the case of non-hindered phenols, be a measure of the phenoxyl radical stability are 284, 15.0, and 9.8 for 4-methoxyphenol, 3,5-di-*tert*-butylphenol, and phenol respectively. The shape of the oxidation curves A and B will depend upon the relative rates of the termination reactions.

An examination of the kinetic parameters for 3,5-di-*tert*-butylphenol as an antioxidant in the 9,10-dihydroanthracene-tetraphenylbutane (*2*) system strongly suggests that the rates of termination reactions involving the sterically hindered phenoxyl radical derived from it are quite slow.

The values of k_{12}/k_3 for 3,5-dimethylphenol and 3,5-di-*tert*-butylphenol are 10.0 and 15.0 while the values of $k_{15}/(2k_{14})^{1/2}$ are 7×10^{-3} and 40×10^{-3} $l^{1/2} \cdot mole^{-1/2}\ sec^{-1/2}$. Since the rate constant for reactions at the –OH group are very similar, the value of k_{15} for both phenols should be similar, and the value of k_{14} for the 3,5-di-*tert*-butylphenol radical should be small.

In agreement with this view the rates of oxidation manifested by mixtures of 4-methoxyphenol and 3,5-di-*tert*-butylphenol are relatively constant until the mole fraction of 3,5-di-*tert*-butylphenol exceeds 95 mole percent. In contrast, the presence of 5 mole percent phenol strongly reduces the rate of oxidation. This suggests that the cross termination reaction of 4-methoxyphenoxyl and phenoxyl radicals is very rapid compared to the dimerization of 4-methoxyphenoxyl and phenoxyl radicals.

A more detailed analysis of such systems is at present difficult since values for the rate of (30) and/or equilibrium constants (k_{30}/k_{-30}) for non-hindered phenol systems are not yet available.

7. Aromatic Amines as Antioxidants

The mechanism of the antioxidant behavior of aromatic amines has been subjected to considerably less systematic study than that of phenols. The results of study of the deuterium isotope effects are consistent with the peroxyl radical abstracting the amino hydrogen atom [46].

Although the kinetic dependence of the initial rates upon initiator, hydrocarbon, hydroperoxide, and inhibitor concentrations are somewhat complex, the relative effectiveness of substituted diphenylamines and *N*-methylanilines may be correlated with σ^+ values to yield ρ values equal to –0.89 and 1.6 respectively [47] in the styrene system.

In addition to the occurrence of chain restarting reactions of the amino radicals with hydroperoxide and hydrocarbon, a very serious complication encountered in the study of amine antioxidants is that the reaction of a peroxyl radical with an aminyl radical, reaction (43), produces a nitroxide radical and an alkoxyl radical [48].

$$RO_2{\cdot} + {\cdot}NR_2 \rightarrow RO{\cdot} + {\cdot}O{-}NR_2 \qquad (43)$$

The alkoxyl radical will regenerate the peroxyl radical *via* reactions with hydroperoxide and hydrocarbon. The subsequent reactions of the nitroxide radicals are very complex; they are apparently capable of reaction with both R· and RO_2· and also with hydroperoxide as indicated by the effect of oxygen pressure and hydroperoxide upon hydrocarbon oxidation inhibited by stable nitroxides [49].

The author wishes to acknowledge the contributions of his collaborators at the Scientific Laboratory of Ford Motor Company, particularly Dr. Margaret A. DaRooge.

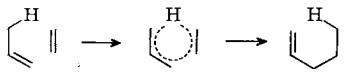
The Ene Reaction



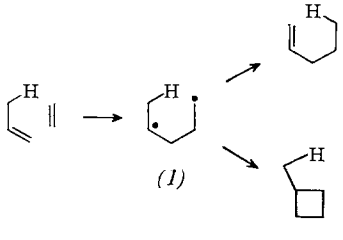
By H. M. R. Hoffmann[*]

The ene reaction is defined as the indirect substituting addition of a compound with a double bond (enophile) to an olefin with an allylic hydrogen (ene). For a long time the reaction has been neglected and has remained overshadowed by the related Diels-Alder addition. It is shown that the ene reaction possesses wide scope and applicability ranging from industrial to biosynthetic processes. Preparative aspects are summarized and current views on the mechanism are discussed.

1. Introduction

Although the ene reaction is one of the most simple and versatile reactions of organic chemistry, it is surprisingly little known and virtually ignored in all textbooks. Isolated examples such as certain reactions of olefins with formaldehyde (Prins reaction; cf. also Section 3.4)[1] as well as retro-ene reactions, *e.g.*, the decarboxylation of β-ketoacids and the formation of olefins by ester pyrolysis have been known at least since the beginning of the century, but many further examples have been buried in the patent literature[2] and in a number of obscure journals. Only after a paper by *Alder*[3] in 1943 did the scope of the ene reaction begin to be recognized. However, until today the "ene synthesis" has remained unfashionable and overshadowed by the related Diels-Alder addition ("diene synthesis"). Furthermore, much of the early work is insecurely based, because the by now common analytical and spectroscopic tools were not available. It is the purpose of this review to discuss what results and mechanistic insight are now available on this reaction.

The ene reaction is the "indirect substituting addition"[3] of a compound with a double bond (enophile) to an olefin possessing an allylic hydrogen (ene) and involves allylic shift of one double bond, transfer of the allylic hydrogen to the enophile and bonding between the two unsaturated termini (Scheme 1). Formally the reaction is not only related to the Diels-Alder addition, but can also be regarded as an intermolecular variant of the symmetry-allowed 1,5-hydrogen shift[4]



Scheme 1

Scheme 2. $\Delta H^{\ddagger} = 35.4$ kcal/mole, $\Delta S^{\ddagger} = -7.1$ e.u. [6].

(Scheme 2), although the transition state geometry of all three reactions is different (Section 6.5). It must be stressed from the very beginning that the ene reaction need not necessarily proceed in concerted fashion. If, for example, the ene component is so constituted that simultaneous bond-making at its carbon and hydrogen termini is geometrically unfavorable, the stepwise reaction involving a biradical *(1)* may occur (Scheme 3). Such a mechanism will usually betray itself on careful product analysis, since it seems clear from the elegant work of *Bartlett*[5] that a biradical such as *(1)* will at least partly leak into the cyclobutane derivative *(2)*. Conversely, current theory suggests that in the absence of any cyclobutane derivatives the ene reaction is most likely to take a concerted course. The other mechanistic extreme, *i.e.*, formation of an intermediate allylic radical by slow transfer of the hydrogen to the enophile, appears to be extremely rare (Section 6.5).

Scheme 3

2. The Ene Component

2.1. Monoolefins

The most simple ene reaction, that of propylene with ethylene (Scheme 1), appears to be unknown and only the reverse reaction, *i.e.*, decomposition of 1-pentene can be achieved at elevated temperatures[6]. However,

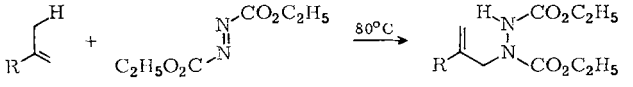
under high pressure acetylene has been proved to react with a number of simple olefins to form 1,4-dienes[7]. For instance, 2-methyl-1,4-pentadiene *(4)* can be isolated in 40% yield when a large excess of isobutylene *(3)* is treated with acetylene in a flow reactor at 170 atm.

(3) *(4)*



Thaler and *Franzus*[8] have treated a number of isomeric butenes and pentenes with diethyl azodicarboxylate (Scheme 4) and identified the products by NMR spectroscopy and gas-liquid chromatography (Table 1). These data demonstrate that the azo ester

Table 1. Monoadducts, yields, and relative rates of the reaction of diethyl azodicarboxylate with butenes and pentenes; Y = $N(CO_2C_2H_5)$—$NHCO_2C_2H_5$ [8] (cf. Scheme 4).

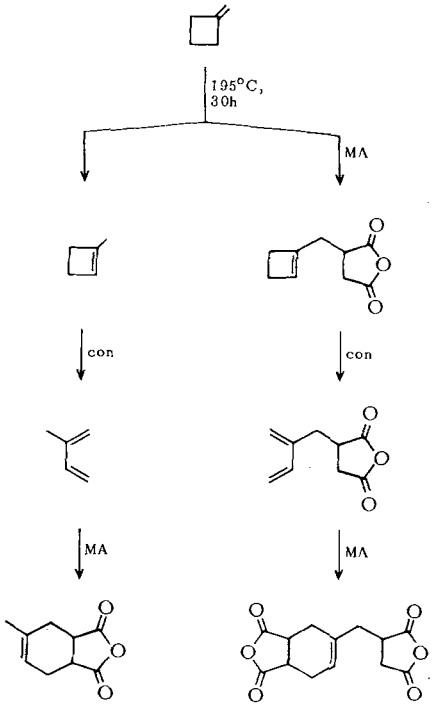
attacks the least substituted allylic position preferentially. In other words, a primary hydrogen is abstracted more readily than a secondary and much faster than a tertiary one (entries 1, 3, 9). The thermodynamic stability of the product is not decisive here. 3-Methyl-1-butene (entry 9), which can only donate its crowded isopropyl hydrogen to the enophile, reacts very slowly despite the fact that the abstracted hydrogen is tertiary. In fact, in the latter reaction it is difficult to isolate the monoadduct, which, having six primary hydrogen atoms, forms the bisadduct very smoothly.



Scheme 4

Substituent effects at the nonterminal vinylic carbon of the ene component have been investigated less thoroughly. However, relative rates obtained from competition experiments indicate that feeding electrons into this position increases rates. Note also that 2-methyl-2-butene forms the adduct in which Y is attached to the secondary but not the tertiary carbon (entry 5) and that *trans*-2-butene reacts faster than the *cis* isomer (entries 2,4).

Substituted allylic compounds such as 1,3-diarylpropenes react with diethyl azodicarboxylate according to Scheme 4[9], and with selenium dioxide in acetic acid[10], but have been claimed not to react with maleic anhydride[11], which admittedly is a less effective enophile.

2.2. Methylenecycloalkanes and 1-Methylcycloalkenes

Methylenecyclobutane affords a 1:2 adduct with maleic anhydride (MA) in easily discernible fashion. The 1:1 adduct which is formed in a side reaction, is visualized

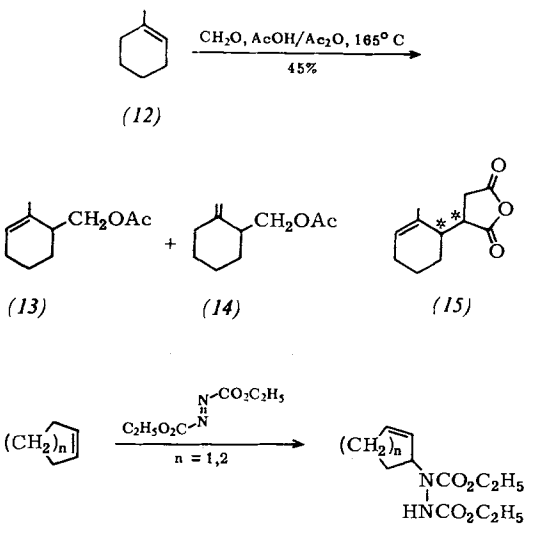
to arise from rearrangement to 1-methylcyclobutene, opening to isoprene, and Diels-Alder trapping (Scheme 5)[12]. Methylenecyclopentane gives rise to *(5)* and *(6)* on heating with, respectively, maleic anhydride and formaldehyde to 200 °C for 2–4 hours. In contrast, the sulfonic acid *(7)* is formed simply on leaving methylenecyclopentane and sulfur trioxide in dioxane at 0 °C[13]. Under the same conditions and with the same reagents methylenecyclohexane forms the adducts corresponding to *(5)*, *(6)*, and *(7)*[14].

(5) *(6)* *(7)*

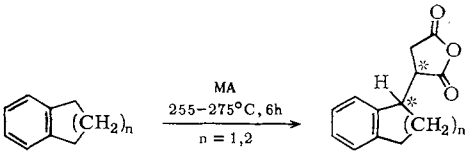
Naturally-occurring β-pinene *(8)* is particularly reactive towards enophiles. It readily forms adducts with maleic anhydride, dimethyl maleate and fumarate, methylenemalonic ester[15a], formaldehyde[15b], trichloroacetaldehyde[15c], carbonyl cyanide[15d], butyl



(8) *(9)* *(10)* *(11)*

glyoxylate[15e], and benzyne[15f]. If these reactions were to proceed *via* a carbonium ion such as *(9)* (or the corresponding radical), much rearranged product would arise. In fact, it has been found that the isolated products retain the pinene carbon skeleton. Presumably, in all these reactions the axial hydrogen which is on the more accessible *endo* face, is abstracted from β-pinene. The homologous myrtenol formed from formaldehyde and β-pinene is valued in the perfumery industry under the trivial name of nopol.

Unlike *(8)*, the endocyclic isomer α-pinene *(10)*, which is thermodynamically more stable, reacts not at all or only very reluctantly. For example, the powerful enophile singlet oxygen gives a minor amount of ene adduct only[16], and paraformaldehyde reacts at 180 °C in the absence of solvent to give *(11)* in 12% yield only[17]. In these reactions α-pinene is attacked generally from the less hindered *endo* side.



Cyclopentene and cyclohexene react with diethyl azodicarboxylate according to Scheme 6. However, these reactions are abnormal in that they can be catalyzed by radical initiators such as dibenzoyl peroxide and retarded by radical inhibitors (*p*-benzoquinone, acrylonitrile)[8,9] (see also Section 6.5). Indan and tetralin

(12) *(13)* *(14)* *(15)*

Scheme 6

react with maleic anhydride to form diastereomeric 1:1 adducts in which the double bond is unshifted (Scheme 7)[18].

Scheme 7

1-Methylcyclohexene *(12)* reacts with formaldehyde at 165 °C, when acetic acid-acetic anhydride is used as a solvent, to give an approximately equal mixture of acetates *(13)* and *(14)*[17,19]. It has been reported in an earlier paper that *(12)* and maleic anhydride afford *(15)* as a mixture of two diastereoisomers, but not the adduct corresponding to *(14)* with an exocyclic double bond[20]. Recently, *Blomquist* and his co-workers have considerably improved the experimental conditions for inducing ene reactions with formaldehyde. For example, the thermal ene reaction of (+)-limonene *(16)* with formaldehyde in an autoclave at 180–200 °C is completely unsatisfactory. However, if *(16)* is treated with formaldehyde in solvent dichloromethane-acetic anhydride in the presence of boron trifluoride dihydrate, the adduct *(17)* is formed in 69% yield after 70 minutes at autogeneous temperature[21]! Interestingly, the disubstituted double bond of *(16)* is inert to singlet oxygen, which selectively attacks the more electron-rich internal double bond[20a].

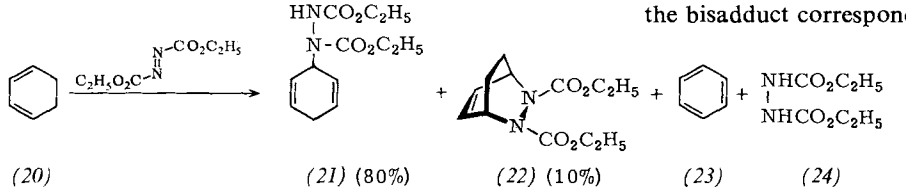
(16) (17)

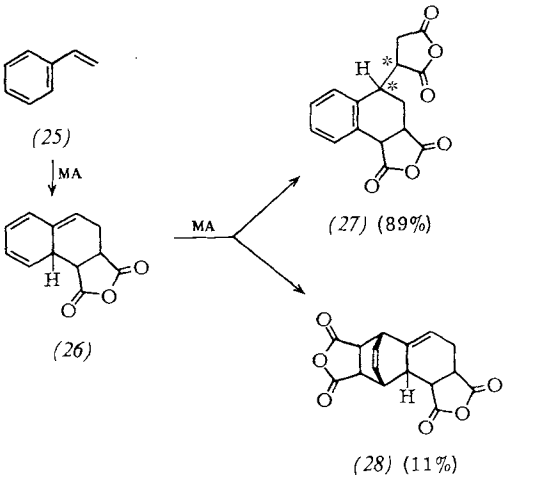
(18) (19)



(19a)

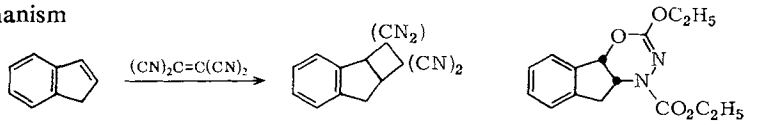
On treatment with formaldehyde in dichloromethane containing boron trifluoride dihydrate or, alternatively, stannic chloride, camphene *(18)* forms adduct *(19)* as the main product (57%)[22a]. In contrast, on heating *(18)* to 105 °C with formaldehyde in acetic acid one obtains *(19a)* in 75% yield; *(19a)* is also formed from *(19)* in hot acetic acid[22b]. Consequently, the conversion of *(18)* into *(19)* could represent the first example of a homo-ene reaction as formulated here, although *Blomquist* has suggested a stepwise mechanism *via* a carbonium ion intermediate[22a].

2.3. 1,3-Dienes



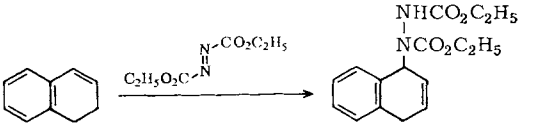
Special factors are required if the ene reaction is to proceed with conjugated dienes in preference to the Diels-Alder addition. It was reported originally that 1,3-cyclohexadiene *(20)* forms exclusively the ene product *(21)* with diethyl azodicarboxylate and no Diels-Alder adduct *(22)*[23]. Reinvestigation revealed that *(22)* is formed albeit in low yields (5–15%)[24]. However, cycloadduct *(22)* may be obtained in 87%

(20) (21) (80%) (22) (10%) (23) (24)



yield without any admixed *(21)* if the reaction solution is irradiated below room temperature[25]. It has been shown that UV irradiation of diethyl azodicarboxylate which normally possesses the more stable *trans* configuration, produces some *cis* isomer in photostationary equilibrium[26]; *cis* azo derivatives are generally much more reactive in both 4 + 2[26,27] and 2 + 2 cycloadditions[28].

A comparison of the benzoannelated dienes *(25)*, *(29)*, and *(32)* is informative. Styrene *(25)* and maleic anhydride first form the Diels-Alder adduct *(26)*, which apparently cannot be isolated, since it possesses a



(25) (26) (27) (89%) (28) (11%)

carbon-hydrogen bond weakened by both allyl and pentadienyl resonance. Reaction with a second molecule of maleic anhydride yields the ene product *(27)*

(29) (30) (31)

(32) (33)

and the 4 + 2 adduct *(28)* in a ratio of *ca.* 8:1[29]. In contrast, styrene and diethyl azodicarboxylate form the bisadduct corresponding to *(27)* only[30].

Indene *(29)* and tetracyanoethylene afford the 2 + 2 adduct *(30)* [31a]. Originally, the reaction with diethyl azodicarboxylate was assumed to yield the analogous 2 + 2 product [31a], but more recent work has shown that the 4 + 2 adduct *(31)* is formed instead [31b].

1,2-Dihydronaphthalene *(32)* does not undergo a Diels-Alder addition with diethyl azodicarboxylate but forms *(33)* [9]. In this reaction free radical initiators and inhibitors have shown no effect [9]. Not surprisingly, the Diels-Alder addition is completely suppressed for conjugated dienes including a variety of steroidal dienes [34–36], which are highly alkylated at the carbon termini. Apparently, only ene products have been isolated for the reactions listed in Table 2.

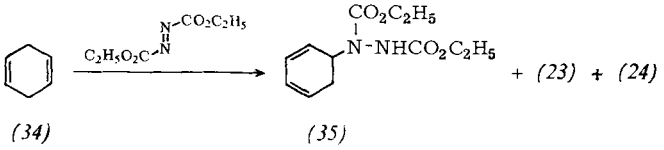

Table 2. Ene reactions of sterically hindered 1,3-dienes.

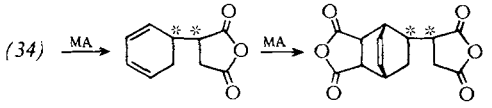
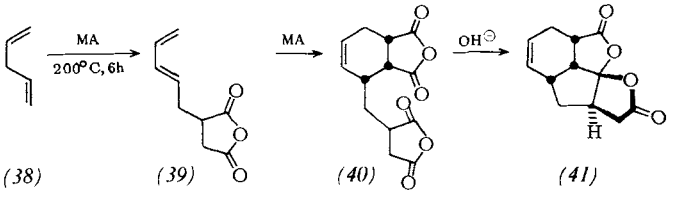
No.	Reactions	Ref.
1		[32]
2	 78.5% 21.5%	[33]
3		[34]



The competition of ene and diene synthesis in the thermal and catalyzed reactions of acyclic 1,3-dienes with carbonyl compounds is described in Section 6.4; see also Table 3.

2.4. 1,4-Dienes

1,4-Cyclohexadiene *(34)* reacts some fifteen times less readily with diethyl azodicarboxylate than 1,3-cyclohexadiene although conjugation energy is gained in the former and lost in the latter reaction. The equilibration of *(34)* and *(20)* with strong base has revealed that the conjugated diene *(20)* is more stable than *(34)* by only 600 cal [24, 36a]. This free energy difference corresponds to a ratio of *(20)*:*(34)* = 2.85:1 at equilibrium!



(34) *(35)* + *(23)* + *(24)*

(36) *(37)*

Maleic anhydride is generally less effective as an enophile than diethyl azodicarboxylate, but more efficient as a dienophile. Consistently, the reaction of 1,4-cyclohexadiene *(34)* and maleic anhydride cannot be stopped at the stage of the monoadduct *(36)*, and *(37)* is isolated as the final product [37]. Similarly, heating of 1,4-pentadiene *(38)* with maleic anhydride affords in 40% yield the bisanhydride *(40)*, which is decarboxylated to the spirodilactone *(41)* by traces of alkali [38]. On heating to 120 °C in benzene solvent, maleic anhydride forms the normal ene product with 1,4-dihydronaphthalene [39] and cinnamylsuccinic anhydride

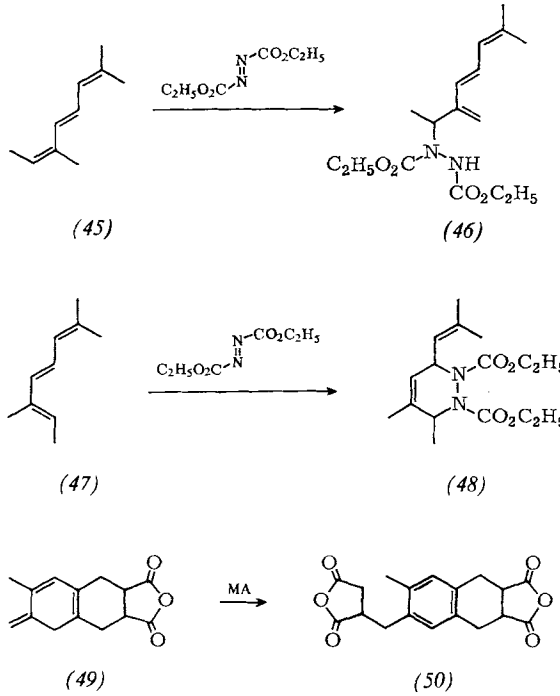
(42) (43)

(43) with allylbenzene (42) [40]. Whether (43) is formed as the *trans* and/or *cis* isomer is unknown.

In norbornadiene (44) a shift of the double bond is forbidden by Bredt's rule. With diethyl azodicarboxylate the 2 + 2 + 2 adduct (44a) and an isomeric compound have been detected in approximately equimolar quantities [41]. Later work has suggested the unusual



(44) (44a) (44b)

structure (44b) for the second adduct, *i.e.*, the azo ester behaves as a heterodiene [42] analogous to the formation of (31).

2.5. Conjugated Trienes

The allocimene (45) [43], a naturally occurring triene, reacts cleanly with diethyl azodicarboxylate to form (46) under self-heating, while the isomeric triene (47) yields the Diels-Alder adduct (48) only [44a]. Clearly, any cisoid diene component of triene (45) contains at least one terminal *cis* alkyl group, an unfavorable situation in a Diels-Alder addition [45]. On the other hand, the *cis* configuration of the vicinal methyl groups in (47) impedes the ene reaction (Table 1, entry 4), while the methyl and isobutenyl group attached to the reacting cisoid diene system are *trans* and probably promote the cycloaddition. Interestingly, the less hindered and more reactive singlet oxygen gives only one stable ene adduct with either allocimene; cycloperoxides are not formed [44b]. Not surprisingly, triene (49) undergoes the ene rather than diene synthesis [46].

(45) (46) (47) (48) (49) (50)

Cycloheptatriene reacts with a variety of dienophiles such as maleic anhydride [47a,47b], 4-phenyl-1,2,4-triazoline-3,5-dione [27], fumaryl chloride [47a], and dimethyl and diethyl acetylenedicarboxylate [47c] to form Diels-Alder adducts of the general structure (52), in which the cyclopropane ring is oriented *syn* to the double bond. Recently, *Woodward* and *Houk* [48] have concluded that (52) arises from a 2 + 2 + 2 cycloaddition rather than from attack on the norcaradiene valence tautomer as had been frequently suggested [49]. Dimethyl acetylenedicarboxylate does not only form the Diels-Alder product (26% yield); in addition, a minor product (55) (12%) has been observed which seems to arise from an ene reaction followed by electrocyclic closure and a 3,3-sigmatropic process [50]. With diethyl azodicarboxylate [51a,b] and singlet oxygen [51b] cycloheptatriene undergoes the ene reaction exclusively to form adducts (56a) and (56b), respectively. It is of interest how (56a) is actually formed. By using [7-D]-cycloheptatriene, *Koerner von Gustorf* has

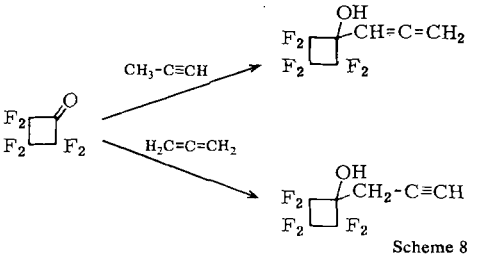
(53) (54) (55)

(56a), Y = (56b), Y = $-O_2H$

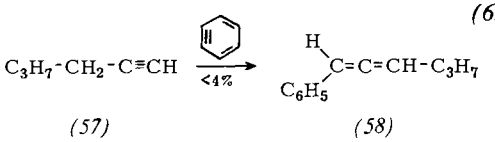


(56c) (56d)

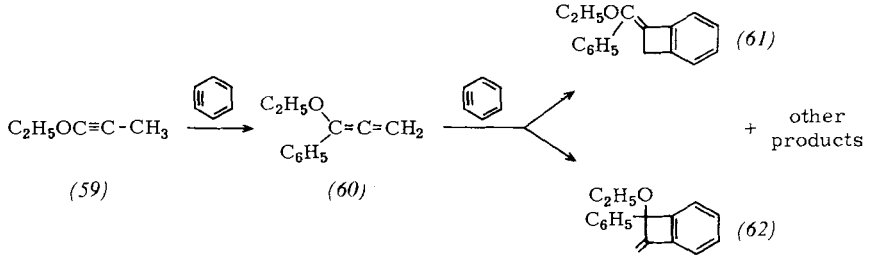
shown recently that *(56c)* and *(56d)* arise in a ratio of 7:1, no deuterium being detectable at the C-3 and C-4 carbon. Apparently, the ene reaction cannot only proceed *via* a 6-membered ring, but also a 10-membered one, provided the loss in entropy is not too high. Clearly both reaction modes are symmetry allowed [51c]. (Cf. also the ene reaction in Scheme 12a, which may be regarded as a 10-electron or even a 14-electron process.)

2.6. Propynes and Allenes

Only the most powerful enophiles react with propynes in the sense of the ene reaction and few examples have been reported. 1-Hexyne *(57)* reacts with benzyne to form the allene *(58)* in less than 4% yield [52], while 1-ethoxypropyne *(59) inter alia* affords *(61)* and *(62)*. The two bis-adducts seem to arise from the reaction of the intermediate allene *(60)* with an excess of benzyne [53]. Whether the allenes *(58)* and *(60)* are formed in a concerted process or not is presently not clear. A further "record enophile" is perfluorocyclobutanone which undergoes the ene reaction with methylacetylene and allene (Scheme 8) [54]. Tetramethylallene reacts



Scheme 8

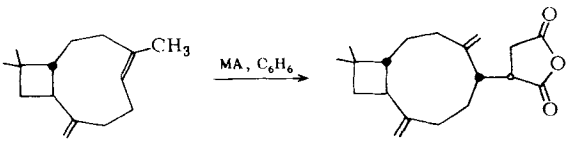


smoothly with azodicarboxylic esters and 5-phenyl-1,2,4-triazoline-3,5-dione to give the corresponding ene adducts at room temperature [51d]; in these reactions the enophile attacks the central carbon of tetramethylallene.

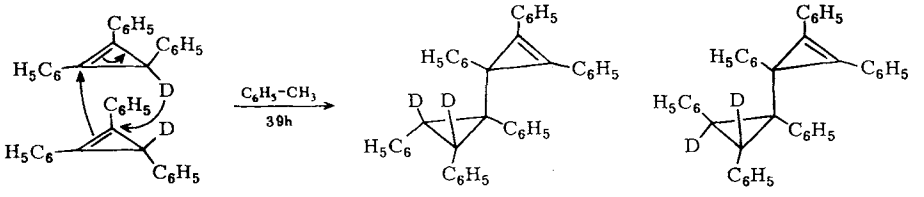
2.7. Strained π- and σ-Bonds

Olefins with strained double bonds seem particularly prone to enter into ene reactions. For example, the naturally occurring sesquiterpene caryophyllene *(63)*, which contains a strained *trans* double bond,

(57) (58)



(59) (60) (61) (62)



[52] *M. Stiles* and *A. Haag*, private communication to *R. W. Hoffmann*, cited in: Dehydrobenzene and Cycloalkynes. Academic Press, New York 1967, p. 198.

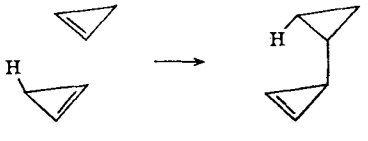
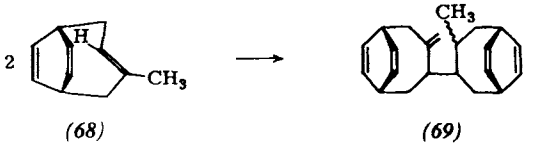
[54] *D. C. England*, J. Amer. chem. Soc. *83*, 2205 (1961).



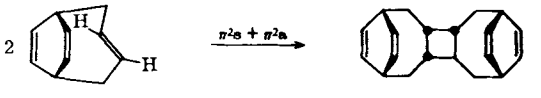
(63) (64)

(65) (66) (67)

reacts smoothly with maleic anhydride in refluxing benzene. Originally the product was formulated as a Diels-Alder adduct[55b,c,d] but after the structure of caryophyllene had been elucidated *Nickon* deduced structure *(64)* for the product[55a]. However, when the comparatively energy rich singlet oxygen is used as the enophile, caryophyllene reacts only about 5–6 times faster than its *cis* isomer (iso-caryophyllene)[55e]. The exocyclic double bond is not attacked by singlet oxygen[55f], although it is more accessible.



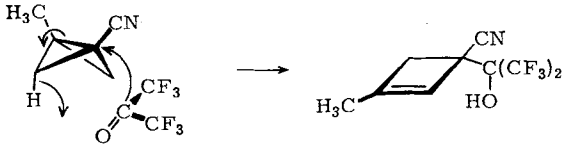
The deuterated triphenylcyclopropene *(65)* dimerizes in 20% yield on heating in toluene; the product has been formulated as the *cis* dimer *(66)* rather than *(67)* because in the formation of *(66)* the deuterium is transferred to the less hindered face of the second cyclopropene system[56]. Even more spectacular is the dimerization of the parent cyclopropene, which has been observed recently by *Dowd* and *Gold*[57]. Such is the reactivity of this hydrocarbon that it polymerizes with explosive violence at room temperature. However, if it is allowed to react in dilute dichloromethane



Scheme 9

solution at −25 °C, the extremely labile dimer can be isolated (Scheme 9). This reaction is probably not a free radical process as had been suggested earlier, since neither added nitrobenzene nor *p*-benzoquinone have shown any effect on the rate of dimerization.

The behavior of some bridged *cis,trans*-1,5-cyclooctadienes whose *trans* double bond is considerably twisted is also of great interest. Thus, the photoadduct *(68)* of benzene and isoprene dimerizes to *(69)*, a single compound or a mixture of two stereoisomers being formed below room temperature[58a]! In contrast, olefin *(70)*, which contains a less crowded *trans* double bond, affords *(71)*[58b] in a symmetry-allowed $\pi 2s + \pi 2a$ cycloaddition[59].



(68) (69)

(70) (71)

Considerable interest has focused recently on reactions of strained hydrocarbons such as bicyclo[1.1.0]-butanes and bicyclo[2.1.0]pentanes, in which the zero bridge exhibits a major degree of unsaturation[60]. 3-Methylbicyclo[1.1.0]butanecarbonitrile *(72)* has

(72) (73) (74)

been treated with a variety of olefins and carbonyl compounds; with hexafluoroacetone in ether solution the cyclobutene derivative *(74)* is formed in 82% yield below room temperature[61a]; dicyanoacetylene

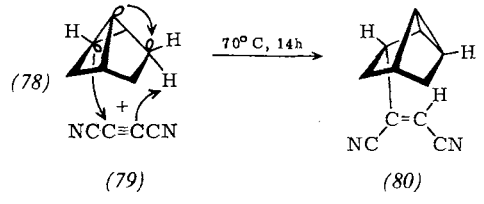
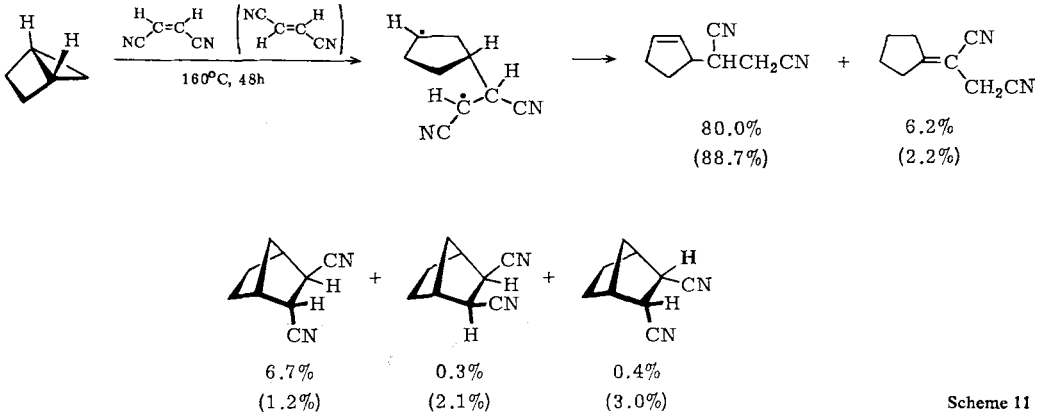
(75)



6.5 : 1

Scheme 10

(76) (77)

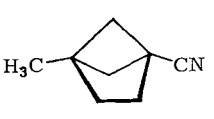


(78) (79) (80)

gives rise to *(75)* and three unidentified very minor by-products [61b].

In analogous fashion 1,3-dimethylbicyclo[1.1.0]butane reacts with dehydrobenzene [62a], hexafluoroacetone [62b], and maleic anhydride [62b]. The propano-bridged bicyclobutane *(76)* and dehydrobenzene afford *(77)* in 61% yield [63] while hydrocarbon *(78)* which contains the structural element of bicyclo[2.1.0]-pentane reacts with dicyanoacetylene *(79)* to form *(80)* in 46% yield [64].

Frequently, bicyclobutanes and bicyclopentanes react with olefins to give not only ene products, but also cycloadducts. In these cases a stepwise mechanism involving biradical intermediates seems assured, at least for the formation of the cycloadducts (cf. also Scheme 3). For example, the reaction of bicyclobutane with dehydrobenzene gives rise to benzobicyclo[2.1.1]-hexene as a by-product [65] (Scheme 10), in contrast to 1,3-dimethylbicyclo[1.1.0]butane, which under the same conditions yields the ene adduct only [62a].



Five of seven products have been identified in the reaction of bicyclo[2.1.0]pentane with maleonitrile and fumaronitrile, respectively (Scheme 11; the yields in brackets refer to the reaction with fumaronitrile). Clearly, the three isomeric 2,3-dicyanonorbornanes are formed in either reaction, and hence rotation about the central bond of maleonitrile and fumaronitrile must have occurred at some stage during the reaction. Since a concerted formation of the cycloadducts is also forbidden by orbital symmetry conservation, the experimental findings are best accommodated by a biradical intermediate, in which rotation about a carbon-carbon single bond may compete with intramolecular radical combination [66]. 1:1 Cycloadducts which are derived from the bicyclo[2.1.1]hexane skeleton *(81)* can also be isolated in reactions of 3-methylbicyclo-[1.1.0]butane-1-carbonitrile *(72)* with ethylene, butadiene, styrene, acrylonitrile, maleonitrile, fumaronitrile, and 1-(*N*,*N*-dimethylamino)cyclopentene [67].

Scheme 11

(81)

(82)

As regards stereochemistry the enophile could attack the zero bridge from the *exo* or *endo* direction *(82)*. The formation of the *endo* adducts *(77)* and *(80)* demonstrates for two specific examples that it is the backlobe of the zero bridge which is most vulnerable

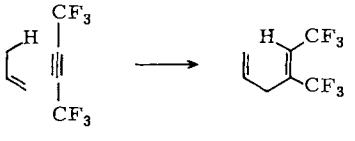
to attack from enophiles. In fact, much further work with deuterium labeled substrates suggests that *endo* attack is a general feature of these reactions [68,69] [cf. also the pyrolysis of *(118)*].



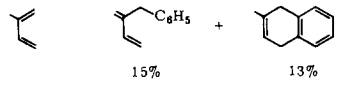
3. The Enophile

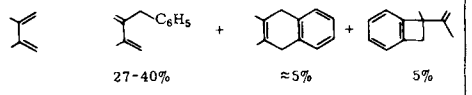
3.1. Alkenes

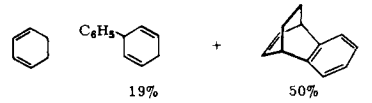
One of the most widely used enophiles of this type is maleic anhydride. In fact, its reactions with caryophyllene [55] and with naturally occurring unsaturated fatty acids and esters [2,3] represent the first recorded examples of ene reactions in all-carbon systems, and much further work has been reported since then [12,14,70]. Typical conditions for reactions of simple allylic compounds are 20 hours and 220 °C, an aromatic solvent generally being used. Trichlorobenzene is a particularly suitable solvent owing to its high boiling point (200–210 °C) which makes an autoclave unnecessary. Polymerization of the reactants and products can be inhibited by adding thionine or phenothiazine. Under these conditions the ene adducts have been isolated in up to 80% yield [71]. Tetracyanoethylene appears to have been used only rarely as an enophile [35,72]. α,β-Unsaturated ketones [73], esters [73], and nitriles [73a], in which the olefinic bond is activated by only one electron-attracting group, are less reactive than maleic anhydride.

3.2. Alkynes

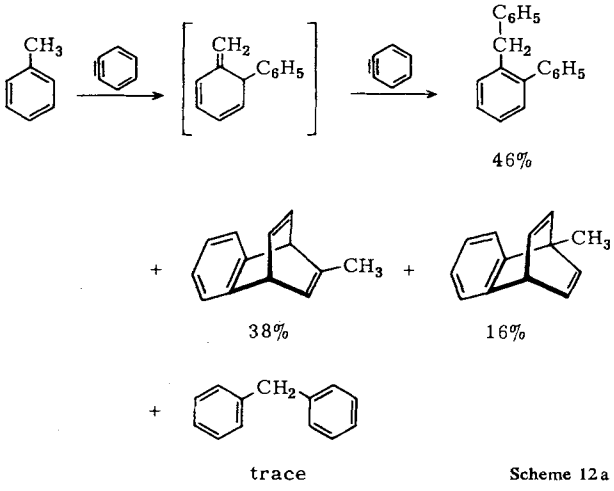
The parent acetylene has been shown to react with isobutene at 350 °C under special conditions [7]. Acetylenedicarboxylic esters [50,73b,74], propiolic ester [73b,74], and dicyanoacetylene [61b,64] generally react below 200 °C, even with unactivated ene components. Hexafluoro-2-butyne readily forms 1,4-dienes with isobutene and 2-butene according to







Scheme 12



Scheme 12; in fact, it seems somewhat difficult to isolate the monoadduct in these reactions. Trifluoropropyne is less reactive, requiring temperatures of *ca.* 225 °C [74].

Dehydrobenzene is strongly electrophilic and is also one of the most powerful enophiles. Simple olefins such as isobutene [75a], 2,3-dimethyl-2-butene [75b], and cyclohexene [75c] are readily phenylated with shift of the double bond. The ene synthesis can also compete favorably with the Diels-Alder addition in reactions of dehydrobenzene with open-chain dienes, but less so with cyclic dienes, where the cisoid conformation

Table 3. Ene synthesis *versus* Diels-Alder addition in reactions of dehydrobenzene with conjugated dienes.

No.	Olefine	Products	Ref.
1		15% 13%	[75a]
2		27-40% ≈5% 5%	[75a]
3		19% 50%	[75d]

necessary for a 4 + 2 addition is enforced (Table 3). Apparently, in all three reactions listed in Table 3, further as yet unidentified products are formed [75a,75d]. Interestingly, even alkylarenes enter into ene reactions with dehydrobenzene as could be shown recently by *Friedman et al.* For example, the major product (46%) in the reaction of dehydrobenzene with toluene is 1-benzyl-2-phenylbenzene, which is formed in a "double-ene reaction"; Diels-Alder addition and insertion to diphenylmethane (trace) are less important here (Scheme 12a). Ethylbenzene and isopropylbenzene

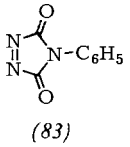
react similarly, but *tert*-butylbenzene, which does not contain an allylic hydrogen, failed to give any ene product, as expected. Tetrafluorobenzyne and tetrachlorobenzyne only yield Diels-Alder adducts with toluene.

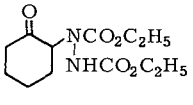
1-Methylnaphthalene undergoes (4 + 2) cycloaddition exclusively with preferential attack (63 %) of the methylated ring. In contrast, 2-methylnaphthalene not only forms Diels-Alder adducts, but also the double ene product 2-benzyl-1-phenylnaphthalene in 38 % yield. Apparently, this difference is due to a simple electronic effect, *i.e.*, enophiles, like electrophiles, attack preferentially the more electron-rich α-carbon of naphthalenes [76].

Altogether, alkynes undergo the ene reaction more readily than comparable alkenes (cf. also Section 6.1).



3.3. Azo Compounds

The most widely used derivative is diethyl azodicarboxylate, which reacts under rather mild conditions with ene components, heating to 80 °C for a few hours being sufficient to complete the reaction [8, 77]. The same compound also enters into ene reactions

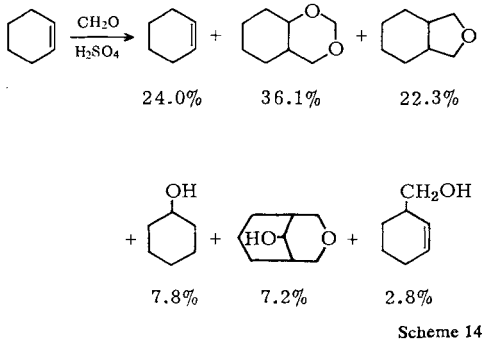


Scheme 13

with conjugated dienes and trienes, 1,4-dienes (see above) and with aldehyde hydrazones (Scheme 13) [78]. If the azo-linkage is present in the *cis*-configuration as in photochemically generated azodicarboxylate [25, 26, 79] and in 4-phenyl-1,2,4-triazoline-3,5-dione *(83)* [27] the dienophilic properties are considerably enhanced. In fact, *(83)* is a "record dienophile" which reacts smoothly with a variety of conjugated dienes [27, 80] and cycloheptatriene [27].

(83)

(84)



It must be mentioned that diethyl azodicarboxylate has general hydrogen-abstracting properties. For example, it smoothly oxidizes primary and secondary alcohols, thiols, anilines, and hydrazobenzene to aldehydes, ketones, disulfides, azobenzenes, and azobenzene, respectively, while itself being converted into diethyl hydrazodicarboxylate [81a]. Similarly, it abstracts hydrogen α to oxygen in ethers [81b] and α to sulfur in sulfides [81c]. Reaction with cyclohexanone affords *(84)*, the formation of which is weakly catalyzed by free radical initiators but strongly base-catalyzed [81d].

3.4. Carbonyl Compounds

The reaction of formaldehyde with olefins is of industrial interest and has been studied with unusual intensity. When the reaction is carried out thermally in the absence of catalyst, the products are generally those expected from ene reactions. However, there still exists a great deal of mechanistic uncertainty and even confusion about acid-catalyzed reactions ("Prins reactions") [83], which appear to react partly in the sense of the ene reaction, partly *via* an electrophilic addition of protonated formaldehyde (cf. also Section 6.5 and Table 5, No. 5).

The reaction of cyclohexene with aqueous formaldehyde in sulfuric acid may serve as an example for the complexity of the product mixtures (Scheme 14) [82] that may be obtained.

Clearly, the presence of mineral acids makes it difficult to determine the products of kinetic control and only little mechanistic insight can be gained. Investigations with *Blomquist*'s system of catalysts [21] could be of interest.

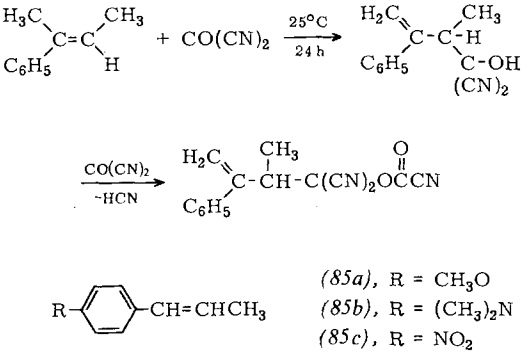
Higher aldehydes react less readily and apparently only if enolization is blocked. Trichloroacetaldehyde[15c] and phenylglyoxal[14] react with monoolefins of the methylenecyclohexane type, but the former has been reported not to react with less active ene components[84], although it does react readily if an electrophilic catalyst such as stannic chloride is present (see Section 6.4).

A variety of ketones has been employed as enophiles. Diethyl mesoxalate reacts with 1-pentene (Scheme 15), cyclohexene, and α-methylstyrene; as an enophile it

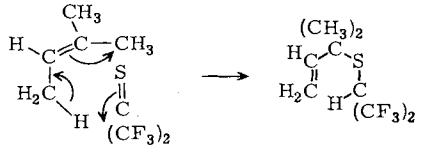
Scheme 15



appears to be superior to formaldehyde, but inferior to carbonyl cyanide[85]. Methyl pyruvate and β-pinene form an adduct (55%) in a readily reversible process (Scheme 16)[86] (cf. also Section 5.2).

Scheme 16

Perhaloketones such as hexafluoroacetone and *sym*-dichlorotetrafluoroacetone add to a variety of ene components. The reaction with isobutene, β-pinene, and isopropenyl methyl ether occurs already at room temperature in high yields (80%). It has been asserted on rather little evidence that a stepwise rather than concerted mechanism best accounts for the experimental observations[87]. The most remarkable of all perhaloketones is perfluorocyclobutanone which reacts with alkynes and allenes (Scheme 8)[54].



Ene reactions with carbonyl cyanide have been studied in some detail by a Polish group. Generally, the first formed adduct alcohols are not so easy to isolate; as they are fairly acidic, they readily lose hydrogen cyanide and react with a second molecule of carbonyl cyanide[88] (Scheme 17). In analogy to Diels-Alder additions electron-rich ene components such as the *p*-methoxystyrene derivative *(85a)* and, even more so, *(85b)* react readily with carbonyl cyanide[89a], while the electron-deficient *p*-nitro derivative *(85c)* failed to react[89b]. Ene reactions with carbonyl chloride and carbonyl fluoride have to the knowledge of the author not yet been described or have failed[84]. Possibly, the ene components employed have not been sufficiently reactive, or alternatively the first formed adducts liberate acid which destroys reactants and products alike (cf also Scheme 17). The presence of a suitable acid trapping reagent might bring about a change.

(85a), R = CH_3O
(85b), R = $(CH_3)_2N$
(85c), R = NO_2

Scheme 17

Hexafluorothioacetone is not only a highly active dienophile which reacts instantaneously with butadiene at −78 °C, thus allowing a titration of the diene[90], but also forms adducts with ene components under similar conditions. It is worthy of note that the orientation (Scheme 18) is the reverse of that for ene reactions with carbonyl compounds[91] (cf. Section 6.1).

Scheme 18

3.5. Singlet Oxygen

The dye-sensitized photooxygenation of olefins and dienes has long been known[16,92], but only recently *Foote*[16] has shown that the reactive intermediate is the first excited singlet state of molecular oxygen [$O_2(^1\Delta g)$], which is only 22 kcal above the ground state; $O_2(^1\Delta g)$ resembles ethylene electronically, but is more electron-deficient. The reactions with singlet oxygen have contributed substantially to our mechanistic understanding of the ene reaction and lead to allylic hydroperoxides which can be reduced smoothly

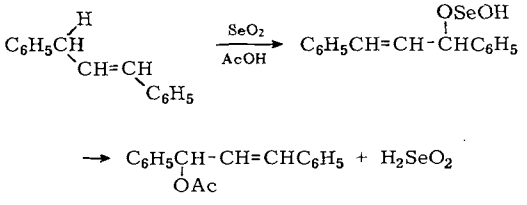
to the allylic alcohols. The alcohols derived from limonene *(16)* are natural products, and in the case of the carveyl alcohols are formed *via* the carveyl hydroperoxides *(85d)* and *(85e)* with complete conservation of chirality at the C-4 carbon, *i.e.*, this reaction does not involve a substituted cyclohexenyl radical intermediate *(85f)* which is symmetrical [20a].

(85d) *(85e)* *(85f)*

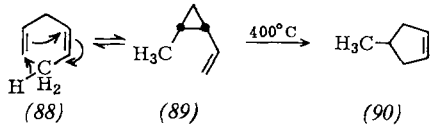


3.6. Sulfur Trioxide and Selenium Dioxide

Sulfur trioxide reacts with a variety of ene components [93] and it has been suggested that the sulfonic acid *(7)* is formed from methylenecyclopentane in concerted fashion [13]. Until recently, selenium dioxide was believed to form cyclic selenones *(86)* with

(86) *(87)*

various substituted butadienes. A reinvestigation has revealed that unlike sulfur dioxide, selenium dioxide possesses dienophilic properties and forms adducts *(87)* instead [94]. Therefore, it seems reasonable to conclude that selenium dioxide also possesses enophilic properties and that allylic oxidations with this compound proceed at least in part by an ene reaction. In fact, *Schaefer* [10] and *Trachtenberg* [95] have proposed an ene type mechanism *via* a hypothetical selenium(II) ester which is solvolyzed to the products



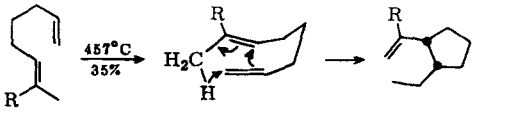
Scheme 19

(Scheme 19). What has been said above for the Prins reaction is even more relevant to this reaction, *i.e.* the products of kinetic control are hard to isolate.

4. Intramolecular Ene Reactions

4.1. 1,3- and 1,4-Dienes

The 1,5-hydrogen shift of *cis*-1,3-pentadienes (Scheme 2) occurs smoothly at about 150–200 °C and may be classified as an intramolecular ene reaction. The most simple homovariant of this reaction is provided



(88) *(89)* *(90)*

by the isomerization of *cis*-1,4-hexadiene *(88)*, which on heating to 400 °C forms *(90)*; a rapid pre-equilibrium of *(88)* and *(89)* is followed by irreversible formation of the product *(90)* [96]. Both 1,5-hydrogen shifts [6,97] and their homocounterpart [6,97,98] have been reviewed. 1,5-Dienes undergo 3,3 shifts (Cope rearrangement).

4.2. 1,6-Dienes

1,6-Octadiene *(91a)* (a mixture of the *cis* and *trans* form being used) has been reported to cyclize at elevated temperatures to the *cis* substituted cyclopentane *(92a)* exclusively; similarly, *(91b)* has been assumed to furnish the *cis* isomer *(92b)* only [99]. In contrast,

(91a), R = H *(92a)*, R = H
(91b), R = CH_3 *(92b)*, R = CH_3

3,7-dimethyl-1,6-octadiene *(94)*, which may be prepared in 90% yield [100] from *cis*-pinane *(93)* *via* a 2+2 cycloelimination, cyclizes under the same conditions to

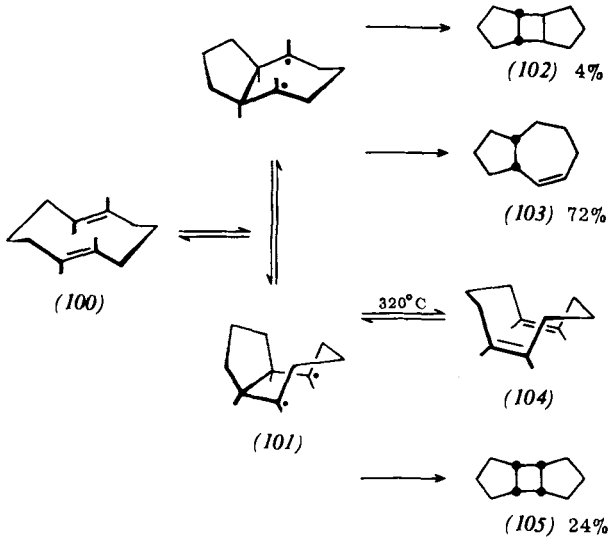
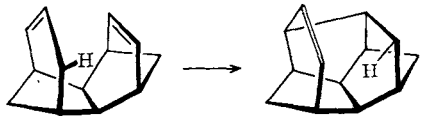
give a mixture of isomeric cyclopentanes considered to be *(95)* (main product) and *(96)* (minor product) [101]. The steric course of the cyclization of linalool

(93) *(94)* *(95)* *(96)* *(97)* *(98)* *(99)*



(97) has been investigated in much greater detail and it has been shown that *all four possible* diastereomeric plinols *(97a)–(97d)* are formed. The formation

(97) *(97a)*, 15% *(97b)*, 9% *(97c)*, 50% *(97d)*, 26%

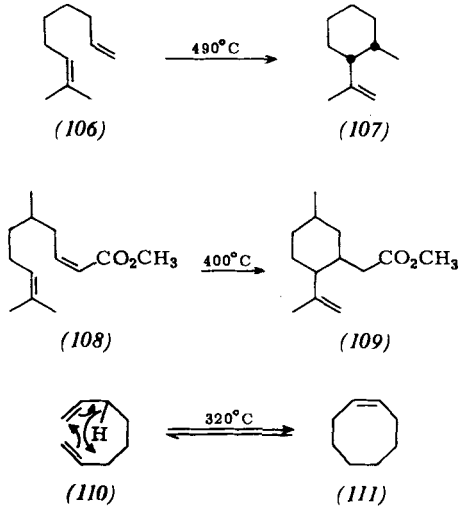


tendency of the four isomers can be related qualitatively to the number of conformations which are favorable and unfavorable for the respective cyclizations [101a].

6-Octen-1-yne *(98)* cyclizes at 400 °C to *(99)* in 65%, yield. Clearly, rupture of an acetylenic π-bond requires less energy than that of an ethylenic π-bond, and the alkenyne is still sufficiently flexible for the reaction to occur [102]. An interesting intramolecular ene reaction of a 1,6-diene has been described by *Roth* [6]. On heating to only 250 °C the strained *trans*, *trans*-1,6-cyclodecadiene *(100)* isomerizes to a mixture of *(102)*, *(103)*, *(105)*, and *cis*,*cis*-1,6-cyclodecadiene *(104)*. A product mixture of identical composition is obtained from *cis*,*cis*-1,6-cyclodecadiene at 320 °C. These findings are best accommodated by the biradical intermediate *(101)*, which not only forms *(103)* (main product), but also collapses to the isomeric cyclobutanes *(102)* and *(105)* (cf. also Scheme 3). Molecular models show that a concerted intramolecular ene reaction of *cis*,*cis*-1,6-cyclodecadiene is geometrically not feasible. The transformations of *(100)* into *(103)* and of *(104)* into *(103)* represent two examples of stepwise ene reactions which are conformationally enforced.

(100) *(101)* *(102)* 4% *(103)* 72% *(104)* *(105)* 24%

The two π-bonds of the birdcage homolog *(105a)* are relatively strain-free, but they are held rigidly in almost parallel planes and separated by only about 2 Å;



(105a) *(105b)*

(105a) has been found to cyclize to *(105b)* with a half-life of about six hours at 45 °C [102a]! The most simple 1,6-diene, *i.e.*, 1,6-heptadiene does not possess a terminal methyl group and fails to cyclize up to 500 °C [99].

4.3. 1,7-Dienes

A priori, the cyclization of 1,7-dienes can yield either six- or eight-membered rings, and both reactions have been observed. Generally, cyclohexane derivatives are formed less readily than cyclopentanes in intramolecular ene reactions. Thus, 8-methyl-1,7-nonadiene

(106) *(107)* *(108)* *(109)* *(110)* *(111)*

[101] *H. Pines, N. E. Hoffman*, and *V. N. Ipatieff*, J. Amer. chem. Soc. *76*, 4412 (1954); see also *W. D. Huntsman* and *T. H. Curry*, *ibid. 80*, 2252 (1958).

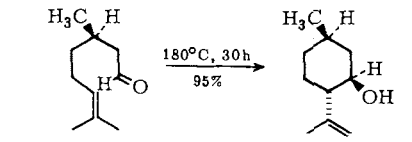
[102] *W. D. Huntsman* and *R. P. Hall*, J. org. Chemistry *27*, 1988 (1962).

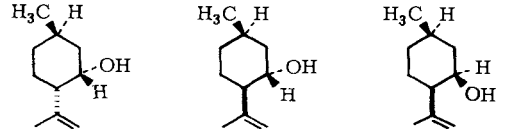
[102a] *J. M. Brown*, J. chem. Soc. (B) (London) *1969*, in press.

(106) fails to cyclize at 440 °C, but on raising the temperature to 490 °C an appreciable amount of *(107)* is formed. However, the stereospecific formation of the *cis* derivative could not be confirmed for related examples which were investigated more thoroughly (cf. below). The introduction of a terminal methoxycarbonyl group as in *(108)* facilitates cyclization, as shown by the smooth formation of three diastereomeric menthene acetates *(109)* from *(108)*. Which stereoisomer(s) arise by kinetic control is not clear, since the acetates *(109)* epimerize under the reaction conditions[103]. 1,7-Octadiene *(110)* can be equilibrated with cyclooctene *(111)* above 320 °C. At higher temperature the open chain isomer is favored[6] (cf. also Section 5).

4.4. Unsaturated Carbonyl Compounds



Conia and his co-workers have cyclized a great variety of ethylenic ketones of the general type *(112)* to the corresponding cycloalkyl ketones *(114)*. The

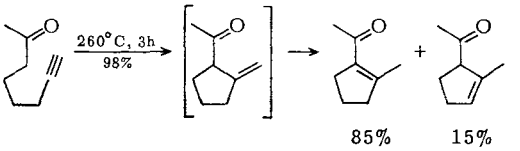


(112) *(113)* *(114)*

reactions proceed under comparatively mild conditions (*ca.* 300 °C, 1 h); cyclopentyl ketones (n = 5) are generally formed quantitatively. Seven- and eight-membered rings (n = 7,8) can also be obtained, albeit in lower yield. On heating to 390 °C for 30 min even 11-dodecen-2-one [*(112)*, R = CH_3, R^1 = H; n = 9] forms the corresponding nine-membered ketone in a respectable yield of 30%[104d]. Of necessity, the cyclization involves enol *(113)*, the formation of which from *(112)* *via* a concerted thermal 1,3-hydrogen shift is forbidden[4]. Interestingly, the formation of the enol and hence cyclization can be accelerated by catalytic amounts of water and by using reaction vessels made of ordinary glass instead of Pyrex[104f].

If $R^1 \neq H$, the product *(114)* cannot epimerize *via* enolization and more detailed investigations have shown very recently that not only the *cis* but also the *trans* isomers are formed[104f].

(+)-ß-Citronellal (−)-Isopulegol (60%)



(+)-*neo*-Isopulegol (20%) (+)-*iso*-Isopulegol (15%) (+)-*neoiso*-Isopulegol (5%)

Scheme 19a

Ohloff[105a] has investigated in detail the cyclization of (+)-β-citronellal, an example of a 6-heptenal [Scheme 19a]. All four possible diastereomers are formed in varying amounts. Isopulegol which is formed in 60% yield is an intermediate in the technical synthesis of (−)-menthol.

7-Octyn-2-one cyclizes at 260 °C to give two isomeric cyclopentenes in practically quantitative yield (Scheme 20)[104g,105].

5. The Retro Ene Reaction

5.1. Acyclic and Cyclic Olefins

On thermodynamic grounds the retro-ene reaction is favored with increasing temperature while the ene reaction is facilitated by increasing pressure. The most simple example, the decomposition of 1-pentene (cf. Scheme 1) has been reported to occur above 400 °C. However, whether the products of this reaction are actually propene and ethylene, has not been investigated[106]. Intramolecular variants of this reaction can be realized more readily, particularly in strained medium-sized cycloalkenes (n = 8–11) which form α,ω-dienes (Scheme 21). For instance, above 320 °C *cis*-cyclooctene *(111)* can be converted into 1,7-octadiene *(110)*[6]. The more strained *trans*-cyclooctene opens more easily, temperatures of *ca.* 250 °C being

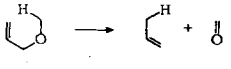
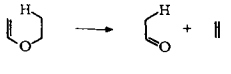
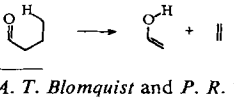
n = 8-11

Scheme 21

sufficient to observe the diene. Pure *trans*-cyclononene forms 1,8-nonadiene (85%) and *cis*-cyclononene (15%) on heating to 500 °C, while under the same conditions *cis*-cyclononene yields only *ca.* 20% diene, 80% of the starting material remaining unchanged[107]. In contrast, *cis*-cyclodecene does not only afford 1,9-decadiene, but also vinylcyclooctane (5%) in a side reaction[100] (Scheme 22) (see also Section 6.5). It is advantageous to pyrolyze the cycloalkenes in a cyclic







Scheme 22

reactor, in which the dienes are removed immediately as they are formed and the starting material can be recycled continuously[100b]. Since the alkadienes boil about 20 °C lower than the corresponding cycloalkenes, the product can be distilled off readily. Thus, under reduced pressure and at temperatures around 600 °C it has been possible to isolate the α,ω-dienes in yields up to 90% and higher[100]!

5.2. Heteroatom Analogs

Numerous heteroatom analogs of retro ene reactions have been reported over a span of a hundred years or so, and Table 4[107a] summarizes the reaction types generated by permutation of one oxygen atom. The cleavage of γ,δ-unsaturated alcohols represents the reverse of the formation of unsaturated alcohols from ene components and carbonyl compounds (see Section 3.4) and proceeds in the vicinity of 500 °C, unless

extra allylic resonance or other factors facilitate the breaking of the C–C bond (Table 5). The first two reactions in Table 5 are clearly kinetically controlled, while reactions 3 and 4 exemplify the competition of the retro-ene reaction and the 3,3-shift (Cope rearrangement).

[a] E_a = 41.8 kcal/mole; $\Delta S^{\neq} = -4.8$ e.u.

Presumably, the ene cleavage in entry 5 is facilitated by the rigidity of the allylic system, which allows the transition state to be reached more readily (cf. also Section 6.5). The retro-ene reaction in Scheme 16 could be favored for the same entropy reasons as well as by the methoxycarbonyl group which generates a retro-Claisen-like system. The smooth ene cleavage of *trans*-1,2-divinylcyclopentane-1,2-diol (Table 5, entry 6) is of interest. However, with increasing ring size the retro-

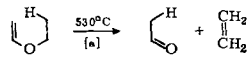
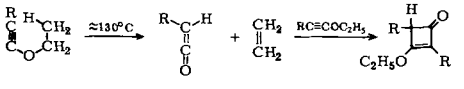
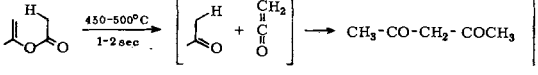
ene reaction is completely suppressed in favor of the 3,3-shift [111a]. The decarboxylation of β,γ-unsaturated acids requires temperatures in the range of 250–300 °C [112]. A more recent variant is the decarboxylative opening of cyclopropaneacetic acids. For example, on heating above its melting point carboxylic

(115) (116)

acid *(115)* smoothly loses carbon dioxide to form *(116)* with introduction of an angular methyl group [113]. The steric requirements for decarboxylation of bicyclobutanecarboxylic acids (cf. also Section 2.7) are demonstrated nicely by the relative stability of the







(117) (118) (119)

exo acid *(117)* (no reaction up to 200 °C), whereas the structurally related *endo* acid *(118)* affords 1,3-diphenylcyclobutene *(119)* quantitatively on heating to only 85 °C [114].

The ene cleavage of allyl ethers (Table 4, entry 2) constitutes the microscopic reverse of the "wrongly oriented" addition of a carbonyl compound to an ene component and has been investigated and discussed recently by *Cookson* and *Wallis* [115].

The retro-ene reaction of vinyl ethers (Table 4, entry 3 and Table 6, entry 1) proceeds at temperatures [116]

Table 6. Pyrolysis of vinyl ethers.

Entry	Reaction	Ref.
1		[116]

[a] E_a = 43.8 kcal/mole; $\Delta S^{\ddagger}$ = −10.2 e.u. at 530 °C.

comparable to those required for unactivated analogs (*ca.* 500 °C), while acetylenic ethers break up under rather mild conditions (*ca.* 130 °C) to form aldoketenes which are trapped by the starting material to give ethoxycyclobutenones (Table 6, entry 2).

The well-known pyrolysis of esters [119] and xanthates [120] is related to the ene cleavage of carbonyl compounds (Table 4, entry 4).

6. Reaction Mechanisms

6.1. Bond Energies and Reactivity

For a discussion of reactivities it is useful to consider the change in bond energy during an ene reaction. In the generalized Scheme 23 the debit side contains the energy required for breaking the C_3–H σ-bond and the X=Y π-bond, while energy is gained by making

Bond energy expended	Bond energy gained
$D(C_3–H)$	$D(X–H)$
$D_\pi(X=Y)$	$D(C_1–Y)$
$D_\pi(C_2=C_1)$	$D_\pi(C_2=C_3)$

$\Delta F = \Delta H - T\Delta S$;
$\Delta H = D(X–H) + D(C_1–Y) - D(C_3–H) - D_\pi(X=Y)$

Scheme 23

the X–H and C_1–Y bonds; the last items in each column cancel on balance unless one of the two double bonds is particularly strained (see below). Provided that steric and solvent effects remain constant in a series of related reactions (as is indeed frequently the case; cf. Section 6.3) then

$$\delta_R \Delta S = 0 \text{ [*]}.$$

Hence,

$$\delta_R \Delta F = \delta_R \Delta H$$

i.e., the difference in free energy of two reactions is equal to the corresponding differential heat of reaction [121]. One now assumes that the calculated ground state energy term $\delta_R \Delta F$ is proportional to the differential free energy of activation $\delta_R \Delta F^{\ddagger}$. Such an

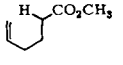
approximation is more drastic, but presumably not bad, if bond-making and bond-breaking, respectively, have proceeded to about the same extent in the transition states of the reactions to be compared. Clearly, this approximation allows that the new σ-bonds are formed with considerable asymmetry within one reaction class (see Section 6.2).

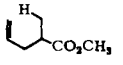
Several conclusions follow: First, the dependence of the reactivity of the ene component on $D(C_3-H)$ has been obvious throughout Section 1 and needs no more comment. Further, the enhanced reactivity of acetylenic *vis-à-vis* olefinic enophiles can be seen to be not only the consequence of the reduced π-bond energy of the triple bond, but also of the increased energy of the vinylic carbon-hydrogen bond [$D(C_2H_3-H) = 104 \pm 2$ *versus* $D(C_2H_5-H) = 98 \bullet 1$ kcal/mole][122].

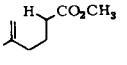
The distinction of enophilic and dienophilic reactivity now emerges also more clearly. For instance, it has been seen that cycloheptatriene forms a 4 + 2 adduct with maleic anhydride[47a,47b], while in the reaction with acetylenedicarboxylic ester an ene adduct is formed as a by-product[50]. Since D_π (C≡C) enters the energy balance of both diene and ene synthesis, but a new carbon-hydrogen bond is only made in the ene reaction, alkynes are expected to be relatively more enophilic than dienophilic when compared with alkenes. That dehydrobenzene is such an efficient enophile should be the consequence of internal strain and, possibly, of a steric effect. Similarly, the quite remarkable reactivity of ene components with strained or "soft" π-bonds (Section 2.7) appears to be primarily the consequence of a lowering of $D_\pi(C_2 = C_1)$ (Scheme 23).

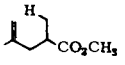
[122] All bond energies are taken from *J. A. Kerr*, Chem. Rev. 66, 465 (1966).

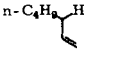
Bond energies are also useful for predicting the orientation of enophilic attack. For instance, the exclusive formation of the alcohol rather than the ether when carbonyl compounds are used as enophiles (Scheme 24) can be rationalized by the greater gain in bond energy for the observed reaction. Similarly, the reversal in orientation with thioketones[91] as enophiles is probably partly due to the fact that $D(C-H) = 98$, while $D(S-H) = 90$ kcal/mole only [$D(C-S)$ appears to be unknown][122].

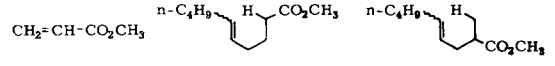


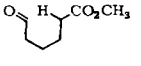


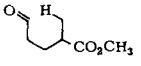


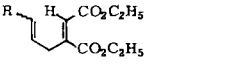


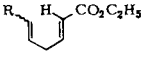


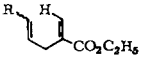












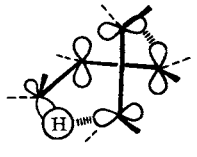
Scheme 24

6.2. Orientation Phenomena

Little work has been reported here and the few observations of *Alder* and *von Brachel*[73b] on propiolic and acrylic ester are compiled in Table 7. Apparently,

Table 7. Orientation phenomena in ene reactions [73b].

Entry	Ene	Enophile	Products	
1		$CH_2=CH-CO_2CH_3$	 88%	 12%
2		$CH_2=CH-CO_2CH_3$	 95%	 5%
3		$CH_2=CH-CO_2CH_3$	75%	 25%
4		$CH_2=CH-CO_2CH_3$	 60%	 40%
5		$C_2H_5O_2CC{\equiv}CCO_2C_2H_5$		
6		$HC{\equiv}CCO_2C_2H_5$	 80%	 20%



the linear isomer, in which the position of the ester grouping is "*para*" with respect to the vinylic carbon C_2 (cf. Scheme 23), predominates over the branched or "*meta*" isomer. Thus, in contrast to an earlier report[73a], a mixture of isomers rather than a single product appears to be formed generally. The preferred formation of the linear isomer suggests that bond-

making in the transition state is somewhat more efficient between the unsaturated termini than between the allylic hydrogen and the corresponding carbon atom of the enophile; or to rephrase, a double bond is a better Michael-type donor than an allylic carbon-hydrogen bond. Note that the analogy to the Michael addition is purely formal, since, *e.g.*, ene reactions are not catalyzed by bases. Furthermore, while the clean orientation with carbonyl enophiles (Scheme 24) is consistent with advanced bond-making between the unsaturated termini, the observed opposite orientation with hexafluorothioacetone probably indicates that the transition state may by variable.

6.2.1. The *cis*-Principle

The Diels-Alder addition entails stereospecific *cis*-addition. Likewise, the adducts of 1-hexene and 1-heptene with acetylenedicarboxylic ester have been found to be derivatives of maleic rather than fumaric esters (Table 7, entry 5), and the linear isomer formed in the reaction of ethyl propiolate with ene components is a derivative of acrylic ester containing a *trans* double bond (Table 7, entry 6) [see also Scheme 12 and the formation of *(53)*].

It is worthy of mention that the *anti,anti* ene reaction [*anti* with respect to the ene and enophile; cf. *(119c)*] is also symmetry-allowed. Obviously, such a transition state is far less likely than *(122)* for steric reasons, but

(119c)

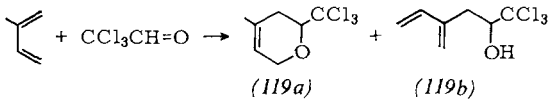
it remains an interesting speculation for special cases such as ene components containing twisted double bonds and enophiles which are sterically readily accessible. In any case, such a reaction mode seems more probable here than for the related and better investigated Diels-Alder addition, where, as implied above, the *anti, anti* attack has never been observed.

6.3. Solvent Effects and Activation Parameters

In analogy to other "no mechanism" reactions [123] the ene synthesis is little affected by solvent changes. *Huisgen* and *Pohl* [9] have measured the rate of reaction of 1,3-diarylpropenes with diethyl azodicarboxylate. On changing the solvent from cyclohexane to nitrobenzene the rate increases by a factor of 4 only (Table 8).

For the ene reaction of diethyl azodicarboxylate with some cyclic dienes *Franzus* [24] has found a highly negative entropy of activation ($\Delta S^{\neq}$ = −30 to −40 e.u.) similar to Diels-Alder additions. As expected, $\Delta S^{\neq}$ is less negative for intramolecular ene reactions, since less molecular motion has to be frozen in the transition state (cf. Table 5, entry 2, Table 6 entry 1, and Scheme 2).

Table 8. Solvent effect on the ene reaction of diethyl azodicarboxylic ester with 1-phenyl-3-(*p*-tolyl)propene [9].



Solvent	Rate constant $10^4\,k_2$ [l mole^{-1} sec^{-1}] at 50 °C
cyclohexane	1.02
dioxane	1.12
dimethylformamide	2.0
acetonitrile	2.2
1,2-dichloroethane	3.2
nitrobenzene	4.0

6.4. Catalysis of Ene Reactions

The facilitation of intermolecular ene reactions by an increase in pressure and that of the retro-ene reaction by high temperatures needs no comment. Likewise, the enhanced reactivity of certain enophiles in the presence of organic and aqueous mineral acids is familiar.

Attention is drawn to the catalyst system CH_2Cl_2/Ac_2O/$BF_3 \cdot 2H_2O$ [21,22], in which the boron trifluoride dihydrate is present presumably as $\overset{\oplus}{H}\overset{\ominus}{B}F_3OAc + 3\,AcOH$, as well as stannic chloride [21,22,124,125] and aluminum chloride, which has been used as such and as the etherate [125c]. With these catalysts the reaction times can be shortened dramatically, and it would be of preparative interest to know whether allylic oxidations by selenium dioxide can be catalyzed similarly.

The reaction of isoprene with trichloroacetaldehyde in dichloromethane affords 5% Diels-Alder *(119a)* and 95% ene adduct *(119b)*, if the reaction is run at room temperature in the presence of stannic chloride. In the absence of catalyst, however, the reaction requires temperatures around 150 °C, and the ratio of *(119a)*: *(119b)* is reversed completely, being 90:10. A similarly characteristic reversal in the composition of products has been observed for other catalytic and thermal reactions of isoprene and 2,3-dimethylbutadiene with carbonyl compounds [125a]. As one possible reason for this remarkable observation it should be considered that the proportion of the cisoid diene conformer is greater at higher temperature so that the cycloaddition is preferred.

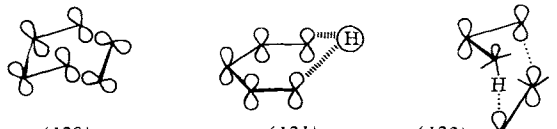
The interesting case of a photo-ene reaction has been described for 2,6-dimethyl-7-octen-3-one, which on irradiation with ultraviolet light forms terpinen-4-ol (2.5%) amongst other products. Although the yield is low the terpinen-4-ol arises with complete transfer of chirality, suggestive of a concerted transformation of the excited ketone into the product (Scheme 24a) [126a].



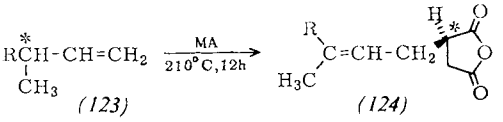
Scheme 24a

The reverse reaction proceeds thermally and also entails complete induction of chirality [126b].

To summarize, ene reactions proceed most readily if the ene is electron-rich and the enophile electron-deficient. Ene reactions with inverse electron demand have not yet been described.

6.5. The Geometry and Timing of Bond Changes in the Transition State

The Diels-Alder addition, 1,5-hydrogen shift, and the ene reaction are structurally related cyclic six-electron processes, although bonding in the transition state is maximized in each reaction in a different way. The transition state of the Diels-Alder reaction is boat-like [127], *i.e.*, the π-orbitals of the reactants overlap partly π-wise, partly σ-wise *(120)*.



(120) *(121)* *(122)*

The optimum geometry for a 1,5-hydrogen shift involves a planar carbon framework with a suprafacial [4] placement of the hydrogen *(121)*, while a concerted ene reaction maximizes allylic resonance by turning the axis of the breaking carbon-hydrogen bond parallel to the p-orbitals of the neighboring double bond *(122)*.

The ene cleavage of (−)-6-hydroxymethyl-Δ^1-*p*-menthene smoothly forms (+)-Δ^1-*p*-menthene with 100% conservation of chirality (Table 5, entry 5). If this retro-ene reaction were to proceed *via* a substituted cyclohexenyl radical intermediate, much racemic menthene would have to be formed [cf. also the formation of *(85d)* and *(85e)*].

Microscopic reversibility demands that the reverse reaction is also completely stereospecific. While the reaction of (+)-Δ^1-*p*-menthene with formaldehyde requires acid catalysis, the γ,δ-unsaturated alcohol is formed with more than 98% retention of configuration at the C-4 carbon [19b]. Thus, it is proven that the Prins reaction may proceed *via* a concerted ene reaction (cf. also Section 3.4).

The reaction of maleic anhydride with optically active olefin *(123)* has been shown to give optically active adduct *(124)*; however, it is unknown to what extent precisely chirality is preserved during this reaction [128].

(123) *(124)*

The ene reaction of cyclopentene and cyclohexene with diethyl azodicarboxylate can be catalyzed by free radical initiators and retarded by free radical inhibitors [8,9]. However, whether cyclopentenyl and cyclohexenyl radicals are actually intermediates in these reactions has not yet been shown clearly. Since one would expect that shift of the double bond is incomplete if a free allylic radical is involved, experiments with cycloalkenes possessing a positional or radioactive label might provide further clues.

Molecular models show that cyclopentene and cyclohexene are relatively rigid and that it may be difficult to achieve the optimum geometry *(122)*. Alternatively, one could argue that the relative stability of the cyclopentenyl and cyclohexenyl radicals [129] favors a stepwise process. However, 1,2-dihydronaphthalene *(32)* and the 1,4-dihydro isomer seem to react in concerted fashion [9] although any potential intermediate radical would be even more stable. Models suggest a greater flexibility for these two compounds so that the *p*-orbitals of the developing double bond can become coaxial in the transition state.

A concerted mechanism is geometrically impossible for the pyrolysis of *trans,trans*-1,6-cyclodecadiene *(100)* and of *(104)*. Presumably, cyclodecene rearranges also at least in part *via* a biradical, which would account for the formation of vinylcyclooctane (Scheme 22). In any case, the thermal formation of vinylcyclooctane from cyclodecene by a concerted suprafacial 1,3-carbon shift is forbidden [4]. The twisted bicyclobutane and bicyclopentanes enter into stepwise ene reactions also. However, to conclude that *all* bicyclobutanes and bicyclopentanes react in a stepwise manner may be premature, since these compounds appear to form

[126a] *K. H. Schulte-Elte* and *G. Ohloff*, Tetrahedron Letters *1964*, 1143; a related reaction has been described by *N. C. Yang, A. Morduchowitz*, and *D.-D. H. Yang*, J. Amer. chem. Soc. *85*, 1017 (1963); however, these authors postulated a unified stepwise mechanism *via* free radicals; cf. also *N. J. Turro*: Molecular Photochemistry. Benjamin, New York 1965, p. 155; for the photo-ene reaction of methyl- and dimethylmaleic anhydride with α-cedrene see *C. H. Krauch* and *H. Küster*, Chem. Ber. *97*, 2085 (1964).

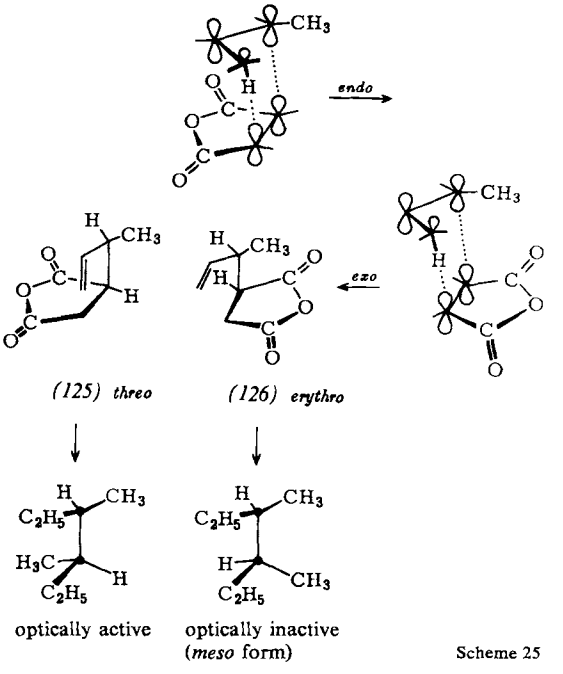
exclusively the ene adduct without any admixed 2 +2 product in a number of reactions.

It should be borne in mind that the initial rate-limiting abstraction of an allylic hydrogen (possibly followed in certain reactions of cyclopentene and cyclohexene; cf. also Scheme 7) and the similarly rate-limiting formation of the biradical (Scheme 3) represent but two mechanistic extremes which demarcate a broad spectrum of *concerted* ene reactions.

A useful criterion forprobing the timing of bond changes is the deuterium isotope effect k_H/k_D, which has been measured for a few ene reactions. For the reaction of 1,4-dihydronaphthalene *(32)* with diethyl azodicarboxylate $k_H/k_D = 2.8–4.1$ between 60 and 80 °C[9], and for the benzylic oxidation of 1,3-diphenylpropene with selenium dioxide in acetic acid at 115 °C k_H/k_D = 3.2[10]. By comparison, for the intramolecular 1,5-hydrogen shift in *cis*-1,3-pentadiene (Scheme 2) k_H/k_D is greater, being 12.2 at 25 °C, suggestive of a highly symmetric transition state with a half-transferred hydrogen in this case[6]. Clearly, carbon-hydrogen bond-breaking is energetically costly and presumably not fully compensated by formation of the new H–X bond, at least when X = carbon (cf. Scheme 23). The limited data on orientational phenomena discussed above (Section 6.2) seem to reinforce this conclusion and suggest that within the province of concerted ene reactions involving all-carbon systems, the making of the new carbon-carbon bond may well be in the lead in many cases.

For the reaction of two conformationally defined 1-methylcyclohexene systems with singlet oxygen *Nickon* has shown recently that k_H/k_D is also rather low (1.1–2.4); chemical studies indicate that neither C–H bond breaking nor C–O bond making have advanced very far, *i.e.* the transition state is reactant-like in this particular reaction[131].

The few isotope effects measured for the retro-ene reaction again seem to suggest a variable transition state. For example allyl α-deuteriodiphenylmethyl ether undergoes cleavage at 430 °C only about 10% more slowly than the undeuterated compound (k_H/k_D = 1.1)[115]. On the other hand, $k_H/k_D \approx 2$ at 400–500 °C for the pyrolysis of acetates. The latter value appears to be close to the theoretical maximum of 2.1 at this temperature[119].



In summary, ene reactions may proceed by a broad spectrum of transition states. While most Diels-Alder additions are considered to be concerted[45], the mechanism of the ene reaction is janus-faced in that both concerted and stepwise routes may be followed. A concerted course is generally preferred, but the stepwise process may occur, provided the optimum geometry of the transition state is inaccessible and, perhaps less urgently, the intermediate radical or biradical is stabilized.

[130] *J. A. Berson, R. G. Wahl,* and *H. D. Perlmutter,* J. Amer. chem. Soc. *88*, 187 (1966).

[131] *A. Nickon, V. Chuang, P.J.L.Daniels, J. B. DiGiorgio, H. G. Vilhuber,* and *E. Werstiuk,* to be published.

6.6. *endo* or *exo* Transition State?

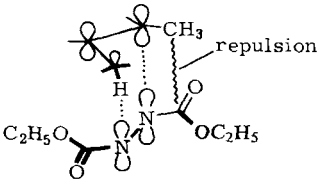
Since the ene reaction does not lead to cyclic adducts, a distinction of *endo* and *exo* transition states is more difficult than in the Diels-Alder addition. Only three ene reactions have so far been scrutinized from this point of view, and all three examples are due to the work of *Berson* and his collaborators[130]. *cis*-2-Butene has been shown to react with maleic anhydride to give two diastereomeric 3-(1-butenyl)succinic anhydrides *(125)* and *(126)* in a ratio of 80–85% to 15–20%. *trans*-2-Butene and maleic anhydride, on the other hand, afford 43% *(125)* and 57% *(126)*. The configurational assignments have been reached by a six-step degradation to 3,4-dimethylhexane: (i) hydrogenation, (ii) hydrolysis, (iii) reaction with 2 CH_2N_2, (iv) reaction with $LiAlH_4$, (v) reaction with 2 *p*-$CH_3C_6H_4$–SO_2Cl in pyridine, and (vi) further reaction with $LiAlH_4$. (see Scheme 25). Clearly, the selectivity

Scheme 25

is considerably reduced with *trans*-2-butene, yet the *endo* preference is qualitatively preserved, because the major diastereomer from *cis*-2-butene is the minor one from the *trans* isomer. For the ene reaction of cyclopentene with maleic anhydride there exists a 3.5:1 preference for the *endo* transition state[130]. The *endo*/*exo* ratio in another ene reaction amounts to either 29:23 or 23:29[36]. Apparently the *endo* selectivity is not particularly striking and is sensitive to steric effects (see below); any generalization on the preferred steric course must be regarded with caution.

6.7. Steric Effects

Ene reactions are notoriously sensitive to steric effects, just like cycloadditions[45]. For example, the reduced *endo* selectivity (57%) for the reaction of *trans*-2-butene with maleic anhydride as compared with more



than 80% selectivity for the reaction with *cis*-2-butene (cf. Scheme 25) is probably the consequence of nonbonded repulsion between the nonreacting methyl group of *trans*-2-butene and the opposing carbonyl grouping in the *endo* transition state. Similarly, the formation of the *endo* adducts from α-pinene [cf. *e.g. (11)*], the considerably enhanced reactivity of the parent cyclopropene (Scheme 9) *vis-à-vis* its triphenyl counterpart *(65)*, the formation of the *cis* dimer *(66)* from *(65)*, and the different reactions of *(68)* and *(70)* attest to the importance of steric effects.

In the ene reaction of dehydrobenzene with 1-octene the *trans* isomer has been reported to be formed as the major product (Scheme 26), although the other products were not identified. It has been suggested that the bulky and flexible *n*-pentyl chain prefers to be oriented away from the attacking dehydrobenzene[75c] (cf. also Table 1, entry 3 for the *trans/cis* ratio with a *trans* enophile).

Scheme 26

Steric effects are also manifest in the data of Table 1 which suggest that the enophile attacks the least crowded olefinic terminus preferentially and abstracts the least crowded hydrogen most readily. Interestingly, *trans*-2-butene reacts about 3.7 times faster than the *cis*-isomer with diethyl azodicarboxylate. As can be seen in Scheme 27, one ethoxycarbonyl grouping of the azo ester (which is usually present in its more stable *trans* form) and the opposing methyl group of the *cis*-2-butene clash in the transition state[8]. In

Scheme 27

contrast, no such repulsion is present in the reaction of *trans*-2-butene so that the situation is exactly reversed to that for the reactions with maleic anhydride, which is a *cis*-enophile and would be expected to react more readily with *cis*-2-butene than with the *trans* isomer.

A distinction of *endo* and *exo* transition state is no longer possible when alkynes and dehydrobenzenes act as enophiles. It has been found that *trans* as well as *cis*-alkoxypropenes and dehydrobenzenes afford 2 + 2 cycloadducts and also ene products. In all the reactions studied the *trans* propene derivative enters the ene reaction more readily than the *cis* isomer. Furthermore, the ene reaction is inhibited more with *cis*-ethoxypropene[132a] than with *cis*-methoxypropene[132b]. That all these differences are probably of steric origin is suggested by an inspection of models.

7. Outlook

Much further work is needed before we may claim to understand the ene reaction. On the preparative side further heteroatom analogs await discovery, and new enophiles should be found which react in the presence or absence of electrophilic catalysts. Much of what has been said about the mechanism and particularly the reactivity of the ene reaction has been based on fragmentary data and perhaps even some speculation. Future work will have to explore in a more quantitative way the reactivities, orientation phenomena, and steric effects as well as the variable transition state and its geometry.

I thank Prof. R. B. Woodward for his hospitality at Harvard University, where much of the work on this paper was done, Prof. L. Friedman and Dr. G. Ohloff for stimulating discussions, and Drs. O. Achmatowicz, Jr., R. Alder, J. M. Brown, Prof. J.-M. Conia, Dr. P. Dowd, Dr. E. Koerner von Gustorf, Prof. A. Nickon, Prof. E. Trachtenberg, and Prof. M. C. Whiting for personal communications regarding the manuscript. The support given by the Penrose Fund of the American Philosophical Society is gratefully acknowledged.

Chemical Investigations of the Molecular Origin of Biological Radiation Damage

By E. Fahr[*]

The radiation damage observed when UV and ionizing radiations react on biological objects is caused in many cases by changes in the nucleic acids. Exposure of these compounds to UV radiation in vitro and in vivo leads, inter alia, to dimerization of the pyrimidine bases with formation of cyclobutane derivatives, and to addition of water to the 5,6-double bond of the pyrimidine bases to form derivatives of the 6-hydroxyhydropyrimidine system. The structure of the irradiation products has been established. The dimerization prevents the reduplication of the DNA, and the addition of water appears to be the cause of UV mutations. Ionizing radiation in aqueous solution results e.g. in addition of H and/or HO radicals to the 5,6-double bond of the pyrimidine bases and cleavage of the imidazole ring of the purine bases. The mutations caused by ionizing radiation are probably also due, in part, to the formation of 6-hydroxydihydropyrimidine derivatives.

1. Introduction

The first scientifically based observations on the biological effects of radiation were made in the second half of the last century. It was found that UV radiation from a mercury lamp can not only tan the skin, but can also cause burns, skin cancer, mutations, and the death of microorganisms. The very pronounced biological effects of ionizing radiation were discovered immediately after the discovery of radioactivity and X radiation in the last decade of the 19th century, but their danger was not fully appreciated at once. Detailed information about the biological and medicinal effects of UV and ionizing radiation was gained during the first few decades of the present century, after the medical world had at first greeted radium and its radiation as a sort of "miracle drug".

After the second world war, the dropping of the first atomic bombs, the atomic bomb tests, and the use of radioactive material in research and industry, the question of the biological effects of radiation, and particularly that of genetic effects, became of pressing importance.

Though these effects of UV and ionizing radiations have been known for more than a century, knowledge of the chemical processes involved was relatively sparse up to about 20 years ago, since radiation-biologists and biophysicists confined their investigations mainly to the relations between radiation dose and other physical parameters and the biological (and medicinal) effect. The study of the chemical processes that occur when radiation acts on biological material has been made possible only by the methods developed in the last few decades for the separation of substances in mixtures. Since deoxyribonucleic acid (DNA) is the carrier of genetic information, the mutations caused by radiation should be traceable to chemically detectable changes in the DNA; since, moreover, the spectrum of action for the destruction of microorganisms by UV radiation coincides very closely with the absorption spectrum of the nucleic acid, special attention has been given to the action of radiation on nucleic acids and their components.

Exposure of biological objects to UV and ionizing radiation (X rays, γ rays, corpuscular radiation) leads to a number of successive processes that depend on the nature of the radiation, the radiation dose, the nature of the biological object, and other factors. These processes are:

a) The primary physical interaction between the radiation and the molecular components of the biological object.

b) The radiation-chemical process of the high-energy molecule resulting from interaction with the radiation, which leads to specific chemical reactions (photochemical processes on irradiation with UV and/or visible light, formation of ions and/or radicals by ionizing radiation).

c) The actual biological effect that results from these processes.

The present discussion is confined mainly to the radiation-chemical processes[1].

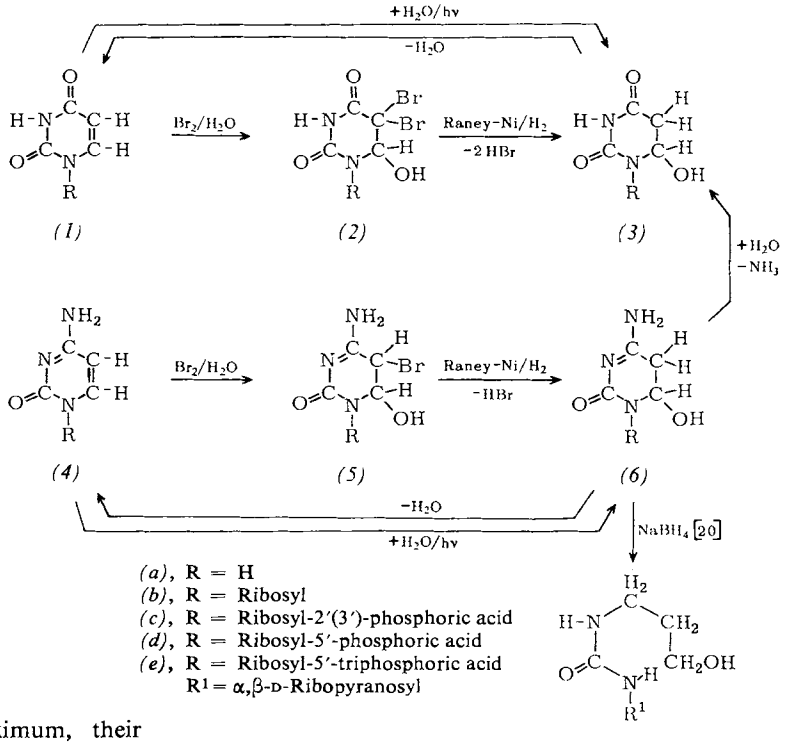
2. Action of UV Radiation on Nucleic Acids and their Components[2]



2.1. "Reversible" Irradiation Products

In 1949, *Sinsheimer* and *Hastings*[3] reported that UV irradiation of uracil *(1a)* and uridine *(1b)* in aqueous solution leads to products that change back into the starting materials on standing, or more rapidly when heated. These substances are therefore known as *reversible irradiation products*. Since they do not absorb in the region around 260 nm, where uracil and uridine have a characteristic absorption maximum, their formation and their conversion back into the starting materials can be followed quantitatively. The structure of these compounds has been investigated by *Moore* and *Thomson*[4] and by *Wang*[5,6]. These authors have shown that the formation of the reversible irradiation products probably involves the addition of water to the 5,6-double bond of the uracil system; the reversible irradiation products of the bases occurring in the nucleic acids were not isolated.

We have prepared the reversible irradiation products of *(1a)–(1e)* by UV irradiation of aqueous solutions of these compounds and separated them from the solutions[8].

If the irradiation is carried out with cooling in ice and using low pressure mercury lamps to suppress the thermal back-reaction[7b], chromatography of the irradiation solution on a column is unnecessary in the case of the uridylic acids *(1c)–(1e)*. The reversible irradiation products *(3c)–(3e)* are obtained in purities of about 90% on freeze-drying of the solution[8c].

The 6-hydroxydihydrouracil structure *(3)* of the reversible irradiation products has been proved by chemical synthesis[8] *(1a)→(2a)→(3a)*. The resulting compound *(3a)*, according to its IR spectrum and chromatographic data, is identical with the reversible irradiation product of uracil. We also prepared *(3b)* to *(3e)* in a similar manner.

Scheme 1.

The behavior of cytosine *(4a)*, cytidine *(4b)*, and cytidylic acid *(4c)* on UV irradiation in aqueous solution has been discussed in several publications[6]. Cytosine

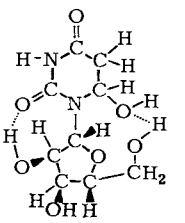
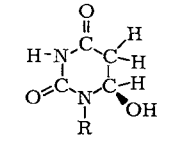
and cytidylic acid form very unstable reversible irradiation products, for which some authors, by analogy with uracil, have assumed a 6-hydroxydihydrocytosine structure, whereas *Wang* [10] believes that photoisomerization of the cytosine ring occurs. By means of a special irradiation apparatus [7a,9b], we obtained the reversible irradiation products of *(4a)–(4c)* in such high concentrations that it was possible to study the thermal back-reaction and to separate the reversible irradiation product of cytidylic acid by thin layer chromatography on cooled polyethyleneiminecellulose [9]. *Johns et al.* [11–13] separated the same irradiation product from the solution by paper electrophoresis. The 6-hydroxydihydrocytosine structure *(6)* of these irradiation products was demonstrated by the reaction sequence *(4c)*→*(5c)*→*(6c)* [9].

The products *(6)* undergo deamination on standing (dark reaction) to form the compounds *(3)*, so that the cytosine system can be converted into the uracil system by the path *(4)*→*(6)*→*(3)* [9, 11–14, 15].

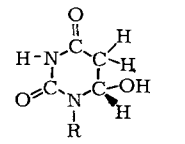


It is not yet certain whether thymine, thymidine, and thymidylic acid *(7)* can form a reversible irradiation product *(8)*. On UV irradiation of thymine in aqueous solution we were able to detect a very unstable reversible irradiation product (half life about 1–2 min) [9b,22]. Our attempts to synthesize a 6-hydroxydihydrothymine *(8)* by the method used for uracil, cytosine, and their derivatives were unsuccessful. *Nofre* [16], on the other hand, obtained *(8)* by debromination of the corresponding thymine compound with Zn/glacial acetic acid [17].

On column-chromatographic separation of the products resulting from the UV irradiation of uridine in frozen aqueous solution, we obtained two reversible irradiation products of uridine [21e]. It is not yet certain whether these are two isomers differing in their H-bonding in accordance with formulations *(9a)* and *(9b)* [18] or the diastereoisomers *(10)* [19].



The detailed kinetic investigation [8b,8c,9b,21a–21d] of the decomposition of the reversible irradiation products *(3a)–(3e)* and *(6a)–(6c)* showed that the stability of the 6-hydroxydihydropyrimidine system is



(9a)

(9b)

(10a)

(10b)

R = D-Ribosyl

very strongly influenced by the sugar or sugar phosphate residue on N-1, and increases in the order base→nucleoside→nucleotide. Investigations by *Logan* and *Whitmore* [23] show that this effect does not end with the nucleotide, but that the stability of the 6-hydroxydihydrouracil system in polynucleotides increases with increasing chain length, *i.e.* toward the nucleic acid. This influence on the reactivity of the pyrimidine system, which has also been observed in other investigations [24, 123b], is presumably due to H bonds between parts of the pyrimidine ring and the OH groups of the sugar residue, to "steric screening" of the reactive centers of the pyrimidine ring by the phosphate group(s), and to electrostatic interactions between the pyrimidine ring or individual parts of rings and the phosphate group(s) [24]. In polynucleotides and nucleic acids, other steric effects (*e.g.* the screening of the base by individual parts of the macromolecule) and electrostatic effects of the electric field of the nucleic acid on attacking ionic reactants also occur. These effects can influence the reactivity of a pyrimidine base [25] to such an extent that it reacts quite differently as the free base than it does in the form of its nucleotide or when it is incorporated into a nucleic acid. Thus an effect observed with a pyrimidine base [25] cannot be immediately assumed to be applicable also to the corresponding nucleoside or nucleotide, or even to a nucleic acid [26].

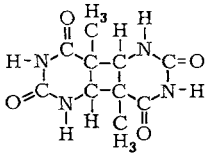
[24] See [8c].



[25] Preliminary experiments indicate that the above assumptions are also valid for purine bases.

[26] Effects of this type are probably responsible for the unusual behavior of free radicals produced by ionizing radiation in nucleic acids [77b] as compared with "normal" organic free radicals.

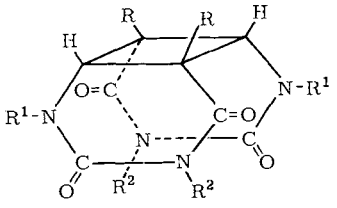
2.2. Dimeric Irradiation Products

2.2.1. Structure of the Dimeric Irradiation Products

In 1958–1960, *Rörsch, Beukers, Ijlstra,* and *Berends* [27] and *Wang* [28] reported observations according to which a *thermally irreversible* irradiation product is formed on UV irradiation of thymine in frozen aqueous solution (referred to hereafter as ice matrix). The authors suggested (without providing further evidence) that photochemical dimerization had occurred, with formation of a tricyclic cyclobutane derivative [*(11)*

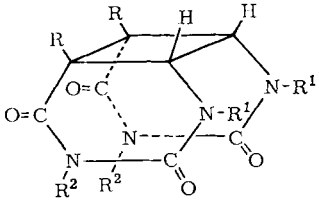
(11)

according to the formulation of [27c, 28c]]. The choice of irradiation in the ice matrix was based on observations by *A. v. Szent-Györgyi*, according to which the ice matrix should correspond more closely to the biological conditions than an aqueous solution [27, 28]. The discovery of these irreversible irradiation products, the formation of which has also been observed with other pyrimidine derivatives, immediately led to very intensive investigation of this field. The following questions had to be answered:



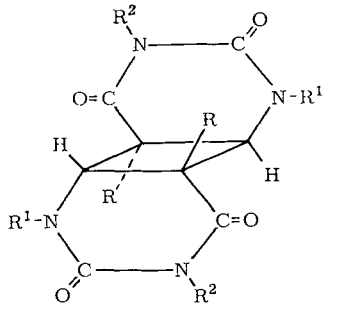
(i) Are these irradiation products really cyclobutane derivatives in accordance with the formulation *(11)*?

(ii) If so, which of the four possible isomers *(12)* to *(15)* are formed?

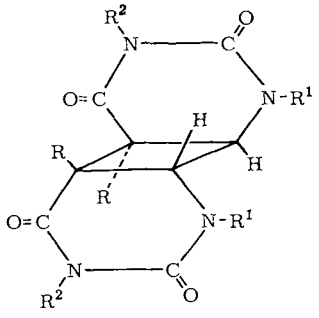


(iii) Are similar irradiation products formed on UV irradiation of nucleic acids?

The cyclobutane structure of the irreversible irradiation products has been demonstrated by several research groups. *Anet* [29] and *Blackburn* and *Davies* [30a] showed by NMR spectroscopy and with the aid of a novel degradation (see Section 2.2.2) that the dimeric thymine formed in the ice matrix has the *cis/syn* structure *(13a)*. The structure *(13b)* of the dimeric uracil has been proved by us by degradation [21i], by NMR spectroscopy (*Blackburn* and *Davies*) [30b], and by X-ray analysis (*Adman, Gordon,* and *Jensen*) [31]. Several research groups (see Section 4) have shown that the ice-matrix dimers of thymine and uracil are also formed on UV irradiation of nucleic acids.



It is much more difficult to establish whether the UV irradiation of thymine and uracil, as well as of nucleosides, nucleotides, and nucleic acids, leads only to the *cis/syn*-isomer *(13)* or also to the other isomers *(12)*, *(14)*, and *(15)*. Some authors assumed that the four isomers of dimeric thymine and of dimeric uracil can



(12)

(13)

(14)

(15)

(a), R = CH_3, R^1 = R^2 = H
(b), R = R^1 = R^2 = H
(c), R = CH_3, R^2 = H, R^1 = Deoxyribosyl
(d), R = R^2 = H, R^1 = Ribosyl
(e), R = R^1 = H, R^2 = CH_3

be distinguished by thin layer or paper chromatography. However, we have shown with mixtures of these isomers [21e, 21f] that this is not necessarily so. Furthermore, the isomers cannot be reliably separated from one another by fractional recrystallization and similar operations. Other methods are therefore necessary to distinguish them.

Mass spectrometry, which is particularly suitable for the identification of small quantities of material, is completely unsuccessful in this case. The dimers are broken down in the ion chamber both thermally and by the electrons [121] from the ion source. Experiments with various mass spectrometers and under various sets of conditions gave only the mass spectra of the monomers.

Though the dimers can be distinguished and hence identified by *NMR spectroscopy* [21f], this method requires at least mg quantities of the substance, whereas such quantities are generally not available on isolation of the dimers from biological systems.

A reliable identification of the dimers is possible by *IR spectroscopy* [32, 33, 59], which can be used without serious technical difficulties even in the μg range. As little as 10% of one isomer can be detected in a mixture of two isomeric dimers [21f, 32].

The dimers required as reference substances can be prepared in the following way: Dimerization of

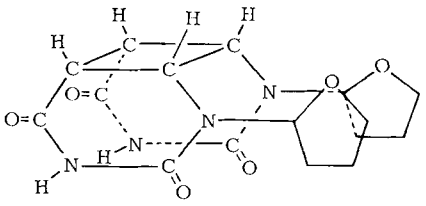
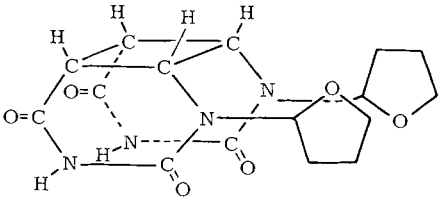
[33] To increase the identification capacity, it is recommended that measurements be carried out up to about 35 μm [32].



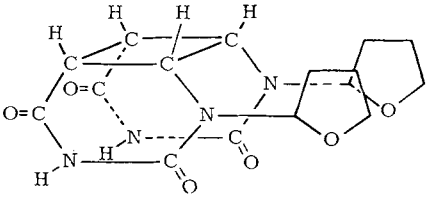
thymidine in the ice matrix followed by chromatographic separation of the irradiation products on a column gives the three dimeric thymidines *(12c)*, *(13c)*, and *(14c)* [34]. Hydrolysis of these compounds yields the dimeric thymines *(12a)*, *(13a)*, and *(14a)* [35]. The fourth dimeric thymine *(15a)* was prepared by *Weinblum* and *Johns* [35] by UV dimerization of thymidyl-(3′–5′)-thymidine followed by hydrolysis [36].

Dimerization of thymidine in *tert*-butanol with acetone as a sensitizer led to the four dimeric thymidines *(12c)* to *(15c)* [37]. The dimeric thymines *(14a)* and *(15a)* were formed on irradiation of thymine in the presence of acetone, benzophenone, and other ketones as sensitizers [38].



We obtained the dimeric uracil *(12b)* in the two optically active forms by UV irradiation of uridine in the ice matrix [7c], separation of the irradiation solution by column chromatography, and hydrolysis of the corresponding dimeric uridines [21e, 39]. We have been able to obtain all four dimeric uracils by total synthesis (see Section 2.2.3) [21h, 40].

On separation of the irradiation products of uridine (ice matrix), we obtained two fractions which gave the same dimeric uracil *(13b)* on hydrolysis. Examination of molecular models [41] showed that in the *cis/syn* dimeric uridine *(13d)*, rotation of the ribose residue about the N-1/C-1′ axis, which is restricted in any case by H bonding between the 2-C=O groups and the HO groups of the sugar residue, must be prevented by the bulk of the two neighboring ribose residues. Three isomers, corresponding to the formulas *(16)*, *(17)*, and *(18)* can be formed, though the formation of *(18)*, with the *trans/trans* arrangement of the ribose O atoms in relation to the H atoms of the cyclobutane ring is opposed by steric factors. We believe that the two fractions mentioned above are the uridine dimers *(16)* and *(17)* [21e].



Detailed investigation of the dimerization showed that it is not confined to the ice matrix, or to the solid state in general [50], but also occurs in solution, though in a poorer yield. The yield depends on the wavelength of the radiation used [47]; a photochemical equilibrium is established with a maximum dimer content at about 275 nm. Even cyclobutane derivatives containing only one dihydropyrimidine ring, *e.g. (26)*, are broken down into the monomer by short-wave UV radiation (about 230 nm).

(16)

(17)

(18)

The stability of the cyclobutane ring in the dimers is influenced by the sugar or sugar phosphate group on N-1 in the same way as in the case of the 6-hydroxydihydropyrimidine ring systems *(3)* and *(6)* (see Section 2.1). Whereas the dimeric uracil *(13b)* is perfectly stable towards 6 N HCl, the dimeric uridine *(13d)* yields not only the dimeric uracil *(13b)* by loss of the sugar residue, but also forms uracil [21e]; thus as in the case of the 6-hydroxydihydropyrimidine derivatives, no direct conclusions concerning the behavior of a nucleoside, nucleotide, or base segment in the nucleic acids can be drawn from the behavior of the corresponding base.

Investigations by several research groups on the quantitative relation between the radiation dose received and the quantity of dimer *(13a)* or *(13b)* obtained by acid hydrolysis must be regarded as uncertain, since the quantity of *(13a)* and *(13b)* isolated does not correspond to the quantity of dimer formed in the nucleic acid, since part of the dimer formed may be broken down into monomer or destroyed in some other way during isolation [43].

The identification of the dimers isolated from nucleic acids purely on the basis of their chromatographic behavior must always be regarded as uncertain. IR spectroscopy must also be used to check that the isolated irradiation product does not contain other dimers as well as *(13a)* or *(13b)* [21e, 21f].

[34] The dimers *(12a)* and *(12b)* and *(15a)* and *(15b)*, which have the symmetry group C_2, must be capable of being resolved into optical antipodes. The dimerization of thymidine and uridine accordingly yields the dimers *(12c)* and *(12d)* in two diastereoisomeric forms, which give the dimers *(12a)* and *(12b)* in optical antipodes on hydrolysis.

2.2.2. Reactions of the Dimeric Thymines and Dimeric Uracils

When dissolved in 0.1 N NaOH, the dimeric thymine *(13a)* forms a disodium salt, which changes into the diureido compound *(19a)* when heated at 60 °C with 5 N NaOH [21f,30a,44a,44b]. Similar diureido compounds are formed by the dimers *(12a)* and *(14a)* [38,44a]. Treatment of *(19a)* with 40% NaOH and bromine yields the compound *(20a)*, which reacts with HNO_2 to form *(20b)*. When heated to 240 °C, *(20a)* and *(20b)* give *(21)* and *(22)* [30a,44b]. The conversion of *(13a)* into *(21)* and *(22)* was taken by *Blackburn* and *Davies* [30,44b] as evidence of the structure of *(13a)*. Unlike the dimeric uracils (Section 2.2.3), the dimeric thymines can be converted into the tetramethyl derivatives by reaction with dimethyl sulfate [36a,44c,44d]. The reaction of *(13a)* with $NaBH_4$ yields *(19b)*, which gives *(19a)* on reaction with $KMnO_4$ [44a]. The dimers *(12a)* and *(14a)* behave similarly with $NaBH_4$.

The dimeric uracil *(13b)* also dissolves in dilute NaOH to give a disodium salt, which forms the diureido compound *(23)* when heated at 50 °C in 0.5 N NaOH; *(23)* can be converted back into *(13b)* by heating with dilute acid [21e,30b].

The reaction sequences *(13a)*→*(19a)*→*(13a)* and *(13b)*→*(23)*→*(13b)* conclusively rule out the otherwise conceivable

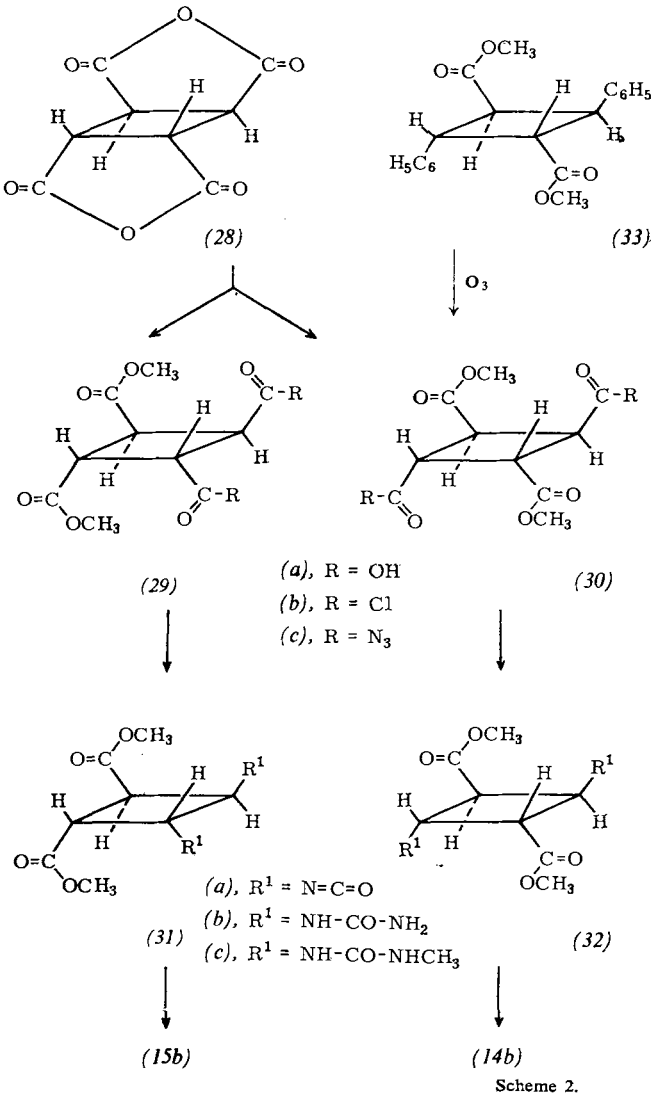
possibility of *trans* linkage of the heterocyclic rings [*e.g. (27)*]. A ring system as strained as this could be formed in the photochemical dimerization[45], but not on addition of acid to *(19a)* or *(23)*.

When heated at 50 °C with 10 N NaOH, *(23)* and *(13b)* are converted into a complex mixture of products, which include the diamino dicarboxylic acids *(24)* and *(25)*[46]. On reaction with potassium cyanate, the mixture gives some dimer *(13b)*, probably together with the compound *(26)*, which can be converted into *(13b)* by prolonged heating with concentrated hydrochloric acid[21e]. On methylation of *(13b)* with dimethyl sulfate, we obtained some trimethylated dimeric uracil[21e] as well as the dimethyl dimer *(13e)*[30b]. The tetramethylated dimer could not be obtained even with diazomethane.



2.2.3. Total Synthesis of the Dimeric Uracils[21h,40]

We were able to prepare all four dimeric uracils by sterically comprehensive syntheses.

On boiling in methanol, the dianhydride *(28)* forms a mixture of the two isomeric half-esters *(29a)/(30a)*, which can be separated by fractional crystallization. The structure of *(30a)* was proved by ozonolysis of the α-truxillic acid ester *(33)*. *(29a)* and *(30a)* are converted *via* the acid chlorides *(29b)* and *(30b)* into the azides *(29c)* and *(30c)*, the Curtius degradation of which yields the isocyanates *(31a)* and *(32a)* respectively.

The reaction of *(31a)* and *(32a)* with NH_3 leads to the diureido components *(31b)* and *(32b)*, which are converted by acid into the dimeric uracils *(15b)* and *(14b)* respectively. Reaction of *(31a)* and *(32a)* with methylamine leads to *(31c)* and *(32c)*, which yield the methylated dimers *(14e)* and *(15e)* on ring closure.

The *cis* dimeric uracils *(12b)* and *(13b)* were synthesized by a similar route. When the dianhydride *(70)* is boiled with methanol, it forms a mixture of the half-esters *(71a)* and *(72a)* which were converted into the *cis* dimeric uracils *(12b)* and *(13b)* by the following reaction steps *(71a)*→*(71b)*→*(71c)*→*(73a)*→*(73b)* or *(72a)*→*(72b)*→*(72c)*→*(74a)*→*(74b)*[*]. The resulting *cis/anti* dimeric uracil *(12b)* is identical with the dimer that we obtained from uridine by UV irradiation[21e,39] (see Section 2.2.1), and thus confirms its structure.

Scheme 2.

2.2.4. Dimeric Cytosines and Mixed Dimers

The questions whether cytosine, as a base or as a component of nucleic acids, is capable of dimerizing and which of the four possible dimers are formed have not yet been finally settled. The experimental results suggest that dimerization is possible in dinucleotides[12,51,105] and nucleic acids[52–55], *e.g.* to form the dimer *(34)*, which, as a derivative of dihydrocytosine, readily undergoes thermal deamination to form *(13b)*. In no case was dimeric cytosine isolated. UV irradiation of cytosine, cytidine, and cytidylic acid in the ice matrix yields either no dimeric uracil deriv-

[45] See the formation of a *trans*-linked cyclobutane ring observed by *E. J. Corey, J. D. Bass, R. LeMahieu*, and *R. B. Mitra*, J. Amer. chem. Soc. *86*, 5570 (1964), on UV irradiation of a mixture of 2-cyclohexenone and isobutylene.

[46] The formation of *(25)* and *(26)* and the conversion of *(26)* into *(13b)* require the isomerization of a COOH group on the cyclobutane ring. Isomerizations of this type have been described by *E. R. Buchman, A. O. Reims, T. Skei*, and *M. J. Schlatter*, J. Amer. chem. Soc. *64*, 2696 (1942).

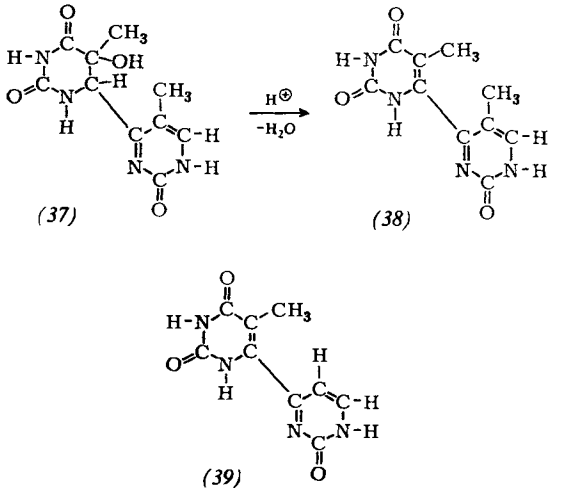
atives[21f,14,50] or so little[48,49] that direct photochemical deamination followed by dimerization must also be taken into account in these cases[15].



On exposure of thymine/uracil mixtures in the ice matrix to UV radiation, a mixed uracil/thymine dimer is obtained as well as dimeric thymine *(13a)* and dimeric uracil *(13b)*[21f,27c,48,56–58]. This mixed dimer is identical with that obtained on irradiation of DNA[59], which presumably results from deamination of a mixed cytosine/thymine dimer[52,55,59–64,105]. *Weinblum*[59] has suggested the structure *(36)* for the mixed uracil/thymine dimer, so that the mixed cytosine/thymine dimer should have the structure *(35)*. On UV irradiation of a mixture of uridine and thymidine in the ice matrix we obtained, in addition to the dimeric uridines and thymidines, several mixed thymidine/uridine dimers, which gave three other mixed thymine/uracil dimers as well as *(36)* on hydrolysis[21f,21g].

2.3. Other Photochemical Reactions[65]

Several authors have found evidence that other photochemical reactions occur as well as the photochemical addition of water to the 5,6-double bond and the for-

mation of dimers on UV irradiation of nucleic acids. On irradiation of DNA, dinucleotides and thymine in the ice matrix, photoproducts having a specific absorp-

tion maximum at about 320 nm are formed [48,66–70]. *Wang* and *Varghese* [67,68] proposed the structure *(37)* for the product (λ_{max} = 316 nm) obtained on UV irradiation of thymine in the ice matrix [71]. When heated with acid, *(37)* is converted into *(38)*. A similar product having the structure *(39)* was obtained by these authors [68] on hydrolysis of UV-irradiated DNA. The uracil residue of the substance is presumably derived from the cytosine part of the DNA [68].

It is possible that we have obtained a product of uracil analogous to *(38)* on dimerization of uridine in the ice matrix [21e, 76]. On UV irradiation of thymine, the formation of dihydrothymine [73] and the oxidation of the CH_3 group [74, 75] were observed.

3. Action of Ionizing Radiation on Nucleic Acids and their Components [77]

Unlike the processes brought about by UV radiation, which are selectively influenced by the wavelength of the radiation used, the processes caused by ionizing radiation are much more complex. Several reaction possibilities must be considered:

The direct interaction of the radiation with the nucleic acid (N–M), which produces a positive charge on the nucleic acid strand at or near the point of impact, and leads to the formation of free radicals [eq. (1)].

(1)

The nature and the chemical behavior of the reaction products $(N-M)^{\oplus}$, N·, M·, $N^{\oplus}$, and $M^{\oplus}$ depend on the point of impact on the nucleic acid, *i.e.* the nucleic acid macromolecule can yield many different species $(N-M)^{\oplus}$, N·, M·, $N^{\oplus}$, and $M^{\oplus}$. The reaction is further complicated by the liberated electrons, which can reattack the nucleic acid.

The interaction between the radiation and the other cell components. Corresponding to equation (1), free-radical and ionic particles are formed, and these can again attack the nucleic acid.

The interaction between the radiation and the water. This leads to a small extent directly to HO and H radicals [78], but mainly to $H_2O^{\oplus}$ and electrons [equations (2) and (3)]. The electrons can now form further $H_2O^{\oplus}$ particles, whereupon they themselves are converted into electrons of lower energy ($e_p^{\ominus}$) and liberate further electrons ($e_s^{\ominus}$). The interaction between the ionizing radiation and the water thus leads to an avalanche of $H_2O^{\oplus}$ particles and electrons having various energies. The reaction sequence ends when the energy of the electrons has fallen below about 30 eV. The electrons are then "trapped" and stabilized as thermal electrons by hydration ($e^{\ominus}_{Hydr.}$). Their energy is dissipated *e.g.* in the formation of H radicals [eq. (6)] [79].

$$H_2O \rightsquigarrow H_2O^* \longrightarrow HO\cdot + H\cdot \quad (2)$$

$$H_2O \rightsquigarrow H_2O^* \longrightarrow H_2O^{\oplus} + e_p^{\ominus} \quad (3)$$

$$e_p^{\ominus} + H_2O \rightarrow \begin{cases} H_2O^* + e_p^{\ominus\prime} \\ H_2O^{\oplus} + e_p^{\ominus\prime} + e_s^{\ominus} \end{cases} \longrightarrow HO\cdot + H\cdot \quad (4)$$

$$H_2O^{\oplus} + H_2O \rightleftarrows HO\cdot + H_3O^{\oplus} \quad (5)$$

$$e^{\ominus}_{Hydr.} + H_3O^{\oplus} \rightleftarrows H\cdot + H_2O \quad (6)$$

If the irradiated systems contain oxygen, the reactions formulated in equations (7) to (9) also take place.

$$e^{\ominus}_{Hydr.} + O_2 \longrightarrow O_2^{\ominus} \quad (7)$$

$$H\cdot + O_2 \longrightarrow HO_2\cdot \quad (8)$$

$$HO_2\cdot + H_2O \rightleftarrows O_2^{\ominus} + H_3O^{\oplus} \quad (9)$$

The processes that can occur on irradiation of nucleic acids with ionizing radiation are as follows:

a) The "direct hit" on the nucleic acid in accordance with equation (1), which is difficult to detect chemically because of the many possibilities.

b) Reactions of the nucleic acid with the particles H·, HO·, $H_2O^{\oplus}$, and $e^{\ominus}_{Hydr.}$ formed from water and with reactive particles obtained from other cell components in accordance with eq. (1).

The action of ionizing radiation on aqueous solutions of nucleic acids thus leads to a number of reactions that also depend on other factors such as the nature of the radiation, the radiation dose and its time distribution, the concentration, and the pH value of the solution, and that become increasingly complicated on irradiation of cells and larger biological objects. We have concentrated our investigations mainly on the chemical processes that take place on irradiation of nucleic acid components in aqueous solution [2c, 80]. Investigations by other workers had shown that large radiation doses (more than 10^6 rad) are required to obtain mg quantities of irradiation products. ^{60}Co sources and X-ray tubes, however, seldom yield more than 1000 rad/min, so that long irradiation times are necessary to obtain the quantities of substances required for the structure investigations. The result is that the thermally unstable irradiation products decompose during irradiation and cannot be isolated. The processes that occur in accordance with equations (4) to (6) on irradiation in aqueous solution can also be initiated independently of processes (2) and (3) by direct injection of electrons into the aqueous system [primary process corresponding to eq. (4)] [81].

We therefore carried out the irradiation as follows (see Fig. 1) [80]:

The electrons are accelerated in an accelerator tube by the voltage of an electrostatic generator (approx. 1 MV) and focused in a system of magnetic lenses. At the end of the system they emerge through an Al window (about 0.33 mm thick) into the air (energy of the electrons on emerging approx. 800 keV; diameter of the beam about 1—2 mm). The irradiation cell, situated a few centimeters behind the exit window is made of apparatus glass (3.5 × 4.5 × 10 cm) and has an Al window (0.02 mm thick and 2.8 cm in diameter) in its broad side; this window acts as a collecting electrode for the injected charges. The window is connected to an electronic current integrator, by means of which the number of electrons injected can be determined. We generally used doses of 8000 to 9000 rad/sec (irradiation times of about 1 to 3 min). The solutions were vigorously agitated with a magnetic stirrer during the irradiation, and were frozen immediately after irradiation. The solutions were then separated by thin layer, paper, or column chromatography; the products were generally identified by IR and UV spectroscopy, and in some cases also by NMR and mass spectroscopy.

3.1. Uracil, Thymine, and Cytosine

Irradiation of aqueous solutions of uracil, thymine, and cytosine in the absence of oxygen leads to the formation of the products indicated in Schemes 3 and 4, which result mainly from the attack of H and/or HO radicals and of $e^{\ominus}_{Hydr.}$ on the 5,6-double bond of the pyridine system [16,80,83–90].

Since the formation of the reactive particles and the reactivity of the pyrimidines used toward the radicals and $e^{\ominus}_{Hydr.}$ depend on the pH value of the solution, some of the reaction courses shown in Schemes 3 and 4 are also strongly influenced by the pH value [91]. These reactions can theoretically be formulated as proceeding both by attack of H or HO radicals and with the participation of $e^{\ominus}_{Hydr.}$. Since no systematic studies allowing a distinction between the two possibilities in every case have yet been reported, we have formulated both possibilities for uracil and thymine, whereas only the reaction involving free radicals is shown in the case of cytosine for the sake of clarity.

The irradiation of uracil leads by formal addition of two H radicals to dihydrouracil *(47a)* [92], by formal

[81] Detailed differences in action may be due to the differences in the spectral distribution of the electrons in electron, X, and γ radiation. As was shown by calculation of the electron spectra by *D. Harder*, Intern. atomic Energy Agency, Vienna, Techn. Rep. Ser. *58*, 140 (1966), the differences between irradiation with electrons having an initial energy of 1 MeV and with ^{60}Co-γ radiation are very small. On the other hand, distinct differences are found in the electron spectra of X radiation for tube voltages of 100 and 200 kV.

[82] Schemes 3 and 4 show the most important substances formed on irradiation; for other irradiation products, see *R. Pleticha-Lansky* and *J. J. Weiss*, Analyt. Biochem. *16*, 510 (1966); *K. C. Smith* and *J. E. Hays*, Radiat. Res. *33*, 129 (1968).

[92] On irradiation of dihydrouracil in aqueous solution with ^{60}Co-γ radiation in the presence of air, the formation of uracil and of the uracil irradiation products *(41a)*, *(48a)*, *(53)* and *(54a)* was observed; see *G. Vincendon, A. Cier*, and *C. Nofre*, Bull. Soc. chim. France *1965*, 1997; *W. Snipes* and *W. Bernhard*, Radiat. Res. *33*, 162 (1968).

Scheme 3. Reactions occurring on irradiation of uracil and thymine [96] with ionizing radiation in deaerated aqueous solution [82].

addition of two HO radicals to the unstable uracil glycols *(54a)*, which readily change into isobarbituric acid *(53)*, and by addition of H and HO to 5- or 6-hydroxydihydrouracil *(48a)* or *(41a)*.

The mechanism of the formation of the hydroxy compounds *(48a)* and *(41a)* [93] has not been established. Simultaneous addition of H· and HO· seems unlikely, while successive addition of the two radicals is opposed by their short lives. A reaction in accordance with

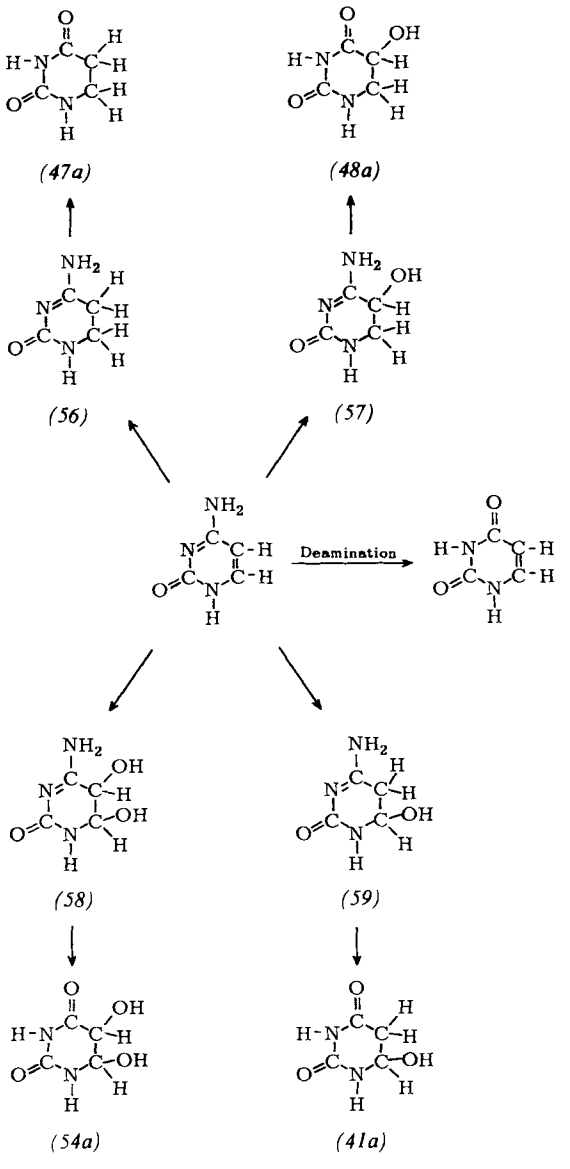
$$(43a)/(46a) + H_2O \rightarrow (41a)/(48a) + H\cdot$$

and

$$(50a)/(51a) + H_2O \rightarrow (41a)/(48a) + H\cdot$$

should scarcely be possible, in view of the resonance stabilization of the radicals *(43a)/(46a)* and *(50a)/(51a)*. The most probable course in our view is the reaction of *(50a)* and *(51a)* with $e^{\ominus}_{Hydr.}$ to form the anions *(49a)* and *(52a)*, which then give *(41a)* and *(58a)* by protonation.

The reactions in the thymine system proceed similarly. In this case the stable *cis*- and *trans*-thymine glycols *(54b)* can be detected. The formation of *(55)* predominates at very high pH values, presumably because the resonance-stabilized system of the thymine dianion present at such pH values escapes the attack on the 5,6-C=C bond [94].



In the case of cytosine, the addition of H and/or HO radicals leads to derivatives of the unstable 5,6-dihydrocytosine system *(56)–(59)*, which undergo deamination to give the corresponding dihydrouracil derivatives *(41a)*, *(47a)*, *(48a)*, and *(54a)*.

If the irradiation is carried out in the presence of oxygen, peroxides are formed [86–90,95]. Thymine gave the peroxides *(60)* and *(61)*, the structures of which were

[93] The same is true of the corresponding compounds of thymine and cytosine.

Scheme 4. Reactions in the irradiation of cytosine [96] with ionizing radiation in degassed aqueous solution [82].

proved by independent synthesis[95]. Similarly, cytosine gives the peroxide *(62)*, which decomposes into cytosine and uracil glycols[87]

3.2. Purines

Purines are more stable towards ionizing radiation than are pyrimidines[98a,99]. The attack by the radicals takes place at the imidazole ring and leads to the formation of the triamino derivatives *(63)* (R^2 = H)[98,99,101] (see Scheme 5). Deamination has also been observed.

In the irradiation of purine nucleosides and nucleotides the radicals partly attack the sugar residue[97–100,102b] – the purine base being released – but mainly attack the purine system with formation of the pyrimidine derivatives *(63)*[98,102b]. *(63b)* could be detected during irradiation of DNA. Peroxides were not found in the irradiations carried out in the presence of oxygen.

Keck and *Hagen* found that the radicals *(65)*, *(66)*, and *(67)* are formed during the irradiation of purine nucleotides[102] as a result of a primary attack by H or HO radicals on the C-5′ or C-8′ atom. Both *(66)* and *(67)* disproportionate to give *(68)* and *(69)*; *(69)* is converted into *(63)* (see Scheme 5).

4. Discussion of the Molecular Origin of Biological Radiation Damage[103]

The observations described in Sections 2 and 3 were obtained from the bases as well as their nucleosides and nucleotides, and we assume that they are not immediately applicable to nucleic acids (Section 2.1). We are therefore faced with the following questions:

(i) Are the photochemical and radiation-chemical findings for bases and their nucleosides and nucleotides valid only for these, or do these reactions also occur on irradiation of the nucleic acids?

(ii) Can definite types of biological damage be attributed to these photochemical and radiation-chemical reactions?

Both questions have been extensively studied[104], mainly for UV radiation, and very definite answers can be given in some respects. The question of the effects of ionizing radiation, on the other hand, is still largely unanswered.

[96] The reaction courses indicated here are also valid for the corresponding nucleosides and nucleotides [80]; as with the purine nucleosides and nucleotides, however, the sugar or sugar phosphate residue is again split off [97].

[97] The ribose residue is more sensitive than the deoxyribose residue [94]

R^2 = Ribosyl(deoxyribosyl) or Ribosyl(deoxyribosyl)phosphate

Scheme 5. Reactions in the irradiation of purine nucleotides with ionizing radiation in aqueous solution.

The observation that isolated bases dimerize on UV irradiation of DNA[105] *in vitro* and *in vivo* was made immediately after the discovery of the dimerization in the ice matrix. Thus *Wacker*, *Dellweg*, and *Weinblum*[107], as well as other workers[53,108,109], were able to show that a substance in the DNA hydrolyzate of UV-irradiated bacteria has the same chromatographic properties as dimeric thymine.

A mixed dimer $\widehat{UT}$, which is thought to result from the deamination of $\widehat{CT}$, has also been detected on irradiation of bacteria[60,61].

The dimerization that occurs between two adjacent bases of the same single strand to form the *cis/syn* dimer *(13a)* causes inhibition of the reduplication of the DNA[111] and alters the behavior of the nucleic acid on enzymatic hydrolysis. This leads to oligonucleotides containing the dimer, which cannot be further broken down by enzymes[111–113,123a], and the nature of which depends on the base composition

[105] The processes that occur on UV irradiation of dinucleotides have been studied by *H. E. Johns et al.* [12, 72, 51, 66, 76, 106] and supported by detailed kinetic measurements. These authors showed that TpT [103] forms two dimers. For UpU and CpC, addition of water (*e.g.* to form C*pC, CpC*, and C*pC*) and dimerization occur simultaneously. The $\widehat{CpC}$ dimers undergo deamination to give $\widehat{UpU}$ dimers.

of the DNA and on the wavelength and dose of the radiation used.

The formation of dimers in the DNA permits an interpretation of the well known reactivation of UV-damaged microorganisms (reactivation by short-wave UV radiation, enzymatic "dark reactivation", photo-reactivation) [114].

On *reactivation by irradiation with short-wave UV radiation* (about 230 nm), the dimers are broken down into monomers [115]; the quantity of dimeric thymine formed in DNA on UV irradiation accordingly depends on the wavelength of the radiation [116, 132e] (see Section 2.2.1).

The *enzymatic reactivation* (also called "*dark reactivation*" to distinguish it from photo-reactivation) is one of the most interesting reactivation phenomena known [117] (Fig. 2). Attack by one enzyme results in cleavage of a phosphate linkage of the DNA double strand that was damaged by the dimerization [(a) and (b)]. Another enzyme cuts out the dimeric portion, starting at the dimeric nucleotide, together with a few other attached nucleotides [(c)]. The portion removed is replaced by resynthesis (DNA polymerase) with the undamaged DNA strand as a pattern [(d)]. Another enzyme (polynucleotide ligase) then closes the 3′/5′ bond.

The enzymatic dark reactivation also explains the widely differing resistances of bacteria to UV radiation. The radiation-resistant bacteria contain enzymes that can repair the damage caused by UV radiation by the above or similar mechanisms.

In *photo-reactivation*, the radiation damage is repaired by irradiation with visible light (350–420 nm) [118]; photo-reactivating enzymes act as sensitizers and bring about the photochemical cleavage of the dimer into monomer [119].

According to *Wacker et al.*, similar reactivations occur with visible light and uranyl acetate or H_2O_2 [120]. Poly-U can also be reactivated [121] with H_2O_2 or uranyl acetate in the absence of visible light [120b].

It is not certain whether and to what extent photochemical addition of water occurs on UV irradiation of nucleic acids [122]. It appears to take place only in nucleic acids that do not consist of double strands [110, 123], but also appears to be possible to a small extent in DNA [124] by local cleavage of the double strand and dimerization (cleavage of the double strand at the dimerization site, followed by addition of water to adjacent cytosine molecules) [123a].

The possible biological importance of the photochemical addition of water has been studied by *Grossman*,

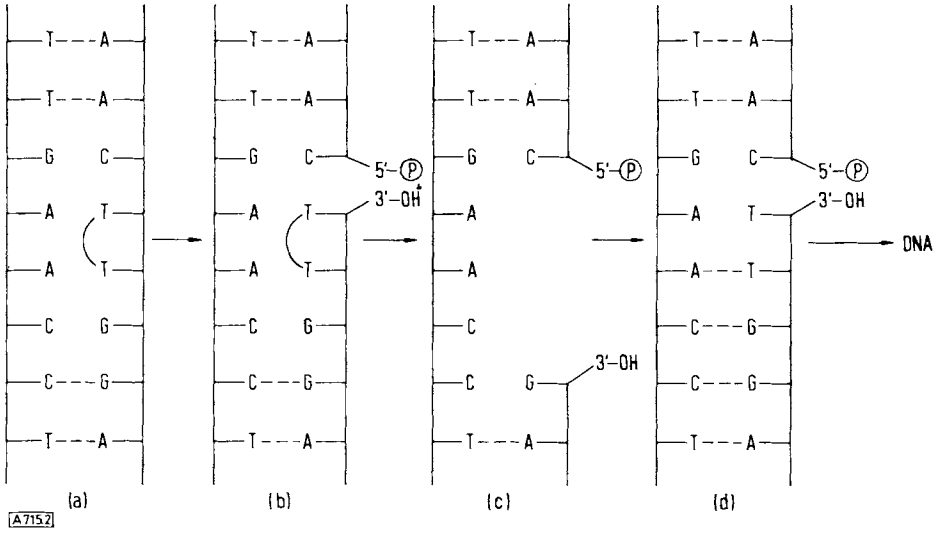

Fig. 2. Scheme of enzymatic dark reactivation [for explanation of (a)–(d) see text].

[124] Since segments of single strands occur for short periods during reduplication of DNA, there is a possibility of addition of water during this phase.

Ono, and *Wilson* [125], *Ottensmeyer* and *Whitmore* [126b], and *Wacker et al.* [126a]. The results can be partly interpreted by assuming that 6-hydroxydihydrouracil (U*), as a component of an RNA codon, behaves as cytosine in the enzymatic protein synthesis *in vitro* [126c]. In agreement with this, the incorporation of GTP as well as ATP has been observed in the enzymatic synthesis of polyadenylic acid with UV-irradiated poly-U as the pattern [125b] (see Fig. 3).

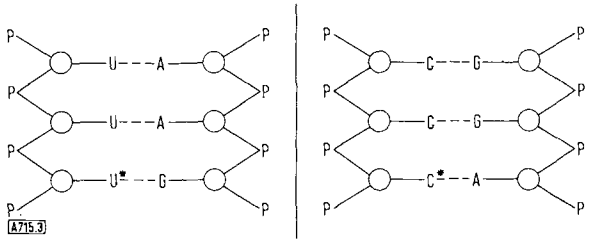

Fig. 3. Scheme of the effect of addition of water to uracil and cytosine in the nucleic acid double strand.

Similarly, the 6-hydroxydihydrocytosine part (C*) [125b, 125c] of UV-irradiated polycytidylic acid causes the incorporation of ATP in the enzymatic synthesis of polyguanylic acid, *i.e.* the C* part codes in the same way as uracil. This effect is not due to conversion of cytosine into uracil in accordance with the reaction sequence *(4)→(6)→(3)→(1)* (Section 2.1), as is shown by the reversibility of the findings; on heating at 37 °C, the poly-C* is converted back into poly-C [127], which causes the incorporation of GTP only.

These results indicate that any 6-hydroxydihydrocytosine parts formed in the DNA cause the incorporation of adenine instead of guanine into the complementary strand, and so lead to "error signals"* in the reading of the genetic code [128].

Several experimental observations indicate that in addition to dimerization and the addition of water UV radiation also causes other effects in nucleic acids, the nature of which is still largely unknown. Some of the effects observed were the breakdown of the nucleic acid strand, breakdown of the intermolecular and intramolecular main valence bridges between nucleic acid strands, and changes in the secondary structure [129]. Whereas breaks in one strand of a DNA double strand can presumably be repaired as in dark reactivation, breaks in the double strand and main valence bridges between the strands are probably irreparable.

The photochemical addition of amino acids to the pyrimidine parts of nucleic acids has been investigated by *K. C. Smith et al.* [64, 130]. The results show that photochemical crosslinking between the nucleic acid and the protein must also be taken into account in the interpretation of UV-radiation damage [131]. The formation of UV products having the characteristic maximum at about 320 nm (see Section 2.3) on irradiation of nucleic acids has been observed by various authors. Bacterial spores give only a little dimer on UV irradiation [132a,b]. Irradiation products of unknown structure are formed that correspond in their chromatographic behavior to those obtained on UV irradiation of DNA in the dried state or in the ice matrix [132].

All the available chemical, physical, and biological evidence on the molecular interpretation of UV-radiation damage adds up to give the following picture:

i) Dimerization and the addition of water play a decisive role in many cases. The contributions of these processes to radiation damage depends on the nature of the nucleic acid, the irradiation conditions, and the wavelength and dose of the radiation [133]. Apart from these two processes, it is also necessary to consider photochemical chain cleavage, main-valence crosslinking between nucleic acid strands, reactions between nucleic acids and proteins, and other, as yet unknown reactions of the pyrimidine bases.

ii) The dimerization prevents reduplication of the DNA; addition of water (and possibly also dimerization [134]) leads *inter alia* to the UV mutations.

Knowledge of the molecular causes of the biological damage caused by ionizing radiation is still far from complete, since ionizing radiation can lead simultaneously to various types of damage [135]. The observations

[125] a) *L. Grossman*, Proc. nat. Acad. Sci. USA *50*, 657 (1963); b) *J. Ono*, *R. G. Wilson*, and *L. Grossman*, J. molecular Biol. *11*, 600 (1965); c) *L. Grossman*, *J. Ono*, and *R. Wilson*, Symp. Fundamental Cancer Res. *18*, 107 (1964); Chem. Abstr. *63*, 3221 (1965), Federat. Proc. *24*, p. 80 (1965).

Whitmore*, J. molecular Biol. *38*, 1 (1968); *ibid.* *38*, 17 (1968); c) the $\widehat{UU}$ codes in the same way as the base pair GU and unmodified UU.

[127] An alternative interpretation of the above observations is that C* is deaminated on heating to give the thermally very stable U* [8, 9], which codes in the same way as cytosine.

[128] The direct photochemical deamination of cytosine to form uracil [15] should, in principle, also be considered here.

[131] *J. Goddard*, *D. Streeter*, *C. Weber*, and *M. P. Gordon*, Photochem. and Photobiol. *5*, 213 (1966), *ibid.* *8*, 81 (1968), observed the bonding of protein subunits to RNA on UV irradiation of tobacco mosaic virus.

[132] a) *J. E. Donellan jr.* and *R. B. Setlow*, Science (Washington) *149*, 308 (1965); b) *K. C. Smith* and *H. Yoshikawa*, Photochem. and Photobiol. *5*, 777 (1966); c) *R. S. Stafford* and *J. E Donnellan jr.*, Proc. nat. Acad. Sci. USA *59*, 822 (1968), see also *J. W. Longworth*, *ibid.* *59*, 829 (1968); d) *R. O. Rahn* and *J. L. Hosszu*, Photochem. and Photobiol. *8*, 53 (1968); *7*, 637 (1968); e) *R. B. Setlow*, *ibid.* *7*, 643 (1968).

[133] It has been found, for example, that dimerization accounts for 90% of the UV damage with low doses, but only about 50% with high doses.

[134] See *E. M. Witkin*, Radiat. Res. Suppl. *6*, 30 (1966).

[135] The polymerization of nucleotides by ionizing radiation to form polynucleotides has been observed by various authors, *e.g.*, *S. Fischer* and *A. Ohlbaum*, Inter-Amer. Symp. Peaceful Appl. Nucl. Energy *5*, 19 (1965); Chem. Abstr. *63*, 11967 (1965); *A. Aguilera*, *E. Colombara*, *R. Jiménez*, and *J. Toha*, Biochim. biophysica Acta *95*, 569 (1965); *A. Aguilera*, *Z. Gampel*, *M. Pieber*, and *J. Tohá*, Photochem. and Photobiol. *7*, 711 (1968).

described in Section 3, the results of unpublished experiments[80], and knowledge of the results of UV irradiation suggest the following possibilities[136]:

i) A "direct hit" by the radiation can lead to irreparable breakdown of the nucleic acid molecule.

ii) The breakdown of one strand of the DNA double strand can in certain circumstances (depending on the nature of the break) be repaired by a mechanism corresponding to enzymatic reactivation.

iii) The addition of water (*via* H and HO radicals) to the cytosine portion of the DNA leads to a change in the base pairing during the reduplication of the DNA; this could lead *inter alia* to the mutations resulting from ionizing radiation.

iv) The biological importance of other products [peroxides, dihydrothymine, dihydrouracil, thymine glycols, *etc.* (see Schemes 3 and 4)] formed on irradiation is largely unknown. It is necessary to consider both blockage of the reduplication of the DNA at the modified base and the modification of the genetic code[137]. It is not known whether and how the cell is able to recognize and eliminate bases that have been "modified" in this way.

I am grateful to Dr. G. Dörhöfer, Dr. G. Fürst, Dr. H. Gattner, Dr. R. Kleber, B. Lösche, R. Pastille, H. Popp, P. Richter, Dr. W. Rohlfing, G. Roos, Dr. B. Sojka, H. Wieser, Frau B. Leitermeier, and Fräulein E. Boebinger for their collaboration in our investigations.

We are indebted to Professor M. Scheer, Physikalisches Institut der Universität Würzburg, who made it possible for us to carry out the irradiations with ionizing radiation. We also thank Dr. T. Nowak and Dr. W. Järisch for carrying out the irradiations and Dozent Dr. D. Harder and Dr. A. Przybylski for their advice. Special thanks are due to Professor G. Hartmann, Institut für Biochemie der Universität Würzburg, for his advice and suggestions. We are grateful to the Deutsche Forschungsgemeinschaft and to the Verband der Chemischen Industrie (Fonds der Chemischen Industrie) for their generous support of these investigations.

10,10-Bis(dimethylamino)nonafulvene[**]

By *K. Hafner* and *H. Tappe*[*]

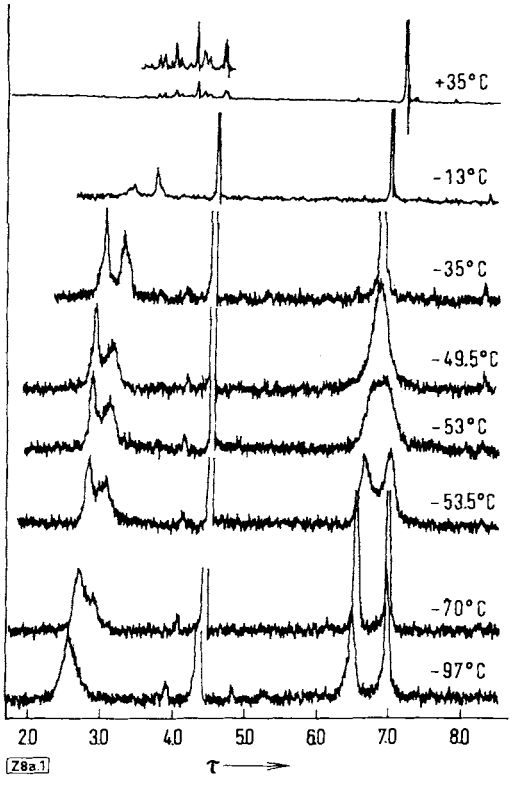
Dedicated to Professor Cl. Schöpf on the occasion of his 70th birthday

Li-, K- and $[(CH_3)_4N]$ cyclononatetraenides *(1)*[1] are the only monocyclic derivatives of the hypothetical cyclononatetraene that have been isolated so far[2]. Nonafulvenes, being cross-conjugated 10 π electron systems and homologs of the fulvenes, are of particular interest. Like the fulvene and isobenzofulvene systems[3], nonafulvenes should also be stabilized by electron-donating substituents on the exocyclic C-atom. The successful synthesis of 10,10-bis(dimethylamino)-nonafulvene *(4)* confirms this presumption.

Compound *(1)*, M = Li, reacts with *N,N,N',N'*-tetramethylchloroformamidinium chloride *(2)*[4] at −70 °C in tetrahydrofuran to give the so far non-isolable cyclononatetraene derivative *(3)*, which, in the presence of an excess of *(1)*, is rapidly converted into the nonafulvene *(4)* as yellow crystals that are sensitive to light and air [yield 7%; m.p. 109–110 °C (from ethanol)][5]. In addition, 3a,7a-dihydroindene[6] is formed as a result of protonation of *(1)* and subsequent valence isomerization of the cyclononatetraene thus formed. Elemental analysis and molecular weight determination confirm the constitution of *(4)*; its configuration, however, has not yet been elucidated[7]. During quantitative microhydrogenation, compound *(4)* takes up H_2 in amounts calculated for five double bonds. The mass spectrum of *(4)* shows several, but uncharacteristic, fragmentation peaks in addition to the molecular peak *m/e* = 216.

UV and NMR spectra of *(4)* indicate the presence of a temperature- and solvent-dependent conformational equilibrium. In *n*-hexane at room temperature, compound *(4)* absorbs at 330 nm (log ε = 4.34), whereas in methylene chloride it absorbs at 403 (3.90), 340 (4.05), 298 (4.05), and 244 (4.28) nm (log ε), and in tetrahydrofuran at 334 (4.19) and at 240 (4.15) nm (log ε). Although the UV spectrum of *(4)* in *n*-hexane remains unchanged at low temperatures, in methylene chloride the extinction of the bands at 403, 296, and 244 increases whereas the absorption maximum of the band at 340 decreases; at −80 °C that at 340 disappears. [λ_{max} at 0 °C: 403 (3.9), 340 (4.0), 296 (4.1), 244 (4.3); at −35 °C: 403 (3.9), 296 (4.2), 244 (4.4); at −80 °C[7a]: 403 (4.1), 294 (4.4), 244 (4.7) nm (log ε)]. In tetrahydrofuran at temperatures below 0 °C, two additional maxima appear at 404 and 296 nm whose intensities increase on lowering the temperature [λ_{max} at −35 °C[7a]: 404 (3.8), 335 (4.1), 296 (4.1), 244 (4.4); at −80 °C: 404 (4.1), 335 (4.0), 296 (4.3), 244 (4.6) nm (log ε)].

The NMR spectrum of *(4)* (in CD_2Cl_2) (Fig. 1) at 35 °C shows a sharp singlet at τ = 7.22 for the twelve methyl



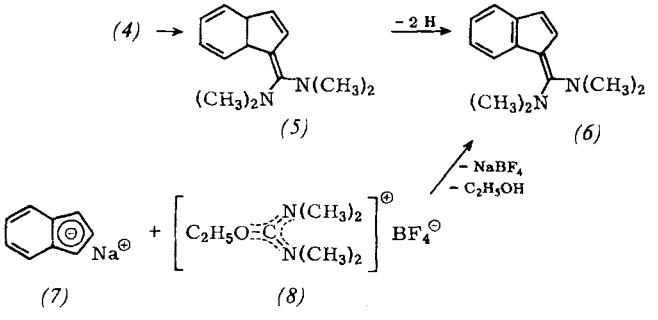


Fig. 1. NMR spectra of 10,10-bis(dimethylamino)nonafulvene *(4)* at various temperatures in CD_2Cl_2 (60MHz; tetramethylsilane as internal standard).

protons, in addition to a complicated multiplet between τ = 3.63 and 4.67 for the eight ring protons. At lower temperatures the multiplet of the ring protons is shifted to lower field with diminution of the fine structure, while the singlet of the methyl protons is split into a doublet (coalescence point: *ca.* −53 °C). This may be ascribed to either restricted rotation of the C—N bonds or formation of an unsymmetrical conformation of the nine-membered ring relative to the dimethylamino groups at low temperatures[8]. The temperature-dependent changes in the NMR and UV spectra of *(4)* are reversible.

As a derivative of the hypothetical cyclononatetraene, compound *(4)* undergoes an irreversible thermal valence isomerization in benzene, slowly at room temperature but rapidly at 60 °C, to give the 3a,7a-dihydroindene derivative *(5)* [yield 50%; yellow oil, sensitive to oxygen; b.p. 80 °C/0.003 torr; UV spectrum (in *n*-hexane): 302 (4.17), 270 (4.12), 260 (4.06) nm (log ε); NMR spectrum (in $CDCl_3$); doublet centered at τ = 7.34 ($4CH_3$), multiplets centered at τ = 6.17 (H-3a, H-7a), at 4.55 (H-2, H-3, H-4, H-5, H-6), and at 3.65 (H-7)]. The NMR spectrum of *(5)* does not provide sufficient data for a differentiation between the *cis* and *trans* isomer. Oxidation of *(5)* with active lead dioxide[9] leads to the formation of 6,6-bis(dimethylamino)benzo[*b*]fulvene[1-(tetramethyldiaminomethylene)indene] *(6)*, which can also be prepared from sodium indenide *(7)* and bis(dimethylamino)ethoxycarbonium fluoroborate *(8)*[10] [yellow crystals, sensitive to light, m.p. 55 °C; UV spectrum (in *n*-hexane): 375 (4.36), 279 (4.08), 255 (3.96) nm (log ε); NMR spectrum (in $CDCl_3$): singlet at τ = 6.99 ($4CH_3$), AB system at τ = 3.32 and 3.42 (2H) (J_{AB} = 5 Hz), multiplet centered at τ = 2.75 (4 benzenoid H)].

cis,cis,cis,cis-1,3,5,7-Cyclononatetraene

By *G. Boche*, *H. Böhme*, and *D. Martens*[*]

Cyclononatetraenes possibly occur as intermediates in the thermal and in the photochemical valence isomerization of *cis*-bicyclo[6.1.0]nona-2,4,6-triene or various 9- and 9,9'-substituted *cis*-bicyclo[6.1.0]nona-2,4,6-trienes into *cis*- and *trans*-bicyclo[4.3.0]nona-2,4,7-trienes (*cis*- and *trans*-dihydroindenes)[1]. Furthermore, *cis,cis,cis,cis*-1,3,5,7-cyclononatetraene[1g] *(2)* and 9-methyl-*cis,cis,cis,cis*-1,3,5,7-cyclononatetraene[1k] are assumed to occur as non-isolable primary products in the protonation and methylation of the cyclononatetraenyl anion *(1)*. *King* and *Stone*[2] have reported that the tricarbonylmetal complexes obtained in small yield by reaction of dihydroindene with $Cr(CO)_6$, $Mo(CO)_6$, and $W(CO)_6$ probably contain *cis,trans,cis,trans*-1,3,5,7-cyclononatetraene as olefinic ligand.

We have found that the light-yellow *cis,cis,cis,cis*-1,3,5,7-cyclononatetraene *(2)* is formed in good yield when the potassium salt *(1)* is protonated with 0.1 N acetic acid at 0 °C.

Compound *(2)* always contains about 2—4% *cis*-dihydroindene *(3)*, which presumably is formed during the working up and distillation at 0 °C. The method of preparation and the catalytic hydrogenation at 0 °C that leads to formation of cyclononane, as well as the practically quantitative valence isomerization to *(3)* [3], afford chemical proof of the structure of *(2)*. The half-life of the first-order rearrangement *(2)*→*(3)* is 16 min at 35 °C; the activation parameters, determined at temperatures between 18 °C and 35 °C, have the following values: $\Delta H^{\neq} = 19.8 \pm 1$ kcal/mole, $\Delta S^{\neq} = -10.4$ e.u. On the basis of orbital symmetry considerations [4,5], simple disrotatory ring closure of the type $6\pi \rightarrow 4\pi + 2\sigma$ to *(3)* is to be expected in the case of the strained compound *(2)*. Moreover, *(2)* regenerates *(1)* on treatment with potassium *tert*-butoxide in tetrahydrofuran at temperatures below 0 °C.

Spectroscopic findings confirm the structure of *(2)*. The NMR spectrum of *(2)* (in CCl_4) contains the expected absorption bands of the eight olefinic protons (multiplet with intense signal at $\tau = 4.28$) and of the two CH_2 protons (broadened triplet at $\tau = 6.95$, apparent coupling constant $J = 5.5$ Hz). The low-intensity, broadened absorption band of the C=C stetching vibration occurs in the IR spectrum (in CCl_4) at 1632 cm^{-1}; the out-of-plane deformation vibrations of the *cis* double bonds give rise to a band at 700 cm^{-1}. Essentially no absorption takes place in the region of the C—H deformation vibrations of the *trans* double bond. The UV spectrum of *(2)* (in ether) is unusual for a tetraene having four alternating double bonds but is, however, similar to that of cyclooctatetraene [6,7]: up to 2100 Å it shows only increase of the extinction towards shorter wave lengths with a shoulder at 2450 Å ($\varepsilon_0 = 2600$). An absorption maximum does not occur. The spectrum is consistent with *(2)* having a relatively rigid boat configuration in which the neighboring double bonds are not conjugated.

Reaction of *(2)* with silver nitrate in water leads to the formation of a 1:2 complex, m.p. 86—88 °C. That *(2)* occurs in the complex as a ligand was confirmed by displacement of the cycloolefin by aqueous ammonia at 0 °C; pure *(2)* is recovered. The NMR spectrum of the complex (recorded in D_2O at 0 °C) also proves the presence of *(2)* as ligand. In contrast to the spectrum of free *(2)* it shows the shifted signals of the eight olefin protons (multiplet, centered at $\tau = 3.6$) and the two methylene protons (multiplet centered at $\tau = 6.64$).

The thermal rearrangement of *cis*-bicyclo[6.1.0]nona-2,4,6-triene affords *cis*- and *trans*-dihydroindene in the ratio 9:1 [1a,1c,1h]. Synchronous ring opening and ring closure should convert the highly strained *cis,cis,cis,trans*-1,3,5,7-cyclononatetraene into *trans*-dihydroindene [4,5]. The questions (i) whether *(2)* also occurs as intermediate and rapidly isomerizes to *(3)* and (ii) how *(2)* is actually formed have yet to be answered.

Crystal Structure of Uridine 2′,3′-*O*,*O*-Cyclophosphorothioate

By *W. Saenger* and *F. Eckstein* [*]

We have recently accomplished the synthesis of uridine 2′,3′-*O*,*O*-cyclophosphorothioate [1] and successfully isolated one of the two diastereomers by crystallization [2]. This isomer *(1)* is a substrate for pancreatic ribonuclease with the same K_m value as uridine 2′,3′-cyclophosphate [2]. In the presence of methanol, the enzyme converts the substrate into uridine 3′-*O*-(*O*-methyl)phosphorothioate, which we have also been able to obtain in crystalline form. Knowledge of the absolute configurations of these two compounds would deepen our understanding of the course of enzymatic methanolysis and hydrolysis.

The triethylammonium salt of *(1)* crystallizes from ethanol in the form of prisms in the orthorhombic space group $P2_12_12_1$, the unit cell having the dimensions $a = 12.495$, $b = 7.079$, $c = 22.574$ Å. About 1200 reflection intensities were measured on a four-circle diffractometer and the data were corrected for geometric factors but not for absorption. The

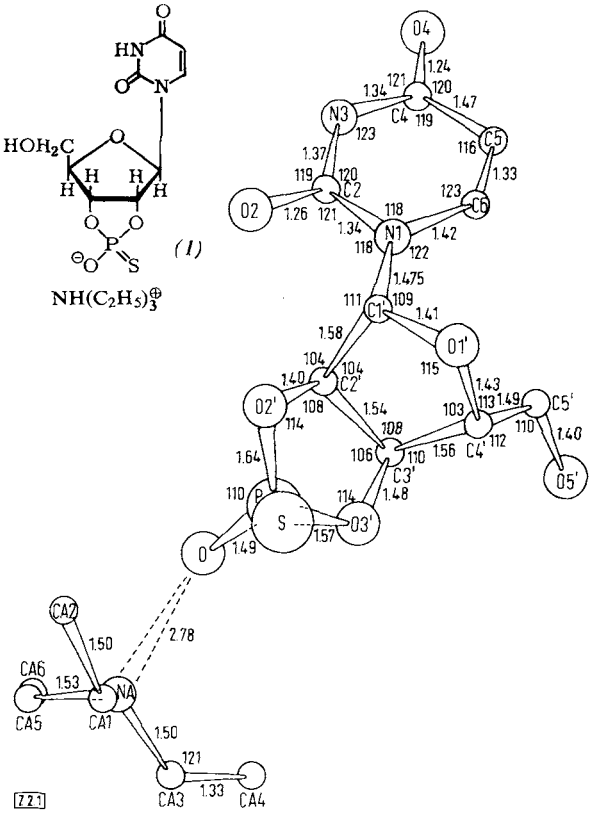

Fig. 1. Crystal structure of triethylammonium uridine 2′,3′-*O*,*O*-cyclophosphorothioate *(1)*. Projection on 001. Standard deviations for bond lengths and angles are ±0.01 Å and ±0.7 ° for bonds involving phosphorus, otherwise ±0.02 Å and ±1.0 °. The bond lengths (Å) and angles (°) not given in the Figure are:

P—S	= 1.96	CA3—NA—CA1	= 105
NA—CA1	= 1.53	CA3—NA—CA5	= 111
CA5—CA6	= 1.37	NA—CA1—CA2	= 109
O2′—P—S	= 112	CA1—NA—CA5	= 106
O2′—P—O3′	= 96	NA—CA5—CA6	= 115
O3′—P—S	= 110	C2′—C1′—O1′	= 106
O3′—P—O	= 109		
S—P—O	= 117		

structure of the molecule was determined by the "heavy-atom" method. Two cycles of isotropic and three cycles of anisotropic full-matrix refinement by the method of least squares led to an R factor of 0.094 for the 986 strongest reflections. A projection of the molecule on the 001 plane is shown in Fig. 1.

The heterocyclic ring has a not uncommon geometry. The structural data found agree well with those obtained for 1-methyluracil[3] and uridine 5'-phosphate[4]. The ring atoms and all the substituents except C-1' lie in a planar arrangement, the maximum deviation from the "best" plane being 0.08 Å.

A considerable puckering of the ribose unit has been found in all the nucleosides investigated previously, one atom jutting out of the plane described by the other four atoms by about 0.6 Å[5,6]. In the case of *(1)*, however, C-3' is displaced from the "best plane" through C-4', O-1', C-1', and C-2' by only 0.15 Å; thus the ribose ring is almost planar and the substituents on C-1', C-2', C-3', and O-4' are staggered. Compared to nucleosides without 2',3'-cyclization[6], the bond lengths C-1'–C-2', C-2'–C-3', and C-3'–C-4' in *(1)*, but not C-4'–O-1' and O-1'–C-1', are therefore lengthened by about 0.06, 0.01, and 0.04 Å, respectively, whereas the bond angles in the ribose part of the molecule are changed only slightly. The bond length O-1'–C-1' is somewhat shorter than C-4'–O-1', as has always been found previously.

The bond lengths and angles found in the cyclophosphorothioate ring are similar to those found in methyl ethylene 1,2-cyclophosphate[7]. The configurations of the two molecules also show a close resemblance: the four atoms O-3', C-3', C-2', and O-2' are in a planar arrangement and the phosphorus atom is situated 0.23 Å from the plane on the same side as the oxygen atom O which is oriented away from the ribose, whereas the sulfur atom is found under the ribose in the *endo* position.

The P–S bond has predominantly double-bond character[8]; the P–O bond length is characteristic for $P-O^{\ominus}$[9]. This charge distribution is also indicated by the facts that the cation is unequivocally positioned opposite the oxygen atom O and that the O–N distance of 2.78 Å corresponds to a hydrogen bond.

The position of the heterocycle relative to the ribose corresponds to the *anti*-conformation. The angle of twist about the glycosidic bond, φ_{CN}, which was defined[10] as the dihedral angle C-6–N-1–C-1'–C-2', is 128.8 °.

The triethylammonium ion possesses almost trigonal symmetry. The interatomic distances C-A5–C-A6 and C-A3–C-A4 (and likewise C-5'–O-5' in the ribose group) are shortened[11] because the atoms C-A6, C-A4, and O-5' undergo considerable thermal vibrations.

New Syntheses of Quinoxaline and Phenazine Di-*N*-oxides

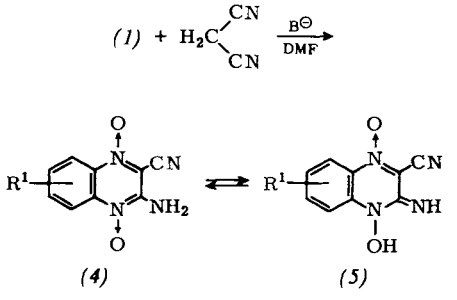
By *K. Ley*, *F. Seng*, *U. Eholzer*, *R. Nast*, and *R. Schubart*[*]

The benzofuroxanes *(1)*[1], which are readily accessible by dehydrogenation of *o*-nitroanilines with sodium hypochlorite, react with ketimines or aldimines or with ketones or aldehydes and primary amines or ammonia[2] to give quinoxaline di-*N*-oxides *(3)*. The reaction is of a general nature and is widely modifiable with respect to the carbonyl component.

(1) *(2)* *(3)*

R^1 = H, alkyl, CH_3O, C_2H_5O, halogen, COOR

R^2 = CH_3, H

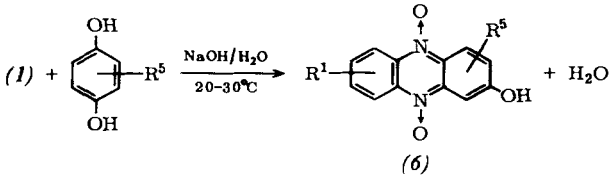


R^3 = *e.g.* alkyl, aryl; CH_3CO, XO–CO, X–NH–CO, X_2N–CO, XO–CO–CH_2, X–NH–CO–CH_2, X_2N–CO–CH_2, XC(=NOH);

R^2 and R^3 can also be coupled cyclically;

X = alkyl or aryl

Reaction of oxaloacetate [*(2)*, R^2 = R^3 = $COOC_2H_5$] and *(1)* (NH_3/CH_3OH, 20–40 °C) leads to the formation of *(3)* in which R^2 = R^3 = $CONH_2$. On reaction with potassium hydroxide, methylisoxazole is converted into the potassium salt of 1-cyanoacetone, which affords compound *(3)*, R^2 = CN, R^3 = CH_3, when reacted with *(1)* in the presence of NH_3/NH_4Cl[3]. Reaction of *(1)* and chloroacetaldehyde with primary amines leads to the formation of monoalkyl aminoquinoxaline di-*N*-oxides *(3)*, R^2 = H, R^3 = NH-alkyl or NH-cycloalkyl[4].

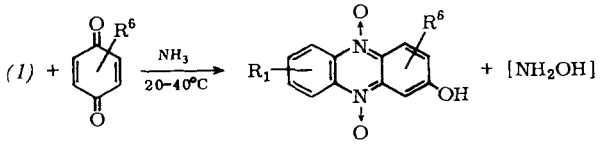


A further variant of the method is the reaction of *(1)* with ynamines $C_2H_5(R^4)N-C\equiv C-C_2H_5$ (THF, 10–30 °C) to give *(3)*, R^2 = C_2H_5, R^3 = $N(R^4)C_2H_5$ with R^4 = CH_3 or C_6H_5.

(4) *(5)*

(1) adds on malonodinitrile in the presence of amines or ammonia to give 2-amino-3-cyanoquinoxaline di-*N*-oxides[5].

The deep-red compounds *(4)* occur in tautomeric equilibrium with *(5)*.



(6)

R^5 = H, alkyl, aryl, halogen, C_6H_5–SO_2, NO_2, –COOH, –SO_2-alkyl, CH_2–CO–NR_2

In aqueous alkaline suspension at temperatures between 20—30 °C, the benzofuroxanes *(1)* undergo a coupling reaction with hydroquinones, naphthohydroquinones, β-naphthols, and with α-naphthols (or phenols, 60 °C) with simultaneous cyclization to give good, in some cases quantitative, yields of phenazine *(6)* or benzophenazine di-*N*-oxides[6,9].

Compounds *(6)* can also be obtained by reaction of *(1)* with benzoquinone or 1,4-naphthoquinone in alcohol or carbon tetrachloride in the presence of ammonia at 20—40 °C[7] (yield 90%).

(7)

R^6 = H, aryl, substituted aryl, halogen, C_6H_5—SO_2

2,3-Dimethylquinoxaline di-N-oxide (3), $R^1 = H$, $R^2 = R^3 = CH_3$

Benzofuroxane (204 g, 1.5 moles) and methyl ethyl ketone (118 g, 1.64 moles) are dissolved in methanol (700 ml) and ammonia is fed into the resulting solution for 8 hours. During reaction the mixture is kept at a temperature of 50 to 55 °C by some suitable form of cooling; finally, the reaction mixture is cooled to 5 °C and the precipitate is separated off by suction. 260 g (91%) 2,3-dimethylquinoxaline di-*N*-oxide is obtained in the form of yellow crystals, which, after recrystallization from ethanol, melt with decomposition at 189 °C.

2-Hydroxyphenazine di-N-oxide (6), $R^1 = R^5 = H$

Hydroquinone (110 g, 1 mole) and sodium hydroxide (2 g, 0.05 mole) are added to a suspension of benzofuroxane (136 g, 1 mole) in water (2 l) and the whole is stirred for 10 hours at room temperature. The mixture is then acidified and filtered with suction. 222 g (97%) 2-hydroxyphenazine di-*N*-oxide is obtained as red crystals which, after recrystallization from dimethylformamide, melt with decomposition at 255 to 260 °C[8]. If stoichiometric amounts of sodium hydroxide are used an exothermic reaction takes place within a few minutes resulting in the formation of the intense blue-violet salt solution of 2-hydroxyphenazine di-*N*-oxide, from which the free compound can be obtained by acidification.

2-Amino-3-cyanoquinoxaline di-N-oxide (4), $R^1 = H$

Triethylamine (50 g, 0.5 mole) is added over a period of 30 minutes to a mixture of benzofuroxane (326 g, 2.4 moles) and malonodinitrile (132 g, 2 moles) in dimethylformamide (750 ml). During the ensuing strongly exothermic reaction, the mixture is kept at a temperature between 20 and 30 °C by some suitable form of cooling. When reaction dies down the mixture is stirred for a further 90 minutes, cooled with ice, and filtered by suction. After washing with methanol, 335 g (83%) of analytically pure 2-amino-3-cyanoquinoxaline di-*N*-oxide (decomp. 232 °C) is obtained.

The Structure of Perchloro-[4]radialene

By *F. P. van Remoortere* and *F. P. Boer*[*]

The synthesis of perchloro-[4]radialene by thermal dimerization of perchlorobutatriene has recently been reported by *Heinrich* and *Roedig*[1]. Radialenes are of considerable spectroscopic and theoretical interest: their ultraviolet spectra show unusual low energy transitions which, for radialenes with an even number (*n*) of carbons in the central ring, have been attributed to reduction of molecular symmetry from planar D_{nh} to $D_{\frac{n}{2}d}$ *via* either permanent deformation or strong bending modes[2]. We present below direct confirmation of the structure of perchloro-[4]radialene by a single crystal X-ray diffraction study.

The compound crystallizes[3] in space group Pbcn with lattice parameters $a = 14.719 \pm 0.007$, $b = 9.156 \pm 0.003$, and $c = 9.923 \pm 0.005$ Å and four molecules per unit cell. The intensities of 1528 independent reflections were measured on a Picker automatic diffractometer by the $\theta/2\theta$ scan technique using MoK_α radiation. The structure was solved by reiterative application of *Sayre*'s equation[4] and refined by full-matrix least-squares to an *R*-factor of 4.2% for the 1034 reflections above background.

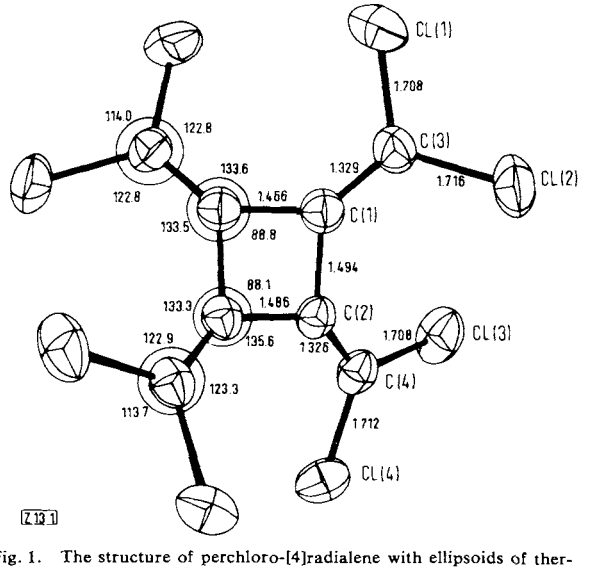

Fig. 1. The structure of perchloro-[4]radialene with ellipsoids of thermal motion, bond lengths, and bond angles. The calculated standard deviations are all less than 0.007 Å for the distances and less than 0.3° for the angles.

The molecule is found to be highly nonplanar and to conform very closely to molecular D_{2d} symmetry, although only a single twofold axis is required by the space group. This result is consistent with the theoretical interpretation of the UV spectrum proposed by *Heilbronner*[2]. Deformation of the molecule from a planar geometry is achieved largely by bending the four-membered ring to a dihedral angle of 153.5 ± 0.6°, a value characteristic of puckered cyclobut-

anes[5]. As a result the intramolecular Cl...Cl contacts are increased to values ranging from 3.308 to 3.338 Å, and the planes of the four chlorines above, and the four chlorines below the central ring are separated by 2.454 Å.

The bond distances give no evidence for conjugation. The distances in the ring are normal for single bonds between sp^2 hybridized carbons, and the C=C and C–Cl bonds compare closely to their respective values (1.324 and 1.710 Å) in 1,1-dichloroethylene[6].

The Bis(chlorosulfur)nitrogen Cation in $[NS_2Cl_2]^+[BCl_4]^-$

By *O. Glemser, B. Krebs, J. Wegener*, and *E. Kindler*[*]

If boron trifluoride (p = 450 torr) is allowed to react with sulfur nitride trifluoride (p = 300 torr) for a few days in a 2-l glass flask, 3–4 g of a yellow crystalline substance is formed which has the composition BNS_2Cl_6 and which proved to be the ionic compound $[NS_2Cl_2]^+[BCl_4]^-$.

$$2\,NSF_3 + 3\,BCl_3 \rightarrow [NS_2Cl_2]^+[BCl_4]^- + {}^1/_2\,N_2 + {}^3/_2\,Cl_2 + 2\,BF_3$$

The gaseous products of this reaction are N_2, Cl_2, BF_3, and BF_2Cl. The new compound is also formed in the reaction of trithiazyl chloride, $N_3S_3Cl_3$, with Cl_2 and BCl_3 or SCl_2 and BCl_3.

Bis(chlorosulfur)nitrogen tetrachloroborate, $[NS_2Cl_3]^+[BCl_4]^-$ *(1)* is very hygroscopic and rapidly decomposes with incomplete evolution of BCl_3; the stoichiometric amounts of N_2, S_2Cl_2, SCl_2, and BCl_3 corresponding to the empirical formula are liberated on heating in a bomb tube at 80 °C. d_4^{20} = 1.98 g/cm³. Mass spectrum (rel. intensities): SN^+ (100), SCl^+ (79), BCl_2^+ (33), $NSCl^+$ (33), Cl^+ (33), S^+ (25), SCl_2^+(10), BCl_3^+ (3). Infrared spectrum (cm^{-1}): 1380 (s), 1340 (s), 1325 (s), 1265 (m), 705 (w), 525 (s), 423 (s), 408 (s). Raman spectrum (cm^{-1}): 720 (s), 706 (w), 652 (w), 516 (s), 499 (m), 452 (s), 408 (m), 200 (s), 132 (s), 83 (s), 38 (m), 21 (m). The molecular weight was determined cryoscopically in benzene as 156.6 (calc. 301.7), thus indicating dissociation of the compound into two parts.

Compound *(1)* crystallizes monoclinically in the space group C_{2h}^5 $P2_1/C$ with a = 6.441 ± 0.005, b = 16.008 ± 0.010, c = 9.864 ± 0.007 Å, β = 103.30 ± 0.05 °. Z = 4; $d_{X\text{-}xay}$ = 2.024 gm/cm³. The composition and structure of the compound was determined by X-ray structural analysis. The structure could be determined directly by iterative use of the Sayre equation. For this purpose about 1800 independent reflections were determined on a single crystal diffractometer ($Mo_{K\alpha}$ radiation, scintillation counter). After refinement by the method of least squares, a discrepancy factor R = 5.9% was obtained. The structures and structural parameters of the cation and anion are as shown in Figures 1a and 1b. Two doubly degenerate resonance structures are possible for the $[NS_2Cl_2]^+$ ion.

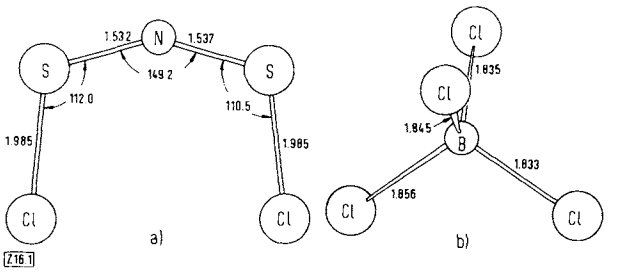

Fig. 1. Bond lengths (Å) and bond angles (°) (a) in the $[NS_2Cl_2]^+$ ion and (b) in the $[BCl_4]^-$ ion.

The experimentally determined dimensions are in good agreement with such a type of bonding: a previously derived empirical relation[1] gave a bond order of about 1.7–1.8 for the observed N–S bond length; the S–Cl bond length corresponds to that of an ideal single bond. The $[NS_2Cl_2]^+$ ion is, within the limits of error, planar and has *cis* configuration with approximate C_{2v} symmetry. On the basis of the electron pair repulsion model, the bond angles are plausible if one assumes an approximately equal participation of the resonance structures *(2)* and *(3)*. The structure of the remarkably stable tetrahedral $[BCl_4]^-$ ion in compound *(1)* has not as yet been investigated; in this compound there is virtually no distortion of the tetrahedron, the bond angles varying between 109.0 and 109.9 °.

Dithieno[3,4-*b*,3′,4′-*e*]-[1,4]-dithiine

By *M. J. Janssen* and *J. Bos*[*]

Woronkow and *Pereferkowitsch*[1] have recently reported on the preparation of dithieno[2,3-*b*,3′,2′-*e*]-[1,4]-dithiine. We have now prepared the isomeric compound dithieno[3,4-*b*,3′,-4′-*e*]-[1,4]-dithiine *(1)*[2] by heating 3-bromo-4-thiophenethiol (15.6 g, 0.08 mole)[3] with 4.5 g KOH (0.08 mole) and 5.7 g Cu_2O (0.04 mole) in 300 ml dimethylformamide for 20 h at 130 °C (yield 3.7 g = 40%, after recrystallization from cyclohexane m.p. 145–146 °C). NMR: δ = 7.40 ppm (s); UV: λ_{max} (ethanol) = 270 nm (ε = 9100).

(1)

(2)

Oxidation of *(1)* with one equivalent of hydrogen peroxide in methylene chloride/acetic acid (2:1) (6 days at room temperature) affords the 4-monoxide (yield 66%, after recrystallization from $CHCl_3/CCl_4$ m.p. 183.5–184 °C). The NMR spectrum shows two doublets at δ = 8.04 and 7.36 ppm (J = 3 Hz). This spectrum is consistent with the given structure only, since the coupling constant of 3 Hz is characteristic of 2,5-hydrogen atoms in thiophene[4]. UV: λ_{max} (ethanol) = 244 nm (ε = 15400). The 4,8-dioxide *(2)* is formed when *(1)* is boiled under reflux for 24 h with two equivalents (or the 4-oxide with one equivalent) of H_2O_2 in acetic acid/methylene chloride. The yield of *(2)*, after recrystallization from acetic acid, amounts to 40% [from *(1)*]; m.p. 230 °C, λ_{max} (ethanol) = 250 nm (shoulder) (ε = *ca.* 8600).

The NMR-spectrum of *(2)* (in [D_6]-DMSO) shows two sharp signals of unequal height at $\delta = 8.50$ and 8.60 ppm. At 120 °C the signals broaden, at 180 °C there is only one sharp absorption ($\delta = 8.55$). Compound *(2)* obviously gives rise to two isomers in which the SO groups are either *cis* or *trans*[5] and which are interconverted rapidly at higher temperatures. The original signals are observed in the same intensity ratio when the solution is cooled. Prolonged heating at 200 °C does not alter the ratio of the components.

2,2'-Bipyridine Adducts of Disilanes

By *D. Kummer*, *H. Köster*, and *M. Speck*[*]

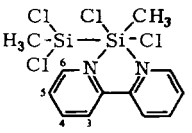
During studies of the chemistry of polysilanes we succeeded in the first synthesis of amine complexes of disilanes, namely, tetrachlorodimethyldisilane-bipyridine *(1)* and hexachlorodisilane-bipyridine *(2)*. Previous attempts to isolate such substances failed because of base-catalyzed rearrangement of the disilanes[1,2]. Compounds *(1)* and *(2)* provide examples of a class of compound that is important for, *inter alia*, the study of the nature of donor-acceptor complexes and of the rearrangements of di- and poly-silanes.

The 1:1 bipyridine (= bipy) addition compound of *(1)* is formed smoothly from the components in apolar organic solvents at room temperature, separating as a lemon-yellow crystalline powder.

$$Cl_2CH_3SiSiCH_3Cl_2 + x\ \text{bipy} \xrightarrow{\text{Pentane}} Cl_2CH_3SiSiCH_3Cl_2 \cdot \text{bipy} + (x-1)\ \text{bipy}$$

(1)

Analysis and ^{1}H-NMR spectra confirm the 1:1 composition; it was not possible to obtain an addition compound containing more bipyridine (*e.g.*, 1:2) even when using a large excess of bipy.



The complex *(1)* dissolves easily in benzene and tetrahydrofuran with a pale yellow color, but according to the cryoscopically determined molecular weight (found, 177 in benzene) and the NMR spectra it is widely dissociated therein into the starting materials (see Table). The UV spectrum of the colorless THF solution (10^{-3} mole/l) shows only the two unchanged bands of bipy (235, 281 nm); in the solid state spectrum (Nujol suspension) there appears also a broad, weaker absorption band without a definite maximum, stretching to 600 nm. The yellow color is ascribed to charge-transfer transitions. Measurements of conductivity of *(1)* in acetonitrile at 25 °C show no change from that of the pure solvent.

Compound *(1)* sublimes in a vacuum at 40–50 °C, being thereby completely dissociated also in the vapor state, according to the mass spectrum. The dissociation equilibrium in solution:

$$(Cl_2CH_3Si)_2 + \text{bipy} \rightleftarrows (Cl_2CH_3Si)_2 \cdot \text{bipy}$$

can be shifted at lower temperatures largely towards the complex. In THF solution the simple $SiCH_3$ proton resonance signal splits at −85 °C into two lines of equal intensity, and the signals for bipy correspond to bipy bound as complex [cf. $(C_2H_5)_2Ni \cdot$ bipy[3]].

These results accord with the proposed structure *(1a)*, in agreement with binding of the bipy to only one Si atom of a molecular adduct (non-equivalence of the two Si-methyl groups!).

(1a)

No further indication can yet be given about the arrangement of the bipy in this structure (*cis-cis* or *cis-trans* to the neighboring Si atom). A single-crystal X-ray structure determination is in progress[4]. Although the solid compound remains unchanged for months at room temperature, solutions of *(1)* in THF or dioxane are not stable at 25 °C; they change within a few weeks to deep reddish-brown solutions from which a new bipyridine-silicon complex can be isolated; this is amorphous (X-rays) and, according to ^{1}H-NMR studies, is of stoichiometric composition. This intermediate also decomposes above 150 °C giving CH_3SiCl_3 and unidentified higher methylchlorosilicon compounds. Chlorosilane catalyzes the solution reaction.

Like $(Cl_2CH_3Si)_2$, Si_2Cl_6 reacts with bipy in pentane giving exclusively the yellowish-white 1:1 adduct *(2)*, whose existence is secured by analyses, X-ray powder diagrams (individual diagram, no bipy, $SiCl_4 \cdot$ bipy, bipy · HCl), and thermal sensitivity (formation of a dark green color above 80 °C). In tetrahydrofuran another reaction takes place at 25 °C, formation of a dark green color and decomposition occurring within a few minutes; but the solid complex *(2)* is completely stable at 25 °C.

^{1}H-NMR data (ν in Hz at 60MHz; TMS = 0 Hz) of *(1)* and its components (*ca.* 10% in THF).

	T(°C)	$SiCH_3$	bipy-H^3	-H^4	-H^5	-H^6
$(Cl_2CH_3Si)_2$	32	61.0	—	—	—	—

(1)	−85	50.5; 47.5	552.5	531.3	499.6	619.2

Tetrachlorodimethylsilane-2,2'-bipyridine (1)

$(Cl_2CH_3Si)_2$ (3.19 g, 15.0 mmoles) is condensed under reduced pressure onto bipy (2.87 g, 18.4 mmoles) in pure pentane. The mixture is allowed to warm slowly to room temperature with stirring. A yellow precipitate is formed which two hours later is filtered off in absence of air and washed several times with dry pentane. Recrystallization from acetonitrile affords *(1)* as large, yellow, transparent crystals, m.p. 102 °C (decomp.) (3.7 g, 70%). If there is even a slight excess of the chlorosilane component, the precipitate, which is yellow at first, becomes dark green within an hour, giving, *inter alia*, CH_3SiCl_3.

Hexachlorodisilane-2,2'-bipyridine (2)

The preparation is analogous to that above, with condensation of less than an equivalent amount of $(Cl_3Si)_2$ onto a bipy solution in pentane. The yield is almost quantitative. It was not possible to find a solvent for the complex. Decomp. pt. 108 °C (green color).

Application of the Mössbauer Effect to Investigation of the Solid State Reaction of Iron(II) Sulfate with Potassium Cyanide[1]

By *P. Gütlich* and *K. M. Hasselbach* [*]

The Mössbauer effect[2] has been used to study the reaction of iron(II) sulfate with potassium cyanide in the solid state as a function of reaction time, temperature, and content of water of crystallization of the iron(II) sulfate.

The reactants were mixed in the molar ratio $FeSO_4 \cdot 7H_2O$: KCN = 1 : 6 (particle size of both components = 0.2—0.3 mm) and pressed to tablets. The course of the reaction was followed at 5 °C and at 20 °C [Mössbauer spectra measured at −96 °C (temperature of the absorber); radiation source: ^{57}Co in platinum (room temperature)].

Depending on the reaction time, the Mössbauer spectra contained up to five, partially overlapping resonance lines. The iron compounds assigned to the experimentally observed data are shown in the Table.

Complex	Chemical isomer shift δ (mm/s)	Quadrupole splitting ΔE_Q (mm/s)
$FeSO_4 \cdot 7H_2O$	+0.98 ± 0.02	3.41 ± 0.02
$K_4[Fe(CN)_6] \cdot 3H_2O$	−0.34 ± 0.02	0
$K_3[Fe(CN)_5H_2O]$	−0.21 ± 0.02	0.75 ± 0.03

The values of the chemical isomer shifts and quadrupole splittings agree very well with those reported in the literature[3].

During the reaction the water molecules in the coordination sphere of the magnetically normal ("high spin") complex $[Fe(H_2O)_6]^{2+}$ are replaced by cyanide ions. Under the experimental conditions used the sole intermediate visible in the Mössbauer spectrum is the magnetically abnormal ("low spin") complex $[Fe(CN)_5H_2O]^{3-}$, which is unstable and reacts with further cyanide ions to give the stable complex $[Fe(CN)_6]^{4-}$.

After suitable standardization of the Mössbauer spectra the three complexes $[Fe(H_2O)_6]^{2+}$, $[Fe(CN)_6]^{4-}$, and $[Fe(CN)_5H_2O]^{3-}$ can be determined quantitatively (mean error $< \pm 3\%$) in the presence of each other as a function of various reaction conditions.

Surprisingly, the reaction between $FeSO_4 \cdot 7H_2O$ and KCN in the solid state is relatively fast at 5 °C: the iron(II) sulfate has reacted almost quantitatively after about 30 h. Two partial steps were observed for the consumption of iron(II) sulfate, the rate constants being $k(I)_5 = (3.75 \pm 0.20) \times 10^{-2}$ min^{-1} and $k(II)_5 = (1.5 \pm 0.1) \times 10^{-3}$ min^{-1}. The two steps are ascribed to diffusion of cyanide ions and $[Fe(H_2O)_6]^{2+}$ ions, respectively, through a zone that is softened by water liberated on substitution by cyanide ions in the coordination sphere of the iron; the activation energies for the two diffusion steps are $\Delta E_A(I) = 12.5 \pm 2.0$ and $\Delta E_A(II) = 17.5 \pm 2.5$ kcal mole^{-1}.

The water content of the iron(II) sulfate plays a very important part in the reaction. This was shown by experiments with $FeSO_4 \cdot 2.5H_2O$ instead of $FeSO_4 \cdot 7H_2O$; in these experiments no change was observed even after 30 days at 5 °C. Use of the Mössbauer effect for the investigation of solid state reactions of the kind described here has the particular advantage that the samples remain in closed containers and can be analyzed without destruction.

Potassium Hexacyanopalladate(IV)

By *H. Siebert* and *A. Siebert* [*]

Hexacyanoplatinates(IV) were first described several years ago[1]. $K_2[Pt(CN)_6]$ *(1)* is formed on reaction of $K_2[PtI_6]$ and KCN in the solid state and is very stable. This made it seem possible that hexacyanopalladates(IV) might also exist although Pd^{IV} compounds are in general much less stable than their Pt^{IV} analogs.

An attempted synthesis analogous to that of *(1)* failed. $K_2[PdI_6]$ is unknown; $K_2[PdCl_6]$ and $K_2[PdBr_6]$ react with KCN in the solid state and in aqueous solution with complete reduction of the Pd^{IV}, partly to tetracyanopalladate(II) and partly to metallic palladium. However, $[Pd(CN)_6]^{2-}$ can be synthesized in aqueous solution if the reduction is prevented by addition of potassium peroxodisulfate.

$$K_2[PdCl_6] + 6\,KCN \xrightarrow{K_2S_2O_8} K_2[Pd(CN)_6] + 6\,KCl \qquad (2)$$

On fractional crystallization of the reaction mixture, $K_2S_2O_8$ separates first, then *(2)*, and finally $K_2[Pd(CN)_4]$ and K_2SO_4. The presence of *(2)* in individual fractions can be determined through the characteristic IR band at 2185 cm^{-1}. The yield averages 19%; use of $K_2[PdBr_6]$ as starting material gives lower yields.

Crystals of *(2)* are colorless, six-sided, domed prisms. The salt is moderately soluble in water, very slightly soluble in ethanol, and insoluble in ether. Above 160 °C it decomposes slowly; it is stable at room temperature to water, dilute acids, concentrated nitric acid, and bromine water. Concentrated sulfuric or hydrochloric acid at room temperature and boiling water decompose it slowly, with reduction to tetracyanopalladate(II) and palladium(II) cyanide. The CN stretching vibration appears in the IR spectrum of *(2)* at 2185 cm^{-1}, which is appreciably higher than that for $[Pd(CN)_4]^{2-}$ (2136 cm^{-1}). The relations are similar to those for the corresponding platinum compounds[2].

Potassium hexacyanopalladate(IV) (2)

A solution of KCN (29.3 g, 0.45 mole) and $K_2S_2O_8$ (12.2 g, 0.045 mole) in water (2.3 l) is added slowly and with stirring to a suspension of K_2PdCl_6 (20.0 g, 0.05 mole) in a solution of $K_2S_2O_8$ (1.35 g, 5 mmoles) in water (250 ml). The prod-

ucts crystallize fractionally on evaporation of the clear, yellow solution in a vacuum below 40 °C. The fractions that contain $K_2[Pd(CN)_6]$ (IR band at 2185 cm^{-1}) are united and recrystallized from hot water.

Simple Preparation of Cyanogen Fluoride

By *E. Mayer* [*]

Pure cyanogen fluoride was prepared for the first time in 1960, by pyrolysis of cyanuric trifluoride at 1300 °C [1,2]. This synthesis requires special, rather complicated equipment for the decomposition and for fractionation of the mixed products. Because of these experimental difficulties FCN is one of the least investigated of the three-atomic molecules.

Tetracyanomethane reacts with alkali-metal chlorides or bromides to yield tricyanomethyl-alkali metal and cyanogen chloride or bromide [3], so that it was appropriate to investigate the reaction with fluorides.

$C(CN)_4$ reacts with CsF with formation of tricyanomethyl-cesium and pure cyanogen fluoride:

$$C(CN)_4 + CsF \rightarrow CsC(CN)_3 + FCN$$

Finely powdered $C(CN)_4$ is mixed as thoroughly as possible with an excess of CsF in a shaking apparatus at room temperature, the FCN formed in the reaction being pumped off and condensed at the temperature of liquid nitrogen. Yields are up to 95 %.

The way in which the reactants are mixed has a pronounced effect on the rate of formation of FCN: to obtain *ca.* 1 mmole of FCN we had to carry out the reaction for 5 hours in the shaker, but about 30 hours were required when magnetic stirring was used. IR and mass spectra of the FCN produced in this way agree with spectra recorded in the literature [2,4] and show minor amounts of CO_2 as the only impurity.

$C(CN)_4$ also reacts quantitatively with KF at room temperature, with formation of tricyanomethylpotassium, but the FCN formed at the same time largely polymerizes and the yield thereof is only about 5 %. (Since the polymerization of FCN is catalyzed by Lewis acids [2], the polymerization may be caused by HF present in the KF as impurity.)

No reaction occurs when $C(CN)_4$ is mixed with NaF at room temperature.

From the various behaviors of the alkali-metal fluorides it can be concluded that formation of a tricyanomethyl-alkali metal is energetically favored by a large cation such as K^+ or Cs^+.

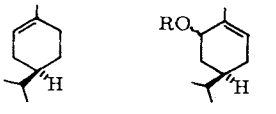
Catalytic Oxidation of Olefins *via* an Allyl Radical [**]



By *J. E. Baldwin* and *J. C. Swallow* [*]

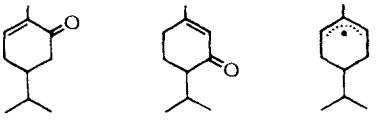
We have recently commented on the similarity between the oxygenation patterns found in the reactions of singlet oxygen with olefins and those observed in many natural product series [1], and have suggested the possibility that some singlet oxygen-like species is operative in certain oxidase mechanisms [2]. Since most oxidases are metalloenzymes [2], the observation that a number of transition metal complexes catalyze allylic oxidation and epoxidation caused us to examine these reports [3] in order to compare the product oxygen patterns with that expected from the well-known "ene" addition pathway of singlet oxygen, that is, *(1)* to *(2)* [4].

(1) *(2)*

Thus (+)-carvomenthene *(3)* is converted in part by photosensitized oxidation to isomeric carvotanacetols *(4)* by way of the corresponding hydroperoxide *(5)* [5].

(4), R = H
(5), R = OH

(3)



Consequently, an "ene" addition of oxygen by the rhodium catalyst, chlorotris(triphenylphosphine)rhodium(I), would be expected to follow the same course. An alternative process could be the specific insertion of oxygen into the allyl methylene group yielding in this case the enantiomorph of *(5)*. In either case, α-elimination of the hydroperoxide [6] would yield optically active carvotanacetone *(6)*. We have observed that the oxygenation of *(3)* catalyzed by chlorotris(triphenylphosphine)rhodium(I) (10^{-2} M) in benzene at 60 °C (monitored by gas-liquid chromatography), gives a mixture of carvotanacetone *(6)*, piperitone *(7)*, and several of the derived alcohols.

Careful separation (preparative gas-liquid chromatography) of the mechanistically significant enone *(6)* was followed by characterization as the 2,4-dinitrophenylhydrazone (m.p. 196 °C), identical in spectral properties with that prepared from authentic (—)-carvotanacetone [m.p. 194—196 °C, $[\alpha]_D^{25}$ −104, (*c* = 0.64, chloroform)]. The carvotanacetone obtained from this oxidation was completely racemized.

In order to exclude the possibility of prior racemization in the olefin by a rapid valence tautomerism of a reversibly formed π-allyl rhodium complex [7], which could conceivably have been an intermediate in the oxygenation, a reaction taken to 50 % conversion was stopped and unchanged carvomenthene reisolated (preparative gas-liquid chromatography). It retained its full optical rotation.

Since the hydroperoxide *(5)* is optically stable under these mild conditions [5] we conclude that the mechanism of this oxygenation involves a symmetrized intermediate, which is most probably the radical *(8)*.

Other workers [8] have noted that the product distribution in these reactions is similar to that observed in classical autoxi-

(6) *(7)* *(8)*

dation chains and have also observed phenolic inhibition and polymerization initiation. The latter observations, however, raise the question of catalyst inactivation.

We have here reported direct evidence for an allyl radical intermediate in an unperturbed system, and concur with the previous conclusions that a Haber-Weiss oxidation chain process[9] is in operation in these reactions, as opposed to insertions or concerted additions.

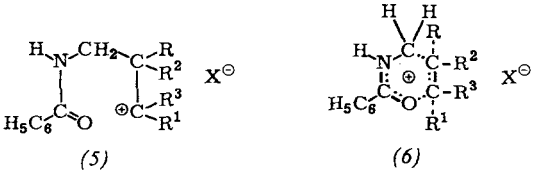
Stereospecific Synthesis of 5,6-Dihydro-4*H*-1,3-oxazines *via* Polar 1,4-Cycloaddition[1] [**]

By *R. R. Schmidt* [*]



Polar 1,4-cycloaddition[2] can formally be assigned a place intermediate between the concerted Diels-Alder reaction and two-step 1,4-dipolar cycloaddition[3].

(1) *(2)*

(3) *(4)*

(5) *(6)*

$X^{\ominus} = {}^1/_2\ SnCl_6^{2\ominus}$

Polar 1,4-cycloaddition of the benzamidomethylium ion *(2)* to olefins[4] leads to an unexpected result of mechanistic importance[2e]: If *(2)* is produced from *N*-(hydroxymethyl)-benzamide by proton catalysis in glacial acetic acid[4] or *in situ* by treatment of *N*-(chloromethyl)benzamide *(1)* with tin(IV) chloride in glacial acetic acid, carbon tetrachloride, or chloroform[2c], regiospecific[5] and stereospecific reaction ensues to form 5,6-dihydro-4*H*-1,3-oxazinium salts *(3)*, which are isolated in the form of the free bases *(4)*. The latter method gives almost quantitative yields. Specific formation of the 5,6-dihydro-4*H*-1,3-oxazines *(4a)–(4f)* was deduced from NMR studies. The experimental coupling constants correspond to the values estimated from structural models of *(4a)–(4f)* with the aid of the Karplus equation[6].

The stereospecificity of the reaction casts doubt on a two-step mechanism with *(5)* as intermediate[4]. Rather, the above observations suggest concerted formation of the two new σ bonds[7], although not necessarily at the same rate, with *(6)* as intermediate.

Table 1. 5,6-Dihydro-4*H*-1,3-oxazines *(4)* synthesized from *(1)*, olefins, and $SnCl_4$.

Azomethine Ylides from Aziridinedicarboxylic Esters: Kinetics of the *cis-trans* Isomerization and of the Ring Opening

By *R. Huisgen, W. Scheer,* and *H. Mäder* [*]

Although the epimeric dimethyl 1-(4-methoxyphenyl)aziridine-2,3-dicarboxylates, *cis-(1)* and *trans-(1)*, are stable at room temperature, they equilibrate at 100 °C. The fact that

this *cis-trans* isomerization proceeds *via* a novel aziridine ring opening at the C–C bond to give the geometrically isomeric azomethine ylide dicarboxylic esters, *trans-(2)* and *cis-(2)*, is proved by 1,3-dipolar cycloadditions of *(2)* with dipolarophiles a–b [1,2]. Active dipolarophiles suppress the stereoisomerization *trans-(2)* ⇆ *cis-(2)*; the stereospecific formation of adducts with dimethyl acetylenedicarboxylate establishes the *conrotatory* opening of the aziridine ring [2]. Conrotation was predicted by *Woodward* and *Hoffmann* [3] for the ring opening of the isoelectronic cyclopropyl anion to give the allyl anion.

R = *p*-CH_3O-C_6H_4

Kinetics of the ring opening: Dilatometric studies of the formation of *cis-(3)* and *trans-(3)* from *trans-(1)* and *cis-(1)*, respectively, with an excess of tetracyanoethylene in ethyl acetate gave first order rate constants, which, surprisingly, are independent of the concentration of tetracyanoethylene (Table 1). Thus, the rate-determining step is not the bimolecular combination with the dipolarophile, but a preceding first order reaction. Tetracyanoethylene is such an effective trapping agent for the azomethine ylides that not only the isomerization *cis-(2)* ⇄ *trans-(2)* but also the electrocyclic

Table 1. Kinetics of ring opening of *(1)* in ethyl acetate; measurement of adduct formation with tetracyanoethylene (TCNE).

trans-(1), 30.6 mmole/l; $\Delta H^{\ddagger}$ = 29.5 kcal/mole, $\Delta S^{\ddagger}$ = +0.5 (e.u.)

TCNE (mol. equiv.)	10	20	30
$k_d \times 10^5$ (s^{-1}) at 100.2 °C	5.13	5.16	5.15
$k_d \times 10^5$ (s^{-1}) at 110.0 °C	15.1	15.0	14.8
$k_d \times 10^5$ (s^{-1}) at 119.7 °C	39.0	39.1	39.1

cis-(1), 40 mmole/l; $\Delta H^{\ddagger}$ = 28.6 kcal/mole, $\Delta S^{\ddagger}$ = −1.7 (e.u.)

TCNE (mol. equiv.)	7.5	15
$k_d \times 10^5$ (s^{-1}) at 100.0 °C	6.24	6.12
$k_d \times 10^5$ (s^{-1}) at 110.0 °C	17.5	17.5
$k_d \times 10^5$ (s^{-1}) at 120.0 °C	46.2	46.1

regeneration of *trans-(1)* and *cis-(1)* is completely suppressed. The dilatometric rate constants k_d are thus the ring-opening constants k_1 and k_1', respectively. The Eyring parameters (Table 1) are similar for the *cis* and *trans* forms; the low entropy of activation is indicative of the conversion of one rigid molecule into a new rigid molecule. The structures of the adducts *(3)* were confirmed by NMR spectra and elemental analyses.

Aziridine equilibration and rate of *cis-trans* isomerization: The course of the isomerization can be followed NMR spectroscopically by means of the singlet due to the ring protons of *trans-(1)* and *cis-(1)*. The rate constant for the equilibration,

$$trans\text{-}(1) \underset{k_{-I}}{\overset{k_I}{\rightleftharpoons}} cis\text{-}(1)$$

$k_I + k_{-I}$, is measured from both sides of the equation (Table 2). The difference in the free enthalpies of activation

Table 2. Kinetics of *cis-trans* isomerization of *(1)* in ethyl acetate.

T (°C)	$10^5 (k_I + k_{-I})$ (s^{-1})	$10^5 k_I$ (s^{-1})	$10^5 k_{-I}$ (s^{-1})
100	2.44	0.71	1.73
110	6.55	1.93	4.62
120	17.04	5.01	12.03

	$\Delta H^{\ddagger}$ (kcal/mole)	$\Delta S^{\ddagger}$ (e.u.)	$\Delta G^{\ddagger}$ (kcal/mole)
trans-(1) → *cis-(1)*	28.6	−6.1	30.9 (100 °C)
cis-(1) → *trans-(1)*	28.1	−5.6	30.2 (100 °C)

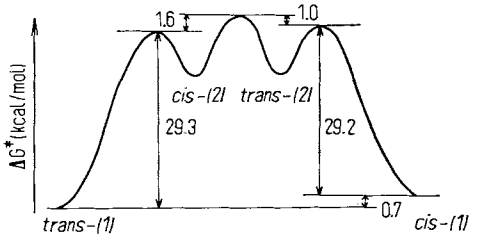
agrees with the value of ΔG = 0.65 kcal/mole determined from the equilibrium constant, K = 0.42.

The content of *cis-(1)* in the equilibrium mixture increases with increasing polarity of the solvent (Table 3). The calculated free energy changes show a linear correlation with the polarity parameter E_T [4]. A similar solvent effect leading to an even stronger preference of the *cis* isomer was observed with 1-benzyl-2,3-dibenzoylaziridine [5]. Slow dimerization of *trans-(1)* and *cis-(1)* to diastereomeric *N,N'*-bis(*p*-methoxyphenyl)piperazinetetracarboxylic esters occurs as an interfering reaction [1].

Table 3. Percentage of *cis-(1)* in *cis-trans* equilibrium mixture at 120 °C.

Solvent	*cis-(1)* (%)	E_T
Carbon tetrachloride	22	32.5
Ether	26	34.6
Dioxane	29	36.0
Ethyl acetate	30	38.1
Deuteriochloroform	32	39.1
Methylene chloride	32	41.1
Acetone	36	42.2
1,3-Dioxolan-2-one	47	46.6

Energy profile: By combination of the kinetic data obtained, it is possible to construct a free energy profile for ring opening and isomerization (Fig. 1). Only one of eight molecules of *trans-(1)* that reach the energy dip corresponding to the intermediate *cis-(2)* surmounts the next barrier leading to the second intermediate, *trans-(2)*; the remainder revert to *trans-(1)*. In the case of the intermediate *trans-(2)*, cyclization to *cis-(1)* is four times as fast as conversion into *cis-(2)*. The depths of the troughs corresponding to the azomethine ylide intermediates, *cis-(2)* and *trans-(2)*, are unknown.



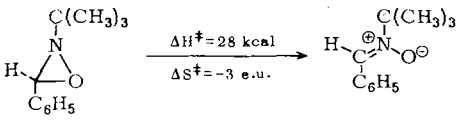


Figure 1. Energy profile for the conversions *trans-(1)* ⇌ *cis-(2)* ⇌ *trans-(2)* ⇌ *cis-(1)* at 100 °C.

In azomethine oxides (nitrones) the oxygen stabilizes the negative charge better than the carbon of the carbanion in

[6]

azomethine ylides. This is responsible for the conversion of oxaziranes into the open-chain nitrones.

Differing 1,3-Dipolar Activity of *cis-trans* Isomeric Azomethine Ylide Dicarboxylic Esters[**]

By *R. Huisgen, W. Scheer, H. Mäder,* and *E. Brunn*[*]

The stereoisomeric dimethyl azomethine ylide dicarboxylates, *cis-(2)* and *trans-(2)*, which arise from the dimethyl aziridinedicarboxylates *trans-(1)* and *cis-(1)*, combine stereospecifically with highly active dipolarophiles such as acetylenedicarboxylic ester[1] or tetracyanoethylene[2]. If the dipolarophilic activity of the multiple bond system a=b is reduced, *cis-trans* isomerization of the azomethine ylides competes with cycloaddition to a=b.

A characteristic difference between *trans-(2)* and *cis-(2)* becomes apparent under the above conditions. Cycloadditions of *trans-(2)* remain stereospecific, even with "poor" dipolarophiles (Table 1); *trans-(3)* is the sole product detectable by NMR spectroscopy. With *cis-(2)*, on the other hand, the lower the activity of the dipolarophile the greater the amount of the sterically "wrong" adduct *trans-(3)*. With norbornene nearly half of the *cis-(2)* isomerizes to *trans-(2)* before it enters into cycloaddition with a=b; the cyclohexene adduct has 83% *trans* configuration with respect to the carboxylate groups. Finally, with phenanthrene the sequence *trans-(1)* → *cis-(2)* → *trans-(2)* leads to the adduct-2,5-*trans*-diester, *trans-(3)*. No subsequent stereoisomerization of the adducts *(3)* could be detected under the reaction conditions or during the work-up procedure.

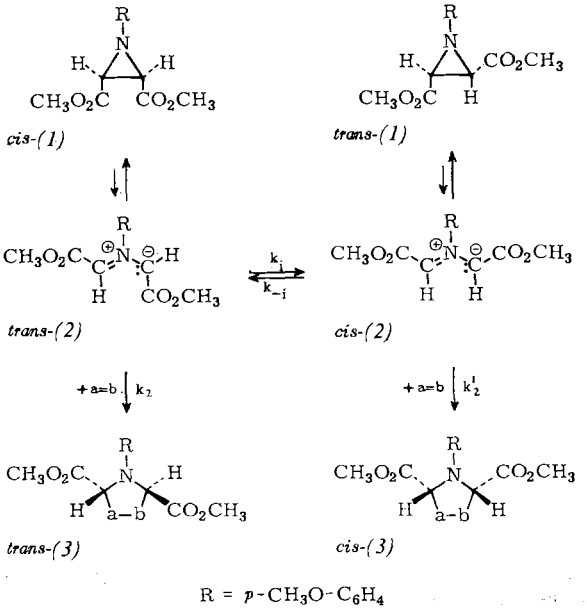

Table 1. Steric course of some reactions of *cis-(1)* [*via trans-(2)*] and *trans-(1)* [*via cis-(2)*] with dipolarophiles at 100–140 °C [a].

Dipolarophile a = b	From *cis-(1)* [b] *(3)*, yield (%)	From *trans-(1)* *(3)*, yield (%)	*trans-(3)*:*cis(3)*
Tetracyanoethylene	88	100	0:100
Dimethyl acetylenedicarboxylate	98	78	0:100
Diethyl azodicarboxylate	96	78	6: 94
Diethyl mesoxalate	94	75	7: 93
Dimethyl fumarate	100	93	9: 91
Tetraethyl ethylene-tetracarboxylate	99	90	25: 75
Norbornene	86	98	45: 55
Cyclohexene	78	71	83: 17
Phenanthrene		36	100: 0

[a] Most of the adducts *(3)* listed in the Table are new and gave correct analyses.

[b] The ratio of *trans-(3)* to *cis-(3)* was 100:0 in all these cases.

What is the cause of this striking phenomenon? Initially we suspected that the azomethine ylide equilibrium lies largely on the side of *trans-(2)*, *i.e.* that $k_{-i} \gg k_i$. However, the energy profile of the ring opening and isomerization[2] does not lead one to expect such an energy difference between *trans-(2)* and *cis-(2)*; differing rate constants for the cycloaddition, namely $k_2 > k_2'$, must therefore be responsible. A molecular model shows that strong van der Waals repulsion and restriction of rotation of the *cis* ester groups in *cis-(3)* can occur. It is also possible that the transition state of the cycloaddition – here the carbon atoms of *(2)* are intermediate between sp^2 and sp^3 hybridization – is affected by such an overlapping of the substituent radii as well. It is only with extremely active dipolarophiles that k_2' remains large enough to preclude competition from k_{-i}.

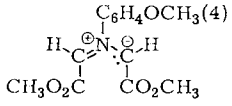
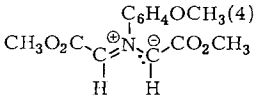
Configuration of a *cis*-Disubstituted Azomethine Ylide



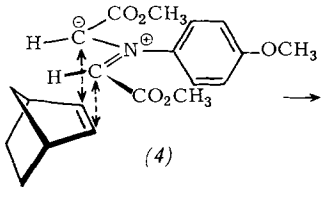
By *R. Huisgen* and *H. Mäder*[*]

The *conrotatory* ring opening of dimethyl 1-(4-methoxyphenyl)aziridine-*cis*-2,3-dicarboxylate[1] to give the azomethine ylide *trans*-dicarboxylate is structurally unambiguous. In contrast, the conrotation of the *trans*-isomer *(1)* can give the azomethine ylide dicarboxylate in the horse-shoe form *(2)* or in the W form *(3)*; in the latter form the van der

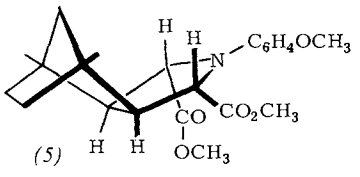


Waals strain is lower if no stipulations are made regarding coplanarity of the methoxyphenyl group with the planar azomethine ylide system.

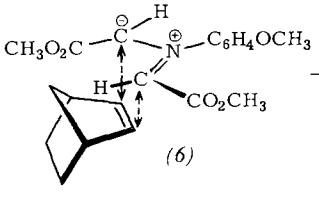
(1)



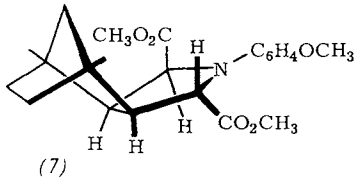
(2)



(3)



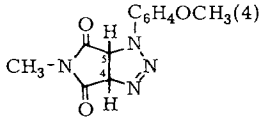
The reaction of *(1)* with norbornene at 100 °C afforded 98% of a mixture of the *exo*-adducts *(5)* and *(7)* in the ratio 55:45; the configurations of the adducts were determined from the NMR spectra[2]. The main component is the *cis* diester *(5)*, whose ester groups are directed "downwards". Formation of the *trans*-diester *(7)* was preceded by an isomerization of the azomethine ylide *cis*-dicarboxylate to the *trans*-dicarboxylate[3].



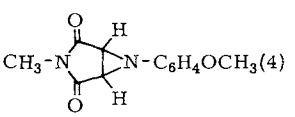
(4)

(5)

(6)



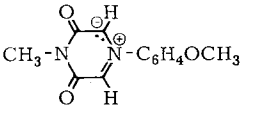
(7)



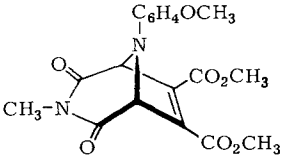
Two biplanar orientation complexes[4,5] of the 1,3-dipolar cycloaddition to norbornene that lead to *exo*-adducts can be predicted for the horse-shoe form *(2)* and for the W form *(3)*.

Examination of models shows that the arrangement *(4)* is the sterically most favorable. In confirmation, *(5)* was the only *cis*-diester adduct.

Both of the orientation complexes derived from the horse-shoe form *(2)* should be about equally unfavorable. A study of the cycloaddition of the model compound *(10)*, which is fixed in the horse-shoe form, confirmed this prediction. The cycloaddition of 4-methoxyphenyl azide to *N*-methylmaleimide at 120 °C gave 79% of the triazoline *(8)* having m.p. 131–132 °C (decomp.)[6]; NMR ($CDCl_3$): τ = 4.37 (4-H, d) and 5.29 (5-H, d) with J_{45} = 11.0 Hz, τ = 6.22 (OCH_3, s), τ = 7.02 (NCH_3, s). A solution of *(8)* in toluene at 100 °C liberated one mol. equiv. of nitrogen over a period of five hours.



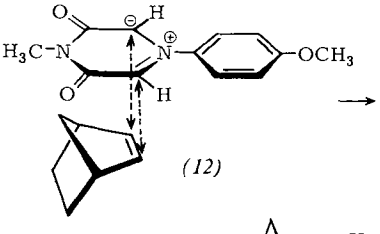
(8)



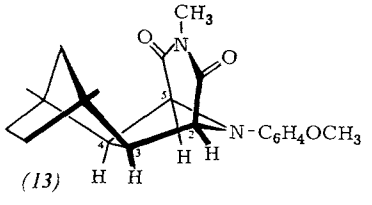
(9)

We isolated a 97% yield of the bicyclic aziridine *(9)* having m.p. 98 °C; IR (KBr): C=O 1698 (st) and 1776 cm^{-1} (w); NMR ($CDCl_3$): τ = 6.40 (2 tertiary protons, s), τ = 6.25 (OCH_3, s), τ = 7.35 (NCH_3, s). In earlier experiments on the thermolysis of maleimide-azide adducts[7,8] it was not determined whether enamines or aziridines are formed; however, *Awad et al.*[9] isolated a mixture of both compounds.

(10)

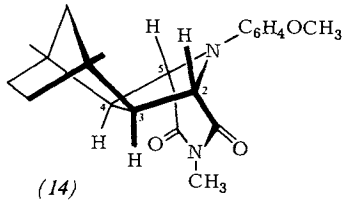


(11)



The geometry of the bicyclic ring system *(9)* permits only *disrotatory* ring opening. Since thermally only conrotation is the allowed concerted process[10], it is hardly surprising that cycloaddition of *(9)* to norbornene could not be accomplished even at 180 °C. *Disrotatory* photolysis of aziridines to azomethine ylides was established in our laboratory[1]. The photochemical ring opening of *(9)* to give *(10)* occurred readily (high-pressure mercury arc, quartz vessel); reaction in the presence of dimethyl acetylenedicarboxylate in dioxane afforded 70% of *(11)* having m.p. 202–203 °C; NMR ($CDCl_3$): τ = 4.82 (2 tertiary protons, s), τ = 6.14 (2 ester CH_3, s), τ = 6.27 (ether CH_3, s), τ = 7.08 (NCH_3, s). *Oida* and *Ohki*[11] recently reported on the photolysis of a similar bicyclic aziridine which was found to give 4% of a dimethyl acetylenedicarboxylate adduct analogous to *(11)*, along with 36% of an isomeric photoadduct.

We irradiated *(9)* in the presence of 20 mol. equiv. of norbornene in dioxane at 9 °C and obtained 33% of a mixture of the *exo*-adducts *(13)* and *(14)* in the ratio 46:54; they were separated by thick-layer chromatography.



Isomer *(13)*: m.p. 170 °C; NMR ($CDCl_3$): the tertiary protons at C-2 and C-5 show τ = 5.38 and couple with 3-H and 4-H (τ = 7.34) to give an AA'MM' spectrum without any

(12)

(13)

(14)

coupling of 3-H and 4-H with the norbornane bridgehead protons, τ = 6.28 (OCH_3, s), τ = 7.17 (NCH_3, s).

Isomer *(14)*: m.p. 142–143 °C, NMR ($CDCl_3$): The somewhat broadened singlet due to 2-H and 5-H (τ = 5.58), *i.e.* the absence of any significant coupling with 3-H and 4-H, indicates a *trans* relationship, τ = 6.27 (OCH_3, s), τ = 7.17 (NCH_3, s).

The cycloaddition of *(10)* to norbornene therefore proceeds to almost equal extents *via (12)* and the corresponding orientation complex that leads to *(14)*. Consideration of

models shows that the van der Waals repulsions to be overcome in each case are comparable.

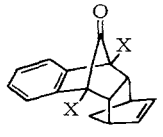
Reactivity of 1,3-Dihalogenoisoindenones

By *K. Blatt* and *R. W. Hoffmann*[*]



Isoindenones *(2)* are cross-conjugated 10π electron systems whose reactivity can be determined by an "oxyallyl" resonance structure *(3)* [1]. Treatment of *(1a)* with NaI in acetone

(1) *(2)* *(3)*

(4) *(5)* *(6)*

(7)

(a), X = Br
(b), X = Br or I

liberates isoindenones *(2)* [2] which can be trapped *in situ* by cycloaddition to olefins [3]. Lower yields of adduct are obtained on dehalogenation of *(1a)* with Zn in DMF.

Addition to cyclopentadiene provides us with information regarding the reactivity of *(2)*: If *(2)* were to react as a diene, compound *(5)* would result; if *(2)* reacted as an oxyallyl, compound *(4)* would be obtained [4]. The adduct obtained is actually *(5)*, as is shown by its hydrogenation to *(6)*. It therefore follows – insofar as the cycloaddition is irreversible – that compound *(2)* behaves as a cyclopentadienone rather than as an oxyallyl derivative.

During the liberation of *(2)* from *(1a)* with NaI, competing iodine/bromine exchange gives rise to iodine-containing cycloadducts. Since the adducts are stable toward iodide, exchange of iodine for bromine could take place, *e.g.* by addition of iodine or of iodine bromide to *(2)* with formation of *(1b)* [5]. The iodine/bromine exchange should proceed at a constant rate under standard conditions. The extent of the observed incorporation of iodine into the adducts depends on the relative rate of the competing irreversible Diels-Alder reaction. It therefore follows from the iodine contents of the adducts that the rate of addition of *(2)* to olefins decreases in the order: norbornadiene > cyclopentadiene > cyclopentene > norbornene > 2,3-dihydropyran (see Table). The yield of adduct also decreases correspondingly.

Adduct with		Yield (%)	M.p. (°C)	IR (cm^{-1})	Remarks	Halogen content (%) 2 Br	BrI	2 I
Norbornadiene	*(7)*	55	130–131	1810	One-proton signal at τ = 10.7 [a, b]	100	—	—
Cyclopentadiene	*(5)*	67	137–139	1805		95	5	—
Cyclopentene	*(6)*	63	101–102	1800	One-proton signal at τ = 9.4–9.9	80	20	—
Norbornene		19	174–176	1810	One-proton signal at τ = 10.6 [a]	32	65	3
2,3-Dihydropyran		8	140–141	1810	*exo/endo* mixture	—	< 1	>99

[a] Position of this signal is not shifted after reduction of the carbonyl group with $NaBH_4$.
[b] Pyrolysis at 220 °C gives 1,4-dibromonaphthalene in 60% yield.

N-Chlorochloroformimidoyl Chloride[**] from Cyanogen Chloride and Chlorine

By *H. Hagemann, D. Arlt,* and *I. Ugi*[*]

Cyanogen chloride adds on chlorine with formation of *N*-chlorochloroformimidoyl chloride *(1)* [1].

$$Cl-C\equiv N + Cl_2 \rightarrow Cl_2C=N-Cl \quad (1)$$

If chlorine and cyanogen chloride in the molar ratio 3:2 are heated in the presence of *ca.* 1% active charcoal in a bomb tube or in a nickel autoclave at 60 °C for 18 hours a 77% conversion (based on cyanogen chloride) occurs with formation of 95% *(1)* and less than 5% cyanuric chloride.

Previously, this chlorination could not be achieved because in most systems cyanogen chloride is rapidly trimerized to

cyanuric chloride. Conditions which accelerate the trimerization of the cyanogen chloride, such as presence of Lewis acids, HCl, H_2O, and a ratio of $Cl_2 : ClCN < 1:1$, should therefore be avoided. Compound *(1)*, which is a colorless liquid having b.p. 87 °C, can be distilled under normal pressure. *(1)* is comparable with sulfuryl chloride regarding its tendency to lose chlorine. It is a strong chlorinating agent but, like other *N*-halogen compounds, also adds on olefins. The corresponding fluorine compound [2] boils at −60 °C and explodes on warming.

The characteristic intense IR bands at 1560, 945, and 730 cm^{-1}, the molecular weights determined by mass spectrometry, and the result of elemental analyses confirm the given structure of *(1)*.

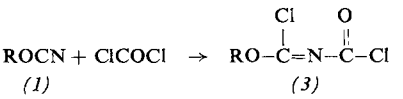
Addition of Acyl Chlorides to the C≡N Bond of Cyanates

By *E. Grigat* [*]

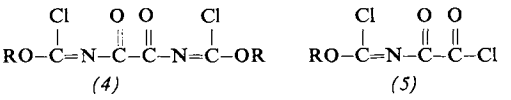
Because of the pronounced electrophilic character of their N≡C–O group, cyanates *(1)* show only a slight tendency to add electrophilic agents at the nitrogen atom [1]. Attempts to carry out *N*-acylations of cyanates usually fail since the cyanates are trimerized by small amounts of liberated acid [2] or by added catalysts [3] and are thus not available for reaction.

The only successful reaction with an acid chloride was afforded by reaction of benzoyl chloride with 2 moles of *(1)* in the presence of $SbCl_5$ which, in two special cases, leads to formation of 4,6-bis(aryloxy)-3,5-diazapyrylium hexachloroantimonate [3]; a 1:1-addition product could not be isolated. Previously, addition of an acyl chloride to the nitrile group of the cyanate was possible only with halide salts of *N,N*-dialkylated imido chlorides [4,5].



We have now found that the new *N*-acyliminocarbonic ester halides *(2)* are formed in yields of 45 to 90% [6] along with small amounts of the trimerizate of *(1)* when pure acyl chlorides are heated with cyanates in inert solvents (aliphatic acyl chlorides: 20–120 °C; aromatic acyl chlorides: up to 220 °C, also without solvent). The compounts *(2)* are surprisingly

(1) *(2)*



stable, the majority even being distillable. Their halogen atom is readily replaced by nucleophiles:

At temperatures as low as 0–20 °C, phosgene adds smoothly to *(1)* to give *N*-chloroformyliminocarbonic halides *(3)* [7].

(1) *(3)*

The halogen atom on the formyl groups is the more reactive; the chlorine atoms can be successively replaced by nucleophiles. Reaction of *(1)* with half-molar amounts of oxalyl chloride affords homogeneously *N,N*-bis[alkoxy-(or aroxy-)-chloromethylene]oxamide *(4)* while on reaction with an excess of oxalyl chloride only compound *(5)* is obtained [8,9].

(4) *(5)*

The halogen atoms in *(4)* and *(5)* and in *(2)* and *(3)* are of similar reactivity.

The same type of reactions take place with cyanamides in place of cyanates and oxalic acid esters (acid thioester, acid amide)-halides, (thio-)carbonic esters halides, trichloromethylsulfenyl chloride and chlorocarbonylsulfenyl chloride instead of acyl chlorides.

Experimental:

Phenyl cyanate (23.8 g, 0.2 mole) is added dropwise and slowly to a solution of dichloroacetyl chloride (29.4 g, 0.2 mole) in toluene (100 ml). Reaction is complete after one hour's stirring at the reflux temperature (116 °C). A small amount of trisphenyl cyanurate precipitates out; this is filtered off and the filtrate is concentrated by evaporation under vacuum (water-pump). Distillation of the crude product (50 g) yields 38 g (72% yield) of compound *(2)* with R = C_6H_5 and R′ = $CHCl_2$; b.p. 99 °C/0.2 torr.

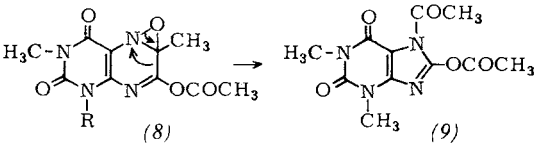
A New Pteridine → Purine Transformation



By *W. Hutzenlaub, G. B. Barlin,* and *W. Pfleiderer* [*]

Whereas the conversion of purines into pteridines by chemical methods [1,2] has already been described on a number of occasions and a ring expansion of this kind plays a decisive role in the biosynthesis of pteridines [3], the reverse reaction, *i.e.* the ring contraction of the pyrazine to the imidazole nucleus, has hitherto only been observed in an enzymatic reaction that proceeds in the presence of the organism *Alcaligenes faecalis* [4,5]. We have now found that the 5-oxides *(4)* and *(5)*, formed by H_2O_2 oxidation of 7-hydroxy-1,3,6-trimethyl-2,4-dioxotetrahydropteridine *(1)* and the 3,6-dimethyl-1-phenyl derivative *(2)*, respectively, do not undergo Boekelheide rearrangement to give the 6-acetoxymethyl derivatives when boiled with acetic anhydride but instead undergo ring contraction to give 1,3-dimethyluric acid *(10)* and 1-methyl-3-phenyluric acid *(11)*, respectively.

	R	R^1
(1)	CH_3	H
(2)	C_6H_5	H
(3)	CH_3	CH_3

	R	R^1
(4)	CH_3	H
(5)	C_6H_5	H
(6)	CH_3	CH_3
(7)	CH_3	$COCH_3$

(8) *(9)*

	R
(10)	CH_3
(11)	C_6H_5

In order to elucidate the course of this ring contraction we first attempted to bring about reaction of 1,3,6-trimethyl-7-methoxy-2,4-dioxotetrahydropteridine 5-oxide *(6)* with acetic anhydride in the same way; however, deoxygenation to the starting material *(3)* was the only reaction that took place. Experiments with isotopes showed that radioactive 1,3-dimethyluric acid is obtained only when position 7 of compound *(4)* is labeled with [^{14}C], whereas neither the [6-^{14}C] derivative of *(4)* nor reaction with [1-^{14}C]-acetic anhydride lead to activity in the purine derivative. It may be concluded from these findings that *(4)* is first acetylated to 7-acetoxy-1,3,6-trimethyl-2,4-dioxotetrahydropteridine 5-oxide *(7)* by the acetic anhydride, thus facilitating nucleophilic attack of the *N*-oxide oxygen on the neighboring C-6 atom to give *(8)*. Stabilization of *(8)* by valence isomerization then takes place to give 8-acetoxy-7-acetyl-1,3-dimethylxanthine *(9)*, which has, however, not yet been isolated as the pure substance but only in the form of its hydrolysis product 1,3-dimethyluric acid *(10)*.

This novel rearrangement appears to be of a general nature since ring contraction of quinoxalones to benzimidazol-2-ones [6] has also been observed recently.

7-Hydroxy-1,3,6-trimethyl-2,4-dioxotetrahydropteridine *(4)* (0.5 g) is refluxed for 20 min in acetic anhydride (5 ml). The mixture is then evaporated to dryness, and the residue is taken up in water and reprecipitated from dilute ammonia/HCl. Recrystallization from a large volume of water gives 0.32 g (84%) of colorless, crystalline 1,3-dimethyluric acid *(10)*, m.p. $>360\,^{\circ}C$ (literature value [7]: $>360\,^{\circ}C$), which proves to be identical with authentic material on chromatography.

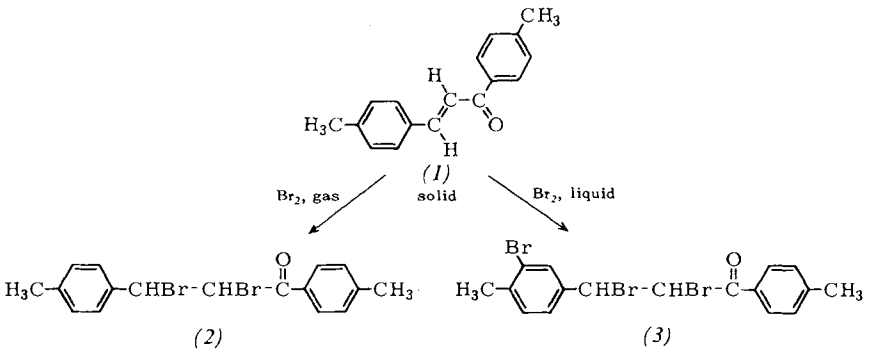
Reactions in Chiral Crystals: An Absolute Asymmetric Synthesis

By *K. Penzien* and *G. M. J. Schmidt* [*]

An absolute optical synthesis has been carried out in a chemical system composed of optically inactive molecules, *i.e.* molecules which are either achiral or whose chiral conformations interconvert so rapidly that optical rotation cannot be measured in the disperse phases; as the required chiral influence we have successfully used the enantiomorphic crystal structure of one of the reactants [1].



The underlying thesis that the crystal lattice maintains control over the configuration and conformation of the reacting components, at least until the formation of a transition state of defined geometry, has been developed in the topochemical studies conducted in this Laboratory [2].

Three lines of work have merged in the design of appropriate experiments: first, in our study of molecular packing modes [3] we have observed that α,β-unsaturated ketones frequently crystallize in non-centrosymmetric and occasionally in enantiomorphic space groups [4]. Secondly, molecular conformation of this group of compounds has been shown to be a function of packing arrangement [4]. Thirdly, a study of gas/solid reactions has shown that reaction of bromine in the vapor phase with solid 1,2-disubstituted *trans*-ethylenes yields the *meso*- or *erythro*-dibromides in suitable crystal structures [5]. Following these leads we have carried out the gas/solid and liquid/solid brominations of individual monocrystals (space group $P2_12_12_1$; D_2^4) of 4,4'-dimethylchalcone *(1)*; the reactions afford, in chemical yields $>90\%$, one of the diastereoisomers of *(2)* or *(3)*, with one enantiomer in excess.

Rotations approximately (±10%) proportional to the weight of the crystals (6–60 mg) of $\alpha_D = 0.06$ to 0.6° and having either sign were observed consistently.

The specific rotation $[\alpha]_D^{28} = 9.8$ of the product of the gas/solid reaction, and the specific rotation of optically pure *(2)*, $[\alpha]_D^{28} = 167$, indicate an average optical yield of 6%.

The following control experiments have been carried out: a single crystal (~200 mg) of *(1)* was cut, and one half bro-

minated in chloroform solution: zero rotation. The other half was directly exposed to bromine gas and gave optically active dibromide. Bromination of a mixture made up of crystals grown in separate vessels (to eliminate observed inoculation effects) gave a product having zero rotation.

Because of the absence of well defined { *hkl* } forms and our inability to measure optical rotation of the crystals, correlation between the sign of rotation of the initial matrix and of the reaction product could not be achieved.

We believe that experiments of the kind described are relevant, apart from their synthetic implications, to the analysis of solid-state and enzymatic reaction mechanisms.

Experimental:

Adequately homogeneous crystals of 4,4′-dimethylchalcone, m.p. 132 °C, were grown from slowly cooled solutions (60 to 20 °C in 10 days) in ethyl acetate. Crystallographic constants [6]: $a = 15.26$, $b = 5.91$, $c = 14.65$ Å. Space group $P2_12_12_1$. D_X ($Z = 4$): 1.19 g/cm³.

The gas/solid reaction has been carried out in a flask containing a powdered single crystal of *(1)*; bromine (10% excess) was admitted as vapor and the material agitated at room temperature with a magnetic stirrer. After the reaction had been completed (2–3 h) the product was chromatographed (hexane : benzene) over a Kieselgel column to remove traces of *(1)* or *(3)*. Alternately, the crushed crystal in a round-bottom flask was covered with cold liquid bromine (excess) and the whole shaken for 5 min at 0 °C. Excess bromine was partially removed in a stream of nitrogen. The remaining brown oil was dissolved in chloroform, and the solvent, some bromine and HBr evaporated with nitrogen; three such operations produced crystalline material which, if still slightly yellow, was passed through a short Kieselgel column.

Rotation of the colorless chloroform solutions of the so purified compounds ($c = 1.2$–12 g/100 ml) was measured in a polarimeter [Perkin-Elmer 141; 1 ml cuvette, $l = 10$ cm]. Rotation was constant over weeks, even after addition of acid or of small amounts of bromine. An optically pure enantiomer of *(2)* ($[\alpha]_D^{28} = 167$) was obtained from the reaction product after nine recrystallizations (constant specific rotation) from benzene : hexane (1:1) in the temperature range 60–10 °C.

The structure of *(2)* (m.p. 175–179 °C, decomp., from benzene : hexane) is based on elemental analysis and its NMR spectrum. *(3)* (m.p. 153–154 °C, from hexane : chloroform) has been prepared independently from 3-bromo-4,4′-dimethylchalcone (m.p. 140 °C, from benzene) by bromine addition; elemental analysis and its NMR spectrum afford proof of structure.

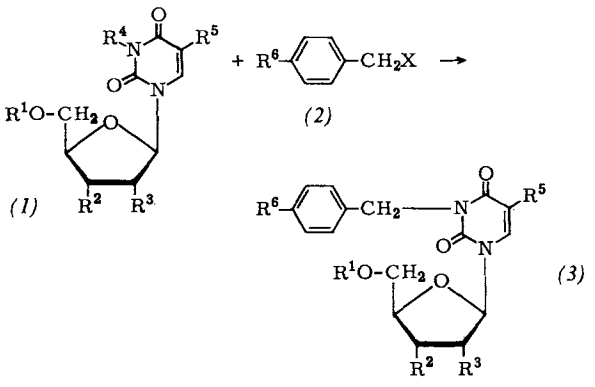
Nucleophilic Substitutions with Pyrimidine Nucleoside N³ Sodium Salts

By *H. Seliger* and *F. Cramer* [*]



As can be deduced from the pH dependence of the ultraviolet spectrum of pyrimidine nucleosides [1], the nucleobases are deprotonated at N³ in alkaline media. The resulting pyrimidine nucleoside N³-anions can act as nucleophiles in addition and in substitution reactions [2]. We have prepared the N³ sodium salts of derivatives of uridine and thymidine in non-aqueous medium and studied their reactions with aralkyl halides.

2′,3′-*O*,*O*-(2,4-Dimethoxybenzylidene)uridine *(1a)* [3], dissolved in 1,2-dichloroethane, is treated with the stoichiometric amount of sodium ethoxide in ethanol. After removal of the solvent, the sodium salt *(1b)* is precipitated by addition of light petroleum. 3′,5′-*O*,*O*-Ditritylthymidine *(1c)* is converted into the sodium salt *(1d)* in a similar manner. The uridine N³ sodium salt *(1e)* precipitates from an ethanolic solution of uridine on addition of sodium ethoxide. The UV spectra of the sodium salts, recorded in absolute CH_2Cl_2 or $C_2H_4Cl_2$, agree with the spectra of the corresponding nucleosides and nucleoside derivatives in aqueous-alcoholic KOH (pH > 12): *(1b)*, $\lambda_{max} = 261$ nm, $\lambda_{min} = 246$ nm; *(1d)*, $\lambda_{max} = 264$ nm, $\lambda_{min} = 250$ nm; *(1e)*, $\lambda_{max} = 261$ nm, $\lambda_{min} = 242$ nm.

The reaction of pyrimidine nucleoside sodium salts with aralkyl halides *(2)* in inert, anhydrous solvents yields N³-aralkylated derivatives *(3)*, whose UV spectra no longer change on going from neutral to alkaline media. Substitution of the sugar alcohol group or removal of the protective groups does not occur under the above conditions. The reaction conditions and yields are given in the Table. As expected, the reaction is facilitated by electron-attracting *p*-substituents on the benzyl halide; the reactivity, and also the tendency to undergo side reactions, increases on going from chloride to iodide.

The sugar protective group is removed by treatment with 80% acetic acid. After 60–100 min at room temperature, *(3ba)*, *(3bb)*, *(3bc)*, and *(3bd)* give quantitative yields of the N³-aralkylated uridines. Removal of the trityl groups from *(3dc)* and *(3dd)* (two hours at 100 °C) gave 93% of *p*-nitrobenzylthymidine and 80% of *p*-bromobenzylthymidine respectively.

In contrast to techniques used previously for the aralkylation of pyrimidine nucleosides [4,5], in which predominantly or ex-

(1) (2) (3)

clusively the sugar component is substituted, the present method permits the preparation, in high yield, of pyrimidine nucleosides that are aralkylated at the base only.

Compound *(1b)* also reacts with chloromethylated polystyrene and thus makes possible the linkage of nucleotides and oligonucleotides with "Merrifield polymers"[6] *via* dimethoxybenzylideneuridine as phosphate-protecting group[7]. Studies on the use of this possible mode of linkage in the synthesis of oligonucleotides on carriers[8] are in progress.

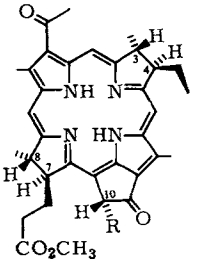
The Absolute Configuration of Bacteriochlorophyll-*a*[1] [**]

By *H. Brockmann jr.* and *Ingrid Kleber*[*]

We recently derived the absolute configuration (3*R*, 4*R*, 7*S*, 8*S*) for bacteriochlorophyll-*a*[2] and thus also for bacteriomethylpheophorbide-*a* *(1)*[1b]. In order to confirm unequivocally this configurational assignment two experiments remained to be carried out:



1. Direct comparison of the bis(*p*-bromophenacyl) 3-ethyl-2′ methylsuccinate *(4)* obtained by oxidative degradation of bacteriochlorophyll-*a* derivatives with an authentic sample[1b] of known absolute configuration[3].

	(1) R¹	R²	R³	R⁴	R⁵	(2)	R⁶	X	Solvent	Time (h)	*T* (°C)	Product [a]	Yield (%)[b]
(a)	H	*O,O*-(2,4-dimethoxybenzylidene)		H	H								
(b)	H	*O,O*-(2,4-dimethoxybenzylidene)		Na	H	*(a)*	H	Cl	CH_2Cl_2	72	90	*(3ba)*	52
									acetonitrile	48	90	*(3ba)*	80
						(a′)	H	Br	CH_2Cl_2	48	90	*(3ba)*	73
						(a″)	H	I	CH_2Cl_2	72	80	*(3ba)*	15
						(b)	Cl	Cl	acetonitrile	48	90	*(3bb)*	58
						(c)	NO_2	Br	acetonitrile	132	20	*(3bc)*	78

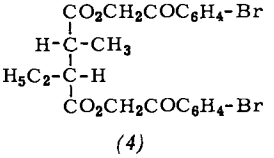
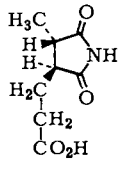
(e)	H	OH	OH	Na	H								



[a] R^1—R^6 as for *(1)* and *(2)*. [b] Products obtained analytically pure by preparative thin-layer chromatography and crystallization

2. Confirmation of the (7*S*, 8*S*) configuration of bacteriochlorophyll-*a*.



The latter follows from the identity of 3,4-dehydrobacteriochlorophyll-*a* derivatives[4–6] with compounds that are accessible from chlorophyll-*a*[7,8] whose (7*S*, 8*S*) configuration has been proved[9,10]. The proofs of identity used

(1), R = CO_2CH_3
(2), R = H
(3), R = H, double bond between C-3 and C-4

(4)

(5)

hitherto were based mainly on agreement of melting points, basicity, crystalline form, absorption spectra, and Debye-Scherrer photographs, whereas the values obtained for optical rotation agreed only qualitatively[5]. Moreover, the acidic, levorotatory oil obtained on oxidative degradation of bacteriochlorophyll-*a* could only be insufficiently characterized as (—)-*threo*-dihydrohematinimide *(5)*[5,6].

We have isolated bacteriochlorophyll-*a* from *Rhodospirillum rubrum* and thence prepared bacteriomethylpheophorbide-*a* *(1)*[11]. Oxidative degradation of *(1)* with CrO_3 in 25% H_2SO_4 (3 h at —10 °C[12]) and subsequent chromatography on silica gel with light petroleum (40—60 °C), ethyl acetate, isopropanol (44:5:1) afforded *threo*-3-ethyl-2-methylsuccin-

imide as a colorless oil ($[\alpha]_D^{20} = +57°$, $c = 1.2$ in chloroform) which yielded the ester *(4)* (m.p. 114–115 °C, $[\alpha]_D^{20} = -35 \pm 3°$, $c = 0.9$ in chloroform) on hydrolysis (3 hours' boiling with 5 N HCl) and subsequent esterification with *p*-bromophenacyl bromide. No depression of melting point was observed with a mixture of *(4)* with an authentic sample[1b], but such a depression was found with a mixture of *(4)* with *rac-(4)*. Optical rotation, chromatographic behavior, and IR spectrum (KBr)[13] of *(4)* were as for the authentic material.

Treatment of bacteriomethylpheophorbide-*a* *(1)* with tetrachloro-*o*-benzoquinone in benzene at 25 °C led to 3,4-dehydro compounds (absorption spectrum); the reaction is, however, accompanied by oxidation at C-10[14]. In order to avoid such oxidation we removed the methoxycarbonyl group from *(1)* by boiling it for 48 h in pyridine. The resulting bacteriopyromethylpheophorbide-*a* *(2)* reacted smoothly with tetrachloro-*o*-benzoquinone in benzene to give 2-acetyl-2-devinylpyromethylpheophorbide-*a* *(3)* whose physical properties (m.p., absorption spectrum, IR, NMR, mass spectrum), and particularly the ORD spectrum[15], all agreed with those of a sample prepared from chlorophyll-*a*[16].

Preparation of the Compounds $R_3El-Hg-ElR_3$ (El = C, Si, Ge, Sn) and their Synthetic Applications[1]

By *W. P. Neumann* and *U. Blaukat*[*]

The wide variety of reactions possible with R_3Si-Hg and R_3Ge-Hg bonds, *e.g.* additions[2,3], prompted an inquiry into the behavior of the analogous R_3C-Hg group.

The simplest bis(*tert*-alkyl)mercury compound $[(CH_3)_3C]_2Hg$[4] *(1)* is formed in a Grignard reaction at 0 °C in tetrahydrofuran and is obtained in 60% yield as colorless crystals [m.p. 56–58 °C, b.p. 80 °C/10^{-4} torr after purification by chromatography (neutral Al_2O_3; ether)]. It was characterized by elemental analysis as well as by its ^{1}H-NMR spectrum (τ 8.8, $J(^{199}Hg-CH_3) = 103.6$ Hz), and is homogeneous on gas chromatography, sensitive to air, and decomposes under argon at temperatures above 120 °C.

The reactivity of the C–Hg bonds in *(1)* is extremely high, exceeding that of such bonds in $(C_2H_5)_2Hg$[**]. We have investigated additions to, *e.g.*, $-N=N-$ or $-C\equiv C-$ groups (see Table 1): The mercury-containing adducts were identified, either immediately or after hydrolysis, by elemental analysis and by their IR and ^{1}H-NMR spectra; the *cis* or *trans* structures given were deduced from the NMR spectra.

Reaction of *(1)* and the hydrides R_3ElH (El = Si, Ge, Sn) in the absence of a solvent proceeds smoothly[6] to give the corresponding compounds $(R_3El)_2Hg$ (see Table 2).

$$[(CH_3)_3C]_2Hg + 2\ R_3ElH \rightarrow (R_3El)_2Hg + 2\ \text{iso-}C_4H_{10} \qquad (1)$$
(1)

Tin-mercury compounds containing aliphatic groups were previously inaccessible[7]; they generate stannyl radicals even at low temperatures and are therefore of significance for studies on radical reaction mechanisms[8].

Table 1. Addition of $[(CH_3)_3C]_2Hg$ to $-N=N-$ and $-C\equiv C-$ bonds.

Preparation of Dinitrodiazomethane by Nitration of Nitrodiazomethane

By *U. Schöllkopf* and *P. Markusch* [*]

During our studies on heterocarbenes our interest was attracted to dinitrocarbene because theory predicts that this species should be the most electrophilic of all carbenes [1]. Since photolysis and thermolysis are generally recognized as being the most reliable routes to carbenes we synthesized the unusual compound dinitrodiazomethane *(2)* by nitration of nitrodiazomethane *(1)* [2] with dinitrogen pentoxide [3].

(1) *(2)*

The colorless compound *(2)*, m.p. 65 °C (decomp.), explodes on impact, when heated rapidly, and on treatment with concentrated sulfuric acid [4]. Its characteristic IR bands (KBr) are observed at 2120 [5] (νN_2) and 1475 and 1315 cm^{-1} (ν_s and $\nu_{as}NO_2$, respectively).

Procedure:

9 ml (9.7 mmoles) of a 1.08 M solution of dinitrogen pentoxide in methylene chloride is added dropwise at −30 °C to a solution of 1.6 g (19 mmoles) of nitrodiazomethane [2] in 120 ml of methylene chloride over a period of 30 min. After four hours' stirring the solution is evaporated down to a volume of about 30 ml at room temperature in a vacuum. Dinitrodiazomethane crystallizes from the concentrated solution on standing for a few hours at −15 °C; yield 480 mg (42%).

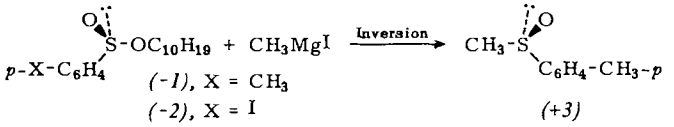
Stereochemical Course of Grignard Reactions at Asymmetric Sulfur [***]

By *H. Hope, U. de la Camp, G. D. Homer, A. W. Messing*, and *L. H. Sommer* [*]

Nucleophilic displacement of the alkoxy group from sulfur in a sulfinate provides a general route to sulfoxides *via* reaction with a Grignard reagent, and (−)-menthyl (−)-*p*-toluenesulfinate *(−1)* is an easily prepared diastereomeric precursor that gives optically active sulfoxides, $p\text{-}CH_3C_6H_4S^*OR$ [1, 2].



The most direct and rigorous solution of the problem of whether this Grignard synthesis proceeds with retention or inversion at asymmetric sulfur would be X-ray determinations of absolute configuration at sulfur in *(−1)* and in a derived, optically active sulfoxide. The first part of this task has already been substantially completed by an X-ray determination of absolute configuration at sulfur in (−)-menthyl (−)-*p*-iodobenzenesulfinate *(−2)*, which has the same configuration as *(−1)* [2, 3]. Considering, for nomenclature purposes, that the S—O bonds in *(−1)* and *(−2)* are single bonds, the configuration at sulfur was found to be (*S*) in both molecules.

We now wish to report the X-ray determination of the absolute configuration at sulfur in (+)-methyl *p*-tolyl sulfoxide *(+3)*, $[\alpha]_D = +145°$ (*c* = 1.1, acetone), derived from reaction of *(−1)*, $[\alpha]_D = -196°$ (*c* = 1.3, acetone), with CH_3MgBr.

Crystals of *(+3)* are orthorhombic, space group $P2_12_12_1$, with four molecules in the unit cell of dimensions a = 5.826 (6), b = 8.621 (8), and c = 16.433 (3) Å. Three-dimensional intensity data for one octant were collected with $Cu_{K\alpha}$ radiation with a Picker automatic diffractometer. The structure was solved by use of the sulfur as a heavy atom. The positional parameters for all atoms, together with anisotropic temperature parameters for the nonhydrogen atoms and isotropic ones for hydrogen, were refined by full-matrix least-squares methods. When anomalous scattering terms were included in the scattering factor of sulfur ($\Delta f_S' = 0.3$, $\Delta f_S'' = 0.6$) [4], and after correction for secondary extinction effects [5], the (*R*) configuration could be refined to a final *R* index of 3.4% whereas the lowest value of *R* for the (*S*) configuration was 4.4%. Application of *Hamilton*'s "R index test" [6] to these results indicates that the absolute configuration of *(+3)* is (*R*) to a significance level of better than 99.99% [7]. *Mislow* and co-workers have previously adduced

evidence based on ORD and CD data for *(−1)* and a variety of sulfoxides, including *(+3)*, which is in complete accord with our present finding of an (*R*) configuration for *(+3)*.

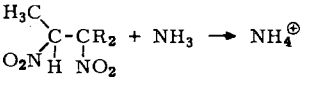
Thus, the evidence is now complete for rigorous formulation of the Grignard synthesis of optically active sulfoxides as proceeding with *inversion of configuration* at asymmetric sulfur.

On the basis of ORD and CD evidence for (+)-phenyl *p*-tolyl sulfoxide *(+4)*, *Mislow et al.*[2] have assigned the (*R*) configuration to this substance as derived from *(−1)* by an inversion path in the Grignard synthesis. We have extended this synthesis of *(+4)* to include organometallic reagents other than the Grignard (Table 1). It is of considerable interest that rather drastic changes in the nature of the organometallic reagent leave both the stereochemical path and the stereospecificity unchanged. In the case of methylmethoxy-α-naphthylphenylsilane, sensitivity of stereochemistry to the nature of the organometallic reagent has been demonstrated for nucleophilic displacement of methoxy.

Table 1. Phenyl *p*-tolyl sulfoxide from (−)-menthyl (−)-(*S*)-*p*-toluenesulfinate *(−1)* [a].

Reagent [b]	Sulfoxide, configuration	$[\alpha]_D$ in acetone (°)	M.p. (°C)	Yield (%)
C_6H_5MgBr	(*R*) − (+)	+21.2	90–92	73
$(C_6H_5)_2Zn$ [c]	(*R*) − (+)	+21.6	90–92	70
$(C_6H_5)_2Cd$ [c]	(*R*) − (+)	+21.6	90–92	68

[a] $[\alpha]_D = -198°$ (in acetone).
[b] C_6H_5Li metalates the benzylic protons in *(−1)*.
[c] The reactions were run in refluxing benzene for 16 hours.



Simple alkyl or aryl organometallic reagents (Grignards and RLi reagents) give *retention* of configuration, whereas charge-delocalized reagents such as $C_6H_5CH_2Li$ give *inversion* of configuration[8]. In the organosilicon stereochemistry of monofunctional R_3Si^*-systems, inversion and an S_N2–Si mechanism appear to be the most common, but many examples of retention reactions involving poor leaving groups are also known[9]. In organosulfur stereochemistry, nucleophilic displacement reactions at the asymmetric sulfur center appear, thus far, to involve only inversion of configuration[10].

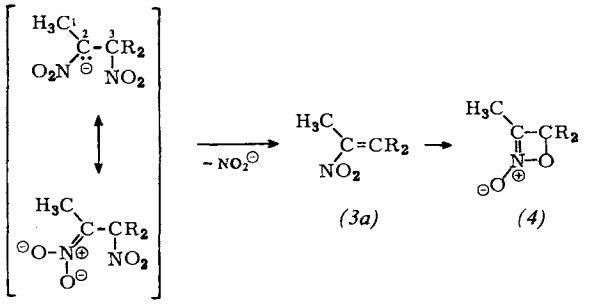
Isolation and Decomposition of the Intermediate of an ElcB Elimination

By *A. Berndt* [*]

ElcB reactions are two-step 1,2-eliminations; in the first step the conjugate base *(2)* is formed from the substrate *(1)*; in the second step *(2)* decomposes by way of a first order reaction to give the elimination product *(3)* and $X^{\ominus}$[1].



(1) *(2)* *(3)*

In all previous investigations, *(2)* occurred in such low concentration that its intermediary character could be detected only indirectly[2]. We have now been able to isolate the conjugate base of a 1,2-elimination in substance and investigate the kinetics of its decomposition in solution.

If a solution of *(1a)*[3] in ether is added with stirring to an ice-cooled saturated solution of NH_3 in ether, a yellowish-white precipitate separates after 5–10 minutes which is also insoluble in other aprotic organic solvents and in water. The substance can be recrystallized from methanol at temperatures below 0 °C. It melts at 85–90 °C. C, H, N analyses and the other experimental data support the structure of the ammonium salt of the conjugate base *(2a)* (ammonium 3-*tert*-butyl-4,4-dimethyl-2,3-dinitro-2-pentanide), which is obtained in almost quantitative yield. In methanol, the NH_4 salt of *(2a)* decomposes within a few minutes at 30 °C to give nitrite and the olefin *(3a)*, which cyclizes to 4,4-di-*tert*-butyl-3-methyl-4*H*-1,2-oxazete *N*-oxide *(4)*[4]. In the solid state the NH_4 salt of *(2a)* is transformed into *(4)* within a few weeks.

On shaking a suspension of the salt in chloroform with dilute mineral acid, products are obtained in which only the nitro group at C-3 is still present in the molecule[5]; this nitro group cleaves off as nitrite during the elimination. It is thus shown that *(2a)* still contains both nitro groups.

(2a) *(3a)* *(4)*

This finding is confirmed by the IR spectrum of the salt of *(2a)* (in Nujol) which shows, beside the band of the $NH_4^{\oplus}$ ion, two bands at 1510 and 1550 cm^{-1} in the region of the assymetric vibrations of nitro groups. The NMR spectrum (in CD_3OD at 10 °C) shows two singlets at δ = 2.18 and 1.37 ppm in the ratio 1:6.

The kinetics of decomposition of *(2a)* was studied by NMR spectroscopy (in CD_3OD between 20 and 33 °C). In all the cases investigated the results pointed to reactions of first order, the half-lives being between *ca.* 10 minutes at 20 °C and *ca.* 2 minutes at 30 °C. The activation energy of the decomposition proved to be 22 ± 5 kcal/mole.

The unusual stability of the ammonium salt of *(2a)* must be due to steric hindrance; no intermediate can be isolated in the case of 2-*tert*-butyl-3,3-dimethyl-1,2-dinitrobutane, which contains only one methyl group less than *(1a)*.

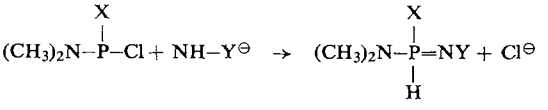
The Prototropic System Aminophosphine/Iminophosphorane[1]

By *A. Schmidpeter* and *H. Rossknecht* [*]

Although hydroxyphosphines as such are, with very few exceptions, unstable and rearrange to phosphine oxides with transference of the proton onto the phosphorus, quite the reverse is the rule in the case of aminophosphines (phosphazanes) *(1)*. Phosphazanes are always present as such and no proton migration from nitrogen to phosphorus takes place — not even in the sense of an equilibrium[2]: Accordingly (P)H-iminophosphoranes (phosphazenes) also could not be prepared; they rearrange spontaneously to the tautomeric (N)H-aminophosphines *(1)* [3,4,5].



(1) *(2)* *(3)* *(4)*

Previously, the sole exception to this rule were compounds in which the phosphazene grouping *(2)* is part of a cyclotriphosphazene ring *(3)* or triazaphosphorine ring *(4)* [6].

Is the (P)H form possible only as a part of such a ring system or may it not be achieved even in simple, open-chain compounds by suitable substituent effects? Substituents X capable of increasing the basicity at the P atom and substituents Y capable of increasing the acidity at the N atom should favor the bonding of the proton to the phosphorus *i.e.* favor structure *(2)*; on the other hand, however, they should also weaken the phosphazene bond and the stability of *(2)*.

A compound in which X = NR_2 and Y = SO_2R would represent a typical case in this connection. Such a compound can be prepared from the aminochlorophosphine *(5)*, X = $N(CH_3)_2$, and the sodium salt of *p*-toluenesulfonamide *(6)*, Y = $SO_2C_6H_4CH_3$. Adverse secondary reactions can be avoided by keeping the concentration of *(5)* very low. The product is a colorless, viscous liquid that does not react with sulfur in boiling benzene as would be expected for an aminophosphine *(1)*. The IR spectrum shows the characteristic absorptions of the P—H- and P=N-vibrations (Table) and thus substantiates the phosphazene structure *(2)*. The most convincing evidence for structure *(7)*, however, is provided by the large doublet splitting of the NMR signals of the single proton and of the phosphorus.

(5) *(6)* *(7)*

A similar result is obtained in the reaction of *(5)* with the potassium salt of diphenylthiophosphoric, diphenylphosphinic, or diphenylthiophosphinic acid amide *(6)*, Y = $PS(OC_6H_5)_2$, $PO(C_6H_5)_2$, $PS(C_6H_5)_2$, if it is carried out at −70 °C, thus avoiding side-reactions. The (P)H-iminophosphorane *(7)* is formed in each case. The values νPH and J_{PH} for the compounds *(7b–d)* obtained from the above mentioned series of amides change proportionally [7] and decrease both with decreasing acidity of the amide.

[a] Measured in CH_2Cl_2 against 85% phosphoric acid (external) or TMS (internal); shifts to lower field strengths negative.
[b] Signal or signal components broadened by splitting, multiplet structure not (clearly) recognizable.
[c] Indirect, not measurable directly because of superposition.
[d] Not measurable because of superposition.
[e] We are grateful to Dipl.-Chem. *K. Schumann* for recording the ^{31}P—NMR spectra.

The reaction is more sensitive to variation of X than to variation of Y: with dimethylaminomethylchlorophosphine *(5)*, X = CH_3, iminophosphorane *(7e)* is still the only product formed; with dimethylchlorophosphine, the (P)H-iminophosphorane can also be detected spectroscopically in the reaction product; however, it is not stable enough to avoid entering into secondary reactions. Finally, the corresponding diphenyl compounds (with Y = $SO_2C_6H_4CH_3$[8] and $PO(C_6H_5)_2$[4]) are described only as aminophosphines *(1)*. In the equilibrium *(1)* ⇌ *(2)* the tendency to form *(2)* increases in the series X = C_6H_5, CH_3, $N(CH_3)_2$.

Experimental:

A solution of chlorophosphine *(5)* (10 mmoles) in methylene chloride or ether (100 ml) is added dropwise over a period of one hour at −70 °C and with vigorous stirring to a suspension of the sodium or potassium acid amide *(6)* (10 mmoles) in the same solvent (100 ml). The reaction mixture is then filtered under nitrogen at room temperature to remove precipitated alkali metal chloride and the solvent is subsequently removed from the filtrate by evaporation under vacuum at 20 °C.

Two New Products of Ammonolysis of Phosphorus Pentachloride $[P(NH_2)_4]Cl$ and $[P(NPCl_3)_4]Cl$[1]

By *A. Schmidpeter* and *C. Weingand*[*]

It has recently been reported[3] that triaminophosphoranylideneaminotriaminophosphonium chloride *(2)*, X = Cl, was obtained from the much investigated reaction of PCl_5 with NH_3[2].

$$PCl_5 + 8\ NH_3 \rightarrow \left[H_2N\text{-}P(NH_2)_2\text{-}NH_2 \right]^+ Cl^- + 4\ NH_4Cl$$

(1)

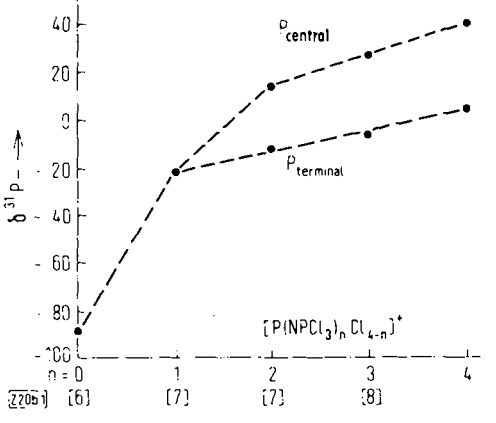
This represents the lowest condensation product so far obtained from PCl_5 and NH_3; the expected and long sought for uncondensed substitution product *(1)* was not isolable. We have been able to prepare the tetraaminophosphonium iodide *(1)*, I instead of Cl, $\delta^{31}P$ (H_2O) = −31.6 ppm (H_3PO_4), by an indirect route[4] and have found that it is remarkably stable towards heat but readily condenses in the presence of bases.

On re-examination of the reaction of PCl_5 with liquid NH_3 it has now been shown that actually only *(1)*, $\delta^{31}P$ (H_2O) = 28.4 ppm[10], is formed first and condenses during working up with diethylamine/chloroform, according to the method

$$2\left[H_2N\text{-}P(NH_2)_2\text{-}NH_2 \right]^+ X^- + B \rightarrow$$

$$\left[H_2N\text{-}P(NH_2)=N\text{-}P(NH_2)_2\text{-}NH_2 \right]^+ X^- + NH_3 + BHX$$

(2)



of *Klement* and *Koch*[5], to give *(2)*, X = Cl, $\delta^{31}P$ (H_2O) = −15.5 ppm (ref.[3] (CH_3OH or NH_3): −15.6 ppm). If, however, NH_4Cl is removed from the reaction product by sublimation in vacuum at 150 °C and the residue is extracted with methanol, pure *(1)* can be obtained.

If carried out in one stage, the ammonolysis of PCl_5 affords linear or cyclic phosphazenes, each phosphorus atom contributing only one or two of its four coordination sites bonds; the phosphazenes thus formed are consequently unbranched. Furthermore, branching condensation is avoided at lower NH_3/PCl_5 ratios by deficiency of PNH_2 functions and at higher NH_3/PCl_5 ratios by shortage of PCl functions[2]. On the other hand, chain branching should be achieved by successive reactions with NH_3 and PCl_5 in excess. Thus, the first doubly branched open-chain phosphazene *(3)* was obtained from *(1)* by reaction with PCl_5.

$$(1) + 4\ PCl_5 \rightarrow \left[Cl_2P(NPCl_2)_2NPCl_3 \right]^+ Cl^- + 8\ HCl$$

(3)

With this cation, which we call neo-$[P_5N_4Cl_{12}]^+$ in order to differentiate it from its isomers by analogy with neopentane, one can also prepare the hexachloroantimonate, from *(3)* and $SbCl_5$, the dichloroiodate [$\delta^{31}P$ (C_2Cl_4) = +3.4 ppm (doublet), +38.5 ppm (quintet); J_{PNP} = 29.9 Hz], from tetraaminophosphonium iodide and phosphorus pentachloride, as well as the triiodomercurate [$\delta^{31}P$ ($C_6H_5NO_2$) = +4.1 ppm (doublet), +39.3 ppm (quintet); J_{PNP} = 28.7 Hz]. Its ^{31}P-NMR spectrum[**] shows the characteristic set of peaks (as such, not previously observed) of an AB_4 spin system (J/ν_0 = 0.02) and thus affords evidence for the symmetrical structure. The large shifts correspond to the considerable increase with n of all $\delta^{31}P$ values of the cations $[P(NPCl_3)_n\ Cl_{4-n}]^+$; *(3)* completes this series with n = 4. $\delta^{31}P$ (terminal) reveals the additive dependence of the substituents on the neighboring phosphorus atoms in PNP systems[9].

Tetraaminophosphonium chloride (1)

PCl_5 is added portionwise with vigorous stirring to liquid NH_3 at −70 °C. An almost clear solution is obtained which yields a white powder when the NH_3 is evaporated off. The weight of the final precipitate reveals that 8 moles of NH_3 have been taken up for each mole of PCl_5. The product is kept at 150—155 °C and at 5×10^{-3} torr for 30 hours whence 4 moles NH_4Cl/mole PCl_5 sublimes off. The residue is taken up in anhydrous methanol and the resulting solution is filtered off and treated with an equal volume of ether. *(1)* precipitates as fine crystals, which are immediately separated off and dried. About 3 g of *(1)* dissolves in 100 ml CH_3OH. Yield 46%. *(1)* decomposes without melting at 200 °C.

Tetrakis(trichlorophosphazo)phosphonium-chloride (3) and -dichloroiodate

A suspension of *(1)* and PCl_5 (molar ratio 1:4) in $CHCl_3$ is prepared and heated under reflux. Liberation of HCl is complete after 3 hours. *(3)* can be reprecipitated from C_2Cl_4 with CCl_4. The salt having ICl_2^- in place of Cl^- can be obtained as large pale yellow crystals from $[P(NH_2)_4]I$ and PCl_5 (molar ratio 1:5); it is much more readily soluble than *(3)*.

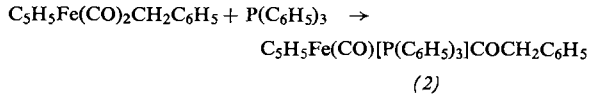
Magnetic Non-equivalence of Methylene Protons and *gem*-Methyl Groups in Asymmetric Iron Complexes

By *H. Brunner* and *E. Schmidt* [*]

After separation of diastereoisomeric compounds containing an asymmetric Mn atom [1] we have been able to demonstrate asymmetric metallic centers also by ^1H-NMR spectroscopy.

The protons of methylene or *gem*-methyl groups in compounds of the "ethane type" are magnetically non-equivalent if these groups are attached to an optically active center [2]. The non-equivalence arises because the H atoms or CH_3 groups are in different surroundings, no matter what the conformation, because of the symmetry at the neighboring atom. Further, the magnetic non-equivalence is not destroyed by rapid rotation.

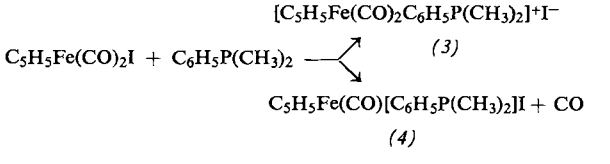
In the reaction of dicarbonylcyclopentadienylmethyliron(II) with dimethyl(phenyl)phosphine in boiling THF the methyl



(1)

group migrates from the Fe atom to one of the carbonyl ligands [3] so that a compound of the "ethane type" is formed with two *gem*-methyl groups on P and an asymmetric center at the Fe atom.

The orange-yellow crystals of *(1)* give a solution of monomer in benzene. In the KBr spectrum the band of the metal-CO group occurs at 1894 cm^{-1} and that of the acetyl-CO group at 1597 cm^{-1}. In the ^1H-NMR spectrum (see Figure and Table) the signals of the phenyl protons of the phosphine, of the cyclopentadienyl protons, and the protons of the acetyl group are accompanied by four signals that are to be assigned to the two non-equivalent methyl groups. If the spectrum is recorded at 100 MHz instead of at 60 MHz the inner and the outer pairs of signals become further apart from each other, this fact being of decisive importance in the assignment. At higher temperatures the separation of the two doublets decreases, and at lower temperatures increases. These shifts are to be ascribed to differing population of the three staggered conformations, which are energetically different; thus increasing temperature should decrease the differences in population. At −100 °C the methyl signals become broader; separation into the signals of the three different conformations is thus to be expected at a still lower temperature.



An orange-yellow complex *(2)* prepared as follows:

(2)

has in its KBr spectrum the metal-CO vibration at 1912 cm^{-1}, the CO vibration of the phenylacetyl group at 1603 cm^{-1}. In *(2)* the methylene group is separated from the asymmetry center on the Fe atom by a CO group; in spite of this a clearly split AB system is observed for the two non-equivalent methylene protons H^1 and H^2 (cf. Table).

$C_6H_5P(CH_3)_2$ reacts with $C_5H_5Fe(CO)_2I$ thus:

(3) *(4)*

with formation of an ionic compound *(3)* and a neutral complex *(4)* [4].

In its IR spectrum the yellow salt *(3)* shows two CO bands at 2110 and 1996 cm^{-1}. Since the complex cation has a symmetry plane the two *gem*-methyl groups on the P atom are magnetically equivalent, so that only a doublet is observed in the ^1H-NMR spectrum (cf. Table). However, in the green complex *(4)* (ν_{CO} = 1946 cm^{-1}) the Fe atom is attached to four different ligands, wherefore the ^1H-NMR spectrum contains two doublets for the pair of non-equivalent methyl groups (see Table). The intensity ratios of the signals in all the ^1H-NMR spectra are in accord with the formulas given here.

Table: ^{1}H-NMR spectra of the complexes *(1)*—*(4)*; chemical shifts in τ (TMS as internal standard), and coupling constants J in Hz; *(1)*, *(2)*, and *(4)* in CS_2, *(3)* in CD_3COCD_3 solution.

Figure: ^{1}H-NMR spectrum of $C_5H_5Fe(CO)(COCH_3)C_6H_5P(CH_3)_2$ in CS_2-solution.

Magnetic non-equivalence of methylene protons or of *gem*-methyl groups attached to asymmetric centers has been often demonstrated for organic compounds and for compounds of elements of the main groups [2]; among transition metals this effect was used to explain the complex ^{19}F-NMR spectrum of $C_5H_5Co(CO)(C_2F_5)_2I$ [5]. Further, magnetic non-equivalence has been demonstrated during determination of the configuration of multi-substituted octahedral complexes [6,7].

In the communication "Preparation of Cyclic Amidines by Reduction of Dinitriles with $LiAlH_4$" by *H. U. Sieveking* and *W. Lüttke*, Volume 8, June 1969, p. 457 (Angew. Chem. *81*, 431 (1969)) the following correction should be made:

The numbers *(2b)* and *(2d)* in Scheme 1 should read *(1b)* and *(1d)*.

CONFERENCE REPORTS

Oligomeric and Polymeric Nitrogen-Phosphorus Compounds: New Aspects of Plant Nutrition

By *W. Waněk*

The trend in the development of industrial fertilizers has been toward higher nutrient contents. This trend has resulted from technical developments and leads *e.g.* in the case of phosphate fertilizers from decomposition of the crude phosphate with sulfuric acid, *via* decomposition with nitric acid, to decomposition with phosphoric acid as well as to the preparation of phosphates and polyphosphates (nutrient content: product of H_2SO_4 decomposition *ca.* 17% P_2O_5; product of HNO_3 decomposition 33—40% P_2O_5N; ammonium phosphate and ammonium polyphosphate *ca.* 80% P_2O_5N). Criteria for "ideal fertilizers" were worked out as a basis for research work on future fertilizers: highest nutrition coefficient: no complex formation with soil micelles (retrogradation, particularly of phosphates); adequate sorption in soil (elutriation *e.g.* of nitrate ions); ready assimilation by plants; little or no ion formation in the soil-(nutrient) solution (shift of the plasmolysis boundary to higher nutrient values); controllable release of biogenic elements in the soil solution.

Experiments with fully or partially covalent nitrogen-phosphorus compounds [$(NH_4)HPO_3NH_2$, $NH_4PO_2(NH_2)_2$, $OP(NH_2)_3$, $[NP(NH_2)_2]_3$, $[NP(NH_2)_2]_4$, $[NH_4PO_2NH]_3$] showed that they are better fertilizers than $(NH_4)_2HPO_4$.

Laboratory experiments *inter alia* on oats and barley showed that these covalent compounds are taken up by plants more rapidly than are the pure ionic compounds; furthermore they do not retrograde in soils and plasmolysis phenomena occur only at higher concentrations. Crops 25—35% higher than with $(NH_4)_2HPO_4$ could be achieved in experiments carried and in vessels according to the method of *Mitscherlich*.

Recent Investigations on Chlorophylls

By *K. Ballschmiter* [*]

The coordinative properties of the central magnesium atom play a much greater role in intermolecular interactions of chlorophylls than was previously assumed, the coordination number 5 being preferred over 6 [1]. The coordinatively unsaturated magnesium is saturated by molecules of the solvent acting as axial ligands in polar solvents. If a solvent, such as benzene or carbon tetrachloride, is unable to function as a

ligand, the keto group in ring V of a further molecule of chlorophyll-*a* *(1)* enters into coordinative interaction with the magnesium atom[2].

(1)

Molecular-weight determinations show that the dimers, contrary to widespread belief, do not dissociate at higher temperatures (65 °C)[3]. Electronic spectra show that no significant dissociation occurs[4], even in highly dilute solutions (10^{-6} M) in carbon tetrachloride at 23 °C when all polar impurities have been removed — water being the most likely such impurity.

Anhydrous chlorophyll-*a* is readily soluble in aliphatic hydrocarbons such as cyclohexane, *n*-hexane, and hexadecane[5]; solutions can be prepared having concentrations up to 10^{-1} mole/l. IR spectroscopic investigations[6] and molecular-weight determinations[3] show that in these solvents the chlorophyll-*a* dimers combine to form larger aggregates; the highest value measured for *n* in $(Chl_2)_n$ was 12 for a 10^{-1} M solution in *n*-hexane at 25 °C. The aggregation proceeds *via* a new coordination of the magnesium with the free keto groups in ring V. The oligomer C=O/Mg band is shifted toward lower energies compared to the dimer C=O/Mg band in the IR spectrum.

When prepared by the usual methods, which involve precipitation from light petroleum in the presence of water as the last step, chlorophyll-*a* is obtained as the monohydrate[5]. The spectral and other physical properties of the monohydrate are fundamentally different from those of anhydrous chlorophyll-*a*. Water represents an essential structural component of crystalline chlorophyll-*a* and -*b*; in chlorophyll-*a* it is coordinated to the magnesium and is also involved in a hydrogen bond to the keto group in ring V of the neighboring chlorophyll molecule, Mg · · OH_2 · · O=C[6]. This arrangement is retained in aliphatic hydrocarbons.

The specificity of the structure of chlorophyll-*a* with regard to the C=O/Mg and C=O/H_2O/Mg interactions described above has been demonstrated by investigations on pyrochlorophyll-*a*, chlorophyll-*b*, bacteriochlorophyll, and pheophytin-*a*; in all cases deviations from the behavior of chlorophyll-*a* were observed[3,5,6].

Information on the molecular interactions of chlorophylls *in vitro* permit conclusions to be drawn regarding the state of chorophyll *in vivo*[7].

Lecture at Mainz on June 26, 1969 [VB 209 IE]

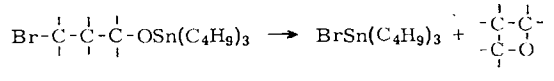
SELECTED ABSTRACTS

The preparation and properties of californium(III) compounds has been reported on by *J. C. Copeland* and *B. B. Cunningham*. Californium(III) oxychloride, CfOCl was prepared by three different methods: from Cf_2O_3 in a HCl/H_2O mixture at 505 °C; by pyrolysis of $CfCl_3 \cdot x\ H_2O$ in H_2 atmosphere at 555–585 °C; and by vacuum pyrolysis of $CfCl_3 \cdot xH_2O$ at 450 °C. The californium oxychloride prepared by each of these three methods crystallizes tetragonally and has the PbFCl type structure with a = 3.956 and c = 6.662 Å. In a N_2/water vapor stream at 500–638 °C, CfOCl reacts to give the cubic (C) modification of californium sesquioxide, which can also be obtained by reaction of the oxychloride in a stream of O_2 at 730 °C. C-Cf_2O_3 crystallizes with a Mn_2O_3 type structure in which a = 10.84 Å. In an O_2 stream partial oxidation to higher Cf oxides takes place; this is recognizable by a reduction of the lattice constant to a = 10.809 Å. / J. inorg. nuclear Chem. *31*, 733 (1969) / –FW. [Rd 45 IE]

The radiation damage in oriented polytetrafluoroethylene caused by a pulsed electron beam has been investigated by *N. R. Lerner* by means of ESR. The orientation (by stretching) of the samples when material is irradiated in air makes it possible to distinguish two ESR signals; the relative intensities of the two signals vary as a function of the radiation dose. When large doses are used the signal ascribable to a $-CF_2-(CF-O-O\cdot)-CF_2$ group predominates; with small doses, the signal due to the $-CF_2-O-O\cdot$ group has the greater intensity. The precursors of these groups, *i.e.* $-CF_2-(CF\cdot)-CF_2$ and $-CF_2\cdot$, are observable if the irradiation is carried out in vacuum. / J. chem. Physics *50*, 2902 (1969) / –Hz. [Rd 41 IE]

The Raman spectra of melts of $InCl_3$ and LiCl, KCl, or CsCl in the temperature range 400–700 °C have been investigated by *J. H. R. Clarke* and *R. E. Hester*. Equimolar mixtures of $InCl_3$ and each of the other three salts give essentially the same spectrum, which can be ascribed to the tetrahedral ion $InCl_4^-$. Further addition of KCl or CsCl gives rise to changes in the spectrum which are indicative of formation of $InCl_5^{2-}$ and $InCl_6^{3-}$; with an excess of LiCl, however, $InCl_4^-$ remains the principal product. / J. chem. Physics *50*, 3106 (1969) / –Hz. [Rd 42 IE]



The formation of linear polycyclic diquinones by a new dimerization reaction has been reported by *I. Baxter*, *D. W. Cameron*, and *R. B. Titman*. A few 2-methyl-1,4-quinones dimerize in the presence of *N*-methylcyclohexylamine in ethanolic solution. 2-Methyl-, 3-bromo-2-methyl-, and 3-chloro-2-methyl-1,4-naphthoquinones afford the pentacenediquinone *(1)* (m.p. > 350 °C, pale yellow) in 15% yield on standing for 24 h. 2-Methyl-1,4-anthraquinone gives analogously the 6,8,15,17-heptacenediquinone (golden yellow) in 24% yield.

(1)

After five days' reaction, the red 7,9,18,20-nonacenequinone can be obtained in 35% yield from 2-methyl-1,4-naphthacenequinone. / Chem. Commun. *1969*, 563 / —Ma. [Rd 46 IE]

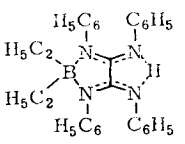
A new method for the synthesis of oxetanes has been reported by *B. Delmond, J. C. Pommier*, and *J. Valade*. Whereas 3-bromopropoxytributyltin is stable, the substituted homologs *(1)* form oxetanes *(2)* in quantitative yields on heating to *ca.* 170 °C. *(1)* can be obtained from ethoxytributyltin by transalkoxylation with 3-bromopropanols. The oxetane is formed

(1) *(2)*

in 80—90% yield; no by-products are formed. For example: 3-bromo-2-methylpropanol → 3-methyloxetane, 85%; 2-ethyl-3-bromopropanol, 85%; 3-bromo-2,2-dimethyl-propanol, 90%; 3-bromo-2-phenylpropanol, 90%; 3-bromobutan-2-ol, 80%. / Tetrahedron Letters *1969*, 2089 / —Ma. [Rd 49 IE]

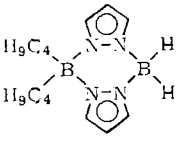
A rhodium complex containing CO_2 ligands, *(2)*, has been obtained by *Y. Iwashita* and *A. Hayata* by oxidation of the rhodium(0) complex *(1)* with O_2 in aromatic solvents. Complex *(1)* was prepared from $Rh_4(CO)_{12}$ and $P(C_6H_5)_3$.

$$Rh_2(CO)_4[P(C_6H_5)_3]_4 + O_2 \rightarrow$$



(1) $Rh_2(CO)_2(CO_2)[P(C_6H_5)_3]_3 + CO + O{=}P(C_6H_5)_3$ *(2)*

When the oxidation of *(1)* was carried out with $^{18}O_2$, the CO_2 in complex *(2)* consisted of $^{16}O{=}C{=}^{16}O$, $^{18}O{=}C{=}^{16}O$, and $^{18}O{=}C{=}^{18}O$ in the ratio 1:2:1. ^{16}O- and ^{18}O-triphenyl oxide are formed in the ratio 1:1. These results suggest an intermediate containing four symmetrically arranged oxygen atoms and two symmetrically arranged carbon atoms. The moderately stable yellow complex *(2)*, which still contains solvent (*e.g.* one C_6H_6), decomposes at 118 °C in the presence of oxygen but does not melt below 150 °C in an inert gas. According to the IR spectrum the CO_2 group is angled. / J. Amer. chem. Soc. *91*, 2525 (1969) / —Kr. [Rd 64 IE]



A new group of borylating agents, boryl sulfonates, has been described by *S. Trofimenko*. Dialkylboryl sulfonates *(1)*, the first example of compounds having an RSO_3 group bound to a boron atom, are readily obtained in a one-step synthesis by heating equimolar amounts of trialkylboranes with aromatic or aliphatic sulfonic acids, such as methanesulfonic acid, *p*-toluenesulfonic acid, mesitylenesulfonic acid, *m*- and *p*-nitrobenzenesulfonic acid, *p*-chlorosulfonic acid, and 4,4'-diphenylsulfonic acid, with loss of one equivalent of alkane. Reaction with sulfuric acid yields bis(dialkylboryl) sulfate. Diethylboryl methanesulfonate, b.p. 70—73 °C/2.5 torr, is a pyrophoric liquid. All compounds *(1)* are soluble in aromatic hydrocarbons.

$$R'SO_3H + BR_3 \longrightarrow \underset{(1)}{RH + R'SO_3BR_2} \xrightarrow{Z^-} \underset{(2)}{ZBR_2 + R'SO_3^-}$$

Reactions of *(1)* with nucleophilic compounds afford the borylated derivatives ZBR_2 *(2)*. The reactivity of *(1)* is very similar to that of the difficulty accessible dialkylboryl halides. As examples of syntheses with *(1)* may be quoted the preparation of *N*-(diethylboryl)-*sym*-tetraphenyloxamidine *(3)* from $CH_3SO_3B(C_2H_5)_2$ and the Na salt of *sym*-tetraphenyloxamidine (74% yield) and compound *(4)* from $CH_3SO_3B(C_4H_9)_2$ and $KH_2B(1\text{-pyrazolyl})_2$. / J. Amer. chem. Soc. *91*, 2139 (1969) / —Ma. [Rd 51 IE]

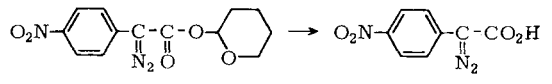
(4)

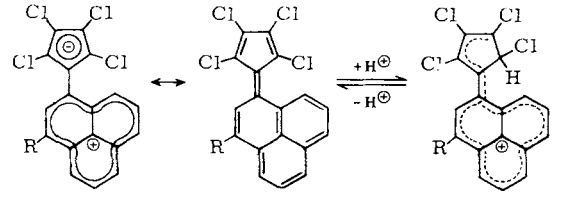
The adsorption of hexafluorobenzene on graphitized carbon black has been studied by *C. Pierce*. It may be deduced from the course of the adsorption isotherm that at low surface occupation six-carbon aromatic rings are adsorbed onto fixed sites at certain positions of the graphite lattice. At higher occupations, a change in the curvature of the isotherm indicates a different heat of adsorption and a transition to mobile adsorption until a tightly packed first layer has formed. Taking a value of 47.2 Å² for the adsorption cross-section of benzene on graphite, that of C_6F_6 is found to be 70 Å² for localized adsorption and 55 Å² for mobile adsorption. — The value of 16.2 Å² generally assumed for the cross-section of nitrogen is correct for a close-packed monolayer; for an apparent monolayer of nitrogen on graphite the effective area is 19.3 Å². BET surface areas of graphite should therefore be increased by a corresponding factor. / J. physic. Chem. *73*, 813 (1969) / —Hz. [Rd 67 IE]



The ESR spectrum of irradiated chlorophyll (Chl) has been investigated under various conditions by *M. Garcia-Morin, R. A. Uphaus, J. R. Norris*, and *J. J. Katz*. Chlorophyll containing no water or oxygen gives no ESR signal in the dark or on irradiation with red light (600—900 nm). Chlorophyll-water micelles, such as are formed in aliphatic hydrocarbons, give a sharp, reversible signal (*i.e.* one that disappears in the dark) on irradiation with red light, which can be explained by delocalization of an electron in the micelle. Under conditions unfavorable for micelle formation, *e.g.* in benzene solution, photooxidation, which is evidenced by a broad, irreversible signal, proceeds much more rapidly than in the presence of micelles. A primary photoproduct of structure *(1)* is proposed in order to explain the experimental findings; it can

(1)

be regarded as precursor of the radical ions $Chl^{\ominus}$ and $Chl^{\oplus}$ which are responsible for the reduction of CO_2 and the oxidation of H_2O during photosynthesis. / J. physic. Chem. *73*, 1066 (1969) / —Hz. [Rd 54 IE]

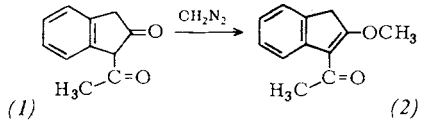


The preparation of a free α-diazocarboxylic acid has been accomplished for the first time by *K. Schank*. Transesterification of tetrahydropyranyl *p*-nitrophenyldiazoacetate *(1)* with glacial acetic acid in the presence of *p*-toluenesulfonic acid with ice-cooling gave 4-nitrophenyldiazoacetic acid *(2)*, m.p.

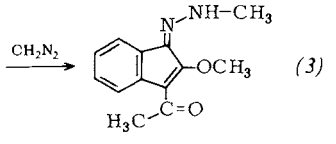
(1) (2)

125 °C (decomp.) in 77% yield. The constitution of the stable acid was confirmed by the IR spectrum and by conversion into the methyl ester. / Liebigs Ann. Chem. *723*, 205 (1969) / —Ma. [Rd 55 IE]

2-Ethoxy-9,10,11,12-tetrachloropentaphenafulvalene, *(2)*, the first derivative of the hitherto unknown pentaphenafulvalene, has been prepared by *I. Murata, I. Nakazawa,* and *M. Okazaki.* The compound was obtained in the form of dark blue needle-shaped crystals (recrystallized from benzene, m.p. > 250 °C) by reaction of ethoxyphenalenium tetrafluoroborate with sodium tetrachlorocyclopentadienide. The weak base *(2)* dissolves reversibly in 80% sulfuric acid to form the red cation *(3)*. (The position shown for the proton has not



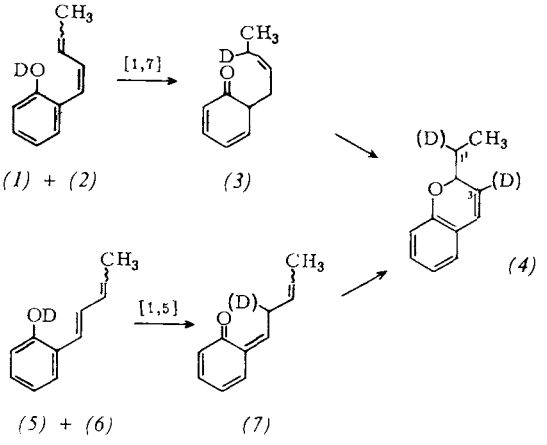
(1) (2) (3)



R = C_2H_5O

yet been confirmed unequivocally.) Dipole moment and the NMR spectrum indicate that a dipolar resonance structure such as *(1)* makes a significant contribution to the ground state of *(2)*. Such a contribution is in agreement with HMO calculations on unsubstituted pentaphenafulvalene. / Tetrahedron Letters *1969*, 1921 / — Kr. [Rd 56 IE]

A novel reaction of diazomethane has been observed by *K. Hartke* and *W. Uhde,* who obtained, *inter alia,* 3-acetyl-2-methoxy-1-indenonehydrazone *(3)* (red needle-shaped crystals from cyclohexane; m.p. 120—121 °C, yield 83%) from 1-acetyl-2-indanone *(1) via* 3-acetyl-2-methoxyindene *(2)*. The

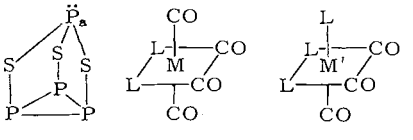


(1) (2)

(3)

result of this reaction corresponds to the coupling of aromatic diazonium salts with CH acidic compounds to give arylhydrazones. 3-Acetyl-2-ethylthio- and 3-acetyl-2-morpholinoindene also form methylhydrazones with diazomethane. / Tetrahedron Letters *1969*, 1967 / —Kr. [Rd 57 IE]

Aromatic [1,7]- and [1,5]-sigmatropic H shifts are the subject of a report by *R. Hug, H.-J. Hanser,* and *H. Schmid.* These authors studied mixtures of isomers that are obtained on reaction of the sodium salt of salicylaldehyde with crotyltriphenylphosphonium bromide (*trans*/*cis* mixture). [*(1)* + *(2)*] = *cis,trans-* + *cis,cis-o*-(1,3-pentadienyl)phenol (7:3) is converted quantitatively into 2-ethyl-2*H*-chromene *(4)* at 121 °C in octane (20 h). [*(5)* + *(6)*] = *trans,trans-* + *trans,cis-o*-(1,3-pentadienyl)phenol gives the same product but only at or

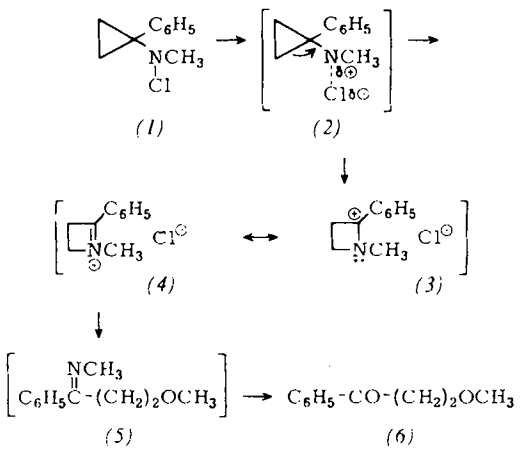


(1) + (2) (3) (4)

(5) + (6) (7)

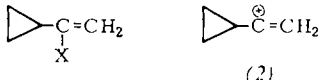
above 190 °C. Deuterium labeling of the phenolic H atom showed that [*(1)* + *(2)*] is transformed into [1'-D]-*(4)* by a [1,7]-sigmatropic H shift *via (3)*. [*(5)* + *(6)*] affords a compound *(4)* having 0.5 D on C-1' and 0.4 D on C-3, which is formed by [1,5]-sigmatropic H shift *via (7)* or by fast H/D exchange at O and subsequent [1,7]-sigmatropic shift. The 1,3-butadienyl derivatives react in a similar manner. / Chimia *23*, 108 (1969) / —Kr. [Rd 58 IE]

Transition-metal complexes of tetraphosphorus trisulfide *(1)* have been described by *R. Jefferson, H. F. Klein,* and *J. F. Nixon.* $C_7H_8M(CO)_4$ (M = Cr, Mo, W) and $C_7H_8M'(CO)_3$ (M' = Cr, Mo) react with P_4S_3 in boiling CS_2 to give the orange-yellow complexes *cis*-$(P_4S_3)_2M(CO)_4$ *(2)* and *cis*-$(P_4S_3)_3M'(CO)_3$ *(3)*, respectively. Compound *(2)*, M = Mo, reacts with PF_3 to give a poor yield of *cis*-$(PF_3)_2$-$Mo(CO)_4$, but remains unchanged when heated with a small amount of sulfur. P_4S_7 is formed only in the presence of a



(1) = L (2) (3)

large excess of sulfur. The nickel(0) complex, $Ni(P_4S_3)_4$, is formed on reaction of bis(π-allyl)nickel with P_4S_3 or from nickelocene. The coordination of P_a to the transition metal atom in these compounds was established by NMR spectroscopy. / Chem. Commun. *1969*, 536 / —Kr. [Rd 59 IE]



The position of the inner H atoms in phthalocyanin has been established by *B. F. Hoskins* and *S. A. Mason* with the aid of neutron diffraction. They found that these H atoms lie in the plane of the "large ring" — the phthalocyanin skeleton is planar within the limits of experimental accuracy — and that on average 1/2 H is bonded to each of the four pyrrole N atoms. Thus the bonding is similar to that in two porphine structures. The four "half H atoms" lie very close to the connecting line between the centrosymmetric pyrrole N atoms. / Chem. Commun. *1969*, 554 / —Kr. [Rd 60 IE]

***N*-Methyl-1-phenylcyclopropylnitrenium chloride** *(2)*, a nitrogen analog of the cyclopropylmethyl compounds, has been obtained, by *P. G. Gassman* and *A. Carrasquillo,* as an intermediate during the heterolytic cleavage of *N*-chloro-*N*-methyl-1-phenylcyclopropylamine *(1)*, which yields β-methoxypropiophenone *(6)* as main product (85%). The nitrenium

chloride *(2)* is reported not to exist in the form of free ions but to undergo ring expansion yielding *(3)* as the positive charge on the nitrogen begins to increase. Compound *(6)* is then formed *via (4)* and *(5)*. The *p*-methoxyderivative of *(1)* reacts in a similar manner. / Chem. Commun. *1969*, 495 / —Kr. [Rd 61 IE]

The 1-cyclopropylvinyl cation *(2)* has been detected independently by *S. A. Sherrod* and *R. G. Bergmann* and by *M. Hanack* and *T. Bässler*. *Bergmann et al.* produced the cation from 1-cyclopropyl-1-iodoethylene *(1a)* with aqueous-ethanolic $AgNO_3$ at room temperature. Cyclopropyl methyl ketone is formed as final product. The corresponding reaction of the analogous compound 2-iodo-3-methyl-1-butene takes place only under more drastic conditions. Reaction of *(1a)* with Ag acetate and Ag tosylate at room temperature gives the acetate *(1c)* and the tosylate *(1d)*, respectively. *Hanack et al.* treated 1-chloro-1-cyclopropylethylene *(1b)* with $AgClO_4$ in acetic acid at room temperature to give the cyclo-

(1a), X = I
(1b), X = Cl
(1c), X = CH_3COO
(1d), X = OTs

propylvinyl cation *(2)* [final product: cyclopropyl methyl ketone]; with $AgClO_4$/Na acetate and *(1b)* they obtained the acetate *(1c)*. 2-Chloro-3,3-dimethyl-1-butene does not react under these conditions. / J. Amer. chem. Soc. *91*, 2115, 2117 (1969) / —Kr. [Rd 63 IE]

Hexameric $(HF)_6$ is a main constituent, along with the monomer and traces of a dimer, of gaseous hydrogen fluoride at —19 and +22 °C, at which temperatures the gas mixture has the composition HF + $(HF)_6$ and 4.2 HF + $(HF)_6$. This became apparent in electron-diffraction studies by *J. Janzen* and *L. S. Bartell*. The six F atoms of $(HF)_6$ form a puckered six-membered ring, the F—F bond lengths being 2.525 (—19 °C) and 2.533 ± 0.003 Å (22 °C) [2.49 Å in crystalline HF at —125 °C]; the FFF angle is 104 °. Owing to the large deformation amplitudes of the ring, the conformations lying between the boat and the chair forms are rapidly passed through. About half of the FHF bridges are asymmetric with one short HF bond, which is 0.040 Å longer than in monomeric HF. In the other symmetrical FHF bridges the hydrogen appears to prefer a position lying off the FF axis. / J. chem. Physics *50*, 3611 (1969) / —HB. [Rd 65 IE]

A planar tropylium ring having mean C–C bond lengths of 1.401 Å is present in $[C_7H_7Mo(CO)_3]^+[BF_4]^-$, according to an X-ray structure analysis by *G. R. Clark* and *G. J. Palenik*. The Mo atom is surrounded octahedrally by three CO groups (dMoC = 2.035 Å) and the tropylium ring (dMoC$_{ring}$ lying between 2.29 Å and 2.33 Å). The $C_7H_7^+$ ion is bonded as a 6 π-aromatic system and not as a triolefin. The MoC(O) distance is significantly greater than in analogous olefin complexes such as (cycloheptatriene)$Mo(CO)_3$, and the MoC(O) π-bond order is therefore not greater than in $Mo(CO)_6$, unlike the case in olefin complexes. / Chem. Commun. *1969*, 667 / —HB. [Rd 66 IE]

A linear RuNRu bridge with an unusually short RuN bond length of 1.718 Å (σ 0.006) is found, from an X-ray structure determination by *M. Ciechanowicz* and *A. C. Skapski*, to occur in $K_3[(H_2O)Cl_4RuNRuCl_4(OH_2)]$, which crystallizes in the space group C2/m with a = 15.89, b = 7.34, c = 8.16 Å, β = 120.4 °, and Z = 2. The N atom lies in the center of symmetry of the anion; owing to the strong π-character of the RuN bonds two $RuCl_4$ groups are eclipsed, as in $Re_2Cl_8^{2-}$, and distorted towards the H_2O [∢ NRuCl 94.1 and 95.1 ° (σ 0.2), dRuCl 2.363 and 2.364 Å (σ 0.006)]. The H_2O molecules, which are *trans* to the nitrogen, are held by means of long RuO bonds of 2.180 Å (σ 0.026). / Chem. Commun. *1969*, 574 / —HB. [Rd 52 IE]

Trichlorobis(triphenylphosphine)indium *(1)* is the first In complex for which a trigonal-bipyramidal structure could be confirmed by X-ray techniques. According to *M. D. Veidis* and *G. J. Palenik*, complex *(1)* crystallizes orthorhombically in the space group Pcab with a = 18.117 ± 0.002, b = 22.533 ± 0.006, c = 17.198 ± 0.004 Å; Z = 8. The data collected with an automatic diffractometer yield unusually large InP bond lengths; the trigonal bipyramid is slightly distorted, having a PInP angle of 173.0 ± 0.1 °. The average InCl distance (2.383 Å) lies between that in $InCl_4^-$ and that in $InCl_5^{2-}$; the InP distance is 0.2 Å longer than expected for a single bond. / Chem. Commun. *1969*, 586 / —HB. [Rd 53 IE]

BOOK REVIEWS

Analytische Methoden zur Untersuchung von Aminosäuren, Peptiden und Proteinen. (Analytical Methods for the Investigation of Amino Acids, Peptides, and Proteins). By *T. Dévényi* and *J. Gergely*. Vol. 10 in the Series "Methoden der Analyse in der Chemie" (Analytical Methods in Chemistry) edited by *F. Hecht*, *R. Kaiser*, *H. Kriegsmann*, and *W. Simon*. Akademische Verlagsgesellschaft, Frankfurt/Main, 1968, 1st Edit., x + 347 pp., many illustrations; DM 39.– [1].

Protein Chemistry is going through a particularly lively phase today, and this is reflected in the large number of new books concerned with the subject. The analytical side, which is very important, is similarly well covered, and all recent works deal amply with the applications of chromatography and electrophoresis to amino acids, peptides, and proteins. Any further book must therefore be really new and have some novel features. The present book is the translation of a Hungarian compilation from 1963, which was supplemented by (too

few) updating remarks in or after the translation, together with a modern account of gas-chromatographic applications, written by *R. Kaiser* and *A. Prox*. The result is stylistic non-uniformity. Thus, the recent supplement discusses in full even unimportant details, while the main text has gaps, which are sometimes caused by recent progress. Here, the phenol-ammonia atmosphere of the early days of paper chromatography lingers on, thin-layer chromatography is used only for dinitrophenylamino acids, the higly sensitive Dansyl technique receives no mention, and the microgram-scale technique of the Edman degradation of peptides is considered only in solution and not on paper strips. Incidentally, thiazolidone is invariablyshown with a trivalent sulfur. A freely suspended high-voltage arrangement without cooling, said to be devised in 1927 (instead of 1957), is recommended for electrophoresis, but is described elsewhere in the book as unsuitable for the resolution of complex peptide mixtures. Since thin-layer and disk electrophoresis are not included, blood proteins and their separation and characterization by diffusion methods are discussed at length. However, this and the useful tables for ion-exchange resins are insufficient to turn the scales in favor of the book. *T. Wieland* [NB 814 IE]

Handbuch der Lebensmittelchemie (Manual of Food Chemistry). Vol. V, Part I: High-Carbohydrate Foods. Edited by *L. Acker, K. G. Berner, W. Diemair, W. Heimann, F. Kiermeier, J. Schormüller*, and *S. W. Souci*. Springer-Verlag, Berlin-Heidelberg-New York 1967. 1st Edit., XXIV, 819 pp., 398 figures, 7 plates with 63 individual illustrations, stitched DM 228.—, $ 57.00.

The completely revised Manual of Food Chemistry [1] deals mainly with foods containing carbohydrates.

The raw materials are described first, then the components of the material in question and changes that can occur *e.g.* during storage; investigation methods are then reviewed, and this is followed by a section on legal evaluation. The volume begins with grain and grain flour products (*M. Rohrlich* and *B. Thomas*). This is followed by a discussion of flour products and their use, the technique of milling grain, the chemical composition of the products, and their investigation and evaluation. The principles of bakability and the testing of baking quality (Farinograph, Extensograph, Amylograph) are discussed. The next section deals with the starches (*G. Graefe*) and products derived from them, such as swelling starches, thin-boiling starches, dextrins, starch esters, starch ethers, pudding powders, *etc.* The microscopic investigation of starch flours and mill products is described by *A. Th. Czaja*.

The section "Bread, Baker's Produce, and Baking Aids" consists of individual chapters by different authors: "Bread" (*A. Schulz*), "Baker's Produce" and "Aids and Additives for the Production of Bread and Baker's Produce" (*A. Rotsch*), "Investigation and Evaluation of Bread, Baker's Produce, and Baking Aids" (*A. Rotsch* and *A. Menger*). The microscopic investigation of these products (*Th. Czaja*) completes the set of articles, which occupy a total of 400 pages. The section on microscopy contains many extremely beautiful and clear photomicrographs and photographs taken through a magnifying glass.

The section on "Leguminous Plants" (*L. Wassermann*), which is naturally smaller, includes information of the products obtained from soybeans in Eastern Asia, such as soy sauce, tofu, miso, *etc.* The chapter "Microscopic Investigation of Leguminous Plants" (*Th. Czaja*) deals not only with the few generally used seeds, but also with flat peas, adzuki beans, hyacinth beans, and other rare products.

The aricle "Diet Foods Based on Grain" (*R. Franck*) is short, as might be expected, since the raw material has already been described in earlier articles. It deals mainly with digested grain products and diabetic baked goods. The chapter "Dough Products" (*A. Menger* and *L. Acker*) is very thorough, and starts with definitions and raw materials.

The next set of articles deals with sugar and products made from it. The articles "Honey and Artificial Honey" (*H. Duisberg*) and "Cane and Beet Sugar" (*F. Schneider*) are outstanding. The discussion of the microscopic investigation of honey (*J. Evenius* and *E. Focke*) is again accompanied by excellent photomicrographs of pollen grains and extraneous objects in honey. The articles on "Glucose Syrup, Glucose and Dextrose" (*G. Graefe*) and "Other Sugars and Syrups" (*G. Graefe*) are also comprehensive, the chapters on maple syrup and sugar, on sugar alcohols (sorbitol, mannitol, dulcitol, and iditol, xylitol), and on caramel being particularly notable. *H. Viermann*'s short but very informative article on "Malt Extract and Malt Syrup" completes the series of articles on sugars.

The article "Confectionery" (*A. Fincke*) describes the products made from sugar. Briefly, but extremely clearly and systematically, the article deals with fifteen different products, from candy to marzipan nougat, and chewing gum, and with their general and special investigation. The series ends with the article "Ice Cream", which is by several authors. *J. Klose* deals with definitions and evaluation, *E. Loeser* with the technology of ice-cream manufacture, and *W. Pelz* with the investigation of ice cream. Those three chapters again constitute a short monograph. The same is true of the last article in the volume "Baker's Yeast" (*R. Kautzmann* and *W. Zoberst*).

A more or less long bibliography is given at the end of each article, with the titles of the publications cited as well as the usual data. This takes up more space, but it is sometimes of interest to the user of the book to know the subject of the article in question. The bibliography extends up to about 1966. The volume closes with a 30-page subject index. The present, excellently presented volume is a worthy successor to the earlier volumes. It will be of great value to all who are concerned with the chemical, and particularly the food-chemical, problems of products based on seeds containing starch, and on sugar. *H. Thaler* [NB 819 IE]

Determination of the Structures of Organic Molecules and Quantitative Analyses with the Field Ionization Mass Spectrometer

By H. D. Beckey[*]

Field ionization and electron impact mass spectrometry complement each other well. Whereas bombardment of organic molecules with 70 eV electrons yields many characteristic fragment ions, which give valuable information about the structure of the molecules, the "soft" field ionization even of very unstable substances leads to the formation of relatively intense molecular ions which are often undetectable on ionization by electron bombardment. Field ionization also gives fragment ions that, though not very intense, are often very characteristic, and yield further information about the structure. The field desorption technique greatly reduces the degree of thermal decomposition of solid organic samples.

New activation methods for field ion emitters lead to more intense ion beams and prolong the life of the emitters. Quantitative analyses using the field ionization mass spectrometer are of interest for hydrocarbon mixtures containing a very large number of components (e.g. several hundred). Simplified analyses are possible in particular for high-boiling petroleum fractions.

1. Introduction

The importance of the qualitative and quantitative investigation of organic molecules with the aid of the mass spectrometer has grown steadily in recent years. Earlier articles on the use of the mass spectrometer for the determination of the structures of large organic molecules[1,2] and on the mass-spectrometric investigation of rearrangements of organic ions[3] rightly concentrated on the production of ions by electron bombardment, the technique most commonly used in analytical laboratories. The determination of the structure of a complicated organic molecule requires a large number of specific fragment ions, from which the overall structure of a molecule that is at least partly unknown can be built up like a mosaic after accurate determination of their weights. Large numbers of fragment ions, which are frequently characteristic, are obtained by ionization of organic molecules with electrons having an energy of about 70 eV. An appreciable part of the energy difference between 70 eV and the ionization energy of the molecules (of the order of 10 eV) is transferred from the bombarding electrons to the ionized molecules. The increase in the internal energy of the molecules then leads to numerous fragmentation reactions.

Despite these advantages of the electron bombardment method, the field ionization method has recently shown a steady growth of importance as a frequently ideal complement of the electron bombardment method. This is partly due to the fact that on ionization by electric fields of the order of 5×10^7 V/cm, a much smaller quantity of internal energy is supplied to the molecule, so that this is a "soft" ionization method, and partly to the fact that the field ionization method is specific for the detection of chemical processes on the surfaces of solids, whereas the electron bombardment method is specific for the detection of molecules that are ionized in the gas phase. Finally it has recently been found possible, with the aid of the field ionization mass spectrometer, to study the kinetics of

extremely fast unimolecular decomposition processes [4], and the "atom probe" has now made it possible to analyze a single atom, *i.e.* to determine its atomic weight accurately after it has been made optically visible in the field ion microscope [5].

It should be noted that soft ionization is also possible in the electron bombardment technique if the energy of the electrons is reduced to a value just above the ionization potential of the molecules in question. This yields valuable information about the mechanism of the degradation of organic ions [6]. Characteristic differences nevertheless exist between the mass spectra produced by low-energy electrons and those produced by field ionization. Owing to these differences, each of the two methods has its own specific applications (see Section 4; for reviews on FI mass spectroscopy [*], see [7,8]).

2. Principle of the Field Ionization Method

Field ionization occurs when an atom or molecule is acted upon by an electric field of the order of 10^7–10^8 V/cm. The removal of an electron from a molecule is not a discontinuous process like ionization by electron impact, in which ionization occurs only above a sharply defined bombardment energy, the ionization energy. Field ionization is a process whose probability increases continuously with the field strength. At low field ionization probabilities, however, the field ion current I increases with such a high power of the field strength F ($I \simeq$ const. $\times F^{30}$ according to *Southon* and *Brandon* [9]) that below a relatively well defined "threshold field strength" the field ion current rapidly becomes too small to be measured.

The removal of an electron from a molecule by a high electric field is based on the quantum-mechanical tunnel effect. The process can be most simply explained by considering the field ionization of a hydrogen atom. In a classical electrodynamic treatment, the potential of the electron of the H atom would have to be increased by an amount I (the ionization potential) to become completely separated from the proton in the absence of an electric field (Fig. 1a). In the presence of a high electric field, however, the potential of the atom is deformed (Fig. 1b) in such a way that the electron of the H atom is faced in one direction with a potential barrier of finite thickness. According to the laws of quantum mechanics it is not necessary for the electron to pass over the energy barrier in order to become separated from the proton, since it can also pass through the barrier with a finite probability. It can be seen from Figure 1 that the resulting potential of the atom in a high electric field consists essentially of three components: the atomic potential of the system in the absence of a field; the external potential, which corresponds to the applied electric field; and the image potential, *i.e.* the interaction potential between the electron and the image charges produced by it and the proton in the metal surface producing the field.

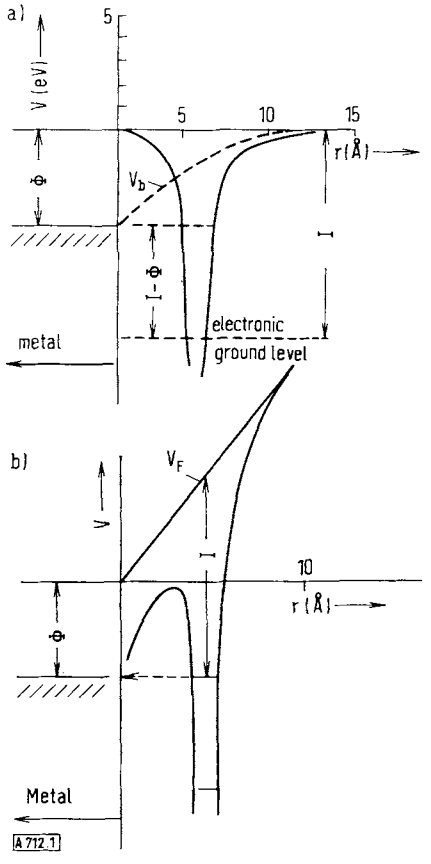

Fig. 1. Potential (V) of an atom in the vicinity of a metal surface. (a) without field, (b) with field.
I = ionization energy, Φ = work function of the metal
V_b = image potential (broken curve)
V_F = external electric potential = eFr (F = field strength).

It can also be seen from Figure 1 that the electron of the H atom must be promoted by the external electric field at least to the potential of the highest occupied level of electrons of the metal to enable it to tunnel through the potential barrier into unoccupied states of the metal producing the field. This leads to a condition for the minimum distance d_{min} from the metal surface at which field ionization is possible:

$$d_{min} \times F \simeq I - \Phi \qquad (1)$$

where Φ is the work function of the metal, and the image potential has been neglected. Thus at a field strength of 5×10^7 V/cm, an H atom cannot undergo field ionization in direct contact with the metal surface producing the field (*e.g.* the surface of a metal spike), but must be at a distance of at least

$$d_{min} \approx \frac{I-\Phi}{F} \simeq 3.4 \text{ Å} \quad (I = 13.5 \text{ V}, \Phi = 5.0 \text{ V}, F = 2.5 \text{ V/Å})$$

For organic molecules having an ionization potential of about 10 V, this distance amounts to about 10 Å at $F = 0.5$ V/Å. The organic molecule can undergo field ionization in the adsorbed state if it is at least 10 Å long, and even shorter adsorbed molecules can be ionized at higher field strengths. This is referred to as "field desorption". The desorption field strengths for single atoms are naturally very high (up to 5×10^8 V/cm [10, 11]).

The strength of the ion current produced is decisively influenced by the supply of neutral molecules to the field ion emitter. For the sake of simplicity let us assume for the moment that the high electric field is produced by a single metal spike having the shape of a hyperboloid of revolution, which is at a high positive potential with respect to a counter-electrode whose surface is large in relation to that of the spike.

The supply of particles to the field ion emission center is made up of two components; the supply from the gas phase and the supply, by surface diffusion, from the particles adsorbed on the shank of the spike. We shall consider the former component first. The number n_0 of particles arriving per second from the gas phase in the absence of an electric field is found to be

$$\dot{n}_0 = \frac{{}^1n\,\bar{c}}{4}\,O \qquad (2)$$

where ${}^1n$ is the number of particles per cm³, $\bar{c}$ is the average molecular velocity, and O is the area of the ion emission center. *Müller* showed some time ago, in connection with field ion microscopy, that the supply of particles can be greatly increased in the presence of high electric fields, since the atoms or molecules are preferentially drawn into the regions of increased field strength as a result of induced or permanent polarization [12]. The multiplication factor σ can have values of up to about 100 for atoms or apolar molecules such as H_2 at very high field strengths (approximately 5×10^8 V/cm), and can be considerable even at about 1×10^8 V/cm in the case of polar organic molecules having large permanent dipole moments.

The factor σ is given by the equations

$$\sigma = 1 + \tfrac{2}{3}\,V_{(F)}/kT \qquad (3)$$

$$V_{(F)} = \frac{\alpha}{2}\,F^2 + \mu F \qquad (4)$$

where k is Boltzmann's constant, T is the absolute temperature, $V_{(F)}$ is the polarization energy, α is the polarizability, and μ is the average permanent dipole moment in the direction of the field. [For strongly polar substances with $\mu \simeq 3$ Debye and at $F \simeq 5 \times 10^7$ V/cm, the second term in eq. (4) predominates.]

At sufficiently high field strengths, practically every molecule that reaches the vicinity of the emission point undergoes field ionization. The ion current is then given by the equation

$$I = e\dot{n}_0\,\sigma \qquad (5)$$

If the point is assumed to have a radius of 1 to 10×10^{-5} cm (emitting area about 10^{-8} cm²) and the gas pressure is 10^{-3} torr, a value of $\sigma = 5$ in eq. (5) gives $I \simeq 5 \times 10^{-10}$ A. The current can be increased to about 5×10^{-6} A by the use of an emitter having numerous micro-points.

The field ion current at low field strengths cannot be represented by a relation as simple as eq. (5). The ionization probability decreases rapidly from unity to smaller values with decreasing field strength.

The second component of the supply of particles consists of the diffusion current of adsorbed molecules from the shank of the spike to its center. The theoretical treatment of this component is more difficult than that of the component from the gas phase [13]. It can be shown in general that the supply from the surface increases with the adsorption energy of the adsorbed molecules and that it can in certain circumstances amount to an appreciable fraction of the supply from the gas phase.

3. Apparatus

3.1. Field Ion Emitter

High electric fields can be produced by strongly curved electrically conducting electrode surfaces at a high electric potential with respect to an oppositely charged electrode. The smaller the radius of curvature of the electrode producing the field (typically 100–10000 Å), the higher is the field strength. Fine metal points, fine wires, and sharp metal edges have been used as field electrodes.

3.1.1. Metal Points as Field Anodes

In the early stages of the development of FI mass spectrometry, fine metal points were used to produce the field [14–16]. The advantages of point emitters are their geometrically well defined surface shape and the possibility of obtaining extremely high field strengths (about 5×10^8 V/cm), at which wire or edge emitters are damaged or destroyed. The disadvantage of point emitters is that they have a very small emitting area in comparison with the other two types, and so give only a small field ion current. Moreover, the random ion emission fluctuations are considerably greater for point emitters than *e.g.* for wire emitters. Wire or edge emitters are therefore generally used for qualitative

[16] *H. D. Beckey*, Naturwissenschaften *45*, 259 (1958).

and quantitative organic analyses. Nevertheless, point emitters still have a firm place in FI mass spectrometry, particularly for physico-chemical studies either on phenomena occurring in extremely high electric fields, which can be produced only with single points, or on the dependence of surface reactions on the material from which the point is made (see *e.g.* [17]).

The use of point emitters has recently received new impetus from the development of the "atom probe" by *E. W. Müller et al.* [5]. In this device the mass-spectrometric analysis is preceded by observation of the emitter surface with the aid of a field ion microscope; this is possible only for geometrically well defined and clean single points, and not for wire or edge emitters.

The field strength obtained with a single point is given by

$$F_0 = \frac{V_0}{kr_0} \tag{6}$$

(F_0 = field strength on the surface of the point, V_0 = potential of the point, k = geometric factor, r_0 = radius of curvature at the tip of the point.) The geometric factor depends on the geometrical shape of the point, which may be *e.g.* parabolic or hyperbolic. A typical value is $k = 5$. With $V_0 = 10^4$, $k = 5$, and $r_0 = 10^{-5}$ cm, we obtain $F_0 = 2 \times 10^8$ V/cm.

Fine metal points are mainly produced by chemical or electrochemical etching [18]. Tungsten points are preferred for the production of very high field strengths, since tungsten has a very high tensile strength and the field strengths required for the "field evaporation" of individual surface atoms are higher than for other metals.

By the use of relatively blunt points ($r_0 > 10^4$ Å) ion currents of up to about 10^{-8} A can be produced with polar compounds.

3.1.2. Fine Wires as Field Anodes

Much higher field ion currents can be obtained with fine wires instead of single points as field anodes. This method [19,20] is based on the fact that though the radius of curvature of the wires used is comparable with that of a blunt point, because of the length of the wire (a few mm) its emitting area is greater by a factor of about 10^4 than that of a blunt point. On the other hand, since the field line density in front of a cylindrical electrode is lower than that in front of a paraboloid electrode, the field strength at the surface of a wire would be insufficient for the field ionization of organic molecules but for a local increase in the field strength. Such increases are due to innumerable micro-needle crystals that grow on the surface of a wire during the field ionization process. At the tips of these needle crystals, the field strength is greater by a factor of h/r than the field strength of an ideally smooth wire (h = height, r = radius of the needle crystal). A typical value for the "field intensification factor" h/r is about 7.

The sum of the emitting point surfaces of the needle crystals is naturally only a fraction of the total area of the smooth wire. The optimum value of this fraction is about 1/100, so that the factor relating the area of the smooth wire to that of a point is decreased from 10^4 to about 100. It has in fact been found that well activated (*i.e.* densely covered with needle crystals) wire emitters can give field ion currents of up to 100 times the values obtained with single points ($I_{max} \simeq$ a few μA at a gas pressure of 10^{-3} torr, $V_0 \simeq$ 8—10 kV, r_0 wire = 1.25×10^{-4} cm).

The growth of needle crystals in the presence of organic substances and at high electric fields was first observed with an electron microscope as a secondary process of field ionization. The optimum conditions for the growth of these needle crystals were later studied systematically as a function of various parameters such as pressure, time, voltage, temperature, point material, and nature of the organic substance [21]. Optimum needle growth occurs if the wire is activated as rapidly as possible in a diode arrangement outside the mass spectrometer at a relatively high pressure (about 3×10^{-3} torr), at a voltage of about 10 kV (r_0 wire = 1.25×10^{-4} cm), and in the presence of a strongly polar substance having a low ionization energy.

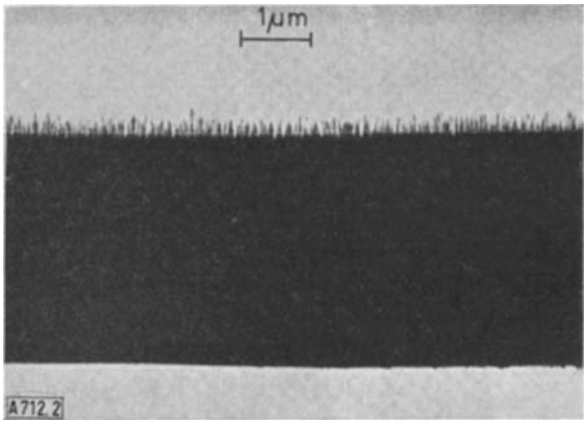

Fig. 2. Electron micrograph of a platinum wire having a diameter of about 3 μm, which has been activated at an acetone pressure of 3×10^{-3} torr and at a voltage of 10 kV. Average length of the micro-needles approx. 2500 Å (electron micrograph by *A. Maas*, Bonn).

Figure 2 shows a very dense, uniform growth of relatively short needles on a platinum filament ($r_0 = 1.25 \times 10^{-4}$ cm) in the presence of acetone. On systematic variation of the organic substance, it was found that needles grown in the presence of benzonitrile give even more intense ion emission [22].

Figure 3 shows needle crystals grown on a platinum wire used as a FI emitter in the presence of benzonitrile. The needles are up to ten times as long as those shown in Figure 2, and their structure is more

dendritic. The growth rate is considerably greater than when acetone is used (approximately 30 minutes for complete activation). The results of several investigations indicate that these needles consist of organic polymers having low hydrogen contents, and of graphite in the limiting case.

Fine metal or semiconductor wires having high tensile strengths may be used as emitter wires. A detailed comparison has shown that platinum Wollaston wires having a diameter of about 3 μm are particularly suitable [23]. The Wollaston wires are commercially available, and allow relatively high accuracy in the preparation of the emitter. Their average tensile strength, however, is only about 50 kg/mm which is only slightly above the order of magnitude of the mechanical force exerted on the wire by the electric field. These wires are easily broken by improper treatment or by arcing.

Field ionization emitters have recently been made from carbon whiskers about 5 mm long and 2–3 μm in diameter [22] by *Bacon*'s method [24] in a high-current high-pressure carbon arc. These carbon whiskers are single crystals having extremely high tensile strengths (about 750 kg/mm on average). With careful handling, emitters of this type can give weeks or months of service in an FI mass spectrometer. Since graphite whiskers are not commercially available at present and are very difficult to produce, the use of tungsten wires 10 μm in diameter is recommended, since these have a tensile strength about 160 times as high as that of 2.5-μm platinum wire, and since in spite of their large diameter they give a sufficiently high local field strength because of the length of the micro-needles grown with the aid of benzonitrile. The activation method is described in ref. [22].

3.1.3. Sharp Metal Edges as Field Anodes

We also introduced sharp metal edges into FI mass spectrometry [19, 20]. *Robertson* later carried out a detailed investigation on the structure and field strength distribution of such emitters [25–27]. The edges used may be those either of untreated commercial razor blades (from which it may be necessary to remove a coating of grease) or of etched thin foils, preferably of platinum or tungsten.

It is widely held that fine wires could easily break in a high field, whereas this is obviously impossible in the case of metal blades. It must however be remembered that when blades or thin foils are used, arcing to the counter-electrode, which is only a few tenths of a mm away, can often occur at potential differences greater than 10 kV, and this can quickly make the sharp part of the blade unsuitable for ion emission. Moreover, the rear portion of the blade causes electrostatic screening, which leads to a decrease in the field strength as compared with that of a wire emitter. The radius of curvature of the edge must therefore be smaller by a factor of 10 to 100 than that of a wire, and the ion current is accordingly decreased. The variations of the FI current emitted are generally greater with edges than with wires.

Nevertheless, edge emitters are frequently used as well as wires. This is justifiable in particular at some distance from the detection limits and in the purely qualitative detection of ions, where somewhat larger fluctuations of the ion current can be tolerated (for a comparison of point, wire, and edge emitters, see [28]).

3.1.4. Multiple Thin Layer Films as Field Anodes

It should be mentioned that *Gentsch* [29] has recently produced FI emitters in which a thin insulating film a few hundred Å thick is deposited from the vapor on a metal support, and a perforated covering film of metal having a lattice or comb structure is deposited on the insulating film. The physical principle of the field production and field ionization is the same as for the edge emitters described in Section 3.1.3. The system differs however, in that by reduction of the radius of curvature to 10–100 Å and of the distance from the counter-electrode to about 1000 Å, the voltage required to obtain a field strength of 10^7–10^8 V/cm can be reduced from the 10 kV range to about 100 V. A diagrammatic sketch of such an emitter is shown in Fig. 4.

The technological difficulties are that the metal film must not be evaporated by the field, and that electrical breakdown of the thin insulating film must not occur. The diffusion of ions in the insulator must also be kept small. Though these emitters are not yet stable in continuous operation, *Gentsch* has shown in principle that they can be used to produce FI mass spectra. Substantial technological improvements appear entirely feasible.

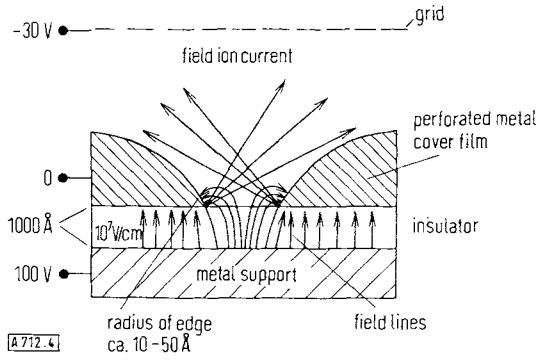

Fig. 4. Multiple thin layer film field ion emitter after *Gentsch* [29] (schematic).

3.2. Field Ion Sources

As was shown in Section 3.1, field ion currents of the order of 10^{-6} A can be produced with well activated wire emitters. This is much higher than the primary ion current produced in electron bombardment ion sources. However, fewer ions reach the collector of the mass spectrometer with field ionization than with electron bombardment, since the ion beam leaving the source is practically parallel in EB, whereas in FI the ions leave the emitter over a very large angle, and after a few thousand Å they have been accelerated to an energy of several kV. Ion beams of this type are difficult to focus into a narrow mass spectrometer entry slit with a small entry angle (about 1 °). It may be assumed as a rule of thumb that the intensity at the detector of the mass spectrometer is smaller by a factor of about 100 for field ionization than for ionization by electron bombardment. With strongly polar substances and very well activated emitters, this factor can be reduced to about ten. Further improvement of the ion optics of FI sources appears possible [30].

The mass resolving power is somewhat lower for FI than for EB sources. This is partly due to the fact that there is a certain potential drop along the length of the micro-needles on an FI emitting wire, this drop depending on the length and diameter of the needles. To obtain a good resolving power, the highest possible voltage must be applied between the FI emitter and the counter-electrode. *Brunnée et al.* [31], for example, obtained a resolving power of $M/\Delta M = 800$ at 18 kV with a single-focusing mass spectrometer (type Varian CH5).

With double-focusing mass spectrometers there is evidently no limit to the resolving power of field ion sources as compared with electron bombardment ion sources. *Chait* and *McLafferty*, for example, obtained a resolving power of 30000 with a double-focusing mass spectrometer having an FI source, and a precision mass determination could even be carried out in the usual manner [32].

Another problem is the combination of FI and EB sources. As was mentioned earlier, the FI and EB spectra often complement each other very well. It therefore often proves expedient to be able to change quickly from one method to another without the need for mechanical conversion. This problem is easy to solve for measurements on gaseous substances, since the FI emitter can be situated away from the electron beam in a rear part of the source. The gas molecules diffuse uniformly into the electron bombardment and field ionization chambers. After we had produced the prototype of such a source [33] (see Fig. 5), *Brunnée et al.* developed an FI/EB combination source, which also allows alternate measurements on solids by both methods [31] (manufacturer: Varian-MAT).

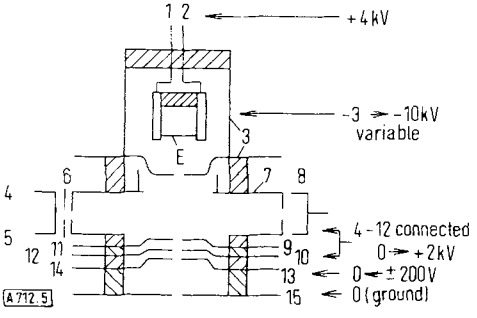

Fig. 5. Prototype of a combined electron bombardment-field ionization source (schematic) [33]. Shaded parts: Insulators. E = FI emitter, 1 and 2 = leads for electric heating of the FI emitter and for the positive high voltage, 3 = counter-electrode, 4 and 5 = cathodes for electron emission. 7 = electron bombardment ionization chamber, 8 = electron collector. Potentials for FI operation are given next to the drawing on the right. Potentials for electron bombardment operation: (7) + 3 kV; accelerating electrodes (9)—(12) and lenses (13) and (14) have the usual potential values. The gas is introduced into the ionization chamber (7).

The electron beam passes through a beam of molecules of the solid evaporating from a furnace. During this EB operation, the FI emitter occupies a rear position. For FI operation, the electron beam is switched off and the FI emitter is moved forward a few millimeters into the molecule beam by a swivel mechanism. The ion source potentials are varied by means of a switch.

4. Determination of the Structures of Organic Molecules with the FI Mass Spectrometer

The electron bombardment method is ideally suited for the determination of the structures of large organic molecules; since the energy transferred to the molecules on electron bombardment is so great that many more or less structure-specific fragments are formed. The procedure for the determination of the structure of an unknown molecule in general is therefore roughly as follows: Some information about the nature of the substance can generally be obtained from the source of the substance or its preparation, and often from preliminary chemical tests. Further information is obtained by physico-chemical methods such as IR,

[33] *H. D. Beckey, H. Knöppel, H. G. Metzinger*, and *P. Schulze*, Advances Mass Spectrometry *3*, 35 (1966).

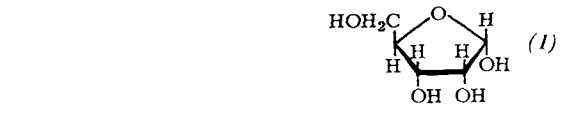
Raman, UV, and NMR spectroscopy, and a mass spectrometric analysis is carried out with an electron bombardment ion source. This very often provides sufficient information for an unambiguous reconstruction of the structure.

In many cases, however, further information is still required after these steps have been completed, and FI mass spectroscopy can often be of assistance in such cases. The most important data that can be obtained by the FI method in this connection are:

1. the molecular weight of the substance and its empirical formula, and

2. a characteristic fragment-ion spectrum that differs from the EB fragment-ion spectrum.

4.1. Determination of Molecular Weight and Empirical Formula with the FI Mass Spectrometer



The stability of organic molecules to 70 eV electrons or thermal energy is often so low that no ions of the undecomposed molecules (molecular ions) can be detected in the mass spectrometer. In such cases, the molecular ions can usually be detected in an FI mass spectrum.

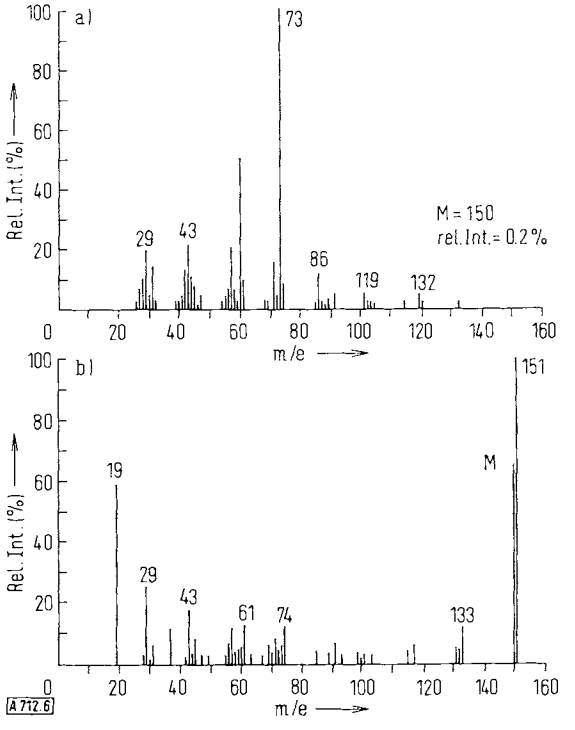
In field ionization a molecule is nearly always ionized from the electronic ground state, as can be seen from Figure 1. The probability of tunneling of an electron increases with decreasing height of the potential barrier above an electronic state. The vibrational energy excited in the molecular ion on field ionization is also small. Thus, except where the molecular ions are extremely unstable, they can generally be detected with good intensity even for substances that give vanishingly small molecular ion intensities on ionization with 70 eV electrons.

The decrease in the supply of heat due to lowering of the temperature of the ion source can lead to a considerable increase in the intensity of the molecular ions in electron bombardment mass spectra [6]. Since there are no hot strips for the production of electrons in field ion sources, FI sources are inherently suitable for use as "cold" ion sources. If no molecular ions can be detected for a given substance with an EB source at the lowest possible ion source and substance evaporation temperatures, and with 70 eV electrons, it will not be possible to detect them by reducing the energy of the electrons. Though a decrease in the energy of the electrons increases the intensity of the molecular ions relative to that of the fragment ions the absolute molecular ion intensity is always decreased.

Some substances, such as mono- and oligosaccharides, have high sublimation temperatures and do not give clearly detectable molecular ions on mass-spectrometric analysis with EB sources, even when the temperature and the energy of the electrons are reduced. The field ionization method, on the other hand, gives clearly detectable more or less intense molecular ions for these substances.

Figure 6 shows the EB and FI mass spectra of D-ribose *(1)*. In the EB mass spectrum the molecular ion line M is so weak (<0.2%) that a definite assignment becomes difficult in the presence of a back-ground spectrum or of impurities of the order of 0.2%. In addition to the very intense molecular ion line, the FI mass spectrum contains an (M+1) mass line, which is the

(1)



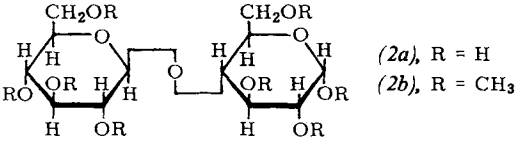


Fig. 6. a) Electron bombardment and b) field ionization mass spectra of D-ribose *(1)* [33].

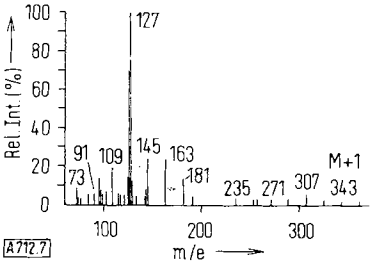
most intense line in the mass spectrum. This is due to an ion-molecule reaction between two ribose molecules adsorbed on the emitter surface:

$$M^+ + M \rightarrow (M+1)^+ + (M-1)$$

"Hydride ion lines" of this type are very often found for strongly adsorbed polar molecules, and particularly for molecules containing hydroxyl groups.

(2a), R = H
(2b), R = CH_3



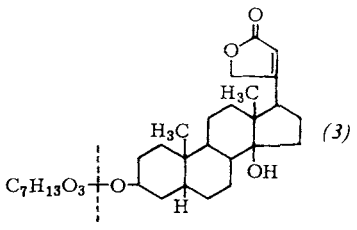


Fig. 7. Field ionization mass spectrum of cellobiose *(2a)*.

There could be doubt in the determination of the molecular weights as to whether the two intense mass lines are M^+ and $(M+1)^+$ or $(M-1)^+$ and M. However, this uncertainty can be readily resolved in view of the fact that with wire emitters the intensity of the $(M-1)^+$ line is usually only a few per cent of the M^+ intensity (generally less than 1%). The fragment ion lines also

(3)

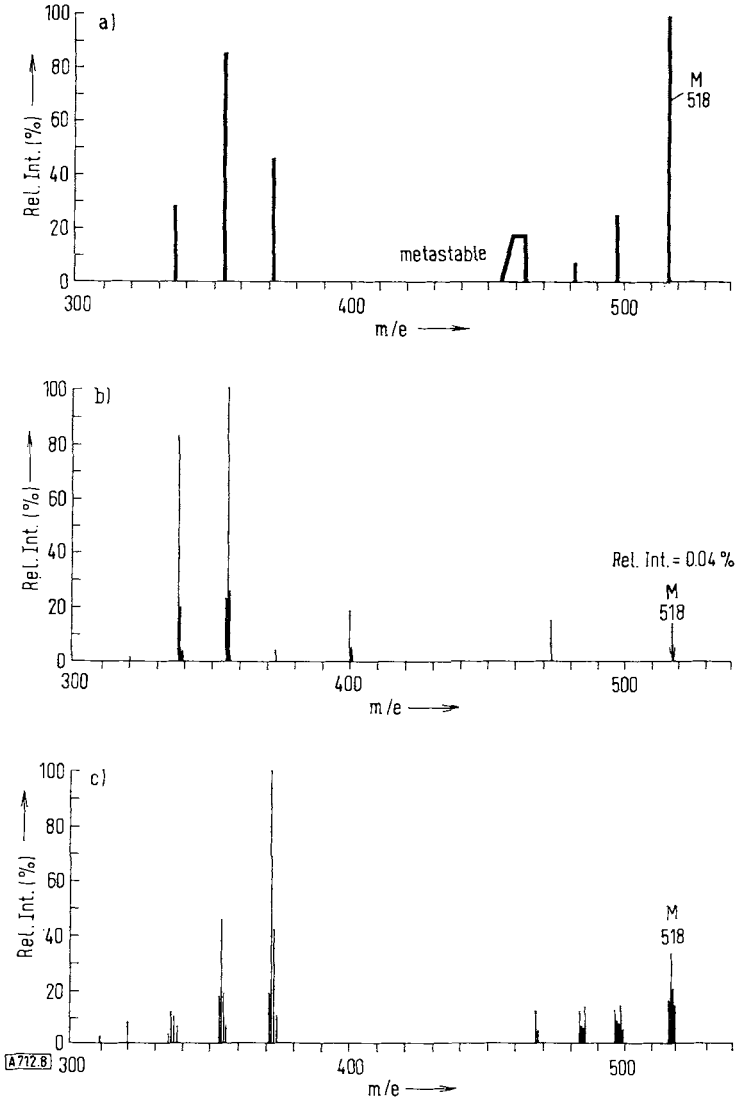

Fig. 8. Mass spectra of somalin *(3)* ($C_7H_{13}O_3$ = cymarose residue) (upper mass range) [34]; a) field ionization, b) electron bombardment ionization, c) electron attachment ionization [36, 37].

lead to definite conclusions concerning the molecular ion peaks.

The intensity of the molecular ion lines of disaccharides in the EB mass spectrum is generally even lower than that of monosaccharides. Consequently, these molecular ion lines usually cannot be definitely detected in the EB spectrum. It can be seen from Figure 7, on the other hand, that the molecular ion line of cellobiose *(2a)* can be detected in the FI mass spectrum [35].

It is interesting to compare the relative molecular ion intensities for electron bombardment, field ionization, electron attachment, and chemical ionization. The last two of these methods, like field ionization, increase the relative molecular ion intensities. Figure 8 shows a comparison of the FI, EB, and EA (electron attachment) spectra of somalin *(3)* [34]. The EA mass spectrum exhibits a certain similarity to the FI spectrum. The EA mass spectrum was recorded by *v. Ardenne*'s method [36] for the addition of slow electrons to molecules [37]. The advantage of the FI method over the EA method is the simple construction of an FI/EB combination source, which allows rapid changes from one type of operation to the other.

Table 1 shows a comparison of the molecular ion intensities of eight isomeric decanes for FI and ChI (chemical ionization).

Table 1. Relative intensities of the molecular ion lines (in %) of eight isomeric decanes [38, 39].

	FI M^+	ChI [a] $(M-1)^+$
5-Ethyl-2-methylheptane	98.2	20.0
2,3,6-Trimethylheptane	98.0	9.4
3-Isopropyl-2,4-dimethylpentane	95.7	1.9
2,2,4-Trimethylheptane	50.0	5.7
2,2,6-Trimethylheptane	59.2	9.2
3,3,5-Trimethylheptane	42.6	4.5
2,2,3,3-Tetramethylhexane	14.4	0.5
2,2,5,5-Tetramethylhexane	26.3	2.0

[a] ChI = chemical ionization.

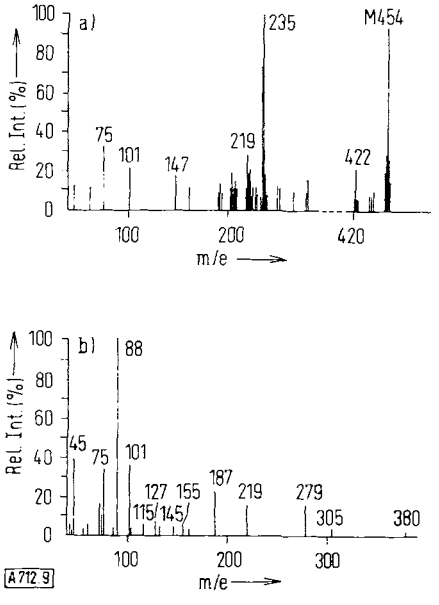
The chemical ionization method, which was developed in particular by *Munson* and *Field*[40], consists in allowing a "reaction gas", *e.g.* methane, to undergo an ion-molecule reaction in a mass spectrometer ion source at a relatively high pressure:

$$CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3$$

(In addition to the CH_5^+ ion, some other reactive ions are formed with decreasing abundance by ion-molecule reactions). The very reactive CH_5^+ ion reacts with the organic molecule to be examined (decane in this case) in accordance with the following overall equation:

$$M + CH_5^+ \rightarrow (M-1)^+ + H_2 + CH_4 \text{ [*]}$$

Very little energy is transferred to the $(M-1)^+$ ions. The $(M-1)^+$ ions in ChI mass spectrometry thus correspond in some measure to the M^+ ions in FI mass spectrometry. It can be seen from Table 1, however, that the relative intensities of the FI molecular ion lines are still considerably greater than those of the corresponding ChI molecule ion lines.



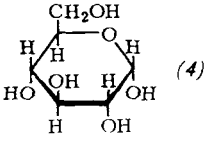


Fig. 9. a) Field ionization and b) electron bombardment mass spectra of octa-*O*-methylcellobiose *(2b)* [35].

The intensity of the molecular ion lines in the FI spectra in relation to those in the EB spectra could be demonstrated for many other examples. However, this effect is limited in molecules that have no stable states in the ionized, positively charged state. This class of molecules appears to include CCl_4 and other perhalogenated organic molecules, in whose FI mass spectra no molecular ions have so far been observed. Some oligosaccharides give such weak molecular ion lines in the FI spectra that it is difficult to assign these lines with certainty. A valuable aid in such cases is the well known technique of methylation, which often makes the molecular ion lines the most intense in the FI mass spectrum, whereas the same substances give only vanishingly small molecular ion lines (if any) in the EB spectrum despite methylation. Figure 9 shows the EB and FI mass spectra of octa-*O*-methylcellobiose *(2b)* [35].

We recently developed a new method [41] that further increases the molecular ion intensity in relation to that found in the normal FI technique, increases the detection sensitivity, and greatly decreases the degree of thermal decomposition of the sample.

Solid organic samples having low vapor pressures are normally introduced into the vicinity of the ionization zone of EB or FI sources through an air lock with the aid of a sliding rod. The substances are then evaporated into the ionization zone as a molecular beam from a micro-crucible by heating.

In thermally unstable substances, the energy required to remove molecules from the lattice is often comparable with the energy required for the thermal removal of smaller molecules from the parent molecule. A well known example is the removal of water molecules from carbohydrate molecules.

[*] The $(M-H)^+$ ions are denoted in Table 1 and in the following discussion by $(M-1)^+$.

[41] *H. D. Beckey*, Int. J. Mass Spectrometry Ion Physics *2*, 500 (1969).

Figure 10a shows that the molecular ion intensity in the EB mass spectrum of D-glucose is negligible. Though the $(M+1)^+$ intensity is the highest in the FI spectrum (Fig. 10b), species resulting from the removal of one, two, or three water molecules and of a $C_2H_4O_2$ molecule from the glucose molecule are very intense. Thermal cleavage may be assumed to precede the ionization. The thermal breakdown is due to the conversion of the substance from a solid into a gas before the ionization. Some other methods of sample supply must therefore be used if thermal decomposition is to be reduced.

In the new sample supply method, the substance is applied directly from a solution to the field ion emitter and then undergoes field desorption from the adsorbed state. The molecules simultaneously become positively charged, and can then be detected mass-spectroscopically in the usual manner. Though this idea seems obvious in itself, it is only recently that it has become practicable, since the active emitter surfaces available for the adsorption of the molecules had previously been too small to take up enough of the substance for recording of a mass spectrum over a period of a few minutes.

However, our new activation process for field ion emitters, in which benzonitrile is used for activation [22], leads to such a large increase in the active emitter surface that sufficient material can be adsorbed for mass-spectrometric analysis by the field desorption technique.

The advantage of this new supply method is that whereas thermally unstable solids decompose on evaporation, no decomposition occurs when molecules suitable for this method are dissolved in a solvent. The FI wire emitter is dipped into a small drop (1–2 mm in diameter) of a solution (saturated if possible) of the sample, whereupon the molecules of the sample are adsorbed on the FI emitter. They are probably held only weakly by van der Waals forces on a monolayer of the solvent adsorbed on the surface of the emitter. Field evaporation of the physically adsorbed molecules can then occur in the ion source at temperatures so low that the molecules do not suffer appreciable decomposition.

Figure 10c shows the field desorption (FD) mass spectrum of D-glucose *(4)*. In comparison with the FI mass spectrum, it shows considerably less removal of one, two, or three water molecules and of a $C_2H_4O_2$ molecule from the parent molecule. The method is therefore of theoretical as well as practical importance, since it provides an indication of what proportion of certain fragmentation processes is due to the ionization and what proportion to thermal decomposition.

The FD mass spectrum of glucose was recorded with a strongly activated wire [22] having a diameter of 10 μm. After immersion in a saturated aqueous solution of glucose, the wire was inserted into the ion source of an FI mass spectrometer. The spectrometer was evacuated for one hour without heating of the ion source or of the FI wire to remove residual solvent. Again without heating of the FI wire, a background spectrum, which showed only a very small contribution due to D-glucose, was then recorded. The temperature of the FI wire was then carefully raised by passage of a current of a few mA through the wire. The molecular ion line ultimately became sufficiently intense without excessively fast consumption of the small quantity of sample adsorbed on the wire. By optimization of the temperature, it was possible to obtain useful spectra over a period of about 15 min. The intensities then decreased rapidly.

The name "field desorption" is not, strictly speaking, confined to the method used here, but is also applicable to the usual technique of molecular beam evaporation of the sample onto the FI emitter. Some of the molecules are "field ionized" in the gas phase as they approach the FI emitter, while others are first adsorbed and then ionized by "field desorption" [7, 42]. The proportions of these two reactions are not yet accurately known. However, since some of the molecules are field ionized in the molecular beam technique whereas all the molecules are field desorbed in the emitter immersion technique, it is justifiable to speak of field desorption mass spectra in the latter case.

In addition to the increase in the relative molecular ion intensities and the decrease in the thermal decomposition of the sample, the FD technique has the advantage of an increase in sensitivity as compared with the molecular beam FI technique.

On evaporation of the substance from a micro-crucible, a large part of the substances flies past the FI emitter, whereas in the FD technique a large part of the small quantity of solute present in a very small droplet of solution can be deposited on the emitter by evaporation of the solvent. The smallest quantities of substance that can be detected are thus in the microgram range. It had previously been necessary in general to use considerably larger quantities of material in the FI technique, which had therefore been inferior to the EB technique in its detection sensitivity. The elimination of this shortcoming by the FD technique is naturally restricted to substances having relatively low volatilities. One conceivable procedure for more volatile substances would be to cool the FI emitter, adsorb the sample on it, and then carefully heat the emitter.

Strong micro-needle growth can be induced even on the edges of sharp metal blades or of thin metal foils by the benzonitrile activation technique. The field desorption technique can thus also be used with FI emitters of this type.

Good spectra can be obtained in this way *e.g.* by heating a strip of razor blade about 2 mm wide and 8 mm long with a current of about 1 A [41]. However, the use of fine wires as FI emitters offers the advantages of somewhat higher ion current intensities (based on equal pressures) and somewhat better reproducibility of the spectra. In this case currents of the order of only 10 mA are sufficient for heating of the wire.

So far we have discussed only the analysis of relatively nonvolatile solid organic substances, which is carried out either by the molecular beam FI technique or by the FD technique. However, various authors have also

[42] Regarding field desorption see, *e.g.*: *E. W. Müller*, Physic. Rev. *102*, 618 (1956); *R. Gomer*: Field Emission and Field Ionization. Harvard University Press, Cambridge (Mass.) 1961.

investigated many gaseous, liquid, or solid organic substances whose volatility is so great that a normal gas inlet system with a pressure-reduction stage between the gas reservoir and the ion source may be used.

Molecular ions were detectable in the FI mass spectra of all these substances except (as was mentioned earlier) a few halogenated compounds. In some cases molecular ions were found even where the EB mass spectra forced one to conclude that no stable molecular ion state existed. A relevant example is neopentane *(5)*, which gives no molecular ions in the EB spectrum, but gives up to about 8% of molecular ions in the FI spectrum (see Fig. 11). A stable molecular ion state must therefore exist in this case, though with only a small potential trough.

No theoretical explanation has yet been found for the fact that this state is accessible by FI but not by EB. It is possible that an adsorption state of neopentane increases the probability of transition into the stable ionic state, or, as is assumed by *Robertson*[43], that the selection rules are considerably altered in the presence of a very high electric field.

To summarize, therefore, the molecular ions of the great majority of substances that do not give distinct molecular ion peaks on electron bombardment can be detected by the use of the FI or FD techniques. This allows not only the determination of the molecular weights of very small quantities of substance, but also, by the use of a high-resolution mass spectrometer, the determination of the empirical formula (see[1,2]) of the molecules under investigation.

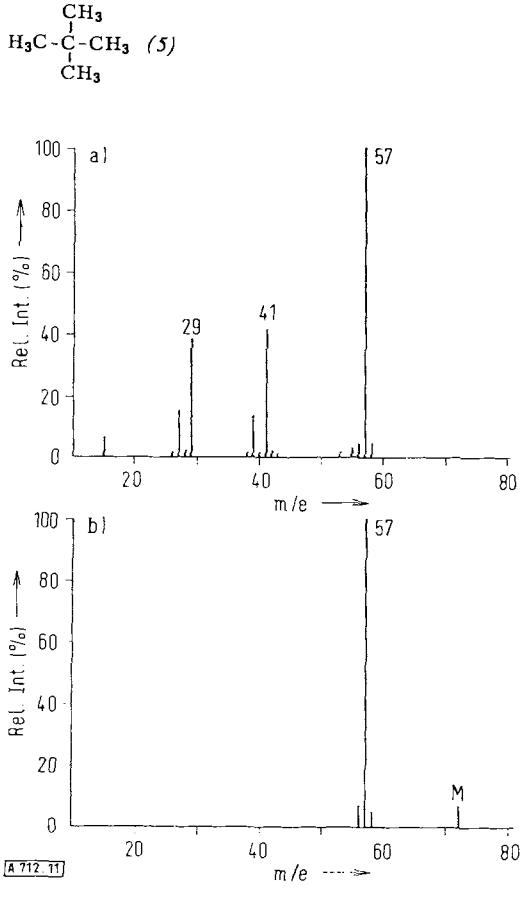

Fig. 11. a) Electron bombardment and b) field ionization mass spectra of neopentane *(5)*.

4.2. Information Obtainable from FI Fragmentation for Structure Determination

The FI mass spectra, like the EB spectra, contain characteristic mass lines of fragment ions that provide clues to the structure of the compounds in question. The intensities of the fragment lines are much smaller for FI than for EB, but the number of these lines is also considerably smaller in field ionization, since the number of possible reaction paths for the decomposition of the molecular ions is very much smaller than on ionization of the molecules with 70 eV electrons. Reactions that proceed in several consecutive steps are rare in FI and give only very low intensities.

The FI fragment ion spectrum often represents a valuable complement to the EB spectrum for two reasons:

1. The intensity distribution of the fragment ions in FI is different from that in EB because of the strong polarization of the molecules, and the spectra are often much easier to interpret because of the small number of lines.

2. There are extremely unstable molecular ions that are characterized in the EB technique, not only by the absence of molecular ion lines, but also by the absence of some fragment ion lines in the mass region slightly below the molecular ion lines. These mass lines, which are often important for the determination of structures, frequently become visible with FI, as will be shown later with the aid of some examples.

In connection with the first of these points it should be noted that the most characteristic fragment lines in FI spectra are those of aliphatic compounds or cyclic compounds with long side chains. In the absence of such side chains, the FI mass spectra of cyclic systems are often not very characteristic.

The FI fragment ions that appear in their normal mass positions in relation to the molecular ions are formed by "field dissociation"[44]. Their intensities increase very rapidly with the field strength. For wire or edge emitters covered with micro-needles, the field strength is about 5×10^7 to 7×10^7 V/cm. (At appreciably higher field strengths the micro-needles break off.) In this range of field strengths *n*-alkanes give fragment ions with a maximum relative intensity of about 1%. With point emitters, on the other hand, with which much higher fields can be produced, the intensity of the $C_2H_5^+$ fragment lines (m/e = 29) can be increased to 100%, as is shown by Figure 12.

The fragment m/e = 29 is the most characteristic fragment in the FI mass spectra of *n*-alkanes, irrespective of their molecular weight. The predominance of this fragment is due to the fact that after ionization, the *n*-alkanes are situated in front of the surface of the point in the extended state. The field tends to displace

[43] *A. J. B. Robertson*, personal communication.

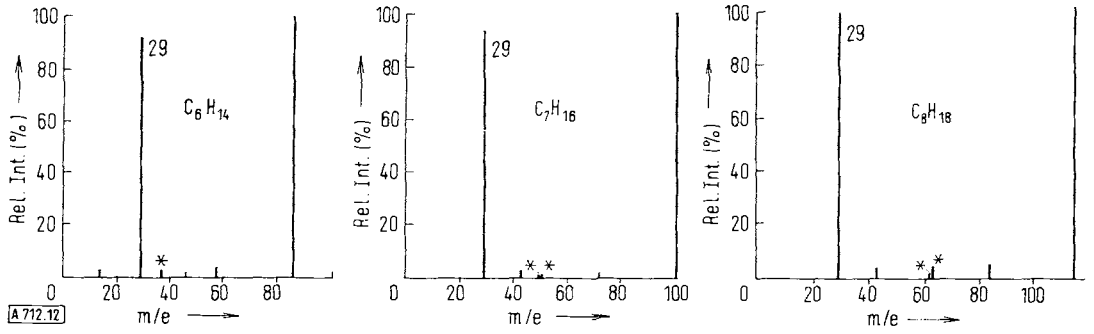

Fig. 12. FI mass spectra of *n*-hexane, *n*-heptane, and *n*-octane with platinum points at high field strengths. Characteristic $C_2H_5^+$ fragment ions (m/e = 29). Metastable ions are denoted by crosses.

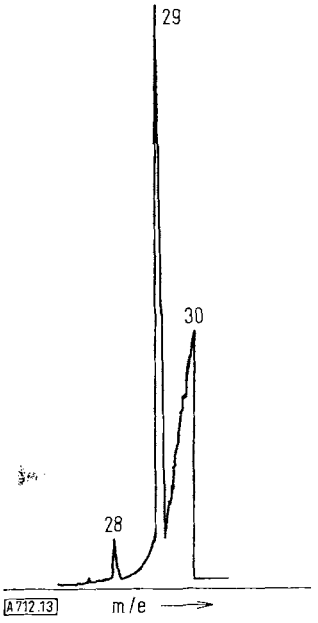
the charge to the end of the molecule that is farthest from the point, this tendency being opposed by the decrease in the ionization energy from orbitals nearer the end of the molecule toward orbitals nearer the center of the molecule. An energy balance shows that the removal of a $C_2H_5^+$ ion from the molecular ion is the most strongly favored process[44]. *Lorquet*[45] obtained the same result by a quantum-mechanical calculation of the charge distribution in extended *n*-alkane ions in a high electric field.

Linear primary amines are characterized by the removal of $CH_2NH_2^+$ fragments (m/e = 30). The pronounced unsymmetrical broadening of the lines[46], as shown in Figure 13, is typical of these fragments.



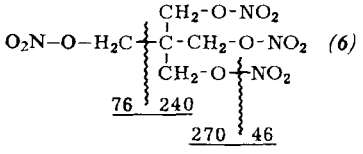


Fig. 13. Section of the FI mass spectrum of 1-pentylamine. Typical broadening of the $CH_2NH_2^+$ mass line (m/e = 30).

Other homologous series of organic compounds have other characteristic fragment lines. Thus primary alcohols[47] are characterized by CH_2OH^+ ions (m/e = 31), and 1-olefins[48] by $CH_2{=}CH_2{-}CH_2^+$ ions (m/e = 41).

Some examples will now be given of cases in which the absence of molecular ions on EB is accompanied by the absence of some important fragment ions from the higher mass range.

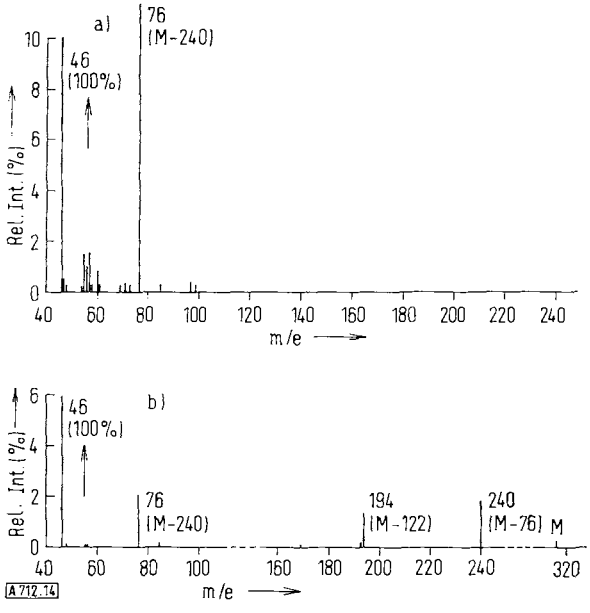

Fig. 14. a) Electron bombardment and b) field ionization mass spectra of pentaerythrityl tetranitrate *(6)* [31].

Figure 14 shows the EB and FI mass spectra of pentaerythrityl tetranitrate *(6)*, an extremely unstable compound used for the ignition of solid rocket fuels and explosives (after *C. Brunnée*[31]). No recognizable fragments are found above m/e = 76 in the EB spectrum, whereas the FI spectrum contains two very characteristic fragment ion lines at m/e = 194 and 240, as well as a weak molecular ion line.

Damico[49] has compared the EB and FI mass spectra of a series of pesticides. Figure 15 shows the spectra of Temik sulfoxide *(7)*. The EB spectrum lacks the molec-

5. Kinetic Studies with the FI Mass Spectrometer

Questions of the kinetics and the mechanism of the decomposition of organic ions are closely related to the problem of structure analysis. FI mass spectrometry can make new contributions to these problems, which will be briefly discussed here [4].

The most important aspect is the fact that extremely fast decomposition processes can be isolated from the slower processes in the FI mass spectrometer, in contrast with the EB mass spectrometer, which integrates fast and slow reactions over a wide range. Fragment ions that appear at their normal mass numbers (based on the molecular ions) in the FI mass spectrometer must be formed within a time range of 5×10^{-14} to 3×10^{-12} sec. Fragment ions formed later appear either as tails of strongly broadened mass lines or as metastable mass lines. The normal fragment ion mass lines in the EB spectrum, on the other hand, result from decomposition processes occurring in a range of about 5×10^{-14} to 10^{-6} sec after the ionization of the molecule.

The reason for the fact that only extremely rapidly formed fragment ions are detected in the normal mass positions in the FI spectrum is the extremely large potential gradient in front of the FI emitter. For a field of 10^8 V/cm, *i.e.* 1 V/Å, a molecular ion has passed through a potential difference of several volts after traveling a distance of only a few Å. If it then decomposes at this point of lower potential, the fragment ions have a lower kinetic energy than the fragment ions formed at the ionization site. This results in a shift of the mass positions in the spectrum toward lower mass numbers.

Without going into mathematical details [4, 50, 51], it will be shown briefly here how the reaction time Δt of the decomposing ion is found from the observed mass displacement ΔM. The observed ΔM value, together with the fundamental equation for the mass spectrometer, can be used to calculate the potential difference ΔU between the points of ionization and of decomposition. The geometry of the FI emitter and the counter-electrode is used to calculate the potential distribution between these electrodes, and the distance Δx between the points of ionization and of decomposition can be deduced from the ΔU value. The decomposition time Δt is finally found by integration of the equation of motion for the molecular ion. Thus the complete scheme of correlations is

$$\Delta M \rightarrow \Delta U \rightarrow \Delta x \rightarrow \Delta t$$

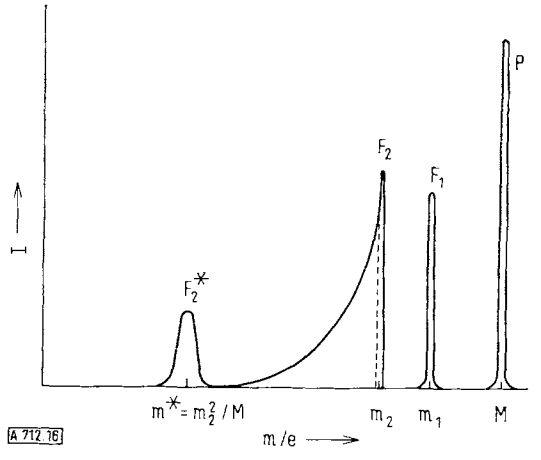

Fig. 16. Schematic representation of the line shapes in FI mass spectra. P = molecular ion line, F_1 = mass line of fragment ions formed on the emitter surface, F_2 = strongly broadened mass line of fragment ions that decompose in the gas phase in the electric field, F_2^* = mass line of metastable ions formed in the field-free space of the mass spectrometer before entry into the magnetic field.

[50] *H. D. Beckey*, Z. Naturforsch. *16a*, 505 (1961).

[51] *H. D. Beckey* and *H. Knöppel*, Z. Naturforsch. *21a*, 1920 (1966).

Figure 16 shows schematically the line shapes for the molecular ions and the various fragment ions in the FI mass spectrometer. The shape of the fragment ions F_1 formed either on the surface of the emitter or in the gas phase within 10^{-13} to 3×10^{-12} sec is as sharp as that of the molecular ions. Strongly broadened fragment ion lines F_2 can be attributed to decomposition processes between 3×10^{-11} and 10^{-8} sec. The "metastable" fragment peak F_2^* contains fragmentations formed within 10^{-8} to 3×10^{-6} sec. As in the EB mass spectrum, these metastable ions occur at an apparent mass number $m^* = m_2^2/M$, where m_2 is the true mass of the fragment and M is the mass of the molecular ion. By evaluation of the strongly broadened mass line as described above and analysis of the decomposition time spectrum of the metastable ions by a retarding potential method [52], it was possible for the first time together with *Tenschert* [4], to follow the mean decomposition times of several organic ions over an extremely wide range of times (3×10^{-11} to 3×10^{-6} sec).

The most important result was the observation that instead of only one or a few discrete rate constants k for these decomposition reactions, there is a whole spectrum of such constants, this spectrum being quasi-continuous to within the accuracy of the measurements. This confirmed one of the fundamental hypotheses of the quasi-equilibrium theory (QET) [53, 54] of mass spectra for large molecules. Similar conclusions were reached by *Hertel*, *Osberghaus*, and *Ottinger* [55–57] on the basis of electron bombardment experiments, though the time range covered in these experiments was not so wide as that covered in the FI experiments described here.

Figure 17 shows the distribution of the mean rate constants as a function of the decomposition time

$$\bar{k}(t) = \frac{1}{N(t)} \cdot \frac{dN}{dt}(t)$$

Possible kinetic applications can be deduced from the fact that it is possible to distinguish between very fast (5×10^{-14} to 3×10^{-12} sec) and slower (3×10^{-12} to 3×10^{-6} sec) decomposition reactions by FI mass spectroscopy.

Rearrangements of organic ions are often associated on the one hand with a low frequency factor and on the other with a low activation energy. If, as in the EB mass spectrometer, the ions have sufficient time available (max. 3×10^{-6} sec), the rearrangement process will be very intense because of the low activation energy, and the corresponding "rearrangement lines"

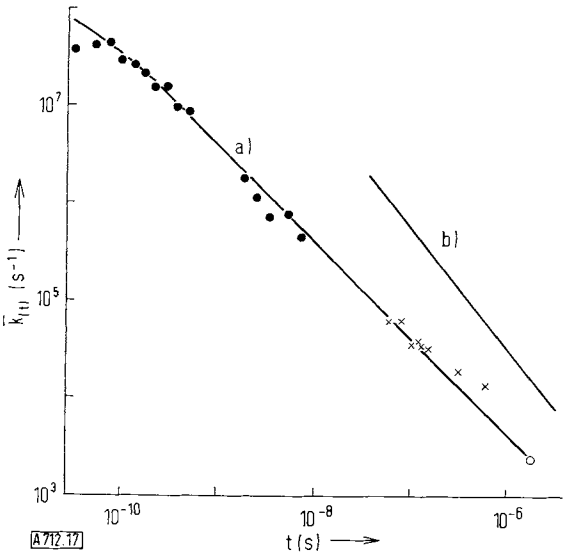

Fig. 17. a) Average rate constants $\bar{k}(t)$ for the decomposition of *n*-heptane ions

$C_7H_{16}^+ \rightarrow C_5H_{11}^+ + C_2H_5$

as a function of time after field ionization. The $\bar{k}(t)$ values were obtained from (●) the strongly broadened fragment-ion line, (×) the mass line produced with a retarding potential, (○) the normal metastable mass line, b) For comparison: $\bar{k}(t)$ values from electron bombardment experiments by *Hertel* and *Ottinger* [56, 57]. (Higher $\bar{k}(t)$ values because of greater energy transfer by 70 eV electrons.)

are often the strongest in the mass spectrum. In field ionization, on the other hand, the molecular ion has a maximum of only about 3×10^{-12} sec available if the rearrangement fragment is to appear in the normal mass position. This time is often insufficient in rearrangement reactions, and the corresponding mass line is then extremely small or completely undetectable. It is of interest for these reasons to compare electron bombardment and field ionization mass spectra of rearrangement reactions. This comparison is carried out by forming the ratio

$$R = \frac{I_{FI}^i / I_{FI}^b}{I_{EB}^i / I_{EB}^b}$$

where the I are the ion intensities and the indices i and b refer to the i-th fragment and to the reference line (the most intense line in the spectrum) respectively. This factor R_r for rearrangements should be very small, whereas the corresponding factor R_d for direct bond rupture should be considerably greater.

Together with *Levsen*, we have shown [4] that the ratio of the smallest R_d factor for a given molecule ($R_{d\,min}$) is always greater than the R_r value for the same molecule in the case of skeletal rearrangements. Figure 18 illustrates this effect for the EB and FI mass spectra of diphenyl ether *(8)*. Even at a very high sensitivity, the FI mass spectrum contains no (M – CO) mass line, whereas the relative intensity of this line in the EB spectrum is 20.3% (see [3]). However, this fragment ion can also be formed in the FI mass spectrometer later in the decomposition. It can then be detected in the mass position of the metastable ion, as is shown in Figure 18.

The mass lines of all skeletal rearrangement processes studied so far were extremely weak in the FI mass

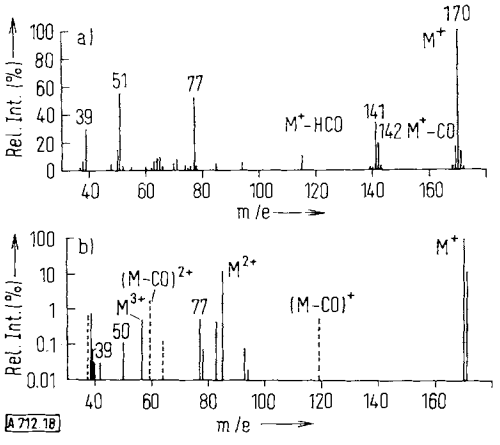

Fig. 18. a) Electron bombardment and b) field ionization mass spectra of diphenyl ether *(8)* (*Levsen* [4]). (Note: Upper intensity scale linear, lower logarithmic.) Metastable mass lines are shown by broken lines in the observed mass position. Temperature of wire 350 °C.

spectra. However, intense lines were found for a number of hydrogen rearrangement processes in the FI spectra [32, 49, 58]. This can be explained in a few cases at the present state of the investigations by assuming that certain states of adsorption favor a rearrangement process already at the surface of the FI emitter. Dissociation of the rearranged molecular ion occurs during field desorption.

In most cases, however, intense H-rearrangement lines do not appear in the FI mass spectrum at the "normal" mass position but are shifted by several tenths of a mass unit towards smaller mass numbers, *i.e.* decomposition occurs after about 10^{-11} sec in the gas phase. This agrees well with the above-mentioned general postulate that the frequency factors for rearrangement reactions, ν_r, are strongly diminished as compared to the frequency factors for direct bond fissions, ν_d, ($\nu_d \simeq 3 \times 10^{13}$ sec^{-1}; $\nu_r \simeq 10^{11}$ sec^{-1} as a result of a rough estimation).

6. Quantitative Analyses with the FI Mass Spectrometer

The electron bombardment mass spectrometer has proved successful over a long period for the quantitative analysis of mixtures of organic compounds. There thus appears to be no need to supplement this method with the field ionization technique for mixtures having relatively few components. The situation is different for mixtures containing a very large number of components (petroleum or gasoline samples with 300–500 components). All the components cannot then be identified by means of the EB mass spectrometer alone, and it is usual to make do with a mass-spectrometric group analysis [59], which gives the relative quantities of *n*-alkanes, *n*-alkenes, cycloalkanes, cycloalkenes, aromatic compounds, *etc.* On the other hand, a complete analysis of such a mixture is possible in principle if all the components are first separated by means of a capillary gas chromatograph and then identified by EB mass spectrometry. In many cases, however, the components are not all separated by gas chromatography. Moreover, when this combination procedure is used, one must be prepared to deal with a large quantity of data.

Frequently, *e.g.* in the characterization of a new fuel, it is unnecessary to identify all 300–500 components, the information required being only slightly more than that provided by a normal group analysis. An important piece of additional information might be *e.g.* the molecular weight distribution within each group. This distribution can be found with the FI mass spectrometer by a method much simpler than the EB method. However, the isomer distribution at a given mass number cannot be deduced from the FI mass spectrum. A combination of molecular weight analysis by the FI method and an EB group analysis is then recommended.

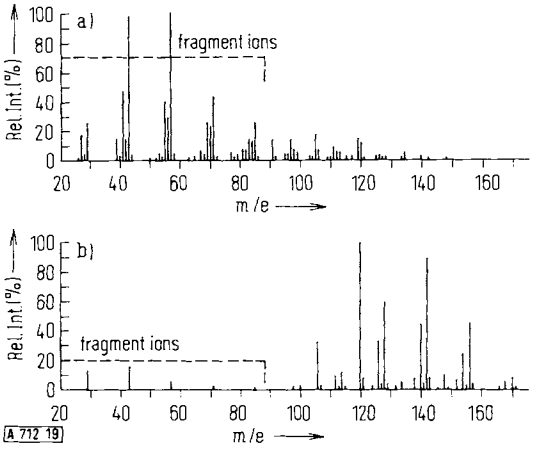

Fig. 19. a) 70 eV electron bombardment and b) field ionization mass spectra of a gasoline sample [62].

Figure 19 illustrates why the determination of the molecular weight distribution is easier with the FI than with the EB mass spectrometer. With electron bombardment, the molecular ion intensities of some components are extremely small, and they may be masked by fragmentations from molecules with higher mass numbers. Both of these difficulties are avoided in the FI method.

For quantitative determination of the molecular weight distribution in a mixture, it is necessary to find the sensitivity coefficients for the various mass groups with the aid of a calibration mixture. The measured heights of the mass lines in the calibration spectrum divided by the quantities of the corresponding substances introduced give directly the average sensitivity coefficients for the substances having the same mass. It is essential for this very simple method that the compositions of the calibration mixture and of the unknown sample should be very similar. If this condition is satisfied a very accurate analysis is possible

[58] *P. Schulze, W. J. Richter,* and *A. L. Burlingame,* 17th Annual Conference on Mass Spectrometry, Dallas (1969).

with the FI mass spectrometer, as is shown by Table 2. This table is based on experiments by *Hippe* [60], in which two synthetic gasoline samples [*] were used, one as the calibration mixture and the other as the sample for analysis.

Table 2. FI mass-spectrometric analysis of a synthetic gasoline mixture.

Mass	Quantity introduced (wt-%)	Analytical results Dec. 16 (wt-%)	Jan. 4 (wt-%)	Mean deviation (wt-%)
68	0.49	0.45	0.48	−0.02
70	3.23	3.04	3.15	−0.13
72	9.38	8.57	9.19	−0.50

134	1.39	1.29	1.56	+0.03
142	0.10	0.09	0.11	−0.01
148	0.35	0.31	0.46	+0.03

The composition of a new sample will normally be known only roughly, so that the condition of close similarity of the compositions of the sample and of the calibration mixture will not be satisfied. *Hippe* [60] was able to show that the sensitivity coefficients of substances in the C_1 to C_{10} range in field ionization depend on many more parameters and vary to a much greater degree with these parameters than in electron bombardment ionization. For example, the sensitivity factors of the FI mass lines are strongly dependent, *inter alia*, on the composition of the mixture, the chemical properties of the components, the order in which the components are introduced, and the state of the FI emitter surfaces coated with chemisorbed material. These effects are due to the fact that the molecules are field ionized predominantly in the adsorbed state, in which they are exposed to various interactions with the adsorbent and the neighboring molecules.

For more accurate analyses, therefore, it is necessary to use an iterative process in which *e.g.* all the components are initially present in equal proportions in the calibration mixture. After the result of the analysis has been found to a first approximation, a second calibration mixture having a composition closer to the result of the first analysis is prepared. The calibration mixture need not contain all the components that are present in the sample, but only a few components for each mass number that occurs in the sample. Representative calibration components must be selected for each mass group. The gain resulting from the simplicity of the FI mass spectra is partly offset by the need for the iterative process.

The complications just described obviously do not arise if the sensitivity coefficients of all the components of a mixture are approximately equal. These conditions are apparently satisfied in high-boiling alkane fractions. Firstly, the differences in the probability of field ionization decrease with increasing molecular weight, and secondly these samples do not contain olefins, which strongly influence the sensitivity coefficients.

Mead [61] has used an FI mass spectrometer for the study of alkane fractions in the boiling range 300 to 500 °C. Repeated recording of the spectra showed variations of about ±5% in the relative heights of the mass lines. Each spectrum was therefore recorded three or four times, and the results were averaged. Calibration data were obtained for the principal types of components (*n*-alkanes, iso- and cycloalkanes, and alkylbenzenes). It was found that the sensitivity coefficients of the other groups of compounds are also only within the limits of the measuring error in the C_{20} to C_{40} range. It is therefore possible, for each of the four important groups of compounds (*n*-alkanes, iso- and cycloalkanes, alkylbenzenes) to give an average sensitivity coefficient that is constant in the C_{20}–C_{40} range.

The ratio of *n*-alkanes to isoalkanes naturally cannot be deduced directly from the FI mass spectra, since they give the same molecular ion lines. As was mentioned above, however, this ratio can be found either by the usual electron bombardment group analysis with the aid of characteristic fragment ion lines, or more simply by the molecular sieve technique. In the latter case, an FI mass spectrum is recorded before and after the treatment with the molecular sieve. The *n*-alkanes are adsorbed practically quantitatively by the molecular sieve, so that their relative quantity is given by the difference between the two spectra.

Table 3. Analysis of ASTM Wax No. I.
(EB analysis: average of the results from eight laboratories.)

		EB (wt-%)	FI (wt-%)
n-Alkanes	C_nH_{2n+2}	70.0	65.7 [a]
Isoalkanes	C_nH_{2n+2}	12.8	16.4
Monocycloalkanes	C_nH_{2n}	14.2	14.9
Bicycloalkanes	C_nH_{2n-2}	2.1	1.8
Tricycloalkanes	C_nH_{2n-4}	...	0.3
Alkylbenzenes	C_nH_{2n-6}	0.8	0.7
Indans- and tetralins	C_nH_{2n-8}	0.09	0.2

[a] Absorption by molecular sieve.

Table 3 shows the result of an FI analysis of this type carried out by *Mead* [61], together with the average analytical values obtained in eight laboratories with EB mass spectrometers. The agreement of the results is very good, except in the ratio of the *n*-alkanes to isoalkanes. However, these discrepancies may not be the fault of the field ionization method.

[60] *K. G. Hippe* and *H. D. Beckey*, unpublished results.

[*] The samples were supplied by Dr. *R. D. Behling*, BP-Hamburg.

[61] *W. L. Mead*, Analytic. Chem. *40*, 743 (1968).

[62] *H. D. Beckey* and *G. Wagner*, Z. analyt. Chem. *197*, 58 (1963).

The detection of tricycloalkanes appears to be more definite with FI than with EB, since no data were reported in the latter case. The same is true of the indans and tetralins, whose presence in the sample was reported by some of the laboratories using EB mass spectrometers and not by others. The molecular weight distribution for the groups is given directly by the FI mass spectra.

To summarize, therefore, the analysis of high-boiling hydrocarbon mixtures containing many components by means of an FI mass spectrometer is much simpler if the sensitivity coefficients of the groups of substances are constant. Long calculations are avoided in the evaluation of the spectra, and it is unnecessary to solve extremely large matrix systems or to make allowance for the masking of fragments of heavier components by the lighter components. The detection of trace components in a mixture is more definite with FI than with EB; this observation is not confined to the high-boiling hydrocarbon mixtures discussed here.

Finally, it should be mentioned that *Wanless* [63,64] has constructed "FI metastable maps", which simplify the identification of isomers in hydrocarbon mixtures. On field ionization of apolar compounds, metastable fragments are formed almost exclusively from the molecular ions, and not from primary fragment ions. Accurate measurement of the apparent mass m^* of the metastable fragments ($m^* = m^2/M$, m = true mass of the fragment, M = mass of the molecular ion) allows the definite assignment of the metastable ions to the corresponding molecular ions with the aid of the tables (FI metastable maps). Isomers having the same mass number differ in the abundance distribution of the corresponding metastable ions. Thus a simple correlation is obtained between the structure of the compounds and the metastable ions, without the FI spectrum of mixtures being overloaded with fragment ions that can appear at the same mass number on electron bombardment despite the fact that they are formed from compounds having different molecular weights.

We are grateful to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Union Rheinische Braunkohlenkraftstoffe for their support of our work in this field.

Methods and Possibilities of Nucleophilic Acylation[1]

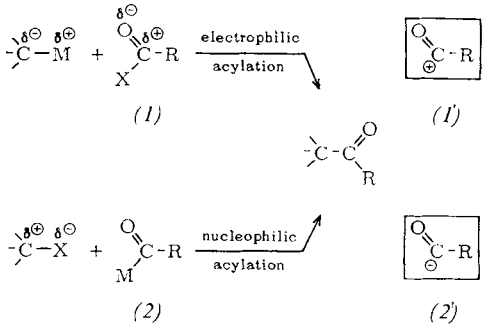
By D. Seebach[*]

Nucleophilic acylation is the attachment of an $R-\overset{\ominus}{C}=O$ group to an electrophilic center. A brief discussion of the advantages offered by acylations of this type in syntheses is followed by a description of the direct methods (reactions with acylmetal compounds) and the methods proceeding via "masked" acyl anions. The latter methods are based on the use of either metalated vinyl ether derivatives or carbanions derived from acetals. Organyllithiums of sulfur-stabilized carbanions are important reagents of this type.

1. Introduction

The synthetic methods of organic chemistry have always been greatly enriched by the direct or indirect "reversal" of the mode of reaction of a reagent. Thus when water is added to unsymmetrically substituted double bonds, the OH group in the product is always attached to the carbon atom carrying the greater number of alkyl substituents (*Markownikoff*'s rule). A general method allowing the reverse mode of addition would require $HO^{\oplus}$ as an electrophile, the intermediate resulting from the primary attack by this species then being "neutralized" by an $H^{\ominus}$. This is not

Scheme 1.



[*] Priv.-Doz. Dr. D. Seebach

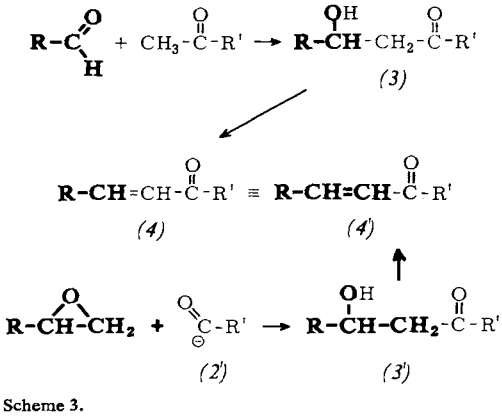
[1] A separate review of the dithiane method of nucleophilic acylation has already been published [84].

possible directly, but it can be achieved indirectly, according to *H. C. Brown* [2], by hydroboration.

In this reaction, if one considers only the starting materials and the final products, the mode of reaction of water is reversed. This may also be regarded as "symmetrization" [3] of the reactivity (Scheme 1).

The present article is concerned with reversal of the mode of reaction of the carbonyl carbon atom. In reactions of conventional acylating agents *(1)*, X = halogen, OR, NR_2, *etc.* with carbanions [4], the



(1) *(1')* *(2)* *(2')*

Scheme 2. M = metal.

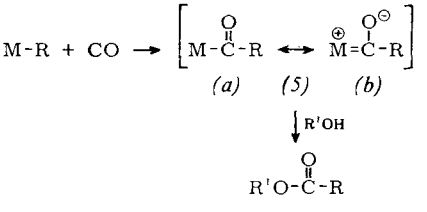
acylating component used is formally (though not usually as a "true" intermediate) an acyl cation *(1')*, *i.e.* an electrophile. A nucleophilic acylation should then logically be the addition of an acyl anion *(2')* to a positively polarized C atom. The conventional acylating agents *(1)* are electrophiles, whereas a nucleophilic acylating agent *(2)* appears, at first sight at least, to be an impossibility. Acylating agents of both types should yield identical products [we cannot expect to be able to prepare novel carbonyl compounds with the aid of *(2)*], but the starting materials used may be entirely different (Scheme 2). Instead of a metal derivative having a negatively polarized C atom, a halide with a positively polarized C atom is used. The possibility of using different starting materials is illustrated in Scheme 3 for the preparation of an α,β-unsaturated ketone.

The aldol *(3)* can be prepared by the methods of classical carbonyl chemistry from an aldehyde and a

(3) *(4)* *(4')* *(2')* *(3')*

Scheme 3.

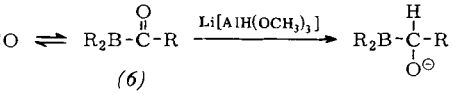
[2] *H. C. Brown*: Hydroboration. Benjamin, New York 1962.



[3] *E. J. Corey*, Pure appl. Chem. *14*, 19 (1967).

[4] Apart from Si- and Ge-acylation, the present article will be concerned only with C-acylation.

methyl ketone; we should be able to obtain the same aldol *(3')* from an epoxide by means of a nucleophilic acylating agent. Elimination of water leads to the identical α-β unsaturated ketones *(4)* and *(4')*. Since the epoxide is readily formed from the olefin, the formation of *(4')* corresponds in its final effect to the replacement of one of the hydrogen atoms on the less substituted C atom of the olefin by an acyl group. One starting compound is often predetermined in a synthesis, so the possibility of varying the building units ("synthons" [3]) can be of great value.



2. "Direct" Acylmetal Compounds *(2)*

The oldest known type of acylmetal compound is obtained by insertion of CO into metal-carbon bonds in which the metal is a transition metal of the group 6 to 8 triads [5]. Like the boryl ketones *(6)* obtained *e.g.* from boranes and carbon monoxide [6] or the silyl and germanyl ketones mentioned below, the acyl derivatives *(5)* which appear from the IR frequency to involve a contribution due to limiting structures *(5b)*, are generally not nucleophilic acylating agents. The transition metal compounds *(5)* react with alcohols

(a) *(5)* *(b)*

to form esters, and the boryl ketones *(6)* react with complex hydride to give alkoxides; the usual electrophilicity of the carbonyl carbon atom is thus evident in both types of compound. Nucleophilic acylations have, however, been observed with ionic compounds of the type *(5)* in which the acyl group is contained in an anion. Thus the reaction of tetracarbonylnickel with aryllithiums [7a,8a] leads to complex salts *(7)*

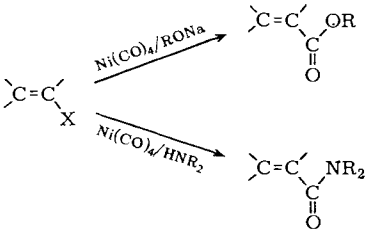
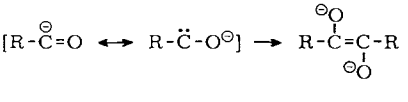
(8) (9)



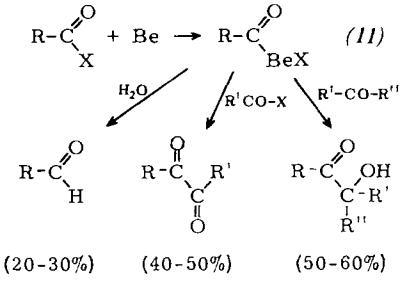
which give aldehydes on treatment with acid and react with benzyl chloride to form the α-hydroxy ketone *(8)* together with a little ketone *(9)*. The ketone *(9)* is the aroylation product of benzyl chloride, and the hydroxy ketone is probably the product of the nucleophilic acylation of the ketone *(9)*.

A useful application of reagents of this type was found by *Corey* and *Hegedus* [7b]. The reagents analogous to *(7)* that are formed in the reaction of methyl-, *n*-butyl-, or phenyllithium with tetracarbonylnickel add on in high yields to α,β-unsaturated carbonyl compounds in the 1,4-position, *i.e.* after the manner of a Michael addition; after hydrolysis, the 1,4-dioxo compounds *(10)* are isolated.



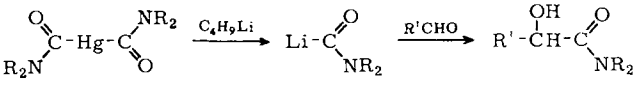
(10)

The alkoxycarbonylations and carbamoylations of vinyl halides with tetracarbonylnickel and alkoxides and amines [7c] are undoubtedly also mechanistically related.



A benzoyl anion intermediate can possibly also be postulated in the reaction of phenyllithium, phenylsodium, or phenylmagnesium bromide with carbon monoxide [8b] to explain the formation of the products (benzhydryl phenyl ketone, benzoin, benzophenone, triphenylmethanol). The formation of benzoin leads to the conclusion that organometallic acylalkali metal compounds, the anions of which are carbenes in one of their limiting resonance structures, can dimerize to give dialkali metal salts of enediols, which are known from the acyloin reaction.

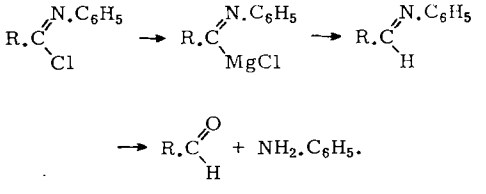
The problem of secondary reactions *e.g. (7)→(9)→(8)* can also arise in all *direct* nucleophilic acylations, since the *free* carbonyl derivatives formed in the reaction with electrophiles are themselves electrophiles.



Three years ago, *Lapkin et al.* [9] described the reaction of acyl chlorides, bromides and iodides with beryllium, which, like the formation of Grignard reagents, is exothermic. The resulting ether soluble beryllium derivatives are formulated as *(11)*, and exhibit the expected reactions of acyl anions. Thus hydrolysis leads to aldehydes, acylation to 1,2-diketones, and reaction with ketones to α-hydroxy ketones in the yields indicated. So far as we know, the range of application of these new reagents has not yet been investigated [10].

(11)

(20-30%) (40-50%) (50-60%)



Schöllkopf and *Gerhart* [11] found only recently that treatment of bis(carbamoyl)mercury compounds with two moles of butyllithium yields products *(12)* that can effect nucleophilic carbamoylation; with aldehydes, for example, they form α-hydroxy amides *(13)*.

(12) *(13)*

(11) and *(12)* are the simplest direct nucleophilic acylating agents known at present.

While seeking an aldehyde synthesis more than 60 years ago, *Staudinger* pointed out the possible synthetic value of acylmetal compounds [12]: "If acyl chlorides (bromides) could be converted into the corresponding *Grignard* compounds, this would provide a general method for the reduction of the COOH to the COH group, since the *Grignard* compounds should give aldehydes on cleavage with water:

This process cannot be achieved with acyl chlorides, but a similar reaction takes place with the *imidoyl*

[9] *I. I. Lapkin, G. Y. Anvarova,* and *T. N. Povarnitsyna,* Ž. obšč. Chim. *36*, 1952 (1966); J. gen. Chem. (USSR) (English transl.) *36*, 1945 (1966).

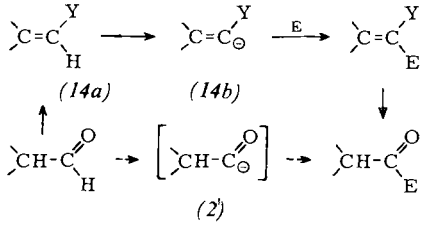
[10] The ease with which *(11)* can be prepared is evidently very strongly dependent on the purity of the metal used (cf. many Grignard reactions). We could not reach these yields with 98.5% beryllium powder; the reaction started only with difficulty.

[11] *U. Schöllkopf* and *F. Gerhart,* Angew. Chem. *79*, 819, 990 (1967); Angew. Chem. internat. Edit. *6*, 805, 970 (1967).

[12] *H. Staudinger,* Ber. dtsch. chem. Ges. *41*, 2217 (1908).

chlorides, since the *chlorine atom* in this case reacts with magnesium [13].

In this little-cited [14] article, *Staudinger* reported that *e.g. N*-phenylbenzimidoyl chloride reacts exothermally with magnesium in ether [15], and that benzylideneanilide can be isolated after hydrolysis; the latter can be readily converted into benzaldehyde. The Grignard compound of the imidoyl chloride would be a carbonyl analog of *(11)* and *(12)* [15].



3. Possibilities of Indirect Nucleophilic Acylation

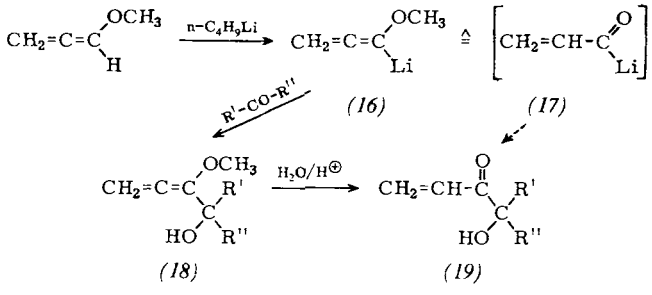
Carbanions (or more precisely organometallic compounds) of such a type that their products can be converted into carbonyl compounds by *hydrolysis*, will be referred to in this discussion as "masked" nucleophilic acylating agents. This requires removal of the hydrogen atom from the carbonyl carbon of an aldehyde, *i.e.* conversion of the aldehyde into its conjugate base.

This should be possible by two general methods.

3.1. Metalated Enol Derivatives

The aldehyde is converted into an enol derivative *(14a)*, which can be metalated to form *(14b)*. *(14b)* is a masked acyl anion, since reaction with an electrophile followed by hydrolysis converts it into a ketone, in which the hydrogen of the aldehyde is electrophilically substituted (dotted arrows). This method is

(14a) *(14b)* *(2)*



E = electrophile

of limited applicability, since the aldehyde must have at least *one* α-hydrogen atom; for example, nucleophilic benzoylation is not possible by this method because aryl aldehydes cannot be used. The metalation of *(14a)* is favored by anion-stabilizing groups Y. Oxygen rather destabilizes (see below) an α-carbanion, and only one derivative of an α-alkoxy carbanion has been preparatively obtained so far (CH_3-O-CH_2-Li [16]). Though sp^2-bound hydrogen is more acidic than sp^3-bound, enol ethers *(14a)*, Y = OR, can be metalated as indicated above only under very forcing conditions (amylsodium [17a], *tert*-butyllithium / *N,N,N',N'*-tetramethylethylenediamine [17b]). Furan like thiophene (see below), is doubly metalated by amylsodium [to give *(15a)*] [18a]; *(15a)* is the masked succinyl dianion *(15b)*.

(15a) *(15b)*

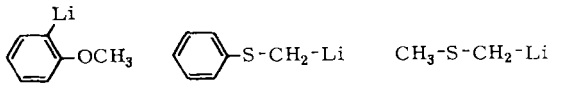
The ease of metalation of alkyl allenyl ethers [18b] (readily obtainable from propargyl ethers) is particularly interesting; the lithium derivative *(16)* is obtained under "standard conditions" (ether/tetrahydrofuran, −20 °C).

(16) *(17)* *(18)* *(19)*

Deuterolysis, alkylation, hydroxyalkylation, and thiolation lead to the expected products. The product *(18)* obtained by addition to a carbonyl compound is hydrolyzed to the hydroxy ketone *(19)* under very mild conditions (0 to 5 °C, 1 hour); the structure of *(19)* shows that *(16)* is a masked acyllithium derivative of acrolein [*(17)*] (see dotted arrow). *(16)* is the best of the known preparatively usable acylating agents, in that the "demasking" of the products [*e.g. (18)→(19)*] takes place under the mildest conditions. Replacement of the oxygen in enol ethers by sulfur [*(14a)*, *(14b)*, Y = SR] should lead to considerable stabilization of the vinyl anion.

There is no longer any doubt about the stabilizing effect of sulfur, even in the dicoordinate state, on adjacent anionic centers. On metalation of anisole and thioanisole with butyllithium, *Gilman* and *Webb* [19a] found that anisole exchanges an sp^2-bound ring proton α to the oxygen [→*(20)*], whereas thioanisole exchanges an sp^3-bound proton on the methyl group [→*(21)*].

[13] a) Recent attempts to prepare "acyl Grignard compounds" have also been unsuccessful (*A. Eschenmoser*, personal communication); b) reaction of benzoyl chloride with naphthalene-sodium followed by hydrolysis yields benzoin, the formation of which was explained as involving the intermediate formation of benzoylsodium [*W. Schlenk* and *E. Bergmann*, Liebigs Ann. Chem. *463*, 19 (1928)]; the reaction could, however, also proceed by a free-radical mechanism (see ketyls and the acyloin reaction).



[14] *F. Runge*: Organometallverbindungen. Wissenschaftliche Verlagsgesellschaft, Stuttgart 1944, p. 490.

[15] No Mg-derivative of the imidoyl chloride is formed under the conditions used by *Staudinger* (ether/ethylacetate): on hydrolysis of the reaction product with D_2O we obtained exclusively non-deuterated (according to the ^{1}H-NMR spectrum) benzaldehyde (yield as given in [12]). On varying the reaction conditions (ether, THF; 20–65 °C) we could not detect more than 2% (theoretical) of aldehyde according to the given procedure in the absence of ethyl acetate.

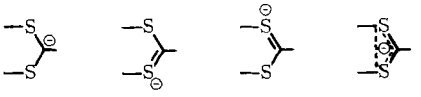
(20) (21) (22)

Amine-activated[21] *n*-butyllithium is necessary for the quantitative production of *(21)*[19b,c] and *(22)*[20] from the corresponding CH compounds, while the derivatives *(23)* of allyl thioethers[22,23], *(24)* of vinyl thioethers[22], *(25)* of thioacetals[19b,24], and *(26)* of orthotrithioformic esters[24–27] can be prepared with butyllithium in tetrahydrofuran. Since *(26)* is formed from tris(phenylthio)methane with tritylithium[26a], the pK_A value of this sulfur compound must be at least two orders of magnitude lower than that of triphenylmethane (pK_A value 28–32, depending on the scale[28]).



(23) (24) (25)

(26) (27) (28)

It is generally assumed that the stabilization of these anions results from overlap of the "anion orbital" with d shells of the sulfur[28–38]. This picture of d-orbital overlap is possibly too primitive[39], but it is certainly very useful. The looseness of the stereoelectronic requirements for stabilization can be seen from a comparison of the Li derivatives *(21)*–*(28)*. The central C atom in the anions of *(21)*–*(23)*, *(25)*, and *(26)* may be sp^2-hybridized, and p-d overlap then occurs, in *(24)* the $C^{\ominus}$ atom could be sp-hybridized (p-d overlap) or sp^2-hybridized (sp^2-d overlap) while in the anions of *(27)*[26a] and *(28)*[30c,41] the anionic C atom cannot be forced into coplanarity with the neighboring sulfur atoms. so that sp^3-d overlap should occur [cf. the trisulfone derived from *(27)*[42]]; the stabilization of α-sulfonyl carbanions may occur without the participation of d shells[43]. In the undissociated Li compounds *(21)*–*(28)* with the exception of *(24)*, stabilization is possible only by sp^3-d overlap[30c]. The metal atom and the medium used are of decisive importance in stability considerations.

To explain the results of D/H and T/H exchange experiments with thioacetals[33a] and orthotrithioformic esters[33] (see also Table 1), it was assumed[33a] that not only the identical limiting structures *(b)* and *(c)* (which are also decisive for monothiocarbanions), but also delocalization by "1,3-overlap" of the d orbitals of two or three sulfur atoms is involved as indicated in *(d)* for a dithiocarbanion. Dicoordinate selenium, the d shells of which have a higher energy level and should be more diffuse[38] than those of sulfur, also stabilizes carbanions[26d].

(a) (b) (c) (d)

Similar conclusions were drawn from the UV spectra[30c,33a,34,44,45] of thioacetals, where zwitterionic[44] or biradical[33a] excited states with delocalization (d) are assumed. Acceptor properties have also been ascribed to sulfur in the stabilization

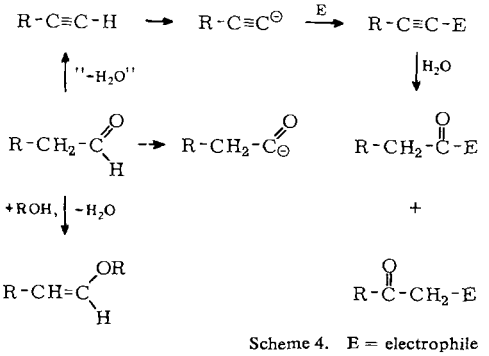
of sextet species (carbene[26b,26c], nitrene[37]). The mathematical description[30c,37,38,43] of the d orbitals, which are normally unoccupied ("absent"), is therefore difficult, since neither their extent nor their energy is adequately known, and these two quantities are of decisive importance to the result of calculations using the Hückel approximation.

According to this explanation, therefore, anions of the type *(14b)*, Y = SR, *e.g.* as Li derivatives *(24)*, should be much better reagents for nucleophilic acylations than the metalated enol ethers. A careful investigation of *(14)*, Y = SC_6H_5, SC_2H_5, and S-*tert*-C_4H_9, with R'Li = *n*-butyl-, *tert*-butyl- and phenyllithium as metalating agents showed that under optimum conditions only about 80% of the desired H/Li exchange to give *(24)* can be achieved[22]; the competing addition of the Li compounds to form *(29)*[22,46] could not be entirely suppressed. Difficulties of this nature appear to be reduced by the use of butyllithium "activated"

(14a), Y = SR *(24)* *(29)*

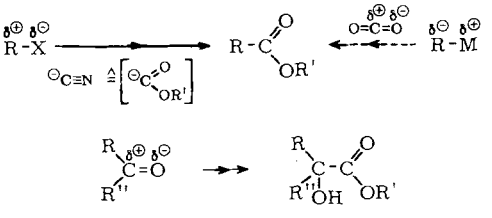
with *N,N,N',N'*-tetramethylethylenediamine or triethylenediamine (the basicity of the butyllithium in these complexes is increased at the expense of its nucleophilicity)[47]. The nucleophilicity of the vinyllithium *(24)*, R = C_6H_5, was found to be good; this compound reacts with D_2O, CO_2, CH_3I, aldehydes, and ketones to give the expected products in good yields[22,23]. Thiophene can be metalated to give a disodium compound of the type *(24)*[8b,18a] (see above in connection with furan). The acid hydrolysis[47b–47d] of thioenol ethers (see also Section 3.2.1) to carbonyl compounds proceeds particularly smoothly in the presence of $HgCl_2$[47a,62a].

Anions *(30)* of allenyl thioethers are obtained from alkynyl thioethers and sodamide in liquid ammonia[48,49], *i.e.* under conditions such that even the simple metal derivatives of thioenol ethers should be obtainable, since the nucleophilicity of NH_2 is much less than that of the lithium derivatives used, and the side reaction of addition should be suppressed.



It should in principle also be worth considering the use of compounds containing halogens, such as $CH_2{=}CClLi$[50a]. However, the low stability of such carbenoids and the great resistance of the products to

(30)



hydrolysis [cf. Cl_3CH with $(CH_3O)_3CH$, $R{-}CCl_2R'$ with $R{-}C(OCH_3)_2{-}R'$, or $CH_2{=}CRCl$ with $CH_2{=}CR(OR)$] have so far prevented their use as nucleophilic acylating agents.

The enol ether-like group of masked acylmetals also includes acetylides. The products of their reaction with electrophiles give carbonyl compounds on *hydrolysis* (addition of water catalyzed by Hg(II) salts). However, the direction of the addition of water cannot usually be controlled[51a]. The reaction yields two isomeric carbonyl compounds, only one of which may be regarded as an acylated electrophile (scheme 4).

Scheme 4. E = electrophile

A well known indirect nucleophilic carboxylating agent, the counterpart of carbon dioxide (dotted arrow in Scheme 5) is the cyanide ion[51b], with the aid of which an ROOC group can be introduced into an

Scheme 5.

electrophilic center. The relatively drastic conditions of the complete acidic or alkaline hydrolysis to the acid stage may be a disadvantage in the synthesis of sensitive compounds (cf. Section 3.2.2).

3.2. Metal Derivatives of Acetals and Related Compounds

3.2.1. Principle and Possible Reagents

In addition to enol derivatives *(14a)*, acetal-like derivatives *(31)* of aldehydes should also be suitable for the production of masked acyl anions *(32)*. The descrip-

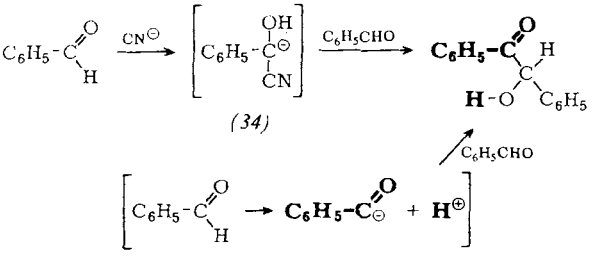
tion "acetal-like" is applied here to derivatives *(31)* and *(33)* that can be converted into the free carbonyl compounds by hydrolysis. Like the vinyl anions *(14b)*,

E = electrophile

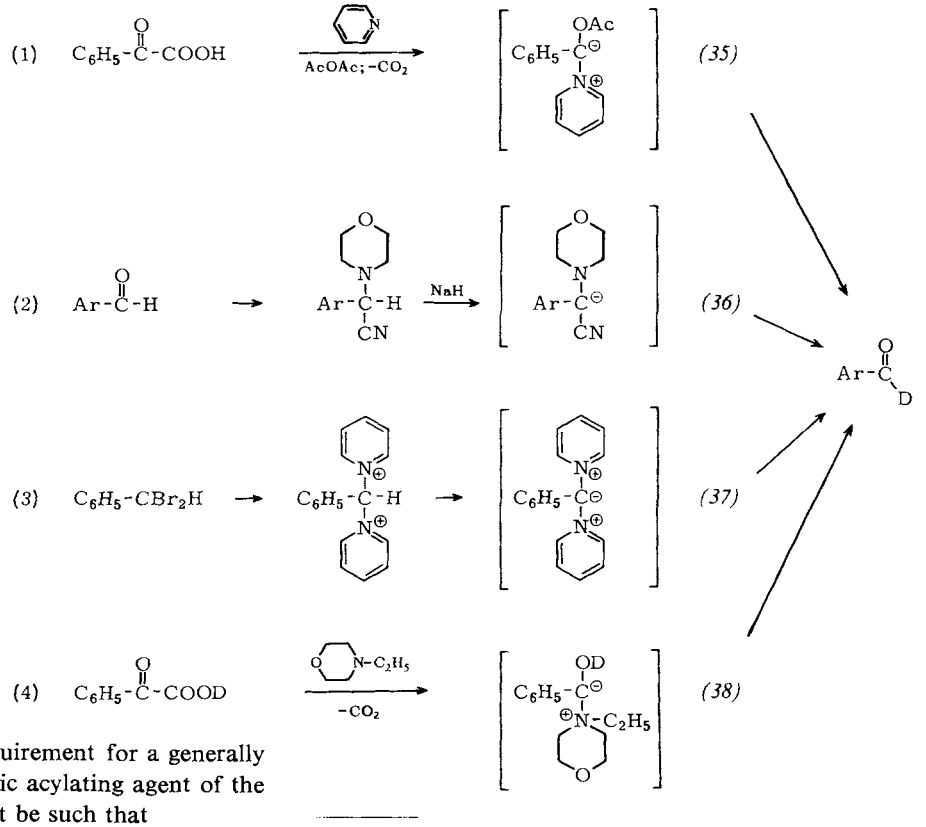
anions *(32)* (*i.e.* conjugate bases of aldehydes) should be able to act as acylating agents. They appear less suitable at first sight, since *(32)* is a trisubstituted carbanion, the nucleophilicity of which may be low because of steric hindrance, but whose basicity may be high for the same reason. R could also be a group linked *via* a trisubstituted C atom or an aromatic ring in this case. The restriction on the use of metalated enol ether derivatives (Section 3.1), *i.e.* that the aldehyde must have at least one α-hydrogen atom, is not valid here.



The conversion of an aldehyde *via (31)*, *(32)*, and *(33)* into a ketone (dotted arrows) would, according to the definition in Section 1, be a "reversible symmetrization" of the mode of reaction of the carbonyl group. The electrophilic carbonyl C atom of the aldehyde has become nucleophilic in *(32)*, and after reaction with an electrophile, the electrophilic carbonyl C atom can be restored by hydrolysis of the product *(33)*.

We impose the following requirement for a generally applicable masked nucleophilic acylating agent of the type *(32)*. The groups Y must be such that

1. *(31)* is preparatively readily obtainable.
2. the conversion into the anion *(32)* proceeds easily and quantitatively,
3. the anion is not so stable that it no longer exhibits high reactivity,
4. the carbanionic center is subject to a minimum of hindrance,
5. no carbenoid decomposition [*(32)* → $R-\ddot{C}-Y + Y^{\ominus}$] or other rearrangements occur, and
6. the hydrolysis of the reaction products *(33)* can be carried out under the mildest possible, and also the most specific possible conditions.

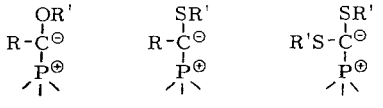


With so many conditions to be satisfied, compromises seem inevitable.

The oldest known reaction involving "masked" acyl anions of the type *(32)* is the preparation of benzoins from aromatic aldehydes [52], as illustrated in Scheme 6

Scheme 6.

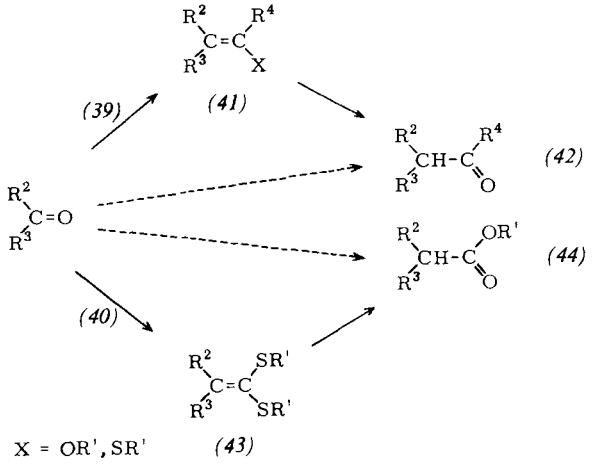
for benzaldehyde. The decisive intermediate in this reaction is assumed to be an anion *(34)*, which adds onto an aldehyde molecule. The final product is formally the result of addition of a benzoyl anion and a



[52] *M. S. Ide* and *J. S. Buck*, Org. Reactions *4*, 269 (1948); cf. also *S. M. McElvain*, *ibid. 4*, 256 (1948).

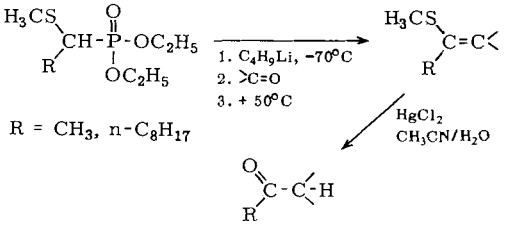
proton to benzaldehyde; *(34)* is mechanistically equivalent to an acyl anion. The reaction is applicable only to aldehydes having no α-hydrogen atoms (otherwise the aldol reaction competes); attempts to prepare mixed acyloins must be expected to yield mixtures of products. Quantitative production of anions such as *(34)* is not possible.

Several methods for the preparation of deuterated aromatic aldehydes have been published in recent years. Intermediates *(35)–(38)* resembling *(34)* were postulated or prepared in every case [eqs. (1)–(4)].



To prove occurrence of these intermediates, they were allowed to react with D_2O, or deuterated starting materials were used; deuterated aldehydes were formed [53–56]. The compounds *(35)–(38)* cannot be used as generally applicable reagents for the introduction of acyl groups, since they are not formed in high concentrations and/or they exhibit strong steric hindrance [for example, *(37)* is of the triarylmethyl type], *i.e.* they do not satisfy the above conditions; even the acylation of $D^{\oplus}$ has so far been preparatively developed for several examples only by the reaction described in eq. (2) [54].

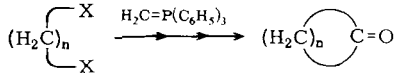
Alkoxy-(alkylthio-) *(39)* and dialkylthiomethylene phosphoranes *(40)* are also nucleophilic acylating or carboxylating



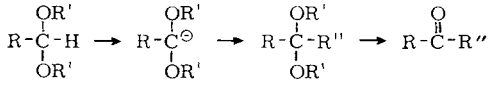
(39a) *(39b)* *(40)*

reagents in a certain sense. Reaction with carbonyl compounds leads in the one case to enol ethers (thioenol ethers), *(41)* [47d,57–59], and in the other case, which has so far been observed only with the sulfur derivatives *(40)*, to ketene thioacetals *(43)* [26b,60–62]. The hydrolysis [47,62a,84] yields the carbonyl compounds *(42)* and *(44)*. In the final effect (dotted arrows), the only respect in which these reactions differ from the nucleophilic acylations is in the absence of the α-hydroxyl group in the final product; the oxygen atom is removed with the phosphorus in the olefination step.

X = OR', SR' *(43)*



A more recent application of this principle, using phosphonates [62a] is shown in the following Scheme.



Scheme 7.

If one considers only the overall reaction in Scheme 7 (dotted arrow), the reaction sequence shown here is also a nucleophilic acylation [35].

However, the final product, *i.e.* the free carbonyl compound, is formed by an oxidative process in this case. Cyclanones can be prepared in good yields by this method [63] (cf. below, dithiane method [82,84]).

Since the acetal grouping is readily hydrolyzed, an anion *(45)* would be a welcome masked acylating agent, the products of which would also satisfy the condition that the free carbonyl group should be easily obtainable under mild and specific conditions by hydrolysis. It is well known that acetals are stable in alkaline solution, but can be readily hydrolyzed with acids. As was mentioned in connection with the

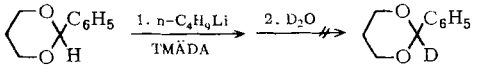
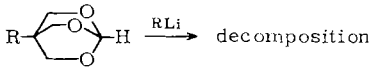
metalated enol ether derivatives, however, α-alkoxy and α-aryloxy carbanions are not generally obtainable; the ether oxygen does not stabilize negative charges, whereas it is an excellent stabilizer for carbonium ions. Aryloxy carbanions can undergo Wittig rearrangement [64]. The only simple alkoxy carbanion derivative

that can be obtained preparatively is methoxymethyllithium, which was mentioned earlier [16]. No dialkoxy carbanions of the type *(45)* have been obtained as yet.

As is known from H-isotope exchange experiments [33] (see also Table 1) and from conductivity measurements [24], the kinetic and thermodynamic acidity [28] of aldehyde acetals is so low that it cannot be measured directly; it has been shown by indirect methods that the kinetic acidity of an α-alkoxy proton (>CH–OR) is about six orders of magnitude lower than that of an α-alkylthio proton (>CH–SR) [33]. This tells us nothing about the thermodynamic stability of corresponding carbanions. Attempts to metalate dialkoxyacetals with strong bases have either been unsuccessful or led to cleavage of the compound used. Thus when organolithium compounds and 2-aryldioxolanes are brought together at room temperature in ether, an exothermic reaction occurs; the products indicate that this reaction proceeds *via* an anion *(46)*. As indicated in eq. (5),



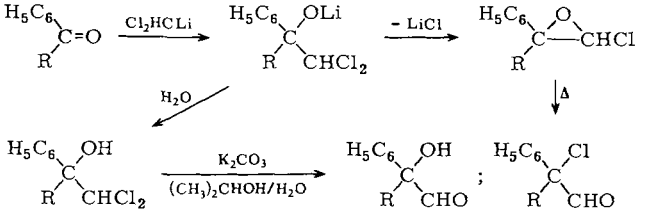
(5)



(46)

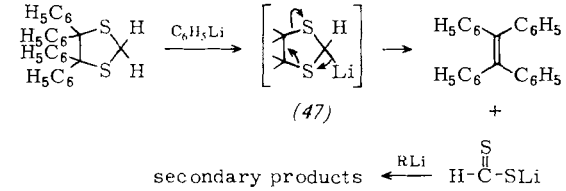
secondary products

(6)



(7)

this decomposes into ethylene and arenecarboxylate [65] (cf. the olefin synthesis described by *Corey* and *Winter* [66]). Even in experiments with 2-phenyl-1,3-dioxane [eq. (6)], the anion of which cannot "fragment" in this way, with the very effective metalating agent *n*-butyllithium/*N*,*N*,*N*′,*N*′-tetramethylethylenediamine [21], in tetrahydrofuran at −78 to +20 °C it was not possible to detect an anion, which should be stabilized, like *(46)*, as a benzyl-like carbanion by conjugation with the aromatic system [62b]. (Under the same conditions, toluene is metalated to give benzyllithium [21,67]; the kinetic acidification due to an α-phenyl group is about ten times as large as that due to an α-ethylthio group [33a].) The orthoformic acid derivative [eq. (7)] also failed to give a directly detectable anion, but decomposed with butyllithium in ether *via* carbenes or carbenoids [65a]. Thus, in none of these cases can the desired metalated acetals or ortho esters be produced under conditions such that they are still stable.



The use of chloro- and bromocarbenoids [50] (R–CCl_2–Li, R–CBr_2–Li) as masked acyllithium compounds is somewhat limited, the reasons being the same as in the case of vinyl halogenocarbenoids (see Section 3.1). Only recently has it been shown [50b,c] that arylketones can be converted into α-hydroxy- and α-chloroaldehydes by dichloromethyllithium, which is stable at temperatures below −90 °C:

In view of the observations described in Section 3.1 on the stabilization of carbanions by adjacent dicoordinate sulfur [see Li derivatives of the anions *(21)* to *(28)*,] it is not surprising that preparatively useful reagents of the type *(32)* have been found among the thioacetals [68]. [The methylene groups in corresponding "diphosphinoacetals", *e.g.* bis(diphenylphosphino)-methane $(C_6H_5)_2P–CH_2–P(C_6H_5)_2$, appear to be much more active than those in thioacetals [69,70]; nothing is known about the possibility of using metalated derivatives *(32)*, Y = PR_2, for nucleophilic acylation.]

Schönberg et al. [71] were probably the first to produce a dithiomethyllithium compound *(47)* when they treated tetraphenyl-1,3-dithiolane in ether with phenyllithium [eq. (8)]. They observed the olefin formation discovered much later for dioxolanes [eq. (5)].

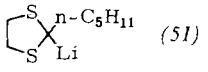
In 1959 and 1962, *Arens* and *Fröling*[24] described the preparation of solutions containing alkali metal derivatives of dithio carbanions *(48)*. Treatment of open-chain aldehyde thioacetals in liquid ammonia with alkali metal amides yields colored solutions, and ketone thioacetal can be obtained on addition of an alkali metal halide. The authors recognized the significance of the reaction sequence as a novel method for the preparation of higher aldehydes from formaldehyde (R′ = H) and of ketones from aldehydes (dotted arrow in Scheme 8). They also found, however, that this method is of limited application, and no further investigations were carried out. The limitations of the method were that (i) only thioacetals of formaldehyde, acetaldehyde, and benzaldehyde could be metalated in this way, (ii) to obtain good yields it was necessary

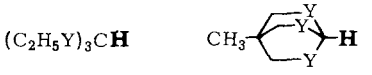


Scheme 8.

to use excess amide, and hence also excess halide, (iii) only the anion of formaldehyde bis(phenylthio)acetal *(48)*, R = C_6H_5, R′ = H, reacted (in moderate yields) with carbonyl compounds, (iv) very reactive electrophiles, such as acyl chlorides, cannot be used in the medium in question, and (v) the hydrolysis of thioacetals, *i.e.* the last step of the cycle, is generally believed to be difficult[72].

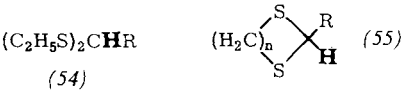
Truce and *Roberts*[73] who concluded from literature references[71,74] that phenyllithium and *n*-butyllithium cleave thiacetals, prepared the sodium derivative *(49)* of benzaldehyde bis(phenylthio)acetal in dimethylformamide with the aid of sodium hydride; *(49)* could

(49) *(25)* *(50)*



(51)

be alkylated and acylated. They obtained sulfur-free products by hydrolysis and desulfurization (Raney Ni or $NiCl_2/NaBH_4$). *Normant* and *Cuvigny*[75] obtained the Na derivative *(49)* with NaH in hexamethylphosphoric triamide (HMPT), whereas other thioacetals are cleaved by sodamide in this solvent. *n*-Butyllithium in tetrahydrofuran gives excellent results in the preparation of bis(phenylthio)methyllithium *(25)* from the CH_2 compound[19b]; however, this simple method fails in attempts to obtain *(50)* by metalation of the corresponding acetaldehyde derivative. Under these conditions, thioacetals having a dithiolane structure give the same results as were obtained by *Schönberg, i.e. (51)* decomposes[76] under the conditions of its formation (−20 °C) [cf. eqs. (5) and (8)].



3.2.2. Dithiane and Trithiane Method

Though the relative acidities (as was mentioned, kinetic acidities often give no reliable information on the thermodynamic stabilities of the metal derivatives or their anions) listed in Table 1 gave no reason to expect any very pronounced difference between open-chain and six-membered ring thioacetals [cf. *(54b)* with *(55e)*], *Corey* and *Seebach*[68,76] found that the 1,3-dithianes *(55)*, *n* = 3, occupy a special place.

Table 1. Relative rates of D/H or T/H exchange for acetals, thioacetals, orthoformic esters, and trithioorthoformic esters with K *tert.*-butoxide in *tert.*-butanol [33a]. H = D or T.

(52) *(53)*

(54) *(55)*

Compound	Y	*n*	R	Relative rate
(52a)	O			[a]
(52b)	S			1.5×10^4
(53a)	O			[a]
(53b)	S			1.8×10^7
(54a)			H	40
(54b)			C_2H_5	1
(55a)		2	H	515
(55b)		2	C_2H_5	20
(55c)		3	H	215
(55d)		3	CH_3	0.4
(55e)		3	C_2H_5	1.5
(55f)		3	$(CH_3)_2CH$	1.3
(55g)		3	$(CH_3)_3C$	1.2
(55h)		4	C_2H_5	5.4

[a] No exchange in 20 hours at 110—140 °C.

Under the conditions mentioned above (tetrahydrofuran, *n*-butyllithium, −20 °C, 1–5 hours), many dithianes *(56)* with a wide range of groups R can be quantitatively metalated to give the 1,3-dithian-2-yllithium compounds *(57)*, which are stable below 0 °C. The reagents *(57)* exhibit good nucleophilic properties, and the products of their reactions with electrophiles can be hydrolyzed under mild conditions. s-Trithian-2-yllithium compounds *(58)* can also be used[76–78].

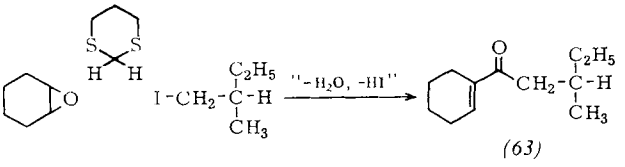
(56) (57) (58)

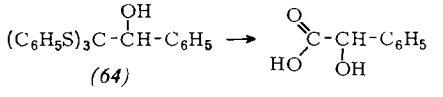
The dithiane method is the most extensively studied of all the nucleophilic acylation methods. It has proved successful in the preparation of 1-deuterated aldehydes [79], silyl and germanyl ketones [80], optically active aldehydes and ketones [77,81], and cyclic carbonyl compounds and hydrocarbons [82], as well as in the most prolific prostaglandin synthesis known at present [83]. One advantage is the chemical stability of the dithianyl protective group for the carbonyl group under various conditions, so that reactions on the C-2 substituents of the dithiane or trithiane system with the reaction products of *(57)* and *(58)* can be carried out. The free carbonyl compound is obtained, when desired, by hydrolysis. Since a comprehensive review of the chemistry of 1,3-dithian-2-yllithium compounds is at present being published [84], we shall merely demonstrate their application to the preparation of aldols and α,β-unsaturated carbonyl compounds as mentioned in the introduction [68,76,77].



(59)

(60) (62)

(61)



The Li compounds *(57)* add onto epoxides in high yields; the *n*-hexanal derivative *(59)* and propylene oxide give the dithiane derivative *(60)* of an aldol (90%). Hydrolysis with mercuric chloride/mercuric oxide yields the free aldol *(62)* (90%), which is then dehydrated to obtain the aldol condensation product *(61)* (85%). [The mild and extremely specific hydrolysis does not lead directly to the dehydrated product *(61)*!] The aldehyde from which the thioacetal *(56)* is derived is not required for the preparation of a dithianyllithium *(57)*. For example, successive reaction of unsubstituted dithiane [82] with (*S*)-(+)-1-iodo-2-methylbutane and 1,2-epoxycyclohexane in a single reaction

(63)

vessel, followed by hydrolysis and dehydration leads to the optically active ketone *(63)* in an overall yield of 40% from simple starting materials.

Metalated orthotrithioformic esters, *e.g (26)* and *(27)* can be used in a similar manner for nucleophilic carboxylation. Hydrolysis of the product *(64)* obtained from *(26)* and benzaldehyde to mandelic acid can be achieved merely by stirring a solution in acetone in the presence of mercuric salts at room temperature [26a]

(64)

The requirements listed above for a "good" masked nucleophilic acylating agent are only incompletely satisfied by the trithiocarbanion derivatives. Unlike the Li dithianes, these compounds tend to undergo carbenoid decomposition [24–27].

The above outline of the methods of nucleophilic acylation is intended to direct the attention of synthetic chemists toward this variant of carbonyl chemistry, which permits the use of little-noticed "short cuts" in syntheses. For this reason, the development of new methods and the extension of the known principles of nucleophilic acylation should not be neglected.

Non-Enzymatic Activation of Molecular Nitrogen

By G. Henrici-Olivé and S. Olivé[*]

Several transition metal complexes that can absorb nitrogen from the gas phase are now known. Some of the N_2-metal complexes are stable enough to be isolated and their structure elucidated, the N_2 molecule remaining chemically inert. In other cases reduction to N^{3-} is possible, but the structure of the reactive intermediate N_2-metal complex can be approached only by mechanistic studies. In the stable complexes the nitrogen is bound via a lone pair of electrons in the direction of the molecular axis ("end-on"), in the reducible complexes possibly "edge-on".

1. Introduction

The problem of the enzymatic fixation of nitrogen in nature is of interest to chemists, biochemists, and biologists alike. Whereas in nature the nitrogen is taken from the air under very mild conditions with the aid of microorganisms and incorporated, *via* ammonia, into organic nitrogen compounds that are important to life, temperatures of 300 to 600 °C and nitrogen pressures of several hundred atmospheres are required in industry to overcome the inertness of the nitrogen molecule and convert N_2 into NH_3 (Haber-Bosch process).

Whereas biochemists are trying to probe the secrets of nature by extracting the nitrogen-fixing enzymes from the biological cell environment and investigating them separately, chemists have been trying for a number of years to imitate nature *in vitro* by fixing nitrogen on synthetic compounds and complexes. The biochemical investigations have shown that certain transition metals, particularly iron and molybdenum, are always present in the natural systems, and are presumably directly involved in the process of the fixation and reduction of nitrogen. Transition metals, in fact, are the deciding factors also in most synthetic systems.

The research carried out in both directions during the past few years has been summarized by *Murray* and *Smith*[1], and smaller areas of the field have been reviewed by other authors[2–4].

The present article is confined to the non-enzymatic fixation of nitrogen. In order to mark the trends and to illustrate how far the frontiers of science have advanced in this field, a brief account on the relevant research is given. The main part of the article, however, is concerned specifically with mechanistic aspects of the fixation and activation of nitrogen, and hence particular attention is devoted to the processes occurring at the transition metal center.

2. The Characteristics of the Nitrogen Molecule

The nitrogen molecule is well known to be particularly resistant to chemical attack, with the result that it has become accepted as an ideal inert gas. Its dissociation energy is very high (225.8 kcal/mole), and no appreciable dissociation into atoms occurs at normal pressure even at 3000 °C. Apart from biological activation, only one reaction of nitrogen at room temperature was known until recently; this was the reduction to Li_3N by metallic lithium.

The part played by transition metals in the activation of this inert molecule, both in enzyme systems and in the Haber-Bosch process, almost certainly involves the formation of a metal-nitrogen complex, leading to weakening of the multiple bond. Processes of this type are familiar from homogeneous catalysis on transition metal centers, as in the polymerization of ethylene on titanium complexes. The possibility of the existence of such complexes of the $N \equiv N$ molecule had been predicted on theoretical grounds in 1960, both by *Ruch*[5] and by *Orgel*[6]. No evidence of their occurrence was, however, found until 1965 (see Section 3); and relatively few complexes of N_2 are known even now, in comparison with the innumerable coordination compounds of the isoelectronic CO.

What is the reason for this inertness as compared with other compounds containing triple bonds, such as $H-C \equiv C-H$ or $R-C \equiv N$, and why is the tendency to complex formation so small?

SCF–LCAO–MO[*] calculations have shown[7–9] that the nitrogen molecule has the electronic configuration

$$(1\sigma_g)^2\,(1\sigma_u)^2\,(2\sigma_g)^2\,(2\sigma_u)^2\,(1\pi_u)^4\,(3\sigma_g)^2$$

The highest occupied orbital is thus a σ orbital, and not the degenerate π orbital as in *e.g.* acetylene. According to these calculations, the 3 σ_g orbital consists essentially of the $2p_\sigma$ orbitals of the N atoms (about 25 % s-character). The first empty MO is the degenerate antibonding π orbital $1\pi_g$. These calculations are confirmed by spectroscopic observations [7,8,10].

Figure 1 shows the surface of the MO's that are important to any complex formation or reaction (after *Chatt* [2]).

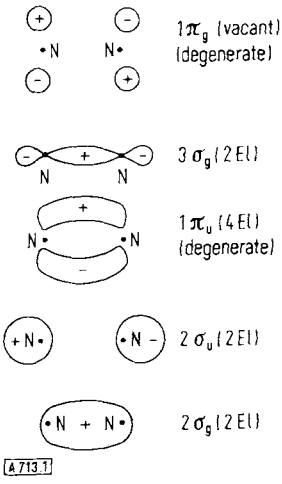

Fig. 1. Schematic representation of the LCAO—MO's in the nitrogen molecule (after *Chatt* [2]).

Chatt [3] has suggested that the low reactivity of N_2 is essentially due to the energetically unfavorable position of the highest occupied orbital. The $3\sigma_g$ orbital of the N_2 molecule, which has an energy of −15.5 eV, is much more stable than *e.g.* the degenerate pair of π orbitals of acetylene (−11.4 eV).

Jaffé and *Orchin* [11] proposed a qualitative MO scheme to explain the difference in the complex-forming tendencies of N_2 and CO. The model is based in principle on the fact that the 2s orbital of oxygen is very low in energy in relation to the 2s orbital of carbon, so that $2p_\sigma$ of oxygen is better suited, on energy grounds, for combination with 2s of carbon. The lone pair of electrons on the carbon consequently has a relatively high energy, is predominantly of p-character, points in the opposite direction to the C=O bond, and is therefore available for complex formation. In N_2, on the other hand, the lone pairs of electrons on the two N atoms, according to this model, occupy low-lying orbitals having predominantly s-character.

According to more recent calculations of the two molecules by *Edmiston* and *Ruedenberg* [12], however, this picture does not appear to be quite correct. Localized molecular orbitals (LMO's) were calculated on the basis of the SCF–LCAO–MO's for the two molecules N_2 and CO. It was found that the two isoelectronic molecules can be represented by almost the same schematic diagram (Fig. 2), *i.e.* each of the atoms carries a localized lone pair of electrons; these electron pairs are predominantly 2s, but they have sufficiently strong $2p_\sigma$ components to enable them to point "backward" (at 180° to the bond). Between the two atoms are three equivalent banana-shaped bonding orbitals (which are slightly polarized toward the O in CO).

Fig. 2. Schematic representation of the LMO's for N_2 and CO (after *Edmiston* and *Ruedenberg* [12]).

It can be seen from Table 1, however, that the calculated s-character of the lone pairs of electrons shows a trend parallel to that assumed by *Jaffé*. The figures show that the s-character of the bonding orbitals steadily decreases from left to right in the periodic system (C, N, O), whereas that of the lone pair of electrons increases.

Table 1. Variation of the s character in the bonding LMO's and in the LMO's for the lone pairs of electrons on C, N, and O in N_2 and CO [12].

Atom	2 s character	
	bonding [a]	lone pair
C	0.60	0.60
N	0.46	0.75
O	0.25	0.79

[a] In the three equivalent bonding orbitals.

The comparison of the two schematic representations of MO's in Figures 1 and 2 may at first sight seem rather confusing. The chemist whose theoretical background is not so extensive has a strong tendency to attach an excessively concrete physical significance to a calculated set of SCF—MO's or to the qualitative pictures of the surfaces built up from these MO's, and to forget that another set can represent an equally correct solution. Roughly speaking, it may be said that the "electron cloud" in a given molecule can be divided into different regions by mathematical tricks, so that different calculation methods may give a different pattern.

The localized molecular orbitals (LMO's) are constituted in such a way as to minimize interorbital electronic interaction. In contrast with the SCF SCF–LCAO–MO's on which they are based (cf. Fig. 1), orbitals localized on *one* atom are often found here for the lower shells and for lone pairs of electrons, as well as bonding orbitals localized between the two atoms. These calculations are thus much more closely allied to the chemist's concept of chemical bonding.

It can be concluded from a comparison of the electronic situations in N_2 and CO that the differences between the two molecules should be quantitative rather than qualitative (cf. [6]). There is, however, a possibly important difference in the energies of the highest occupied orbitals of the two molecules; the difference is about 1.4 eV in favor of CO [9,13]. Another difference is the polarity of CO. Nevertheless, the problem of the fixation of nitrogen on transition metal

[11] *H. H. Jaffé* and *M. Orchin*, Tetrahedron *10*, 212 (1960).

[12] *C. Edmiston* and *K. Ruedenberg*, J. chem. Physics *43*, 97 (1965).

[13] *R. Sahni*, Trans. Faraday Soc. *49*, 1246 (1953).

complexes looks hopeful, and several such complexes with N_2 ligands have, in fact, already become known (see Section 3).

There still remains the question how such complexes are to be pictured. By analogy with CO, one would expect bonding to occur *via* the lone pairs of electrons (end-on). On the other hand, comparison with other substances containing triple bonds, such as the alkynes, forces us to consider a complex bond normal to the axis of the N_2 molecule (edge-on), particularly since it has been shown that the biological systems that are to be imitated here can reduce acetylene (to ethylene) as well as N_2.

Bonding in the direction of the molecular axis (end-on)

Bonding normal to the molecular axis (edge-on)

Some indications clearly favor bonding in the direction of the molecular axis in a number of isolable, stable complexes (cf. Section 4.2). However, this does not tell us anything definite about the configurations that really activate the nitrogen molecule.

3. Present State of Research on the Fixation of Nitrogen

In 1965, *Allen* and *Senoff*[14] reported the first isolable ruthenium complex containing an N_2 molecule as a ligand:

$[Ru(NH_3)_5N_2]^{2\oplus}$ *(1)*

anions: $Br^{\ominus}$, $I^{\ominus}$, $BF_4^{\ominus}$, $PF_6^{\ominus}$

The nitrogen had not in fact been absorbed from the gas phase in this case, but had been formed in the reaction of $RuCl_3$ with hydrazine in aqueous solution by disproportionation of the hydrazine, with simultaneous formation of NH_3. Soon afterwards, however, *Shilov et al.*[15] showed that free molecular nitrogen can also be taken up as a ligand in Ru(II) complexes.

Several other methods for the preparation of the complex *(1)* and a series of similar complexes were subsequently described. Only a few important developments will be mentioned briefly here.

Isolable complexes are so far confined to Group VIII of the periodic system. Complexes with elements of the first period appear to be relatively unstable, and difficulties are often encountered in their isolation An interesting cobalt complex has been described, in which N_2 and H_2 can be reversibly exchanged[16]:

$$[CoH_3(P(C_6H_5)_3)_3] + N_2 \rightleftarrows [CoH(N_2)(P(C_6H_5)_3)_3] + H_2$$

The osmium analog of *(1)* has been found to be particularly stable[17]. The nitrogen is so strongly bound in this complex that it withstands boiling in strong hydrochloric acid.

The unexpected thermodynamic stability of such nitrogen complexes is also shown by the fact that even water can be displaced by nitrogen in some cases[18]:

$$[Ru(NH_3)_5H_2O]^{2\oplus} + N_2 \rightarrow [Ru(NH_3)_5N_2]^{2\oplus} + H_2O$$

It should be mentioned, finally, that binuclear complexes in which the nitrogen molecule forms a bridge between two transition metal units have also been found. In the case of Ru^{II}, a complex of this type is formed as follows:

$$[Ru(NH_3)_5H_2O]^{2\oplus} + [Ru(NH_3)_5N_2]^{2\oplus} \rightarrow [(NH_3)_5RuN_2Ru(NH_3)_5]^{4\oplus} + H_2O$$

again by displacement of water. The compound was isolated from aqueous solution with $[BF_4]^{\ominus}$ as the anion[18]. A nitrogen-nickel(0) complex of this type is formed[19] on reduction of bis(2,4-pentanedionate)-nickel(II) with trimethylaluminum in the presence of tricyclohexylphosphine and nitrogen; this complex is formulated as follows:

$$[(C_6H_{11})_3P]_2NiN_2Ni[P(C_6H_{11})_3]_2$$

These novel compounds naturally present a temptation to hopeful comparisons with the biological activation of nitrogen. Might this not be an analog at least of the fixation step? Unfortunately, no evidence has so far been found to indicate that the nitrogen, once fixed in these stable complexes, is susceptible to chemical attack. Early success reports, according to which the nitrogen in *(1)* had been reduced to NH_3 by $NaBH_4$[14] were found to be fallacious since *Chatt* showed that when $^{15}N_2$ is used, the NH_3 liberated from the complex contains no ^{15}N[3].

An entirely different line of investigation is based on the observation by *Volpin* and *Shur*[20] that Ziegler-Natta systems and similar combinations of a transition metal compound and an organometallic reducing agent take up gaseous nitrogen and reduce it to $N^{3\ominus}$. After hydrolysis, the nitrogen is collected as NH_3. Up to 0.4 N_2 molecule per transition metal center was fixed and reduced in these early experiments.

This approach was adopted by a number of authors and developed in different directions[21–26].

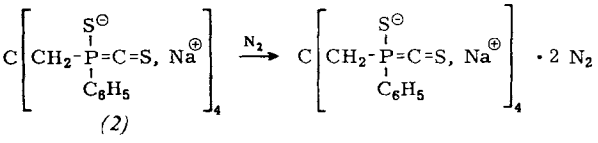
The reactions proceed at room temperature and at nitrogen pressures of 1 to 150 atm; because of the presence of the organometallic component in the system (*e.g.* Grignard reagent, alkylaluminum, or alkali metal naphthalide), organic solvents (usually ethers) must be used. The nitrogen molecule is presumably coordinately fixed to the transition metal and reduced by the organometallic component which is always present in great excess (cf. Sections 4.4 and 4.5). The disadvantage of this reaction is that the nitrogen appears to adhere very strongly to the transition metal species in the nitride form; with one exception, which will be described later, the only method found so far for the removal of the reduced nitrogen from the metal is hydrolysis or alcoholysis.



The conversion in the fixation process has been increased to 100% with respect to the metal, *i.e.* one N_2 molecule per transition metal center. This was achieved with VCl_3 and Li naphthalide in tetrahydrofuran [22a]. *Van Tamelen et al.* [25,26] developed a similar process into a cycle of fixation, reduction, and alcoholysis. The fixing and reducing system is a combination of titanium tetraisopropoxide and Na naphthalide in tetrahydrofuran. $N^{3\ominus}$ is converted into ammonia with an accurately measured quantity of isopropyl alcohol, and is thus separated from the metal. The original combination is regenerated by introduction of fresh Na naphthalide (or simply of Na, since the naphthalene is still available in the system). By five such cycles it was possible to convert up to 1.7 molecules of N_2 per titanium center into ammonia at normal pressure.

Volpin et al. [27] recently managed to remove the nitride nitrogen from the transition metal in a batch procedure, so making it available for further fixation. These authors used the reducing combination of Al and aluminum bromide, which is well known *e.g.* from the Fischer-Hafner synthesis of aromatic complexes of transition metals [28]. When this combination was used with salts such as $TiCl_4$ or $CrCl_3$, they found that more than 100 nitrogen molecules per transition metal center could be reduced to $N^{3\ominus}$ by the use of a large excess of aluminum and Lewis acid (for example, Ti : Al : $AlBr_3$ = 1 : 600 : 1000, 30 hours, 130 °C, 100 atm of N_2; 142 molecules of N_2 were reduced per titanium atom). The nitrogen is presumably present as $N^{3\ominus}$ attached to an aluminum species; it is liberated as NH_3 on hydrolysis.

Another development that could show promise also comes from *Volpin*'s laboratory. With phenyllithium as the reducing agent together with $(C_5H_5)_2TiCl_2$ in ether, some aniline was found as well as NH_3 on hydrolysis (0.65 mole of NH_3, 0.15 mole of $C_6H_5NH_2$ per mole of Ti complex at 20 °C and 100 atm of N_2) [29].

A carbon-nitrogen bond was thus obtained for the first time in this case, though only to a small extent.

Transition metal compounds, however, are no longer the only synthetic nitrogen fixers. In 1967 it was reported for the first time that the phenylsulfenium cation ($C_6H_5S^+$) takes up gaseous nitrogen [30]; the reaction products could not be isolated. *Ellermann et al.* [31], however, recently prepared an organic compound, again containing ionic sulfur, that "avidly absorbs molecular nitrogen". The reaction product, which contains two nitrogen molecules per complex unit, has been isolated. The authors assumed that the nitrogen molecules were bound in a spirocyclic complex by the compound *(2)* which acts as a doubly bidentate chelating agent.

(2)

These new compounds may raise the question whether the transition metal centers are really of decisive importance in the enzymatic fixation of nitrogen, as has been assumed until now.

4. Attempts to Elucidate the Mechanism of the Activation of Nitrogen

4.1. Metal Surfaces

From the point of view of the industrial activation of nitrogen (Haber-Bosch), great efforts were made to establish the reaction mechanism of this industrially important process, but these have not yet led to any satisfactory conclusion. The active species and the rate-determining step are still in dispute (for reviews see [1,32,33]). Most of these investigations were carried out on extremely pure metal surfaces (Group VIII). Two studies that are related in some measure to the nitrogen complexes will be mentioned.

Eischen and *Jacknow* [34] investigated the fixation of nitrogen by nickel on silica supports. The authors found with the aid of IR spectroscopy that N_2 is chemisorbed on nickel at room temperature. A number of interesting conclusions are drawn from the presence of a strong absorption band at 2202 cm^{-1}. The free nitrogen molecule gives a band at 2331 cm^{-1}, which is due to an N≡N stretching vibration; owing to the symmetry of the N_2 molecule, this band does not ap-

pear in the IR spectrum, but is observed only in the Raman spectrum. The relatively high extinction coefficient of the observed IR band suggests that considerable polarization of the N_2 molecule must have occurred. The frequency shift, on the other hand, indicates chemisorption with (at least partial) chemical bonding between the metal and the N_2 molecule. (No shift would occur if the polarization was due to the action of asymmetric surface electric fields on a purely physically adsorbed molecule.) If the isotope $^{15}N_2$ is chemisorbed instead of $^{14}N_2$, the IR band appears at 2128 cm^{-1}. A mixture of the three isotopes $^{14}N_2$ $^{14}N-^{15}N$, and $^{15}N_2$ gives three bands in the correct intensity ratio. This shows that no atomic species are present. It is concluded from the observations as a whole that the nitrogen molecule is attached end-on to the nickel(0). It can be calculated from the isotopic shift of the IR band that the force constants for this structure are 19×10^5 dyne/cm for the N–N bond and 3×10^5 dyne/cm for the metal-N bond [35]. The end-on structure would be conclusively proved if it were possible to separate the IR bands of $Ni \leftarrow {}^{14}N \equiv {}^{15}N$ and $Ni \leftarrow {}^{15}N \equiv {}^{14}N$, for which a difference of 5–6 cm^{-1} is predicted from theory [34]. However, the resolution of the instrument used was not sufficient for this.

Another interesting investigation that also points to end-on binding of the nitrogen, in this case to iron, was carried out by *Brill et al.* [36], who studied the action of nitrogen on an iron point in a field electron microscope. The point was exposed to a nitrogen atmosphere at 76 °K. After heating for a short time at 400 °C, the micrograph shows a distinct prominence of the 111 faces of the iron. It is thus concluded that the nitrogen is preferentially chemisorbed on these faces, with the result that their surface energy is reduced, and these non-equilibrium faces consequently grow. The authors interpret the preferential deposition of the N_2 molecule on the 111 face as follows: The iron atoms are arranged in these faces in such a way that the atoms of the top layer surround holes having trigonal symmetry. It is assumed that the surface atoms make unoccupied orbitals available, and that these can be used for the construction of molecular orbitals having π character with respect to the axis of the trigonal hole. These can then interact with the occupied π orbitals of an N_2 molecule arranged along the trigonal axis (π bonding).

4.2. Complexes with Nitrogen Ligands

The first N_2 complex *(1)* isolated gave a strong IR band at 2118 to 2167 cm^{-1} (depending on the anion), and all other complexes having an N_2 ligand also give this band, the wave number of which differs by 150 to 300 cm^{-1} from the (Raman-active) stretching vibration of the free nitrogen molecule. As in the case of N_2 on metal surfaces (Section 4.1), therefore, the end-on configuration is also assumed for the coordinately bound nitrogen. This has been proved by X-ray analysis in two cases, *i.e. Allen* and *Senoff*'s ruthenium complex (octahedron with linear Ru–N–N grouping [37]) and the complex $[Co(N_2)(P(C_6H_5)_3)_3]$ (trigonal bipyramid with H at one apex and N_2 at the other; 5° deviation from linearity in the grouping Co–N–N [38]).

The nitrogen-metal bond in these complexes is formulated by *Chatt* [2,3] as a sort of double bond, unlike that discussed by *Brill et al.* [36] for the chemisorption on iron. *Chatt*'s interpretation agrees with the formulation normally given for the carbonyl complexes [6]. An occupied σ orbital (this refers to one of the lone pairs of electrons according to Figure 2, and to the orbital $3\sigma_g$ according to Figure 1) interacts with an unoccupied d_σ orbital of the metal (d_{z^2} or $d_{x^2-y^2}$ in the octahedral complex). Electron back-donation (see Fig. 3) occurs *via* an occupied $d\pi$ orbital of the metal (d_{xy}, d_{xz}, d_{yz} and the empty antibonding $1\pi_g$ orbital of the nitrogen (π symmetry with respect to the M–N–N axis).

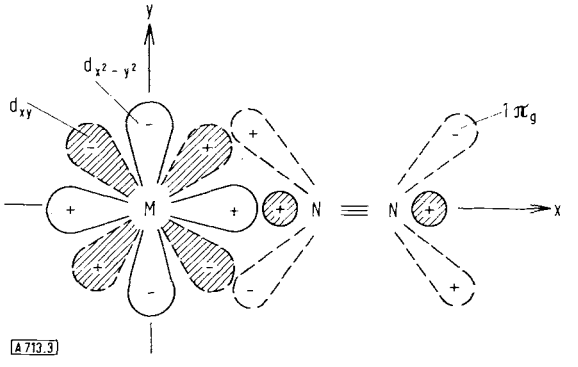

Fig. 3. Double-bond-like interaction between metal and nitrogen molecule (shaded: occupied orbitals).

The electron density passing in this way into the antibonding nitrogen orbital should weaken the bonding between the two nitrogen atoms. The displacement of the stretching vibration $\nu(N \equiv N)$ by 150–300 cm^{-1} indicates that this indeed has happened. However, the weakening is evidently not enough to make the coordinately bound nitrogen accessible to chemical reactions (*e.g.* hydrolysis or reduction). Even in complexes of the type $M-N_2-M$ [18,19], in which one should expect double weakening of the $N \equiv N$ bond according to these views, the nitrogen molecule still remains in the unreactive state. It should be noted that for these complexes, because of the symmetry of the molecule, the $N \equiv N$ stretching vibration is only Raman-active, as in the free N_2 molecule.

The energy conditions for the formation of an N_2 complex seem to be extremely critical. *Chatt et al.* [3] have shown that small changes in the other ligands of the metal center can make the isolation of a stable complex impossible. For example, the iridium complex

$IrCl(N_2)[P(C_6H_5)_3]_2$

is very easy to prepare. The corresponding iodide, on the other hand, is too unstable to be isolated in the pure state. The same is found when one attempts to replace the triphenylphosphine ligands with ethyldiphenylphosphine. (It should, however, be remembered that the isolability of the complex is not necessarily related to the chemical reactivity of the coordinately bound N_2 molecule; cf. also Section 5.)

Undoubtedly it will be interesting to follow the weakening of the N≡N bond (as indicated by the displacement of the IR band) as a function of the other ligands in the complex [39].

4.3. The System Bis(π-cyclopentadienyl)titanium Dichloride/Ethylmagnesium Bromide

The combination bis(π-cyclopentadienyl)titanium dichloride/ethylmagnesium bromide in ether was one of the first systems with which *Volpin* and *Shur* [20] observed the fixation and reduction of gaseous nitrogen in 1964. Several attempts have been made since then to explain the mechanism of this reduction.

The first important contribution was made by *Shilov et al.* [40]. These authors showed by experiments with deuterated Grignard reagent and with deuterated ether that the nitrogen is present as nitride, and is liberated as NH_3 only on hydrolysis. *Volpin* had assumed at first that the coordinately bound nitrogen could take up hydrogen from the solvent or the Grignard reagent [20]. On hydrolysis of the (undeuterated) reaction solution with heavy water, *Shilov et al.* also found that the isotope distribution in the hydrogen-deuterium mixture liberated indicated the presence of a metal hydride. This was in fact later definitely confirmed by *Brintzinger* [21a] by electron spin resonance measurements.

At that time, *Shilov et al.* assumed that the active species was an unstable intermediate occurring during the reduction; this could not be confirmed by other authors. *Maskill* and *Pratt* [23] showed that the quantity of nitrogen fixed does not change appreciably if the components of the system are first allowed to react under argon, the nitrogen only being introduced later (cf. also Table 2).

Further information was provided by our own investigations of the same system in benzene [41]. ESR measurements on the nitrogen-free system gave the same signal as had been observed by *Brintzinger* using ethereal solvents [21a,42] (see Fig. 4).

This signal is a 1:2:1 triplet, in which each of the three lines shows further multiplet splitting due to the ring protons of the cyclopentadienyl groups. The triplet is due to the interaction of the unpaired electron of a Ti(III) species with two equivalent protons, and so points to a hydride structure. The intensity of this signal increases for 1 to 1.5 hours from the moment of mixing of the two components, and then remains constant. The titanium has thus been reduced to the ESR-active state Ti^{III} ($3d^1$) during this period, and then remains in this state. The reduction is probably similar to that in the Ziegler-Natta system $Cp_2TiCl_2/C_2H_5AlCl_2$, with alkylation of the titanium followed by decomposition of the relatively unstable alkyltitanium compound (see *e.g.* [43]).

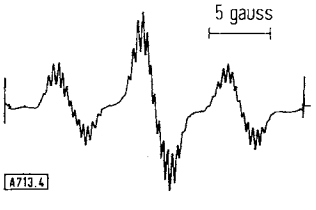

Fig. 4. ESR signal in the reaction solution Cp_2TiCl_2/C_2H_5MgBr in benzene. Mg/Ti = 12; high dilution; $T = 20$ °C. Cp = cyclopentadienyl.

Measurement of the magnetic susceptibility of such a system after about 2 hours shows that the Ti(III) concentration is only about 50% of the original Ti(IV) concentration. Since all the experiments with this system were carried out with a large excess of Grignard reagent [20,21,40] (Mg/Ti = 12 in the experiments described here), it is hardly to be expected that only partial reduction has occurred. It is probable, therefore, that part of the titanium has been reduced beyond the Ti(III) stage.

The system Cp_2TiCl_2/C_2H_5MgBr in benzene also fixes and reduces nitrogen. The process is again independent of whether the components are brought together under nitrogen or exposed to nitrogen only at the time of maximum hydride concentration (after about 1 hour). This can be seen from Table 2.

Table 2. Fixation of nitrogen on the system Cp_2TiCl_2/C_2H_5MgBr in benzene. [Ti] = 10×10^{-3} mole/l; Mg/Ti = 12; $T = 22$ °C; 110 atm of N_2 [41].

No.	N_2 added	Time	NH_3/Ti (h)
1	immediately	17	1.0
2	after 1 h	17	0.88
3	immediately	70	0.96
4	after 1 h	70	1.0

The ESR signal of the reaction solution was recorded at the end of experiment 1. The hydride signal was still present with a comparable intensity at this time, although one nitrogen atom per titanium was already present in the reduced form. This again shows clearly that the hydride hydrogen is not involved in the reduction process [*]. It can also be seen from Table 2 that the fixation of nitrogen has already reached its final value of $NH_3/Ti \simeq 1$ after 17 hours; this value cannot be increased by the use of either a higher Mg/Ti ratio or of higher pressures. Since not more than one N_2 molecule can be fixed per two titanium centers, we believe that the process takes place on a binuclear complex.

Brintzinger had initially assumed the binuclear structure *(3)* for the hydride [21a], but later became convinced that the hydride is better described by formula

[39] *J. Chatt* and *R. L. Richards*, personal communication.

[*] *Brintzinger* had thought at first that the ESR data pointed to participation of the hydride hydrogens [21b], but he himself disproved this by further detailed investigations [42].

(4) [42]. The results of our work reported here, particularly in conjunction with the data for the similar system described in the next section, lead us to assume that the active species is a binuclear complex containing titanium in different valence states [structure *(5)*].

(3) *(4)* *(5)*

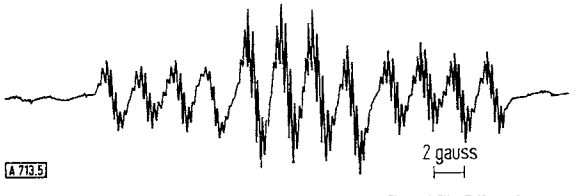
It is possible, in our view, that the nitrogen is fixed to the Ti(II) side of the complex, and that the ESR activity of the Ti(III) side is consequently not appreciably changed.

4.4. The System Cp_2TiCl_2/Alkali Metal Naphthalide

If an alkali metal naphthalide (*e.g.* Li^+Np^- or Na^+Np^-) is used as the reducing agent instead of a Grignard reagent, fixation of nitrogen occurs even at normal pressure. In the system Cp_2TiCl_2/LiNp in tetrahydrofuran, for example, 0.96 molecule of NH_3 is obtained per titanium center after 16 hours with Li/Ti = 6 and under one atmosphere of nitrogen [22b]. The ratio NH_3/Ti again cannot be increased beyond about 1 under any conditions. The fixation takes place slowly; under the same conditions, 0.5 NH_3 molecule per titanium is obtained after 2 hours, and 0.7 molecule after 4 hours.

ESR studies again provided a number of clues as to the mechanism in this system.

Let us first consider the system in the absence of nitrogen. A readily resolvable ESR signal is observed (see Fig. 5), but in contrast with the Grignard system, the ratio of reducing agent to titanium component is critical here. The signal is observed only at molar ratios $3 \leqslant$ Li/Ti $\leqslant 4$. Its intensity passes through a maximum at Li/Ti = 3.5, and is almost 0 at Li/Ti = 4.0. At higher values of the ratio, the lithium naphthalide signal appears. The stronger reducing agent LiNp is evidently capable of reducing the ESR-active Ti(III) species further.



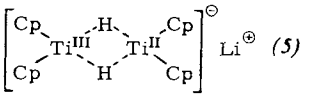


Fig. 5. ESR signal of the reaction solution Cp_2TiCl_2/LiNp in tetrahydrofuran. Li/Ti = 3.5; high dilution. $T = -40$ °C [22b].

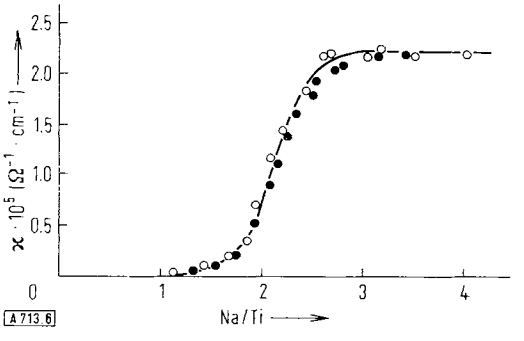
The predominant hyperfine splitting is again a 1:2:1 triplet indicating the presence of two equivalent protons. The coupling constant is similar to that of the hydride in Figure 4 [21a, 22b]. In this case, however, each line is further split into four components of equal intensity; the only possible cause for this is a lithium nucleus (^{7}Li, nuclear spin $I = 3/2$). Since the Li coupling constant is relatively large and is practically independent of temperature in an interval of 100 °C, it may be assumed that the lithium is fairly firmly bound, presumably in the inner coordination sphere of the titanium. (The same is true of Na [22b].) Finally the interaction with the ring protons of the Cp groups again occurs, leading to splitting of each of the twelve principal lines into a multiplet. From these data, and taking into account the fixation of nitrogen, the most probable formula for the ESR-active species, as in the last section, is found to be *(5)* [*]. The exact location of the lithium ion is not yet known.

(5)

Unlike in the Grignard system (preceding section), the bridge hydrogen in this case comes from the solvent. This is shown by the fact that an identical spectrum is obtained with LiNp prepared from $C_{10}D_8$ [41]. The hydride formation mechanism is thus evidently different in this case. A conductometric titration was carried out to clarify this mechanism. NaNp was used to avoid interference by the soluble LiCl (NaNp and LiNp behave almost identically in these reactions [22b]). It can be seen from Figure 6 that the conductivity increases rapidly in the range $2 \leqslant$ Na/Ti $\leqslant 3$, indicating the occurrence of ionic species.



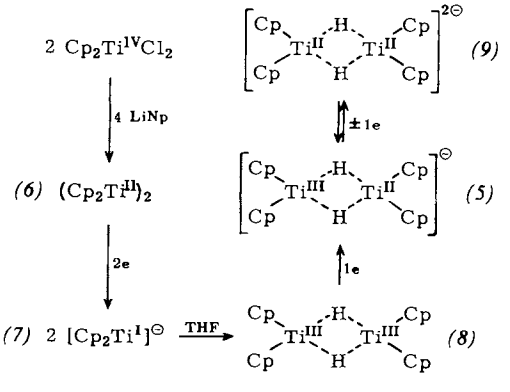


Fig. 6. Conductometric titration of Cp_2TiCl_2 with NaNp in THF. $[Cp_2TiCl_2]_0 = 10 \times 10^{-3}$ mole/l. ○, ●: two sets of measurements [41].

Combination of all the data mentioned leads to the following reaction scheme for the nitrogen-free system:

(9) *(6)* $(Cp_2Ti^{II})_2$ *(5)* *(7)* $2\,[Cp_2Ti^{I}]^{\ominus}$ *(8)*

[*] Complexes containing two Ti(III) centers can also be ruled out on the basis of various ESR consideration [22b, 42].

The reaction of 2 Cp_2TiCl_2 with 4 LiNp leads to the formation of dimeric titanocene *(6)*, the synthesis of which by this route is known from the literature [44]. Since titanocene is stable in tetrahydrofuran, the further reaction must be attributed to excess naphthalide. It is assumed that the ionic Ti(I) compounds *(7)* are formed as intermediates, and that these attack the solvent. The dimeric hydride species *(8)* are formed, as well as ionic reaction products of tetrahydrofuran. The latter are considered to be responsible for the electric conductivity, the occurrence of which in this range was shown by conductometric titration (Fig. 6).

The consumption of a total of four LiNp per titanium shows that further reduction of *(8)* is to be expected. The complex *(5)* is the ESR-active form. The disappearance of the ESR signal in the range $3.5 \leqslant Li/Ti \leqslant 4$ requires a further reduction to the diamagnetic complex *(9)*. Above Li/Ti = 4, as was mentioned earlier, the excess LiNp appears in the ESR spectrum, *i.e.* the reduction process is complete.

It is of interest in connection with the nitrogen fixation mechanism that the system fixes nitrogen both at Li/Ti = 3.5 [maximum ESR signal, complex *(5)*] and at Li/Ti = 4.0 [no ESR signal, complex *(9)*] ($NH_3/Ti \simeq 0.2$). In the former case, however, the signal disappears on addition of nitrogen. Since only one of the two species *(5)* and *(9)* is presumably responsible for the fixation, we have assumed that an equilibrium exists between them.

According to observations on polymerization catalysis (for example, ethylene can be polymerized on Ti^{III}/Ti^{IV} or on Ti^{II}/Ti^{III} complexes), the species *(5)*, in which the titanium atoms have different valences, seems the more likely candidate. The difference in the numbers of ligands means that the two titanium centers will differ in their symmetries. A proposal that agrees with the ESR data is shown in Figure 7. The Ti^{III} has a tetrahedral environment, whereas the Ti^{II} is situated in a trigonal bipyramid. (The equivalence of the two bridge hydrogens requires that the lithium be symmetrically placed in relation to these atoms.)

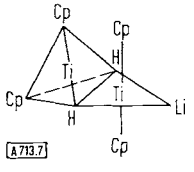

Fig. 7. Suggested configuration of the ESR-active species *(5)*.

On entry of a nitrogen molecule, the Ti(II) part of the complex could be opened out to octahedral symmetry (Fig. 8). It is not yet possible to tell whether the nitrogen is end-on, as in the stable complexes (Section 4.2), or edge-on. Again by analogy with the polymerization of ethylene on titanium complexes, an edge-on formulation is chosen for these assumed reactive intermediates. *Cis*-migration of the lithium (or insertion of the N_2 at the site of the lithium) could lead to the azo structure. (This would explain the disappearance of the ESR signal on addition of N_2.) The –N=N– grouping is well known to be unstable in the presence of alkali metal naphthalide, and would immediately be reduced further to two N^{3-}. One of the two N^{3-} evidently remains attached to the Ti center and so blocks the path to further fixation of nitrogen.

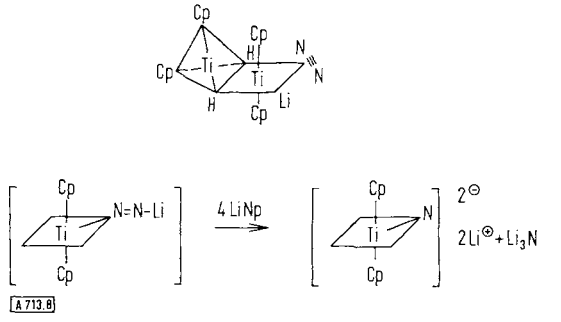

Fig. 8. Suggested mechanism for the fixation of nitrogen in the system Cp_2TiCl_2/LiNp. (The tetrahedral Ti(III) portion has been omitted from the bottom two complexes.)

As was mentioned, the fixation-reduction process in this system takes several hours. Since the ESR signal disappears rapidly on admission of N_2 and the reduction to the azo compound should also be relatively fast, the rate-determining step could be the supply of the active species from the equilibrium.

4.5. "Electron Reservoir" Complexes of Transition Metals

A somewhat different mechanism occurs if simple halides of the transition metals are used with lithium naphthalide instead of the bis(cyclopentadienyl) compound [22a]. This is shown by the fact that, under favorable conditions, two NH_3 molecules can be obtained per transition metal center in this case (Table 3). Thus one N_2 molecule is fixed per transition metal center; the active species cannot, therefore, be binuclear complexes.

The fixation-reduction process again takes a certain time, as can be seen from Figure 9. Particularly at 1 atm of N_2, the time taken appears to be of the same order of magnitude as for the system Cp_2TiCl_2/LiNp discussed in the last section.

Table 3. Fixation of nitrogen on reduced transition metal solutions, solvent THF [22a].

Salt	LiNp/metal	N_2 pressure (atm)	NH_3/metal

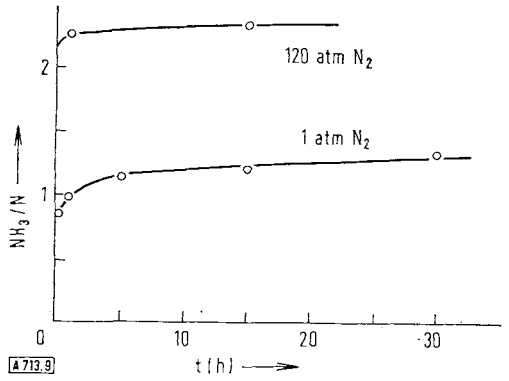

Fig. 9. Time-dependence of the N_2 fixation reaction in the case of the system VCl_3/LiNp [41].

ESR measurements show that in these systems the metal is reduced to the zerovalent stage and beyond. On addition of three reduction equivalents (Li/V = 3), the signal of the bis(naphthalene)vanadium(0) sandwich complex is observed in the reaction solution, and at higher Li/V ratios another signal, which can be assigned to a V(−II) species, is observed [45]. In the $CrCl_3$/LiNp system, it is found that as the Li/Cr ratio is increased, the ESR signal of bis(naphthalene)-chromium(I) appears first, and then that of bis(naphthalene)chromium(−I) [41]. Free LiNp can be detected in the ESR signal only above Li/M = 6 in both cases (M = metal). The intensity of the ESR signal, however, is still low in relation to the quantity of LiNp introduced. Evidently a further electron transfer occurs from LiNp to M(0), with formation of negatively charged M(−x) species, which are held in solution by the naphthalene ligands.

On hydrolysis of the reduced metal solutions, considerable quantities of hydrogen are liberated, as can be seen from Figures 10 and 11. The preparation and hydrolysis were carried out under argon in these experiments. (LiNp does not liberate hydrogen during the hydrolysis, but reacts to form dihydronaphthalene [46].)

It is significant in connection with the fixation of nitrogen that considerably less hydrogen is evolved if

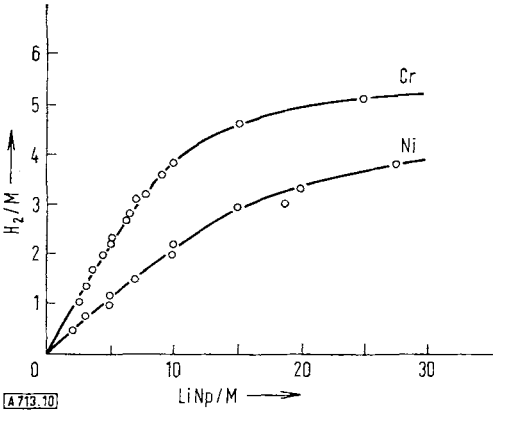

Fig. 10. Evolution of hydrogen during hydrolysis in the systems $CrCl_3$/LiNp (top) and $NiBr_2$/LiNp (bottom) [45].

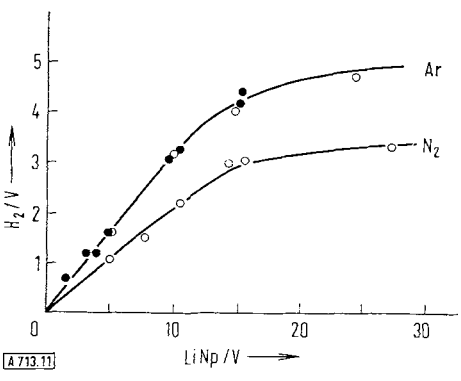

Fig. 11. Evolution of hydrogen during hydrolysis in the system VCl_3/LiNp; reaction carried out under argon (top) and under nitrogen (bottom).

● in dimethoxyethane; ○ in tetrahydrofuran [41].

the reduction is carried out under nitrogen (see Fig. 11; a similar observation was reported by *Shilov et al.* for the Grignard system [40]). This decrease in the quantity of hydrogen liberated does not, however, occur in systems that are not able to fix nitrogen, such as $NiBr_2$/LiNp (see Table 4).

Table 4. Hydrolysis of transition metal solutions reduced under argon or under nitrogen LiNp/metal = 10; T = 20 °C; 1 atm of N_2 [22a].

M	H_2/M under Ar	H_2/M under N_2	NH_3/M found
V	3.1	1.9	0.9
Cr	3.6	2.8	0.4
Ni	2.0	2.0	–

Information about the source of the gas evolved can be obtained by the use of heavy water. Figure 12 shows the results of the mass-spectroscopic analysis of the deuterolysis gases for the $CrCl_3$/LiNp system.

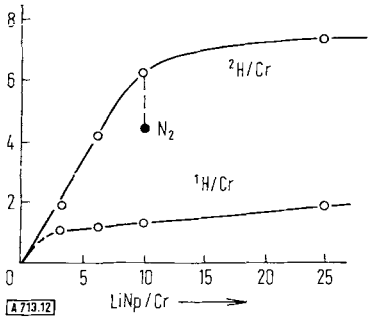

Fig. 12. Results of deuterolysis for $CrCl_3$/LiNp. ○: reduction under argon; ●: reduction under nitrogen [41].

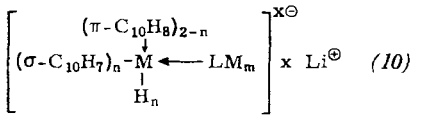

It can be seen that by far most of the gas evolved is deuterium; it must therefore have been formed by decomposition of the heavy water.

The fact that some hydrogen is liberated points to the presence of metal-hydrogen bonds. The number of hydrogen atoms per metal atom is in the neighborhood of 1 up to Li/M = 10, but increases slightly and appears to tend toward a limiting value of two.

Figure 12 also shows the results of a comparison experiment in which the reduction was carried out under

nitrogen, *i.e.* under conditions such that the system fixed nitrogen. It is found that the quantity of deuterium liberated decreases, but not the quantity of hydrogen.

From all these observations, the formulation *(10)* can be deduced for the nitrogen-fixing species.

(10)

The presence of naphthalene is shown by the ESR experiments. The presence of metal-hydrogen bonds is interpreted as resulting from the removal of H from π-bonded naphthalene and simultaneous transition into a σ-naphthyl-metal bond (cf. similar processes on an Ru(0)–Np complex studied by *Chatt et al.* [47]).

Solvent molecules (LM) must also be introduced, their number *m* being such as to satisfy the symmetry requirements of the metal in question. The hydrolysis experiments show that the complex can accept further electrons supplied by LiNp molecules These extra charges are presumably delocalized, particularly in the antibonding π orbitals of the aromatic ligands, and compensated for by Li^+ cations. The maximum number of these extra charges appears to be 6. This is shown by the deuterolysis experiments (Fig. 12), taking into account the well known fact that finely divided zerovalent Cr or V decomposes heavy water in accordance with

$$M^0 + 2\,{}^2H_2O \rightarrow M^{II} + {}^2H_2 + 2\,O^2H^{\ominus}$$

The fixation of nitrogen may be assumed to involve coordination of the N_2 molecule to the metal center, with displacement of a solvent molecule.

The extra charges are used to reduce the nitrogen in accordance with

$$N_2 \xrightarrow{6e} 2\,N^{3-}$$

Several complexes with different charges *x* are presumably present in equilibrium, but only one species (*e.g.* that with $x = 6$) is capable of attacking the nitrogen molecule. This would explain why the ratio NH_3/M can reach a value of 2 only when LiNp is present in a large excess. The supply of the active species from the equilibrium could again be the rate-determining step. Since the ratio NH_3/M cannot be increased above 2, it must be assumed that the reduced $N^{3\ominus}$ again remains in the complex, and is liberated only on hydrolysis.

5. Outlook

Nitrogen has evidently lost some of its eminence as an inert gas in recent years. On the one hand it is to be expected that the number of new stable complexes with N_2 ligands will grow steadily. On the other hand nitrogen has been reduced to $N^{3\ominus}$ under mild conditions (with regard to temperature and pressure) with strong reducing agents in aprotic solvents.

One might ask whether this can be expected to mean competition for the industrial processes for the production of ammonia. In view of the present price of NH_3, the answer to this must be no. However, the question as asked is wrongly phrased, since ammonia is only the industrial starting point for the chemistry of nitrogen. A more sensible question would be whether any competition is to be expected with the current processes for the production of amines, amides, nitriles, *etc.* In view of the outstanding progress that has been made in homogeneous catalysis on transition metal complexes in the course of the last 10–20 years, this possibility must be taken very seriously.

The $N^{3\ominus}$ stage attached to the transition metal is probably of no more value in this respect than the isolable stable N_2 complexes. If we may be allowed a (possibly somewhat daring) comparsion with olefin chemistry, a large number of stable complexes of olefins with transition metals are known, but these are not generally catalysts. The catalytically active intermediates formulated for reactions such as the oxo process, the Wacker process, cyclooligomerization of butadiene, Ziegler-Natta polymerization, *etc.*, on the other hand, in which the olefin is supposed to be coordinately bound to the transition metal center, have so far never been isolated.

Let us turn again briefly to the question of end-on or edge-on bonding. In all the stable complexes studied so far, the nitrogen is most probably attached end-on. However, edge-on attachment of N_2 molecules cannot be detected as easily as end-on attachment, which is indicated by the IR band at $\simeq 2100\ cm^{-1}$. The only relatively simple method of recognizing complexes of the edge-on type, apart from elemental analysis, would be from their Raman spectra. Who knows whether edge-on complexes have already passed through the hands of chemists without being recognized? Concerning the active species in the reduction process $N_2 \rightarrow 2\,N^{3-}$, the question of end-on or edge-on must necessarily remain open, since these intermediates cannot be isolated.

Concluding this report, it may be said that the investigation of the systems known at present has yielded some information about the interrelations between transition metal species and the nitrogen molecule. Above all, however, it has shown which directions lead to dead ends and which should be followed in further work.

We are grateful to Professor H. H. Zeiss, Monsanto Research S.A., who brought the interesting subject of the fixation of nitrogen to our notice, and to Professor J. Chatt, University of Sussex, for stimulating discussions.

Phosphorus

From Elemental Light to Chemical Element

By F. Krafft[*]

Exactly 300 years ago in the city of Hamburg, a certain Hennig Brand, self-styled doctor medicinae, and chymist, discovered a strange substance in human urine, which was later called phosphorus (light bearer), a name then common to various luminous substances, and which created much excitement in the latter years of the 17th century on account of its properties. However, it was not Brand who profited from the discovery but others: Johann Daniel Krafft, Johann Kunckel, and Gottfried Wilhelm Leibniz, men who knew only too well how to exploit the weaknesses of the discoverer. "Cold fire", Brand's own name for the new substance, was originally regarded as elemental light or fire, and it was not until the conception of the antiphlogistic theory by Antoine Laurent Lavoisier that the proper position of phosphorus among the chemical elements was recognized. In fact, the element played a decisive role in the overthrow of the phlogiston doctrine, a little over one hundred years after its discovery and almost two hundred years ago.

1. The Year of the Discovery

In his paper 'Historia inventionis phosphori' [1], which was published in 1710, *Gottfried Wilhelm Leibniz* writes: "Inter inventa nostri saeculi non minimum habendum est phosphorus igneus . . ." "Not least amongst the discoveries of our time is phosphorus igneus, which differs from other substances in that it is nothing other than a hidden fire (ignis quidam tectus) that manifests itself in light and smoke and bursts into flames when rubbed. This discovery became public knowledge around the year 1677 (Id inventum circa annum 1677 prodiit . . .). . ."

Johann Daniel Krafft (Kraft, Crafft; 1624–1697), however, Councillor of Commerce to the Saxon elector at Dresden, had already demonstrated the substance, together with three other kinds of "phosphorus," at the court of the Grand Elector *Friedrich Wilhelm von Brandenburg* at Berlin on April 24, 1676, but without making any reference to the discoverer or to the origin of the substance. The demonstration is recorded by the Court Physician *Johann Sigismund Elsholz* (1623–1688) in a document entitled 'De phosphoris quatuor observatio' and dated May 20, 1676 [46]. In September 1677 the same *Krafft* informed *Robert Boyle* (1627–1691) that one of the samples of phosphorus he had received from *Brand* had continued to luminesce for two years [2].

At the same time, *Johann Kunckel* (1630–1703), one of the most highly esteemed "chymists" of the day, was also in possession of this substance. A friend of his, *Georg Caspar Kirchmaier* (1637–1700), Professor of Rhetoric at Wittenberg, gives an account in his short treatise 'Noctiluca constans et per vices fulgurans, diutissime quaesita, nunc reperta', the foreword to which is dated September 11, 1676 (Chapter 3: De noctiluca aliqua constanti):

"Almost six months have passed since he (*i.e. Kunckel*) first revealed to me that he possesses the 'eternal light' . . . I will not say how long this skilled man spent in collecting and preparing the starting material, but will be content to have mentioned that when he repeated the work – not before July 25 – he obtained but little more than half an ounce, in spite of the fierce fire which was kept burning for many hours."

Kunckel himself reports later in his 'Collegium physico-chymicum experimentale' [3], which was published posthumously, that he learned of *Brand*'s phosphorus while staying at Hamburg just a few weeks after the discovery of *Balduin*'s phosphorus. He states, incorrectly, that the latter, a calcined calcium nitrate, was discovered in the year 1677. In fact, the Saxon magistrate *Christoph Adolph Balduin* (1632–1682) had already reported on his discovery in 1674 in 'Miscellanea curiosa medico-physica Academiae naturae curiosarum sive Ephemerides medico-physicae Germaniae' [4] and written a special treatise in the following year [5]; in neither case, however, does he disclose the method of preparation.

Thus the seventeenth-century printed sources cited here suggest early 1676 as the date of the discovery of phosphorus igneus, as it was called by *Leibniz*. Even in 1784, *Lorenz Crell* referred to these data in a note accompanying his paraphrased translation of *Leibniz*' 'Historia'[6]. He had, however, understood the year 1677 given by *Leibniz* to be the year of the discovery, for he paraphrases the passage quoted above as: "Phosphorus, that remarkable invention of our century, was discovered in 1677." (The same conclusion is reached by *J. S. T. Gehler*[7], *J. C. Fischer*[8], and others.) On the basis of the sources cited, *J. R. Spielmann* had previously, in 1766, decided in favor of the year 1674 or 1675 for *Brand*'s discovery[9], followed shortly by *J. C. Wiegleb*[10].

Thus it is hardly surprising that to our time these years are continually given as the supposed date of the discovery of phosphorus: *E. Färber (Farber)*[11,12], *J. R. Partington*[13]; *A. Wolf*[14] on the other hand writes: "the dates given vary from 1667 to 1674", and simply takes an average: "sometimes about 1670" (with which *P. Walden*[15] also concurs). Even the authors of the historical section of the latest (1965) edition of 'Gmelins Handbuch der anorganischen Chemie'[16] still shared the opinion of *Spielmann* and *Wiegleb* stating: "that ... the years 1674 and 1675 come into question as the date of the discovery of phosphorus."

However, "it is in the interest of science that the history of memorable discoveries (historia inventionum memorabilium) be handed down accurately", as *Leibniz* states in the opening passage of his 'Historia'. In this treatise *Leibniz* himself actually sets the date of the discovery as 1669, provided that one correctly interprets the information that he gives. Unlike *Kunckel*, who lost no opportunity to play down, in a rather ungentlemanly fashion, the credit due to *Brand* in favor of his own claims to the discovery, or at least to the independent rediscovery of phosphorus, and on whose information, both written and oral, all other contemporary versions of the history of the discovery are directly or indirectly based, *Leibniz* takes great pains to provide an objective report, in spite of later differences with *Brand*. He was well acquainted with the Hamburg chymist, recognized also by *Krafft* and *Kunckel* as the first discoverer, or at least better acquainted than those who had met him during a single visit to Hamburg, for he corresponded with him over a considerable period of time, visited him in Hamburg, and on two occasions was able to persuade him to visit Hanover for a relatively long time to prepare phosphorus. Moreover, *Leibniz* himself made no claim to the discovery.

On April 30, 1962, *Wilhelm Homberg* (1652–1715) presented a report to the Paris Academy dealing with the discovery and the purported rediscovery of phosphorus by *Kunckel*. In *Leibniz*' opinion, this paper contains several grave errors which he immediately critized, apparently in vain for no correction ever appeared. Thus, "Itaque ne veritas rei gestae, non multis fortasse hodie nota, intercedat" he published his 'Historia inventionis Phosphori'. Before proceeding to correct the various errors he presents a Latin version of Homberg's report[17]:

"Prima inventio huius Phosphori casui debetur, ut multa alia pulchra inventa. Chymista quidam Germanus, cui nomen *Brand*, Hamburgi degens, homo obscurus, humilis originis, ingenio moroso et phantastico, et in omnibus, quae agebat, mysteriosus, materiam hanc luminosam aliud quaerens invenit. Vitrariae artis deditus erat a iuventute, sed hanc deseruerat, ut lapidi philosophico vacaret, cuius spes animum eius invaserat. Cum ergo sibi persuasisset, secretum Lapidis in praeparatione urinae consistere, diu et multipliciter in ea laboravit frustra: tandem anno 1669 post fortem urinae destillationem in recipiente invenit materiam lucidam, quae postea Phosphori nomen obtinuit. Hanc monstravit amicis quibusdam, et inter alios *Kunkelio* Chymistae Electoris Saxoniae, sed cavit, ne quid diceret, inde compositio cognosci posset, obiitque secreto suo nemini communicato. Post obitum eius *Kunkelius* tam pulchrum arcanum perire non aequo animo ferens, resuscitationem inventi aggressus est, et considerans *Brandium* tota vita in urina laborasse, suspicatus est, in ea Phosphorum esse quaerendum. Huic ergo operam dedit, et post pertinacem quadriennii laborem, tandem, quod quaerebat, invenit. Non aeque mysteriosus fuit ac *Brandius*, arcanum ne nonnullis communicavit circa annum 1679. In Gallia et Anglia *Kraftius* Medicus Dresdensium, inventor huius Phosphori habetur, quoniam eum primus illuc attulit. Sed revera non nisi dispensator eius fuit, quem a *Kunkelio* acceperat, ut eruditis exteris ostenderet. Immo ignorabat compositionem *Kraftius* tunc, cum itinera sua obiret."[*]

[*] "Like so many other beautiful discoveries (inventa), the discovery of this phosphorus was due to a coincidence. A German chemist named *Brand* who lived at Hamburg, an unknown man of humble origin, of a morose and fanciful nature, and secretive in all that he did, discovered the luminous substance while searching for something else. From his youth he had occupied himself with the art of glassmaking but had forsaken this art in order to devote time to the philosopher's stone, upon which he had set his hopes. When he reached the conclusion, that the secret of the stone consisted in the treatment of urine, he frequently spent long periods working vainly with the latter. At length, in the year 1669, after vigorous distillation of the urine, he found a luminous material in the receiver which was later given the name phosphorus. This he showed to some friends and, among others,

If this report is compared with information given by *Kunckel* in his own works on the discovery of phosphorus and with that contained in letters to and from *Leibniz* and *Brand* – particularly in the correspondence between *Brand, Leibniz, Krafft*, and *Kunckel* of 1676 to 1679, which was first cited by *H. Peters* in 1902 [18] and then published in its entirety in 1916 [19] it becomes clear that *Homberg* must have heard the details from *Kunckel* himself. *Homberg* also states that he visited *Kunckel*, who had been appointed "Chymist" in the service of the Grand Elector in 1679, in Berlin, and received from him the procedure for the preparation of phosphorus [20]. Thus the mere fact that the name *Brand* and the year 1669 can be traced back to *Kunckel* imparts credibility to these statements. Moreover, *Leibniz*' detailed corrections – the death, the character, and the ability of *Brand*, and concerning *Brand*'s reports to *Krafft* and *Kunckel* – which follow the reprinted passage, make no further mention of the date. It must therefore agree with that which *Brand* had told him (*Kunckel* too can only have heard it from *Brand*), and the fact that *Brand* himself had told *Leibniz* of his discovery is clear from several details that are retold only by *Leibniz*, and particularly from the report that the motivation for his investigations on urine came from a printed work on alchemy: "Inciderat Brandius in processum quendam chymicum in libro typis edito, exantem, qui ex urina parare docebat liquorem aptum (si credimus) particulae argenti in aurum muturandae" [21].

Since phosphorus igneus remained unknown outside Hamburg until 1676, when *Krafft* and *Kunckel* were shown it by *Brand* and given samples, and since no earlier date is given in connection with or by *Krafft* – who only occasionally failed to mention the name of the discoverer but never claimed to be the same – or by *Kunckel*, there was no reason for *Brand* to subsequently pre-date his discovery. So long as no new contradictory sources become available there appears to be little reason for scepsis concerning *Brand*'s claim to have discovered the substance which he called "my fire" or "cold fire" in the year 1669, exactly three hundred years ago.

Kunckel, Chymist to the Saxon Elector, but took care to say nothing that could reveal the composition, and died without having told anyone his secret. After his death, *Kunckel*, who was not indifferent to the loss of such a beautiful secret, set about the resuscitation of the discovery; and considering that *Brand* had spent his whole life working with urine, he suspected that phosphorus was to be found in this substance. He therefore directed his attention to the latter, and, after four years' intense work, discovered that which he sought. He was not so secretive as *Brand* and he made the secret public around the year 1679. In France and in England, *Kraft*, a Dresden physician, is held to be the discoverer of phosphorus since it was he who first took it to those countries. In fact he was merely the distributor of the phosphorus that he had received from *Kunckel* to show to foreign scholars. *Kraft* was not even aware of the preparation when he undertook his journeys."

[21] Cf. ref. [1], p. 93.

The year 1677 (circa annum 1677) given by *Leibniz* does not refer to the discovery of phosphorus but to the disclosure of the discovery (prodiit!) – and outside Hamburg this actually took place in the year 1676/1677. *Leibniz* himself first became acquainted with phosphorus during a demonstration to the Hanoverian court by *Krafft* in mid-1677, and he immediately reported what he had seen in 'Journal des Savants' [22]. There he states: "...if the liquid is placed on any object outside the phial then the light disappears within a short time ..., but if it remains in the closed phial it is preserved for several years. *And it has actually been kept for two years*", *i.e. Leibniz*, too, recognized the discovery as being of an earlier date. (The year 1669 is also given in [7, 8, 23–32], but in no case does the author give any proof.)

2. The Discoverer

In the 17th and 18th centuries the substance known by *Leibniz* as "Phosphorus igneus", "Pyropus" (Greek: fiery-eyed), and "Phosphorus κατ' ἐξοχήν" [33] was given a whole variety of names, some of which referred to its properties, while others were intended to refer to the supposed discoverer. Thus *G. C. Kirchmaier* [34] calls it "*Kunckel*'s phosphorus", a name that rapidly found general acceptance and soon became the only name in common use, since in his publications *Kunckel* had claimed [35] as his own the discovery, or at least the rediscovery and the first planned preparation, while enjoying the support of his friend *Kirchmaier*, and later also that of *Homberg* (1692) [20], *J. H.*

[34] *G. C. Kirchmaier*: Nocticula constans et per vices fulgurans, diutissime quaesita, nunc reperta. Wittenberg 1676, p. 12.

[35] *Kunckel*'s report [3] (Historia von dem Phosphoro, welchen einige Lumen constans genennet) is reprinted in parts in ref. [16], p. 13, as an English translation by *T. L. Davis*, J. chem. Educat. *4*, 1105–1110 (1927).

Cohausen[36], and *Hellot* (1737) – in spite of *Leibniz'* justified opposition – and most of the older versions of the discovery of phosphorus. *Leibniz* comments[37]:

"But it is all the more amazing that he [*i.e. Brand*] is reported dead at the time when *Krafft* and *Kunckel* were spreading the news of the discovery of phosphorus throughout the world by the spoken and written word, and that *Kunckel* should have reawakened the art that had been lost with the original discoverer, while it is beyond doubt that *Kunckel*, while visiting *Brand*, had been initiated in the art by the latter, and that *Brand* lived for a long time and complained about *Kunckel*... But when *Kunckel* had returned home and made not few mistakes in the manipulations (in enchiresi), he was for a long time unable to prepare the phosphorus and sent letters of complaint to *Brand*, which I have seen, and in which he lamented that he had not told him the secret sufficiently openly. However, *Brand*, who regretted that he had been so thoughtless as to divulge his secret, refused to show the erring *Kunckel* the way. In the meantime, *Kunckel* corrected his mistakes himself, whence arose the pretentiousness (praetensio praetextusque), to dare to pose as the discoverer wherever he went, about which *Brand* complained bitterly."

Fortunately, *Leibniz* did not return *Kunckel*'s letters to *Brand* to the latter so that the accuracy of *Leibniz'* information can be confirmed to this day, and likewise *Kunckel*'s untruthfulness when he claimed (1713)[3,35] to have given *Brand* no promise of secrecy. While still on the homeward journey *Kunckel* wrote the following lines to *Brand* from Magdeburg in March, 1676[38]:

"Salve! Insonders hochgeehrter Doctor, zuverlässiger, wehrter Freundt, ehr wird sich wohl entsinnen, was wir mit einander abgeredet, nehmlich dass ehr mihr das lumen in einem Glase wollte nachschicken, nu sehe der Herr zu, dass ehrs in ein fein Cristallglas kricht und sende es mit dem ersten, dass ichs seh, dan ich habe darauf was herrlichs ausgesonnen..." [*]

At Wittenberg he then attempted to prepare phosphorous according to the information given to him by *Brand*; apparently without success for on June 25, 1676 he wrote[39]:

"... Wie angenehm mir des Herrn Doctors Brieflein von 3. Juni gewesen, kann ich nicht genug schreiben. Sehe daraus dessen gute Zuneigung, ehr had dakegen sich zu versichern, wass ich ihm so theur zu geschworen, dass ichs ehrlich halten wil, lebe auch der Hoffnung, der Herr Doct. wirt mir sein Feur getreuhlig geben; die Entschuldigung, dass ehrs der Feder nicht zu trauen darf, davohr trage ehr keine Sorge; der Herr Doctor schreibe so, ehr nehme die bewusste Materie, so oder so vihl, setze dieses darzu und mache es so, wehr wil das verstehn... Ich bitte dem Herrn, ehr solle mihr als ein gutter Freunt trauen, gebe es keinen Menschen mehr und lass mihr sorgen; so verne ehr es mir communicirt, wil ich, so wahr ich wil teihl an Gottes Gnade haben, so mit ihm handeln, dass ehr und die Seinigen sollen mihr Dank wissen, aber ehr muss mihr ohn Massgebung folgen... Der bewussten Matterie habe ich ein ziemlich Teyl. Habe es 2 mahl destilliert, aber kein Feuer gekricht. Bitte der Herr lasse meine Mühe nicht umbsonst sein; so baldt ein Schif geht, wil ich ihm mit Weitzen Mehl versehn; so er verlangt dass zu haben, womit ehr den Corallen die Tinctur extrahieren kann und in eine Massa als Pillen gebrauchen kan, wil ich ihm senden, was ehr von chymischen Medicamenten verlangt. Schreibe ehr mihr, weihl ich ohn dem hier eine Collectio chymicorum halte; muss ich sie doch machen und stehn mir übern Halse. Wil mihr der Herr eine kleine Probe von seinem Feuer schicken, nehme ichs zu Dank an und ich erwartte des Herrn Antwort und Communication. Befehl ihm sambt seiner Liebsten und kleinen Dochter in den Schutz des Höchsten... P.S. Der Herr Doctor schreibe mihr, was ich ihm von dem Provit, den ich mache, geben sol, oder wenn ich mehr mache, als so und so vihl, wie ihm deucht, dass ehr mit diesen wil vergnüget sein und wan ich et wem bei einem Grossen Herrn kohme, da ein Stück Gelt vohr die Communication kriegen könnte, die dem Herrn anständig und ich möchte wegen Ablegenheit seinen Consens nicht kriegen können, was ehr haben wil, dass ichs frey meines Eydes und Gewissen ohnbeschedigt thun mach, nehmlich wenn ichs einen communicirt. So ichs diese Post kriege und so vil davon gemacht als mir deucht, so wil ich in Persohn nach Florentz uns beiden zum Nutz damit; aber der Herr seh sich vohr, sehe nu wenigs nicht an und gebe nicht mehr hiervon; schreibe mihr der Herr cito, ich will allen den nachkommen, denn in Deutschland verlohnt es der Mühe nicht." [**]

However, *Brand* does not seem to have been inclined to give *Kunckel* further information regarding the preparation, in spite of the latter's promises. He had already heard the essential facts – indeed, he expresses in no uncertain terms his concern that Brand might tell others just as much – and deviated from *Brand*'s procedure only in that he mixed the urine extract with sand prior to distillation[40]. He than met with success. Such a practice, however, would seem to have been common enough in those days, for *Robert Boyle* adopted it immediately[41] once he had heard from

[*] "Salve! Most honorable Doctor, trusted and esteemed friend, you will no doubt remember our agreement, namely that you would send me the "lumen" in a glass. Now see that you get it into a suitable crystal glass and dispatch it soon, so that I can see it, for I have thought of something wonderful to do with it..."

[39] Cf. ref. [18], p. 1196.

[**] "I cannot say enough how pleased I was to receive your letter of June 3. In it I perceive your good will and can assure you that I will honestly keep that which I have sworn to you. I hope that you will give me your fire; the excuse that you did not dare to write it down should cause you no uneasiness. You should write it thus: You take the known material, so much, add another substance, and proceed thus; who will understand that ...? I bid you to trust me as a good friend, give it to no other people, and let me arrange the matter. If you tell it to me, then I – as sure as I wish to partake of God's grace – will behave in a manner such that you and yours will be grateful to me – but you must follow me unconditionally ... I possess a considerable amount of the known material; I have distilled it twice, but not obtained any fire. I ask you so that my efforts may not have been in vain. As soon as a ship departs I shall send you wheat flour. If you wish to have that with which you extract the tincture from coral and can make pills of the substance, then I shall send you all the chemical medicine that you desire. Write and tell me since I have here a collectio chymicorum as it is; I have to look after it nevertheless and it is beyond that which is sufficient. If you send me a small amount of your fire I shall gladly accept it. I expect to hear your answer and communication. I commend you and your dearest one and little daughter to the care of the Almighty ...

P.S. You should inform me how much I should give you of the profit I shall make; or if I obtain more then a certain sum you should tell me how much you require in order to be satisfied, likewise if I show it to an important man and can receive as much money for its communication as he deems fit, that without your consent, if I tell it to anybody I should like to do so while no longer bound by my oath and without hurting my conscience. When I have received this information by the next post and have done as much as I think proper, then I shall journey to Florence myself to our mutual benefit. But you should be certain that you give none of it to anybody else. Write to me soon and I will do so anyhow, because in Germany there is no use whatsoever."

[40] Cf. ref. [16], p. 25ff.

[41] *R. Boyle*: The Aerial Noctiluca, or new Phaenomena and a Process of a Factitious self-shining Substance. London 1680.– The Works of the Honourable Robert Boyle. New edition. Vol. 4, London 1772, p. 379–404.

Krafft, "...that at least the principle matter of his phosphorus was something that belonged to the body of man" [42] – without proceeding to make any claim to the discovery or rediscovery (thus *e.g. P. Walden* [15] still for *Kunckel* and *Boyle*), although he was the first to actually examine phosphorus closely and to find, *inter alia*, that "dry phosphorus" only luminesces in contact with air, whereas his predecessors had all spoken of an "eternal" light or fire. Moreover, *Boyle*'s procedure was the first to be published [43].

Krafft, whose name was also occasionally given to phosphorus, never made any claim to the first discovery or to any rediscovery himself. He was simply faster and more clever than *Kunckel* (and, of course, than *Brand*), from whom he first learned of *Brand*'s phosphorus in early 1676: He was able to start negotiations with *Brand* before *Kunckel* and "as he openly admitted, to purchase the art from *Brand* for money" [44]. It is doubtful whether he ever succeeded in the preparation himself; he used the samples he received as exhibition pieces and journeyed through various countries demonstrating them, together with other "phosphori", at Royal Courts and before Scientific Societies (as *Kunckel* also suggested to *Brand*), and advertised the "phosphorus" extensively in journals [45]. (The demonstrations at the Berlin Court, whose description by *Elsholz* represents the first publication on the new phosphorus, and also first gives this name to the new substance [46], at the Hanoverian Court where *Leibniz* was Hofrat, and before the Royal Society at London have already been mentioned.) Nevertheless, it was through *Krafft* that phosphorus became widely known – and it is indeed most fortunate that *Kunckel* and he ever came to know of its discovery (see below).

Although *Krafft* appears to have made no mention of the discoverer at Berlin, he named *Brand* as the discoverer at both Hanover – cf. *Leibniz*' letter of recommendation to the Royal Society [47] – and London [48]. And since even Kunckel did not dare to deny *Brand* all credit for the discovery, the latter became almost undisputedly [49] recognized as the discoverer of phosphorus in the late 18th century, when, for topical reasons (see below), interest in the history of the discovery was revived.

[49] *H. E. Fierz-David* represents an exception among modern authors. In his 'Die Entwicklungsgeschichte der Chemie'. 2nd Edit. Birkhäuser, Basel 1952, p. 147 (1945, p. 146), he states: "His [*i.e. Kunckel*'s!] most important contribution was that he first [?] prepared elemental [?] phosphorus by ignition of evaporated urine with charcoal [?]. He [?] called the substance phosphorus ..."

Earlier attempts [50] to trace the discovery of phosphorus to a date previous to *Brand* and 1669, and even back to antiquity have been finally refuted by *Partington* [51] and *Weeks* [52].

Little is known about the discoverer *Hennig* (*Heinrich, Hennig*) *Brand* [53]; not even approximate dates are recorded for his birth and death. According to *O. Sperling*, he attempted, in 1688/1689: "bei Schipbek in dem Berge mit etzlichen Soldaten der Stadt, so er bedungen, zu graben nach einem allda verborgenen grossen Schatze, wovon er Bericht hatte bekommen, und hatte dazu von dem Herzog von Holstein *Christian Albrecht*, der sich zu Hamburg aufhielt, öfters und inständig darum angehalten, Zulassung erhalten ... Fing deswegen an zu graben mit Wünschelrute und anderem Zubehör und Zusehern aus der Stadt bei Tausenden ... Derselbe Chymikus schreibt ihm [d.i. sich] zu, dass er der erster gewesen, der ex spiritu urinae den Phosphor, wie es die Chymiker nennen, wann der Spiritus geschüttelt, feurig scheint, zuwege gebracht ..." (September 1688) [54] "Es hatte ein Schmied einige Nachricht davon erhalten, dass vor Jahren ein Fuhrmann, der Sand führte, wie er am selben Ort gegraben, einen Beutel mit Dukaten gefunden, welches ihnen anzeigen machte, daß noch mehr vorhanden sein müsste, und gruben darauf fort, weil der bemeldete Chymikus und der Schmied in Gesellschaft mit einander getreten, da der dann der Chymikus *Brand*, der sich Doctor nennen liess, bisweilen mit seinem sammeten Rock die Zeche an den Wirth bürgen werden müssen, und auch von den Soldaten, die gegraben hatten, und ihre Bezahlung von ihm nicht erhalten können Schläge mit Scheltworten hat bekommen" [*].

[*] "... to dig for a great treasure of which he had heard near Schipbek in the mountain with some soldiers of the town who he had contracted, and for which he had obtained permission after frequent and urgent application, from the Duke of Holstein, *Christian Albrecht*, who stayed at Hamburg ... Began digging with the aid of a divining-rod and other equipment, and spectators from the town of Hamburg by the thousand ... The same chymist claims to be the first to have obtained ex spiritus urinae, phosphorus, as it is called by chemists, because the spirit appears fiery when shaken ..." "A certain smith had heard that many years ago, a certain carrier, who transported sand, had dug at the same spot and found a purse containing ducats, which made them think that more must be hidden, and continued digging, because the above chymist and the smith had become acquainted, and since the chymist *Brand*, who called himself doctor, had to surrender his velvet coat to the host as surety for the bill and was unable to pay the soldiers who had dug, he received blows and curses." (Spring 1689 [55]) – In 1710, *Leibniz* wrote [56]: "Indeed, as I have heard, he was still alive in the year 1692, when these [*i.e. Homberg*'s] stories were being circulated, and I do not know to this day whether he is dead." – A search in Hamburg archives has so far brought no further details to light.

It is not even known whether *Brand* was born at Hamburg; all we can be certain of is that he worked in this city between 1669 and 1692. The fact that he used low German in common speech, as *Kunckel* disparagingly reported, certainly suggests a North German origin [57]. As a young man *Brand* served as an officer who had worked his way up from humble beginnings. During the period given above he was married to an originally wealthy widow, who had a son by her first marriage and later bore *Brand* a daughter. He practised as a physician and dealt in chemical medicaments, most of which he probably made himself (cf. *Kunckel*'s letter cited above). Although he called himself doctor medicinae, and is also referred to as such by *Leibniz* and in the apparently friendly letters of *Kunckel*, it is doubtful whether *Brand* had been able to complete a course of study in medicine. In any case, his name is not to be found in the list of members of the Hamburg Collegium medicum [57]. Some doubt also surrounds where *Brand* had obtained his extensive "chemical" and metallurgical knowledge, to which *Leibniz* attests in high degree, and which – if we ignore *Brand*'s own statements – also *Krafft* and *Kunckel* were compelled to recognize.

From *Leibniz*' reports to the Duke of Brunswick-Lüneburg and from the correspondence between him, *Brand*, and *Krafft*, we come to know *Brand* as a readily excitable, but also easily soothed personality, as a person who was full of often adventurous plans and ideas, of which he often failed to realize the significance and value [57]. *Leibniz* considered him to be the right man to carry out the process of the "secretum" twenty times a week in the smelting works of the Harz mountains, and in a report to the Duke characterized him in the following way:

"Dr. *Brand* is unable to judge his own capabilities, or to assert himself. Not that he does not often indulge in fanciful and conceited talk, but, like all men, he has a character of his own. He is easily led, lacks a developed power of judgment, and leads a disorderly life, but he is quick to act and an extremely skilled worker ... I have often noticed that he makes a great bustle about trivialities but makes little fuss about things that deserve it. He is always looking for great secrets and fanciful things instead of realizing that he could live better from that which he has already accomplished."

These words seem to portray *Brand*'s character admirably; in any case, other reports – such as the futile treasure hunt involving tremendous effort but no money, so that after the failure of the venture the contracted soldiers had to make up for their trouble with blows and curses – and statements made by *Brand*, of which *Leibniz* could then have had no knowledge, harmonize with this picture. In general, it appears that *Brand* was always short of money – his wife's capital was soon spent on alchemical experiments; *Leibniz* promised to pay his debts to the City of Hamburg – and that in spite of his large income as physician, which still remains when deductions are made from the figures contained in his letters to *Leibniz* since they may represent an attempt to obtain more money for his household at Hamburg and as compensation for loss of income during his visit to the Duke at Hanover.

During an official journey to Hamburg, *Leibniz* had visited *Brand* and made an agreement, subsequently endorsed by the Duke, that the latter tell *Leibniz*, who was committed to secrecy, about the preparation of phosphorus and continually keep him informed regarding his chymical experiments. *Leibniz* then insisted that *Brand* immediately accompany him on the return journey to Hanover, since there was a very real danger that *Johann Joachim Becher* (1635–1682) would try to secure *Brand*'s information for a better price. In fact, *Becher* was most interested in *Brand*'s alleged "secretum" for the transmutation of silver to gold, which *Leibniz* also wished to reserve for his Duke, should it prove successful. By various intrigues he had been able to keep *Brand* unaware of *Becher*'s offer. It is therefore understandable that *Brand* felt cheated – for a second time after his discovery of "cold fire", whose value he had not recognized, had been commercialized by others – when he eventually heard of the offer, and from then on his relationship to *Leibniz* became cooler and cooler, particularly when, after the death of Duke *Johann Friedrich*, the Hanoverian Court failed to fulfil its part of the agreement and various other promises.

Meanwhile, at Hanover, *Brand* set about the preparations for the large-scale manufacture of phosphorus from human urine, to be provided by the local garrison (there are reports of some 100 tons, corresponding to about 13140 liters), and told *Leibniz* the secret of the process, as agreed. When the phosphorus had been made, *Leibniz* immediately sent a sample to *Christian Huygens* at Paris and wrote the following words to the Duke of Chevreuse in December 1778: "At last I have obtained the procedure; I am now the fourth to possess it."

Brand remained at Hanover for five weeks and on his return he complained about the slow and incomplete payment he had received. Nevertheless, he made a second visit in the latter half of the year 1679. However, the planned manufacture of large quantities of phosphorus, for which *Brand* had taken his stepson as assistant, does not appear to have taken place: *Brand* soon fell ill and spent two months recovering at Hanover. The death of the Duke on December 28, 1679, appears to have deprived him completely of any reward for his efforts, for in a letter of April 23, 1682, *Brand* demands the remaining money owing to him, presumably once more in vain. – The Court had run into financial difficulties, and *Brand* had suffered yet another disappointment.

3. The Material Discovered

In his 'Historia' [58] *Leibniz* reports on the motivation for the discovery of 'Phosphorus igneus': "During his studies *Brand* came across a procedure, published in a

[55] Cf. ref. [54], Vol. VI, p. 382.

[56] Cf. ref. [1], p. 93.

[58] Cf. ref. [1], p. 93.

printed work, for the preparation of a certain liquor from urine by means of which pieces of silver could be matured to gold. On following the same procedure he discovered his phosphorus." In a letter of April 11, 1682, he suggested that the said book was one of the works of *Franz Thomas Kessler*[59]. However, *Peters*[60], supposes it to have been 'Alchimia Nova' by *H. Binelli*, a German translation of which had appeared in 1603. Even though this question will probably never be answered unequivocally, the text of *Binelli*'s book makes it quite clear to what end *Brand*'s investigations were directed and what he believed he had found[61]:

"... daß die Alchimy jhren Vrsprung auß keinem Stein oder Metall haben könne. Sintemahl solche Sachen nicht gebähren oder jhres gleichen zielen ... es könne die Alchimy weder aus einem vnuernüfftigen Thier, noch auch auß jrgend einem Gewächse oder Kraut ... herkommen vnd entspringen, so wende dich zu der Empfängnung vnd Geschöpff des Menschen selbst, ... so wirst du befinden, daß der Mensch ein gebährender Anfang oder Vrsprung auch der Alchimistischen Materien vnd Steine sey: Denn er ist ein vegetalisch, rationalisch vnd mineralisch Thier vnnd aller Elementen theilhafftig, vnnd hat Mineras vnd viel Poros oder Schweißlöchlein in sich. Geschicht dir aber mit dieser Antwort nicht genug, so hör vnnd merke für das ander, was die alte Philosophi sagen, daß nehmlich der Mensch die kleine Welt sey: Ist er nun die kleine Welt, so muß er auch alles dasjenige in jhme haben, was die andere grosse Welt in jhr hat, wiewol ein jedes in geringer Mänge. ... frag in diesem dein eygen Gesicht, das wird dich berichten, daß sich mineralische Sachen in deß Menschen Leibe finden, vnnd daß der Mensch zweyerley Potestates oder Vermögen in jhm habe als erstlich einen Samen ... Die andere Krafft aber ist etwas geringer ... als da sind Harn, Schweiß, Koht vnd dergleichen ... Ist demnach der Mensch ein solcher Anfang vnd Geschöpff, aus welchem die Steine vnd Materien der Alchimy jhren Vrsprung her haben ... Wenn man den Harn ansihet, so bekompt derselbige nicht allein für sich selbst vnd von Natur die Härte vnd Natur eines Steins, sondern kan auch durch die Kunst dazu gebracht werden: Kan demnach dasjenige, aus welchem die Alchimy herkompt vnd entspringt, sehr wol seyn. Vnd damit du dessen, daß dem nemlich so sey, noch mehr versichert werdest, so erjnnere dich dessen, so die Philosophi fürgeben, daß nehmlich jhr Stein in der kleinen Welt entspringe .. Sprichstu aber, ... ich ... kan mich aber nicht genugsam verwundern, woher doch dem Harn solche große Kraft ... komme: darauff gib jch dir zur Antwort. Das eben der Harn diese Natur vnd Proprietet oder Eygenschafft hat, daß er zu einem Stein wird. Vnd zwar so sagen die Skribenten, es müsse ein solcher Harn, welchen man hierzu gebrauchen wil, einer reinen Natur vnd ohn allen Schweiß seyn, vnd derowegen von einem jungen gesunden Knaben, so mit den besten Speisen vnd gutem köstlichem Wein vnterhalten vnd ernehret worden vnd sich der Vnkeuschheit weder in der That noch auch mit den Gedanken jemals beflissen, genommen werden."[*] (The generative power must be preserved in its entirely!)

Concepts of the human microcosm as a miniature embodiment of the macrocosm are extremely old. Since late antiquity, *i.e.* from the very beginning, they played an important role in alchemical thought. The fact that they had again assumed a particularly important place in alchemical thought in the 16th and 17th centuries is shown by *Boyle*'s reaction to *Krafft*'s intimation that the starting material for 'cold fire' was of human origin (see Section 2): He immediately started with urine.

But is it not just this general intellectual situation of alchemy that throws light on *Brand*'s relationship to the art and on his chemical aptitude? Was not he, as a crass outsider, actually the only person to have successfully carried out the generally known and recommended (but probably only rarely actually performed) process of extraction from urine until he had indeed obtained a substance possessing wonderful properties? Or was his lack of prejudice concerning the properties of the 'secretum' obtained an additional factor? The alchemists expected to find a "black" substance, the unfermented 'prima materia'; and for the 'spagyric art', 'fire' was only an external conditio sine qua non for the chemical processes that was not permitted to come into direct contact with the starting materials and intermediates, which were sealed off 'hermetically'. Or, was it merely the desperate situation arising from his permanent financial embarrassment that compelled *Brand* to invest such an uncharacteristic measure of patience in the preparation of the desired agent for the transmutation of silver to gold, and to place such faith in the old text. It was probably the fortunate combination of all three factors that actually led to the discovery.

It thus also becomes understandable why *Brand* kept his discovery secret for such a long time. The 'phosphorus' – in neither the liquid nor the solid form – was not the 'secretum' itself, but merely an important component or starting material, which he occasionally showed only to close friends. In 1677 *Brand* was still convinced that he would soon possess the 'secretum', and even two such important men as *Leibniz* and *Becher*, whose preliminary work later formed the

---

[61] *H. Binelli*: Alchimia Nova, das ist die güldne Kunst; verdeutscht von *P. Uffenbach*. Frankfurt a. M. 1603, p. 3ff.

[*] "... that alchemy cannot have its origin in any stone or metal. Since such things cannot give birth and produce their equal ... alchemy cannot arise ... from an irrational animal or from any plant or herb, therefore turn to that which man creates with his body, ... then you will recognize that man is a procreating genesis or origin also of alchemical material and stones; for he is a vegetal, rational, and mineralistic animal and can partake of all elements, and he has mines and many pores or small sweat holes in his body. If this answer should not satisfy you, then listen and note what the philosophers of old said, namely, that man is the microcosm: Now if he is the microcosm then he must contain everything that the macrocosm contains, but in smaller amounts. ... ask yourself, then you will see that minerals are to be found in all men, and that man possess two kinds of potestas or strength: the first is his sperm ... the other strength is somewhat weaker ... that is urine, sweat, feces, and suchlike ... Man is therefore such a beginning or such a creature, from which the stones and materials of alchemy can arise ... If one considers urine, not only does it turn spontaneously and by nature into the hardness and nature of a stone, but it can also be induced to do so by the art: therefore it can well be the source and the origin of alchemy. To provide further support for this concept, keep in mind that the philosophers are of the opinion that their stone originates in the microcosm ... If you should wonder whence urine has its great power, I offer the answer that urine is capable of being transformed to a stone. And indeed the scribes say that the urine used must be a suitable one, of a pure nature and containing no sweat, and therefore from a young, healthy boy, who has been nourished with the best food and good wine, and chaste in thought and deed."

basis of *G. E. Stahl*'s phlogiston theory, opened negotiations to obtain this agent for their respective masters.

It is therefore perfectly feasible that earlier alchemists had already found the 'cold fire' – a procedure given by *Paracelsus* (1493–1541), for example, appears to suggest that this was the case [62]. Even *Brand*'s discovery only became known by a fortunate combination of circumstances.

Brand himself never published any reports concerning his phosphorus, and none of his remaining letters give away any information regarding the method of preparation. However, he did tell *Leibniz* of the preparation as agreed, and the latter successfully carried it out together with a number of assistants: ... *Brand* "honestly informed me of his process; for, with my assistants, I have repeated in another laboratory all that he accomplished" [63]. It has already been mentioned that in December 1678 he boasted to the Duke of Chevreuse of being the fourth (after *Brand*, *Krafft*, and *Kunckel*) to possess the procedure for the preparation of phosphorus. It is therefore a reasonably safe assumption that the procedure which he sent to *Ehrenfried Walter Freiherr von Tschirnhaus* (1651–1708), who was then in Paris seeking admission to the Academy, in an undated letter of the year 1682 was the very same recipe that he had received from Brand. The letter begins with personal and mathematical details and continues [64]:

"Phosphori Process kommt hierbey. Solchen werde, so lange M. Hr. mir nicht den ausgang seiner sach melde, nicht communiciren, zumahlen sie mir noch nicht geschrieben, was sie mir vor curiosa experimenta dafür communiciren wollen. M. Hr. wird solche doch auch leicht erfahren, und werde ich sie also durch ihn bekommen, hat also M. Hr. vom phosphoro nach seinem belieben zu disponieren. Nur dieses muss bekennen, dass das phosphorum zu machen, eine ziemlich beschwehrliche arbeit, und muss man sonderlich bey der letzten arbeit zusehen, dass die retorte nicht springe. Des Mons. *Boyle* ist etwas kürzer, aber wie ich aus seiner Beschreibung sehe, so fehlet er ihr bisweilen, gibt auch keinen so starken phosphorum, und überdies so ist er nicht instructif, denn er weiset nicht analysin subjecti et ex qua ejus parte potissimum veniat phosphorus. Zweifelsohne ist M. *Boyle* darauff gefallen, weil ihm der phosphorus imperfecte communiciret worden. Schicke hiermit beyde processus, sowohl wie ich es gemacht, als wie M. *Boyle*.

Composito des Feuers oder pyropi. Habe genommen urin so eine zeitlang gestanden, etwa eine tonne (wiewohl ich zweifle, obsolche fermentation oder putrefaction nöthig sey, weil mein Diener in Copenhagen den phosphorum noch selbige woche, als er hinkommen, gemacht), kochet es ab bis es beginnet dick zu werden, wie ein dicker sirup, alsdann thut man diesen dicken urin in eine retorte, lässet das phlegma und volatile vollends wegrauchen, und wenn rothe tropfen zu kommen beginnen, leget man einen recipienten vor, und empfängt darinn das oleum urinae. Alsdann schlegt man die retorte in stücken, darinn findet man ein caput mortuum, dessen unter theil ist ein hartes salz, so hieher nicht dienet, das obere theil ist eine schwarze lückere materi, die hebt man auff. Das oleum urinae thut man wieder in eine retorte und ziehet alle feuchtigkeit stark davon ab, so findet man in der retorte eine schwarze lückere materi der ietzgedachten, so in voriger retorte gewesen ganz gleich. Thut sie zusammen und treibt das feuer daraus folgendermassen. Nim eine guthe steinerne retorte, so kein stübgen nicht hält, darin thue etwa 24 Loth von der schwarzen materi oder capite mortuo oleoso, lege einen ziemlichen gläsern recipienten vor, so wohl verlatirt, und treibs also in freyen feuer, doch erstlich gelinde bis die retorte wohl glüet, treibs wohl 16 stunden lang, die letzten 8 stunden aber gar stark. Es kommen bald weisse Nebel oder wolcken und sezet sich wie ein schlammig oel zu boden. Gehet auch wohl etwas von einer materi mit über, die sich ganz hart an das glas anleget, ist wie ein Börnstein, darinn bestehet die beste krafft. Im ... destilliren ist der recipient ganz hell, und leuchtet im finstern. Was übergangen, ist alles leuchtend, doch das siccum mehr als das humidum. Hieraus ersiehet man, dass das feuer stecke in dem capite mortuo oleoso ...

Ich weiss keinen process, der auff die vulgata Chymicorum principia, sal, sulphur und mercurium, besser quadrire, als die compositio dieses feuers oder pyropi, denn dieses feuer komt eigentlich nicht aus dem sale fixo, noch aus dem volatili oder Mercuriali, sondern aus dem medio oder oleo vel sulphure. Und deucht mich, dass dieser process kein geringes licht gebe ..." [*]

[63] Cf. ref. [1], p. 96.

[64] *G. W. Leibniz*: Mathematische Schriften, Vol. 4. G. Olms, Hildesheim 1962 (Halle 1859), p. 496 and 498.

[*] "The process for the preparation of phosphorus is enclosed. I shall not communicate it until you have informed me how your matter has gone, particularly as they have not yet written to tell me what curious experiments they wish to exchange for the communication. You will, however, also have no difficulties in obtaining such experiments, and if I learn of them from you then you will have phosphorus at your disposal. It must, however, be said that the preparation of phosphorus is rather difficult and that towards the end one must be particularly careful that the retort does not crack. The procedure of Mr. *Boyle* is somewhat shorter, but as I see from his description it has sometimes been unsuccessful and, moreover, it has not produced a very strong phosphorus. In addition, his description is not instructive for he does not order analysin subjecti and he does not know from which part of it the best phosphorus originates. This is undoubtedly due to the fact that he has only been imperfectly told of the preparation of phosphorus. Herewith I send you both procedures, not only that which I have used myself but also that of Mr. *Boyle*.

Composition of the fire or pyropus. Take approximately a full ton of urine that has stood for some time (although I doubt that such fermentation or putrefaction is necessary, for my servant has prepared phosphorus within a week of his arrival in Copenhagen), boil it until it begins to thicken, like a thick syrup, then place this thick urine in a retort, allow it to phlegm and the volatile part to vaporize, and when red drops appear a receiver is placed in front of the retort and the oleum urinae is collected. The retort is then broken into pieces. One finds a caput mortuum in it, the lower part of which is a hard salt that cannot be used, the upper part is a black loose material which one keeps. The oleum urinae is again transferred into a retort and all moisture is vigorously removed, one then finds a black loose material in the retort which looks just like that in the previous retort. Both are united and the fire is driven out in the following way. Take a good stone retort that has been very well cleaned, fill it with about 24 Loth of the black material or caput mortuum oleosum, place in front of the retort a suitable glass receptacle that is well stoppered, and heat over an open fire, gently at first, until the retort glows; heat for a total of 16 hours, and fiercely for the last 8 hours. White smoke or clouds soon appear and a kind of muddy oil deposits at the bottom. Some material also distills over which strongly adheres to the glass, it is like amber and that is the best material. On ... distillation the receptacle is very bright and shines in the dark. All that has distilled over shines, the dry part more than the moist part. One can thus see that the fire is in the capum mortuum oleosum ...

I know of no process that better quadrates the general principles of the 'chymists' – sal, sulphur, mercurium – than the composition of this fire or pyropus, for this fire does not come from the sal fixum or from the volatile or mercuriale, but from the medium or oleum vel sulphur. And it seems to me that this process gives a good light ..."

Robert Hooke (1635–1703) later published a far more complicated procedure "Phosphorus Elementaris, by Dr. *Brandt* of Hamburgh" [65], in a form that could hardly have originated from *Brand*. It is also uncertain how *Hooke* could have learnt of the method from *Brand*. It is in fact one of the many procedures to appear in the early 17th century subsequently ascribed to the discoverer of phosphorus by *Hooke*.

It has already been mentioned that *Brand* called the substance he discovered in urine "cold fire" or just "my fire". He clearly thought that he was in possession of elemental 'fire', one of the four Aristotelean 'elements' (earth, water, air, and fire); an assumption confirmed by his use of the alchemical symbol for 'fire' (Δ) in his letters. The term employed by *Hooke* "phosphorus elementaris" (presumably: "bearer of elemental light"), which has a very different meaning from "elemental phosphorus" in the sense of the later 'chemical' elements of the 19th century, is also suggestive of a similar interpretation.

Other early names are: Phosphorus fulgurans (*Elshloz*, *Kunckel*), Ph. igneus (*Leibniz*, *Boerhaave*), Ph. mirabilis or Wunder-Licht (miraculous light) (*Kunckel*); Lumen constans (*Kunckel*, *Elsholz*), L. perpetuum (*Kirchmaier*); Lux condensata (*Sturm*), Ignis perpetuus (*Krafft*), feu corporel (*Leibniz* in a letter accompanying the first sample he sent to *Huygens* [66]), Noctiluca constans (*Kirchmaier*, *Cohausen*), Noctiluca aerea (*Boyle*), Pyropus (*Leibniz*), *etc.*

All these names show that *Brand*'s discovery was regarded as a kind of light or fire material, or at least a "bearer of light" or "of fire". Even after *Stahl*'s proposal of the phlogiston theory (1703), *Nicolas Lémery* (1645–1715) 'pensionnaire chimiste' of the Paris Academy since 1699, wrote the following lines in his 'Muthmassungen und Betrachtungen über die Feuer- oder Lichtmaterie' [67]:

"Die Feuermaterie ist das vorzüglichste und mächtigste Auflösungsmittel irdischer Körper. — Man muß zugeben, daß sie der wahrhafte Stoff der Wärme, des Lichts und selbst der Flüßigkeit oder die Ursach der Schmelzung der mehresten irdischen Körper sey, die ohne diese Materie immer vest bleiben würden. Sie ist aber nicht immer so häufig da, oder sie trifft nicht immer Körper an, die ihr so wenig Widerstand leisten, daß sie dieselbe zum Fließen brächte, ja, man bemerkt oft, daß sie, anstatt diese zu schmelzen oder sie in der Flüssigkeit zu erhalten, die sie ihnen anfänglich mitgeteilt hatte, sich an dieselben hängt, und darinn so eingewickelt wird, daß sie eingekerkert zurückbleibt, und nicht eher heraustritt, als bis eine äußere Ursache ihr zu Hülfe kommt, und die Zellen, worinn sie zurückgehalten wurde, öfnet.

Hierbei ist ein doppelter Umstand zu bemerken, daß sie nämlich 1) manchmal das Gewicht der Körper, worinn sie enthalten ist, merklich vermehrt [!]; und daß sie 2) während der ganzen Zeit ihrer Einkerkerung doch die eigenthümlichen Eigenschaften der Feuermaterie behält, die sie deutlich äussert, so bald sie frey wird ... Spießglaskönig, Bley, Zinn und selbst Quecksilber wiegen nach der Verwandlung in Kalk mehr, als im metallischen Zustande, ob gleich viel von ihnen bey der Operation verflüchtigt wird. Da nun die Feuermaterie sie in den verkalkten Zustand gebracht hat, soll man ihr nicht auch das vermehrte Gewicht zuschreiben? ... Unter allen Körpern, worinn die Feuermaterie am losesten eingeschlossen ist, sind die Phosphoren. Man braucht sie nur ans Licht zu stellen, da sie sogleich neue annehmen, die die erstere in Bewegung setzt. Es sind Lichtschwämme, die es eben so leicht von sich geben, als sie es annehmen ..." [*]

This view was destined to persist in a more or less similar form for a considerable time; even towards the end of the 18th century yellow phosphorus was still regarded merely as a particularly striking example of a whole series of "phosphorus", of "light (or fire) bearers" or "light imbibers", which differed from the others in that it did not have to be first exposed to light or fire in order to luminesce, as *Leibniz* put it.

As late as 1790 the following description appears in *Gehler*'s 'Physikalisches Wörterbuch' under the heading 'Phosphorus' [68]:

"According to its entymological meaning, the name phosphorus (light bearer) applies to any body that luminesces in the dark. However, the sun, the fixed stars, and burning or glowing bodies, whose luminescence is an everyday phenomenon, are excepted, and the name phosphorus applied only to the other substances that luminesce of themselves, whose light in the dark belongs rather to the rare and unexpected phenomena. Such substances are either natural or artificial phosphors. A number of the natural ones are considered under the heading 'luminous bodies'; the artificial phosphors therefore represent the main subject of this article".

The enumeration starts off in chronological order, beginning with Bologna phosphorus (BaS), whose discovery is incorrectly cited as having occurred in 1630 – it is first mentioned by *Julius Caesar la Galla* ('De Phaenomenis in Orbe Lunae'; Venice 1612), and a detailed description was given by *Fortuno Liceti* ("Litheophosphorus, sive de lapide Bononiensi'; Udine 1640) and *Athanasius Kircher* (Magnes, sive de arte magnetica ...'; Cologne 1643, as well as 'Ars Magna Lucis et Umbrae ...'; Rome 1656); the discovery occurred between 1602 and 1604, and is attributed to the Bolognese shoemaker *Vincenzo Cascioroli* [69]:

[*] "The fire material is the most powerful solvent for earthly substance – One has to admit that it is actually the substance of heat, of light, and even of liquid or the cause of the melting of most earthly substances, which, without this material, would always be solid. It is not, however, always present in such a degree, or it does not always find substance which offer so little resistance that they are made to flow; moreover, one often notices that, instead of melting these bodies or keeping them liquid as in the beginning, it attaches itself to them and becomes so intimately mixed with them that it remains imprisoned within them and cannot be freed until an external cause assists and opens the cell in which it is held back.

Two things are to be noted, namely that the fire material 1) sometimes increases considerably the weight of the bodies in which it is contained [!]; and 2) retains the properties of the fire material which it clearly exhibits when it is freed, for the duration of its imprisonment ... antimony, lead, tin, and even mercury, weigh more after calcination than in the metallic state, although large amounts of them are volatilized during the operation. Since the fire material transformed them to their calcined state, why should one not also attribute the increase in weight to it? ... The phosphors belong to the substances in which the fire material is most loosely bound. If they are exposed to light they immediately take up fresh fire material, which sets the confined fire material in motion. They are light sponges which release light just as readily as they absorb it ..."

"It became luminous on exposure to both sunlight and candles, but not to the light of the moon or of another phosphor ... This discovery naturally led to the corpuscular concept of light, which not long afterwards became the basis of *Newton*'s theory of light. Here one saw, as it were, bodies, which attracted light and re-emitted it, light imbibers or light magnets (corpora lumen bibentia), which names have also been adopted" [70].

The second "phosphorus" to be dealt with by *Gehler* is *Balduin*'s phosphorus, which was first reported on by its discoverer in 1674 (see Section 1); he then goes on to discuss *Homberg*'s phosphorus ($CaCl_2$) and a series of other "artificial" phosphors, *i.e.* phosphorescing substances, before he comes to "*Kunckel*'s or urine-phosphorus".

The Bologna phosphorus and *Balduin*'s phosphorus (ignited calcium nitrate) indeed created great excitement in the scientific world and stimulated the search for other "phosphoruses". For example, *Homberg* had studied the former in Italy and as soon as he heard of *Balduin*'s discovery he payed the Saxon magistrate a visit at Grossenhain. In continuation of his journey he came to Berlin, where he met *Kunckel* who told him about another new phosphorus, *i.e. Brand*'s 'cold fire', and gave him a sample. *Kunckel* himself reports that a few weeks after his having become acquainted with *Balduin*'s discovery and been given a small sample, he was demonstrating the same during a visit to Hamburg when he heard that a Herr *Brand* of Hamburg had also discovered a luminous substance [71]. His informant was *Peter Hessel*, who was preacher at the Hamburg plague spital from 1670 to December 26, 1677, and apparently one of the few friends to whom *Brand* had shown his "fire" – fortunately, as we can now appreciate; for it is only due to facts that *Kunckel* had learnt of *Balduin*'s phosphorus from the discoverers publications and had been able to secure a small sample, that he demonstrated this at Hamburg, and that the versatile and literarily very active preacher, who had already seen *Brand*'s phosphorus, also happened to be present at the demonstration that *Brand*'s discovery ever came to *Kunckel*'s notice. He described what he had seen in a letter to his friend *Krafft* at Dresden and thus set in motion the course of events whose beginning are described above. *Brand* himself could never have dreamed of the significance of his discovery, or even of the possibility of a financial exploitation, so that we actually owe our knowledge of it to an unlikely combination of various chance circumstances – even though the discovery of the substance would certainly have followed later, and that in a less fortuitous and unconscious manner.

It has already been mentioned that "phosphorus" was originally prepared in one of two forms, either as a grayish or yellow solid or as "phosphorus liquidus" – *Elsholz* [46] reports *e.g.* that *Krafft* possessed samples of both kinds. Recent investigations on earlier reports and procedures have shown that the liquid form must have been a suspension of finely divided phosphorus in water (*Brand*, *Krafft*) or must have contained impurities. Such contamination, particularly with sulfur, would lead to a melting point below the normal temperature [72]. And the frequent contamination with sulfur, along with the ready combustibility (ascribed to the former principium sulphur), seems to have led to phosphorus being regarded as "a sulfur or a sulfurous substance" after the original idea of elemental light or fire had gradually been abandoned, or modified as in the above passage by *Lémery*, as a consequence of *Boyle*'s discovery that contact with air was an essential condition for luminescence of the solid material.

Homberg (1692), for example, like *Leibniz*, considered it to be the sulfurous principle of pre-phlogiston chemistry, when he said that phosphorus is the fattiest, *i.e.* the most combustible, part of urine, which is concentrated on a highly flammable earth.

Nevertheless, *Boyle* [73] had already recognized that the residue left by burning phosphorus possesses acid properties, so that it was only natural for *Stahl*, the founder of the phlogiston theory, to regard phosphorus as a compound of phlogiston and a concentrated acid. It is, however, remarkable that he was thinking, not of a specific acid, but of hydrochloric acid. Certain experiments by *Boyle*, which cannot be considered here, led him to this conclusion; he was so convinced of the correctness of his assumption that he, and his successors, considered any proof entirely superfluous. The deciding factor in the preparation of phosphorus was then thought to be the choice of the correct method of combining the phlogiston with the hydrochloric acid. Thus it can be read, *e.g.* in *Johann Juncker*'s widely read work 'Conspectus Chemicae' of 1730: "Phosphorus consists primarily of hydrochloric acid and phlogiston, which are bound most intimately by fire, and is therefore a kind of sulfur" [74]. The symbol $\overset{\triangle}{\ddagger}$, derived from the old symbol for the 'element' fire ($\triangle$), which *Brand* himself had used for phosphorus, found general acceptance (sulfur: $\overset{\triangle}{+}$).

It is clear that this theory made the preparation of phosphorus no easier. The only methods available were still the old, time-consuming, and inconvenient processes used by *Brand*, *Kunckel*, *Krafft*, and *Boyle*, which had undergone only slight modification. It was much simpler, although more expensive, to import phosphorus from England, where *Ambrose Godfrey Hanckwitz* (1660–1741), a pharmacist of Göthen in Anhalt who had emigrated to England and had become assistant to *Robert Boyle*, had set about producing phosphorus on a large scale. By closely guarding the secret of his preparation, which only became known sketchily in the 1730's, he had almost suc-

[74] *G. J. Mielke* in *A. S. Marggraf*: Einige neue Methoden, den Phosphor im festen Zustande sowohl leichter als bisher aus dem Urin darzustellen als auch denselben bequem und rein aus brennbarer Materie (Phlogiston) und einem eigentümlichen, aus dem Urin abzuscheidenden Salze zu gewinnen. Translated from the Latin and French and edited by *G. Mielke*. W. Engelmann, Leipzig 1913, p. 45.

ceeded in establishing a monopoly for the production of phosphorus. The first records of shipments of phosphorus from London to Germany refer to the year 1685, and in the same year *Hanckwitz* advertised his product in London in the following way: "He sells Solid Phosphorus, wholesale, 50 s. an ounce, and retail, £ 3 sterling, the ounce." The prices remained at this level – in 1731 *Stahl* gives the price as 40 shillings the ounce in London and 32 Belgian guilders in Amsterdam –, and after the death of their father, *Hanckwitz*' sons were able to continue production for the same high profit [75].

It is thus also understandable that in 1736 the Paris Academy commissioned *Hellot*, *Du Fay*, *Geoffroy*, and *Du Hamel* to examine an offer of a more economical process for production of phosphorus which had been made by an unnamed foreigner, and that they subsequently bought the process. According to the report given by *Jean Hellot* (1685–1766) to the Academy on November 13, 1737, $3^1/_2$ pounds of calcined starting material gave 9 gros and a few grains of a phosphorus that was "at least as beautiful as that coming from England" [76]. The novelty of the process – and the only direct influence of the phlogiston theory on the preparation of phosphorus – was the addition of powdered charcoal *i.e.* "highly concentrated phlogiston", apart from sand or earthenware fragments (to ensure even heat distribution), to the starting material, putrified urine.

Then, a few years later, in 1743, *Andreas Sigismund Marggraf* (1709–1782) published a treatise in 'Miscellanea Berolinensia' which not only stripped phosphorus of its mystery, but also considerably simplified its preparation [77]. The author described what prompted him to undertake his experiments in the following lines [78]:

"Around the year 1734 I was fortunate enough to receive tuition by the famous and skilled *Henckel* [*Johann Friedrich Henckel*, 1679–1744] in Freiburg ... We frequently discussed phosphorus and its high price and exchanged our views on the matter, and on one such occasion he assured me that quite by chance, he had once produced phosphorus using only low heat," – the fierce heating, which had to be kept up for a considerable length of time had always caused difficulties – "while engaged in work on the mercurificatio [experiments to obtain 'mercurius' from metals]; he had already published this method in his 'Pyritologia' ['Pyritologia Oder Kiess-Historie'; Leipzig 1725]. I searched for the place and found on p. 1004, paragraph 14, the following words: 'Bleykalk mit Salmiak, Weinstein und altem Urin digeriert, endlich destilliert, giebt einen arsenikalischen Geruch, ja endlich einen schönen Phosphor' [*] ..."

Henckel provided him with further detailed information about the process, which was then studied systematically by *Marggraf* with the result that it became easier to prepare phosphorus, using less heat, and in greater yields when not only charcoal (as had become common practice since 1737), but also molten lead chloride [Hornblei] ($PbCl_2$ in the solid state), horn silver (AgCl), or cadmia fornacum (ZnO) was added to the concentrated urine. He studied which part of the urine actually gave rise to the phosphorus, or whether it might even have arisen from the substances added, particularly those containing chlorine, thus proving the conclusion reached by *Stahl* from his theory to be correct and phosphorus could be prepared without urine. During these studies he came across the "highly remarkable urine salt" ($NaNH_4HPO_4$), which had long been known under the name of sal microcosmicum (see above) and from which, in admixture with charcoal only, with charcoal and sand, or with charcoal and horn silver, could be prepared a "very beautiful and pure phosphorus". It should be only this salt that came into question for the preparation, as well as an "acid" obtained by ignition ($NaPO_3$), which is reduced to phosphorus by charcoal. Phosphorus could, however, be more readily obtained by reduction of the acid, upon which the urine salt is based, by charcoal.

According to this reasoning phosphorus was the compound of a specific acid, *i.e.* phosphoric acid, with phlogiston. As far as phosphorus was concerned, *Stahl*'s thesis had been disproved. Phosphorus, or rather phosphoric acid, had been recognized for the first time as a specific substance.

Carl Wilhelm Scheele (1742–1786) and his assistant *J. G. Gahn* (1745–1818) then discovered, in spring 1770 although it did not become known until 1774, the composition of "animal earth", *i.e.* of bone ash, and thereby found a new starting material for the preparation of phosphorus, before *Antoine Laurent Lavoisier* (1743–1794) opened, with his many experiments on the combustion of phosphorus and sulfur in 1772, "the crucial year", as it is called by *Henry Guerlac* in a recent presentation of *Lavoisier*'s experiments in this year.

On November 1, 1772, *Lavoisier* deposited a short, sealed note in the Academy, which was opened in May of the following year and published. The text runs thus [79]:

"il y a environs huit jours que j'ay decouvert que le Souphre en brulant loin de perdre de Son poids (en brulant) en acquieroit au contraire; Cest a dire que d'une livre de Souphre on pouvoit retirer beacoup plus dune livre dacide vitriolique, abstraction faitte de l'humidité de l'air. il en est de meme du phosphore Cette augmentation de Poids vient dune quantite prodigieuse d'air qui Se fixe pendant la combustion et qui Se Comnine avec les vapeurs.

Cette decouverte que j'ay Constaté par des experiences que je regarde Comme decisives m'a fait penser (ce) que Ce qui Sobservoit dans la Combustion du Souphre et du phosphore pouvoit bien avoir lieu a l'egard de tous les Corps qui acquier rent du poids par la Combustion et la Calcination et je me

Suis persuade que laugmentation de poids (de l) des chaux metalliques tenoit a la meme Cause. experience a Complettement Confirme mes Conjectures ... Cette decouverte me paroit une des plus interessantes qui ait ete faitte depuis *Sthal* [*Stahl*] et Comme il est difficile de ne pas laisser entrevoir a Ses amis dans la Conservation quelque chose qui puisse les mettre Sur la voye de la verité j'ay Cru devoir faire le present depost entre les mains de M. le Secretaire de lacademie (pour) en attendant que je rende mes experiences publiques [*]."

Two further notices dating from an earlier period have recently been discovered [80], which deal primarily with investigations on phosphorus, one written on October 10, and the other on October 20, 1772 ('Memoire Sur lacide du Phosphore et Sur Ses Combinaisons avec differentes Substances Salines terreuses et métalliques'). The paper 'On the combustion of *Kunckel*'s phosphorus and the nature of the acid formed by this combustion', which was read on April 16, 1777, possesses as great a significance as a step along the path to the further development of *Lavoisier*'s theory of combustion, as does the 'treatise on a particular process for the conversion of phosphorus into phosphoric acid without combustion' from the year 1780.

Yet in none of these reports does *Lavoisier* speak out against the phlogiston theory. However, he contends that the theory assumes unproven facts and expresses the hope that he will soon be able to provide experimental proof that combustion and calcination can be explained without the need for the assumption of a special basic substance such as phlogiston [81].

[*] "About eight days ago I discovered that sulfur does not lose weight on combustion but rather gains weight; that is to say, much more than a pound of sulfuric acid is obtained from one pound of sulfur, after deduction has been made for the humidity of the air. It is the same with phosphorus. This increase in weight is due to a considerable amount of air which is fixed during the combustion and combines with the vapors.

I concluded from these facts, which I have determined from experiments that appear decisive to me, that which is observed on combustion of sulfur and phosphorus might well take place with all bodies which gain in weight on combustion or calcination, and I have become convinced that the increase in weight on calcination of metals is due to the same cause. The experiment completely confirmed my supposition ... This discovery seems to be one of the most interesting since *Sthal* [*i.e. Stahl*]: I therefore believe to have acquired the priority of the same in that I place this in the hands of the Secretary of the Academy, where it should remain secret until I publish my experiments".

[80] Cf. ref. [79], p. 223–227.

[81] *M. Speter*: Lavoisier und seine Vorläufer. Eine historisch-kritische Studie. F. Enke, Stuttgart 1910, p. 12ff. (Special edition from: Sammlung chemischer und chemisch-technischer Vorträge, Vol. 15, Numbers 4–6.)

At this time, *Lavoisier*'s theory that a component of the air was responsible for all combustion and calcination had too many weaknesses, which he also recognized himself, for anyone other than he to be able to follow it. It seems, however, that it was precisely the combustion experiments with phosphorus and sulfur that were decisive for *Lavoisier*. Yet it was not until the discovery of the composition of water by *Henry Cavendish* (1731–1810), which came to *Lavoisier*'s notice in June 1783, that the theory received welcome confirmation, and was then, in 1789, brilliantly developed in 'Traité élémentaire de Chimie'. Rapidly accepted in France, the theory soon won general recognition by the chemists of Europe.

On the basis of this "antiphlogistic" theory, phosphorus was relegated to a simple, undecomposable substance, a chemical element. Thus, in 1795, *Gehler*, who as short a time ago as 1790 had been a convinced supporter of the phlogiston theory and had made just brief mention of *Lavoisier*'s work on phosphorus as a recent theory [82], had no alternative but to begin his remarks on phosphorus in a supplement to his dictionary with the words [83]:

"The name phosphorus has become reserved almost exclusively for *Kunckel*'s phosphorus or urine phosphorus, particularly since the antiphlogistic theory has come to regard it as a simple substance and has adopted a large number of derivations from its name in the nomenclature" ... It "has become an uncommonly important object in recent chemistry. The phenomenon of its combustion in atmosphere or dephlogistated air provides the antiphlogistic system its most important support, and proves with undisputable certainty that the basic part of the breath of life combines with the burning body on combustion ..."

Thus it took more than one hundred years for the material discovered by the Hamburg Chymist *Hennig Brand* to become the chemical element phosphorus. However, the credit for the discovery remains his; for while it is true that a science develops by continually wrestling with new interpretations from that which it observes, this is only made possible by the existence of a foundation established in history; and that stone provided by *Brand* was by no means unimportant. We can hardly reproach him for not realizing that his contribution would later assume a significant place in this foundation.

α-(Formylamino)acrylic Esters from α-Metalated Isocyanoacetic Esters and Carbonyl Compounds[1]

By *U. Schöllkopf, F. Gerhart,* and *R. Schröder*[*]

The conversion of carbonyl compounds *(3)* into β-substituted α-(acylamino)acrylic acids is preparatively important because these acids can undergo a variety of changes[2], *e.g.* to α-amino and α-keto acids. Previously the carbonyl compounds were condensed with acylglycines, and the resulting azlactones were hydrolyzed (Erlenmeyer synthesis); however, this procedure requires forcing conditions and is limited to carbonyl compounds that cannot undergo an aldol condensation[2].

We have now found that good yields of ethyl α-(formylamino)acrylate *(9)* are obtained if α-metalated ethyl isocyanoacetate *(2)* [prepared from ethyl isocyanoacetate *(1)*[3] and, *e.g.*, butyllithium or sodium hydride] is allowed to react with aromatic or aliphatic aldehydes or ketones *(3)* (cf. Table).

M = Li, Na

Oxazoline anions *(5)* are presumably formed as intermediates by way of the carbonyl adducts *(4)*, and pass into the anions *(6)* by intra- or intermolecular proton transfer from C-4 to C-2[4]. The ions *(6)* are converted by electrocyclic ring fission into the "pentadienyl anions"[5] *(7)*, which can be isolated in the form *(9)* after acid hydrolysis. A batch with benzaldehyde as carbonyl component (and butyllithium as base) was hydrolyzed without addition of acid — it then yielded *N*-formyl-β-phenylserine ethyl ester. Since compounds *(9)* are inert to dilute alkali, we assume that an intermediate *(8)* whose double bond is hydrated in an alkaline medium must be formed between *(7)* and *(9)*.

R^1	R^2	*(9)*	Yields (%)
C_6H_5	H	Ethyl β-(formylamino)-cinnamate	74 [a], 69 [b], 28 [c]
CH_3	H	Ethyl 2-(formylamino)-crotonate	13 [a]
$CH(CH_3)_2$	H	Ethyl 2-(formylamino)-4-methyl-2-pentenoate	58 [a]
C_6H_5	CH_3	Ethyl α-(formylamino)-β-methyl-cinnamate	81 [a]
C_6H_5	CH_3	*tert.*-Butyl α-(formylamino)-β-methyl-cinnamate	82 [a, d]
CH_3	CH_3	Ethyl 2-(formylamino)-3-methyl-2-butenoate	77 [a]
$-(CH_2)_5-$		Ethyl β-cyclohexylidene-α-formylaminoacetate	87 [a]
C_6H_5	C_6H_5	Ethyl α-(formylamino)-β-phenylcinnamate	81 [a]

[a] With butyllithium in THF. [b] With sodium hydride in THF. [c] With sodium ethoxide in ethanol (*N*-formyl-β-phenylserine ethyl ester isolated as main product after working up by acid).
[d] Prepared by *P. Markusch* from *tert*-butyl isocyanoacetate.

Ethyl β-(formylamino)cinnamate (9), $R^1 = C_6H_5$, $R^2 = H$:

a) With butyllithium: 0.04 mole of butyllithium (as *ca.* 16 ml. of a 2.5 N solution in pentane) is dropped in *ca.* 30 min, with vigorous stirring, into a solution of ethyl isocyanoacetate (4.52 g, 0.04 mole) in THF (30 ml) whilst the temperature is kept below —70 °C and care is taken that the drops fall directly into the reaction mixture. A solution of benzaldehyde (4.24 g, 0.04 mole) in THF (20 ml) is added to the suspension of ethyl isocyanolithioacetate at —60 °C, the whole is allowed to come to room temperature, the solvent is removed in a vacuum, the residue is treated with a mixture of glacial acetic acid (3.6 g, 0.06 mole) and water (50 ml), and the product is extracted with ether, dried over magnesium sulfate, and worked up in the usual way. This product is chromatographed on silica gel, from which ether removes ethyl β-(formylamino)-cinnamate (6.5 g, 74%; mixed isomers, b.p. 156—158 °C/0.1 torr).

b) With sodium hydride: A mixture of ethyl isocyanoacetate (4.52 g, 0.04 mole), benzaldehyde (4.2 g, 0.4 mole), and THF (30 ml) is added dropwise to a suspension of sodium hydride (0.96 g, 0.04 mole) in THF (50 ml) at room temperature with vigorous stirring. After 3 hours' further stirring, the solvent is removed in a vacuum and the mixture is worked up as in (a), the yield being 69% (6.05 g).

[4] If there is no carbonyl group at position 4, the proton exchange does not take place; the anions of type *(5)* then fragment to olefins and metal cyanates; *U. Schöllkopf* and *F. Gerhart*, Angew. Chem. *80*, 842 (1968); Angew. Chem. internat. Edit. *7*, 10 (1968).

[5] Electrocyclic ring fission of anions has not yet been observed, but it has been shown by control experiments with oxazolines carrying an ethoxycarbonyl group at C-4 that anions of type (6) do suffer ring opening (*M. T. Reetz*, unpublished work).

Platinum(III) Bromide — a New Structural Type of AB_3 Compounds

By *G. Thiele* and *P. Woditsch*[*]

$PtBr_3$ *(1)* is formed on bromination of the metal in a closed system at 900 °C. In a temperature gradient of 900→300 °C compound *(1)* is transported to the colder zone where it

appears as blackish green needles having a metallic sheen. In the presence of an excess of bromine, bluish black needles of $PtBr_4$ *(2)* are also obtained; *(2)* forms rhombic crystals (a = 11.94, b = 14.47, c = 6.34 Å; space group Pbca-D_{2h}^{15}) of the PtI_4 type [1].

Compound *(1)* forms rhombohedral crystals of the space group $R\bar{3}$—C_{3i}^2. The lattice constants of the hexagonal unit cell are a = 22.32 ± 0.03, c = 9.024 ± 0.008 Å; Z = 36; $d_{X\text{-ray}}$ = 6.67 g cm^{-3}. The visually estimated intensities of 1033 reflections *hkl* from Weissenberg and precession photographs were considered in the structure determination; no correction was made for absorption. The structural model was calculated from three-dimensional Patterson syntheses and refinement of the atomic parameters with three-dimensional Fourier syntheses, as well as least-squares refinement with anisotropic temperature factors, to a reliability factor R = 0.096.

The atomic parameters are:

Pt^1:	0.007_0	0.093_6	0.158_1
Pt^3:	0.027_3	0.299_7	0.507_4
Br^{11}:	0.007_3	0.093_5	0.685_9
Br^{12}:	0.177_7	0.078_7	0.000_3
Br^{21}:	0.301_5	0.272_0	0.991_2
Br^{22}:	0.020_1	0.203_3	0.356_4
Br^{23}:	0.281_1	0.064_6	0.673_4
Br^{24}:	0.298_7	0.181_0	0.343_0

The structure of *(1)* contains Pt_6Br_{12} and $\frac{1}{\infty}[PtBr_2Br_{4/2}]$ units. The six Pt atoms of the Pt_6Br_{12} unit form an octahedron [Pt^1—Pt^1: 3.49 (4×) and 4.94 Å (1×)], the twelve Br atoms lying at the edges. In this arrangement, each Pt^1 has a square-planar environment (Pt^1—Br^{11} and Br^{12}: 2.447 ± 0.018 Å). This Pt_6Br_{12} group corresponds to that in the structures of $PtCl_2$ and $PtBr_2$ [2].

Pt^2 is surrounded octahedrally by Br[Pt—Br: 2.57, 2.52, 2.48, 2.47 (2×), and 2.44 Å]. Each octahedron is distorted and is linked to two others *via* common edges to form infinite chains, which run about the screw axes in $R\bar{3}$ along [001]. The two Br atoms that do not participate in linkage are *cis* to each other. This constructional pattern closely resembles that in the PtI_4 structural type [1].

The two structural units are bonded only loosely to each other. An additional Br from the $PtBr_6$ chain is situated above each $PtBr_4$ square plane [Pt^1—Br^{22}: 2.93 Å]; therefore there can only be weak electrostatic bonds in the crystals. Accordingly, the crystalline needles readily cleave into fibers along [001].

A structural principle with Pt^{II} and Pt^{IV} that can be unequivocally distinguished crystallographically has thus been detected by X-ray methods for the first time. Hitherto a structure $Pd^{II}Pd^{IV}F_6$ had been suspected on the basis of magnetic measurements on PdF_3 [3]. The absence of unpaired d electrons is understandable if dsp^2 and d^2sp^3 hybrid bonds are assumed on Pt^{II} and Pt^{IV}, respectively. Accordingly, the substance shows a weak, temperature-independent paramagnetism $\chi_m^{corr} = +280 \times 10^{-6}$ e.m.u.

Photo-oxygenation of 8-Cyanoheptafulvene

By *M. Oda* and *Y. Kitahara* [*]

In the course of our attempts on photochemical (8+8)π dimerization of heptafulvenes, we have found that 8-cyanoheptafulvene *(1)* [1] is subject to photo-sensitized oxygenation in the presence of oxygen.

When the compound *(1)* was irradiated in acetone with a 100 W high-pressure mercury lamp through a water cooled Pyrex filter under oxygen, it slowly absorbed one mole of oxygen to give an epidioxide *(2)* as colorless crystals (m.p. 41—45 °C) which detonates at 106 °C in a capillary tube. In the presence of a sensitizer (Rose Bengal) the reaction goes to completion within two hours (85% yield). With a 300 W tungsten lamp almost the same result was obtained (80.5% yield). Although the epidioxide *(2)* shows one spot on silica-gel thin layer chromatography, the NMR spectrum reveals it to be a mixture of two isomers. The IR spectrum of the mixture *(2)* shows bands at 3050, 2960, 2230, 1634, 1620, 1580, 1364, 972, 955, 933, 917, 896, 838, and 700 cm^{-1} and the UV spectrum shows a band at 254 nm, indicating the presence of α,β,γ,δ-unsaturated cyanide and epidioxy groups. The ^{1}H-NMR spectrum ($CDCl_3$; TMS, internal) exhibits signals at 7.02—6.09 (complex multiplet, 4H), 5.62 (double quartet, J = 7.1, 2.7, and 1 Hz, 0.5 H), 5.33 (doublet?, 1 H) and 5.15—4.77 ppm (multiplet, 1.5 H), which are reasonably explained as *ca.* 1:1 mixture of isomeric epidioxides, *(2a)* and *(2b)*.

Treatment of the mixture *(2)* with triethylamine in methylene chloride [2] at room temperature for a few minutes afforded 6-hydroxy-1-oxaazulane-2-imine *(4)* [3] in 90% yield, thus providing further supporting evidence for the structure of *(2)*. *(4)*: yellow fine needles, m.p. 179—80 °C decomp., IR

ν_{max}(KBr) 3240, 3070, 1658, 1555, 1465, 1323, 1270, 1206, 872, 859, and 800 cm^{-1}; UV λ_{max}(EtOH) 232 nm (log ε = 4.23), 285 (3.62), 301 (3.69), 338 (3.95), and 414 (3.90). The intermediates of this reaction should be 1,4-dihydroxy-8-cyanoheptafulvenes, *(3a)* and *(3b)*, which probably isomerize to each other through the tropone structures, *(3c)* or *(3d)*, particularly under basic conditions. The compound *(4)* can be formed by intramolecular cyclization of *(3a)*.

Dimeric 1,3,4,2-Oxadiaza-P^V-phospholes, Ten-Membered Tricyclic Compounds Containing Pentacoordinated Phosphorus as a Bridgehead Atom[1]

By *J. Ebeling* and *A. Schmidpeter*[*]

Acetohydrazide reacts with trichlorophosphoranes to eliminate 3 mol. equiv. of HCl. The reaction products (see Table), having the composition $C_2H_3N_2OPX_2$, are colorless crystals, readily soluble even in nonpolar solvents, and sublimable in vacuum. They are thermally stable and resistant to oxidation, such behavior ruling out their formulation as acetylphosphinodiimines but being in accord with cyclic phosphazenes isomeric to them; moreover, their molecular weights are found by osmometry and mass spectrometry to correspond to twice that of the empirical formula. Of the various structural isomers consistent with the above data, the nuclear magnetic resonance spectra provide unequivocal evidence in favor of formula *(1)*[2]: The large positive ^{31}P shift can be attributed only to pentacoordinated phosphorus, and the multiplet structure of the ^1H-NMR signal when X = CH_3 and $N(CH_3)_2$ can only be due to a $H_nPP'H_n$ spin system with proximate phosphorus atoms.

[d] Multiplet; $|J_{PCH} + J_{PNPCH}|$ is given as coupling constant for *(1b)*, and $|J_{PNCH} + J_{PNPNCH}|$ is given for *(1c)*.

[e] Solution in CCl_4 with 85% H_3PO_4 as external standard.

Compounds *(1)* should be regarded as products of phosphazene dimerization. Although dimerization of a phosphazene to the 1,3,2,4-diazadiphosphetidine ring is known in principle, the reaction has hitherto been limited to iminotrihalogenophosphoranes with strongly basic imino nitrogen carrying a not too bulky substituent[3]; phosphazines are known only as monomers. The dimerization of an oxadiaza-P^V-phosphole is therefore unexpected, at least when X = CH_3 and $N(CH_3)_2$, and would appear to be connected with the phosphorus becoming member of a small ring. For an oxadiazaphosphole an OPN angle of about 90° is required, which can be readily realized only with pentacoordinated phosphorus(v). Cyclophosphazenes having six or more members in the ring show no tendency to associate.

To satisfy the angle requirements, a phosphorus atom in *(1)* must participate in both the four-membered and the five-membered ring, with one axial and one equatorial bond of the trigonal bipyramid; the five-membered rings can be fused onto the longer (axial) or the shorter (equatorial) sides of the diazadiphosphetidine rectangle. If the two external rings are assumed to be in *trans* position, then two structures are possible for *(1)*, that with the electronegative oxygen in the axial position being the most likely[4]; it is confirmed for *(1b)* and *(1c)* by the equivalence of the methyl protons in the ^1H-NMR spectrum.

2,2,7,7-Tetrachloro-4,9-dimethyl-3,8-dioxa-1,5,6,10-tetraaza-2,7-diphospha-P^V-tricyclo[5.3.0.$0^{2,6}$]deca-4,9-diene (dimeric 2-dichloro-5-methyl-1,3,4,2-oxadiaza-P^V-phospole) (1a)

An intimate equimolar mixture of PCl_5 and acetohydrazide reacts exothermally with liberation of HCl and formation of a melt. Compound *(1a)* sublimes from the crude, glassy reaction product at 120 °C/0.1 torr in the form of needle-shaped crystals (yield 52%).

(1b) and (1c)

Trichlorophosphorane (0.1 mole) is added with stirring at 0 °C to a solution of acetohydrazide (0.1 mole) and triethylamine (0.3 mole) in benzene (120 ml). After the reaction mixture has been kept at 0 °C for 3 h and at 20 °C for 15 h, the triethylammonium chloride is filtered off and the filtrate is evaporated to dryness. *(1b)* can be sublimed at 130 °C/0.1 torr, and *(1c)* can be recrystallized from pentane (yield 80%).

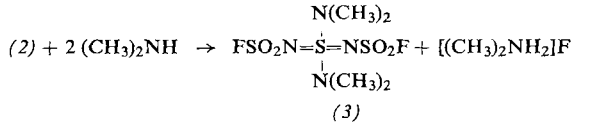
Bis(dimethylamido)bis(*N*-fluorosulfonylimido)-sulfur, a Covalent Compound Containing the SN_4 Group[1]

By *H. W. Roesky* and *D. P. Babb*[*]

During investigations on fluorosulfonyl compounds we succeeded in preparing for the first time a covalent sulfur-nitrogen compound whose sulfur atom is surrounded by four nitrogen atoms.

Bis(*N*-fluorosulfonylimido)sulfur difluoride[2] *(1)* reacts with dimethylamine in diethyl ether to give dimethylamidobis-(*N*-fluorosulfonylimido)sulfur fluoride *(2)*.

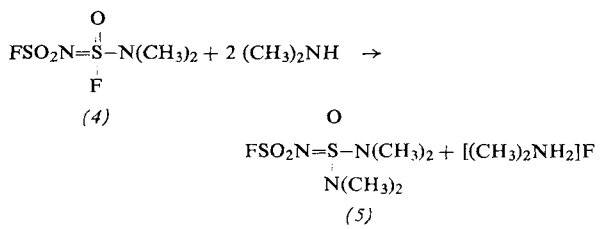


(1) *(2)*

Dimethylamine (6.8 g, 0.15 mole) is passed into a stirred solution of *(1)* (18.5 g, 0.07 mole) in diethyl ether (300 ml) at −78 °C during 1 h. The reaction mixture is then warmed to room temperature and the ethereal phase separated off. Removal of the ether under reduced pressure and subsequent distillation of the residue at oil-pump vacuum affords 6 g (20%) of *(2)*.

Compound *(2)* is a colorless liquid (b.p. 115 °C/0.01 torr) which was identified by elemental analysis and NMR spectroscopy. The ^{19}F-NMR spectrum recorded at room temperature shows a doublet due to the fluorine atoms of the FSO_2 groups, $\delta_{FSO_2} = -60.3$ ppm ($CFCl_3$ as external standard); $J_{FF} = 7.4$ Hz. The fluorine atom of the FSN_3 group gives rise to a multiplet of intensity ratio 1:6:17:32:46:52:46:32:17:6:1 by superposition of a triplet (FF coupling), which is split into three septets as a result of FH coupling. The intensity ratio $F_{SO_2}:F_{SN_3}$ is 2:1; $\delta_{FSN_3} = -58.4$ ppm. IR spectrum: ≈3300 w, ≈3400 w, 1410 s, 1240—1140 vs, 1100 s, 1045 m, 870—770 vs, 660 s cm^{-1}.

Compound *(2)* undergoes exothermic reaction with dimethylamine at room temperature in the absence of a solvent to give bis(dimethylamido)bis(*N*-fluorosulfonylimido)sulfur *(3)*.



(3)

An excess of dimethylamine is passed very slowly — in order to avoid overheating — into compound *(2)* (4 g) in a 100-ml two-necked flask. The reaction product is extracted portionwise with 100 ml of ether and the extract purified, after removal of the ether, by sublimation at oil-pump vacuum. Yield: 1.5 g (34%).

Compound *(3)* is a white solid, m.p. 123 °C, which was characterized by elemental analysis and by its ^{1}H- and ^{19}F-NMR spectra (solution in CD_3CN). ^{19}F-NMR spectrum: one singlet, $\delta_F = -58.7$ ppm ($CFCl_3$ as external standard). ^{1}H-NMR spectrum: one singlet at $\delta_H = -2.90$ ppm (TMS as external standard). IR spectrum: ≈3420 w, ≈2950 w, 1460 m, 1392 vs, 1278 m, 1206 vs, 1100 vs, 1055 m, 962 vs, 860 s, 800 s, 765 s, 740 vs, 662 m, 603 s, 548 vs, 502 w, 460 w cm^{-1}.

Dimethylamido-*N*-fluorosulfonylimidosulfur oxide fluoride[3] *(4)* reacts with dimethylamine at room temperature, in a manner similar to *(2)*, to give bis(dimethylamido)-*N*-fluorosulfonylimidosulfur oxide *(5)*. We found that 18 g of *(4)* gives 8.3 g (41%) of *(5)*.

(4) *(5)*

Compound *(5)* is a colorless solid, m.p. 35 °C, b.p. 116 to 124 °C/0.01 torr. ^{1}H-NMR spectrum: one singlet, $\delta_H = -2.99$ ppm (TMS as external standard). ^{19}F-NMR: one singlet at $\delta_F = -58.5$ ppm ($CFCl_3$ as external standard). Elemental analysis confirmed the composition of the compound. IR spectrum: ≈2950 s, 1470 s, 1380 vs, 1270 vs, 1190 vs, 1090 vs, 1040 s, 960—940 vs, 825 vs, 765 vs, 734 vs, 678 vs, 602 s, 547 vs cm^{-1}.

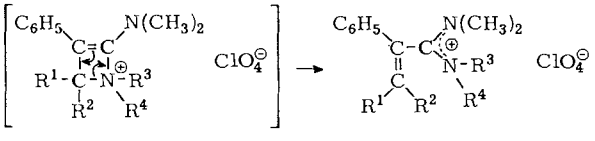
Reactions of Ynamines with Iminium Salts[1]



By *R. Fuks, G. S. D. King,* and *H. G. Viehe*[*]

Ynamines are highly reactive nucleophilic acetylenes[2], which readily undergo cycloadditions with carbonyl compounds[3], imines[3,4], and other isolated[5–9], conjugated, or cumulated multiple bond systems[4,9–12]. In this communication we describe the condensation of ynamines with iminium salts.

N,N-Dimethylphenylethynylamine *(1a)* reacts readily at room temperature in chloroform solution with aliphatic iminium salts *(2a)—(2e)* apparently *via* the cyclic intermediate *(3)* to give acrylamidinium perchlorates *(4a)—(4e)*; in the case of *(2c)—(2e)* this is noteworthy since it represents a C_2-ring expansion.

(1a) *(2)*

(3) *(4)*

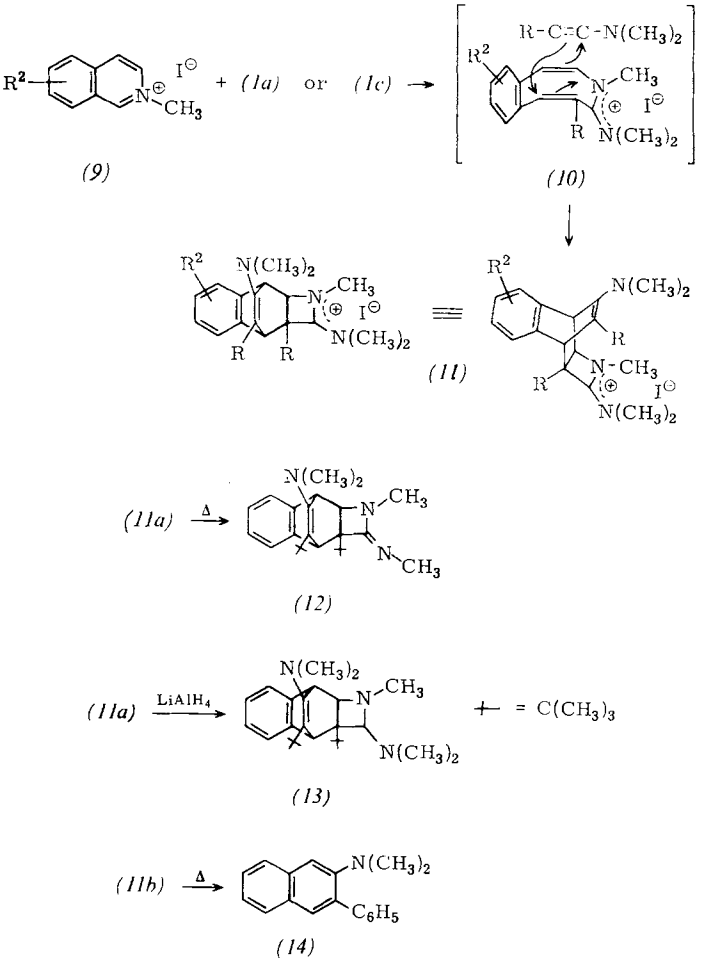
	(4) Yield (%)	M.p. (°C)
(a), $R^1 = R^2 = R^3 = R^4 = CH_3$	60	114
(b), $R^1 = R^2 = R^3 = CH_3$; $R^4 = C_6H_5$	97	208
(c), $R^1 = CH_3$; $R^2 = C_6H_5$; $R^3R^4 = -(CH_2)_4-$	72	172
(d), $R^1R^2 = -(CH_2)_5-$; $R^3R^4 = -(CH_2)_4-$	93	155
(e), $R^1 = R^3 = CH_3$; $R^2R^4 = -(CH_2)_3-$	83	116

The analytical and spectral data (UV, IR and NMR) confirm the proposed structure *(4)*. Hydrolysis of *(4a)* with 30% aqueous NaOH affords β,β,*N,N*-tetramethyl-α-phenylacrylamide in 84% yield. Melting point and mixed melting point (56 °C) are identical with that of the product obtained from *(1a)* and acetone[3].

Heteroaromatic iminium salts also condense easily with ynamines in chloroform at room temperature. Thus, with *N*-methylquinolinium iodide for example, compound *(1)* gives 4-amino-*N*-methylquinolinium iodide derivatives *(7)* possibly *via* intermediate *(6)*, which then loses an unidentified C_2-

unit. Upon hydrolysis in 10% aqueous NaOH compounds *(7)* give 3-substituted *N*-methyl-4-quinolones *(8)*.

The ynamines *(1a)* and *(1c)* react with *N*-methylisoquinolinium iodide derivatives *(9)* to give 2:1 adducts. In the case of *(1c)* and *(9)*, R^2 = H, the structure of the adduct was shown by X-ray analysis to be 2a,10-di-*tert*-butyl-2,9-bis-(dimethylamino)-1-methyl-2a,3,8,8a-tetrahydro-3,8-ethenonaphtho[2,3-*b*]-1-azetinium iodide *(11a)*. *(11a)* crystallizes in two monoclinic forms (C_{2h}^5) having 4 or 8 molecules in the unit cell. At the present stage the discrepancy factor is 0.22. The reaction leading to *(11)* might involve the intermediate *(10)*.



(1) *(5)* *(6)* *(7)* *(8)*

	(7)		*(8)*		
	Yield (%)	M.p. (°C)	Yield (%)	M.p. (°C)	
(a), R = C_6H_5; R^1 = CH_3	45	209	92	126	[13]
(b), R = C_6H_5; R^1 = C_2H_5	50	200	90	126	[13]
(c), R = $C(CH_3)_3$; R^1 = CH_3	75	283	95	132	

(11a) is remarkably stable; it remains unchanged on boiling for several hours in 10% aqueous NaOH or in 6 N HCl in spite of its enamine function. By pyrolysis at 240–270 °C it loses CH_3I with formation of *(12)* in 97% yield, which on treatment with CH_3I reverts to *(11a)*. The amidinium function can be reduced by $LiAlH_4$ to the aminal *(13)*. The analogous product *(11b)* decomposes at 200–240 °C to give 2-dimethylamino-3-phenylnaphthalene *(14)* in 68% yield.

General experimental procedure (in collaboration with *M. A. Hartemink*).

The solid iminium salt is added in small portions to a stirred and ice-cooled chloroform solution of the ynamine (15 ml for 2 mmoles, 10% excess of the stoichiometric quantity). The mixture is kept at room temperature for half an hour after which the solvent is distilled off. The residue is crystallized from chloroform, methanol, or mixed solvents such as

A Convenient Synthesis of Disulfides[1]

By *H. Alper* [*]

Pentacarbonyliron is a useful reagent for the preparation of *S*-alkyl(aryl)thiosulfonates $RSSO_2R$ from sulfonyl chlorides RSO_2Cl[2]. Reaction of sulfonyl chlorides *(1)* with hexacarbonylmolybdenum in anhydrous tetramethylurea (TMU) provides a facile method for obtaining a variety of disulfides *(2)*.

$$\underset{(1)}{RSO_2Cl} \xrightarrow{Mo(CO)_6 \text{ in TMU}} \underset{(2)}{RSSR}$$

The procedure involved is simple and rapid, giving disulfides in good yields. The metal carbonyl does not function as a catalyst and addition of boron trifluoride etherate does not improve the yield[2].

Sulfonyl Chloride	Yield of Disulfide (%)
Benzene	74
2-Naphthalene	68
p-Bromobenzene	55
p-Toluene	80
Methane	68
α-Toluene	60
n-Hexadecane	75

Hexacarbonyl-chromium and -tungsten proved to be relatively ineffective reagents for the reaction. For example, treatment of *p*-toluenesulfonyl chloride with hexacarbonylchromium under identical conditions to those described for $Mo(CO)_6$ (general procedure) gave recovered starting material. Di-*p*-tolyl disulfide was obtained in only 26% yield, along with 2% of the corresponding *S*-thiolsulfonate, even after heating at 85 °C for 12 hours.

General Procedure

A mixture of RSO_2Cl (5—35 mmol) and hexacarbonylmolybdenum, molar ratio 1:1.1 to 1.3 (use of a large excess of $Mo(CO)_6$ should be avoided as disulfides react with the metal carbonyl to form polymeric molybdenum sulfides[3]) in dry TMU (10—25 ml) was heated to 70 °C (oil bath temperature) with stirring under nitrogen for 2.0—2.5 hours. The suspended $Mo(CO)_6$ gradually dissolved. The reaction mixture was then heated to 100 °C for 10—15 minutes, cooled and filtered to remove any unreacted metal carbonyl. The filtrate was added to 20 volumes of water and the resulting precipitate (if the disulfide is a solid) was filtered, washed thoroughly with water, and sucked dry. Pure disulfide could then be obtained by recrystallization from a suitable solvent. Liquid disulfides, *e.g.* CH_3SSCH_3, were isolated by distillation of the reaction mixture.

Bis(pentadienyl)dinickel

By *R. Rienäcker* and *H. Yoshiura* [*]

A suspension of anhydrous nickel(II) chloride in 1,4-pentadiene reacts with triethylaluminum at room temperature with evolution of non-stoichiometric amounts of ethylene and precipitation of bis(pentadienyl)dinickel *(1)* in the form of golden-yellow crystals (75.6% yield). Under similar conditions, suspensions of $NiCl_2$ in ether, benzene, or pentane are reduced to metallic nickel by $Al(C_2H_5)_3$.

The novel complex *(1)*, recrystallized from anhydrous pentane (1 g/l), is sparingly soluble in aprotic solvents and is extremely sensitive to air. Its composition is established by nickel analysis (calculated 46.55, found 46.0%), the mass spectrum [molecular ion *m/e* 250/252 and 254 ($Ni_2C_{10}H_{14}$), main fragments *m/e* 67 (C_5H_7) and 58/60 (Ni)], and X-ray structure analysis[1]. The IR spectrum provides no indication of free double bonds but contains a band that is typical for π-allyl compounds at 1480 cm^{-1} thus showing a certain analogy to the spectrum of bis(pentadienyl)chromium[2], which, however, contains only one metal atom bonded to two pentadienyl moeities. Protonolysis of *(1)* with 2-ethyl-1-hexanol affords small amounts of 1,3-pentadiene and C_{10} hydrocarbons in addition to 1-pentene, *cis*-2-pentene, and *trans*-2-pentene in the molar ratio 3:2:14.

Reaction of *(1)* with triphenylphosphine proceeds almost quantitatively to give 1,3,7,9-decatetraene and tetrakis(triphenylphosphine)nickel; the pentadienyl ligands are linked on displacement.

The reaction involved in formation of *(1)* is clearly of a complex nature: 1,4-Pentadiene loses hydrogen on conversion into pentadienyl; this hydrogen reacts with the excess of 1,4-pentadiene to give pentene. In the organoaluminum component, ethyl groups are replaced by C_5 groups with liberation of ethylene; these C_5 groups are found as pentene and pentane on hydrolysis of the mother liquor. The reaction presumably proceeds *via* nickel hydrides[3]. To summarize, we can formulate the following formation reaction:

$$2\,NiCl_2 + 5\,C_5H_8 + 4\,Al(C_2H_5)_3 \rightarrow \underset{(1)}{Ni_2(C_5H_7)_2} + 4\,AlCl(C_2H_5)_2 + 4\,C_2H_4 + 3\,C_5H_{10}$$

Crystal Structure of Bis(pentadienyl)dinickel

By *C. Krüger* [*]

Bis(pentadienyl)dinickel [1] crystallizes as monoclinic prisms along { 001 } in space group $P2_1/n$ according to Weissenberg and precession photographs. The unit cell contains two centro-symmetric molecules, the calculated density being 1.804 g cm^{-3}.

The structure was determined with an automatic Hoppe-Siemens diffractometer ($Cu_{K\alpha}$ radiation, $\lambda = 1.5418$). Accurate cell constants were calculated by the method of least squares from 44 recorded reflections $\theta > 50°$: $a = 12.731 \pm 0.0004$, $b = 8.591 \pm 0.0003$, $c = 4.233 \pm 0.0004$ Å; $\beta = 90.525 \pm 0.005°$. The intensities of 879 reflections (hkl—$\bar{h}kl$) $\theta < 70°$ of a crystal measuring 0.13 mm × 0.37 mm × 0.69 mm were recorded by the 5-value method, a FORTRAN (IV) program (DIFFRA) having been developed for control of the diffractometer; three reflections were below the detection limit After corrections had been made for Lorentz, polarization, and absorption factors, the structure was determined by the Patterson heavy-atom method followed by least-squares refinement. The atomic positions and anisotropic temperature parameters given in the Table were found at a weighted R factor ($F_0^2/4W_0$) of 0.056 taking into account the hydrogen atoms found in a difference Fourier synthesis [2].

The most important interatomic distances and bond angles of the dimeric molecule symmetry C_{2h} are shown in Fig. 1 [2]; maximum errors ±0.006 Å and ±0.4°, respectively. A unit cell of the crystal is reproduced in Fig. 2.

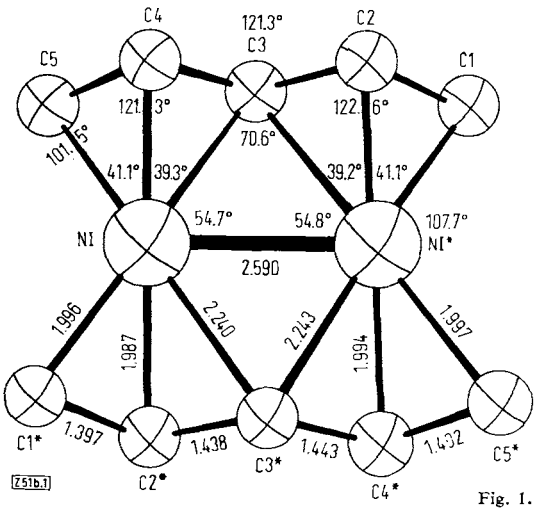

Fig. 1.

The best plane of the sp^2-hybridized carbon chain is described by the equation

$$6.034x + 4.723y - 2.930z - 2.298 = 0$$

C^3 protrudes from the plane C^1—C^2, C^4—C^5 by 0.23 Å. The terminal C—C bonds of the asymmetric π-allyl systems show more double bond character than the bonds C^2—C^3 and C^3—C^4. A typical three-center bond is possible between C^3 and the Ni atoms, which are separated by a bonding distance of 2.540 ± 0.001 Å; the experimental data are consistent with formulation *(1)*, the bonding shown being feasible *via* the geometrically favorable occupied molecular orbitals ψ_1, ψ_2, and ψ_3 of pentadienyl and the d orbitals of the nickel.

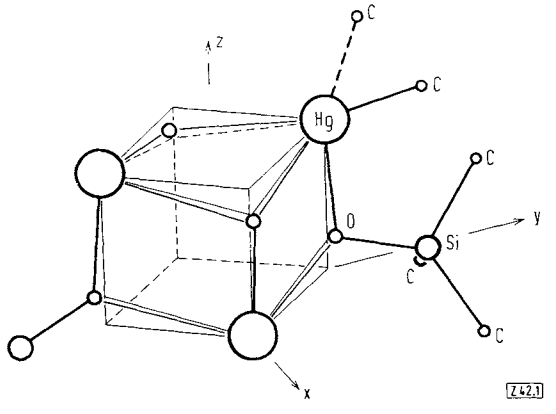
Crystal Structure of Methyltrimethylsiloxomercury



By *G. Dittmar* and *E. Hellner*[*]

$CH_3HgOSi(CH_3)_3$ *(1)* is monomeric in benzene[2] whereas the analogous compounds of zinc and cadmium are present as tetramers in this solvent[1]. A cubane structure has been proposed for $[CH_3MOSi(CH_3)_3]_4$, M = Zn, Cd. Crystal structure analysis also indicates that *(1)* has a cubane-like structure. All these compounds are sensitive to air, moisture, and X-rays.

Crystals of *(1)* were fused in glass capillaries and the intensities of 280 reflections were estimated visually from Weissenberg photographs; an absorption correction could not be carried out. The tetragonal unit cell, space group $P4_2/nmc$ with $a_0 = 13.190 \pm 0.002$, $b_0 = 13.190 \pm 0.002$, $c_0 = 9.798 \pm 0.005$ Å contains eight formula units. $d_{X\text{-ray}} = 2.37$, $d_{exp} = 2.21$ g cm^{-3}.

The structure was determined by the heavy atom method with the help of a Patterson synthesis, four Fourier syntheses, and eighteen refinements according to the method of least squares. An *R*-value of 0.250 was obtained on using individual anisotropic temperature factors with inclusion of unobserved intensities (0.209 for observed intensities alone).

The Hg atoms form a regular tetrahedron about the $\bar{4}$-axis with Hg—Hg distances of 3.71 Å; the O atoms form a distorted tetrahedron in opposing orientation, the Hg—O bond length being 2.11 Å. From the considerable anisotropic temperatures factors observed for the O atom in the Hg—O bond parallel to the *c*-axis it follows that the structure represents a transition from an assemblage of four individual molecules *(1)* about the $\bar{4}$-axis to the ideal cubane structure.

Z 42.1

Atomic coordinates:

Atom	Hg	Si	O	$C^{1,1}$	$C^{1,2}$	$1/2C^2$
x	0.2500	0.250	0.250	0.25	0.37 ± 1	0.38 ± 2
y	0.3899 ± 4	0.510 ± 3	0.389 ± 8	0.61 ± 2	0.54 ± 2	0.47 ± 3
z	0.3848 ± 8	0.110 ± 8	0.170 ± 24	0.25 ± 3	0.01 ± 1	0.46 ± 4

Crystal structure of methyltrimethylsiloxomercury.

Bond lengths and angles (Å)		(°)	
Hg—O	2.11 ± 0.2	O—Hg—C	112 ± 8
Hg—C	2.09 ± 0.4	Hg—O—Si	115 ± 6
Si—O	1.61 ± 0.1	C—Si—C	105 ± 7

O—O	3.90 ± 0.20	O—O—O	76 ± 6
	3.14 ± 0.42	Hg—O—Hg	99 ± 6
Hg—O	2.75 ± 0.20	O—Hg—O	81 ± 6
			91 ± 3

The Si—O bond is directed towards the center of the Hg tetrahedron.

Two methyl groups are situated in the mirror plane of the space group parallel to *y*; these are linked to Hg or Si atoms. Weak reflections of the *hhl* group with $l = 2n-1$ indicate that the CH_3 group attached to Hg does not lie exactly in the plane of symmetry. A Fourier synthesis and intensity calculation on the subcell $P4_2/n$ gives two positions for these CH_3 groups, which are symmetric to the mirror plane and are statistically occupied.

Complexing Behavior of Stannanide Ions: Tetrakis(trichlorostannanido)niccolate(0)[1]

By *Th. Kruck* and *B. Herber*[*]

Not only silanide ions $[SiR_3]^-$ (R = alkyl and aryl)[1] but also the homologous stannanide ions $[SnR_3]^-$ (R = aryl, halogen) have a strong tendency to form complexes with transition metals in low oxidation states. This can be illustrated by reaction of triphenylstannanide $[Sn(C_6H_5)_3]^-$ *(1)* and trichlorostannanide $[SnCl_3]^-$ *(2)* with metal carbonyls.

$Fe(CO)_5$ and $Ni(CO)_4$ react violently with the lithium salt[2] of *(1)* (molar ratio 1.5 : 1) in diethyl ether/tetrahydrofuran (THF) to give the monosubstituted carbonyl metalates *(3)* in almost quantitative yield according to the formulation:

$$M(CO)_n + Li[Sn(C_6H_5)_3] \xrightarrow{THF} [Li(THF)_x]^+[M(CO)_{n-1}Sn(C_6H_5)_3]^- + CO$$

(3)

They can be isolated as solvated lithium salts and in the form of complex salts $[As(C_6H_5)_4][Fe(CO)_4Sn(C_6H_5)_3]$ (yellowish green crystals, $\nu_{CO} = 2001$ (A_1), 1923 (A_1), 1897 (E_1), and 1877 (E_1) cm^{-1}; suspension in Nujol) and $[N(C_2H_5)_4][Ni(CO)_3Sn(C_6H_5)_3]$ (bronze colored leaflets, $\nu_{CO} = 2001$ (A_1) and 1962 (E) cm^{-1}; solution in dimethyl sulfoxide (DMSO)) that are stable towards heat and air.

Further CO substitution was not possible because of the considerable strengthening of the metal-CO bond on formation of the monosubstituted complex. Octacarbonyldicobalt reacts with the potassium salt of *(2)* (molar ratio 1 : 2) mainly *via* disproportionation of the metal carbonyl ($2\,Co^0 \rightarrow Co^I + Co^{-I}$) to give the red neutral complex *(4)* according to the equation:

$$Co_2(CO)_8 + K[SnCl_3] \xrightarrow[THF]{-40 \text{ to } 40\,^\circ C} CoI(CO)_4SnCl_3 + K[Co^{-I}(CO)_4]$$

(4)

Compound *(4)*, which is stable towards air, reacts with $[N(C_2H_5)_4][SnCl_3]$ in DMSO/THF (molar ratio 1 : 1) at 40 °C to give the olive-green crystalline complex $[N(C_2H_5)_4][Co^I(CO)_3(SnCl_3)_2]$ in *ca.* 35% yield.

Although the anionic ligands $[ElR_3]^-$ (El = Si, Sn; R = alkyl or aryl) are stronger donors compared to the isoelectronic neutral phosphines PR_3 and stibines SbR_3, $[SnCl_3]^-$ has a reduced donor character because of the electronegative Cl atoms. In the reaction with tetracarbonylnickel a distinct analogy is recognizable between PCl_3 and *(2)* so far as possibility of complex formation is concerned. Reaction of

tetracarbonylnickel with $K[SnCl_3]$ (molar ratio 1 : 4) over a period of two days and with UV irradiation leads to total loss of CO and formation of the isolable but impure potassium salt of tetrakis(trichlorostannanido)niccolate(0) *(5)*.

$$Ni(CO)_4 + 4\,K[SnCl_3] \xrightarrow[THF]{20\,^\circ C} K_4[Ni(SnCl_3)_4] \cdot x\,THF + 4CO$$
(5)

Compound *(5)* is the first homogeneous complex obtained that contains a ligand whose donor atom is an element of the fourth main group other than carbon.

The existence of the totally substituted complex anion was established by its conversion into the solvated acid *(6)* and into easily identifiable complex salts. On introducing hydrogen chloride into a THF solution of *(5)* the solution becomes hot, KCl separates out, and a bright yellow, pungent oil of low viscosity is formed. This oily compound contains acidic protons whose NMR signal appears at 8.75 ppm (referred to TMS)[3]. The characteristic Sn—Cl stretching vibrations of *(2)* appear in the IR spectrum at 295 (A_1) and 256 (E) cm^{-1}; no ν_{CO} bands appear[3]. Not THF, but its fission product with HCl, 4-chlorobutanol, functions as solvating agent for the protons; the isolated acid has the constitution $H_4[Ni(SnCl_3)_4] \cdot 4\,Cl(CH_2)_4OH$ *(6)* (this composition could also be established analytically). This compound, which is readily soluble in THF and in acetone, rapidly decomposes in air and on warming loses HCl; it is stable almost indefinitely under nitrogen. By reaction of a THF solution of *(5)* with aqueous solutions of bulky cations we have been able to prepare, *inter alia*, the complex salts $[As(C_6H_5)_4]_4[Ni(SnCl_3)_4]$ (beige crystals, decomposing at temperatures above 190 °C; ν_{SnCl} = 301 (A_1) and 242 (E) cm^{-1}) and $[Cr(C_6H_6)_2]_4[Ni(SnCl_3)_4]$ (orange crystals decomposing at temperatures above 190 °C) after reprecipitation from THF/pentane. Further proof for the composition of the acid *(6)* was afforded by reacting it in acetonitrile/THF with $[Cr(C_6H_6)_2]I$ — crystals (orange leaflets) were obtained, which, on the basis of elemental analysis and the IR spectrum, proved to be indentical with $[Cr(C_6H_6)_2]_4[Ni(SnCl_3)_4]$ prepared from the potassium salt *(5)*.

Preparation of Benzene by Pyrolysis of *cis*- and *trans*-1,3-Hexadien-5-yne

By *H. Hopf* and *H. Musso* [*]

Photoisomerizations of benzene, and a few of its derivatives, leading to polycyclic hydrocarbons have been known for some time[1]. Under certain conditions such photolyses can also lead to the formation of acyclic hydrocarbons. Thus, when benzene vapor is irradiated with light of wavelength 1849 Å it is first converted into fulvene and *cis*-1,3-hexadien-5-yne *(2)*; by a secondary reaction *(2)* is then converted into the *trans*-isomer *(1)*. With light of wavelength 2537 Å, a rapid *cis-trans* isomerization of *(1)* and *(2)* takes place in the gas phase, as well as a slow conversion of these compounds into benzene and fulvene[2].

Since excitation of unsaturated hydrocarbons may be achieved either photochemically or thermally[3]; we have investigated the pyrolysis of the hexadienynes *(1)* and *(2)*.

Gas-chromatographically pure samples of *(1)* and *(2)*[4] are stable in the gas phase (35—70 torr) up to temperatures of at least 224 ± 1 °C. At 274 ± 1 °C, however, both compounds undergo simultaneous *cis-trans* isomerization and are converted into benzene.

(1) *(2)* *(3)*

A mixture of 64 % *(1)*, 11 % *(2)*, and 25 % *(3)* as well as small amounts of polymeric material are obtained if *(1)* is heated for 90 min at 274 °C. Similarly, a mixture consisting of 9 % *(1)*, 55 % *(2)*, and 36 % *(3)* is obtained from *(2)* (determined chromatographically by triangulation: 50 m Golay column, polypropylene glycol, 30 °C; relative retention times *(1)* 1.00, *(2)* 0.91, and *(3)* 0.73).

Since, for steric reasons, it is unlikely that *(1)* is converted directly into *(3)*, it is assumed that an isomerization of *(1)* to *(2)* takes place first in the formation of *(3)* from *(1)*. On a preparative scale[5], compound *(3)* may be prepared in 50 % yield by pyrolyzing *(2)* (0.6 g) at 510 °C in a stream of nitrogen, the gas mixture being allowed to remain for 45 s in a tube filled with Raschig rings. Under these conditions *ca.* 20 % of a high-boiling mixture containing a least 15 components is also obtained; two of these components have been identified gas-chromatographically as styrene and naphthalene.

Further investigation ought to show — as is to be expected from the by-products — whether a radical reaction and the last step of the Berthelot benzene synthesis are involved here[6].

The Physics of Liquids

Following the Faraday Society colloquium in April 1967 on the properties of liquids[1] and the International Center for Theoretical Physics course[2] on the theory of condensed matter in the autumn of 1967, The Institute of Physics and The Physical Society organized a conference on the physics of liquids, which took place in Norwich (England) on April 15—18, 1969. This series of events and the numerous recently published monographs[3] on liquids reflect the current strong interest in problems connected with the liquid state.

At present the development seems to be mainly in the direction of fluid dynamics, *i.e.* in investigations of the molecular motions within a fluid. This formed the subject of five out of seven plenary lectures at the conference. In this connection, the main interest centered on two themes:

1) Inelastic scattering experiments with slow neutrons.

2) Computer calculations (using the methods of molecular dynamics) on systems with specified intermolecular forces. In the discussion of the equilibrium properties of liquids, the main emphasis was experimentally on X-ray and neutron scattering, and theoretically on computer calculations (by Monte Carlo and molecular dynamic methods) and on a newly developed perturbation method[4] which considers the perturbing influence of an intermolecular potential on a model assembly of hard spheres (calculated by the Percus-Yevick method or by molecular dynamics).

The lecture by *B. Widom* of Cornell University, Ithaca, N. Y., USA, presently at Imperial College in London, dealt with generalization of the van der Waals equation of state. The thermodynamic consequences when small particles in a model system (*e.g.* point masses or rigid spheres) are embedded in a uniform negative potential were investigated. Previously[5] it had been found that the addition of a uniform negative potential to a computer-calculated system of hard spheres allows the melting process to be simulated. The uniform negative potential is expressed as a function of the density and temperature, from which changes of activity and energy density with respect to the model system are derived. A differential equation for the background potential can be derived from thermodynamic relationships, which establishes a connection between its dependence on density and its dependence on temperature.

The case in which the background potential is independent of temperature and proportional to the density was discussed more thoroughly. This leads to corrections for pressure and energy density corresponding to those of the van der Waals equation: the pressure and energy density of the model fluid should in each case be reduced by a term proportional to the square of the density. A considerable correction for compressibility with respect to the model fluid is also obtained. This, however, gives rise to a principal difficulty: since the background potential is supposed to be uniform, it exerts no force on the molecules. The molecular arrangement should therefore be identical with that of the model system. Since, however, the radial distribution function which describes the arrangement of the molecules is directly related to the compressibility by the so-called compressibility equation, the same molecular arrangements should lead to the same compressibility. *Widom* tried to solve this difficulty by taking into account the effect of fluctuations of the background potential for large molecular distances. Such fluctuations could have a considerable influence on the compressibility without disturbing either the molecular arrangement over smaller distances or the thermodynamic considerations.

It was pointed out in the discussion that the structure factors of many substances, as indicated by neutron and X-ray scattering, differ considerably from that of a model system consisting of hard spheres. It appears that the concept of a fluid as a system of hard spheres under a uniform potential is in many cases a gross simplification.

J. E. Enderby [Battelle Institute, Columbus, Ohio (USA)] spoke about structural investigations by neutron diffraction. While formerly the sources of error in these investigations were not fully understood, and the results were therefore often in error or their accuracy was overestimated, recent developments are marked by an improvement in the method and at the same time by a realistic estimate of the uncertainties. The results of neutron scattering experiments now agree satisfactorily with those gained from X-ray diffraction investigations.

After a discussion of the calculation of radial distribution functions and direct correlation functions from the structure factor $S(Q)$, *Enderby* described some results on systems which contain only one atomic species: the position of the first maximum of the structure factor for lead does not vary with temperature; the structure factor for zinc differs considerably from that of a model fluid consisting of hard spheres. If one can calculate the radial distribution function, and thence the structure factor, from a knowledge of pair interaction energies and statistical theory, it is also possible to draw conclusions about pair interaction energies using the experimentally determined structure factor and statistical theory. If the Percus-Yevick method is used as statistical theory, one obtains for metals a pseudo-pair potential which shows a shallow minimum at the nearest-neighbor distance and a broad positive peak for larger atomic distances. The usual oscillations of the pseudo-pair potential are not reproduced, possibly owing to failure of the Percus-Yevick method.

For systems containing two kinds of atoms, the total scattering cross-section is made up of structure factors related to the radial distribution functions for atoms of the same kind or of different kinds. By using different isotopes having different scattering length for neutrons, it is possible to analyze the total scattering cross section into these individual structure factors. Without such an analysis a misleading picture would be obtained for the molecular distribution function. Analyses of this kind are of particular importance in the investigation of liquid alloys, molecular fluids (carbon tetrachloride), and ionic melts.

The lectures by *P. Schofield*, Harwell (England), and *P. A. Egelstaff*, Harwell (England), dealt with the problems of inelastic neutron scattering.

P. Schofield began his lecture with a review of the formalism used to describe fluid dynamics. The scattering function $S(Q, \omega)$ plays a central role, as it gives the relative frequency of the scattered particles which simultaneously transfer energy $\hbar\omega$ and momentum $\hbar Q$ to the fluid. It is necessary to distinguish between an incoherent scattering function $S_s(Q,\omega)$ and a coherent scattering function $S(Q, \omega)$. The former yields information about the individual movement of atoms and the latter about the correlated movement of many atoms. Starting from $S_s(Q, \omega)$ the velocity autocorrelation function $< v(0)v(t) >$ [*] and the frequency spectrum $\tilde{z}(\omega)$ [**] can be calculated.

The unified theoretical interpretation of the modes of motion of single particles and of the cooperative modes of motion is still an unsolved problem, and a number of models have therefore been developed. Some of the findings strongly resemble those for polycrystalline materials. The best model so far has proved to be one constructed on the basis of a viscoelastic continuum to which is added an adjustable attenuation function, which depends on momentum Q and energy transfer ω.

Egelstaff discussed the experimental results obtained for the coherent inelastic scattering function $S(Q, \omega)$ in relation to models in three ranges of momentum transfer: for small momentum transfers Q, at the maximum of the structure factor $S(Q)$, and for large momentum transfers. For small momentum transfers the characteristic quantity is the position of the subsidiary maxima in the scattered neutron energy distribution [$S(Q, \omega)$ against ω]. At the maximum of the structure factor a detailed investigation of the scattering function at constant energy transfer is of interest. The scattering function $S(Q, \omega)$ for $\omega = 0$ shows a sharper maximum *versus* Q than the structural factor $S(Q)$, while $S(Q, \omega)$ for large constant values of ω shows a minimum for the same values of Q. Finally, for large momentum transfers investigation of the half widths of the energy distribution is necessary. The structure factor, the scattering function for constant energy transfer, as well as the half width all show several maxima and minima as a function of the momentum transfer Q, but the extreme values of these functions do not occur at the same values of Q as one would expect on the basis of the theoretical models.

S. J. Cocking [Harwell (England) at present KFA Jülich] gave the results on inelastic scattering of slow neutrons in liquid lithium and liquid sodium [6]. The main point of the investigation lay in the incoherent scattering at small momentum transfers. From the incoherent scattering function $S_s(Q, \omega)$ the mean square of the distance over which the atoms move in time t was calculated, and from this the frequency spectrum of the liquid was derived. The diffusion model proposed by *Egelstaff* and *Schofield* was used to evaluate the results. The frequency spectrum of sodium thus calculated differs substantially from that given by earlier calculations, which are quoted in *Egelstaff*'s book [3a], and shows a broad maximum for small frequencies and a sharp maximum near the limiting frequency.

The lectures of *A. Rahman* [Institute for Theoretical Studies, Utrecht (Netherlands)] [7] and *L. Verlet* [Université de Paris, Laboratoire de Physique Theorique, Orsay (France)] were devoted to molecular-dynamics calculations. Most of these calculations were carried out on argon using a Lennard-Jones potential; other calculations were carried out with oscillating pseudo-pair potentials of metals or with a Coulomb potential for the electrons in a plasma. The number of particles used for these calculations was usually 864. Thus for argon the mean square of the distance traveled by an atom was calculated as a function of the time interval. The most interesting interval lies between 0.5×10^{-12} and 10×10^{-12} sec, in which time the transition from gas like to macroscopic behavior takes place. The second derivative of this quantity gives the velocity-autocorrelation function, which for high densities shows a weak maximum after the first fall, and then a second minimum before its value approximates to zero. The secondary maximum in the velocity-autocorrelation function only disappears at densities which roughly correspond to the critical density. Concepts in the theory of Brownian movement, such as friction constants, can also be checked by molecular dynamics calculations. Pair distribution functions and structure factors can be calculated directly. The extrapolation of the structure factor $S(Q)$ to $S(0)$ agrees to within 10—15% with the experimentally measured compressibilities. For the structure factor, curves for argon were obtained even in the critical region, which allows conclusions to be drawn on singularities in its compressibility. It is surprising that even in the region of the critical point macroscopic quantities can be well reproduced from calculations involving only 500—1000 particles. Coherent scattering functions could also be calculated as functions of the energy transfer down to a momentum transfer of 0.2 Å^{-1}. Smaller momentum transfers would require the use of more elaborate calculations.

Rahman also reported on a plasma calculation (1024 electrons in a cube with a side of 1500 Å; the Coulomb potential cut off at 500 Å). The pair distribution function and the scattering factor rose to a nearly flat plateau; despite the low particle density, a value near zero for the compressibility was reached by extrapolation.

Verlet investigated the influence of the different pseudo-pair potential functions on the structure factor and the velocity-autocorrelation function in metals. The oscillations of the pseudo-pair potentials had little influence on the above functions. On the other hand, the steepness of the repulsion potential at small atomic distances was important. A soft repulsion potential caused stronger oscillations in the velocity-autocorrelation function and a more rapid damping in the structure factor, as is characteristic for univalent metals.

It was also pointed out in a short paper that both for argon and for a Percus-Yevick calculation for hard spheres, the structure factor shows more oscillations than for rubidium.

J. G. Powles [Department of Physics, University of Kent (England)] talked about the possibility of utilizing light-scattering for problems of liquids. Since the interference effects of neighboring atoms are mostly destructive, the scattering intensity in liquids is very small and the need for optical purity is very acute. The scattered intensity is proportional to the mean square fluctuation of the dielectric constant. If this is taken as a function of pressure and entropy, it then depends on the square of the pressure fluctuation and the square of the entropy fluctuation, respectively. While the entropy fluctuation does not propagate, the pressure fluctuation does: its frequency is given by the product of the momentum transfer Q and the velocity of sound v_s. The scattered light therefore shows three lines, of which the middle one, the Rayleigh line, appears at the frequency of the incident radiation and is caused by the entropy fluctuation; the other two, the Brillouin lines, are displaced to both sides by the frequency Qv_s. One can also interpret this shift as a Doppler effect of the pressure fluctuations, which are moving with the velocity of sound. The width of the Rayleigh line is largely determined by the quotients of heat conductivity and heat capacity C_p, while the much greater width of the Brillouin lines is given by the sound absorption coefficient. The frequencies of the pressure fluctuations depend on the wavelength of the incident light, the angle of scattering, and the velocity of sound and are usually of the order of 10^9 Hz. The sound velocities (hypersound) obtained at these

---

[*] If after a time t the particles move preferentially in the same direction, then the autocorrelation function is positive; if they move preferentially in the opposite direction, the function is negative; if after a time t there is no further 'memory', the function is zero.

[**] A distribution of the vibrational frequencies similar to that in solids also exists in liquids. The $z(0)$ value for this is finite and proportional to the diffusion coefficient.

[6] *S. J. Cocking*, J. physic. Chem., in press.

[7] *A. Rahman*, Proc. european physic. Soc., in press.

frequencies from the shift of the Brillouin lines do not on the whole differ much from those measured in the ultrasonic region (10^6 Hz). For CO_2 the hypersonic velocities for the vapor, liquid, and supercritical regions all lie somewhat higher than the ultrasonic velocities. At the critical point it also appears that the velocity of sound has a value differing from zero. The pressure fluctuations vary with C_v (the heat capacity at constant volume) and the entropy fluctuations with the difference $C_p - C_v$. The Rayleigh line should therefore disappear in water ($C_p \approx C_v$), but in the vicinity of the critical point, where C_p has a much stronger singularity than C_v, it should increase much more strongly than the Brillouin line. The divergence of C_p at the critical point was studied by measurements of the half width of the Rayleigh line. The Rayleigh line becomes very narrow in the vicinity of the critical point, and the measurements therefore require a direct electronic technique. At present only very few measurements of the half width of the Brillouin line are available, but they would be of considerable interest as complementary to the absorption measurements by ultrasonic methods.

The depolarization of the scattered light produced by reorientation (*e.g.* rotation) of anisotropic molecules is an interesting and as yet little explored phenomenon. By measuring the Doppler effect, light scattering might also be used for studying flow conditions. Thus, *Powles* reported a recording of the velocity-profile of a flowing liquid, using light scattering, and the investigation of the degree of turbulence as a function of the Reynolds number.

Views on the behavior of sound velocity in the hypersonic region were expressed by *J. P. Boon* [Université Libre de Bruxelles (Belgium)] and *P. Fleury* [Bell Telephone Laboratories, Holmdel, N. J. (USA)]. From this, a decrease in the velocity of sound at high frequency, an apparently negative dispersion, is to be expected on theoretical grounds. The above authors carried out measurements of the hypersonic velocity in liquid argon (between 85–100 °K) and liquid neon. The resulting values were a little lower than the ultrasonic measurements, but the difference was still within the range of experimental error of the investigations.

Of the other short lectures, a few more are selected because of their bearing on physicochemical problems.

P. Bratby and *N. H. March* [University of Sheffield (England)] attempted to obtain a theoretical interpretation of the fact that the ratio of the heat capacities C_p/C_v for liquid metals near the melting point lies between 1.2 and 1.3, while for argon it is 3. This seems to be connected with the fact that the repulsion branch of the pair potential rises much more steeply for argon, and the attraction branch falls away much more rapidly, than in the case of metals.

S. C. Smelser and *C. J. Pings* [California Institute of Technology, Pasadena, Calif. (USA)] reported on new X-ray scattering measurements on argon in the truly liquid region, at densities between 0.91 and 1.26 g/cm³. The pair distribution function for mean densities shows a shoulder between the first and second distinct maxima. If these results are used to calculate a pair potential by the Percus-Yevick method, one finds for the minimum of the pair-potential an improbably high dependence on density. It appears, therefore, that the Percus-Yevick theory fails at high densities.

The paper read by *D. W. G. White* [Department of Energy, Mines and Resources, Ottawa, Ontario (Canada)] gave an account of measurements of the surface tension of liquid metals (Sn, In, Pb, Zn, Cd) as a function of temperature. These determinations were carried out by the drop method in an atmosphere of hydrogen or helium, between the melting point and 550 °C, and were accurate to 1% (corresponding to ±5 erg/cm³). Of the metals investigated, only Sn shows a linear temperature dependence of the surface tension. For In and Pb, the temperature dependence is at first weakly negative and becomes more strongly negative at higher temperatures (for Pb a flattening sets in again at the highest temperatures); for Zn and Cd the temperature dependence above the melting point is at first actually positive. For Cd, the surface tension reached a maximum and then showed the usual decrease within the temperature interval investigated. The small (and sometimes even negative) value of the surface entropy near the melting point indicates a particularly ordered arrangement of the surface atoms.

C. A. Croxton and *R. P. Ferrier* [Cavendish Laboratory, University of Cambridge (England)] gave an account of electron diffraction measurements with relatively high-energy electrons, but the geometry of the setup was such that the electrons penetrated only to a depth of about six atoms. So far liquid lead, tin, and aluminum could be investigated, of which lead showed a series of subsidiary bands, but not tin or aluminum. This can be correlated with the measured values of the surface entropy. The same authors also presented a two-dimensional calculation of the surface structure for liquid argon by means of a molecular-dynamics method. The coupling to the interior of the liquid was simulated by arranging a number of atoms in a modulated statistical configuration along one side beyond the frame of the dynamical system. In this way the atoms within the framework arrange themselves into some well-ordered layers, in equilibrium with the sparsely populated gas phase.

The Monte Carlo calculations carried out by *K. Singer* [Chemistry Department, Holloway College, Egham, Surrey (England)] are selected from among the various contributions to the problem of liquid mixtures. Assuming the Lennard-Jones pair-potentials (characterized by the parameters ε_{ij}, σ_{ij}), the thermodynamic functions for equimolecular concentrations in a 108-particle system were calculated as follows: the parameters ε_{ii}, σ_{ii} of the pure component i were first transformed continuously into those of the other component j. The resultant changes in the thermodynamic quantities of interest were calculated. The two components which were made identical in this way were then mixed and the parameters were transformed to the set ε_{ii}, ε_{ij}, ε_{jj}, σ_{ii}, σ_{ij}, σ_{jj} valid for the mixture. The difference in the variations of the thermodynamic quantities measured along the changes in the parameter gives the excess thermodynamic functions. This calculation can be compared with theoretical models; it gave good agreement with the van der Waals model [8].

A really worthwhile investigation was carried out by *J. A. Chapman, F. J. Finnimore, P. J. Parpia,* and *B. L. Smith* [School of Mathematical and Physical Sciences, University of Sussex (England)], who investigated the relation between the density and the molar refraction of xenon (calculated by the Lorentz-Lorenz equation) over the whole range of density. They found that in the gas and liquid phase the molar refraction does not vary by more than ±1%, and that there were no anomalies at the critical point. The remaining slight density dependence varied systematically, the molar refraction increasing with the density at low densities, and decreasing at high densities. The temperature dependence is also slight; a small decrease of the refraction could be found with rising temperature. On transition to solid xenon, a small fall in the molar refraction was observed. This investigation justifies many earlier experimental investigations, especially near the critical point, in which the refractive index was measured instead of the density.

J. A. Brace and *J. V. Champion* [Department of Physics, Sir John Cass College, London (England)] gave a new explanation of the Kerr effect in liquids composed of nonpolar and optically isotropic molecules (*e.g.* CCl_4). According to this, the molecular distribution is disturbed by the electrical field in such a way that the internal field becomes optically anisotropic. Since this modification of the pair-distribution varies with the square of the field intensity, it gives rise to a pseudo-hyperpolarizability. The observed Kerr constants and their variation with temperature could be explained semi-quantitatively in this way.

Several short lectures dealt with the introduction of an "effective pair potential" which would take into account the

[8] *T. W. Leland, J. S. Rowlinson,* and *G. A. Sather,* Trans. Faraday Soc. *64*, 1447 (1968).

variations of the actual pair potential brought about by the presence of a triple dipole-interaction effect. It is important to note that the correction depends on the function which should be reproduced exactly. In several attempts, the correction was applied in such a way that the mean potential energy was correctly reproduced, in which case the analyses were carried out by Monte Carlo or perturbation calculations; others again correctly reproduced the radial distribution function and used a graphical method for this purpose. Both solutions result in an effective pair potential somewhat more positive than the two-body potential and showing a weak dependence on volume and temperature.

Finally, reference should be made to a preliminary Monte Carlo calculation on water, by *J. A. Barker* and *R. O. Watts* [University of Waterloo, Ontario (Canada)]. This was based on a charge distribution in the water molecule as given by *Rowlinson* and a Lennard-Jones potential and gave quite good agreement with the experimental results for energy, heat-capacity, and radial distribution. It is significant that, at least for a rough simulation of the properties of water, no specific mechanism of association had to be assumed.

SELECTED ABSTRACTS

Preparation of synthetic graphite by low-temperature pyrolysis of methane has been accomplished by *S. D. Robertson*. Previously synthetic graphite could only be prepared by precipitation at 2000–2500 °C, recrystallization at 3000 °C/400 atm, and annealing at 3400 °C. *Robertson* pyrolyzed methane (600 torr) on the surface of iron, cobalt, or nickel foil at 650 or 750 °C. The crystalline structure of the product was established, *inter alia*, by electron diffraction and Moiré diagrams. / Nature (London) *221*, 1044 (1969) / —Kr.

[Rd 62 IE]

A new analytical method for the quantitative determination of tertiary nitriles has been found as a result of investigations on the reaction of nitriles with solvated electrons from various sources, *e.g.* Na/NH_3 and $Li/C_2H_5NH_2$. Reductive decyanidation of primary, secondary, tertiary aliphatic and of aromatic nitriles leads to the formation of inorganic cyanide, which can be titrated with $AgNO_3$ according to the method of *Liebig*. The loss of cyanide from tertiary nitriles is quantitative. They undergo exclusive reductive removal of CN with formation of the hydrocarbon, whereas primary and secondary nitriles are reduced to the amines. 1,4-Dicyanocyclohexane gives, *inter alia*, cyclohexane as well as 2- and 3-methylpentane. / *P. G. Arapakos, M. R. Scott*, and *F. E. Huber jun.*, J. Amer. chem. Soc. *91*, 2059 (1969) / —Ma.

***E. coli* phenylalanyl tRNA synthetase "recognizes" its specific $tRNA^{Phe}$ by the 5′ loop.** On reduction with $NaBH_4$ or $NaBT_4$, $tRNA^{Phe}$ completely loses its ability to become charged with phenylanalyl. (Other tRNAs such as $tRNA^{Val}$ and $tRNA^{Met}$ show a 20% loss of activity.) As shown by *L. Shugart* and *M. P. Stulberg*, the activity decreases with the amount of hydrogen or tritium taken up. 80% of the tritium is incorporated into the odd bases 5,6-dihydrouridine and 4-thiouridine, and 20% is distributed over the tRNA molecule. Since the inactivation of $tRNA^{Phe}$ by heat also arises from the cleavage of 5,6-dihydrouridine and the partial loss of activity of other tRNAs on treatment with *N*-ethylmaleimide (reaction with 4-thiouridine) can be ascribed to attack at these bases, it seems reasonable to assign the functions of the recognition site to the loop in the proximity of the 5′ terminal of $tRNA^{Phe}$, which contains one molecule of 4-thiouridine and two molecules of 5,6-dihydrouridine. / J. biol. Chemistry *244*, 2806 (1969) / —He.

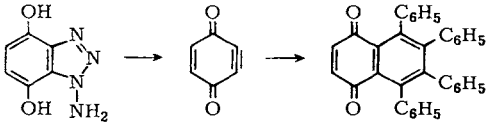
LSD exhibits interactions with calf thymus DNA *in vitro*, which *T. E. Wagner* interprets, on the basis of CD findings, as intercalation into the DNA double strand. However, since it is unlikely that the resulting conformational changes lead to the chromosome breakages observed after administration of LSD, *Wagner* suggests that LSD instead neutralizes the phosphate ions of the DNA helix on intercalation, thus causing the dissociation of histones. The removal of these basic proteins, which are ascribed a protective function, could leave the DNA more open to attack. LSD-induced changes in the CD spectrum of DNA-poly-L-lysine complexes also support this hypothesis. / Nature (London) *222*, 1170 (1969) / —He.

[Rd 69 IE]



A new method for the isolation of the estrogen receptor from rat uterus is suggested by *B. Vonderhaar* and *G. C. Mueller*. Estradiol is bonded *via* a 17α side chain to a polystyrene resin. By working in batches, it is possible with the prepared resin, which contains 83 μmoles of estradiol per gram of dry product, to remove 93% of the estrogen receptor selectively from uterus homogenate. The resin remained stable and retained its selectivity over a period of two years. However,

difficulties are encountered during attempts to elute the receptor, a protein having a highly pronounced affinity for estradiol, in active form from the resin. / Biochim. biophysica Acta *176*, 626 (1969) / —He.

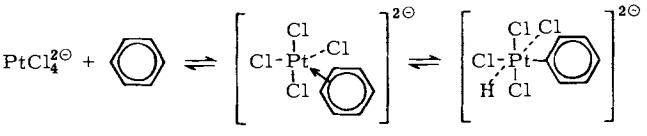
The formation of dehydrobenzoquinone, 2-cyclohexen-5-yne-1,4-dione *(2)*, the simplest dehydroquinone, represents the subject matter of a report by *C. W. Rees* and *D. E. West*. On treatment with HNO_2, cyanic ester, H_2/Pd, HNO_2 + HCl, 2-nitro-3,6-dimethoxyaniline is converted into 1-amino-4,7-dimethoxybenzotriazole, which gives 1-amino-4,7-dihydroxybenzotriazole *(1)* (yield 65%) when demethylated with

(1) *(2)* *(3)*



BBr_3 in CH_2Cl_2. Compound *(1)* is oxidized to 1-aminobenzotriazole-4,7-dione, an unstable orange-brown oil, by Ag_2O in THF + Na_2SO_4. Rapid dissolution in CH_2Cl_2 + 1 equivalent of tetracyclone and lead tetraacetate oxidation

gave a 40% yield of 5,6,7,8-tetraphenyl-1,4-naphthoquinone *(3)* (orange crystals, whose formation is most simply explained by cycloaddition of intermediate *(2)* to tetracyclone and decarbonylation). Oxidation of *(1)* by lead tetraacetate in the presence of tetracyclone afforded *(3)* in 60% yield. / Chem. Commun. *1969*, 647 / —Ma. [Rd 73 IE]

The adduct $BrF_3 \cdot SbF_5$ occurs as $[BrF_2]^+[SbF_6]^-$ according to an X-ray structure analysis carried out by *A. J. Edwards* and *G. R. Jones*. BrF_2SbF_6 crystallizes orthorhombically in the space group Pcca with a = 10.12, b = 5.81, and c = 10.95 Å ± 0.01 Å; Z = 4. The BrF_2^+ ion is bent (93.5 °), the BrF bond lengths having a value of 1.69 Å. The distorted SbF_6 octahedron has four short SbF distances of 1.83 Å (2×) and 1.84 Å (2×). The two remaining F atoms, which are *cis* to each other, are bridging atoms to two different BrF_2 ions (Sb—F, 1.91 Å; $BrF_2 \cdots F$, 2.29 Å; ∢Br ··· F—Sb, 153.5 °); the $F \cdots BrF_2 \cdots F$ unit is planar. Cations and anions combine in this way to form an infinite chain, for which a purely ionic formulation $[BrF_2]^+[SbF_6]^-$ is only of limited validity. / J. chem. Soc. (London) *A 1969*, 1467 / —HB. [Rd 76 IE]

$FXeOSO_2F$, $FeXeOClO_3$, $Xe(OSO_2F)_2$, and $Xe(OClO_3)_2$ have been prepared by *N. Bartlett et al.* by reaction of XeF_2 with stoichiometric amounts of either $HOSO_2F$ or $HOClO_3$ at −110 to −60 °C. All the compounds are colorless to pale yellow; the first three melt at 36.6, 16.5, and 43—45 °C, respectively. $Xe(OSO_2F)_2$ decomposes into Xe and $S_2O_6F_2$ at 20 °C; $Xe(OClO_3)_2$ decomposes in an undefined fashion into Xe, O_2, Cl_2O_7, and ClO_2 at −20 °C. $FXeOSO_2F$ and, presumably, the other compounds have covalent XeO bonds. On the basis of X-ray structure analysis the FXeO group in $FXeOSO_2F$ is almost linear, the Xe—F and Xe—O bond lengths being 1.94 and 2.16 Å resp. and the FXeO angle being 177.5 ± 0.4 °; the XeOS angle is 123.4 ± 0.6 °. In the Raman spectra the XeF stretching vibrations were detected at *ca.* 500 cm^{-1}, the XeO vibrations between 433 and 507 cm^{-1}. / Chem. Commun. *1969*, 703 / —HB. [Rd 77 IE]

The homogeneous catalyzed H—D-exchange in polycyclic aromatic compounds using acetic acid as solvent and tetrachloroplatinate(II) as catalyst has been investigated by *R. J. Hodges* and *J. L. Garnett*. The rates of exchange are found to be related to the highest bond order occurring in the molecule: A sharp maximum in the exchange rate is found at a bond order of about 1.77 (*e.g.* C-9 H and C-10 H bonds of phenanthrene). At smaller bond orders the formation of the π complex *(1)* is rate determining whereas at higher bond orders the formation of the σ complex *(2)* is rate determining.

(1) *(2)*

Polyphenyls exchange several H atoms during a catalytic cycle, condensed aromatic compounds exchange only one H atom. In *ortho*-condensed aromatic compounds, except those which contain condensed five-membered rings (*e.g.* acenaphthylene), the exchange is hindered. / J. physic. Chem. *73*, 1525 (1969) / —Hz. [Rd 78 IE]

BOOK REVIEWS

Grundlagen der photographischen Prozesse mit Silberhalogeniden (Principles of Photographic Processes Involving Silver Halides). Edited by *H. Frieser*, *G. Haase*, and *E. Klein*. Vol. 1: Physical and Chemical Properties of Silver Halides and of Silver; Vol. 2: The Photographic Emulsion and the Processing of Sensitive Materials; Vol. 3: Photographic Sensitivity. Akademische Verlagsgesellschaft, Frankfurt/Main, 1968. 1st Edit., 1500 pp., DM 390.—.

When the publications in a large field of research consist entirely of journal articles and monographs, it is time for existing knowledge to be gathered into one large work and presented without ballast.

The authors of the present three-volume work have succeeded in doing just this, *i.e.* in presenting more information by pruning. They have been able to demonstrate experimental results clearly, to emphasize the problems, and in part even to provide a retrospective view of the early stages of photography. It is surprising, particularly since the three volumes extend to a total of 1500 pages, to find that the book is very up-to-date, the literature being covered in part up to 1967. It contains almost 5000 references to the original literature or to other reviews. The Russian and Japanese literature, which is often treated very sketchily because of language difficulties, is given due recognition.

Volume 1, by *J. Eggers*, *G. Haase*, and *R. Matejec*, deals with the physical properties of silver halides and of metallic silver. The data on structure and bonding, mixed systems with other metal halides, defects, and crystal dislocations, as well as on the thermal, mechanical, electrical, and optical properties, are so comprehensive and up-to-date that they will often avoid the need for laborious searches in the literature, which is widely scattered in some cases. The chemical properties of silver and its compounds are given less space, but the treatment is just as detailed.

It is unfortunate that the work is sold only as a set, since the first volume in particular could be an important reference book to scientists who are concerned with silver, though not with photography.

Volume 2, by *J. Beersmans*, *H. Borginon*, *L. Busch*, *J. Eggers*, *R. Matejec*, *R. Meyer*, *E. Moisar*, and *M. N. Vrancken*, describes the preparation and chemical sensitization of photographic emulsions and their processing. Section 2 (of the complete work) describes, very briefly but impressively, gelatin and its properties. In the reviewer's opinion, more space might have been devoted to this important chapter. A few lines should perhaps also have been written about synthetic binders.

Chapter 3 presents an excellent account of the photographic emulsion and the complex subject of sensitization. The treatment is so skillful that even readers who do not work in this field should have no difficulty in understanding the material. No mention is made of the economically important rhodium effect, on which readily available literature exists.

Chapter 4 consists of three sections on the development of the photographic emulsion. The theory of development, which is based mainly on physical concepts, is followed by a section on the chemistry of the process. This section contains a very good survey of the most important developing agents known at present, and color development is also given the attention it warrants. A more detailed chapter on the Copyrapid process and on the related Polaroid process would have been preferred by the reviewer.

Chapter 5 deals with fixing, washing, and stabilization of the developed silver image. It is regrettable that so little is said

about the topical problem of the life of the silver in the image during storage.

Volume 3, by *W. F. Berg, F. Dörr, J. Eggers, G. Haase, R. Matejec, H. Metz, R. Meyer, E. Moisar,* and *F. Tomamichel,* presents, in Chapter 6, a review of spectral sensitization by dyes. After a description of the properties of sensitizing dyes and of spectrally sensitized emulsions, the two model views of sensitization, *i.e.* energy transfer and electron transfer, are discussed.

Chapter 7 gives an readily understandable description of the production of a blackening curve, and this is followed by a long chapter (8) on photographic effects. The two authors in this section have not only managed to present clearly the present state of knowledge on the bewildering multiplicity of photographic effects, but have also traced the literature back to the early stages of photography, and have thus made a valuable contribution to the history of scientific photography. The last chapter (9) is devoted to the latent image and its formation. The many stages in the formation of a latent image and the calculation models used for the understanding of the process are described in detail. From his own overall view, the author presents a survey that makes it easy for the reader to understand the relations involved.

This three-volume work will be useful to all who are concerned with the fundamentals of photography in theory or in practical research. *W. Bahnmüller* [NB 816 IE]

Physikalisch-chemische Kristallographie (Physico-chemical crystallography). By *K. Meyer.* VEB Deutscher Verlag für Grundstoffindustrie, Leipzig 1968. 1st Edit. 337 pp., 225 figures, 69 tables, bound DM 39.80.

Whereas crystal physics and crystal chemistry are normally treated quite independently in textbooks of crystallography, with seperate, systematically constructed chapters, the value of and the need for a complete, systematic discussion of the typically "physico-chemical" problems of crystallography, such as crystal formation and transformation, crystal habit and changes in habit and the many processes and reactions of and on crystal surfaces (epitaxy, topotaxy corrosion, *etc.*) are evidently not yet sufficiently recognized. This is surprising when one thinks of the importance attached by crystallographers and mineralogists to physico-chemical methods. This is shown in particular by the test methods used in these two fields.

K. Meyer's book probably provides the first systematic treatment, within the scope of a textbook, of the typically "physico-chemical" problems of crystalline materials, in which both the necessary physico-chemical (particularly thermodynamic) principles and their application to the range of crystallographic problems mentioned above are presented in clear, adequate, and neat definitions, formulations, and derivations. The treatment of the material is always carried through to the quantitative description and to the latest position, without the use of excessively demanding mathematics.

The book is fluent, well presented, and always technically adequate. It is unreservedly successful, and is strongly recommended to all crystallographers, mineralogists, chemists, physicists, and material scientists. Better paper would have been preferred for such a good book. The modest price is insufficient compensation from this point of view.

A. Neuhaus [NB 823 IE]

Die natürlichen und künstlichen Aromen. Zusammensetzung und Herstellung. (Natural and Synthetic Flavors. Composition and Preparation.) By *A. M. Burger.* Dr. Alfred Hüthig Verlag, Heidelberg 1968. 3rd Edit., 338 pp., 65 figures, plastic cover DM 48.—.

Behind this new, somewhat pretentious title is concealed the familiar "Buch der Aromen" (Book of Flavors) by the distiller and planter *Alfons M. Burger,* who died some time ago in Africa. Dr. *J. Hilger* of München has revised the manuscript, taking the latest knowledge into account. After the introduction and a short historical section, considerable space is devoted to the description of the various distillation processes and the apparatus required for them. Freeze-drying, spray-drying, extraction, and other industrial processes used in the commercial production of aroma complexes are also discussed at some length. This chapter should be made more concise in future editions, since sufficient first-class literature on these technological problems is already available.

This is followed by a section on the chemically definite aromatic essences, which is necessarily incomplete because of the very rapid progress that is currently being made in this field. Nevertheless, it provides a firm foundation for the newcomer. It would have been helpful to practical workers if the discussion of the individual aromatic essences had been accompanied by some information on their occurrence in natural products. A short chapter dealing with the different legal situations concerning the flavoring of foods and beverages in the principal countries would undoubtedly also have been welcome.

The most useful part to those who work in this field is a section of about 150 pages describing the production of spice oils, brandy flavors, citrus flavors, and fruit flavors. A simple formula is always given for the preparation of the corresponding synthetic flavor, though the legal permissibility of the components used has unfortunately not been considered. The user should therefore check the legal situation in every case.

After a short discussion of flavors of animal products (honey, butter, cheese), the book ends with a section on the flavoring of special products such as baker's produce, vinegar, confectionery and meat, as well as tobacco. An appendix provides information on solvents and solubilities. Whereas there are several very good English books, this volume closes a gap that has existed in the German literature on flavors. It should be welcomed by interested laymen and practical workers, and should always be available in the reference libraries of distillers. *E. Klein* [NB 824 IE]

Disk-Elektrophorese. Theorie und Praxis der diskontinuierlichen Polyacrylamidgel-Elektrophorese (Disc Electrophoresis. Theory and Practice of Discontinuous Electrophoresis on Polyacrylamide Gel). By *H. R. Maurer.* W. de Gruyter und Co., Berlin 1968. 1st Edit. xvi + 221 pp., 82 illustrations, 15 tables, plastic binding, DM 36.—.

Disc electrophoresis, which one connects with the names of *Ornstein* and *Davis,* is a variant of electrophoresis in polyacrylamide gel and differs from this in that discontinuities (discs) are set up with respect to pH and pore size within the separation medium. These cause concentration of the mixture to be separated, which collects as a sharp zone at the upper end of the column of gel and on subsequent separation leads to appearance of disc-like zones containing the individual components.

Technical details about the method — known for almost ten years — and modifications and applications are scattered through many different publications. It is thus especially welcome that the author, who has himself contributed several times to disc electrophoresis, has reviewed the material (602 references) and described the theory and practice of the method in an exemplary concise and precise manner. Fourteen gel systems, differing in pH, buffer composition, acrylamide concentration, *etc.,* have been summarized in tabular form; they should suffice for most problems of separation.

The book is well produced and of convenient form; since it is aimed at the practice of discontinuous polyacrylamide electrophoresis it should be consulted whenever knowledge is or should be sought about this technique needing only a minimum of technical equipment. The book is highly recommended. *B. Kickhöfen* [NB 818a IE]

Electrophoresis. Theory, Methods, and Applications. Edited by *M. Bier*. Academic Press, New York-London 1967. Vol. II. 1st edit., xviii + 553 pp., numerous illustrations and tables, bound, $ 21.00.

In 1959 appeared a book under the above title containing articles by various authors on specific aspects of free electrophoresis. After eight years it is followed by a second volume that is devoted more to the practical application of some of the methods that have meanwhile become established than to a theoretical treatment of electrokinetic phenomena. The only contribution closely connected to the first volume (an article by *J. Overbeek*) is that on electrophoretic mobility (*J. Overbeek* and *P. Wiersema*).

Especial attention will certainly be paid to the articles on gel techniques giving separation with high efficiency (*H. Bloemendal*) and on preparative electrophoresis (*K. Hannig*), since they are written with deep insight into the subjects. *H. Hochstrasser et al.* describe automatic electrophoresis in density gradients as realized in the 'Autophoresis' apparatus of Technicon Instruments Corp. The form of 'free zone electrophoresis' that occurs in a semifluid film stabilized by 0.1—0.2% of agar-agar, is treated by *N. Ressler*; since in this case separation occurs on a quartz plate the migrating zones can be followed directly by measuring the optical density at 200 nm ('Spectrophor', Bausch and Lomb).

It is open to question whether so much space should have been assigned to the results of electrophoretic analysis of gastrointestinal secretions (*G. Jerzy Glass*) and of lymph and cerespinal fluid (*F. Courtice*), each 60 pages. That one can write briefly with advantage was shown by *H. Grey* in his treatment of the electrophoretic behavior of antibodies and myeloma proteins and their fragments. A welcome should be extended to a review by *Barbara Bowman* of all the human serum proteins that occur in genetically controlled variants, since most of these proteins could only be discovered by electrophoretic methods.

P. Burtin and *P. Grabar* describe the nomenclature and identification of normal serum proteins; this article is valuable for those who have to carry out immunoelectrophoretic analyses and is a re-working of Chapter 5 of the book on Immunoelectrophoresis published by these authors in 1964. The article by *F. Šorm* and *B. Meloun* on the 'Primary Structure of Proteins' would have found a better place in a book on proteins since only the last quarter of it deals with electrophoresis (high-voltage electrophoresis of peptides); in this article the Reviewer regretted the absence of mention of *B. Hartley*'s diagonal technique. In summary: a book with a broad spectrum, somewhat related to an 'Advances' series; suitable and useful for libraries of chemical, biological, and medical research organizations.

B. Kickhöfen [NB 818b IE]

The Story of Fritz Haber. By *M. Goran*. University of Oklahoma Press, Norman, Oklahoma 1967. 1st Edit., xi, 212 pp., 4 illustrations, $ 4.95.

Morris Goran calls his book a story, an interesting, true-to-life story about an unusual and dramatic character[1]. The author, who teaches science at Roosevelt University and has written popular books on experimental chemistry, biology, and astronautics, has the gift peculiar to Anglo-Saxons of making scientific subjects simple and interesting. The life of *Fritz Haber* captured his imagination. The book is a simple but interesting tale, presented factually and without adulation, tending rather to a rough realism, though finally the author gets caught up in his subject.

We learn that young Fritz had a strict upbringing. His mother died when he was born and his father was forever telling his children that he had had to "work his fingers to the bone". At the age of 24 *Haber*, who had finished his studies and worked for a time in industry, went into the family business. His father insisted that the should have lessons to improve his handwriting. *Haber* did this, but even so did not see eye to eye with his father. After an unfavorable outcome to a business venture he had proposed, his father sent him away. "Go to university, business life does not suit you".

The book takes us through his life in great detail. The author has made a comprehensive study of his sources and obviously gathered extensive personal data. All the persons who played some part in *Haber*'s life are named and in many cases a character sketch is provided. A good, detailed index makes it easy to look up specific points. Not without interest for the German reader is the description of conditions and the way of life in a German university at the turn of the century from the pen of an American, who treats his subject objectively and without prejudice.

The critical point in *Haber*'s life — his activities in World War I and the organization of gas warfare — is dealt with in detail. The author presents a very factual defense of *Haber*. His patriotism is shown as a characteristic feature: *Goran* calls his patriotism "devotion", not "loyalty". In 1914 *Haber*, who was then 46, volunteered immediately, but was turned down. *Goran* remarks that almost all scientists before *Haber* and very many after him worked on the development of weapons, and in this connection he cites *Leonardo da Vinci* and *Galileo*. We learn that bombs filled with phosphorus and sulfur were used in the American Civil War, and that the Russians used chlorine at the beginning of World War I, but without success owing to the cold and to the weather conditions. In any case, gas was hardly a major weapon: less than 5% of all war casualties resulted from the use of gas; the casualty death rate for poison gas was 2.5%, and that for all other battle injuries 25%. Furthermore, it is difficult to make a moral distinction between gas and, say, submarine warfare. Nevertheless, even during the World War I there was a particular stigma attached to gas warfare, and we learn that *Haber*'s first wife was so distressed by her husband's war activities that in 1915 she committed suicide.

The chapter entitled "Understanding the man Haber" examines *Haber*'s habits, his views, his qualities, his way of life, and his sayings. We see here particularly clearly the biographer's art — our picture of *Haber* illuminated by a wealth of individual snips of information, details, and facts being left to speak for themselves. Here, as all through the book, we find enlightening anecdotes. For instance: *Haber*, who was no soldier, got annoyed because an officer of his company always wore spurs, though his activities were confined to office work. One day he said to him: "Captain, will you please get on your horse and ride into the next room to fetch those papers." *Haber*'s preferred reading is given as *Goethe*, the Bible — from which he loved to quote — and *Edgar Wallace*. He usually had a whodunit with him, and they helped him when he could not sleep. *Goran* thinks that they sharpened his wit, because he was always, like a detective, prying into the unknown. His enormous appetite for work, his activity, and his inner restlessness are attributed by *Goran* to a sense of insecurity resulting from childhood experiences, the loss of his mother, his initial failures, and his Jewish origin. I myself think that these rather manifestations of the normal inner tension of a strong, vital person who not only feels an urge to study and to achieve something, accompanied by ambition and a desire for recognition, but also experiences doubts and inner conflicts. *Goran* gives numerous examples of *Haber*'s sensitivity. — *Haber*'s last years and his bitter path into exile are given somewhat less space.

Despite the realistic and in ways matter-of-fact report, *Goran* sets the hero of his book on a pedestal. He considers him to be the greatest personality from the point of view of the synthesis of scientific research and industrial development. He refers to the way in which he develops an argument as a unique combination of clarity, originality, and conciseness, grounded on wit and irony. He was a romantic who thought about the unusual, applying an "uncommon common sense", a man who would have achieved eminence in any country, in

[1] Cf. Chemie in unserer Zeit *2*, 145 (1968).

England be might have been a Viceroy of India, in America a first-rate businessmann.

The book is an impressive document: The biographer, a man from another country, who did not know *Haber* personally, has diligently compiled the necessary material and has written a book which obscures and glosses over nothing, but which, after a cool examination of the facts, pays homage to a man wronged by his own country. *H. Sachsse* [NB 821 IE]

The Wave Mechanics of Atoms, Molecules, and Ions. By *C. J. H. Schutte.* Edward Arnold (Publishers), London 1967. XIII, 502 pp. numerous figures and tables, bound 84s.

This book is intended for students who wish to obtain a better understanding of the mathematical principles of the quantum-mechanical methods commonly used nowadays in physical chemistry. The book is divided into 16 chapters, the subject matter in each section being supplemented by several examples for practice.

The chapters deal in order with the fundamentals of quantum mechanics, the group theory and the MO methods of quantum chemistry. The applications of the theory in spectroscopy appear only in the third part of the book, with particular reference to the properties of the vibrational, rotational, and nuclear resonance excitation of molecules. An interesting but rather too short chapter for such a comprehensive book is devoted to the transition metal ions.

The book is adequately supplied with tables and figures, and is thus also a valuable reference book for students. The abundant literature references and references to original works are of great practical use to the reader.

Though the author, in his foreword, recommends the book to the practical chemist, it can scarcely be called a text book in the usual sense. The concise arrangement of the material makes familiarity with the manipulation of mathematical formulas a necessity, whereas this is not possessed by most practical chemists. On page 42, for example, the selection rules of the transition moments are discussed with the aid of direct products of irreducible representations without prior explanation of the symbols used. The book, which is crammed with facts, is therefore more useful as a collection of formulas or tables. Similarly, the problems for practice often involve considerable reasoning and numerical calculation, so that the average reader will be reluctant to spare the time required for their solution and discussion. It is nevertheless possible to obtain an insight into quantum-mechanical calculations by means of the solutions discussed in the Appendix. Though the book is well presented, some of the mathematical formulas contain printing errors, which are not always obvious owing to the author's often difficult arguments.

The author must be congratulated on producing a book that fills the gaps between the corresponding works on the precise methods of quantum chemistry and those on the experimental methods of physical chemistry. The fundamentals of quantum chemistry are treated in a readily understandable formal manner, and the results are illustrated by many practical examples. The book will probably be very useful to those who are familiar with the applications of quantum chemistry, and could provide a stimulus to further study.

P. A. Straub [NB 822 IE]

Principles of Organic Chemistry. By *R. A. Geissman.* Freeman and Co., San Francisco-London 1968. 3rd Edit., x+883pp., 98 illustrations, 70 tables, bound 70s.

This is the third edition of *Geissman*'s book, which is written as an introduction to organic chemistry within the framework of a one-year course. Departing from the classical division according to compounds customary in textbooks of organic chemistry, the author lays the main emphasis on reactions of functional groups. Properties and reactions of organic chemical compounds are presented as expressions of the characteristic behavior of the most important functional groups. It becomes apparent, however, that the content of organic chemistry cannot be divided quite systematically in this way; thus, in addition to the chapters corresponding to this division others are inserted dealing with, *e. g.*, absorption spectra of organic compounds, stereoisomerism, optical activity, ring formation, conformation, and molecular rearrangements. In the present, third, edition particular attention is paid to physical methods of characterizing organic compounds.

On the good side it can be noted that, while limiting strictly the amount of material, the author is yet able to bring the reader right up to the front of modern organic chemistry with a series of carefully chosen examples; the introductory chapter on the chemical bond and reaction kinetics is particularly successful. As a whole, the book is characterized by its clear and didactically successful presentation of its material. Its value is enhanced by the problems that are scattered in the text or collected at the end of each chapter.

Alongside the report of these successes some critical remarks may be permissible. It is hard to understand why radical mechanisms are not mentioned when polar reaction mechanisms are treated well and in detail; this leads to the omission of such elementary topics as the radical chain reactions in aliphatic substitution and autoxidation. Short-lived and stable radicals are not described. In the chapter on β-dicarbonyl compounds chelate formation is not mentioned in relation to enolization; complex formation is neglected in this connection and in connection with α-amino acids. It is surprising that the Ruggli-Ziegler dilution principle is not mentioned in treatment of macrocyclic compounds, nor is the special position of medium-sized rings. In the chapter on lactones the special behavior of γ-lactones is not noted. And the conformation of the ester group is not reported.

In spite of these isolated failings, the book as a whole is a success. In particular it will provide a stimulus for revision of the teaching of organic chemistry in German universities.

Vapor Pressure Isotope Effects

By A. Höpfner[*]

The vapor pressure isotope effect is a reflection of the thermodynamic relations in the condensed phase. It is possible to explain the observed effects on the basis of intermolecular vibrations, e.g. hydrogen bond vibrations, and the frequency shifts of the characteristic vibrations on condensation, though other effects must also be discussed. Information about the thermodynamics of liquids, e.g. about the degree of association or the expected positions of the lattice frequencies, can be obtained from the vapor pressure isotope effect.

1. Introduction

The thermodynamics of gases are based on the translational and rotational energies of the molecules and the energy levels of the internal degrees of freedom (vibrations and internal rotations). The intermolecular interactions are involved only as small correction terms (virial coefficients), which are perfectly understood in principle. If the lattice forces are known, the macroscopic thermodynamic functions of crystals can be satisfactorily represented by means of the thermodynamics of crystalline solids, the translational movement of the gas molecules in the crystal corresponding to harmonic or anharmonic vibrations about the lattice sites. Since a molecule remains in a lattice site for a very long time, Heisenberg's uncertainty principle predicts great certainty in the energy.

The interpretation of the properties of liquids, on the other hand, has not led to such satisfactory results. The "physical" theories, which are derived from the concept of the cell theory, are attempts to calculate the thermodynamic functions of liquids from predetermined intermolecular potentials. Against the conceptual clarity of these theories must be set the disadvantage that intermolecular potentials are known with sufficient accuracy only for simple molecules (*e.g.* inert gases). The phenomenological theories, such as *Eyring*'s theory of significant structures [1], do not depend on the intermolecular potentials; in these theories the liquid is described as a perturbed solid, the thermodynamics of which are assumed to be known. The perturbation is described in terms similar to those used for gases. The present article will show how the sign and magnitude of the vapor pressure isotope effect, as well as its dependence on temperature and concentration, can be used to deduce the thermodynamically relevant degrees of freedom in liquids.

2. Experimental Methods

Because of the logarithmic relation between free enthalpy of vaporization and vapor pressure (or more precisely fugacity)

$$\Delta_v G^\circ = -RT \ln p \qquad (1)$$

it is customary to use the ratio p_1/p_2 of the vapor pressures of two isotopic substances at a given temperature (or the logarithm of this ratio) to characterize the vapor pressure isotope effect (VPIE). If the masses differ (*e.g.* for C_2D_6/C_2H_6), the vapor pressure of the heavier substance is taken as the numerator and that of the lighter substance as the denominator. If the masses are equal (*e.g.* for CH_3CD_3/CH_2DCHD_2), the less symmetrical substance may be assigned to the

[1] *H. Eyring* and *R. P. Marchi*, J. chem. Educat. *40*, 562 (1963); *T. S. Ree*, *T. Ree*, and *H. Eyring*, Angew. Chem. *77*, 993 (1965); Angew. Chem. internat. Edit. *4*, 923 (1965).

numerator and the more symmetrical to the denominator. Owing to the historical view that we are concerned only with pure mass effects, the vapor pressure isotope effect is referred to as normal when $p_1/p_2 < 1$, and as inverse when $p_1/p_2 > 1$. If the sign of $\ln(p_1/p_2)$ changes with the temperature, *i.e.* if p_1/p_2 passes through a value of 1, one speaks of the "cross-over" phenomenon.

In some cases the vapor pressure curves $p_1(T)$ and $p_2(T)$ were determined manometrically and used to find the ratio p_1/p_2. However, this method is sufficiently accurate only if the vapor pressure isotope effect is large, *i.e.* if the ratio p_1/p_2 is very different from 1. If the effect is small it may be masked by inaccurate temperature adjustment; the temperature dependence of the vapor pressure is so great that an error of 0.01 degree in the measurement of the temperature can lead to an error of about 0.1 % in the vapor pressure value.

A method in which the difference

$$\Delta p = p_1(T) - p_2(T)$$

is measured directly has consequently become accepted. The vessels containing the substances 1 and 2 are placed in the same temperature bath and connected to the two legs *e.g.* of a simple mercury manometer (Fig. 1), from which Δp can be read off directly. With

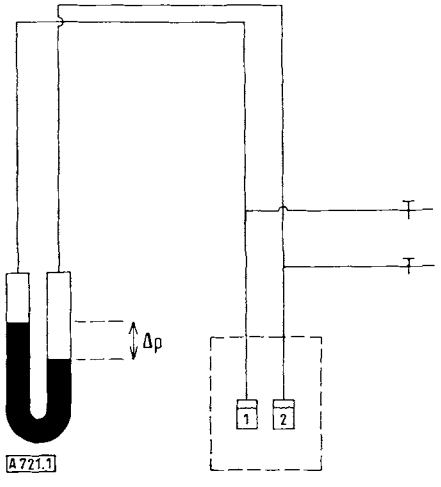

Fig. 1. Diagram of a vapor pressure difference apparatus with a shared temperature bath and a liquid manometer.

this arrangement, the accuracy with which Δp is obtained increases by a factor of ten, particularly since experience has shown that Δp does not depend so strongly on the temperature as the vapor pressures p_1 and p_2 themselves. The vapor pressure isotope effect is calculated from

$$\frac{p_1}{p_2} = 1 + \frac{\Delta p}{p_2} \qquad (2)$$

It is thus still necessary to determine the absolute pressure of one component, but the accuracy required is not very high.

Most of the published data on vapor pressure isotope effects have been determined by this method; if $\ln(p_1/p_2)$ is between 0.001 and 0.1 and p_1 is between 0.01 and 10 atmospheres, it is the most convenient method, provided that the substances can be obtained in the purity necessary for the vapor pressure measurements.

A third method is based on the measurement of the partition coefficient

$$\alpha = \frac{(N_1/N_2)_A}{(N_1/N_2)_B} \qquad (3)$$

for the partition of two isotopic forms between the two phases A and B. Except in extreme cases (see Section 6), mixtures of isotopes are ideal. Then, neglecting the deviation of the gas phase from ideality, we obtain

$$\alpha = p_1/p_2 \qquad (4)$$

and, if the effect is small,

$$\alpha - 1 = \ln (p_1/p_2) \qquad (5)$$

If the mixture of isotopes is slowly distilled, the α of eq. (3) is obtained by isotope analysis of the residue and the distillate. Very small effects (α-1 $\approx 10^{-4}$) can be determined if a column distillation is carried out instead of a single-stage distillation. The purity requirements are much less rigorous in this method than in the measurement of vapor pressures.

3. Experimental Findings

Figure 2 shows typical curves for the temperature dependence of the vapor pressure isotope effect.

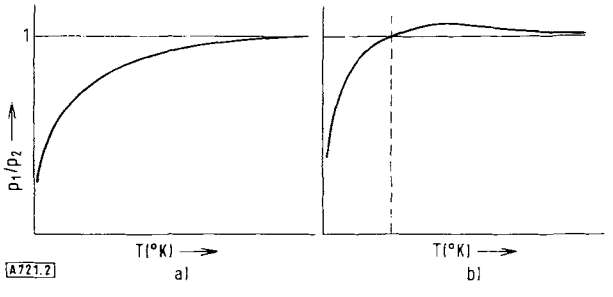

Fig. 2. Typical course of the vapor pressure ratio p_1/p_2, (a) without an inverse effect, (b) with an inverse effect at high temperatures.

A normal effect is always found at sufficiently low temperatures. The magnitude of this increases with falling temperature. Pronounced vapor pressure isotope effects are generally found at lower temperatures; thus the values for hydrogen and for helium are 0.34 and 0.31 respectively (cf. Table 1) at the boiling points of the lighter components. The effects are otherwise much smaller, and, as can be seen in Table 1, amount to only a few percent. Water and ammonia, on the other hand, exhibit strikingly large vapor pressure isotope effects. Vapor pressure ratios of 0.79

and 0.75 respectively are found for these two substances below the triple point.

No inverse effect ($\alpha > 1$) was found at very low temperatures. The cross-over for methane occurs only at about 75 °K; all known substances that exhibit inverse effects boil at higher temperatures than the boiling point of methane.

In every case where a cross-over is observed, $d\alpha/dT$ is positive, *i.e.* the vapor pressure isotope effect is normal below the cross-over temperature, and inverse above it. It cannot be established from the experimental observations whether all substances give a cross-over, at least at very high temperatures. This effect occurs at 220.7 °C for the pair D_2O/H_2O, and it can be inferred for alcohols, amines, and ammonia from the extrapolation of the $\alpha(T)$ curves. At least for helium and hydrogen, α is still well below 1 in the neighborhood of the critical points.

Normal and inverse effects differ markedly in their temperature dependences. Figure 3 shows the values

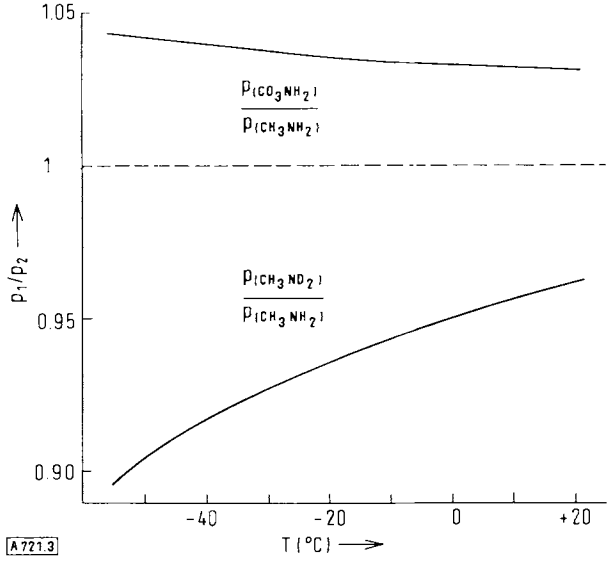

Fig. 3. Difference in the temperature dependences of the normal and inverse effects.

of p_1/p_2 for two pairs of differently deuterated methylamines, illustrating the strongly temperature-dependent normal effect resulting from substitution in the amino group and the weakly temperature-dependent inverse effect for substitution in the methyl group [18]. Whereas $d\alpha/dT$ is always positive for the normal vapor pressure isotope effect, both positive and negative values are found for substances giving an inverse effect. In the example of the ethanes, which is shown in Figure 4, the two cases with the maximum between them are clearly recognizable, despite the greater error at lower pressures [7].

If we regard the curve in Figure 2 as typical of the vapor pressure isotope effect, both the strong temperature dependence of the normal effect and the weak temperature dependence of the inverse effect become understandable. The values found for α and $d\alpha/dT$ depend only on the temperature range in which the measurements are carried out.

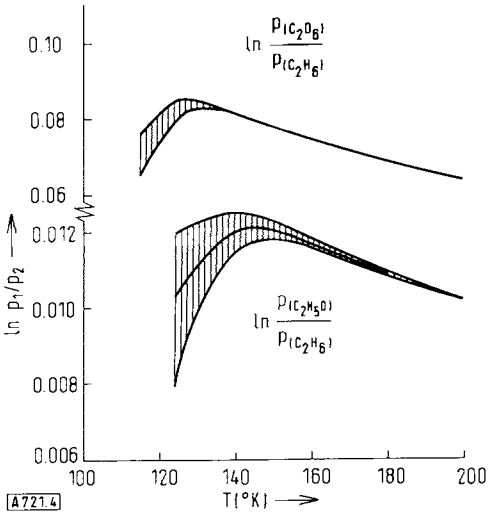

Fig. 4. Maxima in the inverse vapor pressure isotope effect of ethane.

The differences in the vapor pressures of isotopic substances pass through an extremum slightly below the cross-over temperature. The absolute value of Δp passes through a maximum at this point, but Δp itself is negative, so that the extremum is in fact a minimum. It occurs when the relative decrease in α near the cross-over temperature is no longer compensated by the exponential increase in the vapor pressure. This extremum, which has been observed at 171 °C for water (D_2O/H_2O) and at 12 °C for methylamine (CD_3ND_2/CH_3NH_2), should not be confused with the maximum of α, which is found in the region of the inverse effect, *i.e.* at much higher temperatures.

4. Interpretation of the Experimental Findings

The substances investigated at very low temperatures (He, H_2, Ne, N_2, *etc.*), for which a normal effect is found, fit readily into the framework of the theory. We shall first consider the vapor pressure isotope effects on replacement of hydrogen by deuterium in simple compounds whose vapor pressures can be accurately measured. A comparison of the literature data (cf. Table 1) shows that the inverse effect predominates for hydrocarbons and halogenohydrocarbons, except for methane derivatives, the effects of which are normal below 98 °K.

Conspicuous among the substances with normal vapor pressure isotope effects are water and ammonia, the molecules of which are known to be highly associated in the condensed state.

The normal effect of NO [20] must be mentioned here for historical reasons, though this is not a hydrogen compound. NO was the first substance for which an experimentally observed vapor pressure isotope effect was quantitatively traced to association in the condensed state [44].

The picture is rounded off by the data for alcohols and amines, which show that a normal effect occurs if the substance is associated in the condensed state and if the replacement of H by D has occurred in the group responsible for the association (hydroxyl or amino

group). An inverse effect is observed, on the other hand, for unassociated substances or when isotopic substitution has taken place in an inert part of the molecule (as in the case CH_3NH_2/CD_3NH_2).

The existence of a connection between the normal vapor pressure isotope effect and association is also indicated by the strong temperature dependence of the normal effect, which corresponds to the variation of association with temperature. The vapor pressure isotope effect for water (D_2O/H_2O) becomes inverse at 220.7 °C; this could be explained by the decrease in hydrogen-bond association at this temperature, which allows other effects to predominate.

This view is in agreement with the fact that the normal effect of methylamine gives way to an inverse vapor pressure isotope effect on dilution with an inert solvent (*e.g. n*-hexane)[18] (cf. Fig. 5). The change occurs close to a mole fraction of $x_1 = 0.15$, and the inverse effect in this case would be more accurately described

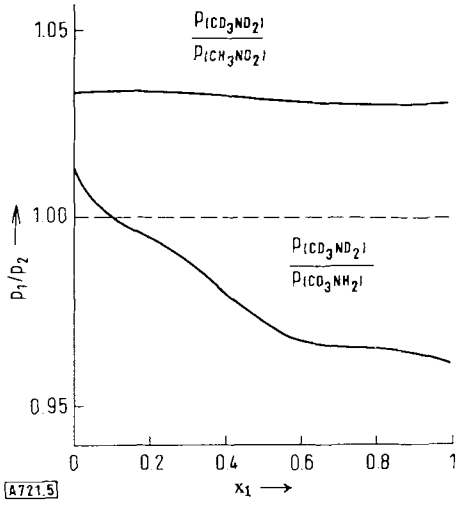

Fig. 5. Concentration dependence of the partial pressure isotope effect of substances that form hydrogen bonds.

as a partial pressure isotope effect. At the mole fraction mentioned, the associates have largely disappeared. The corresponding inverse effect (*e.g.* of the pair CD_3ND_2/CH_3ND_2), on the other hand, shows no concentration dependence. Similar observations have been reported for ammonia[19] and for methanol[21].

5. Theories of the Vapor Pressure Isotope Effect

The temperature dependence of the vapor pressure isotope effect (large effect at low temperatures, vanishing effect for $T \to \infty$) indicates that this is a

typical quantum effect. Whereas *Fajans* [22] assumed in 1914 that the thermodynamic properties of the isotopes are exactly the same, *Lindemann* [23] in 1919 predicted a vapor pressure isotope effect for monatomic solids. According to *Lindemann*, it should be possible, by investigations on the vapor pressure isotope effect (and on the associated isotope effect of the mass action constants), to reach conclusions that could confirm the correctness of the predictions of the quantum theory, particularly in relation to the zero-point energy. According to *Stern*, whose unpublished formula is cited by *Keesom* and *van Dijk* [24], the vapor pressure isotope effect of a monatomic Debye solid should be given by

$$\ln \frac{p_1}{p_2} = -\frac{9}{8}\frac{\Theta}{T}\left(1-\frac{m_1}{m_2}\right)+\frac{3}{40}\left(\frac{\Theta}{T}\right)^2\left(1-\frac{m_1}{m_2}\right)+\cdots \qquad (6)$$

where the first term (with the coefficient 9/8) is omitted in the presence of the zero-point energy. It follows that the vapor pressure isotope effect is normal if the zero-point energy occurs, and is otherwise inverse. Since *Keesom* and *van Dijk*, in 1931, found a normal effect for the pair $^{20}Ne/^{22}Ne$, they regarded this as experimental proof of the zero-point energy.

The first quantum correction for the partition function of the harmonic oscillator

$$Z = Z_{cl}\left[1-\frac{1}{24}\left(\frac{h\nu}{kT}\right)^2\right] \qquad (7)$$

as was noted by *Herzfeld* and *Teller* [25] in 1937, leads to a normal vapor pressure isotope effect. *Herzfeld* and *Teller* made only qualitative attempts to explain the inverse effect, which had been observed *e.g.* in 1936 by *Bailey* and *Topley* [26] for benzene.

The rule of the geometric mean played a part in the earlier discussion of the vapor pressure isotope effect. If the molecular weights M_1, M_2, and M_3 of three isotopic substances form an arithmetic series, the corresponding vapor pressures p_1, p_2, and p_3 form a geometric series. Expansion of the ratios of the vapor pressure as functions of the relative mass ratios, which are assumed to be small, gives

$$\frac{p_2}{p_1} = 1 + a\frac{\Delta m}{m} + b\left(\frac{\Delta m}{m}\right)^2 + \cdots \qquad (8)$$

and

$$\frac{p_3}{p_1} = 1 + a\frac{\Delta m'}{m} + b\left(\frac{\Delta m'}{m}\right)^2 + \cdots \qquad (9)$$

where $m = M$, $\Delta m = M_2 - M_1$, and $\Delta m' = M_3 - M_1$. We obtain

$$p_2^2 = p_1^2\left(1 + 2a\frac{\Delta m}{m} + \cdots\right) \qquad (10)$$

and

$$p_1 p_3 = p_1^2\left(1 + a\frac{\Delta m'}{m} + \cdots\right) \qquad (11)$$

i.e. the values are equal, to a first approximation, for the case

$$\left(\frac{\Delta m'}{m}\right) = 2\left(\frac{\Delta m}{m}\right) \qquad (12)$$

In quantum-statistical notation, the same result is obtained if eq. (25) is considered only for translational degrees of freedom and if the characteristic vibration temperature is replaced by the masses in accordance with

$$\Theta_1^2/\Theta_2^2 = M_2/M_1 \qquad (13)$$

and the sinh expanded into a series. This rule is obeyed with surprising accuracy in the case of hydrogen ($H_2/HD/D_2$), since the rotational degrees of freedom for this system are unchanged on condensation. In general, however, the shape of the molecules has a greater effect than the mass.

5.1. Intermolecular Vibrations

A comprehensive theory of the vapor pressure isotope effect was published in 1961 by *Bigeleisen* [27]. On methodical grounds, we shall start here with the procedure reported by *Wolff* and *Höpfner* [28], which was originally developed only for the description of the vapor pressure isotope effect of substances that form hydrogen bonds.

If p_D and p_H are the vapor pressures of a deuterated (and hence heavier) and an undeuterated substance, and if the isotope effect for a thermodynamic function is denoted by Δ_i, then it follows from eq. (1) that

$$\Delta_i\Delta_v G^o = -RT\ln\frac{p_D}{p_H} \qquad (14)$$

G^o_{gas} and G_{cond} in $\Delta_v G^o = G^o_{gas} - G_{cond}$ must be calculated in accordance with the rules of statistical thermodynamics for each isotopic form.

We shall deal first with the external degrees of freedom. According to *Schäfer* [29], the three translational degrees of freedom for the gas state (deviations from the ideal gas laws will be ignored) at $p = 1$ atm are given by

$$G^o_{trans} = -RT\ln\left[\left(\frac{2\pi k}{N_L h^2}\right)^{\frac{3}{2}}\frac{1}{N_L}\right] - RT\ln g - \frac{3}{2}RT\ln M - \frac{5}{2}RT\ln T - RT\ln R \qquad (15)$$

For the investigation of the vapor pressure isotope effect, we are interested only in the term that changes on isotopic substitution

[22] *K. Fajans*, Physikal. Z. *15*, 935 (1914).

[29] *Kl. Schäfer*: Statistische Theorie der Gase, Göttingen 1960.

$$\Delta_i G^{\circ}_{trans} = -\frac{3}{2} RT \ln \frac{M_D}{M_H} \quad (16)$$

or, if only one translational degree of freedom is considered,

$$\Delta_i G^{\circ}_{trans} = -\frac{1}{2} RT \ln \frac{M_D}{M_H} \quad (17)$$

Similarly, when there are three rotational degrees of freedom, if the temperature is not too low we have

$$G_{rot} = -RT \ln \left[\frac{16\pi^3 \sqrt{2\pi} k^{\frac{3}{2}}}{h^3} \right] + RT \ln s - \frac{3}{2} RT \ln \bar{I} - \frac{3}{2} RT \ln T \quad (18)$$

which leads to

$$\Delta_i G_{rot} = -\frac{3}{2} RT \ln \frac{\bar{I}_D}{\bar{I}_H} + RT \ln \frac{s_D}{s_H} \quad (19)$$

Thus the masses M, the moments of inertia I, and any change in the symmetry number s (*e.g.* between CH_4 and CH_3D) are important. The term $RT \ln(s_D/s_H)$ plays no part in the discussion of the vapor pressure isotope effect, since it is compensated for in the condensed state in all known cases by another term having exactly the same magnitude, which is due to the irregular position of the arbitrarily oriented molecules.

The characteristic vibrations of the molecule will be treated separately (see Section 5.3), since they remain constant to a first approximation on transition from the vapor to the condensate; their changes, must, however, be used for the interpretation in particular of the inverse vapor pressure isotope effect.

In the calculation of G_{cond}, it is necessary to use a liquid model whose parameters are commonly used in thermodynamics, so that the results can also be interpreted thermodynamically. Since only a few experimental investigations with solid condensates have been carried out, all discussions on the vapor pressure isotope effect must be concerned with the liquid state. *Eyring*'s theory of significant structures [1] can be used for the discussion of the vapor pressure isotope effect, since it regards the liquid state as a mixture of the other aggregation states (solid and gaseous), which are assumed to be known in principle, and can give the mixing ratio.

We therefore assume that the external degrees of freedom of the gas molecules in the liquid correspond to either gaslike degrees of freedom (this case is of no interest, since it leads to $\Delta_i \Delta_v G^0 = 0$), or to lattice vibrations. A distinction is made between vibrations or translational oscillations, which correspond to the translational movement in the gas, and librations, which may be regarded as hindered rotations. This distinction is possible because the librations usually have a higher wave number, and are changed to a greater degree than vibrations on isotopic substitution (replacement of H by D in this case). In water, for example, wave numbers of 180 cm^{-1} and 710 cm^{-1} are found for the vibrations and the librations respectively [30, 31]. The high wave numbers of the lattice vibrations in this case are caused by the strong hydrogen bonds in water. The corresponding wave numbers for methyl iodide, the crystals of which are held together only by dispersion and dipole forces, are 60 and 100 cm^{-1} [47].

Instead of the wave number ν, it is customary in thermodynamics to use the characteristic vibration temperature Θ, which can be calculated from ν by means of

$$\Theta = hc\nu/k \text{ where } hc/k = 1.4384 \text{ deg. cm} \quad (20)$$

For each degree of freedom of the condensed state that occurs as a vibration, we can put

$$G_{osc} = \frac{1}{2} R\Theta + RT \ln (1 - e^{-\Theta/T}) = RT \ln 2 \sinh \left(\frac{\Theta}{2T} \right) \quad (21)$$

In the case of vibrations with force constants f and molecular masses M, the frequency law

$$\nu = (1/2\pi) \sqrt{f/M} \quad (22)$$

leads, for two isotopic oscillators, to

$$\Theta_D/\Theta_H = \sqrt{M_H/M_D} \quad (23)$$

For librations, the mass is replaced by the moment of inertia.

$$\Theta_D/\Theta_H = \sqrt{I_H/I_D} \quad (24)$$

Determining the left hand side of eq. (14) using eq. (16) and eq. (23), (or eq. (20) and eq. (24)), we find that the contribution of one degree of freedom to the vapor pressure isotope effect is given by the factor

$$\frac{p_D}{p_H} = \frac{\Theta_H}{\Theta_D} \frac{\sinh \Theta_D/2T}{\sinh \Theta_H/2T} \quad (25)$$

The first factor (Θ_H/Θ_D) comes from the thermodynamics of the gas, while the second comes from the lattice vibrations of the condensed phase. For different conditions in one phase, therefore, only one factor would be affected.

Eq. (25) describes the behavior of the normal vapor pressure isotope effect; it also leads to the observed temperature dependence, with a large effect at low temperatures and a vanishing effect at high temperatures, since, owing to

$$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \cdots \quad (26)$$

the second factor yields Θ_D/Θ_H for large T (and hence small x) and cancels the first factor.

---

[30] *P. A. Giguère* and *K. B. Harvey*, Canad. J. Chem. *34*, 798 (1956).

[31] *D. F. Hornig, H. F. White*, and *F. P. Reding*, Spectrochim. Acta *12*, 338 (1958).

It must be emphasized that though $\Delta_i\Delta_v G^\circ$ vanishes at high temperatures, $\Delta_i G^\circ_{trans}$, $\Delta_i G_{rot}$, and $\Delta_i G_{osc}$ do not.

In Figure 6, numerical values for $\Theta_H/\Theta_D = 1.01$, 1.1, and $\sqrt{2}$ calculated from eq. (25) are represented by continuous curves.

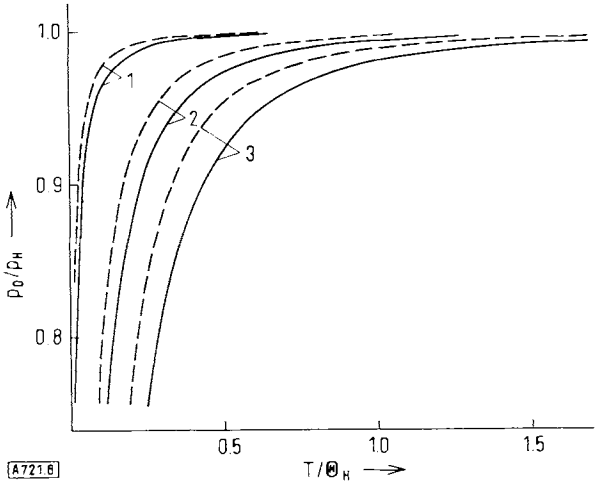

Fig. 6. Theoretical vapor pressure ratios calculated from eq. (25) —— and (30) - - -; 1: $\Theta_H/\Theta_D = 1.01$, 2: $\Theta_H/\Theta_D = 1.1$, 3: $\Theta_H/\Theta_D = \sqrt{2}$.

Table 2, the values in which were calculated from spectroscopic data reported by *Gray* and *Lord*[32], shows the usual values of the isotope effects for the mass and moments of inertia, and hence for $(\Theta_H/\Theta_D)^2$, of organic molecules.

Table 2. Relative masses and moments of inertia of the methylamines.

	CH_3NH_2	CH_3ND_2	CD_3NH_2	CD_3ND_2	Absolute value of CH_3NH_2
M	1	1.0645	1.0986	1.1613	31.056
I_a	1	1.3195	1.6539	1.9702	8.1363
I_b	1	1.1204	1.2260	1.3664	37.1207
I_c	1	1.1619	1.2161	1.3985	38.6802

The replacement of H by D in organic molecules is most strongly reflected in the moments of inertia, whereas the relative changes in the mass are small. Pronounced isotope shifts in the lattice vibrations are consequently found only in the librations (in water by *Giguère* and *Harvey*[30], in ice by *Hornig*, *White*, and *Reding*[31]), whereas the translational vibrations exhibit only a very small isotope effect.

5.2. Frequency Distribution of the Lattice Vibrations

Eq. (25) is based on the assumption that only one frequency can be assigned to each degree of freedom. This is generally not so. In the ideal case, the coupling of the lattice vibrations leads to a Debye frequency distribution, in which the frequency corresponding to the characteristic temperature Θ is now merely the maximum (limiting) frequency, and is accompanied by a continuous spectrum of lower frequencies. This leads even qualitatively to a decrease in the quantum effect calculated for eq. (25).

If we assume a simple Debye distribution, we obtain

$$G_{osc} = \frac{3}{8} R\Theta + RT \ln (1 - e^{-\Theta/T}) - \frac{1}{3} RT D_3\left(\frac{\Theta}{T}\right)$$
$$= -\frac{1}{8} R\Theta + RT \ln \left[2 \sinh \frac{\Theta}{2T}\right] - \frac{1}{3} RT D_3\left(\frac{\Theta}{T}\right) \quad (27)$$

with the Debye function

$$D_3(x) = \frac{3}{x^3} \int_0^x \frac{\xi^3}{e^\xi - 1} d\xi \quad (28)$$

There are two expansions for the numerical evaluation of $D_3(x)$

$$D_3(x) = \sum_{n=0}^{\infty} \frac{3B_n}{(n+3)n!} x^n = \frac{\pi^4}{5x^3} - \sum_{n=1}^{\infty} \left[3 + \frac{9}{nx} + \frac{18}{(nx)^2} + \frac{18}{(nx)^3}\right] \frac{e^{-nx}}{n} \quad (29)$$

with the Bernoulli numbers

$$B_n = 1, -\frac{1}{2}, \frac{1}{6}, 0, -\frac{1}{30}, 0, \frac{1}{42}, 0, -\frac{1}{30}, 0, \frac{5}{66}, 0, -\frac{691}{2730}, 0, \frac{7}{6}, 0 \ldots$$

The first series is suitable for high temperatures ($x < 2$), while the second expansion is used for low temperatures, at which it soon leads to the T^3 law.

If we calculate $\Delta_i\Delta_v G^0$ as above, but using eq. (27) instead of eq. (21), we obtain the following expression for the vapor pressure isotope effect:

$$\frac{p_D}{p_H} = \frac{\Theta_H}{\Theta_D} \cdot \frac{\sinh \Theta_D/2T}{\sinh \Theta_H/2T} \cdot \exp\left[-\frac{1}{8}\left(\frac{\Theta_D}{T} - \frac{\Theta_H}{T}\right) - \frac{1}{3}\left(D_3\left(\frac{\Theta_D}{T}\right) - D_3\left(\frac{\Theta_H}{T}\right)\right)\right] \quad (30)$$

The values calculated from this formula are shown by broken lines in Figure 6. The effect is smaller by about 1/3 in relation to eq. (25).

5.3. Influence of the Intramolecular Vibrations

It has been assumed so far that the frequencies of the intramolecular vibrations remain unchanged on condensation. This is not quite true. Small displacements to longer wavelengths are usually observed, and these also influence the vapor pressure isotope effect.

If the characteristic vibration temperatures of a given degree of freedom are Θ_H and Θ_D in the gas and Θ'_H and Θ'_D in the condensed state, it follows directly from eq. (21) that

$$\Delta_i\Delta_v G_{osc} = RT \ln \frac{\sinh \Theta_D/2T \sinh \Theta'_H/2T}{\sinh \Theta_H/2T \sinh \Theta'_D/2T} \quad (31)$$

The characteristic vibrations of most molecules have Θ values of more than 2000 °C, so that since $\sinh x =$

[32] *A. P. Gray* and *R. C. Lord*, J. chem. Physics *26*, 690 (1957); *H. Wolff* and *E. Wolff*, Ber. Bunsenges. physik. Chem. *69*, 467 (1965).

$^1/_2(e^x - e^{-x})$ becomes $^1/_2 e^x$ for large x, eq. (31) can be replaced in these cases by

$$\Delta_i \Delta_v G_{osc} = \frac{R}{2} (\Theta_D - \Theta'_D) - (\Theta_H - \Theta'_H) \quad (32)$$

and hence

$$\frac{p_D}{p_H} = \exp \frac{(\Theta_H - \Theta'_H) - (\Theta_D - \Theta'_D)}{2T} \quad (33)$$

According to *Buckingham*[33], the ratio $(\Theta - \Theta')/\Theta$ is independent of the nuclear mass to within 1 % (rigorously for diatomic molecules at least). Application of this rule in eq. (33) leads to a positive exponent and to an inverse vapor pressure isotope effect, if it is assumed that $\Theta_H > \Theta_D$.

Mention should be made here of the infrared effect discussed by *Baertschi* and *Kuhn*[34], in which the vapor pressure isotope effect of CCl_4 ($^{12}CCl_4/^{13}CCl_4$ and $C^{35}Cl_4/C^{37}Cl_4$) is attributed to the dispersion forces between the molecules. The question of the frequency distribution on condensation has been discussed by *Ulbrich*[35], though not in relation to the vapor pressure isotope effects.

Apart from the difficulty of giving exact frequencies for liquid bands, it must be noted that the spectroscopically observed bands at strongly anharmonic potentials correspond not to the thermodynamically relevant frequencies, but to the differences between the ground terms and the overtones, which may be considerably displaced from the ideal harmonic position.

For the practical evaluation of measurements of the vapor pressure isotope effect, the experimental values are often expressed by means of the relation

$$\ln p_D/p_H = -A/T^2 + B/T \quad (34)$$

The term in T^{-2} can be identified with the effect of the lattice vibrations in accordance with eq. (25) or (30), and the term in T^{-1} with the effect due to the displacements of the characteristic vibrations of the molecules [eq. (33)]. Good examples of this method are found in *van Hook*'s work on ethanes[7] and in *Bigeleisen*'s work on [D_2]-ethylenes[8].

5.4. Numerical Examples

Wolff[28,36] has given examples in which vapor pressure isotope effects were calculated from spectroscopic data with the aid of equations (25) and (33) and compared with the experimental values.

In the case of water, an effect of 0.99 was found at 0 °C for three translational degrees of freedom, 0.53 for three rotational degrees of freedom, and 1.57 for the intramolecular vibrations in accordance with eq. (33), *i.e.* a total of 0.82, which is in good agreement with the experimental value of 0.80.

The translational degrees of freedom make practically no contribution here and in other cases, partly because M_D/M_H is much smaller than I_D/I_H, and partly because the Θ values of the translational vibrations are so small that the corresponding degrees of freedom are fully excited at the temperature in question and make no further contribution.

The vapor pressure isotope effects of methanol, HCl, HBr, and H_2S have also been calculated from spectroscopic data[36] (cf. Table 3). These calculations present difficulties, since the spectra of the solid or even of the liquid state are known with sufficient accuracy in only a few cases. Liquids in particular give broad IR and Raman bands, the maxima of which are rarely sharp.

Table 3. Calculated and measured vapor pressure isotope effects [28, 36].

Isotopic pairs	t (°C)	Translational degrees of freedom	Rotational degrees of freedom	Intramolecular degrees of freedom	p_D/p_H calc.	p_D/p_H exp.
D_2O/H_2O	100	0.99	0.68	1.39	0.94	0.95
	0	0.99	0.53	1.57	0.82	0.80

5.5. The Anharmonicity of the Lattice Vibrations

The effects described so far yield quantitative information about the vapor pressure isotope effect. They require a knowledge of the positions of the lattice vibrations and of the frequency displacement on condensation. The present state of spectroscopic techniques is such that these data can be obtained in principle, though often only with difficulty.

It was formerly necessary to assume that, contrary to reality, the vibrations were always harmonic. If a condensed substance has a measurable vapor pressure, the probability of a molecule's leaving the force field of its neighbors to pass into the gas phase must be high. This involves its emerging from the region of harmonic forces, for which, by definition, the restoring force is proportional to the displacement from the equilibrium position.

[36] *H. Wolff*, *E. Wolff*, and *H.-E. Höppel*, Ber. Bunsenges. physik. Chem. *72*, 644 (1968).

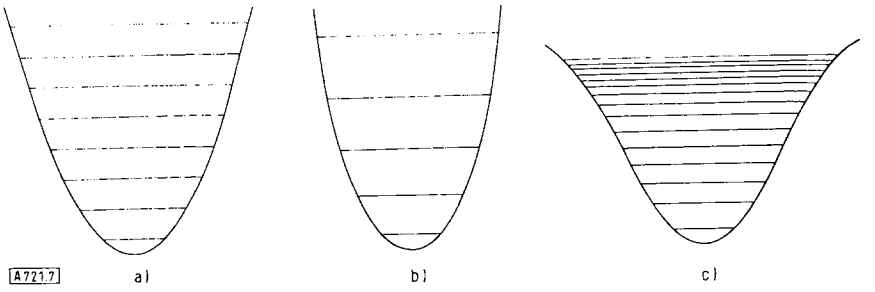

Fig. 7. Influence of anharmonicities on the partition function of the oscillators; (a) Z^*_{cl}, (b) $Z^*_{anh} < Z^*_{cl}$, (c) $Z^*_{anh} > Z^*_{cl}$.

A harmonic potential leading to a series of equidistant energy steps is shown in Figure 7a. Let the corresponding partition function be Z^*_{harm}.

At large displacements of a translational vibration, it must be expected that the repelling forces from the neighboring molecules will become more noticeable because of the high repulsion exponents, so that the potential will rise more steeply than the harmonic potential. According to the quantum theory of the anharmonic oscillator (see *e.g. Pöschel* and *Teller*[37]), therefore, the energy levels will be farther apart, with the result that the partition function Z^*_{trans} will be smaller than for the harmonic case (Fig. 7b).

The librations, on the other hand, will always change into more or less free rotations at large displacements, so that it is necessary to assume a periodic potential, the troughs of which are separated by potential barriers. The result is the case indicated in Figure 7c, in which the potential curve is shallower than in the harmonic case. The states are closer together, and give a greater partition function. These anharmonicities have a greater effect for lighter molecules, since the amplitudes of their vibrational movement are greater. From the relation between the partition function and the free enthalpy

$$G = -RT \ln Z^* \qquad (35)$$

this leads to a contribution $\Delta_i G_{anh} < 0$ for translational vibrations in the solid state and to $\Delta_i G_{anh} > 0$ for the librations, whence we find a normal effect in the former case and an inverse effect in the latter. This effect will appear in particular when the degrees of freedom in question are fully excited, *i.e.* when eq. (25) no longer has any effect.

The prospects of a quantitative treatment of this effect are poor as long as no data on the anharmonicities of lattice vibrations are available.

5.6. The Size of the Molecule

The C–H bond may be expected to be longer than the C–D bond, even if the force constants are assumed to be identical. The corresponding stretching vibrations are not yet excited at normal temperatures, so that the state is that of the zero-point vibration. The energy of the zero-point vibration of deuterium is situated lower in the potential trough because of the greater mass, and in view of the asymmetry of the trough, the time-average position of the deuterium nucleus is closer to

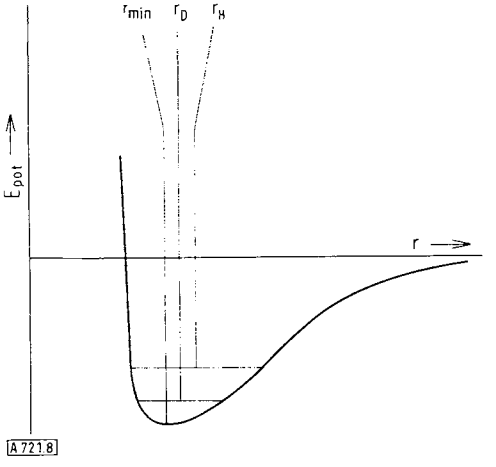

Fig. 8. Because of the anharmonicity of the bonding forces, the average bond length is smaller for the heavier atoms (r_{min} = potential minimum, r_D = position of D at lowest state r_H = position of H at lowest state.

the carbon than that of the hydrogen nucleus. Macroscopically, therefore, deuterated molecules should be smaller than the corresponding undeuterated molecules, and this should be reflected in a negative isotope effect for the molar volume $\Delta_i V < 0$.

Dorfmüller and *Bigeleisen*[38] have carried out measurements on liquid ethylene, which gave an effect of about 1 %. The experimental determination of $\Delta_i V$ is fundamentally difficult, since the molecular weight of the substance, and hence the isotopic composition of the sample, must be known very accurately for the calculation of the molar volume from the densities. Difference measurements, such as were used for the vapor pressure, are not possible in this case.

The denser packing of the heavier molecules leads to an increase in the force constants f or d [in eq. (22)] in relation to those of the lighter substance. An extra factor

$$f_D/f_H > 1 \text{ or } d_D/d_H > 1$$

thus appears on the right-hand sides of equations (23) and (24). In eq. (25) this gives $p_D/p_H > 1$ even at high temperatures, where the vapor pressure isotope effect should have disappeared long ago on condition that $f_D = f_H$.

[38] *Th. Dorfmüller* and *J. Bigeleisen*, Lecture at the "Bunsen-Tagung" in Cologne, May 1967.

6. Isotopic Mixtures

Isotopic mixtures are mixtures of mutually isotopic components, *e.g.* D_2O/H_2O, $^4He/^3He$, HD/H_2, *etc.* The problem is the usual one for mixtures, *i.e.* to what extent can the properties of the mixtures be explained on the basis of the properties of the components?

Very few cases are known at present in which isotopic mixtures deviate from ideal behavior. The free enthalpy of mixing can nearly always be calculated from the mole fractions in accordance with

$$\Delta_m G = RT\,(x_1 \ln x_1 + x_2 \ln x_2) \tag{36}$$

If the corresponding gas phase is also ideal, the vapor pressure over the mixture is described by the well known Raoult line. Deviations from ideal behavior must be expected at very low temperatures for "quantum liquids", when the free enthalpy of a monatomic ideal gas

$$G = RT \ln \left[\frac{N_L}{V_M} \left(\frac{h^2}{2\pi mkT} \right)^{\frac{3}{2}} \right] \tag{37}$$

requires the addition of terms of the form

$$\pm\, RT \frac{N_L}{V_M} \times \left(\frac{h^2}{2\pi mkT} \right)^{\frac{3}{2}} \times \left(\frac{1}{2} \right)^{\frac{3}{2}}$$

and higher terms [29].

Positive deviations from Raoult's law have been found at 20 °K in the system D_2/H_2 [45], and deviations of this type are so strong for $^3He/^4He$ that a miscibility gap occurs below 1 °K [39].

It is generally considered that the deviations observed for helium and hydrogen are due, not to intermolecular forces, but merely to the quantum-statistical condensation effects [40].

The chemist, on the other hand, is interested in cases where deviations from ideal behavior occur even at normal temperatures. Investigations so far have been confined to the system D_2O/H_2O, for which a heat of mixing of 7.5 cal/mole has been found at 25 °C [41], and whose boiling behavior has also been studied. The observed deviations from ideality are again positive, and lead to the occurrence of an azeotrope near the cross-over point at 221 °C [42]. The observations can be explained on the basis of a ternary mixture of D_2O, HDO, and H_2O, the components of which are assumed to exhibit ideal mixing behavior. The variables of the system are thus the equilibrium constant of the reaction

$$D_2O + H_2O \rightleftharpoons 2\ HDO \tag{38}$$

and the vapor pressure of HDO [43].

7. Vapor Pressure Differences Between Equivalent Isomers

Investigations on equivalent isomers, such as the three $[D_2]$-ethylenes [8] or the eight ethanes from C_2H_6 to C_2D_6 [7], which include three pairs of isomers, have led to conclusions regarding the forces acting in the liquid state. Thus *van Hook* [7] showed in the case of the ethanes that the vapor pressure isotope effect of equivalent isomers (higher vapor pressures were found for the more asymmetric isomer) is essentially attributable to a frequency shift of the torsional vibrations toward shorter wavelengths on condensation, which must itself be temperature-dependent (or rather density-dependent).

In the case of the $[D_2]$-ethylenes, the *trans* form has a higher vapor pressure than the *cis* form and the $[1,1\text{-}D_2]$-form. Representation of the experimental values by means of eq. (34) showed that the vapor pressure differences in the $[D_2]$-ethylenes are due to the term A, *i.e.* they result from an effect corresponding to eq. (25). Comparison with the moments of inertia of the ethylenes (Table 4) shows that the effect can be explained by hindered rotation about the axis lying in the direction of the C=C bond with the moment of inertia I_A. This moment of inertia is much smaller for *trans*-$[D_2]$-ethylene than for *cis*-$[D_2]$-ethylene or $[1,1\text{-}D_2]$-ethylene.

Table 4. Parameters of eq. (34) and moments of inertia of $[D_2]$-ethylenes.

	A	B	$I_A \times 10^{40}$	$I_B \times 10^{40}$	$I_C \times 10^{40}$
trans-CHD=CHD	716.0	6.865	8.06	33.70	41.72
cis-CHD=CHD	742.2	6.916	8.45	33.09	41.48
$CD_2{=}CH_2$	748.3	6.995	8.64	32.69	41.33
$CH_2{=}CH_2$	0	0	5.76	28.00	33.75

8. Closing Remarks

The investigations on the vapor pressure isotope effect provide clues for many branches of physical chemistry. The measurements on substances that form hydrogen bonds make it necessary for the spectroscopist to measure the hydrogen bond or lattice vibrations used for the interpretation of the effect in eq. (25) in the far IR region in the solid and liquid states.

It should be noted in this connection that vapor pressure measurements show much more clearly than spectroscopic studies that deuterium bonds are about 5 % stronger than hydrogen bonds [18,21].

The intermolecular forces are generally responsible for the frequency shift of the characteristic vibrations of the molecules on condensation, but in addition to the red shift in the stretching vibration, it is necessary also to assume a blue shift *e.g.* in the torsional vibration of ethane.

Our knowledge of the liquid state will be improved by numerous studies on the vapor pressure isotope

effect on both sides of the triple point, since it will then be possible to follow the various effects beyond the melting point.

The vapor pressure isotope effects of the quantum liquids helium and hydrogen occupy a special position, since the usual method of applying quantum corrections to the classical formulas does not work in these cases. The theory of the quantum effects in liquid hydrogen has been developed by *Bigeleisen* [46] on the basis of the vapor pressures of H_2, D_2, T_2, HD, HT, and DT, the ratios of the partition functions of the liquids being calculated from the vapor pressure isotope effects. The concept of the free rotation of the molecules in liquid hydrogen has thus been confirmed, since the observed effects can be explained in full on the basis of the translational degrees of freedom of the hydrogen molecules [*].

Sorption Promotors in Biopharmaceutics

By W. A. Ritschel[*]

The absorption of drugs depends on the physico-chemical properties of the constituent substances. Drugs that are absorbed only with difficulty or only slowly, or even not at all, can be made to penetrate into the skin and the mucous membrane (penetration) or to pass through them (permeation) with the aid of "sorption promotors". The search for substances of this type and the elucidation of their principles of action form part of the field of biopharmaceutics.

1. Introduction

A drug is only very rarely used therapeutically in the form of the pure substance. The pure drug or a mixture of drugs is generally combined with adjuvants, to form a drug product. These adjuvants may include solvents, emulsifying agents, preservatives, antioxidants, coloring agents, flavoring agents, buffer mixtures, fillers, lubricants, binders, disintegrators, *etc.*, depending on whether the preparation is to be in the form of a solution, tablets, capsules, suppositories, or ointments. The various types of preparation help to ensure the fastest possible action on the target organ and to ensure that the active principle is in fact absorbed in cases where certain forms cannot be used.

2. General Observations on the Absorption of Drugs

Before a drug can act, it must reach the target organ. This organ may be the surface of the skin or of the mucous membrane and the deeper layers of the skin (*local* action), or it may be one of the internal organs or body fluids (*systemic* action). If the drug acts only on the surface of the skin we speak of *adsorption*, while if it passes into deeper-lying layers of the skin we speak of *penetration*. Absorption occurs if the drug passes through the skin barrier (*permeation*) to reach the layers containing the blood vessels, so that it also enters into the metabolism. Penetration and absorption are designated by the collective term "*sorption*". The uptake of a drug from the mouth and the gastrointestinal tract, the active principle being distributed in the body by the blood and lymph, is also absorption. Whether a drug is adsorbed, penetrates, or is absorbed depends on its physico-chemical properties (solubility in water, partition coefficient between lipid and water) and on the adjuvants present in the preparation (type of base, pH value, choice of adjuvants, *etc.*).

The absorption of a drug from a preparation consists essentially of four steps, which do not take place strictly in succession, but partly overlap. These steps are: release of the drug from the preparation, diffusion of the drug to the absorbing organ, penetration and

[*] Prof. Dr. W. A. Ritschel
College of Pharmacy, University of Cincinnati
Cincinnati, Ohio 45221 (USA)

permeation, and distribution in the transport medium (blood and lymph).

Only after it has been absorbed can the drug react with the receptor of the target organ and exert its action.

2.1. Release of the Active Principle and Diffusion

A therapeutic action can occur only if the drug is released in sufficient quantities from the preparation. This process depends largely on the preparation of the drug. Unsuitable adjuvants that interact with the drug by dispersion forces, directional forces, induction forces, hydrogen bonding, or complexing can strongly retard, or even prevent, the release of the drug, quite apart from the possibility of a change in the action of the drug due to chemical reaction. Similar results can, however, also be produced by physical effects, such as an increase in viscosity due to unsuitable adjuvants or unsuitable particle sizes, which would hinder dissolution or the disintegration, *e.g.* of tablets.

A drug can be released from a tablet or capsule only if the tablet or capsule disintegrates rapidly. Disaggregation into granular particles is not enough but must be followed by further disintegration into powder particles. The rate of dissolution of the drug in the gastrointestinal tract will obviously increase with the rate at which the preparation can be broken down into the smallest possible particles. Since the rate of dissolution depends on the surface area, micronized, *i.e.* extremely finely divided, drugs are absorbed particularly rapidly. The dissolved drug then migrates by diffusion to the "boundary organ" or lipoid barrier, *i.e.* to the skin or the mucous membrane.

2.2. Penetration, Permeation, and Distribution in the Transport Medium

To exert its action, the drug must reach the cells of the target organ. Since these cells are surrounded by an aqueous tissue fluid, the drugs must be at least partly water-soluble. They must, however, first penetrate into or through layers of cells in order to reach the tissue fluid, and this means that they must be soluble in the lipids that largely constitute the cell membranes. Absorption thus involves a partition process at membranes having mainly lipid properties. The hydrogen ion concentration influences the water-solubility and lipid solubility of weakly basic and weakly acidic substances, which is what most drugs are.

Molecules can be transported through the membrane either by diffusion or by convection (see Fig. 1)[1].

The diffusion of the dissolved molecules depends on the concentration difference between the outside (c_a) and the inside (c_i) of the membrane. The transport current (q) is proportional to the partition coefficient (f) of the molecular species between the membrane material and the solvent. It is

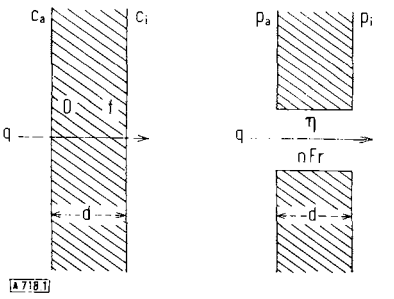

Fig. 1. Transport of dissolved molecules through a membrane by diffusion (left) and by convection (right) [1]; for explanation see text

also proportional to the area of the membrane (F) and the diffusion coefficient (D), and inversely proportional to the thickness of the membrane (d) [see eq. (1)]:

$$q = \frac{D F f}{d} \times (c_a - c_i) \qquad (1)$$

Whereas diffusion involves the transport of the dissolved molecules without displacement of the solvent the transport of dissolved molecules by convection is accompanied by displacement of the solvent, the extent and direction of the transport being determined by the hydrostatic pressure difference between the outside (p_a) and the inside (p_i) of the membrane. If the transport is assumed to take place by laminar flow through round, fairly wide pores of equal size, the transport current (q) is proportional to the cross-sectional area (F) of the individual pores, the number of pores (n), and the square of the radius (r) of the pores, and inversely proportional to the length of the pores, which is equal to the thickness of the membrane (d). The specific resistance of the solution to displacement by convection is given by the viscosity η [see eq. (2)]:

$$q = \frac{1}{\eta} \times \frac{n r^2 F}{d} \times (p_a - p_i) \qquad (2)$$

The membranes can be divided into four types, according to their permeability [1]:

Type I: The membrane consists of a material that is impermeable to molecules. Both diffusion and convection can, however, take place through water-filled pores.

Type II: The membrane consists of a closed, pore-free layer. In this case only diffusion is possible, and that only if the molecules are soluble in the material of the membrane.

Type III: The membrane consists of a material that corresponds to type II but it also contains pores, so that substances can diffuse through the membrane material, and can be transported through the pores both by diffusion and by convection.

Type IV: The membrane consists of a material that is impermeable to molecules. Penetration of the membrane is, however, possible by active transport, *i.e.* with the aid of a "carrier". According to this carrier hypothesis, it is assumed that a cell substance is present on the outside of the membrane and holds the molecule to be transported. The resulting complex diffuses to the inside, where the transported molecule is "released" and whence the carrier diffuses back to the outside. The molecules are bonded to a specific carrier in the same manner as to a receptor.

2.3. Absorption in the Gastrointestinal Tract

Most drugs are weakly acidic or weakly basic substances. The quantity absorbed per unit time and the absorption site depend mainly on the pH value at which the drug is present in the dissociated or in the undissociated form. The ionization constant K_a is expressed by

[1] *L. Dettli* and *P. Spring*, 23rd. Int. Kongress der Pharmazeutischen Wissenschaften, Münster 1963. Kongressbericht, Govi-Verlag, Frankfurt 1964, p. 85.

the pK_a value[2] in analogy with the hydrogen ion concentration.

The degree of dissociation of weak acids increases with the pH value, whereas that of bases decreases. The solubility in water increases with increasing dissociation, and the solubility in lipids increases with the concentration of the undissociated form. Weak acids are therefore more readily absorbed at the low pH value of the stomach, since dissociation is suppressed and most of the substance is in the undissociated form (cf. Fig. 2). Weak bases, on the other hand, are more readily absorbed in the alkaline medium of the intestine.

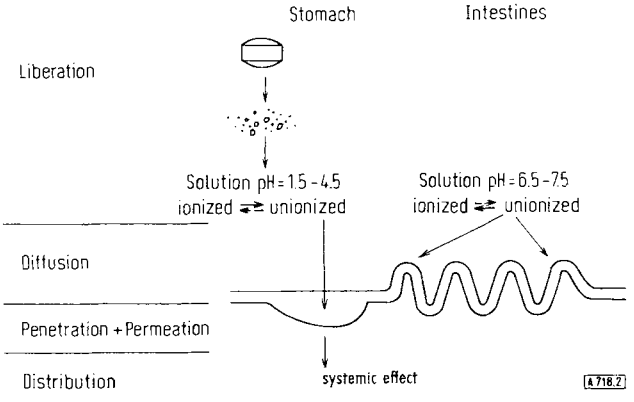

Fig. 2. Absorption of a weakly acidic drug from a tablet in the gastrointestinal tract [3].

The absorption of weakly acidic drugs from the intestine despite the lower content of the undissociated form in the alkaline medium is explained by the very large area of the intestinal tube.

The rate of absorption of the undissociated component of a substance increases with increasing lipid-solubility. The ratio of the solubilities in water and lipids is expressed by the partition coefficient of a drug between an organic solvent (*e.g.* hexane, heptane, chloroform, dodecanol) and an aqueous phase (buffer solution).

Brodie et al.[4–8] deduced rules for the absorption of drugs from the gastrointestinal tract on the basis of their pH hypothesis. These rules were summarized by *Münzel*[9] as follows:

"The gastrointestinal membrane behaves as a lipid barrier. This barrier allows mainly the undissociated form of acids and bases to pass.

The epithelium of the jejunum has a pH of 5.3, which is substantially independent of the pH of the contents of the intestine.

Most drugs are absorbed by passive diffusion.

The absorption rate depends qualitatively and semiquantitatively on the O/W partition coefficient (where O = heptane or chloroform). The more lipophilic the drug the faster, in general, the absorption.

The lowest pK_a value of an acid that still allows fast absorption is about 3.

The highest pK_a value of a base that still allows fast absorption is about 7.8.

In the steady state (equilibrium state) of flow experiments with a basic drug, the concentration of the drug is *higher* in the intestinal lumen than in the plasma; the ratio of these concentrations increases with increasing basicity of the drug until a certain limit is reached.

In the steady state in flow experiments with an acidic drug, the concentration of the drug is *lower* in the intestinal lumen than in the plasma; the ratio of these concentrations decreases with increasing acidity of the drug.

In general, acidic drugs are absorbed from the stomach, whereas basic drugs are not".

2.4. Absorption Through the Skin

The conditions for cutaneous absorption are essentially the same as for gastrointestinal absorption. Additional factors in this case, however, are the condition of the skin (intact or injured), its moisture content, the concentration of the drug in the locally applied preparation, the composition of the base, the area of the skin treated, the thickness of the skin (between 0.5 and 2.0 mm[10, 11]), and the skin type (seborrhoic, sebostatic).

The possibilities of cutaneous and gastrointestinal absorption are summarized in Fig. 3.

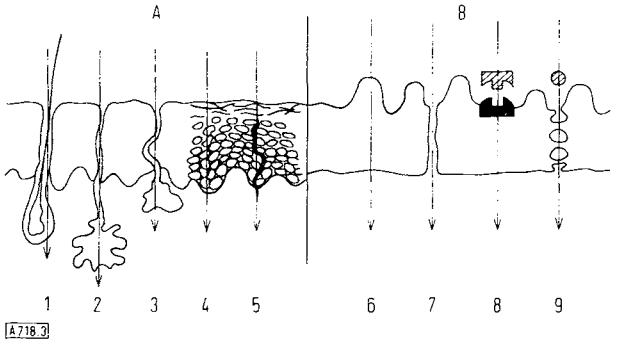

Fig. 3. Possibilities of cutaneous (A) and gastrointestinal (B) absorption of a drug (for explanations of 1 to 9, see text).

In cutaneous absorption (A), the drug can penetrate the skin in the following ways to reach the subcutaneous tissue layers containing the vessels: 1 = through the wall of the hair follicles (follicular absorption); 2 = through the sweat glands (glandular absorption); 3 = through the sebaceous glands (glandular absorption); 4 = through the cells of the horny layer (diffusion); 5 = between the cells of the horny layer (convection). Gastrointestinal absorption (B) can occur in the following ways: 6 = through the membrane (diffusion); 7 = through water-filled pores in the membrane (convection); 8 = by active transport (carrier hypothesis); 9 = by corpuscular absorption to form vacuoles (pinocytosis; persorption).

3. Modification of Absorption

The absorption of drugs can be influenced, *e.g.* by chemical modification of the drug (to obtain a favorable lipid/water partition coefficient), by modification of the size of the molecule, by adjustment of the pH to a suitable value, by micronization (to increase the rate of dissolution), by suitable choice of the point of application and the form in which the drug is applied, and by the use of sorption promotors.

Sorption promotors are substances that have no therapeutic properties of their own, but which can improve the penetration of the drugs from the preparation into the skin, or their permeation through the skin, or can facilitate absorption of the drugs by the mucous membrane. With the aid of these agents the drugs pass through the skin or mucous membrane barrier into the blood and lymph streams, and so participate in the metabolism [12]. Since agents of this type are necessary in most cases to allow or to increase the introduction of drugs into the blood stream, the process involved is not merely penetration into the layers of the skin, but permeation through the skin. It would in fact be justifiable to speak of penetration and permeation promotors. This distinction, however, is very difficult to make. Whereas, *e.g.* the solvent dimethyl sulfoxide actually permeates, the surface active agents and complexing agents act mainly on the membranes; esters of fatty acids merely cause mixing of the carrier with the skin fats, and so do not permeate.

Of the various names commonly used in the German literature for these substances (Gleitschienen, Resorptionsförderer), some are appropriate, while others are less so [13, 14]. The English terms "penetration carrier" and "sorption promotor" are satisfactory in this respect.

4. Survey of Sorption Promotors

4.1. Organic Solvents

The percutaneous absorption of a dissolved drug is strongly influenced by the solvent [13]. For example, fat solvents can assist the absorption both of water-soluble and of oil-soluble substances [15]. The improvement in the absorption of oil-soluble substances is due to the partial leaching of the lipids present in the epidermal membrane by the solvent [16]. The increased absorption of oil-soluble substances in the presence of fat solvents is due to the dissolution of the sebum and the resulting improvement of the conditions for wetting and for transepidermal and transfollicular penetration [17]. It is important that the solvent should not remain on the surface of the skin, retaining with it the substance that is to be absorbed, as is the case, *e.g.* with phenol dissolved in glycerin or vegetable oil [15].

Since many drugs penetrate into the skin more readily from water than from organic solvents alone, it has been suggested that the organic solvent in which a water-soluble drug is dissolved must have a high affinity for water. Thus both the miscibility and the solution properties of the solvent are responsible for the transport of a water-soluble drug through the skin with the aid of organic solvents [18].

In certain circumstances organic solvents can increase the absorption to such an extent that toxic effects occur [19]. It is also known, on the other hand, that degreasing of the surface of the skin with ether before application of a preparation can reduce absorption [20], as has been found, *e.g.* for methyl salicylate. A list of organic solvents that have been referred to in the literature as sorption promotors is given in Table 1.

Table 1. Organic solvents used as sorption promotors.

Acetone	Cyclohexanone
Ethanol	Dimethylacetamide
Ethyl ether	Dimethylformamide
Ethylene glycol	Dimethyl sulfoxide
Benzene	Polyethylene glycol
Chloroform	Propylene glycol
Cyclohexane	Tetrahydrofurfuryl alcohol

Despite numerous investigations on the effects of organic solvents on absorption, it is difficult at present to deduce any general rule. The application of drugs in lipophilic solvents probably leads to a marked change in the penetration resistance of the skin barrier. This in turn probably influences the activity coefficient and the diffusion constant of the penetrating drug in the skin barrier [21].

In penetration experiments with solutions of physostigmine in alcohols and in esters, the quantity absorbed was found to depend on the length of the aliphatic chain [22].

Investigations on the absorption of pentobarbital into erythrocytes showed greater absorption from ethanol than from aqueous solution. It is assumed that ethanol can alter the distribution of weak acids between the cells and the intracellular space [23].

The percutaneous absorption of aminophenazone with organic solvents as carriers has been studied in animal and human experiments. Aminophenazone is absorbed by 40—60% of the body surface from a mixture of 20% of ethylene glycol, 30% of cyclohexane, 10% of cyclohexanone, and 40% of hexanol, but not when the components are used singly [24].

In comparative experiments on the absorption of fluocinolone acetonide from an O/W emulsion, a W/O emulsion, a hydrocarbon base, a polyethylene glycol base, and alcohol, the greatest quantity was absorbed with alcohol [25].

With monohydric alcohols as solvents, the maximum absorption rate is obtained with compounds containing 6 to 8 C atoms [13]. The percutaneous absorption can be increased to such a degree with the aid of carrier mixtures of this type that even cardiac glycosides can be given percutaneously [26,27].

Percutaneous absorption of sex hormones can be brought about by fat solvents. 17β-Estradiol, which is poorly absorbed from vegetable oil and only moderately well from water, exhibits a very high absorption from benzene solution [28].

Hydrocortisone and hydrocortisone acetate have no vasoconstrictive action in O/W emulsion, W/O emulsion, hydrocarbon base, or polyethylene glycol. On addition of tetrahydrofurfuryl alcohol and dimethylacetamide, however, they exhibit vasoconstriction comparable with that caused by the much stronger betamethasone 17-valerate and fluocinolone acetonide [29].

The results on the suitability of *lipophobic* solvents as penetrant carriers are contradictory. Propylene glycol, for example, is found to be effective in some cases, but retards the absorption of many drugs.
